Figure 9: The source code (left), and assembly code (right) used for reading a byte from a serial device. The code reads 32-bits, but immediately discards the top 24-bits. MULTIFUZZ detects this pattern and resizes the load instruction.

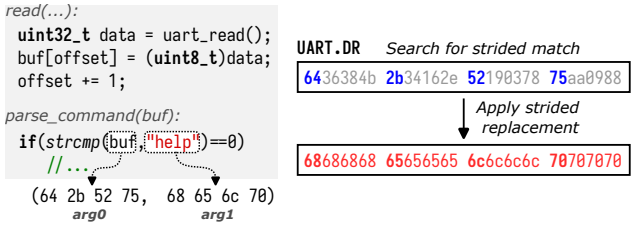

Figure 10: An example illustrating how checks for strided matches enables matching comparison operations even in the presence of oversized reads from the data register.

Tracker binary, triggering the USB ISR (interrupt service routine) could cause the firmware to hang depending on the value read from a peripheral[4]. These states are considered hangs by the fuzzer, and the inputs that reach these states are typically excluded from future mutations. However, if these states are easily reachable, this can result in a significant proportion of extensions leading to hangs. To mitigate this issue, unlike AFL-derived fuzzers, which discard hanging inputs, MULTIFUZZ saves and mutates (but does not attempt to extend) hanging inputs if they reach new coverage.

Code-coverage feedback. MULTIFUZZ uses block-only coverage for feedback instead of using edge hit counts like existing firmware fuzzers. This approach simultaneously addresses two issues. First, block-only coverage inherently avoids the excess edges added on interrupt entry and exit which can cause the fuzzer to waste time exploring equivalent paths, a problem highlighted by Ember-IO [13]. Second, because interrupts are triggered in a round-robin manner after a fixed number of blocks are executed, our length extension strategy is easily able to reach more interrupt triggers by extending input streams by larger and larger amounts. Consequently, inputs that hit edges multiple times are considered to have unique coverage when coverage feedback is based on edge hit counts[5]. This results in the fuzzer saving huge numbers of increasingly larger inputs, which is avoided when using block-only coverage.

One drawback of block-only coverage is that it provides less feedback for code that needs to be repeatedly executed,

[4]This corresponds to a hardware error on a real device.

[5]Although most approaches bucket hit counts to small power-of-two to mitigate this problem, the large number of interrupts and edges within each interrupt, easily overcomes the power-of-two barrier.

such as loops. However, since our length extension strategy is already effective at exploring loops, this does not inhibit the effectiveness of MULTIFUZZ.

Stage scheduling. The input-to-state stage is performed once for each saved input before any extension or havoc mutations are attempted. Then, the first time an input is selected, the fuzzer favors length extension 90% of the time (to accommodate inputs with new MMIO accesses). In later attempts, the fuzzer randomly selects between the length extension and the havoc stage. Whenever a generated input leads to new code coverage, it is trimmed with Auto Trim followed by Smart Trim before being saved.

5 Evaluation

We designed our evaluation of MULTIFUZZ to answer the following questions:

1. How effective is MULTIFUZZ at fuzzing a wide range of firmware targets and hardware? (Section 5.1 and Section 5.2)
2. How does MULTIFUZZ perform relative to previous state-of-the-art firmware fuzzers? (Section 5.2)
3. How effective are the fuzzing strategies enabled by a multi-stream input representation? (Section 5.3)
4. Can MULTIFUZZ find previously undiscovered bugs in real-world firmware? (Section 5.4)

All the experiments were conducted on an AMD Ryzen Threadripper 3990X, with one core allocated per fuzzing instance. MULTIFUZZ is always configured to start with no initial inputs (the inputs are generated from an empty seed during the length extension stage); other fuzzers are configured to start with the seeds specified in their original paper.

5.1 Evaluation On Synthetic Unit Tests

To determine whether MULTIFUZZ generalizes to a wide range of firmware and hardware, we configured the fuzzer to run the 46 binaries introduced by P^{2}IM [16]. Within these 46 binaries P^{2}IM defines 66[6] unit tests that evaluate the fuzzer's ability to reach specific locations in each binary. Within 10 minutes MULTIFUZZ successfully passes 100% of the unit tests, matching the performance of Fuzzware [42] and surpassing both P^{2}IM and μEmu [54]. This result demonstrates that MULTIFUZZ works across a wide range of firmware targets.

5.2 Comparison with the State of the Art

In this section, we compare MULTIFUZZ's fuzzing performance (in terms of block coverage and bug discovery) against two comparable, fully automated state-of-the-art firmware fuzzers: Fuzzware [42] and Ember-IO [13].

We use the set of 20 real-world firmware samples used for benchmarking in prior work [13, 42, 54][7]. This includes firmware from a diverse range of applications, OS libraries, and hardware platforms; 10 from P^{2}IM [16], 6 from μEmu [54], 2 from Pretender [24], and one each from HALucinator [10] and WYCINWYC [38].

We also evaluated three additional firmware targets built on RIOT-OS: *gnrc_networking*, *File system* and *CCN-Lite Relay*. We selected RIOT-OS for its widespread usage, and the three specific targets were chosen to evaluate distinct RIOT subsystems (i.e., the filesystem, the networking stack, and the CCN-Lite library). The *gnrc_networking* and *File system* firmware were compiled to target a STM32F3 MCU and *CCN-Lite Relay* was compiled to target a nRF52832 MCU. Each target was compiled using their default settings without any modifications, and we configured them in a similar manner to the other benchmark binaries, except to allow the triggering of nested interrupts, which is required because the RIOT-OS scheduler runs in handler mode[8]. Each target is fuzzed for 5 trials for 24 hours each, and coverage over time achieved by each fuzzer is shown in Figure 11

In terms of coverage, MULTIFUZZ achieves performance equal to or better than existing techniques across almost all the binaries in the benchmark (statistical analysis is provided in Appendix Table 2). In 13 out of the 23 targets, MULTIFUZZ's *worst* performing trial achieves higher coverage than both Fuzzware and Ember-IO. Across all binaries, MULTIFUZZ is observed to discover new code earlier. This demonstrates that MULTIFUZZ can initialize peripherals more effectively than past approaches due to our multi-stream length extension strategy. This is particularly apparent in several of the binaries including, the *Drone* target, which we analyze in Section 5.3, and the *3D Printer* target where Fuzzware gets stuck in initialization because it fails to generate enough data for the UART peripheral while printing boot messages. For the *Thermostat* target, MULTIFUZZ achieves less coverage, however after further analysis we conclude that the additional code is only reachable using a bug exploit (see Section 5.2.1).

We also evaluated MULTIFUZZ's ability to discover bugs by manually triaging any crashes that were found. To triage crashes, we begin by identifying the root cause issue using a debugger (GDB). Then, to validate the feasibility of reaching the state where the error occurs, we refer to the datasheet corresponding to the microcontroller the firmware was compiled for. For example, we ensure that the data returned from peripherals leading to the state is possible to generate, and that the peripherals are enabled when the corresponding interrupts are triggered. Detailed information about each crash, including the crash-triggering input and a comprehensive root-cause

[6] Fuzzware [42] observed that 4 of the original 70 unit tests were invalid, and one binary has no valid unit tests so is excluded.

[7] We only fuzz one of 6LoWPAN Sender/Receiver since they are almost identical (they differ by just 3 blocks), and both crash with the same inputs.

[8] Ember-IO does support not nested interrupts so we only compare against Fuzzware on these targets.

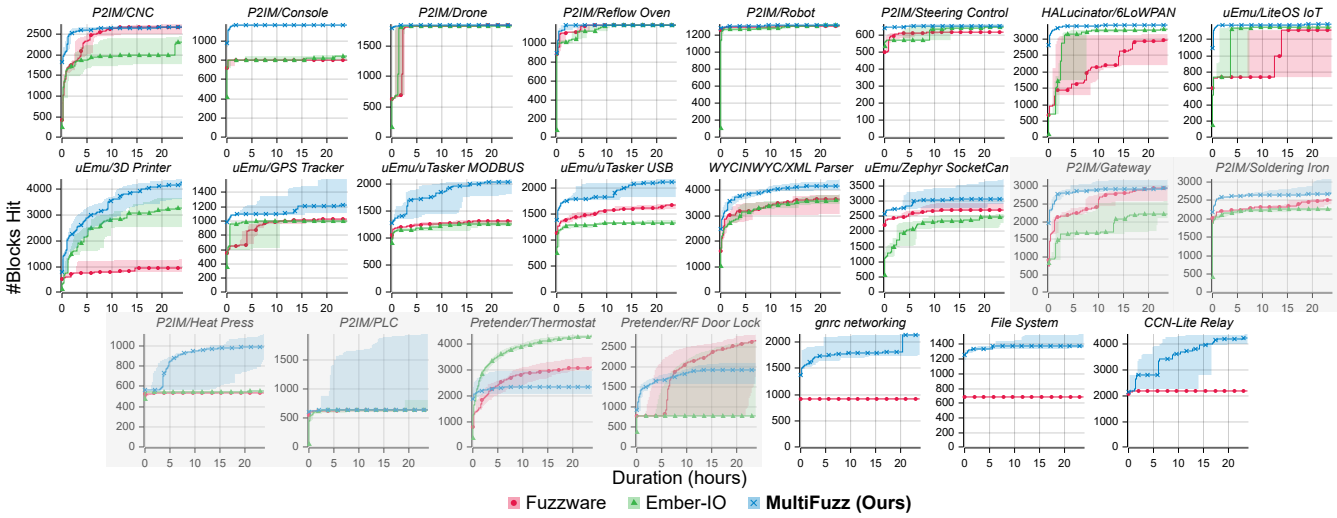

Figure 11: Code coverage for 5 trials of each target over 24 hour period. The solid line represents the median number of unique basic blocks hit, and the area represents the number of blocks hit in the best/worst trials. Subplots shaded in grey represent binaries containing bugs that a fuzzer manages to exploit to reach additional coverage, making the block count metric unreliable.

analysis, is available in our GitHub repository[9]. After identifying the root causes of the crashes found by MULTIFUZZ, we compared the bugs to the ones reported in prior work. We find all 35 unique crashes reported by Fuzzware [42], and the 6 additional crashes found by Ember-IO [13]. Further, MULTIFUZZ finds 13 *new* bugs on the existing benchmark binaries, and 6 bugs in the new binaries, as detailed in Appendix Table 3. On the new binaries, MULTIFUZZ discovered 5 additional bugs (1 in *gnrc networking*, and 4 in *CCN-Lite Relay*). Only one of these bugs could be found by Fuzzware (the reentrancy issue in CCN-Lite Relay)[10].

5.2.1 Bug Exploits Leading to Additional Coverage

Several of the binaries contain bugs that allow arbitrary code execution, enabling the fuzzer to generate inputs that reach code by exploiting these bugs. This can artificially inflate the coverage results for these binaries. Prior work [13, 42] attempts to mitigate this issue by excluding crashing inputs and filtering the coverage results to include only known valid basic blocks (determined using static analysis tools). However, this filtering process is insufficient because a bug exploit can lead to the execution of valid code that is normally unreachable via normal execution.

After analyzing the traces from prior work, we observed bug exploits consistently occurring in both the *Thermostat* and *RF Door Lock* binaries, and occasionally in the *PLC* binary. For example, the *Thermostat* binary contains a bug where the return address of the `get_new_temp` function can be manipulated with fuzzer controlled data by overflowing a stack allocated buffer. By exploiting this bug, the fuzzer can generate inputs that execute code that is normally unreachable. This can include handler functions associated with disabled interrupts, as well as normally unreachable error handlers and print statements. Since bug exploits can lead to a significant increase in the coverage reported by the fuzzer, in our results, the binaries where a bug exploit is detected are shaded in grey.

In the results presented in Figure 11, at least one fuzzer manages to exploit a bug in 6 of the 23 binaries that results in an increase to the number of blocks hit. To detect bug exploits, we analyze the root cause of each bug and add hooks for checking when the bug occurs. For example, in the *Thermostat* target, we inject a hook that checks (by inspecting register values) writes to the stack-allocated buffer do not overflow into the stack slot containing the function return address. If a block is only reachable by inputs that are detected by the hook, then we treat the target as reaching code because of a bug exploit. Additionally, during testing, we observed rare cases where a bug exploit led to increased coverage in both *uTasker USB* and *Zephyr SocketCan*; however, these bug exploits were not observed in the final results.

5.3 Effectiveness of Multi-Stream Techniques

To evaluate the effectiveness of the techniques described in the paper, we conducted 4 additional experiments on each of the firmware targets with MULTIFUZZ configured with subset of the techniques enabled. For configurations where the dynamic dictionary is disabled, only the predefined interesting values (like AFL-style fuzzers) are used for dictionary/value mutations and extensions.

[9] https://github.com/MultiFuzz/MultiFuzz

[10] Fuzzware contains an emulation bug related to the interaction between delayed interrupt checking and instruction barriers. This causes the CCN-Lite Relay target to be emulated incorrectly, complicating bug analysis. However, the reentrancy bug appears to occur prior to encountering the emulation bug.

We start with a basic configuration where only the multi-stream length extension stage (Section 3.1.1) is enabled, then gradually add more complex features. Notably, not all targets require every feature of the fuzzer to fuzz effectively. For example, since the Robot target contains very little code after initialization, the later mutation strategies are not needed to reach all the code in the target. For each target we evaluate whether each addition has a statistically significant impact to the number of blocks reached by the fuzzer in 5 trials. The results of our experiments are shown in Table 1, and we further analyze the impact of the techniques in this section.

Length Extension Only. Our length extension strategy is designed to rapidly discover initial inputs that make it through firmware initialization, serving as an effective starting point for subsequent mutations. As a baseline, we find that length extension proves highly effective, on average reaching 77% of the coverage achieved by the full version of MULTIFUZZ.

As a case study, we analyzed the effectiveness of this configuration on the *Drone* target. By analyzing individual trials (see Appendix Figure 12), we found Fuzzware struggles to progress through 3 functions executed during initialization, each of which involves a significant number of MMIO accesses as part of I2C communication with various subsystems. This requires generating sufficiently large inputs to provide the necessary data for communication. Because Fuzzware does not directly increase the length of inputs, it can take up to 3 hours to complete initialization, while MULTIFUZZ with length extension accomplishes this within minutes.

+Havoc. We then add the multi-stream havoc mutations described in Section 3.3 to the base configuration. The havoc stage enables mutating more than just the end of inputs. Consequently, we see an improvement to the targets that involve logic that depends on different parts of the input. The largest increase occurs in the *Gateway* target which we analyzed (see **Appendix** Figure 13) and determined that the mutations enable the fuzzer to reach several message handlers that length extension alone is unable to reach.

+Trim. In this variant inputs are trimmed using the strategies described in Section 3.1.2 before being added to the input queue. With larger inputs, the fuzzer is less likely to mutate any individual byte, therefore by trimming inputs we make havoc-style mutations more consistent and effective. There are large increases to coverage reached for the *CNC* and *XML Parser* targets, both of which involve parsing structured data where smaller inputs are more likely to be valid data. Trimming also improves the fuzzer's consistency at generating interesting control messages for the *Gateway* target (see **Appendix** Figure 13). We also observed a small decrease in coverage in the *Robot* target, corresponding to code that handles timeouts, that requiring very large inputs to reach. *Heat Press* and *Thermostat* also have large increases, however these can be attributed to bug exploits (Section 5.2.1).

+Input-to-state. In this configuration we combined the previous techniques with a stage that performs input-to-state replacement as described in Section 3.2. MULTIFUZZ achieves substantially higher coverage on binaries that include a shell-like interface (the RIOT-OS binaries, the two uTasker binaries and *Zephyr SocketCan*), as input-to-state allows valid commands and parameters (as analyzed in **Appendix** Figure 14) to be generated more easily. It also provides significant improvements to other targets involving comparisons, including the *3D Printer* target, which uses string comparisons for parsing G-code serial commands, and *Steering Control* which waits for "steer" and "motor" events.

+DynamicDictionary. This configuration represents the full version of MULTIFUZZ, which includes the per-stream dynamic dictionaries described in Section 3.2. Since the input-to-state stage already solves most comparisons, adding a dictionary has a muted effect. The dynamic dictionary is most beneficial for reaching code that requires interactions between multiple strings. For example, in the *File System* target, reaching parts of the code requires first emitting a command to create a file, then a second command that interacts with the same file. However, even with dynamic dictionaries MULTIFUZZ is not always able to find inputs that reach these cases in every trial, reducing statistical significance.

5.4 Analysis of newly discovered bugs

In this section, we analyze a subset of the bugs newly discovered by MULTIFUZZ, focusing on the bugs with a higher security risk. Notably, most of the binaries have been extensively fuzzed by prior work and MULTIFUZZ *still* manages to find 18 new bugs. A summary of all the newly discovered bugs can be found in Appendix Table 3.

Gateway. The firmware processes messages consisting of a command ID and payload. The length of the message is calculated by counting the bytes received up to a termination character. By sending just a termination character, it is possible to send zero-length messages. However, the firmware incorrectly assumes that a command ID is always present, and because the message buffer is reused and not cleared between messages, the command ID read is the value set by the previous message. An integer underflow then occurs when the payload length is adjusted to account for the command ID, eventually resulting in a buffer overflow. Stream-to-stream splicing enhances MULTIFUZZ's ability find this bug by enabling multiple valid messages to be generated more easily.

6LoWPAN Sender/Receiver. The firmware receives 6LoWPAN packets from a SPI bus, storing the packet into a buffer. The firmware then decodes the packet which potentially involves reassembling fragmented payloads. To support reassembly, the packet header includes a fragment offset field. However, the firmware fails to check that the fragment offset is within bounds when copying the payload, causing corruption. MULTIFUZZ's ability to quickly start generating valid

Table 1: Block coverage (median of 5 trials) after 24 hours for different configurations of MULTIFUZZ. Features are added from left to right (e.g., '+Trim' includes: length extension, havoc and the trim stage), the '+DynamicDictionary' column is the full version of MULTIFUZZ. The percentages show the change in coverage compared to the previous configuration. Changes <0.1% are not displayed and statistically significant changes are marked in bold (based on a Mann-Whitney U test with a 0.05 significance threshold). Shaded rows include results where at least one configuration reaches additional blocks via a bug exploit.

packets allows it to spend longer fuzzing the 6lowpan interface enabling it to find this bug. Further analysis revealed the bug is attributable to a known vulnerability in Contiki-OS, which provides the networking interface used by the binary.

uTasker_USB. In one of the bugs within this target, the firmware fails to validate that the interface index used for device/interface requests from the setup packet is in-bounds. For example, when handling a `SET_LINE_CODING` message, if the target interface index is too large, then the settings from the message payload will be copied to arbitrary memory.

gnrc_networking. The code responsible for creating an IPv6 echo packet calculates the total size of the packet by adding the requested payload size to the header size. For a large payload size, an integer overflow occurs when computing the total size. This leads to a packet smaller than the header size. If the overflown value is equal to zero the code dereferences a NULL pointer, for other values smaller than the header size, the code overflows a buffer when filling the packet payload.

6 Discussion

Direct Memory Access (DMA). For MULTIFUZZ we focused on the input-generation aspect of the fuzzing process. We use a similar approach to existing fuzzers such as Fuzzware [42] and Ember-IO [13] when dealing with DMA. MULTIFUZZ does not differentiate between DMA and other MMIO accesses and instead relies on external configuration when necessary. For the binaries included in the benchmarks, we use the configuration files from Fuzzware. However, our approach is fully compatible with other approaches that improve the emulator's ability to handle DMA peripherals, such as DICE [35] or SEmu [55]. Data associated with DMA peripherals could be represented as separate streams in MULTIFUZZ and mutated using operations specialized for DMA.

False positive crashes. In addition to the crashes caused by the bugs found by MULTIFUZZ, we also identified 7 additional false positives, and after further analysis we reclassified 9 of the bugs reported by prior work also as false positives. Most of the false positive crashes are related to interrupts being triggered *before* the firmware fully initializes data related to managing the peripheral (prior work reported these issues as "Unchecked Init"). However, on real ARM MCUs, an interrupt for a peripheral should only be triggered if the bit associated with the interrupt is enabled in the NVIC (nested vectored interrupt controller) *and* the peripheral is enabled and configured to generate the relevant interrupt. For MULTIFUZZ we use the same approach as Fuzzware [42] to handle interrupt triggering, where interrupts can be scheduled as soon as they are enabled in the NVIC. However, firmware may configure the NVIC *before* fully initializing and enabling peripherals, which can result in false positive crashes.

We also found 3 additional false positive crashes related to hardware assumptions. Two of these occurred in *Zephyr Sock-*

etCAN related to the 'canbus attach/detach' sub-commands, causing buffer overflows. The third was related to clock rate initialization in *6LoWPAN Sender* leading to unbounded recursion resulting in a stack overflow. A comprehensive analysis of false-positive crashes is available in our GitHub repository.

Multi-stream fuzzing with MMIO modeling. We have demonstrated that our multi-stream input representation, when used to implement a firmware fuzzer, outperforms prior approaches, including those that utilize modeling techniques. However, our approach is completely independent to MMIO modeling strategies, allowing MULTIFUZZ to be combined with modeling approaches such as Fuzzware [42].

7 Related work

Fuzzing techniques have demonstrated a proven capability to find bugs in diverse software [25, 36]. As such, substantial research effort has been devoted to improving the effectiveness of fuzzers [2, 7, 17, 32, 39]. For example, Angora [7] attempts to explore different input lengths by tracking the return value for `read`-like function calls. However, these approaches are typically focused on testing software written for desktop operating systems and are not directly applicable to fuzzing firmware. Although a range of approaches are proposed to analyze the security of firmware more broadly, including targeted approaches to search for specific vulnerabilities [22, 50], or those involving human analysis [5, 34, 44, 55], we focus on elaborating upon methods explored for fuzzing firmware.

Multiple approaches have explored firmware fuzzing without the need for direct hardware access. Pretender [24] attempts to re-host firmware in an emulated environment by observing interactions between the firmware and hardware during execution on the original hardware. HALucinator [10] makes the observation that many IoT devices utilize a hardware-abstraction-layer (HAL) instead of interacting with the hardware directly and emulates the HAL instead of the underlying hardware. Concurrently with our work, SAFIRE-FUZZ [47] improves the efficiency of this approach by statically rewriting the binary to achieve near-native execution on a more powerful ARM host machine instead of relying on emulation. However, HAL-level emulation requires the time-consuming task of identifying and manually implementing replacements for all HAL functions; a task made more difficult if the functions are inlined as a result of compiler optimizations. P^{2}IM [16] attempts to automatically classify the type of peripheral using several heuristics. Fuzzware [42] infers models for peripherals by locally applying symbolic execution to analyze how peripheral data is used. They demonstrated that their approach to modelling reduces the input overhead, significantly improving the effectiveness of fuzzer mutations. Ember-IO [13] foregoes modelling and introduces two techniques, FERMCov to avoid saving excess inputs added on interrupt entry and exit, and peripheral input playback (PIP) to allow the fuzzer to generate values that are repeated. However, all these approaches either focus on making more efficient use of the inputs consumed by the emulator or preventing the fuzzer from exploring unprofitable paths in a program. In contrast MULTIFUZZ focuses on better input generation as part of the fuzzing frontend. The use of alternative input representations to improve fuzzer effectiveness has been explored in domains outside of firmware fuzzing [1, 3, 4, 23, 40, 41, 49]. For example, Nyx [46] represents bytecode programs for fuzzing hypervisors as directed acyclic graphs. Further, generic fuzzing frameworks such as LibAFL [19] are designed to be compatible with multiple input representations. However, none of the existing input representations are suitable for fuzzing firmware.

Notably, the concurrent work, Hoedur [43], also uses multi-stream inputs to fuzz firmware. MULTIFUZZ places a greater emphasis on length extension strategies compared to Hoedur, incorporating specialized extension mechanisms and generally performing larger extensions. To solve string comparisons, Hoedur constructs a shared dictionary from strings found in the firmware using static analysis. This approach limited to constant string comparisons only, in contrast, MULTIFUZZ's input-to-state stage supports both non-constant string comparisons and non-string memory comparisons. Additionally, Hoedur assigns streams to access contexts (a tuple consisting of the program counter and MMIO address). We define streams solely on MMIO addresses to ensure data read from peripheral registers are contiguous even after inlining optimizations, which improves the consistency of input-to-state replacements. SplITS [14] solves string comparisons in single-stream inputs by introducing an iterative algorithm for matching partial strings that is resistant to data scattering and input stability. This approach has a higher runtime cost to input-to-state replacement in multi-stream inputs and does not address the other issues with single stream inputs.

8 Conclusion

MULTIFUZZ utilizes a novel multi-stream input representation for handling MMIO accesses to fuzz firmware. This new representation is combined with an efficient multi-stream length extension strategy, improved trimming approach, and multi-stream specific mutation operations enables MULTIFUZZ to achieve higher coverage and discover more bugs than existing state-of-the-art firmware fuzzers.

A Appendix

A.1 Block Coverage Statistical Analysis

Table 2: Block coverage after 24 hours for Fuzzware (FW), Ember-IO and MULTIFUZZ (median of 5 trials). To test for statistical significance we conducted Mann-Whitney U tests comparing the results for MULTIFUZZ to Fuzzware and Ember-IO, and report the associated *p*-values in the final two columns. Entries in bold represent the best performing fuzzer with statistical significance (0.05 significance threshold). The metrics for entries shaded in grey may be unreliable due to code reached via bug exploits.

A.2 MULTIFUZZ Component Impact Analysis

To support Section 5.3, we plot the time required by different fuzzer configurations to generate inputs covering specific code regions in various binaries. The right subfigures plot

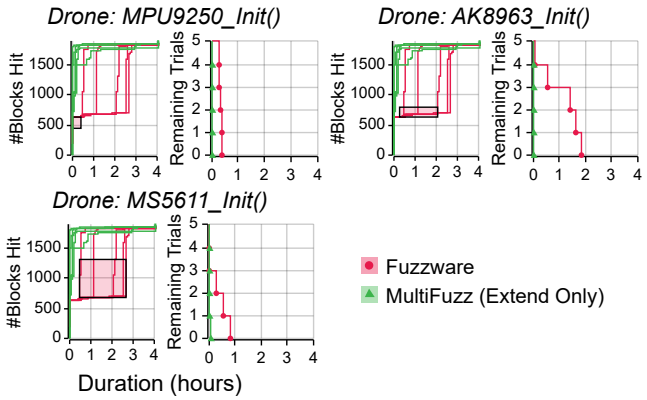

Figure 12: Time required to complete various initialization functions in the *Drone* target.

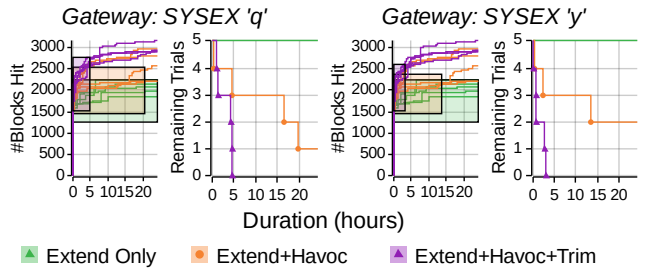

Figure 13: Time required to generate specific control messages in the *Gateway* target.

the amount time each fuzzing trial is stuck at a particular region of code after reaching it for the first time. e.g., the *Drone: AK8963_Init()* plot indicates that two Fuzzware trials cover the function in less than an hour, while the remaining trials take longer. The left subfigures are provided as context to show where within the overall coverage graph the each code snippet is encountered. The shaded rectangular region represents the blocks hit while solving the code fragment.

Figure 12 analyzes the impact of length extension on rapidly progressing through initialization compared to an existing state-of-the-art fuzzer (Fuzzware [42]). It can take Fuzzware almost 3 hours in total to finish initialization in some trials, while MULTIFUZZ with length extension alone completes initialization within minutes.

Figure 13 explore the necessity of havoc-style mutations in reaching various control message handlers in the *Gateway* target. Control messages consist of a command ID framed with start and stop bytes. Without havoc-style mutations (i.e., Extend Only), the fuzzer *never* manages to generate a message with a valid command ID. Introducing havoc-style mutations enables the fuzzer to mutate the command ID while leaving the start and stop bytes alone, albeit inconsistently. Trimming inputs significantly increases the speed and consistency of generating control messages, allowing the configuration with trim enabled to generate both target messages within 5 hours.

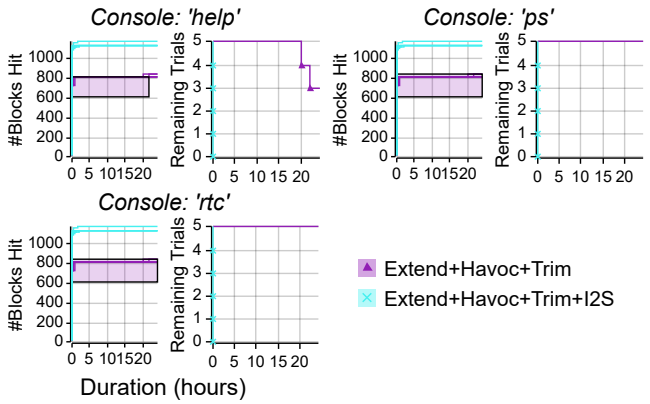

Figure 14: Time required to reach command handler functions in the *Console* target.

Figure 13 investigates the impact of input-to-state (I2S) replacements. Without a mechanism to solve string comparisons, the MULTIFUZZ struggles to reach any of the command handlers. Across all trials, the configuration without I2S only manages to reach a command handler twice. With I2S, all command handlers are reached within minutes of fuzzing.

A.3 Responsible Disclosure

We disclosed security related bugs by sending bug-reports to vendors/developers in accordance with the security policies listed for the associated project. All reported issues have either been fixed, or based on feedback from maintainers, are not considered to be security critical.

Table 3: Summary of the 18 new bugs found by MULTIFUZZ.

Target	Description	Status
6LoWPAN	Fragment offset is not bounds-checked	Fixed upstream at the time of reporting.
Zephyr SocketCan	net pkt command de-references a user provided pointer.	Fixed at the time of reporting.
Zephyr SocketCan	canbus config command fail to validate argument count.	Code rewritten in latest release.
Zephyr SocketCan	canbus sub-commands fail to verify device type.	Noted as a known API limitation.
Zephyr SocketCan	pwm sub-commands fail to verify device type.	Noted as a known API limitation.
Gateway	Incorrect handling of zero length sysex messages.	Reported & Fixed.
utasker MODBUS	Direct manipulation of memory using I/O menu.	Intentional feature for debugging.
utasker USB	Direct manipulation of memory using I/O menu.	Intentional feature for debugging.
utasker USB	Out-of-bounds access from interface index.	Reported & Acknowledged.
GPSTracker	strtok not checked for NULL in gsm_get_imei.	Input is trusted, not reported.
GPSTracker	strstr not checked for NULL in sms_check.	Input is trusted, not reported.
GPSTracker	strstr not checked for NULL in gsm_get_time.	Input is trusted, not reported.
GPSTracker	strtok not checked for NULL in gsm_get_time.	Input is trusted, not reported.
gnrc_networking	Integer overflow when computing echo packet size.	Reported & Fixed.
CCN-Lite Relay	Data race during stdio initialization.	Reported & Fixed.
CCN-Lite Relay	Use-after-free of temporary interface.	Reported & Acknowledged.
CCN-Lite Relay	Re-initialization of shared global variables.	Reported & Acknowledged.
CCN-Lite Relay	Incorrect handling of content messages with invalid URIs.	Reported & Acknowledged.

WhisperFuzz: White-Box Fuzzing for Detecting and Locating Timing Vulnerabilities in Processors

Abstract

Timing vulnerabilities in processors have emerged as a potent threat. As processors are the foundation of any computing system, identifying these flaws is imperative. Recently fuzzing techniques, traditionally used for detecting software vulnerabilities, have shown promising results for uncovering vulnerabilities in large-scale hardware designs, such as processors. Researchers have adapted black-box or grey-box fuzzing to detect timing vulnerabilities in processors. However, they cannot identify the locations or root causes of these timing vulnerabilities, nor do they provide coverage feedback to enable the designer's confidence in the processor's security.

To address the deficiencies of the existing fuzzers, we present *WhisperFuzz*—the first white-box fuzzer with static analysis —aiming to detect and locate timing vulnerabilities in processors and evaluate the coverage of microarchitectural timing behaviors. *WhisperFuzz* uses the fundamental nature of processors' timing behaviors, *microarchitectural state transitions*, to localize timing vulnerabilities. *WhisperFuzz* automatically extracts microarchitectural state transitions from a processor design at the register-transfer level (RTL) and instruments the design to monitor the state transitions as coverage. Moreover, *WhisperFuzz* measures the time a design-under-test (DUT) takes to process tests, identifying any minor, abnormal variations that may hint at a timing vulnerability. *WhisperFuzz* detects 12 new timing vulnerabilities across advanced open-sourced RISC-V processors: `BOOM`, `Rocket Core`, and `CVA6`. Eight of these violate the zero latency requirements of the Zkt extension and are considered serious security vulnerabilities. Moreover, *WhisperFuzz* also pinpoints the locations of the new and the existing vulnerabilities.

1 Introduction

The evolution in computer architecture has significantly amplified the complexity of hardware design, especially in modern processors, which are the foundation of today's computing systems. As technology advances, designers integrate more functionalities into hardware, leading to more intricate architectural and microarchitectural features in processors. However, as the complexity of the design increases, so does the number of design regions to verify and protect. Traditional techniques to verify modern processors cannot scale with the number of (new) hardware vulnerabilities discovered. For example, the number of newly detected hardware common vulnerabilities in the National Vulnerability Database (NVD) increased from three in 2012 to 92 in 2022 [5]. Further, as of 2023, MITRE reported 117 hardware-related vulnerability types, known as Common Weakness Enumerations (CWEs) [41]. These rapidly increasing vulnerabilities threaten the security of the expanding digital landscape across different domains necessitating efficient detection strategies [13, 15, 21, 44, 45].

Timing vulnerabilities are of particular concern as they can leak sensitive information, undermining the entire system's security. Well-known attacks such as Spectre [38], Meltdown [40], Foreshadow [61], LVI [62], RIDL [63], ZombieLoad [54], CrossTalk [50], Zenbleed [4], and Retbleed [68] exploit timing vulnerabilities present in a wide range of commercial processors. Multiple variants of these attacks have been shown to subvert security countermeasures implemented to prevent such attacks. Unlike functional vulnerabilities, timing vulnerabilities can manifest in a logically correct implementation, making them hard to detect. Timing vulnerabilities rely on the difference in execution time of the hardware components to leak sensitive information. These vulnerabilities underscore the need for rigorous security analysis in modern processors. Moreover, unlike software flaws, which can be patched post-deployment, fixing hardware vulnerabilities after manufacturing is difficult, as they are physically ingrained into the Silicon. Therefore, detecting vulnerabilities at the pre-Silicon stage is imperative for secure hardware.

Existing timing vulnerability detection strategies for processors use formal methods or fuzzing. Formal methods, such as theorem proving [20], model checking [18], assertion proving [70], and information-flow tracking [33] explore de-

[*]These authors contributed equally to this work.

sign spaces exhaustively and prove security assertions about hardware. Thus, detecting timing vulnerabilities using formal methods is a rigorous approach to ensure design security [22, 58]. However, these methods are limited by the state explosion problem [10, 17–19]; exhaustively exploring the complex modern hardware is computationally hard [16, 31]. Some approaches aim to handle this scalability issue by modeling hardware at the higher abstraction level and approximating its timing behavior [58]. However, abstracting hardware can lead to over-optimistic results or false positives [16]. Furthermore, these formal approaches require a comprehensive understanding of the designs' security specifications and manually defining properties, an error-prone process [46].

Alternatively, hardware fuzzing has shown its effectiveness in detecting vulnerabilities in large-scale designs [14, 16, 34, 37, 39, 71]. Using fuzzing, Google detected the recent vulnerability on AMD Zen2 processors, *Zenbleed* [4], a speculative execution vulnerability that allows attackers to extract sensitive information through software exploitation [47]. Black-box fuzzing [35, 67] and grey-box fuzzing [51] have been applied to detect timing vulnerabilities in processors. They explore the design spaces by generating different combinations of instructions as inputs and use performance counters to identify potential timing vulnerabilities [35, 51, 67]. While these techniques overcome the scalability issue of formal verification, they suffer from two critical limitations. First, although they successfully find instructions that cause timing vulnerabilities, they rely on confirmation from designers to identify and pinpoint the root cause (locations) [35, 51, 67]. Second, they lack the adequate coverage metric to capture the timing behaviors of the processor. Designers rely on coverage metrics to obtain the necessary confidence before tapeout [27, 36, 57]. Therefore, introducing such metrics to evaluate the progress of fuzzing is typical [69]. We will elaborate on these shortcomings in Section 5.

Our Goals and Contributions. We enhance existing fuzzing strategies to address their limitations by integrating static analysis. This allows us to automatically pinpoint the sources of timing vulnerabilities and compute the coverage of timing behaviors in processor designs. Our fuzzer efficiently explores the design space, detecting timing vulnerabilities, while our novel static approach identifies the root causes and provides timing behavior coverage.

Locating the root cause of timing vulnerabilities and computing timing coverage is non-trivial and poses several challenges: (i) expressing the timing behaviors of processor modules formally is complex, as they do not operate in isolation and can influence each other; (ii) finer measurement of module timing behaviors is needed, which is time-consuming for modern processors with numerous modules [73, 74]; (iii) tracing vulnerabilities to their root causes within the design space is intricate; and (iv) traditional mutation algorithms used in fuzzers are insufficient for detecting timing vulnerabilities due to their reliance on microarchitectural state transitions.

To address these challenges, (i) We have developed the *Micro-Event Graph*, a static program analysis technique that formally expresses module timing behaviors in a processor by extracting microarchitectural state transitions of a design-under-test (DUT) at the register-transfer level (RTL). To efficiently cover the extensive design space, we tailor the technique to generate individual graphs for each RTL module (cf. Section 3.5). (ii) We analyze each RTL module's simulation trace to measure its timing behaviors precisely. To streamline our analysis efforts, we devise a hierarchical strategy based on the characteristics of timing vulnerabilities to prioritize modules for examination (cf. Section 3.6). (iii) We pinpoint the root causes of detected timing vulnerabilities utilizing static analysis techniques and properties of the *Micro-Event Graph*, employing a module-wise strategy to navigate the complex design space. (iv) We have adapted traditional hardware fuzzing methods to efficiently explore a DUT's design spaces and crafted a specialized mutation engine to exploit timing vulnerabilities. Furthermore, we have instrumented graphs into the DUT to monitor module state transitions based on the input (cf. Section 3.8).

In summary, our contributions are:

- We present a novel white-box fuzzer with static analysis, *WhisperFuzz*, for timing vulnerability detection in processors at the RTL. *WhisperFuzz* extracts and monitors microarchitectural state transitions at RTL and measures the timing behaviors of each RTL module to identify timing vulnerabilities. Hardware fuzzing enables *WhisperFuzz* to explore the microarchitectural state space efficiently.
- With static analysis, *WhisperFuzz* will identify the locations/root causes of timing vulnerabilities. Moreover, *WhisperFuzz* introduces a timing coverage metric to help designers evaluate the timing behaviors explored.
- We evaluate the effectiveness of *WhisperFuzz* on three real-world, open-sourced processors from RISC-V instruction set architecture (ISA) – `BOOM` [74], `Rocket Core` [9], and `CVA6` [73], which are widely used as benchmarks in the hardware security community.
- *WhisperFuzz* finds 12 new timing vulnerabilities across all three benchmarks. Eight of them pose serious security vulnerabilities, according to the RISC-V Zkt contract [43]. *WhisperFuzz* also pinpoints the locations of all existing and new vulnerabilities.

2 Background

In this section, we provide a succinct background on hardware fuzzing and microarchitectural timing side channels, which form the basis of *WhisperFuzz*.

2.1 Hardware Fuzzing

Hardware fuzzing is a dynamic verification technique that iteratively generates testing inputs called tests to verify target

Listing 1: A pair of instruction sequences that have identical instructions but operate on different data. The instruction sequence is a timing vulnerability if the execution times differ.

```
1 LI   t6, 0x81321          LI   t6, 0x11235
2 LI   a7, 0xFEEEE          LI   a7, 0xFFFFF
3 LD   t4, 0(a7)            LD   t4, 0(a7)
4 ADDI a9, a5, t4           ADDI a9, a5, t4
5 LD   t5, 0(t6)            LD   t5, 0(t6)
```

hardware [16, 34, 39]. A coverage-feedback fuzzer starts by generating an initial set of tests, called **seeds**, randomly using a *seed generator*. When fuzzing processors, these seeds are executable programs with a sequence of instructions [16, 37]. The fuzzer simulates the target hardware with these tests using open-source or commercial hardware simulation tools such as Verilator [56] and Synopsys VCS [3].

During simulation, the fuzzer collects **coverage** information that quantifies the activities caused by the test in the hardware. For instance, the coverage information can be represented as transitions of finite-state machines (FSMs) [37]. Fuzzers either instrument the hardware to add activity monitors [34, 39], or use the existing coverage monitors of the simulation tools [16, 37] to collect this coverage information. Next, it generates new tests automatically by performing bit manipulation operations, called **mutations** on the current tests, increasing coverage. The fuzzer iterates over this cycle of test generation and simulation to verify target hardware till desired coverage is achieved.

Fuzzers use a *vulnerability detector* to detect vulnerabilities using differential testing or hardware assertions. In differential testing, the fuzzer runs a golden reference model along with the target hardware and compares its outputs to detect vulnerabilities [34, 37]. Alternatively, some fuzzers insert hardware assertions, i.e., rules describing the expected behavior, in the target hardware and detect vulnerabilities as violations of these assertions [42]. While existing black-box [35, 67] and grey-box [51] fuzzers can detect timing vulnerabilities in processors, these approaches fail to locate the root causes of these vulnerabilities. Further, these techniques can not evaluate the explored timing behaviors. These limitations delay the mitigation process and hamper the designer's confidence due to absence of a coverage metric.

2.2 Timing Side-Channel Attacks

Timing side-channel attacks exploit measurable variations in the execution time of instructions to glean secret information from victim applications. These timing variations arise from interactions of different operands with the microarchitecture. For instance, [11] proposed a timing attack to recover AES keys by measuring the cache accesses during encryption across different keys.

Over the years, multiple techniques to perform timing attacks have developed such as PRIME+PROBE [48], EVICT+TIME [48], and FLUSH+RELOAD [30]. The key idea of all these attacks is to target a specific shared resource, such as the cache memory, and exploit its data-dependent timing behavior. Such attacks consist of a sequence of instructions which when executed with different data take different execution times. For example, consider the pair of instruction sequences in Listing 1. The two sequences are identical but differ in the data they operate upon. The sequence can be considered a timing vulnerability if the execution of the two sequences results in different execution times.

The objective of our work is to develop *WhisperFuzz*, which identifies such instruction sequences and pairs of input data that result in different execution times. Furthermore, *WhisperFuzz* localizes the root cause for the differing execution times, thereby assisting in mitigation.

3 Methodology

In this section, we first explain the relationship between timing behaviors and transitions of a digital circuit. We introduce the *Micro-Event Graph* that helps capture the microarchitectural transitions at a fine granularity. We use this graph to identify the location of timing vulnerabilities and monitor the timing behaviors covered. Further, we discuss the challenges of extracting the *Micro-Event Graph* from a processor design. Finally, we give an overview of our solutions to these challenges and elaborate on each solution.

3.1 Microarchitectural Transitions and Timing Behaviors

A finite-state machine (FSM) can model a sequential digital circuit. Given an input, the circuit transitions through various states in the FSM to produce the output. Assuming each state in the FSM takes constant time, the sequence of state transitions to generate the output determines the execution time of the circuit for a given input. Thus, we claim: *two different inputs resulting in the same state transition sequences will take the same execution time.*

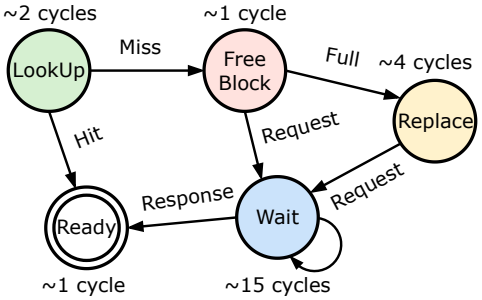

Figure 1: A finite-state machine (FSM) representation of the cache set protocol. Each state is assumed to take a constant time as shown at each node.

Consider the case study of a cache composed of multiple cache sets. Each cache set can be represented as an FSM with five states: `LookUp`, `FreeBlock`, `Replace`, `Wait`, and `Ready`, as shown in Figure 1. When a program accesses data, the cache first performs a look-up for the associated memory address in the `LookUp` state. If the data is found in the cache (cache hit), it will be directly transferred to the `Ready` state, and the processor can access the data without going to the main memory. Thus, an input address that is already present in the cache set causes transitions `{LookUp` $\rightarrow$ `Ready}` taking three clock cycles in its corresponding implementation. However, if the data is not found (cache miss), the cache set will transfer to the `FreeBlock` state to look for a free cache block to store the data. If a free block exists, the cache will transition to the `Wait` state and request the memory for the corresponding data. In case the cache does not have a free block, it will transfer to the `Replace` state, select a block for eviction based on the replacement policy, and then transfer to the `Wait` state. The cache waits in this state until it receives data from memory. It then transitions to the `Ready` state. Thus, if an input address is not present in the cache set, two FSM state transition sequences (and execution times) are possible: (i) `{LookUp` $\rightarrow$ `FreeBlock` $\rightarrow$ `Wait` $\rightarrow$ `Ready}`, taking 19 clock cycles if the cache has a free block or (ii) `{LookUp` $\rightarrow$ `FreeBlock` $\rightarrow$ `Replace` $\rightarrow$ `Wait` $\rightarrow$ `Ready}`, taking 23 cycles if the cache does not have a free block. Assuming each state in the FSM takes a constant execution time, a difference in the execution time of two inputs implies a difference in the sequence of state transitions followed in the FSM. However, in practice, FSM states do not always take a constant execution time. Moreover, an FSM model is abstract and cannot effectively represent complex microarchitectural details in digital circuits. Thus, an FSM representation fails to uncover timing differences arising at the microarchitectural level. Further, it makes localizing the source of timing difference difficult, delaying the mitigation process.

We introduce *Micro-Event Graphs* (MEGs) to overcome these drawbacks. A MEG models a given digital circuit using the register-transfer level (RTL) as a set of events, which we call microarchitectural events. Each microarchitectural event affects the contents of at least one element, such as a wire or a register in the digital circuit. A MEG models a given digital circuit as possible events and dependencies between these events. Each node in the MEG represents an element while a directed edge from a parent node to a child node indicates that an event on the parent element can potentially trigger an event on the child element.

Figure 2 shows a high-level representation of the MEG corresponding to the cache set protocol. The MEG consists of 15 nodes and 115 edges. Each state in the corresponding FSM (refer Figure 1) maps to one or more nodes in the MEG. For example, nodes colored in green (node labels starting with L) correspond to state `LookUp` and those colored in yellow (node labels starting with P) correspond to state `Replace`. Each

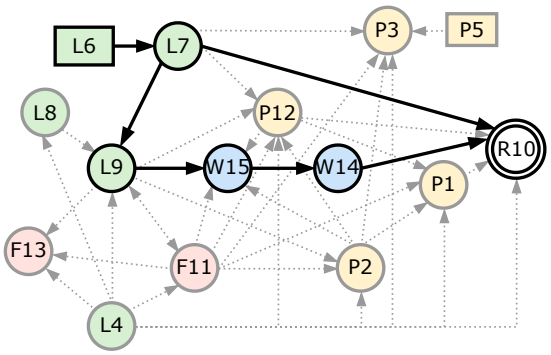

Figure 2: A high level representation of *Micro-Event Graph* (MEG) for cache set protocol represented as an FSM in Figure 1.

execution of the cache set protocol can be mapped to at least one path in the MEG shown. Similar to the state transitions in the FSM, but at the finest granularity, an input triggers a sequence of microarchitectural events in the MEG during its execution, each taking a constant time. Thus, one can have the following observations:

P1. If two inputs to the microarchitecture result in the same event transitions in the MEG, then the execution time for the two inputs is the same.

P2. If there is a difference in the execution time of the two inputs, then the sequence of microarchitectural events followed is different for the two executions.

P3. If two inputs to the microarchitecture result in different event transitions in the MEG, then the execution time for the two inputs may differ.

3.2 Detecting and Localizing Timing Vulnerabilities in Processors: A High-Level Overview

The goal of *WhisperFuzz* is to detect and localize timing vulnerabilities in a processor design-under-test (DUT). To detect timing vulnerabilities, we leverage the strength of hardware fuzzing. The fuzzer generates an instruction sequence and at least two corresponding data inputs of the form shown in Listing 1, that take different execution times when applied to the sequence. For each pair of instruction sequences and inputs, we trace the path of events in the MEG. For example, in Figure 2, each path represents an execution corresponding to different addresses given to a `load` instruction. These paths are then used to localize the root cause of the vulnerability. The root cause is the event prior to the first bifurcation in these two paths.

For example, consider the two highlighted paths in Figure 2. One path traces event sequence { L6, L7, R10}, while the other traces {L6, L7, L9, W15, W14, R10}. Each path corresponds to a different address given to a `load` instruc-

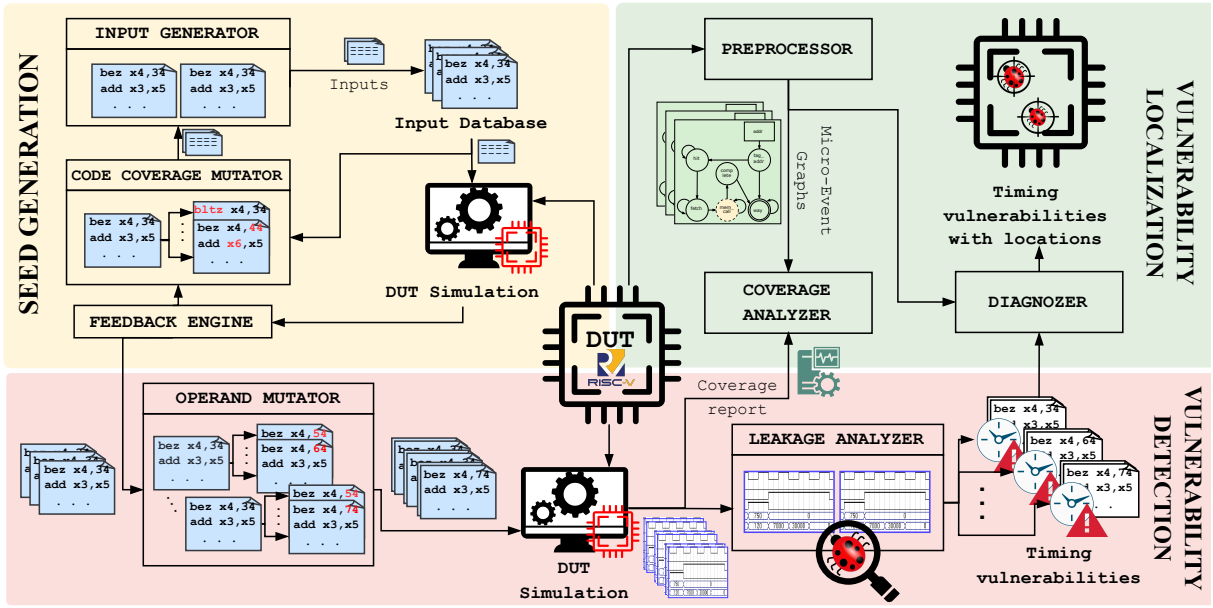

Figure 3: The *WhisperFuzz* framework. It includes three key modules. First, the Seed Generation module internally utilizes a coverage-feedback fuzzer to explore the design space. The generated inputs are recorded in a database. Mutations are performed to improve code coverage. Second, the Vulnerability Detection module uses the generated seed, mutates the instruction operands, and identifies the timing vulnerabilities based on DUT simulations. Finally, the Vulnerability Localization module pinpoints the locations of uncovered vulnerabilities.

tion. Since the two paths are different, they may take different execution times due to **P3** (See Section 3.1), resulting in a timing vulnerability. These paths trace the same events until L7, after which they bifurcate. Hence, an event on node L7 will likely be the vulnerability's root cause. The number of paths covered in the MEG gives a notion of the coverage of timing behaviors of the DUT.

3.3 Challenges

Developing *WhisperFuzz* involves the following challenges.

C1. Generating the MEG. The MEG must capture all possible events and event transitions in a given processor DUT. This is specifically challenging in modern microprocessors due to their complexity and large code bases. We develop an automated strategy to address this challenge that extracts the MEG given the DUT's source code in RTL form. Section 3.5 elaborates on this strategy.

C2. Characterizing timing behavior of each processor module. One way to determine timing behaviors is to input instruction sequences to the DUT and measure the execution time. However, a complete processor design contains thousands of signals, complicating the localization of the vulnerability. An alternate bottom-up approach is to isolate each module in the processor, provide inputs, and measure the timing behavior of the module. However, timing differences detected may not be observable when the module is integrated into the complete processor. Therefore, we follow a two-pronged approach where we first generate instruction sequences for the complete processor to detect timing differences and localize at a module level. We present a *hierarchical analysis strategy* to prioritize the modules to be analyzed, thereby detecting vulnerabilities faster, as discussed in Section 3.6.

C3. Localizing the source of timing vulnerability. The large code space of the processor's DUT makes it challenging to locate the source of a timing vulnerability. It necessitates manual effort and a detailed understanding of the processor's microarchitecture. To address this challenge, we introduce an automated static analysis strategy on the MEG that can identify the root cause of the timing vulnerability within a few seconds. Section 3.7 elaborates on the strategy.

C4. Fuzzing the microarchitectural state space and determining coverage. Hardware fuzzing has shown its effectiveness in detecting vulnerabilities in large-scale designs, such as processors. However, the existing grey-box processor fuzzers [51] are not compatible with timing vulnerability detection. Their mutation algorithms are designed to accelerate coverage increment, but timing vulnerability detection requires sequences of data-dependent instructions that change processors' timing behaviors as seen in Listing 1. Moreover, existing fuzzers lack coverage feedback to demonstrate the timing behaviors covered. Providing such metrics can help designers decide to tape out. To address this challenge, we develop a specialized mutation algorithm that generates data-

dependent instructions. We then use paths of each module's MEG as the timing coverage metric and instrument the DUT to provide coverage feedback.

3.4 The *WhisperFuzz* Framework

To address the challenges discussed in Section 3.3, we develop *WhisperFuzz* that comprises of three major modules: *Seed Generation*, *Vulnerability Detection*, and *Vulnerability Localization*, as shown in Figure 3.

Seed Generation. *WhisperFuzz* first uses the Seed Generation module that contains a coverage-feedback fuzzer [14, 16, 34, 37, 39] to explore design spaces guided by the fuzzer's internal code-coverage metric. The fuzzer utilizes the *Input Generator* to generate input instructions, which are then simulated in the fuzzer's internal *DUT Simulation* unit. The *Feedback Engine* calculates the code-coverage metric of this input. Based on this metric, the *Code Coverage Mutator* mutates the input instructions to improve the coverage. The *Input Database* records various fuzzer-generated inputs and the corresponding code-space covered.

Vulnerability Detection. Based on the *Feedback Engine*, *WhisperFuzz* identifies a sequence of instructions that explore new design spaces as seeds and sends them to the Vulnerability Detection module. The *Operands mutator* in the Vulnerability Detection module mutates the data in the instruction sequence to trigger varying timing behaviors (See Section 3.8). These mutated instruction sequences are simulated in the *DUT Simulation* unit of the Vulnerability Detection module. The *Leakage analyzer* then compares simulation traces and detects timing vulnerabilities (See Section 3.6).

Vulnerability Localization. *WhisperFuzz* invokes the *Preprocessor* in Vulnerability Localization to extract *Micro-Event Graph* of modules (See Section 3.5) and instruments potential timing behaviors based on the *Micro-Event Graph*. For the timing vulnerabilities identified by the *Leakage analyzer*, *WhisperFuzz* invokes the *Diagnozer* to pinpoint the cause of these timing vulnerabilities (See Section 3.7). The *Coverage analyzer* collects simulation traces of all inputs from the Vulnerability Detection module and calculates the timing behaviors covered.

The *WhisperFuzz* framework repeats these steps until there is a timeout, or the fuzzer and *Operand mutator* completely cover the timing behaviors of the DUT.

3.5 Extracting Micro State Transitions

In this section, we elaborate on the MEG used to address challenge **C1**. Using a *Preprocessor*, *WhisperFuzz* parses the RTL code of a given design to generate its MEG representation. Each node in the MEG represents an event corresponding to an element in the RTL, while an edge indicates that there exists an event on the parent node that can trigger a change in the value of the child node. Edges between nodes are also

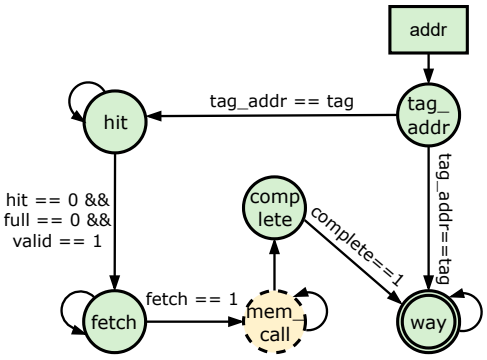

Figure 4: Sub-graph extracted from *Micro-Event Graph* in Figure 2 of the cache set protocol case study. The L6, L7, L9, W15, W14 and R10 nodes from Figure 2 correspond to `addr`, `tag_addr`, `hit`, `mem_call`, `complete`, `way` respectively.

Listing 2: Simplified Verilog code of cache set protocol (refer Figure 1).

```
1  input addr; output way;
2  reg hit, full, valid, fetch;
3  wire tag_addr, complete;
4  assign tag_addr = addr[tag_bits];
5  always@(posedge clock) begin
6     if tag_addr == tag
7        way <= index; hit <= 1;
8     if hit == 0 && full != 1 && valid == 1 begin
9        fetch <= 1; temp_way <= index;
10    if fetch == 1:
11       // Call mem_call for fetching block from next level.
12       // Sub-instance sets complete signal
13       mem_call(addr, complete);
14    if complete:
15       way <= temp_way;
16 end
```

annotated with conditions required to trigger the event and the RTL line number which causes the dependency between the event. Nodes in the MEG can be categorized into sequential nodes or combinational nodes corresponding to the sequential or combinational nature of the hardware element it represents [29]. Formally, we define a MEG as:

Definition 1 *Given the RTL of a module D in a DUT, the corresponding micro-event graph is defined as $\mathbb{G}(D) = (S, \Sigma)$, where the nodes are denoted by $S = \{s_1, s_2, \cdots, s_n\} = \{S_q \cup S_c \cup S_I \cup I \cup O\}$ and include all elements in D; S_q and S_c represent the sequential and combinational elements respectively; S_I represent external modules instantiated in D; I and O are the set of inputs and outputs respectively to the module D. The set Σ represents the edges in the graph, $\mathbb{G}$, such that $(s_i, s_j) \in \Sigma$ if a change in s_i may trigger a change in s_j as per the RTL. Each edge is annotated with the condition required for the change to occur.*

Consider the cache set protocol example given in Section 3.1, with its corresponding simplified Verilog code as in Listing 2. A sub-graph of its MEG is shown in Figure 4, denoting input node `addr` with an incoming edge. Due to

Algorithm 1: Preprocessor in Vulnerability Localization module of *WhisperFuzz*.

```
   Input  : D // RTL code of module
   Output : 𝔾 // MEG of module
1  𝔾(D).I ← ϕ; 𝔾(D).S_I ← ϕ; 𝔾(D).O ← ϕ
2  𝔾(D).S ← ϕ; 𝔾(D).Σ ← ϕ
3  𝔾(D).I, 𝔾(D).S_I, 𝔾(D).O ← GETINOUTPUTS(D)
4  𝔾(D).S ← GETSIGNALS(D)
   /* Iterate RTL code                    */
5  for line ∈ D do
       // Get an operand set that can change
          the value of destination signal
6      s_2 ← GETDESTINATION(line)
7      s_1 ← GETOPERANDS(line)
8      for s_1 ∈ S_1 do
           // Add an edge between each operand
              and the destination signal
9          𝔾(D).Σ ← 𝔾(D).Σ ∪ {s_1, s_2, line_no}
10 return 𝔾
```

the `assign` statement on Line 4, a transition in the value of `addr` triggers a change in the value of `tag_addr`. To denote this dependency, the graph contains a directed edge from the node `addr` to `tag_addr`. Similarly, the value of `tag_address` can influence the value of `way` and `hit` if the condition (`tag_address == tag`) on Line 6 holds. Hence, the edges from `tag_address` to `way` and `hit` are annotated with the condition. The sub-instance call on Line 13 corresponds to the dashed node `mem_call` in the MEG. The accept state from node `way` indicates that it references an output signal. The *Preprocessor* parses the RTL description of the design, translating it into the corresponding graphical representation using Algorithm 1. Given an RTL module D, the *Preprocessor* first extracts into $\mathbb{G}(D).X$ where $X = I, O, S, \Sigma,$ or S_I corresponds to the set of inputs, outputs, nodes, edges, and sub-instance nodes respectively (Lines 3 and 4). Finally, the *Preprocessor* iterates over each line in the RTL, identifies destination signals (Line 6) and operand signals (Line 7), and adds an edge between each operand signal and the destination signal (Line 9). The *Diagnozer* (Section 3.7) and *Coverage Analyzer* (Section 3.8) of *WhisperFuzz* utilize this MEG for further analysis. *WhisperFuzz* generates *Micro-Event Graph* for each module individually to counteract the vast design complexity of processors. The comparitively reduced permodule complexity consumes a reasonable computation cost and resource utilization as shown in Table 3.

Micro-Event Path. We define a *Micro-Event Path* (MEP) as a path that starts at the input node and traces connected nodes until it reaches the output node. Given an input, this path traces the sequence of events triggered in the module. Formally,

Definition 2 *A sequence of directed edges,* $P = \langle (s_1, s_2), (s_2, s_3), \cdots, (s_{n-1}, s_n) \rangle$ *where* $(s_i, s_j) \in \Sigma, \forall (i, j)$ *and* $s_1 \in I$ *and* $s_n \in O$*, is a Micro-Event Path in* $\mathbb{G}(D)$.

Figure 4 notes two different MEPs from the input node `addr` to the output node `way`. Each path can be mapped to a path in the FSM in Figure 1, but at a finer granularity. In case of a cache hit, the module follows the FSM path {`LookUp` → `Ready`} mapped to MEP {`addr` → `tag_addr` → `way`}. In case of a cache miss, if the cache set has a free cache line, the module follows the FSM path {`LookUp` → `FreeBlock` → `Wait` → `Ready`} mapped to {`addr` → `tag_addr` → `hit` → `fetch` → `mem_call` → `complete` → `way`}. A comparison of these two differing MEPs indicates the RTL wire `tag_addr` as the hardware element responsible for the divergence in the two paths. *WhisperFuzz* utilizes this information to trace the root cause of the vulnerability, as elaborated in Section 3.7.

3.6 Characterizing Timing Behaviors

Existing hardware fuzzers detect timing vulnerabilities by measuring the execution time of an entire processor through performance counters [35, 51, 66, 67]. *WhisperFuzz*, however, requires finer information to localize the timing vulnerabilities. Therefore, *WhisperFuzz* computes the execution time taken by each module within the processor. For this purpose, we use simulation of inputs generated by the *Seed Generation* and mutated by the *Operand Mutator*.

For each simulation of the DUT, the *Simulator* generates a set of simulation traces corresponding to each signal within the DUT. A simulation trace is a time series that records all transitions of a signal during an execution. The *Leakage Analyzer* then selects the subset of interesting traces that can lead to a vulnerability. These traces are snipped at the last clock cycle at which any signal within a selected module instance toggles. The duration of this constrained trace is then computed as the execution time of the module instance. The *Leakage analyzer* analyses the timing behaviors of each module instance in a DUT to identify the module instance with timing vulnerabilities.

Hierarchical leakage analysis. Modern processors, however, consist of hundreds of module instances with various inter-module dependencies [9, 73, 74]. Analyzing all their timing behaviors is time-consuming and computationally expensive. Hence, we require a staggered approach for leakage analysis, which prioritizes modules based on their dependencies. A different module-specific execution time indicates that the source of the vulnerability either originates in the current module or a module lower in the hierarchy. For example, the memory control unit (MCU) controls the data accesses in the cache. Upon storing the data at a memory address, the cache sends the `Ready` signal to the MCU. Thus, if a timing difference is in the cache delaying the `Ready` signal, the MCU will also observe the timing difference.

The *Leakage Analyzer* implements a hierarchical method taking a bottom-up approach. In this approach, we map the dependencies between modules and place these modules into various hierarchical levels such that the lower-level modules are sub-instances of a higher-level module. The hierarchical leakage analysis is then carried out incrementally from the lowest module to the highest module. For example, in BOOM [74] there are 431 module instances, when placed hierarchically they constitute 10 levels. Thus, BOOM analysis starts from the tenth level and moves upwards until the top module. This approach also ensures the detection of timing vulnerabilities in all lower levels before detection in a higher level module instance.

Once the *Leakage analyzer* identifies a module instance with execution time differences caused by a pair of inputs, it sends the module instance and the corresponding simulation traces to *Diagnozer* to pinpoint the location of timing differences further.

3.7 Localizing the Source of Timing Vulnerabilities

For a pair of inputs exhibiting a difference in execution time in a particular module instance, the *Diagnozer* localizes the source of the timing difference within the design RTL. The *Diagnozer* takes as input two sets of simulation traces, each corresponding to an execution of the DUT with different data inputs. It operates in two phases: (i) identifying the element causing the divergence and (ii) mapping the cause in the RTL source code of the processor.

Identifying the element causing the divergence. For the given pair of inputs, the *Leakage Analyzer* generates a set of simulation traces corresponding to each input, ST_1 and ST_2 for the module under examination, D. If each trace in the two sets are exactly identical, then the execution time for the two inputs are equal. On the other hand, if the execution time of the two inputs are different, there exists a subset of the traces within the two sets that differ. In this subset of simulation traces, the trace which first deviates, corresponds to the combinational element that instigates the timing difference. Algorithm 2 shows the process of the *Diagnozer*. In the first phase, the *Diagnozer* iterates through every clock cycle of simulation traces and finds the first signals which differ in the two sets of traces (Lines 6,7). It creates the list of signals $temp\_V_s$ whose traces first differ between ST_1 and ST_2.

Mapping the cause in the source code. In a module, a timing difference occurs because some hardware elements take varying clock cycles based on the input. The Sequential element influences the number of clock pulses for execution. Hence, to trace the source of the timing difference within the module, the *Diagnozer* traces dependencies from the identified combinational signals to the sequential nodes in the MEG.

In Algorithm 2, this tracing is done by a Breadth First Search to identify the subsequent sequential elements which originate from each signal in $temp\_V_s$. This is stored in the list V_s along with line numbers where the corresponding event on the sequential element is found in the RTL of D.

Algorithm 2: The Diagnozer in *WhisperFuzz* to locate the timing vulnerabilities in the DUT.

```
   Input  : (ST1, ST2) // Pair of simulation
            traces
1  G(D) // MEG of module under examination
   Output : (Vs, L) // Set of signals identified
            as the cause of the timing difference
            and corresponding line numbers in RTL,
2  Vs ← ϕ; temp_Vs ← ϕ; L ← ϕ
   /* Phase 1                                   */
3  for every clock cycle (clk) in ST1 do
4      for s ∈ G(D) · S do
5          if s ∈ ST1[clk] ≠ s ∈ ST2[clk] then
6              temp_Vs ← temp_Vs ∪ {s}
7      if temp_Vs is not empty then
8          break
   /* Phase 2                                   */
9  for temp_Vs is not empty do
10     new_Vs ← ϕ
11     for s ∈ temp_Vs do
12         for (s, s_child) ∈ G(D) · Σ do
13             if s_child is sequential then
14                 Vs ← Vs ∪ {s_child}
15                 L ← L ∪ {line_no}// RTL line
                       number
16             else
17                 new_Vs ← new_Vs ∪ {s_child}
18     temp_Vs = new_Vs
19 return (Vs, L)
```

3.8 Fuzzing Microarchitectural State Space

WhisperFuzz introduces two components *Operand mutator* and *Coverage analyzer* to generate inputs for timing vulnerability detection and to monitor timing behaviors explored.

Operand mutator consists of specialized mutation algorithms to generate inputs for detecting timing vulnerabilities in processors. Detecting vulnerabilities requires changing the DUT's timing behaviors by triggering different microarchitectural state transitions [35, 51, 67]. Moreover, a valid timing side-channel is data/memory-dependent [8, 25, 48, 64, 72]. Therefore, we constrain *Operand mutator* to mutate only the segments of a test that will change the memory or data values.

Processor fuzzers use sequences of instructions to verify DUTs, as mentioned in Section 2.1. An instruction con-

tains `opcode` and `operand` fields [32, 52]; both of which cause the microarchitectural state transitions. The `opcode` fields determine the instruction's operation. Meanwhile, the *operand* fields provide the source and destination registers (i.e., general-purpose registers (GPRs) and control and status registers (CSRs)) and immediate values/memory addresses. Some instructions contain immediate memory addresses only (e.g., branch operation instructions). To generate data/memory-dependent inputs, we constrain *Operand mutator* to mutate only the immediate values/memory addresses of instructions uniformly at random [32, 55]. To further increase the mutation space, we assign random values to GPRs and valid memory addresses during the processor's initialization.

However, replacing the original mutation algorithms, *Coverage Mutator*, with *Operand mutator* reduces the fuzzer's efficiency in exploring the design space for timing vulnerabilities. This is because the mutator will not change the `opcode` and register-operands of instructions. Therefore, to maintain the efficacy of design space exploration and guarantee the effectiveness of timing vulnerability detection simultaneously, we use *Coverage mutator* to explore design spaces and use *Operand mutator* to exploit time side-channels near the design spaces explored. Any tests achieving new code coverage will be identified as seeds for *Operand mutator*. For each seed, the *Operand mutator* will generate multiple data-dependent inputs, aiming to trigger the microarchitectural state transitions that will cause timing differences compared to the seed.

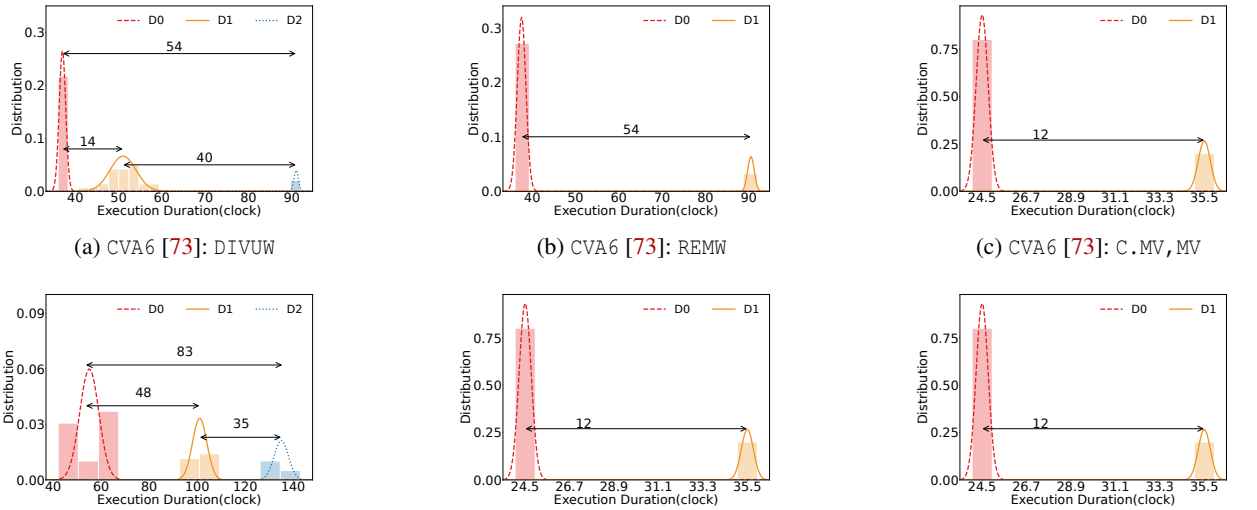
Coverage analyzer monitors timing behaviors covered by mapping microarchitectural state transitions to executed paths. For a given DUT, various paths exist between the input nodes and output nodes of the corresponding MEG. For an input value to the DUT, tracing the execution path followed and mapping it to the MEP poses a challenge.

To address this challenge, we utilize SystemVerilog Assertion (SVA) properties known as `cover` properties [29]. If an `cover` property evaluates to true for a given input, the DUT enters a stage during simulation when the property holds. Each graphical path is converted to a `cover` property using the annotated edge conditions and the timing behavior of the node. The timing behavior of a node depends upon the type of node defined. Algorithm 3 shows the process of generating the conditions of a MEP, $P \in \mathbb{G}(D)$, as the expression of a `cover` property. As combinational nodes are modeled after combinational logic, events occurring on these nodes complete instantaneously (line 4), while those occurring on sequential nodes complete on the next clock edge (line 6). If the value of a signal is from other modules, including input signals and signals connected with subinstances, we assume the events will *eventually* happen (line 8). Appendix A shows the `cover` properties for MEPs in the example cache set. Properties representing all possible paths in the MEG corresponding to the module are instrumented in the RTL. The *DUT Simulation* unit of the Vulnerability Detection module takes as input this modified RTL. The *Coverage Analyzer* utilizes the results of the resultant assertion report for calculating the coverage of the various graphical paths.

Algorithm 3: Coverage analyzer

```
   Input  : P // Micro-Event Path
1  G(D) // MEG of module D
   Output : Condition // Assertion Property
              corresponding to Micro-Event Path P
2  Condition ← ⟨⟩ // Empty Sequence
3  for (s_i1, s_i2) ∈ P do
4      if (s_i1, s_i2) has branch then
5          Condition ← Condition||⟨branch⟩
6      if s_i2 ∈ S_q then
7          Condition ← Condition||⟨1 cycle⟩
8      if s_si1 ∈ S_I then
9          Condition ← Condition||⟨eventually⟩
10 return Condition
```

4 Evaluation



We evaluate *WhisperFuzz* on three most advanced open-sourced processors based on RISC-V [52] instruction set architecture (ISA). We first demonstrate the new vulnerabilities detected by *WhisperFuzz* and provide statistical analysis to prove the existence of the timing side channels. We then leverage the power of *Micro-Event Graph* of *WhisperFuzz* to identify the root causes of these vulnerabilities and evaluate the efficiency of our framework, as shown in Table 2. Finally, we evaluate the timing behaviors covered by fuzzing.

4.1 Evaluation Setup

Benchmark selection. Most commercial processors are protected intellectual properties without available source code. Thus, we pick the three large (in terms of the number of gates) and widely-used open-sourced processors: `Rocket Core` [9], `BOOM` [74], and `CVA6` [73] from the RISC-V ISA. Most recent hardware security tools are evaluated using these processors [16, 34, 37]. The `CVA6` and `BOOM` are more complex compared to the `Rocket Core`. They possess advanced microarchitectural features such as out-of-order execution and support single instruction-multiple data (SIMD) execution.

Evaluation environment. We use the industry-standard tool, Synopsys *VCS* [3] for DUT simulation. We convert timing behaviors of RTL modules into SystemVerilog Assertion (SVA) `cover` properties and instrument them into DUTs. We use *Chipyard* [7] environment for the processors. We collect the coverage report and simulation traces from *VCS* to analyze the timing coverage and timing behaviors, respectively.

Fuzzing setup. We use *HyPFuzz* [16] to generate the seeds for *Operand mutator*. Other processor fuzzers that gener-

(a) CVA6 [73]: DIVUW (b) CVA6 [73]: REMW (c) CVA6 [73]: C.MV,MV

(d) BOOM [74]: DIVUW + REM (e) CVA6 [73]: C.ADD[W],C.SUB[W] (f) CVA6 [73]: C.AND,C.OR,C.XOR

Figure 5: Timing behaviour of detected novel side-channels.

ate sequences of instructions as inputs are also compatible [14, 24, 26, 34, 37, 39, 71]. *HyPFuzz* is a state-of-the-art hardware fuzzer that combines fuzzing and formal tools to maximize coverage and speed up design exploration. *HyPFuzz* is also compatible with various coverage metrics. We use a combination of branch, condition, and FSM metrics for code coverage. Branch and condition metrics monitor the combinational logic of DUTs. The FSM metric monitors the sequential logic of DUTs [3, 16, 37]. Therefore, any new points covered by inputs represent at least one new microarchitectural state transition triggered. We collect these inputs as seeds and use the *Operand mutator* to generate 200 data-dependent inputs for each seed. We ran the entire fuzzing process for 72 hours, and repeated it thrice to collect coverage results.

4.2 Detecting Novel Side Channels

This section will discuss 12 new timing vulnerabilities found by *WhisperFuzz*. Furthermore, Appendix B contains the proof of concept code for mentioned vulnerabilities.

DIVUW + REM in BOOM [74]. The side channel under consideration pertains to the consecutive execution of the DIVUW and REM instructions. In Figure 5d, the operational characteristics of this side channel are graphically depicted across various operand executions. Our analysis revealed median discrepancies of 48 cycles, 35 cycles, and 83 cycles between the divisor equal to 0, 1, and greater than 1 distributions respectively, with a maximum deviation of 101 cycles observed when deliberately selecting operands to maximize the disparity. Establishing a threshold for the median separation facilitates a successful discrimination rate of 100% when distinguishing between binary states 0 and 1. **DIVUW in CVA6 [73].** The side channel pertains to the execution of DIVUW instruction. Figure 5a illustrates the operational characteristics of this side channel across multiple operand executions. Notably, our analysis has unveiled median discrepancies of 14 cycles, 39 cycles, and 54 cycles among the divisor equal to 0, 1, and greater than 1 distributions respectively. Furthermore, we have observed a maximum deviation of 56 cycles when deliberately selecting divide by zero to maximize the disparity. Establishing a threshold for the median separation enables the successful discrimination of binary states 0 and 1 with a 100% accuracy rate. However, our findings indicate that attackers leverage this channel to transmit three states rather than the intended two states by defining two thresholds, achieving a success rate of 91%.

REMW in CVA6 [73]. *WhisperFuzz* detected this novel side channel when fuzzing CVA6 with REMW instruction. Figure 5b shows the operational characteristics of this side channel across multiple instances of operand executions. We demonstrate a median difference of 54 cycles between the the divisor equal to 0 and greater than 0 timing behavior distributions. Additionally, when we select zero as a divisor in the REMW instruction to maximize the timing difference, the maximum deviation is 56 cycles. Attackers can use this channel by establishing a threshold for the median separation to transmit binary states 0 and 1 with 100% accuracy.

C.ADD[W], C.SUB[W], C.AND, C.OR, C.XOR, and [C].MV in CVA6 [73]. *WhisperFuzz* detected multiple novel side channels that occur when executing compressed RISC-V instructions, i.e. C.ADD[W], C.SUB[W], C.AND, C.OR, C.XOR, and [C.]MV. RISC-V Zkt contract has classified these instructions as serious security vulnerabilities

if the instructions are data dependent [2]. The MV instruction has the same timing behavior as its compressed version, i.e., C.MV and causes a timing channel. Figures 5e, 5f, and 5c, show the operational characteristics of these side channels across multiple instances of operand executions. We demonstrate a median difference of 12 cycles between the second operand equal to 0 and greater than 0 timing behavior distributions. Selecting a specific value of zero as the operands of these instructions results in 12 more cycles compared to any other operand values. Establishing a threshold for the median separation allows for the successful discrimination between binary states 0 and 1 with an accuracy rate of 100%.

4.3 Redetecting Known Side Channels

DIV in BOOM [74]. *WhisperFuzz* successfully generated test cases that exposed timing side-channel vulnerabilities related to division instructions (DIV), a vulnerability disclosed in *SIGFuzz* [51] for the BOOM processor. *WhisperFuzz* generated multiple test cases featuring the DIV instruction, and by systematically mutating the input values during the fuzzing process, it revealed variations in the number of clock cycles required for the DIV instruction to complete its operation. Further investigation elucidated that when the divisor was bigger than the dividend, the division unit necessitated more time to conclude the division process.

SC in Rocket Core [9] and BOOM [74]. *WhisperFuzz* also identified a timing side-channel associated with Store-Conditional operations, effectively diagnosing timing disparities resulting from the presence of the dirty bit in the data cache implementation. The vulnerability was discovered in *SIGFuzz* [51] for the Rocket Core and BOOM processors. The test cases feature a SC instruction containing at least one subsequent load instruction. Through the mutation of these test cases, we were able to detect timing discrepancies when the load/store module attempted to access an address not present in the cache. Subsequently, the *Diagnozer* of *WhisperFuzz* pinpointed the root cause of this timing difference, attributing it to the dirty bit that was set by the Store-Conditional instruction for a cache line.

4.4 Pinpointing the Locations of Side Channels

We apply *Diagnozer* (See Section 3.7) to identify the root causes of detected timing vulnerabilities (See Sections 4.3, 4.2). We describe, in detail, the *Diagnozer* results for two novel and two known vulnerabilities. The results for all detected vulnerabilities are summarized in Table 2.

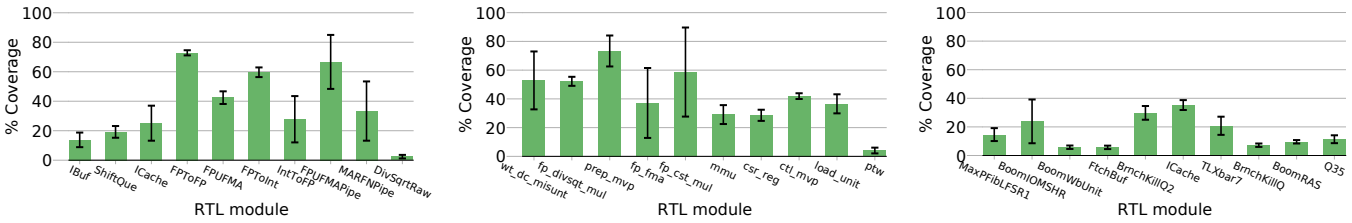
DIVUW in CVA6 [73]. In CVA6, given the instruction sequence in Listing 6, the *Diagnozer* identifies the source of the vulnerability in module serdiv in the lines highlighted in Listing 3. The first phase of the *Diagnozer* identifies 27 signals as the instigating signals, while the second phase pinpoints that these

Listing 3: Source location of **DIVUW** in CVA6 [73].

```
13512    state_q <= state_d;
13513    op_a_q <= op_a_d;
13514    op_b_q <= op_b_d;
13515    res_q <= res_d;
13516    cnt_q <= cnt_d;
13517    id_q <= id_d;
13518    rem_sel_q <= rem_sel_d;
13519    comp_inv_q <= comp_inv_d;
13520    res_inv_q <= res_inv_d;
13521    op_b_zero_q <= op_b_zero_d;
13522    div_res_zero_q <= div_res_zero_d;
```

signals change the values of 8 sequential signals.

Compressed Instructions in CVA6 [73]. Given two trace files corresponding to the instruction sequence in Listing 8 the first phase of the *Diagnozer* identifies the sources of these vulnerabilities in the ALU module. The exact RTL lines are as highlighted in Listing 13. Though the ALU module does not have a sequential component, the effects of its outputs are propagated to the inputs of the other modules thereby influencing further execution.



DIVUW + REM in BOOM [74] and Rocket Core [9]. Given two trace files corresponding to the instruction sequence in Listing 5, the *Diagnozer* identifies the source of this vulnerability in BOOM [74] and Rocket Core [9] at different lines in module MulDiv. The vulnerability is localized to the sequential elements divisor, state, negout in both processors (refer Table 2).

Division by zero in BOOM [74], Rocket Core [9], CVA6 [73]. Given two trace files corresponding to the instruction sequence in Listing 5 with the divisor set to 0, the *Diagnozer* identifies the sources of this vulnerability in BOOM, Rocket Core, CVA6 as shown in Table 2. Though the root cause is localized to the same module in Rocket Core and BOOM, the pinpointed lines differ. While in CVA6, the divide by zero vulnerability is localized to module serdiv.

Hence, though the same timing vulnerability can affect multiple DUTs, due to the differences within the microarchitectural design, the source of the vulnerability in the RTL code differs. Furthermore, consider the two division-related vulnerabilities detected in CVA6 [73]. Although these vulnerabilities affect the same module (serdiv), the source of the vulnerabilities within the module differs. Hence, the automated localization of vulnerability sources performed by *WhisperFuzz* is beneficial and efficient.

4.5 Coverage Analysis

We use *Coverage analyzer* to monitor timing behaviors explored by inputs from *Operand mutator*. *Coverage analyzer* converts paths of *Micro-Event Graph* of an RTL module into cover properties and instrument these properties in to DUT. After simulation, *Coverage analyzer* collects assertion results to calculate the timing behaviors covered (See Sec-

(a) `Rocket Core` [9] (b) `CVA6` [73] (c) `BOOM` [74]

Figure 6: Timing coverage of RTL modules in `CVA6` [73], `Rocket Core` [9], and `BOOM` [74]. The black line indicates the variation in coverage offered.

tion 3.8). Figure 6 shows the coverage achieved in various modules of the three benchmarks. Due to the space limitation, we only show the coverage of 10 modules with the highest total number of timing coverage points. On average, *WhisperFuzz* achieves 39.57%, 33.16%, and 20.20% coverage on `CVA6` [73], `Rocket Core` [9], and `BOOM` [74], respectively.

Since we emphasize covering timing behaviors, our *Operand mutator* generates 200 inputs for each seed generated by the coverage-feedback fuzzer. The overall coverage of *WhisperFuzz* can be increased by using more seeds from coverage-feedback fuzzer and running the fuzzer for more time. Also, many coverage points are left uncovered due to the multiple configurations of DUT. For example, `CVA6` has parameters to configure its float-point unit to support operations from 8-bit to 128-bit [73]. *WhisperFuzz* fuzzes `CVA6` in its default configuration where `CVA6` uses 64-bit operations. Hence, all other operations' timing behaviors are uncoverable. `Rocket Core`'s floating-point unit [9] and `BOOM`'s branch predictor [74] have similar configurations. Therefore, these configurations reduce the overall coverage.

4.6 Exploitability of Detected Vulnerabilities

In this section, we discuss the potential exploitations of the vulnerabilities detected by *WhisperFuzz* as presented in Section 4. Such vulnerabilities can be exploited for information leakage across diverse scenarios as described below.

Covert Channels. A timing covert channel breaks the process isolation guarantees provided by the hardware. A *sender* process can perform operations influencing the execution time of a *receiver* process, which infers a bit value based on this observed timing. For instance, the `DIVUW`-based vulnerability detected by *WhisperFuzz* in `CVA6` [73] can be employed to design a covert channel based on the timing differences. However, realizing such a covert channel requires the communicating processes to execute on the physical core using hyperthreading features which are unavailable on our evaluation processors [9, 73, 74].

Speculative Execution Attacks. Such attacks happen in out-of-order processors when, during the rolled back of speculatively executed instructions, processor leave their footprints on the micro-architectural components such as the cache. This has been exploited in several popular attacks [1, 38, 40, 51]. An attacker can formulate a similar attack with the vulnerabilities found by *WhisperFuzz*. For instance, with speculative execution support on `CVA6`, a combination of the load and time-dependent instructions(any instruction that is detected by *WhisperFuzz*, See Section 4.2) can utilized to encode sensitive data into the cache, which a cache timing attack can then glean. However, the current state of the evaluated processors is limited to non-speculative execution.

Attacking Library Implementations. An adversary can exploit the timing differences discovered by *WhisperFuzz* to glean sensitive information from popular libraries in cryptography or machine learning domains. For such an attack, the library implementation is required to have the same instruction flow, e.g., `DIVUW` followed by `REM` for `BOOM` [74] or `C.ADD` for `CVA6` [73] with the operand dependent on a secret value.

5 Related Work

Existing state-of-the-art techniques for timing side-channel vulnerability detection primarily employ formal approaches [22, 23, 58, 60, 65] and fuzzing [28, 35, 51, 67] techniques. However, these approaches still exhibit critical shortcomings. In contrast to *WhisperFuzz*, these approaches fail to pinpoint the root causes of the detected timing vulnerabilities without manual efforts that take a long time. Thus, the mitigation based on these techniques is coarse-grained rendering them inefficient in terms of the computational resources in DUT. Further, the coverage metrics used by these solutions, such as hardware performance counters or code coverage [35, 51, 67] do not capture the timing behaviors of the DUT, resulting in uncertainty prior to tape-out [27, 36, 57]. In this section, we discuss these perform a comparative analysis with *WhisperFuzz*, as illustrated in Table 1.

Formal approaches for timing vulnerability detection. ***UPEC*** [22,23] is a white-box approach to detect side channels in RISC-V RTL designs using SAT-based bounded model-checking. However, such an approach is not scalable to complex processor designs. Alternatively, ***Checkmate*** [58] employs *micro-happens-before* graphs to analyze transient execution vulnerabilities and timing side channels. It detects patterns within these graphs to assess the susceptibility of architectural models to timing side-channel threats. In contrast

to our methodology, *Checkmate* relies on matching patterns of vulnerable instructions, while *WhisperFuzz* is semantically oriented and automatic.

Fuzzing-based approaches for timing vulnerability detection. ***Osiris*** [67] is a black-box fuzzer that identifies timing vulnerabilities in commercial processors by brute-forcing different combinations of instruction sequences. However, to reduce the search space, it limits the instruction sequence length to one, leaving vulnerabilities requiring multiple instructions [49] or specific operands [48] to trigger undetected. ***ABSynthe*** [28] and ***PLUMBER*** [35] identify combinations of instructions that trigger microarchitectural timing side-channel leakages by deriving a *leakage template*. However, *PLUMBER* requires manual efforts to specify mutation algorithms and potential behaviors of a DUT to generate this template. Further, it is limited to the existing cache module and cannot locate them in the DUT.

SIGFuzz [51] is a grey-box fuzzer that detects the existence of timing vulnerabilities in processors at the RTL. It generates combinations of instructions to identify cycle-accurate microarchitectural timing side-channels. However, replacing instructions can create additional architectural differences, such as differences in general-purpose registers, resulting in a high rate of false positives. Further, ***SIGFuzz*** suffers from limitations in pinpointing vulnerability locations and coverage metrics as the black-box approaches.

WhisperFuzz addresses these limitations of existing works by providing a novel white-box fuzzer with static analysis to detect and pinpoint timing vulnerabilities in executed testcases in processors enabling fine-grained mitigations. *WhisperFuzz* is scalable to complex designs and end-to-end automated with a specialized coverage metric for timing behaviors.

6 Discussion

Use of *Code coverage mutator* and *Operand mutator*. *WhisperFuzz* employs both the *Code coverage mutator* and the *Operand mutator* to explore the design space and generate data-dependent inputs, respectively. The determination of their utilization is an optimization problem that can aid the efficacy of vulnerability detection. We can model the probability of *Operand mutator* covering a timing behavior [53, 75]. When this probability falls below a threshold, the *Code coverage mutator* can be called to generate new seeds. However, such an analysis is beyond the scope of this paper.

Port scanning vulnerabilities. Contention for a port in the architecture can cause execution delays, enabling attackers to create a high-resolution time side-channel by scanning for port contention [6, 12]. However, these attacks primarily depend on the simultaneous multithreading architecture [6, 12, 59] which current open-sourced benchmarks [9, 73, 74] lack, and hence detecting port scanning is outside the scope of *WhisperFuzz*.

Table 1: Comparison with prior works on timing vulnerability detection on processors with *WhisperFuzz*. (*N.A.: Not applicable, TSC: Timing side channel.*)

7 Conclusion

Recent hardware fuzzers have showcased their potential to identify timing vulnerabilities in intricate designs. However, the existing black-box or grey-box fuzzing approaches fall short in pinpointing the root cause of timing vulnerabilities and lack the necessary coverage feedback mechanisms for the exploration of timing behaviors. Addressing these gaps, we develop *WhisperFuzz*, the first approach that combines white-box fuzzing with static analysis. Its primary objectives are not only to accurately determine the locations of timing vulnerabilities but also to evaluate the timing behaviors. *WhisperFuzz* has successfully detected 12 new timing vulnerabilities and all previously known ones in open-source processors and pinpointed their root causes. This opens up novel avenues in vulnerability detection and timely mitigation in processors.

Appendix

A SVA `cover` properties for case study

Listing 4 shows the `cover` property for the graphical paths in the *Micro-Event Graph* of the cache case study as shown in Listing 2. Section 3.5 mentions two *Micro-Event Paths* from its input `addr` to its output `way`: {`addr` → `tag_addr` → `way`} and {`addr` → `tag_addr` → `hit` → `fetch` → `mem_call` → `complete` → `way`} Among these paths, `hit`, `full`, `fetch`, `way` are sequential nodes; the events occurring on these nodes complete on the next clock edge. The value of the `complete` signal is driven by `mem_call`, a subinstance.

Listing 4: SVA `cover` properties for case study.

```
property p1; //{addr, tag_addr, way}
@(posedge clock) (tag_address == tag);
endproperty

property p2; //{addr, tag_addr, hit, fetch, mem_call,
    ↪ complete, way}
@(posedge clock) !(tag_address == tag) ##1 (hit == 0 &&
    ↪ full != 1 && valid[0] == 1) |-> s_eventually (
    ↪ complete == 1);
endproperty
```

B Proof of concept codes for triggering detected vulnerabilities

This section shows the proof of concept code snippets on triggering various timing vulnerabilities in different RISC-V processors. Listing 5 shows the code snippets of `DIVUW + REM` side-channel on `BOOM` [74]. Listing 6 shows the code snippets of `DIVUW` side-channel on `CVA6` [73]. Listing 7 shows the code snippets of `REMW` side-channel on `CVA6` [73]. Listing 8 shows the code snippets of compressed instruction-based side-channels on `CVA6` [73].

Listing 5: `DIVUW + REM` side-channel proof of concept code snippets on `BOOM` [74].

```
LI      a3, 291
LI      a7, -1954
LI      s10, 201
LI      t6, 477
// If t6=477, a7=-1954, s10=256, a3=291 takes
    ↪ 42ns
// If t6=1  , a7=-1954, s10=201, a3=291 takes
    ↪ 143ns
DIVUW   t5, a7, t6
REM     t3, s10, a3
```

C Locations of side channels

This section shows the locations of timing vulnerabilities identified by the *Diagnozer* (See Section 3.7). Listing 9 shows the location of *Division by zero* in `BOOM` [74]. Listing 10 shows the location of *Division by zero* in `Rocket Core` [9]. Listing 11 shows the location of *Division by zero* in `CVA6` [73]. Listing 12 shows the location of `DIVUW+REM` in `BOOM`. Listing 13 shows the location of **compressed instructions** and **`MV`** in `CVA6`; nine vulnerabilities share the same root cause. The results show that the *Diagnozer* of *WhisperFuzz* can successfully identify the location of timing vulnerabilities in processors.

Listing 6: `DIVUW` side-channel proof of concept code snippets on `CVA6` [73].

```
LI      a4, 3
// If a4=0 takes 92ns
// If a4=3 takes 36ns

Marcel Busch
EPFL

Abstract

ARM TrustZone forms the security backbone of mobile devices. TrustZone-based Trusted Execution Environments (TEEs) facilitate security-sensitive tasks like user authentication, disk encryption, and digital rights management (DRM). As such, bugs in the TEE software stack may compromise the entire system's integrity.

EL3XIR introduces a framework to effectively rehost and fuzz the secure monitor firmware layer of proprietary TrustZone-based TEEs. While other approaches have focused on naively rehosting or fuzzing Trusted Applications (EL0) or the TEE OS (EL1), EL3XIR targets the highly-privileged but unexplored secure monitor (EL3) and its unique challenges. Secure monitors expose complex functionality dependent on multiple peripherals through diverse secure monitor calls.

In our evaluation, we demonstrate that state-of-the-art fuzzing approaches are insufficient to effectively fuzz COTS secure monitors. While naive fuzzing appears to achieve reasonable coverage it fails to overcome coverage walls due to missing peripheral emulation and is limited in the capability to trigger bugs due to the large input space and low quality of inputs. We followed responsible disclosure procedures and reported a total of 34 bugs, out of which 17 were classified as security critical. Affected vendors confirmed 14 of these bugs, and as a result, EL3XIR was assigned six CVEs.

1 Introduction

Mobile devices provide critical sensitive services, including authentication [55], mobile payment [49], and DRM [28]. These services depend on hardware-based Trusted Execution Environments (TEE) (such as ARM TrustZone [2]) to protect sensitive data. The TEE enforces the integrity and confidentiality of its software components through hardware features. By shifting security-critical operations from the Rich Execution Environment (REE) into the TEE, users are protected from various application- and kernel-level exploits [3]. The smaller code base of TEEs aspires to have a small attack surface and, consequently, protect devices from full compromise.

However, fueled by market needs and recent research [31, 36, 46], the amount and size of software running inside the TEE continuously increases. Vendors are extending the TEE with more functionality such as device integrity monitoring [10], remote attestation, or secure network communication [51] – all built upon the premise of trusted software. Consequently, the trusted computing base (i.e., the code running as part of the TEE) is growing, leading to a increased risk of bugs. Moreover, regardless of this fact, TEE-based vulnerabilities significantly impact device security, as successful attacks put the entire platform's security at risk [17, 18].

Most mobile devices such as smartphones or tablets are based on the ARMv8-A architecture [1], and as such, ARM TrustZone [2] provides the dominant foundation for TEE implementations on billions of devices. TrustZone logically separates the device into two isolated execution environments; the non-trusted *normal world* and the trusted *secure world* [48]. The normal world on a typical Android device hosts conventional user space applications and a Linux kernel. The secure world exclusively runs vendor-authenticated code consisting of Trusted Applications (TAs), a Trusted Operating System (TEE OS), and the secure monitor. While the security of TAs and TEE OSes have been previously studied [17, 18, 52, 53], the security of the secure monitor remains unexplored. It has been primarily seen as a means to request services and exchange data between the worlds [5]. Indeed, all communication to the TEE and vice versa must pass through the secure monitor, which is the highest privileged component (EL3) on the platform [1].

Surprisingly, the mediation between the normal and secure world is not the only service the secure monitor offers. Additional tasks include the interaction with silicon provider-specific hardware [9], management of system power levels [8], and firmware updates [7]. Furthermore, vendors tailor the secure monitor firmware to the specific needs of their devices by adding drivers for secure peripherals (e.g., eFuses and cryptographic elements), custom TEE OS interfaces, and proprietary bootloader features. Code running in the normal world can request these services by issuing a Secure Monitor Call (SMC)

which switches to the secure monitor context. When the normal world requests such a service, it is directly handled by the secure monitor and not forwarded to the TEE OS. Unsurprisingly, this complexity results in severe bugs potentially leading to full-system compromise [4, 43].

The secure monitor is part of the secure world (Figure 1); thus, vendors do not permit introspection during runtime. This is enforced by memory controllers (e.g., the TrustZone Address Space Controller) that prevent normal world components from accessing code or data of the secure world. Consequently, modern dynamic analyses, such as coverage-guided fuzzing, are infeasible on production devices.

Rehosting offers a remedy for the limitations of on-device approaches. In the context of small embedded systems, we have recently seen significant advancements in *full-system rehosting* [21, 24, 25, 33, 34, 38, 50]. However, these approaches focus on comparatively tiny firmware samples for simple CPUs (e.g., Cortex-M). Cortex-A software stacks (e.g., all components running on the application processor of a mobile device, including the bootloader, secure monitor, TEE OS, TAs, REE OS, and REE applications) are orders of magnitudes more complex and have significantly more hardware dependencies, rendering full-system rehosting approaches infeasible. A trade-off to full-system emulation is *partial rehosting*. The essential idea is to only rehost the targeted relevant logical component and trade hardware dependencies for software dependencies. For example, Harrison et al. [32] focus on rehosting TEE OSes and TAs. Hence, they do not include irrelevant components in their rehosting efforts, excluding the secure monitor or the REE OS. By mimicking hardware behavior with software emulation, partial rehosting approaches avoid requiring complete hardware models.

We discover two limitations of prior work, making them unfit for effectively fuzzing hardware-dependent proprietary firmware components (e.g., secure monitors) with loosely defined interfaces. First, the generic and vast interface of secure monitors is challenging for general-purpose fuzzers to explore due to its large input space. Second, secure monitors in particular depend on vendor-specific hardware interactions. Public emulators lack support for these peripherals and corresponding data sheets are unavailable, thus posing a roadblock for dynamic analysis. Manually implementing simplified hardware models reduces the fidelity of rehosting environments and is not a scalable solution.

EL3XIR solves these two key challenges. First, we perform static value-flow analysis on the REE OS (e.g., Linux kernel) to collect instances of SMC interface usage. Further, we achieve *interface awareness* by probing the existing handlers of a given secure monitor. Then, we combine this knowledge with a set of domain-specific mutations in a fuzzing harness capable of generating high-quality inputs. Second, EL3XIR overcomes coverage roadblocks originating from hardware interactions using *reflected peripheral modeling*. This technique repurposes fuzzing inputs to probe Memory-Mapped I/O (MMIO) behavior and leverages coverage feedback as an oracle for appropriate peripheral behavior.

In our evaluation, we targeted seven different secure monitor binaries scattered across six vendors. Our dataset includes three proprietary implementations deployed on popular mobile devices from Samsung and Huawei. Additionally, we leverage EL3XIR to fuzz four open-source secure monitor implementations running on edge devices from Intel, NXP, Xilinx, and Nvidia showing EL3XIR's scalability. EL3XIR finds crashes in all of the targets, with a total of 34 unique bugs. After triaging and responsible disclosure, a total of 17 are security-critical with six CVEs assigned. Our evaluation shows that *interface awareness* and *reflected peripheral modeling* lead to higher code coverage than state-of-the-art fuzzing approaches. Furthermore, EL3XIR triggered 15 more crashes compared to approaches of prior work.

In summary, our main contributions are:

- The design and implementation of an end-to-end rehosting-based fuzzing framework for proprietary secure monitor implementations.
- Two essential techniques, static analysis-based *interface awareness* and *reflected peripheral modeling*, enabling target-specific fuzzing harness synthesis.
- A comprehensive evaluation of EL3XIR against existing state-of-the-art TEE fuzzing approaches.

2 Background

This section provides the necessary background on the ARMv8-A architecture, the role of the secure monitor, and the threat model of ARM TrustZone.

ARMv8-A Architecture. The 64-bit ARMv8-A architecture [1] dominates the System-on-Chip (SoC) market for embedded devices like smartphones. This architecture supports up to four privilege levels called exception levels (ELs). Further, ARMv8-A features ARM TrustZone [2, 48], a hardware extension capable of partitioning the SoC into two isolated execution environments. Figure 1 shows the separation of the execution into the non-trusted *normal world* which hosts a REE OS at EL1 (e.g., a Linux kernel) and user space applications at EL0 (e.g., an Android App) and the *secure world* which is comprised of vendor-specific software like the TEE OS at EL1 and Trusted Applications at EL0. Software running in the secure world is integrity protected by a secure boot mechanism executing only vendor-signed code. EL3 is the highest privilege level and any context switch between the worlds has to go through this exception level using an SMC.

Secure Monitor. The secure monitor is the runtime software located at EL3, and it has unrestricted access to all device resources. The bootloader authenticates the secure monitor's image during secure boot. As a standard for secure monitor interactions, ARM defined the Secure Monitor Call Calling

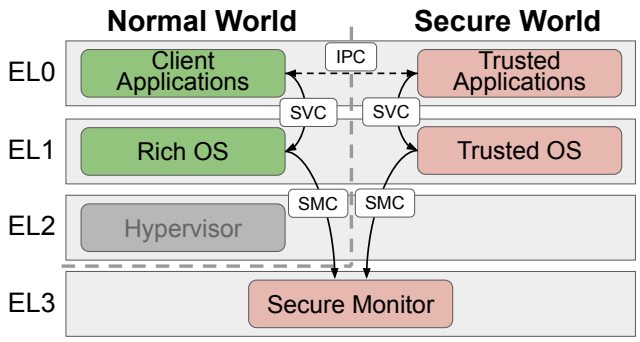

Figure 1: ARMv8-A platforms support up to four privilege levels (EL3 to EL0). On COTS devices, vendors often grant users access to the normal world (green components) but the secure world (red components) is off limits. The dashed lines indicate the security boundary between the two execution environments. The IPC interface provides a conceptual call between the worlds that needs to pass through all layers of the software stack.

Convention [5] (SMCCC). This convention defines the parameter registers (`x0-x17`) and the result registers (`x0-x3`) to be used when interacting with secure monitor services. Besides its role as a relay to the TEE OS, the secure monitor includes services like access to the power state coordination interface or silicon provider service calls intended for chip-specific drivers implemented by each vendor on a per-platform basis. This results in multiple scattered runtime services, each requested by another function identifier (via register `x0`) and a different interface.

ARM provides the ARM Trusted Firmware [6] (ATF) as an open-source reference implementation. Most device vendors use the ATF as a foundation for their TEE architecture and modify or extend the implementation according to the specific needs of their platform. The ATF is designed to be extendable and vendors will usually register runtime services in the silicon provider service call categories to enable the trusted interaction with proprietary secure peripherals. As a result, the ATF includes device drivers directly interacting with hardware components via MMIO. Whereas the ATF's core implementation is open-source, vendors usually keep their extensions private.

TrustZone's Threat Model. ARM TrustZone is designed to provide a secure execution environment for sensitive software and data even if the REE is compromised. This includes attackers taking complete control over the REE OS and sending arbitrary payload to the secure monitor when executing an SMC. Therefore, in our attack scenario, we assume root-level access to our target device to execute arbitrary code in the normal world. Yet, a kernel-level attacker should not be able to violate the integrity and confidentiality of software running inside the TEE.

3 Challenges

Effective fuzzing requires dynamic analysis of the execution to extract coverage information or crash details. We discuss challenges regarding dynamic analysis capabilities in the context of *on-device approaches* and *rehosting approaches*. We conclude that for COTS secure monitor implementations the balance shifts in the direction of favoring rehosting solutions as the locked-down nature of production devices and their TEE firmware increases the burden for on-device approaches.

On-Device Approach. *Feedback-guided* fuzzing is incompatible with COTS secure monitors on production devices. Missing or inaccessible debug interfaces prohibit instrumentation of firmware for coverage collection. Additionally, the secure monitor belongs to the secure world (Figure 1), thus vendors prohibit static modifications through the secure boot mechanism. Dynamic modification is prohibited by memory controller restrictions (e.g., the TrustZone Address Space Controller) which prevent normal world components from accessing code or data of the secure world during runtime.

Consequently, dynamic analysis approaches requiring introspection capabilities (e.g., coverage-guided fuzzing) are infeasible on production devices. Although there have been some successful black-box fuzzers in terms of discovered bugs, their effectiveness and usability are limited [16, 40]. The lack of extensive feedback makes it difficult to mutate potent test cases and the non-determinism of real-world hardware hinders the reproduction and triaging of bugs.

Rehosting Approach. Different from on-device approaches, the target may be run in an emulator. This has multiple benefits: (1) the extended introspection allows for coverage collection enabling *feedback-guided* fuzzing, (2) the absence of non-determinism improves reproduction of test cases and eases bug triaging, and (3) the performance and scalability can be improved by snapshot-based fuzzing.

Unfortunately, public emulators do not support peripherals for SoCs found on production devices running COTS secure monitor implementations. Furthermore, data sheets for these proprietary SoCs are unavailable which renders the implementation of accurate emulators infeasible [24]. While some industry research teams have implemented precise emulators for their devices [32], their emulator is not publicly available and building such emulators requires considerable manual engineering efforts. Nevertheless, the superiority of emulator-based fuzzing approaches urges to address the challenges emerging when trying to design a rehosting-based fuzzing solution for COTS secure monitor implementations.

C1: Interdependencies of Logical Components

Because of the high complexity and size of software stacks deployed on modern devices, a full rehosting approach would require the emulation of multiple intertwined software components. For example, when targeting the secure monitor im-

plementation running on an Android smartphone, this would require building a full-system emulator capable of running a customized version of Android (REE OS), the proprietary TEE OS, and the bootloader because all of those components interact with the secure monitor at some point (Figure 1). The size and complexity of the software stack on modern mobile devices makes this task practically infeasible.

Consequently, to enable rehosting-based fuzzing of COTS secure monitor implementations, we need a partial-rehosting approach that can run the target binary in a standalone way while maintaining the minimal necessary functionality of dependent relevant logical components. Harrison et al. [32] introduced the idea of a partial-rehosting approach. The key concept is to either reuse (i.e., executing the binary) or emulate (i.e., reimplementing the functionality) dependent software components. Partial-rehosting approaches exist for the TEE OS and some standalone TAs [40], while we focus on the secure monitor binary for which there is currently no solution. Ultimately, this challenging rehosting problem entails handling the secure monitor's dependencies to the REE OS, the TEE OS, and the bootloader.

C2: Infeasibility of Manual MMIO Modeling

In addition to solving dependencies on logical components, a rehosting environment capable of running COTS secure monitor implementations must emulate the original production device's hardware sufficiently precise [24]. Thus, mimicking interactions with hardware (e.g., via reading and writing MMIO regions) that would otherwise block the fuzzer from making progress as, there is no replying peripheral. We provide an indicative example for coverage walls caused by missing MMIO behavior in Appendix A.

Recent work [32] tried to manually reverse-engineer and emulate peripheral models, resulting in multiple limitations: (1) the resulting hardware models will be specific to a single SoC, limiting scalability, (2) proprietary peripherals may not be modeled extensively, (3) manual emulation requires extensive work by an expert for each SoC. In contrast, our work focuses on finding a scalable solution for fuzzing secure monitor implementations that heavily rely on hardware interactions.

C3: Complex and Diverse Input Formats

Finding meaningful inputs is a challenging task for fuzzers. This is because of non-standardized and complex input formats found at unexplored interfaces of low-level firmware like the secure monitor. The SMC interface is defined in the ARM SMCCC [5] (Section 2), but the discovery of valid inputs and, thus, the exploration of the secure monitor remains an open challenge.

Test inputs need to comply to custom protocol formats as expected by runtime services. Non-compliant inputs will fail in the parsing logic, generating no new coverage. Listing 1 in Appendix A demonstrates this challenge at the beginning of the function in the form of validation logic checking for alignment and memory pointer validation (`addr_in_nw_range()`). While this is a relatively simple example, manufacturers may include complex validation logic depending on the offered service and the necessary protocols to follow for the interaction with underlying peripherals. Naive fuzzers will struggle to create valid inputs, resulting in coverage walls and bad performance.

Another reason is the broad nature of the SMCCC used to communicate with runtime services. On modern ARMv8-A systems, up to 18 input registers are passed to the secure monitor. All lower 32 bits of `x0` are used as a function identifier and the remaining registers `x1-x17` as arguments. Those can either be a value or a memory reference, whose contents hold runtime service-specific data. This calling convention leads to a large input space since the function identifier, the number of parameters, their types, and valid parameter contents are unknown a priori. As we are dealing with proprietary binaries, manual reverse-engineering to derive the interface of registered runtime services is a tedious effort. Therefore, we need an approach to automatically discover the interface of secure monitors and subsequently equip a fuzzer with this additional knowledge to achieve efficient interface exploration.

4 EL3XIR's Approach

EL3XIR is an extensible rehosting and feedback-guided fuzzing framework for secure monitors. Figure 2 provides an overview of EL3XIR's design.

The initial step to fuzz a new secure monitor requires creating a rehosting environment to boot the secure monitor and taking a snapshot at the desired fuzzing location (①). This location is typically the first transition to the untrusted normal world. EL3XIR comes with an extensible rehosting framework that facilitates partial rehosting of secure monitor binaries, addressing **C1** (Section 3). After completing the one-time effort rehosting, EL3XIR takes a snapshot of the booted secure monitor used for the subsequent automatic fuzzing campaign enabling high execution speed due to fast resets.

To address the lack of peripheral models (**C2** in Section 3), EL3XIR monitors the SoC's MMIO regions in the physical address space and employs reflected peripheral modeling to populate MMIO read registers with raw fuzzing input. This technique mimics peripheral behavior and enables EL3XIR to explore error and success control-flow paths succeeding peripheral interactions and, thus, increases the target's code coverage without any manual intervention.

To deal with the challenge of diverse and complex input formats expected by runtime services (**C3** in Section 3), EL3XIR statically analyzes the source code of the REE OS (e.g., a Linux kernel) that interacts with the secure monitor interface to recover target-specific and interface-aware

seeds (②). Then, EL3XIR probes the 32-bit function identifier (`x0` register) used to select the requested runtime service, using coverage-feedback as an oracle to determine if a service backs a given identifier. This process allows EL3XIR to explore unseen services while filtering out false positives that originated from static analysis. Ultimately, this knowledge is used to synthesize an interface-aware harness equipped with domain-specific mutators to generate high-quality inputs to fuzz the secure monitor (③).

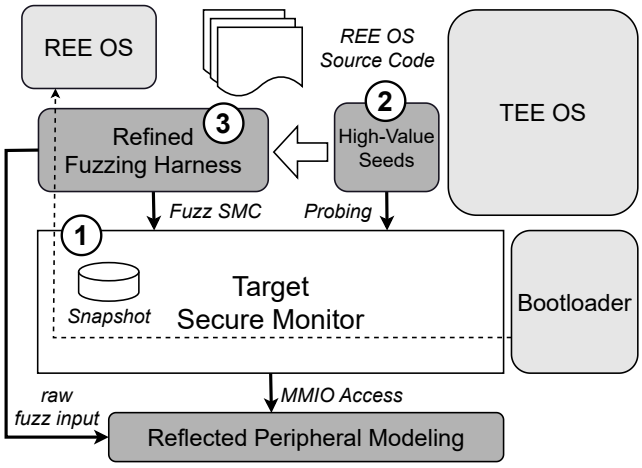

Figure 2: An overview of EL3XIR's design. Software dependencies for partial-rehosting are shown in light gray, while the dark gray components are part of EL3XIR's fuzzing framework. EL3XIR fuzzes a snapshot of the secure monitor by combining an interface-aware refined harness and on-the-fly generated peripheral models leveraging their synergetic effects for extensive code coverage and bug triggering.

4.1 Partial-Rehosting of Secure Monitors

EL3XIR provides a rehosting framework that enables fast and straight-forward partial-rehosting of COTS secure monitor binaries in a pure emulation fashion (i.e., no physical device is required). The framework is designed to drastically reduce the manual effort required to initialize a targeted secure monitor properly. Our partial-rehosting approach addresses **C1** (Section 3) by replacing missing software components with manually crafted stubs and the ability for precise injection of necessary hardware interactions into MMIO registers during boot. We evaluate the manual steps required in Section 6.1.

Our rehosting approach follows an iterative refinement process [24] as illustrated in Figure 3. We start by running the unmodified secure monitor binary in a minimal rehosting environment (e.g., matching CPU architecture and TrustZone extensions) and refine the environment step by step through repeating fidelity evaluations and root cause analysis of misbehavior (e.g., unhandled exceptions or aborts). This process

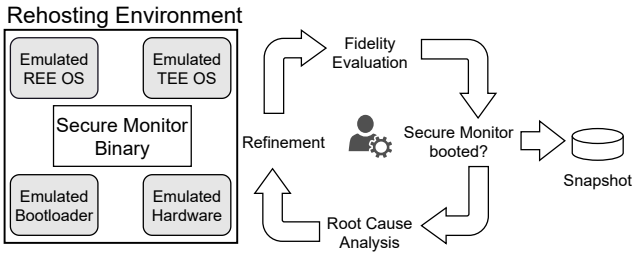

Figure 3: EL3XIR's rehosting framework is designed to help rehost unmodified and proprietary closed-source secure monitor binaries in an iterative refinement process.

continues until the secure monitor successfully boots. Then, EL3XIR takes a snapshot (① in Figure 2), making the manual part a one-time per-target effort. This snapshot is further used for automated fuzzing campaigns.

Our core insight for partial-rehosting is that the secure monitor initialization requires only a small set of emulated software and hardware dependencies. Thus, using a handful of MMIO emulations and less than 20 lines of assembly for the stubs (REE OS, TEE OS, and bootloader), it is feasible to bring the system up until the point where an adversary would take control (EL1 in the normal world), marking our snapshot and fuzzing location (Section 4.3). We decided for manually rehosting the secure monitor boot process because customized boot procedures are challenging to generalize. We discuss this limitation in Section 7. Nevertheless, most of the hardware rehosting effort arises at runtime when the REE OS requests services from the secure monitor and not during the boot process when hardware is only initialized (we solve this problem in Section 4.2).

Our rehosting framework addresses the following challenges when booting a COTS secure monitor in an emulator. First, we describe a systematic way to identify the physical memory layout required to place the secure monitor binary at the correct location in memory. Second, we provide small and adaptable software stubs to easily emulate dependent logical components (i.e., bootloader, TEE OS, and REE OS), directly addressing **C1** (Section 3). Third, our framework allows for precise injection of hardware interactions via breakpoints that are required during boot. Especially MMIO reads of status bits indicating success after the initialization and configuration of peripherals need to be emulated.

Physical Memory Layout. The targeted firmware binary must be appropriately loaded in memory to run correctly [57]. Fortunately, the secure monitor sets up its own virtual address space. For ARMv8-A binaries, the base address of the first level translation table is held in the system register `TTBR0_EL3`. By systematically searching for accesses to this register in the secure monitor binary, we can identify its physical address space.

The necessary steps boil down to (1) finding the access to the register holding the translation table base address and (2) traversing the valid descriptors to locate used physical address ranges. From the permissions in the descriptors, we can pinpoint the executable range (usually only one), thus the physical base address of the secure monitor's executable code. In our experiments, the code parts of the secure monitor where the MMU is enabled (first bit of `SCTLR_EL3` is set) turned out to be a vital oracle to check if the secure monitor is placed correctly.

Software Dependencies. Solving dependencies on other logical software components is one of the challenges faced during partial-rehosting of intertwined software stacks (**C1** in Section 3). The secure monitor directly interacts with three software components: the bootloader, the TEE OS, and the REE OS. We managed to emulate these dependencies across our dataset of seven secure monitors with three small stubs per target comprising no more than 16 AArch64 assembly instructions, demonstrating this task's feasibility. Moreover, most of the stubs are similar and only needed slight adjustment for target-specific values.

The stubs set general purpose registers to pass parameters or return values (e.g., the TEE OS stub indicates a successful boot to the secure monitor) and initiate exception level switches. These stubs are designed to be adaptable and even allow us to influence the secure monitor's behavior. For example, the bootloader passes a boot information structure to the secure monitor, including the TEE and REE OS entry addresses, allowing us to specify these locations in our emulated bootloader stub. Lastly, when the secure monitor gives control to the normal world (e.g., switch to the REE OS), we place a simple REE OS stub just executing SMCs and take a snapshot. From that point on, EL3XIR's fuzzing engine takes over and injects test inputs into the SMC interface, described in more detail in Section 5.3.

Hardware Dependencies. During the boot process, the secure monitor encounters MMIO accesses (e.g., polling of status registers) of peripherals not emulated in the rehosting environment in the first place. To locate these accesses, we can watch for endless loops or unhandled exceptions in the emulator during root cause analysis. By reverse-engineering small code parts around these loops, we can derive reasonable behavior for the concerning MMIO register and refine the emulation with these manually crafted MMIO return values. Note that this is a manual step of peripheral modeling which we evaluate in Section 6.1. Because hardware interactions are intertwined with software dependencies (i.e., they may appear alternatingly during the iterative refinement process), fully automating the boot process is out of scope for EL3XIR. However, during the subsequent fuzzing campaign, we leverage reflected peripheral modeling (Section 4.2) to handle MMIO interactions automatically.

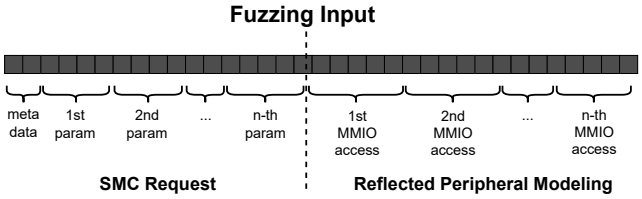

Figure 4: EL3XIR partitions the fuzzing input stream. First, all parameters for the SMC request are populated, then the remaining bytes emulate peripheral behavior in MMIO regions.

4.2 Reflected Peripheral Modeling

After a snapshot of the booted secure monitor is taken, EL3XIR's automated fuzzing campaign can start. One of the challenges during the fuzzing of the secure monitor is to handle hardware interactions in a meaningful way without manual intervention to overcome coverage walls (**C2** in Section 3). In contrast to the boot process, the runtime services exposed by the secure monitor have a more comprehensive range of hardware dependencies making a manual emulation approach infeasible given the diversity of hardware platforms.

To overcome these obstacles, EL3XIR repurposes parts of the fuzzing input to induce *reflected peripheral modeling* (Figure 2). When a memory read operation occurs from defined MMIO regions, EL3XIR captures this event and populates the corresponding MMIO region with fuzzing input simulating the peripheral's behavior.

Figure 4 gives an overview of how EL3XIR partitions the fuzzing input stream. After all parameters for the SMC request are populated, the remaining input is used on a per-MMIO access basis. This technique enables EL3XIR to emulate highly flexible and realistic peripheral behavior.

Our approach ensures that the secure monitor *eventually* receives meaningful values when reading from MMIO registers. Even better, because EL3XIR has complete control over the MMIO behavior, it can generate values that exercise both success and error conditions resulting in extensive code coverage.

4.3 Interface-aware Fuzzing

While Section 4.1 and Section 4.2 describe approaches that increase the fidelity of the rehosting environment, EL3XIR also tackles the orthogonal challenge **C3** (Section 3) of dealing with complex and diverse input formats by generating an interface-aware fuzzing harness. EL3XIR's fuzzing approach is interface-aware because it knows how to interact with the SMC interface using valid function identifiers and respective expected arguments. For an effective exploration of the secure monitor's attack surface, EL3XIR leverages the REE OS's knowledge about the structure and semantics of

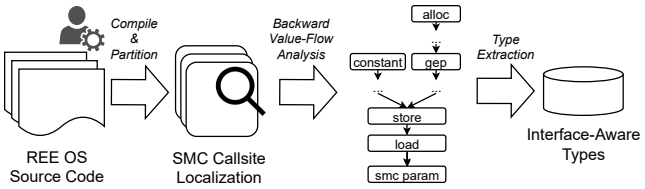

Figure 5: EL3XIR's interface inference is based on a backward value-flow analysis on a manually-picked REE OS source code partition. EL3XIR automatically identifies SMC call sites, localizes corresponding parameters in the value-flow graph, and recovers type-aware function prototypes for the SMC interface.

the SMC interface to generate and mutate highly targeted and meaningful test cases. However, the REE OS is not the only software component interacting with the SMC interface (e.g., bootloader and TEE OS). Thus, results may be incomplete (Section 7). To tackle this problem, EL3XIR performs an additional probing phase to identify all function IDs backed by a corresponding runtime service. The complete list of function IDs and the partially recovered interfaces (② in Figure 2) are combined with domain-specific mutators to generate an interface-aware fuzzing harness (③ in Figure 2).

Step 1: Interface Recovery

EL3XIR utilizes static analysis on relevant parts of the REE OS's code to extract function signatures and parameter values that correspond to the interfaces exposed by runtime services (Figure 5). The intuition is that the REE OS possesses the knowledge required to communicate effectively with the runtime services provided by the secure monitor. By analyzing hand-picked partitions of the REE OS code, EL3XIR can automatically retrieve the arity and semantic type of arguments involved in calls that utilize the SMC interface. We provide an excerpt of REE OS code that prepares and sends an SMC and the corresponding successfully recovered interface by EL3XIR in Appendix B (Listing 2 and Listing 3).

SMC Call Site Localization. The REE OS invokes the secure monitor using the SMC instruction. To identify all call sites, we employ an over-approximating heuristic due to the SMC instruction often being concealed behind indirect function calls (e.g., wrapper functions) that require sophisticated techniques to resolve [41]. Instead, EL3XIR automatically scans all function calls included in the REE OS partition and adds those closely matching the SMCCC to the list of potential SMC call sites. After empirical analysis, we implemented our heuristic to focus on calls with at least five arguments or a scalar value as their first argument. This simple approach ensures that we primarily consider more complex function signatures while filtering out incorrect candidates. The resulting false positives will later be pruned, leaving only high-quality SMC interface descriptions. We provide an overview of recovered interfaces and evaluation of our heuristic in Section 6.2.

SMC Parameter Type Identification. Given potential SMC call sites, EL3XIR performs a backward depth-first search along the value-flow graph to recover type information and scalar values of arguments, starting with each argument node of a call site as a sink. For each source node, we identify scalar values passed directly (i.e., as a constant) or indirectly (i.e., as a variable) to SMC call site locations. We retrieve semantic type information by extracting associated compiler metadata from memory locations whose values are propagated to arguments for SMC call sites.

Function Identifier Probing and Pruning. The static analysis of the open-source REE OS produces a list of potential function identifiers along with their corresponding parameters (number of arguments, types, and possibly constants). However, this list may be incomplete and might contain false positives. For instance, the secure monitor could implement runtime services that the REE OS does not use (e.g., the TEE OS could have exclusive access to some services) or our previous heuristics could simply miss edge cases.

To resolve these cases, EL3XIR performs a "probing and pruning" phase. We probe all 2^{32} function identifiers (passed via `x0`) and leverage the coverage as an oracle to determine if a function identifier is backed by a service. For instance, the coverage map will be the same for the default cases whereas entering an existing service will lead to distinct coverage profiles. Additionally, we prune the list of known function identifiers if it contains function identifiers not backed by services.

Step 2: Harness Synthesis

By utilizing the comprehensive collection of function identifiers and recovered interfaces supported by the secure monitor, we generate a refined fuzzing harness (③ in Figure 2) that leverages this target-specific knowledge and incorporates additional domain-specific mutators for the effective exploration of the secure monitor's interface.

Interface-aware Input Injection. As depicted in Figure 4, the fuzzing harness starts to decode the raw bytes of the fuzzing stream to generate secure monitor requests. To this end, the initial bytes represent metadata that defines the structure of the SMC request (e.g., function arity and type of parameters). At the same time, the harness maps the subsequent raw bytes to the SMC interface by filling registers and memory regions with values according to their inferred type. For example, the first parameter is a four-byte scalar value copied into the `x0` register to define the function identifier (first entry in Listing 3). When the SMC request is injected (all recovered parameters are filled with values), all remaining bytes are held for reflected peripheral modeling (Section 4.2).

Domain-specific Mutators. EL3XIR incorporates three domain-specific mutators into its fuzzing harness, enabling

targeted mutations of fuzzing inputs to generate high-quality test cases. It is important to note that these mutators are tailored explicitly for secure monitor implementations. However, since EL3XIR's harness is a standalone component, the mutators can be customized per-target.

The first mutator ensures that memory references primarily fall within the memory range of the REE OS. This approach is rooted in the expectation that secure monitors implement validation logic to verify that parameter addresses point to memory within the REE OS (Listing 1). If EL3XIR successfully recovered memory reference type information for a parameter (e.g., register `x2` with type `phys_addr_t` in Listing 3), our mutator ensures this parameter primarily holds valid addresses while intentionally introducing occasional invalid ones to identify potential unsanitized memory pointers.

The second mutator addresses the alignment of size values for memory buffers in communication with peripherals via MMIO. Hardware devices often have specific alignment requirements for accessing data, and failing to meet these requirements can lead to hardware errors. As a result, secure monitors incorporate alignment checks to ensure accurate communication with these peripherals that can act as coverage walls (Listing 1). If a size parameter is recovered (e.g., register `x3` with type `size_t` in Listing 3), our mutator strives to satisfy these alignment checks in most cases while still allowing for the rare possibility of sending misaligned data to ensure extensive code coverage.

Lastly, the third mutator aims to reuse known interfaces for runtime services whose interface has not been recovered. The underlying idea is that low-level firmware interfaces that adhere to the same calling convention, such as the SMCCC [5], often share identical function signatures.

5 Implementation Details

As a framework that enables effective end-to-end fuzzing of COTS secure monitors, we designed EL3XIR with expandability and adaptability in mind. In this section, we describe implementation details of EL3XIR's three main components (Section 4). This includes the partial-rehosting framework (Section 5.1), reflected peripheral modeling (Section 5.2), and interface-aware fuzzing (Section 5.3).

5.1 Secure Monitor Rehosting Framework

EL3XIR's rehosting framework (Section 4.1) extends avatar^2 (version 1.3.1) [45] and its configurable machine which is integrated into QEMU [13]. We choose QEMU as our core emulator because it has direct support for ARMv8-A CPUs and the TrustZone extensions. By leveraging avatar^2's flexible physical memory description, we can adjust the memory layout to align with the requirements of the targeted secure monitor and directly write software stub code into memory during setup. EL3XIR comes with prototypes for the bootloader, REE OS, and TEE OS which can be easily adjusted during the iterative refinement rehosting process. We solve the injection of precise hardware emulation during boot by setting breakpoints at the location of failing MMIO read operations and implementing handler functions that allow to *directly* write expected values into destination registers of the load instruction.

5.2 Reflected Peripheral Modeling

EL3XIR repurposes fuzzing data to dynamically emulate MMIO interactions (Section 4.2). This enables EL3XIR to overcome coverage walls caused by MMIO reads by providing fuzzing input at the location of MMIO memory regions mimicking peripheral behavior. For this feature, we modified avatar^2's remote memory peripheral to request fuzz data when a `read` operation occurs. Consequently, we replaced all physical memory regions belonging to MMIO regions with our modified memory peripheral that will return fuzzing data to our target. We ignore MMIO `write` operations because they only result in internal hardware state changes and our fuzzer sends the expected peripheral output to the target on subsequent MMIO reads.

5.3 Interface-Aware Fuzzing

Interface Recovery. EL3XIR's static analysis is based on LLVM (version 14.0.0) and SVF (version 2.5) [54]. We generate LLVM-bitcode by compiling the REE OS source code without any optimizations to retain metadata. Furthermore, EL3XIR only analyzes a smaller hand-picked partition as building the value-flow graph for the entire kernel is infeasible [37]. Picking a REE OS partition can be as simple as including the driver files that communicate with the targeted vendor's secure monitor. Finding these via keywords in the source code is manageable manual effort as the partitions only comprise of a couple of files (Section 6.2).

EL3XIR performs a depth-first search on the value-flow graph for each argument of a potential SMC call site, previously identified by scanning all call instructions. The execution of an SMC instruction is usually written in assembly code and wrapped in a function that consumes the corresponding register values as parameters. Because the kernel makes heavy usage of indirect calls for these wrappers, statically identifying SMC call sites is non-trivial as function pointers may only be resolved at runtime. While there exist more holistic solutions for this problem [41], we employed an over-approximating heuristic (Section 4.3), that was sufficient for this task in combination with the fact that REE OS partitions remained relatively small.

During backward tracing of the value-flow graph, we search for LLVM instructions that load, store or calculate pointer addresses to trigger EL3XIR's extraction routine (example

in Appendix B). While the extraction of scalar values from the value-flow graph was trivial, extracting semantic C-types required more effort. EL3XIR does this by traversing LLVM intrinsic function calls and matching parameters to find LLVM metadata using the source code line as an indicator. We hold the results in a list with the basic block being an identifier. Clustering function prototypes purely by the function identifier (`x0`) is not possible because there might be multiple interfaces for one function identifier. For example, a runtime service might implement a sub-service that uses `x1` as a command identifier. Every recovered interface is saved as a `CVS` file in which each tuple represents the associated register, a C-Type, and an optionally recovered constant (e.g., Listing 3).

Fuzzing Framework. We implemented EL3XIR's fuzzing approach by extending *qemuafl*, the QEMU user-mode of AFL++ (version 3.15a) [26] to support full-system emulation. We achieve this by integrating avatar^2's configurable machine and a forkserver capable of executing copies of the entire VM as child processes. Because QEMU is a multi-threaded process, forking complete VMs turned out to be a non-trivial task. Our solution is inspired by TriforceAFL [30]. We shut down the CPU thread on reaching the initial fuzzing location (e.g., the first instruction in the REE OS) and spin up the forkserver that creates a new CPU thread for each child. By loading the snapshot of the targeted secure monitor beforehand, each new child is initially in a reset state.

Unlike TriforceAFL, our fuzzing harness is implemented as a shared object, thus being part of the QEMU process which saves the effort to run an agent in the VM. Instead, the harness is triggered when a defined address is hit during emulation (e.g., the first instruction in the REE OS stub). EL3XIR's harness takes AFL++'s input via shared memory and writes test cases directly into the VM's registers and memory. For the detection of crashes, we modified the CPU thread to abort if it encounters an exception raised by the MMU (e.g., data or prefetch abort) and forward the signal to AFL++ indicating a crash. Coverage information is fed back to AFL++ through a bitmap in shared memory which is filled by the CPU thread during the translation of instructions.

6 Evaluation

Our evaluation of EL3XIR answers these research questions:

RQ1 Are the manual steps of EL3XIR's partial-rehosting approach feasible? (Section 6.1)

RQ2 Is EL3XIR's interface recovery effective in prototyping function signatures of runtime services? (Section 6.2)

RQ3 Does the reflected peripheral modeling technique improve EL3XIR's exploration capability? (Section 6.3)

RQ4 How does EL3XIR compare against existing methods to fuzz TEE firmware? (Section 6.3 and Section 6.4)

RQ5 Can EL3XIR be used to uncover previously unknown bugs in real-world secure monitors? (Section 6.4)

To answer these questions, we conduct several experiments targeting the secure monitors of different platforms (Table 1). We use a diverse set of platforms from several reputable vendors. EL3XIR enables fuzzing *proprietary* secure monitors. For the open-source targets, we compiled the secure monitors according to the available platform-specific instructions and only used the binaries. Moreover, we obtained proprietary secure monitors from COTS devices or firmware updates.

Table 1: Dataset of secure monitors used for EL3XIR's evaluation. Proprietary (Prop.) indicates if the implementation is closed-source.

Vendor	SoC	Prop.	Size
Intel	Stratix 10 SoC FPGA		45 KB
NXP	i.MX 8 Series		37 KB
Xilinx	Zynq MPSoC		49 KB
Nvidia	Tegra X2 T186		75 KB
Huawei	Kirin 659	✓	112 KB
Samsung	Exynos 7420 Octa	✓	192 KB
Samsung	Exynos 8890 Octa	✓	144 KB

6.1 Manual Effort for Rehosting

We now quantify the manual effort required to build an initial rehosting environment that can be used to properly boot the targeted secure monitor (**RQ1**). Naturally, we were required to carry out some reverse engineering efforts to implement target-specific software stubs and hardware interactions. However, while rehosting the first secure monitor did take multiple weeks, we iteratively improved EL3XIR's rehosting framework which cut this time down to only some days.

Software Stubs. To solve software dependencies, we replace logical dependent components with software stubs implemented in assembly (Section 4.1). We create the bootloader stub by identifying the entry point in the secure monitor binary and reverse-engineer expected arguments (e.g., boot information structure for the TEE OS and REE OS). For each target, we implemented bootloader stubs with around five lines of assembly, that fill registers with expected values and execute a return instruction to jump to the secure monitor's entry address. We replace the TEE OS with a four-line assembly stub that populates the register `x0` with a value indicating the successful initialization of the TEE OS and executes an SMC, handing control back to the secure monitor. We replace the REE OS with two assembly instructions executing the exception level switch to EL3. EL3XIR provides skeletons for each software stub thus the effort to extend it with a new

secure monitor boils down to changing a handful of values in the boot information structures and register parameters.

Hardware Interactions. To boot the secure monitor, we need to place manually crafted hooks, that emulate successful peripheral behavior to keep the target running (Section 4.1). In most scenarios, we can allow the secure monitor to execute from its entrypoint and observe any instances when it gets stuck (e.g., enters an infinite loop) or an exception is thrown. This behavior often indicates the polling of MMIO status registers. We briefly analyze the assembly code at the error location and then insert a hook that sets the relevant destination registers to the expected values to satisfy the control flow graph constraints validating successful peripheral initialization. One exception for MMIO polling were the Exynos-based secure monitors. Depending on MMIO registers, these secure monitors would enable the MMU at different locations, resulting in a crash if the translation tables were not properly set up yet. By investigating the crash location, we identify involved registers, and guide the control flow to boot the secure monitor. In total, we needed one (Kirin 659), two (i.MX 8), three (Stratix 10), three (Tegra T186), seven (Zynqmp MPSoC), eight (Exynos 8890), and ten (Exynos 7420) of these MMIO hooks for the respective chipset.

As detailed in this section, partially rehosting the diverse set of open- and closed-source secure monitors from Table 1 to the point where the REE OS is booted, is feasible (**RQ1**).

6.2 Interface Recovery

In this section, we evaluate EL3XIR's interface recovery (Section 4.3). EL3XIR operates on REE OS partitions handpicked for each target. In total, the partitions consisted of four, eleven, five, and four REE OS files for the Stratix 10, i.MX 8 Series, Zynq MPSoC, and Tegra X2 T186 respectively. The size of partitions ranged from around 400KB to 1.4MB with EL3XIR's analysis time remaining within minutes per target. To answer **RQ2** we compare the number of successfully recovered interfaces Σ_{rt}^{rec} to the total number of offered runtime services by the targeted secure monitor Σ_{rt}, as depicted in Table 2. As we do not have a reliable ground truth for the closed-source targets, we only focus on the open-source ones. Overall EL3XIR recovers between 36% and 61% of all runtime services for our targets. After closer analysis, we found that nearly all of the remaining runtime services were not exercised by the REE OS but rather previous bootloader stages running in the REE which are not part of EL3XIR's analyzed set as there is usually no source code available (Section 7). For example, EL3XIR only recovered 36% of runtime services for the Nvidia Tegra target which is rooted in the fact that our analyzed REE OS did not support all functionality offered by the secure monitor (e.g., the Linux kernel did not support the Software Delegated Exception Interface).

False Positives. In order to evaluate the accuracy of EL3XIR's interface recovery heuristic (Section 4.3), we count the rate of falsely recovered interfaces during static analysis of the REE OS partitions. In column Σ_{rt}^{cand} of Table 2 we count the total number of interface candidates after EL3XIR's static value-flow analysis. After analyzing the results we identified duplicate candidates with the same function identifier Σ_{rt}^{dup}. EL3XIR included these because it successfully recovered multiple scalar values for other registers (e.g., register `x1` is used as a command identifier for a sub-service). Furthermore, EL3XIR recovered interfaces that were not offered by the targeted secure monitor but are still part of the REE OS code Σ_{rt}^{REE}, because SoCs often share REE OS drivers. If we consider candidates that have no or no valid function identifier (Σ_{rt}^{nofid} and $\Sigma_{rt}^{wrongfid}$) we reach between 57 and 96 false positives, with percentage rates 30% and 54%, respectively. After sorting out candidates without any function identifier we can narrow this down to 0% and 12%, resulting in false positive rates between zero and twelve percent. In the end, EL3XIR's probing phase will also sort out candidates with no valid function identifier as they will all result in the same coverage profile.

6.3 Coverage

We provide a comparative evaluation of EL3XIR's achieved coverage (**RQ4**) and investigate the effect of reflected peripheral modeling on the exploration capability (**RQ3**).

To establish a coverage baseline, we repurpose the fuzzing harness originally developed for PartEmu [32]. While PartEmu is the closest work to ours, it does not include evaluation of secure monitors due to their heavy reliance on hardware interactions (**C2** in Section 3). Although the PartEmu prototype was not publicly released, we reimplemented their fuzzing harness based on their publication. To promote reproducibility and support future research, we will make all of our artifacts publicly available.

The PartEmu harness is not interface-aware, meaning that it does not employ any knowledge about the function signatures of runtime services. Thus, we dubbed this approach adhering to the generic SMCCC *interface-unaware*. Additionally, we introduce a *naive* MMIO modeling approach where all MMIO ranges are backed with zeroed `rw` memory always returning the last stored value. EL3XIR is designed such that both *interface awareness* and *reflected peripheral modeling* can be turned on or off before starting a fuzzing campaign.

In total, we compare the following four different fuzzing configurations of EL3XIR targeting the seven targets from Table 1:

- $iface^{-}/mmio^{-}$: Iface-unaware + naive MMIO (PartEmu [32])
- $iface^{+}/mmio^{-}$: Iface-aware + naive MMIO
- $iface^{-}/mmio^{+}$: Iface-unaware + reflected peripheral modeling
- $iface^{+}/mmio^{+}$: Iface-aware + reflected peripheral modeling

Table 2: Σ_{rt} states the number of runtime services we found in each target binary (ground truth), while Σ_{rt}^{rec} counts all successfully recovered ones by EL3XIR (percentage share in parentheses). EL3XIR's static analysis grants Σ_{rt}^{cand} interface candidates with Σ_{rt}^{dup} duplicates. We filter out candidates only present in the REE OS partition (Σ_{rt}^{REE}), those without (Σ_{rt}^{nofid}) or a wrong ($\Sigma_{rt}^{wrongfid}$) function identifier. The false positive rates are given in percentage in parentheses with respect to Σ_{rt}^{cand}.

SoC	Σ_{rt}	Σ_{rt}^{cand}	Σ_{rt}^{dup}	Σ_{rt}^{REE}	Σ_{rt}^{nofid}	$\Sigma_{rt}^{wrongfid}$	Σ_{rt}^{rec}
Stratix 10 SoC FPGA	122	177	2 (1%)	0 (0%)	96 (54%)	5 (3%)	74 (61%)
i.MX 8 Series	68	89	0 (0%)	9 (10%)	42 (47%)	8 (9%)	30 (44%)
Zynq MPSoC	91	188	24 (13%)	31 (17%)	57 (30%)	23 (12%)	53 (58%)
Tegra X2 T186	78	55	2 (4%)	2 (4%)	23 (42%)	0 (0%)	28 (36%)

Figure 6 illustrates the accumulated edge coverage over time for all four fuzzing configurations. For each target, we run each fuzzer eight times for 24 hours, and plot the average coverage and the min/max coverage (shaded area). We run these experiments on a 16-core Intel Xeon Gold 5218 processor (hyperthreading disabled) with 64GB of RAM and limit each 24-hour run to one core.

Reflected Peripheral Modeling. One of EL3XIR's technical contributions is *reflected peripheral modeling* (Section 4.2). In contrast to the *naive* approaches $^{iface^-}/_{mmio^-}$ and $^{iface^+}/_{mmio^-}$, we leverage the fuzzing input to populate read accesses to MMIO registers. We hypothesize that this technique contributes to code exploration (**RQ3**) as naive approaches are not able to overcome MMIO coverage walls (**C2** in Section 3). If we compare the reflected peripheral modeling configurations ($^{iface^-}/_{mmio^+}$ and $^{iface^+}/_{mmio^+}$) to their naive counterparts, we can see a robust gap in edge coverage across all seven targets (Figure 6).

For a deeper evaluation, we identify coverage walls in the four open-source target's runtime services and check if EL3XIR overcomes them through successful MMIO read operations provided by reflected peripheral modeling. We present the results in Table 3 showcasing that EL3XIR's reflected peripheral modeling is used in up to 87% of runtime services Σ_{rt}^{wall} at least once. In all affected ones, reflected peripheral modeling leads to an increase in code coverage. By rerunning all resulting inputs after the fuzzing campaign and counting MMIO access addresses, we identify all unique MMIO addresses across all runtime services in column Σ_{MMIO}. EL3XIR successfully models several unique MMIO register accesses across all targets. Additionally, we count the total number of uniquely returned MMIO *values* for these registers which resulted in 7742, 8815, 1802, and 1866 different values returned for the Stratix 10, i.MX 8 Series, Zynq MPSoC, and Tegra X2 T186 chipsets, respectively. In summary, EL3XIR's reflected peripheral modeling automatically emulates the behavior of several peripherals (with multiple MMIO registers being involved Σ_{MMIO}) by providing thousands of different return values during fuzzing, exercising both success and failure states of MMIO handling routines. Therefore, recent approaches trying to manually emulate these peripheral interactions [32] can not be considered scalable solutions.

Comparison with the State-of-the-Art. By comparing the achieved coverage of $^{iface^-}/_{mmio^-}$ against $^{iface^+}/_{mmio^-}$ (Figure 6), we can reason about **RQ4**. Taking $^{iface^-}/_{mmio^-}$ as an optimistic baseline to represent prior work on fuzzing TEE firmware, we can see that EL3XIR using its contributions $^{iface^+}/_{mmio^+}$, outperforms the state-of-the-art in terms of coverage in every single experiment. Furthermore, we observe that $^{iface^-}/_{mmio^+}$ and $^{iface^+}/_{mmio^-}$ reach coverage levels between the base line and EL3XIR. This indicates that EL3XIR's technical contributions (Section 4.2 and Section 4.3) indeed complement each other. Additionally, when comparing the maximum edge coverage reached (Table 4) by EL3XIR's full configuration ($^{iface^+}/_{mmio^+}$) and our adaption of PartEmu [32] ($^{iface^-}/_{mmio^-}$), we can see that EL3XIR increases the reached coverage by up to 51%.

Table 3: Total number and percentage of runtime services affected by MMIO coverage walls Σ_{rt}^{wall}. Σ_{MMIO} states the number of unique MMIO read registers successfully modeled by EL3XIR across all affected runtime services.

SoC	Σ_{rt}	Σ_{rt}^{wall}	Σ_{MMIO}
Stratix 10	122	51 (42%)	37
i.MX 8 Series	68	6 (9%)	58
Zynq MPSoC	91	79 (87%)	5
Tegra X2 T186	78	24 (31%)	158

6.4 Finding Bugs

Our fuzzing campaigns resulted in a variety of crashes across all seven targets. After deduplication and root cause analysis, we identified 34 bugs with 17 being security relevant.

We compare the number of unique bugs found by the baseline fuzzer and full-featured EL3XIR to reason about **RQ4**. In total, EL3XIR found 34 and $^{iface^-}/_{mmio^-}$ found 19 unique bugs. EL3XIR triggered significantly more crashes, and the

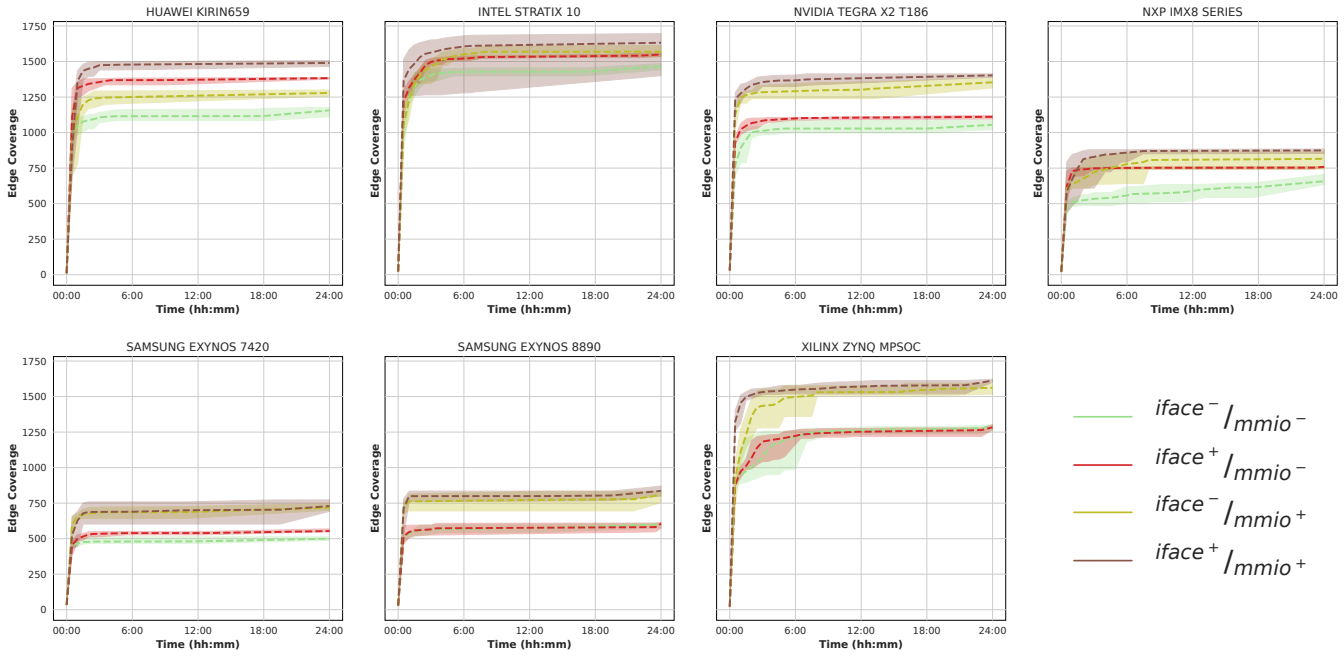

Figure 6: Coverage plots for our seven targets with all four fuzzing configurations. In its full configuration ($^{iface^+}/_{mmio^+}$) EL3XIR achieves the most coverage for every target, while the state-of-the-art fuzzing approach ($^{iface^-}/_{mmio^-}$) finds the least coverage. This shows that EL3XIR's contributions and their interplay are effective in better exercising the secure monitor's interface and overcoming coverage walls through MMIO modeling.

ones found by $^{iface^-}/_{mmio^-}$ are a strict subset of the crashes found by $^{iface^+}/_{mmio^+}$. EL3XIR's crashes contain 17 security-critical bugs whereas the $^{iface^-}/_{mmio^-}$ mode's set of bugs only contains 10. These bugs are distributed over five out of the seven targets, and contain arbitrary read and write primitives that can be leveraged to breach the confidentiality and integrity of the secure monitor and therefore TEE. We present a detailed overview of affected targets and descriptions for security-relevant bugs in Table 5.

To answer **RQ5**, we manually triaged all vulnerabilities and responsibly disclosed them to the respective vendors. While we selectively tested and reproduced some crashes on production devices as well, we did not have access to all devices in question, thus by including the vendor we can verify the reproducibility of bugs found by EL3XIR. In summary, vendors assigned six CVEs and six additional crashes were confirmed with patches already rolled out.

Case Study I: 0-day bugs in Intel's Stratix 10 SoC FPGA EL3XIR uncovered seven previously unknown vulnerabilities in the secure monitor implementation running on Intel's Stratix 10 SoC FPGA for which four CVEs were assigned. The secure monitor implements functionality to interact with a Field Programmable Gate Array (FPGA) for the accelerated and protected calculation of cryptographic actions (e.g., AES). The production device is running a Linux kernel driver that sends a payload to runtime services via shared kernel space memory. The secure monitor receives the physical address and copies the payload to secure memory in order to prepare the request for the FPGA which is only accessible in the TEE.

We identified that the bugs cause bounds validations for `memcpy` calls resulting in out-of-bound writes, corrupting secure memory. Thus, an attacker can overwrite the secure monitor's memory with an arbitrary payload. Due to the lack of stack canaries or ASLR, developing an exploit to gain code execution with this primitive is straightforward. For example, an attacker can overwrite the page tables to map additional memory on behalf of the secure monitor and inject executable payload. As a result, a privilege escalation to the highest privilege level (EL3) is possible, demolishing any security guarantees provided by ARM TrustZone.

Case Study II: N-day bugs in Huawei's Kirin 659 To validate that EL3XIR can also find bugs in proprietary secure monitor implementations, we verified that EL3XIR can reproduce already known bugs in TEE firmware running on Huawei P20lite devices based on the Kirin 659 SoC. Huawei decided to implement multiple runtime services on top of ARM's reference implementation, including drivers for replay-protected memory blocks (RPMB). A statically shared memory location is used to exchange data between the non-trusted kernel drivers and secure runtime services.

In total, EL3XIR found seven unique crashes scattered across three different runtime services, of which three were

Table 4: Maximal edge coverage reached by EL3XIR for each target. We compare the percentage increase of each of EL3XIR's configuration to our baseline PartEmu adaptation ($iface^-/mmio^-$) in parentheses with the highest increase being marked in bold.

Total Edges Covered				
SoC	$iface^-/mmio^-$	$iface^+/mmio^-$	$iface^-/mmio^+$	$iface^+/mmio^+$
Huawei Kirin 659	1178	1388 (18%)	1300 (10%)	1507 (**28%**)
Intel Stratix 10	1485	1560 (5%)	1612 (9%)	1697 (**14%**)
Nvidia Tegra X2 T186	1088	1121 (3%)	1387 (27%)	1413 (**30%**)
NXP i.MX 8 Series	706	762 (8%)	864 (22%)	884 (**25%**)
Samsung Exynos 7420 Octa	513	569 (11%)	747 (46%)	773 (**51%**)
Samsung Exynos 8890 Octa	609	616 (1%)	834 (37%)	870 (**43%**)
Xilinx Zynq MPSoC	1303	1302 (0%)	1594 (22%)	1622 (**24%**)

in the RPMB runtime service. Two of those crash locations turned out to be arbitrary write and read primitives respectively. As found before [56], both crashes are exploitable bugs that can lead to code execution at EL3. EL3XIR was capable of pinpointing the exact crash locations used during the privilege escalation exploit. In essence, an attacker can map non-secure memory on behalf of the secure memory, fill it with payload code, and by overwriting control flow data execute the payload.

7 Discussion

In this section, we discuss design decisions and future research directions of EL3XIR.

Encrypted Binaries. EL3XIR is a rehosting-based fuzzing framework. Thus, similar to other rehosting approaches, we need access to the plaintext target binaries. Obtaining these binaries might be challenging for COTS devices that receive encrypted firmware updates. For instance, we observed that the secure monitor is encrypted in recent updates for the newest phones of Samsung and Huawei.

Manual Effort. Although EL3XIR reduces the manual effort involved in rehosting COTS firmware binaries compared to the state-of-the-art approach described by Harrison et al. [32], we still require the implementation of software stubs to emulate dependent components and smaller hardware emulation during the boot process (Section 4.1). Automating the initial rehosting process proved to be challenging due to the intertwined and non-standardized sequences of the boot flow. For example, Samsung's secure monitor tried to boot separate loadable firmware components before switching to the REE OS. In our experiments, we manually bypassed these loading sequences to focus our fuzzing efforts on the secure monitor and to cut down on additional rehosting effort. Therefore, while EL3XIR still requires some manual work from an expert, we consider our design to be a significant advancement toward achieving a more comprehensive automation solution for rehosting highly-intertwined firmware components.

Modeling Direct Memory Access. Furthermore, EL3XIR's MMIO modeling approach (Section 4.2) cannot deal with direct memory access (DMA). While we did not encounter any DMA-capable peripherals in our dataset, we note that these peripherals are currently out of scope. Supporting DMA-capable peripherals would need dedicated handling partially addressed by prior work [44].

Closed-source Consumers. EL3XIR's approach to recovering interfaces for unknown runtime services requires the source code of corresponding consumers of the SMC interface. In its current implementation EL3XIR only focuses on open-source REE OS drivers to retrieve interfaces. While we did not encounter any proprietary drivers communicating with the secure monitor, vendors might deploy closed-source drivers which would render EL3XIR's current implementation ineffective. However, there is work trying to recover interfaces from unknown function signatures on a binary-level [19]. Beyond that, additional consumer components (e.g. TEE OS or subsequent bootloader) could also be analyzed to collect even more function prototypes for runtime services not exercised by the REE OS. As interface awareness is only one of EL3XIR's components, we believe that these approaches would complement our work.

Horizontal Extension. Since PartEmu [32] was severely limited by the lack of interface- and state-awareness, reflected by low coverage results, our future plans include the extension of EL3XIR to fuzz proprietary TEE OSes and TAs. Furthermore, we believe that EL3XIR's approach is applicable to fuzz components of other highly-intertwined firmware binaries like bootloader components (e.g., uboot or UEFI).

8 Related Work

Prior research on TrustZone-based systems focuses on static analysis of TEE components [15, 17, 27, 42, 52, 53] with relatively few researchers attacking the SMC interface to the secure monitor [43]. Cerdeira et al. [18] give an overview of vulnerabilities in TrustZone-based systems, including publicly

Table 5: Overview of bugs found by EL3XIR.

reported bugs in secure monitor implementations. EL3XIR is the first automatic testing platform tailored for fuzzing exactly this proprietary TEE firmware component.

Dynamically analyzing proprietary TEE components is challenging. On-device approaches [14,16] lack the introspection capabilities to enable feedback-guided fuzzing. Harrison et al. [32] report on the feasibility of enabling dynamic analysis for TEE OSes and TAs by manually building emulators. In contrast, EL3XIR addresses the unexplored secure monitor, and advances approaches like PartEmu by adding interface awareness and automated peripheral modeling.

EL3XIR relies on rehosting techniques [24] to enable dynamic analysis. The majority of rehosting work focuses on small, standalone embedded firmware [21,25,38,50], whereas EL3XIR addresses highly-intertwined components from a significantly larger software stack. However, these approaches share the problem of correct peripheral behavior modeling. HALucinator [21] is based on manually crafted high-level emulation hooks that are infeasible to build for the large number and variety of undocumented custom hardware encountered in secure monitor implementations. Another line of research [25, 50, 58] aims to automate MMIO register behavior. These works have a heavy-weight static or dynamic analysis phase in common. In comparison, EL3XIR uses coverage feedback as an oracle to assess the quality of generated MMIO behavior, and smoothly integrates its reflected peripheral modeling approach into the fuzzing process.

Interface-aware fuzzing has been previously employed for various targets [12, 16, 22, 23, 47]. TEEzz [16] is the first to target ARM TrustZone firmware by trying to recover TEE interface-aware seeds on production devices via recording interactions between the Client Application and TA. Instead EL3XIR automatically derives interface-aware information by statically analyzing the REE OS, eliminating the dependency on real-world devices and enhancing scalability. Several works [23, 37] apply static analysis to the Linux kernel source code to improve fuzzing campaigns. In comparison, EL3XIR does not analyze the closed-source secure monitor (i.e., the target) itself but rather its open-source consumers.

EL3XIR derives function prototypes by analyzing the consumer of the SMC interface (REE OS driver) which is similar to work addressing automated test driver generation from library source code [11, 29, 35]. Moreover, there exist approaches that try to derive interfaces from closed-source binaries [20, 39]. As described in Section 7, we believe that EL3XIR might benefit from statically analyzing additional

closed-source consumers (e.g., TEE OS and bootloader) to uncover even more interfaces of runtime services. However, it is worth noting that even by solely analyzing the REE OS, EL3XIR can already identify the majority of function signatures, leaving the additional tasks for future research.

9 Conclusions

EL3XIR presents the first end-to-end rehosting and fuzzing framework targeting proprietary secure monitor implementations. The secure monitor is part of the TEE and runs on the highest privilege level on ARM-based devices. Because its complex interface is directly exposed to untrusted components (REE OS at EL1), security-critical bugs pose a single point of failure and can annihilate the entire platform's security.

Our evaluation covered seven different platforms, and EL3XIR found 17 security-critical bugs. We systematically evaluated EL3XIR with experiments providing evidence that our interface-awareness approach and peripheral modeling contribute during fuzzing to explored code coverage and the number of bugs found. In contrast, naive fuzzing approaches are ineffective for fuzzing secure monitors.

Acknowledgments

We thank our anonymous reviewers for their valuable feedback and comments. Additionally, we would like to thank our shepherd for guiding us during the major revision process. This work was supported, in part, by the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation program (grant agreement No. 850868), SNSF PCEGP2_186974, and DARPA HR001119S0089-AMP-FP-034.

A Appendix

Example for MMIO Coverage Wall. The problem of coverage walls caused by missing MMIO behavior is illustrated in Listing 1. Each `mmio_read_32` function call to memory regions associated with the underlying crypto engine (e.g., `CRYPTO_CTRL_REG`) will not yield a meaningful value without a proper peripheral model behind the MMIO registers. Consequently, a naive fuzzing approach would never execute the exemplary `sip_encryption` function beyond interactions with the crypto engine, as read operations from `CRYPTO_CTRL_REG` would never return a valid status code to break out of the loop.

```
// parameters are passed via registers x1 - x4
int sip_encryption(u32 src_addr, u32 src_size, u32
    dst_addr, u32 dst_size) {

 // parsing and validation logic
 if (dst_size == NULL || src_size == NULL)
 return SIP_SMC_STATUS_REJECTED;

 if (src_size % 4 != 0, dst_size % 4 != 0)
 return SIP_SMC_STATUS_REJECTED;

 // verify that source and destination memory is in
      normal world
 if (!addr_in_nw_range(src_addr, src_size) ||
 !addr_in_nw_range(dst_addr, dst_size))
 return SIP_SMC_STATUS_REJECTED;

 for (u32 i = 0; i < dst_size; i += 4) {
  // write payload chunk to mmio data register
  mmio_write_32(CRYPTO_DATA_REG, *(src_addr + i));
```

```
19
20   // activate crypto engine with exemplary status
         code
21   mmio_write_32(CRYPTO_CTRL_REG, 0x1);
22
23   // wait for crypto engine to finish or fail
24   do {
25    u32 status = mmio_read_32(MMIO_CTRL_REG);
26    if(status & 0x2) { break; }
27    else if (status & 0x1) { continue; }
28    else { return SIP_SMC_STATUS_REJECTED; }
29
30   } while (1);
31
32   // read encrypted payload chunk
33   *(dst_addr + i) = mmio_read_32(CRYPTO_DATA_REG);
34  }
35
36  return SIP_SMC_STATUS_OK;
37 }

B Appendix

Example for Successfully Recovered Interface. EL3XIR's recovers the SMC interface from the REE OS source code. Our system localizes SMC call site candidates and applies a backward-directed value-flow analysis for each parameter of the interface. Listing 2 shows a code snippet from the Linux kernel of the Stratix 10 SoC FPGA by Intel. EL3XIR identifies line 24 as a potential SMC callsite and follows the value-flow of each parameter `a0 - a7` backwards. EL3XIR recovers both scalars and data types for each parameter (where possible) by scanning for `store`, `load`, and `gep` LLVM instructions in the value-flow graph.

```
1  ...
2  struct stratix10_svc_data {
3   struct stratix10_svc_chan *chan;
4   phys_addr_t paddr;
5   size_t size;
6   phys_addr_t paddr_output;
7   size_t size_output;
8   u32 command;
9   u32 flag;
10  u64 arg[6];
11 };
12 ...
13 struct stratix10_svc_data *pdata = NULL;
14 pdata = kmalloc(sizeof(*pdata), GFP_KERNEL);
15 ...
16 case COMMAND_FCS_DATA_ENCRYPTION:
17  a0 = INTEL_SIP_SMC_FCS_CRYPTION;
18  a1 = 1;
19  a2 = (unsigned long)pdata->paddr;
20  a3 = (unsigned long)pdata->size;
21  a4 = (unsigned long)pdata->paddr_output;
22  a5 = (unsigned long)pdata->size_output;
23 ...
24 arm_smccc_smc(a0, a1, a2, a3, a4, a5, a6, a7);
```

Listing 2: Code snippet from the Linux kernel setting up and executing an SMC call. The a0 parameter is the function ID used to define the requested runtime service.

The successfully recovered interface is illustrated in Listing 3. EL3XIR recovers the function identifier for the `x0` register (`INTEL_SIP_SMC_FCS_CRYPTION = 0x4200005B`) and type information or constants for the remaining parameters (e.g., `a2` holds a physical address and `a1` can hold the constant `0x1`). The interface is saved in a `CVS` file and used to refine EL3XIR's harness.

```
1 0, unsigned long, 0x4200005B
2 1, u64, 0x1
3 2, phys_addr_t,
4 3, size_t,
5 4, phys_addr_t,
6 5, size_t,
```

Listing 3: Recovered interface by EL3XIR with format: `register idx, C-type, constant (optional).`

GridSE: Towards Practical Secure Geographic Search via Prefix Symmetric Searchable Encryption

Abstract

The proliferation of location-based services and applications has brought significant attention to data and location privacy. While general secure computation and privacy-enhancing techniques can partially address this problem, one outstanding challenge is to provide near latency-free search and compatibility with mainstream geographic search techniques, especially the Discrete Global Grid Systems (DGGS). This paper proposes a new construction, namely GridSE, for efficient and DGGS-compatible Secure Geographic Search (SGS) with both backward and forward privacy. We first formulate the notion of a semantic-secure primitive called *symmetric prefix predicate encryption* (SP^{2}E), for predicting whether or not a keyword contains a given prefix, and provide a construction. Then we extend SP^{2}E for dynamic *prefix symmetric searchable encryption* (pSSE), namely GridSE, which supports both backward and forward privacy. GridSE only uses lightweight primitives including cryptographic hash and XOR operations and is extremely efficient. Furthermore, we provide a generic pSSE framework that enables prefix search for traditional dynamic SSE that supports only full keyword search. Experimental results over real-world geographic databases of sizes (by the number of entries) from 10^3 to 10^7 and mainstream DGGS techniques show that GridSE achieves a speedup of 150× - 5000× on search latency and a saving of 99% on communication overhead as compared to the state-of-the-art. Interestingly, even compared to plaintext search, GridSE introduces only 1.4× extra computational cost and 0.9× additional communication cost. Source code of our scheme is available at https://github.com/rykieguo1771/GridSE-RAM.

1 INTRODUCTION

With the increasing deployment of Internet of Things (IoT) devices and the advent of next-generation wireless and mobile communications, the demand for Geographic Information Systems (GIS), particularly Location-Based Services (LBS), and consequently Geographic Searches (GS), has never been greater in various context-aware applications. To deliver accurate LBS services, GS apps usually need to collect fine-grained personal information such as users' real-time locations and interests. For privacy concerns, data stored in GS servers, which are usually hosted in the cloud, shall be well protected, e.g., via encryption, as a preemptive measure in light of data breaches. *Secure Geographic Search* (SGS) thus emerges as a promising data protection technique that supports GS over encrypted geographic data.

Existing GS systems, driven by various functionalities (not limited to searches), have been deeply rooted on a so-called *Discrete Global Grid* (DGG) [1] technique for structuring and indexing two-dimensional spatial data (or higher dimension extension). DGG uses hierarchical tessellation of grids to recursively partition the Earth's surfaces into geometrical cells which are then coded. A sequence of DGG cell codes describe a hierarchical partition with progressively finer resolution. As shown in Fig. 1, a cell code "*dr5r7*" represents a cell (subregion) inside the grid of "*dr5r*" around the Statue of Liberty. DGG systems (DGGS) can also provide indexes/APIs to support various GIS/LBS services such as geographic search, distance comparison and spatial visualization. In real-world systems, DGGS technologies such as Niemeyer's Geohash [2], Google S2 [3] and Uber H3 [4] have been widely adopted.

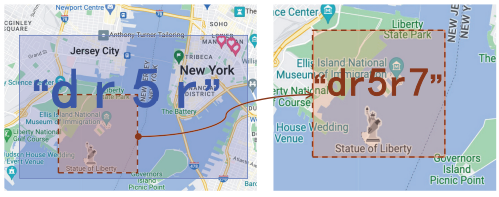

Figure 1: "*dr5r*" tags an area around the Statue of Liberty. Cell code "*dr5r7*" tags an area inside "*dr5r*".

With DGGS, a GS database is indexed by the hierarchical cell codes. A geographic search is essentially to find a prefix match between the indexed cell codes and the search request. To support SGS wherein both index and search request

are encrypted, the problem can be formulated as the general problem of *secure prefix search*.

One outstanding challenge with the design of SGS, however, is to assure near latency-free instant responses for pleasant user experiences while compatible with existing GIS/LBS techniques especially DGGS. Theoretically, many advanced techniques, such as Fully Homomorphic Encryption (FHE) [5, 6] and Multi-Party Computation (MPC) [7], could be employed to realize SGS by performing prefix search over ciphertexts. However, current implementations of these techniques are still far from practical when real-time performances are of concern. For example, MPC requires multiple rounds of interactions between client and server for every single query. Current FHE-based secure search is relatively more efficient but still requires thousands of seconds per 10, 000 search tuples and a heavy communication cost [5]. On the other hand, emerging privacy-enhancing techniques such as Differential Privacy (DP) can be leveraged for *geo-indistinguishability* [8] and hence a more efficient SGS. However, such techniques are intrinsically lossy and will cause the so-called *lack-in-accuracy* issue in geographic services. One branch of privacy-preserving retrieval relies on anonymous technologies like *k-anonymity* [9], which are constrained by data distribution.

Aiming at secure search over encrypted data, searchable symmetric encryption (SSE) provides a generic but viable solution. However, constructing SGS from existing SSE is by no means trivial, especially considering the dynamics of GS databases (e.g., insertion and deletion of entries) and the privacy implications caused by such dynamics. Specifically, additional privacy, including *forward privacy* [10–13] and *backward privacy* [12, 14, 15], shall be considered for dynamic databases. Forward privacy is to ensure newly added data cannot be linked to previous queries while backward privacy further eliminates the link between a query and previously deleted data. These metrics and their definitions construct a strict framework for provable dynamic searchable security.

To our knowledge, the majority of existing SSE techniques focused on keyword search rather than prefix search and thus cannot support SGS, not to mention forward and backward privacy. Few works such as Moataz et. al. [16] enable substring search and provide a semantic-secure SSE but fail to address forward privacy or backward privacy. Moreover, their approach leverages Oblivious RAM (ORAM) which incurs a high communication complexity (quadratic logarithmic). For instance, considering a GS dataset of 10^5 entries, conducting a single search under this scheme needs at least hundreds of interactions which is far from practical for GIS/LBS applications. Another line of research [17–21] build a specialized index for SGS and all exhibit trade-offs between efficiency, security and false-positive rates.

In this paper, we construct an efficient, secure and DGGS-compatible SGS scheme that supports both forward privacy and backward privacy. To this end, we first formally formulate a novel cryptographic primitive *symmetric prefix predicate encryption* (SP^2E) for predicating a prefix, i.e., *evaluating whether a keyword contains a given prefix*, and provide a concrete construction. Based on SP^2E, we design a new cryptographic algorithm *prefix symmetric searchable encryption* (pSSE), namely GridSE, for secure geographic search that supports both forward and backward privacy. Interestingly, the construction of GridSE involves only cryptographic hash and XOR operations and is extremely light-weight. Regarding the search complexity, GridSE only introduces an additional cost linearly proportional to the number of DGGS cells, which is practically a constant in real systems and independent to the global GS database size. Thus, GridSE is highly applicable to large-scale GIS/LBS systems.

Our main contributions are summarized as follows:

- We construct an efficient, scalable and DGGS-compatible SGS scheme GridSE that supports both forward and backward privacy. Based on lightweight cryptographic primitives, GridSE is able to offer near real-time latency for large-scale geographic searches.
- We formulate and design a novel cryptographic primitive - symmetric prefix predicate encryption (SP^2E) - for predicating prefixes. We prove that SP^2E is secure under the random oracle model. Based on SP^2E, we construct a new prefix SSE primitive pSSE which is forward and backward secure. Both SP^2E and pSSE are generic primitives and can be of independent interests.
- We propose a generic dynamic pSSE framework based on the key idea of GridSE. It supports forward and backward privacy and is also compatible with traditional dynamic SSE that supports only full keyword search.
- Experiments on geographic databases with 10^3 - 10^7 entries and major DGGS systems (including Niemeyer's Geohash, Google S2 and Uber H3) show that GridSE achieves a speedup of 150× - 5000×, respectively, in search latency and a saving of 99% in communication overhead as compared to the state-of-the-art [16]. Even compared with plaintext geographic search, GridSE only introduces 1.4× additional computational cost and 0.9× additional communication cost.

The rest of this paper is organized as follows: Section 2 presents the background. Section 3 lists related works which are followed by preliminaries in Section 4. The SP^2E primitive is introduced in Section 5. Section 6 presents our construction of GridSE. The experimental evaluation is shown in Section 7. We conclude this paper in Section 8.

2 BACKGROUND

2.1 Geographic Search Framework

We consider a typical GIS/LBS application scenario with three major entities - *users*, *client* and *server*. A server (e.g.,

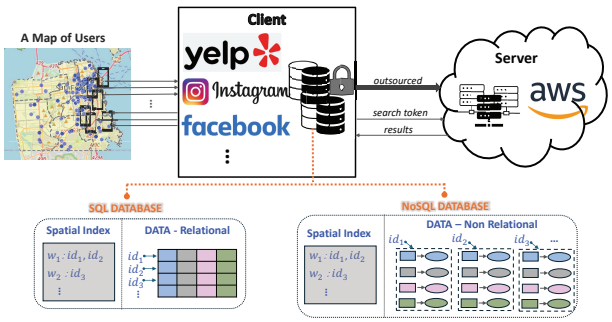

Figure 2: A geographic search framework

AWS) is a cloud provider for computing or storage services; a client is a GIS/LBS provider (e.g., yelp) that outsources its data (after encryption) to the server while keeping some local computation and storage capacity; users (e.g., mobile users) are consumers who make geographic search requests to the client to enjoy GIS/LBS services. We assume the client precomputes encrypted indexes and uploads them to the server to assure search efficiency.

In real GIS/LBS systems, both SQL/relational and NoSQL/non-relational databases are widely adopted. To ensure compatibility, we consider secure geographic search scenarios with both types of databases. In SQL databases, data is organized in tables of columns (i.e., attributes) and rows (i.e., records). A record would be contributed by a user. NoSQL databases, on the other hand, store data as JSON documents which are composed of key-value pairs. For brevity, we use *block* to denote either a record or a JSON document since both of them can be indexed by a certain attribute. Each block is assigned a unique identifier, as shown in Fig. 2.

We logically divide a database into two pools, data and their indexes. Data (namely blocks) are indexed by their locations, and those sharing the same location are included under the same key. To avoid ambiguity, we call a key for indexing locations as *index-key*. For example, assume the index-key w_1 in Fig. 2 is associated with a certain geographic area on Earth (e.g., New York City). When searching for w_1, the data such as id_1, id_2 located in this area will be returned. In this work, we only focus on the location attribute (e.g., DGGS-compatible geographical cell codes) and how to retrieve an exact index-key over its encrypted form such that the queried encrypted blocks will be returned correctly, securely and efficiently.

2.2 Discrete Global Grid System

A Discrete Global Grid System (DGGS) [1] partitions the Earth areas into geometrical grids. Each grid can be further recursively partitioned into smaller regions which are called *cells*, with progressively finer resolution. For ease of calculation, each region or cell is represented by a point and assigned an identifiable string which we refer to as a *cell code*. Each cell can be associated with data objects (e.g., blocks as in Sec. 2.1) to facilitate geographical search. The recursive partition means that the grid is hierarchical, so are the cell codes. A longer cell code means a more precise geographical location and its prefix represents a broader area around it. Different DGGS systems may have different resolutions based on how and the granularity of the partition.

Widely adopted DGGS techniques include Niemeyer's Geohash [2], Google S2 [3] and Uber H3 [4], to name a few. They all decompose the globe into a hierarchy of regular geometric cells. For example, GeoHash partitions Earth into rectangle cells while Google S2 uses square cells and Uber H3 is based on hexagons. Geohash simply follows the hierarchical partition where the grid is recursively divided into smaller rectangular ones. S2 adopts so-called "roads" (for logical parent-child relationship between nodes) inside a cell such that points geographically close to each other are still close in the database. When a point is accessed via its index, its neighbours can also be accessed. These "roads" are coded in the prefix of a cell code. A similar strategy is adopted by H3. Taking the Statue of Liberty (Fig. 1) for instance, *Geohash* uses cell code "**dr5r7**" for the sub-area (the right sub-figure in Fig. 1) with a precision of $20km^2$. To search the similar area, *S2* uses "**b0fdf9d**", and it is **8a2a10** in *H3*. In Geohash, the cell code of the highest resolution of 6 cm^2 in that area is "**dr5r7***7kkekp*9" with 12 levels (i.e., 12 letters) of precision. While in S2, it is "**b0fdf9d**0806*a*6787" for the highest resolution of $0.74cm^2$ with a maximum of 16 levels. H3 uses "**8a2a10**fffffffff" with a maximum of 15 levels for a precision of $8950cm^2$[1]. In essence, geographic search in DGGS is implemented through prefix search no matter what partitioning and cell coding methods are used.

2.3 Geographic Search Through Prefix Search

Consider an index-key w which is a cell code in a geographical database. Geographical search using another cell code w_p returns a match if and only if $w_p \sqsubseteq w$, i.e., w_p *is the prefix of* w. For example, when a tourist searches "best places to visit in New York", it will return a list of specific places such as "Empire State Building" and "Statue of Liberty". Since the query location "New York" (i.e., w_p) is broader than "Empire State Building" or "Statue of Liberty" (i.e., w that is used as an index-key in the geographical database), the former is a prefix of the latter. Evaluating whether a search query is a prefix of an index-key is straightforward and can be illustrated as follows.

Figure 3: Prefix search for index-key "**dr5r7***7kkekp*9"

Assume an index-key "**dr5r7***7kkekp*9". Checking whether **dr5r7** is its prefix is simply to compare each character from

[1]This precision indicates the average hexagon area of H3 grids.

left to right in the order of **d**, then **r**, ..., and then **7**, one by one, as shown in Fig 3. It shall be noted that in SGS where both search queries and index-keys (which are usually called "keywords") are encrypted, the same prefix search process as in Fig. 3 is performed but over encrypted characters.

3 RELATED WORK

Secure Geographic Search (SGS). The notion of Secure Geographic Search (SGS) was coined in 2014 by Ghinita and Rughinis [18] for searching encrypted geographic data. This work exploits Hidden Vector Encryption (HVE) to hierarchically encode and then encrypt data and queries to vectors, each of which is of high dimension. Thereafter, variant solutions [17, 19–23] have been proposed with improved efficiency. For instance, ref. [19] is constructed on a *domain-based* binary tree, and [20] on a Huffman encoding tree, both for faster retrieving of HVE [24] instances. Ref. [17] leverages Shen-Shi-Waters (SSW) encryption [25] to check and verify inner products over vectors converted from data and queries. However, the intrinsic complexities of HVE and SSW hinder the run-time efficiency despite of the theoretical *faster-than-linear* [17] and *logarithmic* [18–20] retrieve complexities, respectively. For retrieve efficiency, ref. [21] introduces a multi-level index mechanism based on bloom filters. However, this work also inherits the security-efficiency trade-off with bloom filters and offers a weaker security when high efficiency is preferred. Ref. [22] exhibits the similar issue and provides at most an equivalence of 17-bit security though only lightweight primitives such as cryptographic hash functions (based on the structure of [21]) and bloom filters are used. Besides, both [21] and [22] require one extra interaction for a single query. The above solutions consider a single server and follow the *single server-client* framework. Ref. [23] adopts two *non-colluding* servers but overlooks the leakage risk by simply clustering points by distance. Among these solutions, only [21] and [22] consider compatibility with the DGGS technologies. However, none of the existing solutions simultaneously satisfies the requirements of near real-time search latency, data dynamics, and forward/backward privacy.

SSE and Dynamic SSE. The problem of SSE was first formulated by Song et al. [26]. Since then, extensive research has been focused on various aspects including query expressiveness [27, 28], search security with controlled leakage [29] and efficiency optimization [30, 31]. This family of SSE schemes allow leakage that is modeled under the notion of *access pattern* and *search pattern*, where the former reveals the actually retrieved items of a query, and the latter leaks previous queries related to the current one.

Stefanov et al. [32] first elaborated the notion of forward and backward privacy for so-called *dynamic SSE*, i.e., SSE that support data dynamics (i.e., data insertion and deletion). After that, a number of dynamic SSE schemes [10–13] were proposed but only supporting forward privacy, i.e, breaking the link between newly added data and previous queries. Zhang et. al. [33] further demonstrated a successful file-injection attack when forward privacy is not assured. The notion of backward privacy for dynamic SSE was first defined by Bost et al. [12], i.e., limiting what the server can learn between newly deleted data and queries afterwards. It regulates three different levels of leakages in the incremental (inclusive) order, from the least of Type-I to the most of Type-III. All these types allow the leakage of identifiers of documents that match the keyword w that is currently being searched and the time when they were inserted. Under this backward privacy framework, Bost et al. [12] and Ghareh Chamami et al. [14] proposed dynamic SSE constructions with all the three types of backward privacy, respectively. Sun et al. [34] proposed a Type-III backward privacy scheme. Recently, three Type-II schemes were proposed by Demertzis et al. [15, 35] and Sun et al. [36]. In addition, Hoang et al. [37] proposed a dynamic SSE framework particularly towards cloud data storage-as-a-service infrastructures. All these schemes focus on whole keyword search without supporting prefix search.

ORAM-TEE-based SSE. The leakage of *access pattern* has drawn increasing attention as discussed by Garg et. al [38]. Although this issue can be mitigated by Oblivious Random Access Machine (ORAM) [39] and its variants [40–42], deploying ORAM in the network environment, especially for searching data from remote cloud servers, incurs a significant bandwidth cost of at least poly-logarithmic complexity [43, 44]. To address this challenge, Hoang et. al [45] combine ORAM with trusted execution environments (TEEs) to alleviate the bandwidth constraints. This approach leverages the trusted enclaves to store the oblivious structure and secret keys. Consequently, the decryption of the data during searches is executed within the enclave through I/O operations, rather than via communication with clients, reducing the bandwidth overhead by around 100× [45]. Another work [46] that adopts a similar methodology focuses on hiding the leakage caused by dynamic updates through utilizing the trusted components provided by TEE. Despite the great advancements, these works rely on a stronger security assumption on the TEE and only support search on the whole keywords.

Secure Substring Search (Prefix Search). Substring SSE was first studied by Shen et al. [47] in the context of static SSE. This construction is based on a suffix tree in which a large extent of the tree structure will be disclosed. Following this initial attempt, ref. [48] further reduces the storage cost of [47] and enhances its security. Leontiadis et. al. [49] then adopted Order-Preserving Encryption (OPE) for substring search. Subsequently, ref. [50] utilizes the SGX technology for substring search. The security of this approach hinges on the security of trusted hardware. Notably, all these constructions are for static SSE and leaks statistical information, e.g., the relation between suffix and prefix data. To support dynamic SSE, Moataz et. al. [51] utilize structure encryption and inner product predicate for substring search and updates.

While accommodating updates, this method also leaks statistical information, such as the frequency of the same letters. In contrast, without compromising statistical leakage, ref. [16] utilizes a hierarchical ORAM tree structure to support substring search. Also, oblivious suffixes are organized by this structure to simultaneously support data update operations. However, this update introduces additional heavy bandwidth overhead due to the ORAM environment. In addition, Mainardi et al. [52] exclusively supports offline model for secure substring search. Other than these works, to our best knowledge, the research on the problem of secure substring or prefix search for dynamic SSE is very limited.

4 PRELIMINARIES

In this section, we define the basic cryptographic primitives used in this work, including the syntax and security definitions of dynamic prefix symmetric searchable encryption (pSSE) and forward/backward privacy.

4.1 Dynamic pSSE

Different from SSE, dynamic prefix symmetric searchable encryption (pSSE) extends the capabilities of SSE by enabling prefix search, alongside the inherent properties of SSE. Essentially, SSE can be viewed as a special case of pSSE where the prefix is the entire keyword. Similar to dynamic SSE, dynamic pSSE is pSSE that supports data dynamics such as insertion and deletion. A dynamic pSSE scheme $\Sigma = (\mathsf{Setup}, \mathsf{Search}, \mathsf{Update})$ is comprised of one algorithm and two protocols:

$\mathsf{Setup}(1^\lambda) \rightarrow K, \sigma, EDB$: It takes as input the security parameter λ and outputs K, σ and EDB, where K is a secret key, σ is the client's local state, and EDB is the (empty) encrypted database that is to be sent to the server.

$\mathsf{Search}(K, \sigma, q; EDB) \rightarrow DB(w_p)$: It is a protocol for searching the database by the server. It gets inputs (K, σ, q) from a client and EDB (including index) from the server. The server outputs $DB(w_p)$ in the form of a result list I_{w_p}. The result would be empty if $w_p \not\sqsubseteq w$ for any index-key w. In this paper, we only consider search queries for a single prefix w_p of possibly multiple keywords (i.e., index-keys) w.

$\mathsf{Update}(K, \sigma, op, in; EDB) \rightarrow K, \sigma, EDB$: It is a protocol for inserting an entry to or deleting an entry from the database. It takes as inputs EDB from a server and (K, σ, op, in) from a client. Operation op can be *add* or *del* and the input *in* is composed of a block B and its identifier *id*. After the protocol, the input block B is added to or (logically) removed from EDB while its identifier *id* is added to or (logically) removed from its corresponding index. The protocol may modify K, σ and EDB as needed.

Above APIs follow the definition of [12] with some minor modifications. In this paper, we consider a database (SQL or NoSQL) composed of index and data, where the data is in the format of *blocks*. As discussed in Section 2.1, a block is either a record in SQL database or a JSON document in NoSQL database. In this work, EDB consists of two encrypted pools - the encrypted indexes and the encrypted blocks. We implicitly assume that after receiving the result identifiers $DB(w_p)$, the client performs an additional round to retrieve the actual blocks. For brevity, we omit this step in our construction.

CORRECTNESS: A dynamic pSSE scheme $\Sigma = (\mathsf{Setup}, \mathsf{Search}, \mathsf{Update})$ is correct if it always returns the correct results, i.e., indices, for each query. The definition aligns with the formal correctness definition of SSE in [29, 53].

SECURITY: The security of pSSE is captured by using a real-world versus ideal-world experimentation [29, 32, 53]. An intuition is that an adversary can not distinguish between the experiments REAL and IDEAL. The security model is parameterized by a leakage function $\mathcal{L} = \{\mathcal{L}^{Stp}, \mathcal{L}^{Srch}, \mathcal{L}^{Upt}\}$ which captures the information learned by an adversarial server. $\mathcal{L}^{Stp}, \mathcal{L}^{Srch}$ and $\mathcal{L}^{Upt}$ correspond to leakage during setup, search and updates in respective. Informally, a secure pSSE scheme with leakage $\mathcal{L}$ should reveal nothing about the database DB except for this explicit leakage.

***Definition* 4.1** (*Adaptive Security of Dynamic pSSE*)**.** A dynamic pSSE scheme Σ is $\mathcal{L}$-adaptively secure (with respect to leakage function $\mathcal{L}$) *iff* for all PPT adversary $\mathcal{A}$ that makes polynomial number of queries q, there exists a stateful PPT simulator Sim such that

$$|Pr[\mathrm{REAL}^{\Sigma}_{\mathcal{A}}(\lambda, q) = 1] - Pr[\mathrm{IDEAL}^{\Sigma}_{\mathcal{A},\mathsf{Sim}}(\lambda, q) = 1]| \leq \mathrm{negl}(\lambda), \quad (1)$$

where $\mathrm{REAL}^{\Sigma}_{\mathcal{A}}(\lambda, q)$ and $\mathrm{IDEAL}^{\Sigma}_{\mathcal{A},\mathsf{Sim}}(\lambda, q)$ are defined as follows:

- $\mathrm{REAL}^{\Sigma}_{\mathcal{A}}(\lambda, q)$: The adversary $\mathcal{A}$ initially chooses a database DB and gets back EDB by calling $\mathsf{Setup}(1^\lambda)$. Then $\mathcal{A}$ is allowed to adaptively perform search (resp. update) queries with input q (resp. input (op, in))) and receives transcript generated by calling $\mathsf{Search}(K, \sigma, q; EDB)$ (resp. $\mathsf{Update}(K, \sigma, op, in; EDB)$). Given these real transcripts, the adversary $\mathcal{A}$ finally outputs a bit b.

- $\mathrm{IDEAL}^{\Sigma}_{\mathcal{A},\mathsf{Sim}}(\lambda, q)$: The adversary $\mathcal{A}$ initially selects a database DB and gets back EDB generated by the simulator $\mathcal{S}(\mathcal{L}^{Stp}(DB))$. Then $\mathcal{A}$ is allowed to adaptively perform search (resp. update) queries with input q (resp. input (op, in))) and receives transcript generated by running $\mathcal{S}(\mathcal{L}^{Srch}(K, \sigma, q; EDB))$ (resp. $\mathcal{S}(\mathcal{L}^{Upt}(K, \sigma, op, in; EDB))$). Given these simulated transcripts, the adversary $\mathcal{A}$ finally outputs a bit b.

4.2 Forward and Backward Privacy of pSSE

Forward and backward privacy are two important properties of dynamic SSE that restrict what information is leaked

by the Update query, so are they in dynamic pSSE. The definition of forward and backward privacy of SSE was first proposed in [32] and then formulated by Bost et al. [11, 12]. In their works, the definition only considers queries on keyword/document pairs, i.e., searching to find out whether a keyword belongs to a certain document. In this paper, we first formulate the definition of *forward and backward privacy* for a SQL (or NoSQL) database structures of index and data. A search is to find out the blocks that are related to an index-key w which is subject to a certain attribute. In brief, forward privacy ensures previous search queries do not reveal any information about the retrieved blocks to be updated. It hides whether an addition is about a new block or one that has been previously searched for. Backward privacy limits the information that the server can learn about blocks that are added previously but deleted later during searches related to them. It guarantees that the adversary cannot obtain extra information about the deleted blocks. For space limit, we include the full definitions of forward/backward privacy for keyword/block pairs in Appendix A, following similar definitions in [12].

4.3 Pseudorandom Function

Let $G : \mathcal{K} \times \mathcal{X} \to \mathcal{Y}$ be a function defined from $\mathcal{X}$ to $\mathcal{Y}$. G is a secure pseudorandom function (PRF) if for all PPT adversaries $\mathcal{A}$, its maximum advantage as $Adv^{PRF}_{\mathcal{A},G}(\lambda) = |Pr[\mathcal{A}^{G(k,\cdot)}(1^\lambda) = 1] - Pr[\mathcal{A}^{F(\cdot)}(1^\lambda) = 1]|$ is negligible in λ, where F is a random function from $\mathcal{X}$ to $\mathcal{Y}$, and $k \xleftarrow{\$} \mathcal{K}$.

5 SYMMETRIC PREFIX PREDICATE ENCRYPTION

In this section, we present a novel cryptographic primitive, *symmetric prefix predicate encryption* (SP^{2}E). We begin with the building block *f-bit bounded symmetric encryption* (SE-f) followed by the syntax, security, and concrete construction of SP^{2}E.

5.1 f-bit Bounded Symmetric Encryption

Let λ be a security parameter and G denote a pseudorandom function with an output length $l(\lambda)$. An f-bit bounded symmetric encryption scheme SE-f with message space $\mathcal{M}$ can be described as a 3-tuple $(\mathsf{SE}\text{-}f.\mathsf{Gen}, \mathsf{SE}\text{-}f.\mathsf{Enc}, \mathsf{SE}\text{-}f.\mathsf{Dec})$. While the proposed scheme is derived from standard symmetric encryption (SE), the difference is in SE-f, only a f-bit interval is decrypted instead of the whole message. We formalize the definition of SE-f as follows:

SE-f.Gen$(1^\lambda) \to k_1, k_2$: On input a security parameter λ, it outputs two random secret keys k_1, k_2 uniformly sampled from key space $\mathcal{K}$.

$\underline{\mathbf{Expt}^{\text{IND-CPA}}_{\mathcal{A},\text{SE-}f}(\lambda):}$
$b \xleftarrow{\$} \{0,1\}; k \xleftarrow{\$} \mathcal{K}$
$(\mathbf{m}_0, \mathbf{m}_1, st) \leftarrow \mathcal{A}'^{O^{\mathsf{Enc}}_k(\cdot)}(1^\lambda)$ *s.t.* $|\mathbf{m}_0| = |\mathbf{m}_1|$
$ct^* \leftarrow \mathsf{SE}\text{-}f.\mathsf{Enc}(k, \mathbf{m}_b)$
$b' \leftarrow \mathcal{A}^{O^{\mathsf{Enc}}_k(\cdot)}(st, ct^*)$
Return $(b' = b)$.

$\underline{O^{\mathsf{Enc}}_k(\mathbf{m}):}$
$ct \leftarrow \mathsf{SE}\text{-}f.\mathsf{Enc}(k, \mathbf{m})$
Return ct.

Figure 4: IND-CPA security of SE-f

SE-f.Enc$(k_1, \mathbf{m}) \to ct$: On input a secret key k_1 and message $\mathbf{m} \in \mathcal{M}$, it computes and outputs ciphertext ct as:

$$ct = G(k_1, \mathbf{m}) \oplus \mathbf{m}. \tag{2}$$

where $G(k_1, \mathbf{m})$ is a PRF output that XOR the message $\mathbf{m}$. Note that $|\mathbf{m}| = |G(k_1, \mathbf{m})|$, $ct \in \{0,1\}^{l(\lambda)}$.

SE-f.Dec$(k_1, k_2, ct) \to \mathbf{m}'$: On input k_1, k_2 and ct, it decrypts some chosen consecutive f bits among a length $l(\lambda)$ of the message $\mathbf{m}$ with the bit position starting from pos_1 to pos_2, where $0 \le pos_1 < pos_2 < l(\lambda)$, $pos_2 - pos_1 = f$. The algorithm computes and outputs $\mathbf{m}'$ as:

$$\begin{aligned}\mathbf{m}' = ct \oplus \\ (G(k_2, \mathbf{m}).\mathsf{sub}(0, pos_1) \parallel G(k_1, \mathbf{m}).\mathsf{sub}(pos_1, pos_2) \parallel \\ (G(k_2, \mathbf{m}).\mathsf{sub}(pos_2, l(\lambda))\end{aligned} \tag{3}$$

where the method $ct.\mathsf{sub}(\mathsf{StartInx}, \mathsf{EndInx})$ extracts the bits from the StartInx-th position to the EndInx-th position in a "left-closure right-open" manner, e.g. for $ct = 100100$, $x.\mathsf{sub}(2,4) = 01$.

CORRECTNESS:

$$\begin{aligned}&\mathbf{m}'.\mathsf{sub}(pos_1, pos_2) \\ &= \mathsf{SE}\text{-}f.\mathsf{Dec}(k_1, k_2, \mathsf{SE}\text{-}f.\mathsf{Enc}(k_1, \mathbf{m})).\mathsf{sub}(pos_1, pos_2) \\ &= (ct \oplus G(k_1, \mathbf{m})).\mathsf{sub}(pos_1, pos_2) \\ &= (G(k_1, \mathbf{m}) \oplus \mathbf{m} \oplus G(k_1, \mathbf{m})).\mathsf{sub}(pos_1, pos_2) \\ &= m.\mathsf{sub}(pos_1, pos_2).\end{aligned} \tag{4}$$

SECURITY: The security of SE-f is defined by an IND-CPA experiment presented in Fig. 4. The security definition of SE-f is similar to the standard indistinguishability definition of symmetric encryption (SE) except for decryption, where a segment of the message is decrypted in SE-f rather than a complete message.

***Definition* 5.1** (*Semantic Security of SE-f*)**.** A symmetric encryption scheme $\mathsf{SE}\text{-}f = (\mathsf{SE}\text{-}f.\mathsf{Gen}, \mathsf{SE}\text{-}f.\mathsf{Enc}, \mathsf{SE}\text{-}f.\mathsf{Dec})$ is IND-CPA secure if for any security parameter $\lambda \in \mathbb{N}$ and PPT (probabilistic polynomial time) adversary $\mathcal{A}$, the advantage of $\mathcal{A}$ is negligible in λ. That is,

$$Adv^{\text{IND-CPA}}_{\mathcal{A},\text{SE-}f}(\lambda) = \left| Pr[\mathbf{Expt}^{\text{IND-CPA}}_{\mathcal{A},\text{SE-}f}(\lambda) = 1] - \frac{1}{2} \right| \le negl(\lambda). \tag{5}$$

5.2 Syntax and Security of SP^{2}E

A symmetric prefix predicate encryption scheme SP^{2}E is defined over a keyword space Λ^t where each character of a keyword belongs to the alphabet Λ, and t is the maximum length of a keyword. SP^{2}E consists of a quintuple of PPT algorithms $(\mathsf{KeyGen}, \mathsf{PreEnc}, \mathsf{Enc}, \mathsf{TKGen}, \mathsf{PrefDec})$. The preliminary encryption algorithm PreEnc encodes the keyword as a fixed-length hash value which serves as a message, an input of the encryption algorithm Enc, to compute the ciphertext ct. The algorithm TKGen outputs a token, namely the encrypted prefix. The prefix decryption algorithm PrefDec identifies if the ciphertext ct contains a specific prefix without revealing the keyword nor message. The definition is formalized as follows:

$\mathsf{KeyGen}(1^\lambda, t) \to SK, MSK$: On input a security parameter λ and a maximum length t of a keyword, it generates a secret key SK for encryption and a master secret key MSK that is used as seed.

$\mathsf{PreEnc}(MSK, seq, w) \to \mathbf{m}$: On input MSK, a string keyword w and a number seq that indicates an identical sequence of w among keywords, the algorithm outputs a fixed-length hash value $\mathbf{m}$.

$\mathsf{Enc}(SK, \mathbf{m}) \to ct, \delta$: On input SK and $\mathbf{m}$, the algorithm outputs a ciphertext ct and a local parameter δ that is stored in the local state.

$\mathsf{TKGen}(SK, MSK, \delta, seq, w_p) \to k'$: On input secret keys SK, MSK, a local parameter δ, a number seq and a prefix w_p, it outputs a token k'.

$\mathsf{PrefDec}(k', ct) \to \perp$ or $w_p \sqsubseteq w$: On input a token k' and ciphertext ct, it outputs $\perp$ or $w_p \sqsubseteq w$.

CORRECTNESS: For security parameter λ, integer $t \in \mathbb{N}^*$, $(SK, MSK) \leftarrow \mathsf{KeyGen}(1^\lambda, t)$ and a keyword $w \in \Lambda^t$, SP^2E is correct if

$$Pr\begin{bmatrix} \mathsf{PrefDec}(k', ct) & ct, \delta \leftarrow \mathsf{Enc}(SK, \mathsf{PreEnc}(MSK, seq, w)) \\ = & : \\ w_p \sqsubseteq w & k' \leftarrow \mathsf{TKGen}(SK, MSK, \delta, seq, w_p), \\ & w_p \sqsubseteq w \end{bmatrix} = 1. \tag{6}$$

SECURITY: The security of SP^{2}E is defined by two experiments, an IND-CPA experiment $\mathbf{Expt}^{\text{IND-CPA}}_{\mathcal{A},\text{SP}^2\text{E.Enc}}(\lambda)$ for encryption and an IND-f-CPA experiment $\mathbf{Expt}^{\text{IND-}f\text{-CPA}}_{\mathcal{A},\text{SP}^2\text{E.TKGen}}(\lambda)$ for token generation. The security definition of IND-f-CPA is similar to the standard IND-CPA indistinguishability definition except for the specific f bits. Concretely speaking, a PPT adversary has the ability to access and query both oracles $O^{\mathsf{Enc}}_{SK}(w)$ and $O^{\mathsf{TKGen}}_{SK,MSK,\delta}(w_p)$ with unlimited times after the adversary submits an input w (or w_p). The details of experiments are presented in Fig. 10 in Appendix B. The formal definition of encryption and token security of SP^{2}E is presented below.

***Definition* 5.2** (*Encryption Security of SP^{2}E*)**.** A symmetric prefix predicate encryption scheme SP^{2}E is IND-CPA encryption secure, if for all PPT adversary $\mathcal{A}$, the advantage pf $\mathcal{A}$ is negligible in λ. That is:

$$Adv^{\text{IND-CPA}}_{\mathcal{A},\text{SP}^2\text{E.Enc}}(\lambda) = \left| Pr[\mathbf{Expt}^{\text{IND-CPA}}_{\mathcal{A},\text{SP}^2\text{E.Enc}}(\lambda) = 1] - \frac{1}{2} \right| \leq negl(\lambda). \tag{7}$$

***Definition* 5.3** (*Token Security of SP^{2}E*)**.** A symmetric prefix predicate encryption scheme SP^{2}E is IND-f-CPA token secure, if for all PPT adversary $\mathcal{A}$, the advantage pf $\mathcal{A}$ is negligible in λ. That is:

$$Adv^{\text{IND-}f\text{-CPA}}_{\mathcal{A},\text{SP}^2\text{E.TKGen}}(\lambda) = \left| Pr[\mathbf{Expt}^{\text{IND-}f\text{-CPA}}_{\mathcal{A},\text{SP}^2\text{E.TKGen}}(\lambda) = 1] - \frac{1}{2} \right| \leq negl(\lambda). \tag{8}$$

According to the encryption and token security defined in Def. 5.2& 5.3, we further define the *adaptive security* for SP^{2}E as follows:

ADAPTIVE SECURITY: We define the adaptive security for SP^{2}E scheme since a PPT adversary $\mathcal{A}$ is allowed to submit the chosen challenged keyword strings w_0, w_1 (or prefixes w_{p_0}, w_{p_1}) adaptively at any point in time while the security is guaranteed.

***Definition* 5.4** (*Adaptive Security of SP^{2}E*)**.** A symmetric prefix predicate encryption scheme SP^{2}E is IND-f-CPA secure, if for all PPT adversary $\mathcal{A}$, it has at a most negligible advantage

$$\begin{aligned} Adv^{\text{IND-}f\text{-CPA}}_{\mathcal{A},\text{SP}^2\text{E}}(\lambda) = \mathsf{MAX}\Big(& |Pr[\mathbf{Expt}^{\text{IND-CPA}}_{\mathcal{A},\text{SP}^2\text{E.Enc}}(\lambda) = 1] - \frac{1}{2}|, \\ & |Pr[\mathbf{Expt}^{\text{IND-}f\text{-CPA}}_{\mathcal{A},\text{SP}^2\text{E.TKGen}}(\lambda) = 1] - \frac{1}{2}| \Big) \\ \leq negl(\lambda). & \end{aligned} \tag{9}$$

5.3 Bit-wise Prefix Recognition SP^{2}E from PRF

In this part, we present the details of SP^{2}E based on a pseudorandom function (PRF) $G : \mathcal{K} \times \mathcal{X} \to \mathcal{Y}$, a cryptographic hash function $H : \mathcal{K} \times \mathbb{N}^* \to \mathcal{K}$ and an f-bit bounded symmetric encryption scheme $\mathsf{SE}\text{-}f = (\mathsf{SE}\text{-}f.\mathsf{Gen}, \mathsf{SE}\text{-}f.\mathsf{Enc}, \mathsf{SE}\text{-}f.\mathsf{Dec})$. Specifically, the proposed scheme $\mathsf{SP^2E} = (\mathsf{KeyGen}, \mathsf{PreEnc}, \mathsf{Enc}, \mathsf{TKGen}, \mathsf{PrefDec})$ is constructed as follows:

$\mathsf{KeyGen}(1^\lambda, t) \to SK, MSK$: On input a security parameter λ and a parameter t that denotes the maximum length of a keyword, it uniformly samples secret keys $sk_1, sk_2, sk_{c_1}, ..., sk_{c_{|\Lambda|}}$ at random from the key space $\mathcal{K}$. Each secret key sk_{c_i} uniquely associates with a character c_i in the textual alphabet Λ, for $1 \leq i \leq |\Lambda|$, and $|\Lambda|$ is the total number of distinct characters. A keyword is a string and all of its characters are from Λ. This algorithm specifies a parameter f for indicating the number of "certain bits" that are indicators of a queried result. f is subject

to $0 < f \leq \left\lfloor \frac{l(\lambda)}{t-1} \right\rfloor$. For simplicity, we denote the outputs with $SK = \{sk_1, sk_2\}$, $MSK = \{sk_{c_1}, ..., sk_{c_{|\Lambda|}}, f\}$.

$\mathsf{PreEnc}(MSK, seq, w) \rightarrow \mathbf{m}$: It takes as input MSK, a keyword w and a number seq that is the sequence of this w among (distinct) keywords. It outputs the fixed-length hash value $\mathbf{m}$ computed by following steps:

(1) Compute the length of a keyword w, $|w|$, i.e., the total number of its characters.

(2) Pick up the associated key sk_{w_i} from MSK for each character of w in sequence. For example, if the i-th character is a textual letter $'a'$, then its associated key is $sk_{'a'}$, namely sk_{w_i} refers to $sk_{'a'}$ in this case.

(3) Output $\mathbf{m}$ as

$$\mathbf{m} = \bigoplus_{i=1}^{|w|} \left(0^{(i-1)f} \parallel H(sk_{w_i} \parallel seq \parallel i)\right).\mathsf{sub}(0, l(\lambda)). \quad (10)$$

$\mathsf{Enc}(SK, \mathbf{m}) \rightarrow ct, \delta$: On input SK and $\mathbf{m}$, by using the secret key sk_1 in SK, it computes the ciphertext as

$$ct = \mathsf{SE}\text{-}f.\mathsf{Enc}(sk_1, \mathbf{m}) = \mathbf{m} \oplus G(sk_1, \mathbf{m}), \quad (11)$$

When the encryption is invoked, $\delta = G(sk_1, \mathbf{m})$ must be recorded in the local state. Note that δ is not public. Instead, it is secretly held by the entity executing this algorithm, usually the client.

$\mathsf{TKGen}(SK, MSK, \delta, seq, w_p) \rightarrow k'$: On input SK, MSK, a local parameter δ, an identifier seq and a queried prefix w_p, it outputs a token k' that will be used to evaluate if the message of a ciphertext ct contains prefix w_p. With both secret keys sk_1 and sk_2 in SK, the algorithm computes k' as:

(1) Calculate the length of the prefix w_p, $|w_p|$.

(2) Pick up the associated key $sk_{w_{p_i}}$ from MSK in sequence for each character of w_p.

(3) Set $pos_1 = (|w_p| - 1) \cdot f$, $pos_2 = |w_p| \cdot f$, and we have $pos_2 - pos_1 = f$. The parameters pos_1 and pos_2 are the respective start and end bit-position of an f-bit segment.

(4) Output k' as

$$\begin{aligned} k' = \bigoplus_{i=1}^{|w_p|} &\left(0^{(i-1)f} \parallel H(sk_{w_{p_i}} \parallel seq \parallel i)\right).\mathsf{sub}(0, l(\lambda)) \\ &\oplus \big(G(sk_2, seq).\mathsf{sub}(0, pos_1) \parallel \delta.\mathsf{sub}(pos_1, pos_2) \parallel \\ &\quad G(sk_2, seq).\mathsf{sub}(pos_2, l(\lambda))\big). \end{aligned} \quad (12)$$

$\mathsf{PrefDec}(k', ct) \rightarrow \perp$ or $w_p \sqsubseteq w$ [2]: On input a token k' and a ciphertext ct, it calculates that

$$r' = k' \oplus ct, \text{ and } 0^f \stackrel{?}{=} r'.\mathsf{sub}(pos_1, pos_2) \quad (13)$$

The algorithm evaluates whether there are consecutive f bits valued with zero located in the segment $[pos_1, pos_2)$ of the result r'. We denote these f bits with 0^f. In brief, 0^f is an indicator for a keyword. By verifying $0^f \stackrel{?}{=} r'.\mathsf{sub}(pos_1, pos_2)$, the algorithm PrefDec can identify whether the the message m contains the prefix w_p. The algorithm outputs $\perp$ if w_p is not a prefix of m. Otherwise, it outputs $w_p \sqsubseteq w$.

CORRECTNESS: The correctness of SP^{2}E is derived from that of PRF G and the symmetric encryption SE-f. That is

$$\text{“}w_p \sqsubseteq w : w_p \textit{ is a prefix of } w\text{” or}$$
$$\text{“}w_p \not\sqsubseteq w : w_p \textit{ is not a prefix of } w\text{”}.$$

In the first case, the bits valued with zero (i.e., 0^f) in the output of SP^{2}E decryption should be revealed such that a keyword w having the queried prefix w_p can be identified correctly. To validate this, we expand the output of PrefDec, namely $k' \oplus ct$. As shown in Fig. 11, If w_p is a prefix of the keyword, the f bits between pos_1 and pos_2 should all be zero. As for the latter case of $w_p \not\sqsubseteq w$, the output of SP^{2}E decryption should be a completely indistinguishable value without any consecutive bits valued at zero visible. We validate this with more details and examples in Fig. 12 in Appendix D.

EXAMPLE ILLUSTRATION: We illustrate each algorithm of SP^{2}E with the example of the Statue of Liberty. Consider a DGGS code $w =$ “**dr5r77**” and a queried prefix $w_p =$ “**dr5r7**”. With all the required parameters of KeyGen, PreEnc computes the fixed-length hash value $\mathbf{m}$ according to the inputs – a keyword w and its sequence seq. A fixed-length string is obtained by XORing several hash substrings that correspond to the characters of w (i.e., “$dr5r77$"), as depicted by a grey rectangular box in Fig. 5 (a). The encryption algorithm Enc generates the ciphertext ct by XORing $\mathbf{m}$ with a mask δ which is generated uniformly at random and stored locally, as shown in Fig. 5 (b).

TKGen outputs an encrypted search token k' for the query prefix w_p (i.e., “$dr5r7$"). As shown in Fig. 5 (c), k' is computed by XORing the hash substrings with a pseudorandom string which is the concatenation of pseudo-random value η and a local secret δ. The hash substrings are associated sequentially with the characters of w_p. If SHA-256 is chosen for producing the hash substrings, for example, the output length $l(\lambda) = 256$.

With the input token k' and a ciphertext ct, the prefix decryption algorithm PrefDec examines whether the f bits in the output (i.e., $k' \oplus ct$) at positions $[pos_1, pos_2)$ are all zeros. All zeros mean a keyword w matches a given prefix w_p. As shown in Fig. 5 (d), bits $[4f, 5f)$ of $k' \oplus ct$ are all zeros, which occurs due to the two same values $\delta.\mathsf{sub}(pos_1, pos_2)$[3] presented in k' and ct, respectively.

[2] This decryption here is logically equivalent to the decryption SE-f.Dec $(sk_1, sk_2, ct) \rightarrow \mathbf{m}$ in Sec. 5.1. The message carried by a token k' corresponds to the mentioned $\mathbf{m}$, that is $\bigoplus_{i=1}^{|w_p|} \left(0^{(i-1)f} \parallel H(sk_{w_{p_i}} \parallel seq \parallel i)\right).\mathsf{sub}(0, l(\lambda))$.

[3] In Fig. 5 (c)-(d) we omit “sub” for simplicity, i.e., $\delta(pos_1, pos_2) = \delta.\mathsf{sub}(pos_1, pos_2), \eta(0, pos_1) = \eta.\mathsf{sub}(0, pos_1)$, etc.

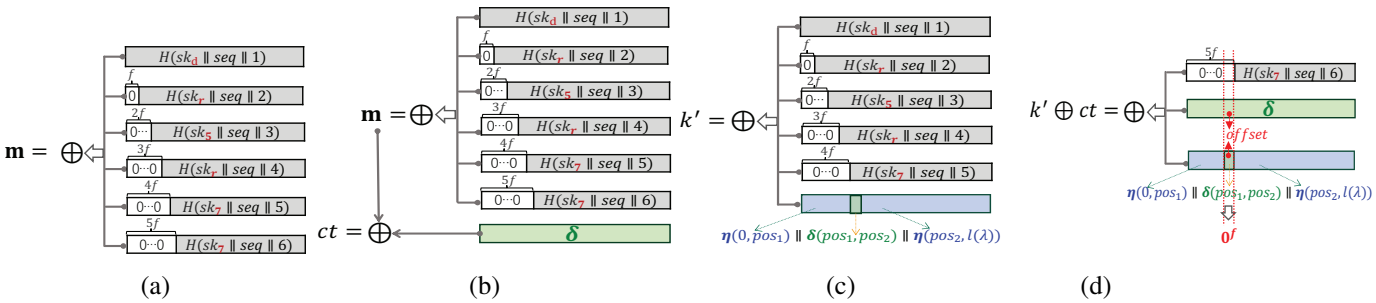

Figure 5: (a) $\mathbf{m} \leftarrow \mathsf{PreEnc}(MSK, seq, w)$ for $w =$ "**dr5r77**". (b) $(ct, \delta) \leftarrow \mathsf{Enc}(SK, \mathbf{m})$, where $\delta = G(sk_1, seq)$. (c) $k' \leftarrow \mathsf{TKGen}(SK, MSK, \delta, seq, w_p)$ for $w_p =$ "**dr5r7**", where $\eta = G(sk_2, seq)$. (d) The PrefDec evaluation on ct for this w and w_p.

5.4 Security Analysis

In this part, we show the proposed SP^{2}E of being proven IND-f-CPA secure in the random oracle model, under the security of cryptographic hash function G, PRF F and f-bit bounded symmetric encryption SE-f.

***Theorem* 5.5** (ADAPTIVE SECURITY). *If $G : \mathcal{K} \times \mathcal{X} \rightarrow \mathcal{Y}$ is a secure PRF, H is a secure cryptographic hash function, H is modeled with a random oracle, and SE-f is an IND-CPA secure symmetric encryption, then the proposed SP^{2}E is IND-f-CPA secure in the random oracle model.*

PROOF SKETCH: We prove the security of our SP^{2}E scheme through two parts, encryption security defined in Def. 5.2 and token security defined in Def. 5.3, for which we give concrete proofs in respective via a series of games. Based on both encryption and token security, the adaptive security of SP^{2}E in Def. 5.4 holds. To complete the proof, we consider a sequence of hybrid games that differ from each other in the *challenge pre-encryption ciphertext* and *challenge token*. The first game in the sequence corresponds to the real IND-f-CPA game for SP^{2}E while the last hybrid one is the standard IND-CPA game for the f-bit bounded symmetric encryption SE-f. The overall advantage of $\mathcal{A}$ changes only by a negligible amount between each successive hybrid game, and is bounded by the advantage gained in IND-f-CPA game for token generation, which is negligible, thereby establishing Thm 5.5. Due to the limited space, the complete proof is provided in the extended version of this paper, which will be available on Arxiv.

6 GridSE: Dynamic pSSE for Secure Geographic Search from SP^{2}E

In this section, we present GridSE, a dynamic prefix symmetric searchable encryption (pSSE) based on symmetric prefix predicate encryption (SP^{2}E) for secure geographic search.

6.1 Construction Details

GridSE follows the standard APIs of a standard dynamic pSSE scheme as discussed in Sec 4.1. By adapting the definitions to a generic SQL or NoSQL database, we implement a practical dynamic pSSE system for fast secure geographic search over DGGS cells. Recall that the database is typically organized by blocks, i.e., files/records. To support forward and backward privacy, GridSE encrypts triplets of (w, id, op) into two ciphertext components which are organized as key-value pairs in a dictionary. The key stored in the dictionary is the ciphertext of *index-key* w, namely the address which indicates whether w is queried by a specific prefix during searches. The value in the dictionary is a list associated with w, consisting of one or multiple encrypted blocks (id, op). The encryption of (id, op) is based on a mask generated by PRF and encapsulates an update counter $updt_{cnt}$ that stores the update times occurred on blocks under index-key w as widely adopted for dynamic SSE. Note that data operations are indicated using $op = add/del$, and any deletion operation is logically recorded instead of executing a physical deletion action.

However, a ciphertext of (id, op) generated only based on $updt_{cnt}$ is not enough to achieve forward and backward privacy for dynamic pSSE. The blocks (i.e., (id, op)) associated with different index-keys but with the same $updt_{cnt}$ will produce the same masks. To solve this issue, we introduce an additional parameter, the sequence of index-keys *seq* that helps to "tag" those blocks. In this way, each block is encrypted based on a unique mask and every update operation accessing the encrypted blocks in GridSE appears randomly to the server. Hence, the server cannot distinguish between insertion and deletion, which achieves backward privacy. Since each block is a separate triplet, the server cannot distinguish a new keyword in a newly added block from a keyword contained in the previously searched block, which achieves forward privacy. To complete a search, after receiving the index-keys for a prefix, the client can generate all masks for correctly decrypting each block. Notice that each index-key encrypted by SP^{2}E corresponds to a DGGS cell code and can iden-

tify the queried cells for the given prefix by the function $\mathsf{SP^2E.PrefDec}$. GridSE hence enables efficient search while supporting forward and backward privacy. Detailed construction of GridSE is as follows:

$\mathsf{Setup}(1^\lambda) \rightarrow K_\Sigma, \sigma, EDB$: On input a security parameter λ, the client generates a local state σ and an empty encrypted database EDB. It obtains secret keys from sampling $K \xleftarrow{\$} \{0,1\}^\lambda$ and secret keys SK, MSK by invoking the Setup algorithm of $\mathsf{SP^2E}$. Next, the client initiates an empty list $\hat{\delta}$ and two maps $(\textbf{InxDict}, \textbf{UpdtCnt})$. $\hat{\delta}$ and **UpdtCnt** are locally maintained while **InxDict** is sent to server. At last, client outputs $K_\Sigma = (K, SK, MSK), \sigma = \{\textbf{UpdtCnt}, \hat{\delta}\}$ and EDB.

$\mathsf{Update}(K_\Sigma, \sigma, op = add/del, in = (w, id); EDB) \rightarrow K_\Sigma, \sigma, EDB$: In the update procedure, the client receives an index-key w, an identifier id and operation $op = add/del$. An input (add, w, id) means *"add a block id in EDB and an entry in **InxDict** for this block that has an index-key w"*. The client has access to the keys K_Σ, the local state **UpdtCnt** and $\hat{\delta}$, where $\hat{\delta}$ keeps the parameter δ that is produced once invoking $\mathsf{SP^2E.Enc}$, and **UpdtCnt** stores for each distinct index-key w a counter that denotes how many updates have taken place on blocks in relation to w. First, the client checks whether **UpdtCnt**$[w]$ has been initialized or not. If not, he sets the counter value of w to 0 (lines 1-4). Here, **UpdtCnt** is the size of current sequence of index-keys which indicates how many index-keys are currently in the dictionary. It increases by 1 once a new distinct index-key is produced with updates. Next, the client produces a key-value pair $(addr, \delta)$ using the algorithm $\mathsf{SP^2E.Enc}$ by encrypting a given index-key and its current sequence. δ is kept local. Notice that if a new but repeated index-key w is associated with an update after it has been counted in **UpdtCnt**, the newly produced address $addr$ associated with this w will be the same as the previous one due to the same sequence and keys as the input (lines 5-7). The client then runs the PRF G with key K and computes $G(K, (seq, \textbf{UpdtCnt}[w]))$ that is XORed with the message $(id \parallel op)$, and this result becomes an encrypted value val (line 8). The pair $(addr, val)$ is sent to the server which stores them by appending val into **InxDict**$[addr]$ or a newly produced **InxDict**$[addr]$ (lines 9-13).

$\mathsf{Search}(K_\Sigma, \sigma, w_p; EDB) \rightarrow \mathrm{I_{w_p}}$: While searching for the index-keys with a certain prefix w_p, the client first generates a list of tokens $TList$. This token generation is submitted to the respective $\mathsf{SP^2E}$ layer, namely $\mathsf{SP^2E.TKGen}$. $TList$ is then sent to the server (lines 1-6). Recall that the corresponding entries to this token are stored in **InxDict** on the server, which enables the server to evaluate these entries with the $\mathsf{SP^2E}$ function $\mathsf{SP^2E.PrefDec}$. If $\mathsf{SP^2E.PrefDec}$ indicates *"w_p is a prefix for the current index-key w"*, the server obtains the associated key-value pairs of w from the index and puts the value and its sequence into R_{w_p}. Specifically, The server retrieves the key-value pairs matching the token $TList$ in **InxDict** and then sends them back to the client (lines 7-17). Then, the client decrypts the returned result R_{w_p} which are composed of pseudorandom values. These values generated via PRF G during the previous updates for w are recovered to the original plaintext since G is a deterministic function. Concretely, the client decrypts the received dictionary R_{w_p} by calculating the PRF values $G(K, (seq, i))$ and XORing them with each element of $valList$ in sequence for $i = 1, ..valList.size$, where seq is the sequence of the key-value pair in which the current $valList$ locates in **InxDict** (lines 18-25). In the end, the client returns a search result I_{w_p} containing all requested block identifiers which correspond to the index-keys of a prefix w_p.

Algorithm 1: GridSE Σ : $\mathsf{Setup}(1^\lambda, DB)$

1: $(EDB, \sigma) \leftarrow \Sigma.\mathsf{Setup}(1^\lambda)$
2: $K \xleftarrow{\$} \{0,1\}^\lambda$, $SK, MSK \leftarrow \mathsf{SP^2E.Setup}(1^\lambda)$
3: $\hat{\delta} \leftarrow$ empty list
4: **UpdtCnt**, **InxDict** $\leftarrow$ empty linked map
5: $\sigma \leftarrow$ **UpdtCnt**, $\hat{\delta}$
6: Return $(K, SK, MSK), (\textbf{UpdtCnt}, \hat{\delta}), EDB$

Algorithm 2: GridSE Σ : Update
$(K_\Sigma, \sigma, op = add/del, in = (w, id); EDB)$

Client:
1: **if** **UpdtCnt**$[w]$ is NULL **then**
2: **UpdtCnt**$[w] = 0$
3: **end if**
4: **UpdtCnt**$[w]$++
5: $seq =$ **UpdtCnt**.getMapSize()
6: $addr, \delta = \mathsf{SP^2E.Enc}(SK, \mathsf{SP^2E.PreEnc}(MSK, seq, w))$
7: $\sigma \leftarrow \delta$
8: $val = (id \parallel op) \oplus G(K, (seq, \textbf{UpdtCnt}[w]))$
9: Returns $(addr, val)$

Server:
10: **if** **InxDict**.containsKey$(addr)$ **then**
11: Set **InxDict**$[addr] \cup val$
12: **else**
Set **InxDict**$[addr] = val$
13: **end if**

***Theorem* 6.1.** *Assuming F is a secure PRF and SP^2E is IND-f-CPA secure, GridSE is an adaptively-secure dynamic pSSE scheme of forward and Type-II backward privacy with $\mathcal{L}^{Updt}(op, w, id) = \perp$ and $\mathcal{L}^{Srch}(w_p) = (\mathsf{TimeDB}(w_p), \mathsf{Update}(w_p))$.*

PROOF SKETCH: We prove the adaptive security of GridSE by constructing a sequence of games and show that the advantage of a PPT adversary against our protocol is negligible. Intuitively, the transcript $(addr, val)$ sent to the server is indistinguishable from uniformly random samples, which is guaranteed by the construction. Notice that the value val is computed by XORing the block/operation tuple $(id||op)$ with $G(K, (seq, \textbf{UpdtCnt}[w]))$ generated by a pseudorandom function G. In this way, the server cannot distinguish whether an

25: **end while**

update is insertion or deletion, which means that the update leakage is thwarted. Regarding backward privacy, notice that when performing a search on prefix w_p, the server can retrieve the corresponding entries in **InxDict** with their sequences. Since these entries are encrypted by $\mathsf{SP^2E}$ and an additional pseudorandom function, the server can learn nothing except the time when each update operation takes place for w_p. This means GridSE provides Type-II backward privacy as defined in Def. A. The complete proof is omitted in this paper and will be available in the extended version in Arxiv.

Remark for Efficiency. We first introduce the notations for analyzing complexity. d_w denotes the number of updates on the distinct index-keys in **InxDict**. a_{w_p} represents the number of updates on a given prefix w_p, which is equivalent to the number of blocks contained in the result I_{w_p}. We show the computation, storage and communication complexity of GridSE in Table 1 for the reference of the following empirical evaluations.

A search comprises a sequence of operations such as generating tokens in the client, sweeping index-keys in the server and decrypting in the client. Particularly, it requires d_w evaluations of **InxDict** in the server, and d_w $\mathsf{SP^2E.TKGen}$ invocations and a_{w_p} PRF instances for decryption in the client. Recall that a $\mathsf{SP^2E.TKGen}$ invocation introduces a PRF and several hash instances while a $\mathsf{SP^2E.PrefDec}$ invocation requires a single XOR operation. Both of these invocations are all evaluated with constant. Thus, the overall complexity of a search operation is $O(a_{w_p} + d_w)$. Regarding the communication cost of a search, it is $O(a_{w_p})$ as the returned result size in a list format is asymptotic a_{w_p}. On the other hand, an update requires $O(1)$ for the communication overhead due to that the client only submits a single entry to the server. After N updates have taken place, regarding the client keeps a local list $\hat{\delta}$ of size d_w, the local storage is merely $O(d_w)$. Finally, GridSE takes an extra roundtrip to fetch the block identifiers for w_p if the actual blocks are necessary to be retrieved.

Recall that an index-key is associated exclusively with a DGGS cell. The maximum value of d_w does not exceed the number of DGGS cells, which is a constant for a given geographical region. A constant-constrained d_w implies a high search efficiency and tolerance of frequent updates in GridSE. This performance advantage is ensured by two properties, the fixed pattern of cell partitioning and the fixed resolution of a cell in DGGS. For instance, given a database located within the United States with a size up to 10^5, 10^6, or 10^7, the number of DGGS cells is stabilized at around 1615 with each cell in the $0.01km^2$ scale.

Cleaning Deleted Items. Allowing the size of EDB to grow with each update including deletions is a common strategy in building dynamic SSE [14,35]. This simplifies the deletions while reaching forward and backward privacy. GridSE can mitigate this growth via a periodic "clean-up" operation that has been adopted in previous schemes [14]. The "clean-up" operation involves the client to remove the deleted identifiers in $valList$ when he decrypts a search result R_{w_p}. The remaining identifiers are then re-encrypted and sent back to the server. However, the deterministic encryption over identifiers with the repeated input to PRFs would lead to "identical" ciphertexts in $valList$ which fail to protect privacy. "Identical" means the same ciphertexts as the previous ones. Hence, as a countermeasure, we add a new counter as input into the PRFs, which increments with every search cycle. To guarantee the correct token generation and decryption for subsequent searches, an additional counter map **IncreCnt** is required to be maintained locally. This design retains the same performance and backward privacy as GridSE. We omit the details of this part in this paper due to the space limit.

6.2 Towards Generic Dynamic pSSE

The key idea of GridSE to achieve forward/backward private dynamic pSSE is its utilization of $\mathsf{SP^2E}$ as a building block to support prefix search and its creation of a key-value dictionary based on the encrypted triplets (w, id, op). These techniques are also compatible with traditional dynamic SSE schemes that support only full keyword search. In this section, we provide a generic dynamic pSSE framework (Fig. 6) by leveraging the techniques in GridSE to enable prefix

Setup

- Same as **Algorithm** 1. Client returns (K, SK, MSK), $(\mathbf{UpdtCnt}, \hat{\delta}), EDB$.

Update

- Client computes $< addr, val >$ and sends it to server, but maintain δ at local. These values are computed as:
  - $addr, \delta = \mathsf{SP^2E.Enc}(SK, \mathsf{SP^2E.PreEnc}(MSK, seq, w))$,
  - $val \leftarrow Forward/Backward.Enc_{seq, \mathbf{UpdtCnt}[w]}(id, op)$,

  where $seq = (current)$ **UpdtCnt**.size.
- Server stores $< addr, val >$ in a linked map.

Search

- Client generates token:

  $tk = \mathsf{SP^2E.TKGen}(SK, MSK, \delta_i, i, w_p)$ for $i = 1, ..., d_w$.
- Server checks whether an index-key matches a prefix or not:

  $\mathsf{SP^2E.PrefDec}(tk, addr) == 0^f$,

  If yes, obtains all associated *val*s related to $addr$, and sends them back to client.
- Client decrypts *val*s.

Figure 6: A generic dynamic pSSE framework with forward/backward privacy

search capabilities for forward/backward private dynamic keyword SSE. In this framework, one vital requirement is that the keywords with the same prefix need to be grouped and associated with the same index-key in the key-value dictionary. The framework consists of two main steps. First, when searching for a specific prefix, the server will identify the corresponding index-keys for this prefix by executing the prefix predicate function $\mathsf{SP^2E.PrefDec}$ over the encrypted index-keys, namely $addr$. Next, the clients decrypt the blocks (i.e. files) returned from the server to obtain the result. Note that the encryption (highlighted in Fig. 6) in our framework is designated for forward/backward privacy and can be varied according to different designs, such as PRF used in ref. [12, 14], puncturable PRF in ref. [12, 34, 36] or encryption based on *oblivious data structure* in ref. [14, 15, 35]. While the framework allows different encryption, to enable prefix search, the message encrypted must include two parameters – *seq* and $\mathbf{UpdtCnt}[w]$), where $\mathbf{UpdtCnt}[w]$ stores the update operations on blocks in relation to an index-key w, and *seq* records the sequence of w in the index, hence making every block unique without compromising forward and backward privacy.

7 EXPERIMENTAL EVALUATION

In this section, we perform an in-depth analysis and report the performance of our scheme GridSE, comparing it with ST-ORAM [16], the state-of-the-art dynamic SSE for substring and plaintext search.

Table 1: Complexity of GridSE.

Computation Time		Storage		Communication Size	
Encryption	Search	Local State	Ciphertext	Update	Search
$O(N+d_w)$	$O(a_{w_p}+d_w)$	$O(d_w)$	$O(N+d_w)$	$O(1)$	$O(a_{w_p})$

d_w: the number of (distinct) index-keys in the encrypted index dictionary **InxDict** at server; N: the total number of updates; a_{w_p}: the number of updates in relation to the prefix w_p.

Setup. We implemented GridSE in Java using the JPBC [54] library for cryptographic operations, in particular, AES-256 as the PRF. All schemes were executed on a single machine while storing the database on RAM. We used an EC2 i3.xlarge AWS instance (Intel Xeon 2.30GHz CPU and 30.5GB RAM). The WAN experiment was run on two machines with a 30ms roundtrip time.

Experiment Overview. The experiment is conducted on the Gowalla location check-in dataset [55], a real-world dataset containing $6,442,890$ records contributed by $196,591$ worldwide users from which we picked $63,369$ distinct users within California by Google API. We tested for various database sizes $|DB| = 10^3$-10^7 by randomly choosing and duplicating users. The cell codes produced from different DGGS methods are evaluated such as Niemeyer's Geohash [2], Google S2 [3] and Uber H3 [4]. The letters of a cell code are from the textual alphabet. When building an index, we standardize the area of each cell to be $0.01km^2$ which is equivalent to a neighboring range of $100m$. Different DGGS methods yield various cell code lengths for a fixed cell area. Query ranges are tested spanning from $100m$ to $5km$ which associates the sizes from $100m^2$ to $100km^2$. We considered variable result between 10-10^5 blocks. Unless otherwise specified, after blocks were inserted, we delete at random 10% of the blocks matching the queried prefix, which is to emulate the impact of deletions on performance. All experimental values are the average obtained by 10 trials. To be precise, a location is kept with five digits such as $(\texttt{Long.} = -97.66712, \texttt{Lat.} = 30.20155)$. This unit of digits corresponds to $1m$ difference in reality.

Two parameters f and queried range are emphasized in our experiments. The queried range varies between $5km$ and $100m$ with the length of a queried prefix ranging from 5 to 10 characters. f is a parameter (in $\mathsf{SP^2E}$) indicating a queried result valued of 16-20 bits *w.r.t* 256-bit AES ciphertexts.

7.1 Search Performance

We tested the computation time and communication size impacted from different f, queried ranges, deletions and WAN experiment for evaluating searches.

Computation Time. The computation time refers to the time needed for a single geographic search. As depicted in Fig. 7 (a)(b), GridSE and SOTA achieve nearly constant search

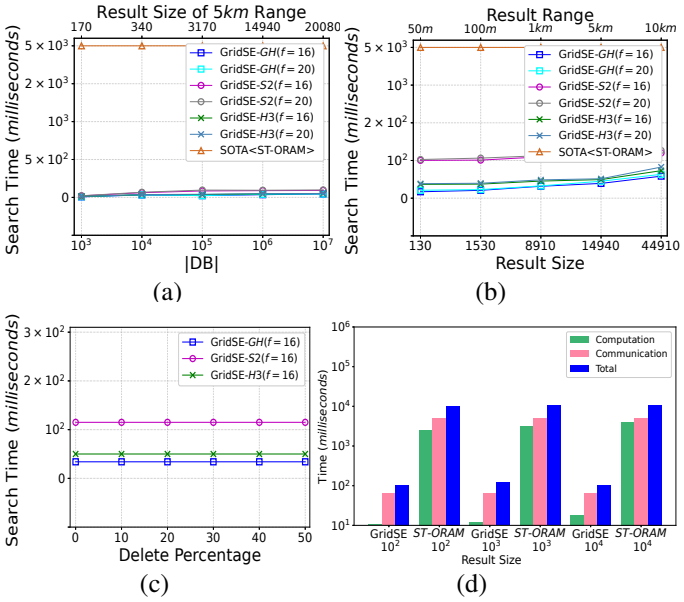

Figure 7: Computation time for (a) search vs. variable $|DB|$ sizes for result range $5km$, (b) search vs. variable result sizes, (c) search vs.% of deletions, (d) search under WAN with $40ms$ latency. (b)-(d) are all for $|DB| = 1M$.

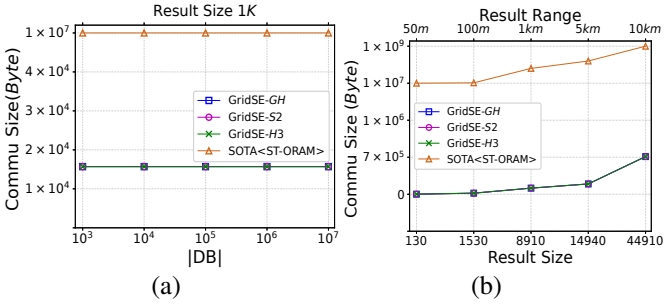
time as the database size varies while the search time for both schemes slightly increases with the result size, as more blocks need to be returned and decrypted.

Comparison with the State of the Art. It is noteworthy that Fig. 7 (a) and (b) show a $150\times - 5000\times$ speedup of our scheme over ST-ORAM. This improvement is as expected, given the fact that ST-ORAM needs to scan every possible prefix within repeated tree structures, organized by every possible suffix (implemented with ORAM) which results in logarithmic cubical complexity. Instead, our solution leverages efficient symmetric encryption, maintaining almost constant complexity. Such improvement provides strong evidence for the feasibility and scalability of GridSE. For example, with a database of $1M$ blocks and a result size of 130, a geographic search over ciphertexts (including decryption) requires only $20ms$. Notably, the majority of the time is spent on the decryption while the server only needs to perform the lookups. This is proved by the unaffected performance with various parameter f as shown in Fig. 7, e.g., a 4-bit difference in f results in a negligible time difference of approximately $2ms$ for an encrypted database size of $|DB| = 1M$. Moreover, it is crucial to highlight the efficiency of GridSE, especially when achieving both forward and backward privacy.

Deletion Impact. One interesting observation is the independence of search time from the volume of deletions. As shown in Fig. 7 (c)., as the percentage of previous deletion increases from 0 to 50%, there is no notable variation in search time for a fixed database size of $1M$ and fixed result size of $10K$. This is because the deleted entries are not physically

Table 2: Comparison evaluation for storage cost, search time and communication size.

Scheme	Local Storage	Search Time	Commu Size
Baseline (Plaintext)	-	$8.3ms$	$7.8KB$
GridSE	$30.7KB$	$20ms$	$15.3KB$
ST-ORAM (SOTA)	$424KB$	$5\times10^3 ms$	$10^4 KB$



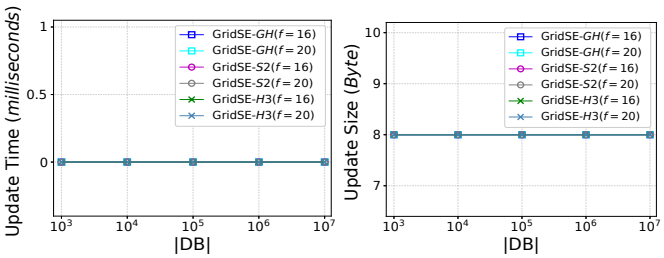


Figure 8: Communication cost for (a) search vs. variable $|DB|$ sizes for result range $5km$, (b) search vs. variable result sizes for $|DB| = 1M$.

removed from the index. Notice that "deletion" is recorded in the parameter op stored within the index. Consequently, the deletion only influences the phase after decryption, i.e., to pick up the block identifiers that have been added but not yet deleted.

Experiment over WAN. To simulate the real-world scenario, we measure the end-to-end search time with separate server and client machines under the WAN setting. The latency between the server and the client is around 40ms. Fig. 7 (d) depicts the search time, breaking down to computation and communication, for database size $|DB| = 1M$. The data reported is for Niemeyer's Geohash. Although communication is the dominant overhead for both schemes, ST-ORAM imposes much heavier communication overhead due to the numerous interactive rounds with poly-logarithmic sizes transferred to the server while in our scheme, only 1 round of communication is needed. From our experiments, GridSE outperforms ST-ORAM by a factor of $67\times$ in terms of the result size.

Consider a database of size 10^6 with returned locations size of 10^3. Under such conditions, GridSE's performance metrics would be $83ms$ for communication, $18ms$ for computation, and a client storage requirement of $30.7KB$. This gives us a clearer grasp of the practical feasibility of our scheme.

Communication Cost. Fig. 8 shows the communication cost for a search under varying database sizes (a) and different result sizes (b). The communication cost grows linearly with the result size but is independent of the database size. Compared with ST-ORAM, GridSE saves 99% communication cost. This is achieved because in our scheme, any search contains only one round of communication between the client

(a) (b)

Figure 9: Update of (a) computation time, (b) communication size vs. variable $|DB|$ sizes.

and server. The client only needs to send one "token" ($TList$) which is nearly constant in size and receive the result from the server. The communication cost can be further optimized by requiring the server to send the encrypted indexes back and then remove the deleted blocks, or asking the client to submit a cleanup process after each search.

7.2 Update Performance

Fig. 9 (a) and (b) show the update time and communication size for one update operation (add or deletion of a block) across varying database sizes, respectively. Notably, both the update time and communication size are constant ($5\mu s$ for update time and 8 bytes for update size) and independent of the database size. This is attributed to the constant communication cost incurred by GridSE, where only a key-value pair $(addr, val)$ needs to be transmitted from client to server, therefore highlighting the scalability of GridSE in real-world GIS systems.

7.3 Comparison with Plaintext Search

To further evaluate the efficiency of GridSE, we compare it with the plaintext prefix search for a database of size 10^6 and a result of 10^3. We implement this baseline via B-tree, the default index in MySQL for common keyword searches [56]. As shown in Table 2, GridSE incurs only $1.4\times$ additional computation cost and $0.9\times$ additional communication overhead compared to the plaintext search. This is because GridSE is built atop lightweight operations, e.g., XOR and hash functions. Considering its privacy-enhancing features, GridSE is promising in terms of real-time response.

8 Conclusion and Future Work

In this work, we propose GridSE, the first dynamic prefix symmetric searchable encryption (pSSE) scheme that supports fast secure geographic search with data dynamics and achieves backward and forward privacy simultaneously. We first introduce a new cryptographic primitive SP^2E for identifying whether a keyword contains a given prefix based on a lightweight cryptographic hash function. By leveraging the lightweight cryptographic operations, GridSE built atop SP^2E introduces almost constant overhead within a given geographical grid and is thus highly scalable. Experimental results show that GridSE achieves $150\times$ - $5000\times$ speedup as compared to the state of the art, and its performance is close to plaintext search, proving its feasibility for large-scale GIS/LBS systems.

Due to the constrained resources, we leave the implementation of GridSE in a real-world GIS/LBS system as a future work. We also provide several potential research directions here. While GridSE achieves the attractive prefix SSE for secure geographic search, which can also be used as generic prefix search primitive in other applications, a more versatile version - substring SSE is of great interest to the community but has not been supported yet. We point out that the lightweightness of GridSE is made possible by leveraging secure bit-wise operations. Combining such bit-level design with more complicated data structures, such as trees, might lead to a potential solution for substring SSE. In addition, extending GridSE to the multi-client setting is also a challenging but appealing direction.

Appendix A Definition for SSE Forward/Backward Privacy

Forward Privacy. Forward privacy ensures that an update remains independent of past operations at the time this update occurs. Namely, previous searches will not leak any information about the blocks to be updated. A *forward private* scheme hides whether an addition is about a new block or one that might have been previously searched for.

***Definition* A.1** (*Forward Privacy of Dynamic SSE*)**.** An $\mathcal{L}$-adaptively secure dynamic SSE scheme is forward private *iff* the leakage function $\mathcal{L}^{Updt}$ can be written as:

$$\mathcal{L}^{Updt}(op, w, id) = \mathcal{L}'^{Updt}(op, id) \tag{14}$$

where $\mathcal{L}'$ is a stateless function, w is an index key, op is insertion or deletion and id is a block identifier.

Backward Privacy. Backward privacy limits the information that the server can learn about blocks which are previously added but later deleted during searches related to them. In an ideal situation, the previously deleted blocks should not revealed to the adversary, at least the identifiers [14]. To capture backward privacy, we first follow the notation of [12] and then give the final definition.

Recall that an update is a tuple (u, op, in) where input $in = (w, id)$ with the modified block id, operation $op = add/del$, and u is the timestamp. For an index-key w, $\mathsf{TimeDB}(w)$ is a function that returns all timestamp/block-identifier pairs (of matching index-key w) that have been added to DB but not deleted later.

$$\begin{aligned}\mathsf{TimeDB}(w) = \{(u, id) | (u, add, (w, id)) \in Q \\ and\ \forall u', (u', del, (w, id)) \notin Q\},\end{aligned} \tag{15}$$

where Q is a list of queries that have been executed. An element of Q indicates a query of the form (u, w) where u is query timestamp, and w is the searched index-key.

The function $\mathsf{Updates(w)}$ returns the timestamp of all insertion and deletion operations on w in the previous queries Q. That is

$$\begin{aligned}\mathsf{Update}(w) = \{(u, id) | (u, add, (w, id)) \in Q \\ or\ (u, del, (w, id)) \notin Q\}.\end{aligned} \tag{16}$$

$\mathsf{DelHist(w)}$ is a function of capturing previously deleted entries, which returns the timestamp of all insertion and deletion operations. The output of it reveals which deletion corresponds to which addition.

$$\begin{aligned}\mathsf{DelList}(w) = \{(u^{add}, u^{del}) | (u, add, (w, id)) \in Q \\ or\ (u, del, (w, id)) \notin Q\}.\end{aligned} \tag{17}$$

From the above functions, we give the formal definition of backward privacy with the three types of leakage, from Type-I which reveals information the least to Type-III which leaks the most. A parameter a_w is introduced here, which indicates the total number of updates associated with w.

***Definition* A.2** (*Backward Privacy of Dynamic SSE*)**.** An $\mathcal{L}$-adaptively secure dynamic SSE scheme is backward private:

BP-Type-I : *iff* $\mathcal{L}^{Updt}(op, w, id) = \mathcal{L}'(op)$, *and*
$\mathcal{L}^{Srch}(w) = \mathcal{L}''(\mathbf{TimeDB}(w), a_w)$.

BP-Type-II : *iff* $\mathcal{L}^{Updt}(op, w, id) = \mathcal{L}'(op, w)$, *and*
$\mathcal{L}^{Srch}(w) = \mathcal{L}''(\mathbf{TimeDB}(w), \mathbf{Updates}(w))$.

BP-Type-III : *iff* $\mathcal{L}^{Updt}(op, w, id) = \mathcal{L}'(op, w)$, *and*
$\mathcal{L}^{Srch}(w) = \mathcal{L}''(\mathbf{TimeDB}(w), \mathbf{DelHist}(w))$.

where $\mathcal{L}'$ and $\mathcal{L}''$ are stateless functions.

Note that the above definition assumes the leakage of actually retrieving blocks will be allowed, namely the blocks that currently contain an index-key w. Specifically, the function **TimeDB** reveals the identifiers of the blocks matching w.

Appendix B Security Experiments of SP^{2}E

Fig. 10 presents the security experiments for encryption and token generation of SP^{2}E in respective.

Appendix C Correctness of PrefDec if $w_p \sqsubseteq w$

Fig. 11 shows the output formula of PrefDec, that correctly exposes the bits 0^f if $w_p \sqsubseteq w$, for which we highlight these bits using the color blue. The correctness of $w_p \sqsubseteq w$ is hold since there exists an indicator if the current keyword w satisfies the prefix query requirement, and 0^f is such an indicator.

Appendix D Correctness of PrefDec if $w_p \not\sqsubseteq w$

If $w_p \not\sqsubseteq w$, the correctness of PrefDec should guarantee that the output of PrefDec is an indistinguishable value without any *indicator-bits*, namely consecutive bits valued at zero. We consider two cases under this condition of $w_p \not\sqsubseteq w$, one is the first letters of w_p are the prefix of w, but w_p is not a prefix of w, e.g., $w_p =$ "$apps$", $w =$ "$apple$"; and the other is any composed parts of the sequence in w_p is not a prefix of w, e.g., $w_p =$ "$star$", $w =$ "$apple$". To formulate both cases, we introduce a set J for denoting each sequence of the character of the difference set w_J, that is $\{w - w_p | w_p\}$ in w_p. For instance, $w_J =$'s' and $J = \{4\}$ if $w_p =$ "$apps$" and $w =$ "$apple$", because 's' is the different letter in w_p compared to w; and 4 indicates the sequence of 's' in w_p. We have $1 \leq |J| \leq |w_p|$, and $|J|$ is the size of J. The output of PrefDec if $w_p \not\sqsubseteq w$ can be derived to the formula in Fig. 12. This formula shows that there exists no *indicator-bits* exposed in the decrypted result. Thus, the correctness of PrefDec for $w_p \not\sqsubseteq w$ is validated.

Abuse-Resistant Location Tracking: Balancing Privacy and Safety in the Offline Finding Ecosystem

Harry Eldridge[*] *Gabrielle Beck*[*] *Matthew Green*[*] *Nadia Heninger*[†] *Abhishek Jain*[*]

Abstract

Location tracking accessories (or "tracking tags") such as those sold by Apple, Samsung, and Tile, allow owners to track the location of their property via offline finding networks. The tracking protocols were designed to ensure that no entity (including the vendor) can use a tag's broadcasts to surveil its owner. These privacy guarantees, however, seem to be at odds with the phenomenon of *tracker-based stalking*, where attackers use these very tags to monitor a target's movements. Numerous such criminal incidents have been reported, and in response, manufacturers have chosen to substantially weaken privacy guarantees in order to allow users to detect stalker tags. This compromise has been adopted in a recent IETF draft jointly proposed by Apple and Google.

We put forth the notion of *abuse-resistant offline finding protocols* that aim to achieve a better balance between user privacy and stalker detection. We present an efficient protocol that achieves stalker detection under realistic conditions without sacrificing honest user privacy. At the heart of our result, and of independent interest, is a new notion of *multi-dealer secret sharing* which strengthens standard secret sharing with novel privacy and correctness guarantees. We show that this primitive can be instantiated efficiently on edge devices using variants of Interleaved Reed-Solomon codes combined with new lattice-based decoding algorithms.

1 Introduction

Vendors such as Apple, Samsung, and Tile have recently begun to deploy large-scale *offline finding networks* to monitor network-disconnected devices. These systems employ short-distance communications networks such as Bluetooth Low Energy (BLE) or Ultra-Wideband (UWB) to transmit periodic advertisement messages to nearby receivers (such as smartphones). The receiving devices upload location reports to servers controlled by the service provider.

[*]Johns Hopkins University, {hme,becgabri,mgreen,abhishek}@cs.jhu.edu

[†]University of California San Diego, nadiah@cs.ucsd.edu

While offline finding networks can be used to locate relatively powerful devices like phones and laptops, the breakout product in this category is the *location tracking accessory* (LTA), colloquially known as a "tracking tag." Exemplified by Apple's AirTag and Tile Trackers, these tags embed a transceiver, microprocessor, and battery in a compact package that can be attached to physical objects. The popularity of tracking tags stems from their low cost (typically under $30 USD) as well as the availability of large volunteer-operated tracking networks that can detect them. As of this writing, the combined tag sales of Tile, Apple, and Samsung exceed 100 million units [33].

Privacy and stalking risks. The widespread deployment of offline finding networks exposes users to new privacy and safety risks. On the one hand, LTAs can undermine the privacy of individuals who carry them: if an LTA emits an unchanging identifier such as a static MAC address, then a *tracking adversary* such as the network operator or a third-party RF tracking network [38, 40] can easily monitor individuals' physical movements. In response to these privacy concerns, manufacturers deploy sophisticated countermeasures: for example, Apple's Find My system employs a cryptographic protocol that rotates pseudonymous identifiers and uses encrypted location reports to hide location information from third parties and from Apple itself [2].

On the other hand, the availability of inexpensive LTAs also enables *tracker-based stalking* [24], in which attackers surreptitiously place a tag on a targeted person or vehicle and then monitor the target's movements via the offline finding network. These devices have been used in hundreds of criminal incidents, including serious cases that culminated in physical assault and murder [5, 11, 19, 28, 42].

Privacy vs stalker detection. Apple, Tile, Samsung and Google have adopted stalker-detection countermeasures to alert users to the presence of an unrecognized tag that "moves with" a user for a pre-defined length of time [3, 13, 26, 27, 39]. Victims can typically trigger an audio alert from the tag, obtain the tag's serial number using Near-Field Communication

Protocol	Epoch duration	Broadcasts per epoch	Stalker detection?	Tracking privacy	Continuous Proximity	Stalker detection
Apple FindMy [2] / IETF [27]:						
Near-owner mode	15 min	450	✗	n/a	n/a	
Separated mode	24 hrs	43,200	●	n/a	✗	15-60 min†
This work (§4):						
4-second epochs / 1-hour window	4 sec	1	●	39 – 46 min*	●	60 min
1-minute epochs / 1-hour window	60 sec	15	●	41 – 47 min*	●	60 min

Figure 1: We compare the detection and privacy guarantees of our scheme with various parameters to existing tag protocols. Our goal in this work is to design a scheme that maximizes tracking privacy within the stalker detection window. "Tracking privacy" indicates the duration that a tracking adversary may receive broadcasts without de-anonymizing an LTA. "Stalking detection" indicates the minimum length of time that broadcasts must be collected before a stalking LTA can be detected. Epoch duration indicates the time between changes to an LTA identifier. Broadcasts/epoch indicates the number of *repeated* broadcasts of the same identifier that an LTA will issue in this time. "Continuous Proximity" means that a tracking adversary must be in the presence of an LTA for the entire unlinkability duration in order to de-anonymize it. *The former number uses current BLE payload sizes, while the second assumes BLE v5. †Apple does not publish their methodology, so this is an estimate.

(NFC), and then query the provider's servers to obtain partial account information.

In order to implement such countermeasures, manufacturers have adopted various compromises: for example, Apple AirTags rotate their identifier every 15 minutes when within range of their owner devices, but reduce this rate to once every 24 hours when out of range. This approach allows potential stalking victims to detect nearby AirTags, but at the cost of reducing privacy against tracking adversaries.[1] Apple and Google have jointly proposed an IETF draft [27] to standardize this approach.

As this solution illustrates, the goal of a stalker detection mechanism appears to be in direct conflict with the goal of preserving privacy against a tracking adversary. To defend against a tracking adversary, tags must routinely change identifiers: this ensures that a listener cannot link a series of broadcasts to a single emitting device. Yet, to detect stalkers, a potential victim must be able to determine that a series of broadcasts belongs to a single device. This raises the following question:

> *Is it possible to provide strong privacy protections against location tracking, while also enabling the detection of stalker abuse?*

Contributions. In this work, we answer the question in the affirmative, designing new protocols that offer strong privacy guarantees while ensuring that stalker tags can be reliably detected. Critically, our solutions *operate in the threat model of today's systems* and do not rely on the creation of new trusted parties or the placement of additional trust in the service provider itself.

1. **Abuse-resistant offline finding protocols:** We put forth the notion of *abuse-resistant offline finding protocols* that simultaneously achieve privacy against tracking adversaries and stalker detection by victim devices. We propose an efficient instantiation that can operate under the constraints of existing systems.
2. **Multi-dealer secret sharing.** To obtain the above result, we define and construct a new cryptographic notion: *multi-dealer secret sharing* (MDSS). MDSS extends standard secret sharing to admit multiple dealers with different secrets while achieving new properties of unlinkability and multi-dealer correctness. We provide two constructions of MDSS, including a practical solution (with heuristic correctness) where the decoder can operate on consumer-grade devices like smartphones based on lattice-based list decoding techniques [14]. Finally, we propose some optimizations, including a new notion of *collision-aware PRFs* that enables a small-state streaming algorithm for MDSS dealers.
3. **Implementation and Evaluation.** We explore parameters for our constructions and demonstrate that existing offline finding networks can be made substantially more private using our protocols. Concretely, we propose parameters that allow users to remain private for up to 40 minutes while still detecting stalkers within an hour (see Figure 1). Finally, we implement our algorithms and demonstrate that they are efficient in practice when running on modest hardware. When using our most efficient parameters, our proposed stalker detection algorithm runs in approximately two seconds on a Raspberry Pi 3 B, and a tenth of a second on a modern laptop.

Ethics and human-subjects research. In the course of this work we conducted experiments to determine the density of Apple LTA (AirTag) broadcasts in several public areas. The data we collected in these efforts includes public BLE advertisement data combined with the approximate time and GPS location noted by our detector. Advertisement data includes a rotating MAC address. We did not engage in any effort to link addresses to non-ephemeral device properties, or through rotations, and the results we present in this work

[1] In practice, our experience shows that many users routinely carry AirTags in "separated mode". This is due at least in part to the fact that users often share physical property with other individuals, and AirTags cannot easily be paired with multiple owner devices.

contain only aggregate statistics about tag broadcast rates. To eliminate the chance of future address linking, all addresses were anonymized[2], and all data was stored on an encrypted volume to be deleted subject to data retention policies.

Prior to conducting these experiments we presented our experiments to an IRB and received a determination that they do not constitute human subjects research.

1.1 Technical Overview

The core challenge we address in this work is that *the goal of a stalking victim is nearly identical to that of the tracking adversary*. As such, it seems intrinsically difficult to develop systems that allow the former to succeed without providing an advantage to the latter.

Separating stalking victims from tracking adversaries. Our work starts with the following insight: while tracking adversaries must solve a problem that is *similar* to that of a stalking victim, the two parties are *not* identical. Stalking victims are (by definition) guaranteed to be in close proximity to a stalking LTA for a relatively long period. In contrast, a tracking adversary may only have brief or intermittent access to a given tag's broadcasts (*e.g.,* as owners enter and leave the physical locations of tracking receivers). Figure 2 illustrates an example of the two different scenarios.

Our goal is to design a scheme that provides strong cryptographic privacy against a tracking adversary that sees a large subset of an LTA's broadcasts, and yet allows full linking (and thus stalker detection) when the receiver obtains a more complete series of broadcasts. Simultaneously, our scheme must handle broadcasts sent by unrelated tags in the vicinity, that is, be robust to substantial "noise." We refer to this goal as *abuse-resistant offline finding* (AROF).

Abuse-Resistant Offline Finding Protocols. Rather than broadcast a constant identifier, we propose to transmit frequently changing and unlinkable broadcast identifiers as a means to maximize privacy, where the rate of identifier turnover is a system configuration parameter. After a (potential) victim device has collected a list of broadcasts for some fixed amount of time, it can then run a detection algorithm to check if any stalkers are nearby and, if so, it can identify and *link* those broadcasts that come from the stalker. However, to a tracking adversary who has only seen some small number of broadcasts, not only will the detection algorithm fail to recover the user's tag, but it will also be unable to link any of the tag's broadcasts to one another. In fact, the distribution will be cryptographically indistinguishable from a series of broadcasts sent by many different tags.

A key desideratum in AROF is that detection should imply that an LTA has been in *continuous proximity* to a given target, not merely that they have seen a few related broadcasts in distant broadcast periods. More formally, we wish to ensure that a tracking adversary who receives an ε-fraction of broadcasts (for some choice of ε) during a detection window will have no advantage in linking those broadcasts, while a victim who receives only a slightly greater fraction can efficiently link and detect the stalker. We call the first property *tag indistinguishability* and the second *tag detectability*. The first property ensures that honest tag users are protected from a tracking adversary while the second ensures that stalkers are detected.

A Flawed Attempt. A simple but flawed approach to realizing AROF is to produce a cyclically repeating sequence of distinct broadcast identifiers. Such a construction provides privacy against tracking adversaries who receive broadcasts for a fixed duration, but is very fragile: a tracking adversary who receives only *two* broadcasts (*e.g.,* one broadcast from each cycle) would immediately link these broadcasts to the same LTA.

Our Approach: Multi-Dealer Secret Sharing. To obtain a better solution, we instead use secret sharing [41]. Recall that in classical t-out-of-n secret sharing, a dealer distributes a secret into n shares such that the original secret can be recovered from any subset of shares of size at least t. The privacy property of secret sharing guarantees that any subset of less than t shares (referred to as an *unauthorized* set) "hides" the secret.

Consider the following proposal for an AROF protocol: at periodic intervals, the LTA samples a fresh secret tag identifier. Then, at each epoch within this period, it outputs a pseudonym similar to the one used in Apple's scheme, *along with a secret share of the secret tag identifier.* By changing the pseudonym and using a different secret share at each epoch (and, critically, having volunteer devices keep these shares local without forwarding them to the service provider), we can hope to preserve the privacy of the tag against tracking adversaries who receive an unauthorized subset of the tag's emitted secret shares within the current period. At the same time, a stalking victim who receives a more complete set of shares can use the secret sharing reconstruction algorithm to recover the tag's identifier and communicate with the tag. The exact parameters to determine both privacy and the stalker-detection threshold can be determined by the chosen parameters of the secret sharing scheme, as well as estimates of likely broadcast traffic.

Unfortunately, this proposal runs into several challenges. Note that the broadcast traffic at any time may consist of broadcasts from *multiple* LTAs in the vicinity of each other. For example, the broadcasts emitted by a stalking LTA might be intermingled with broadcasts from both ephemeral LTAs that a victim is only briefly in range of, as well as additional LTAs that remain persistently near the victim. In this setting, the standard privacy and correctness properties of secret sharing no longer suffice; instead, new properties are necessary in order to realize the above proposal:

[2]MAC addresses were replaced by the HMAC-SHA256 of the address with a randomly sampled 32 byte key. The key was then deleted.

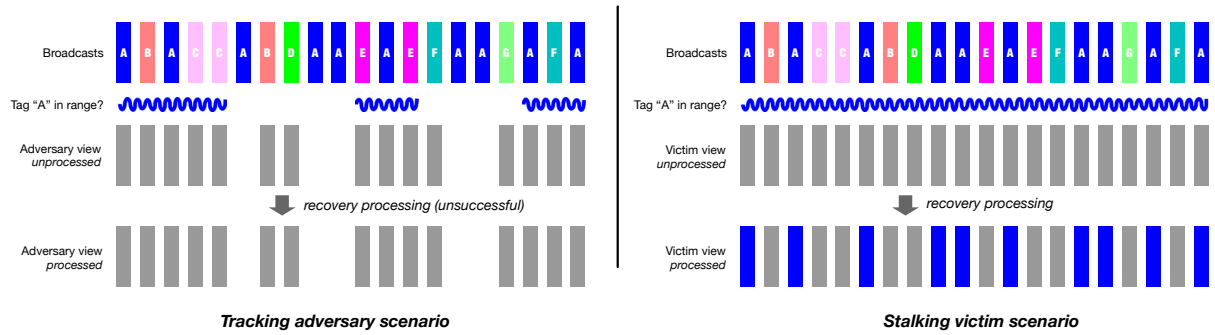

Figure 2: Illustration of two passive detection scenarios. **Left:** a static *tracking adversary* sees many broadcasts from different LTAs, including LTA "A" (blue). However, because "A" is mobile, the adversary is not in continuous range to receive its broadcasts and does not receive enough to enable tracking of the LTA. "A" broadcasts cannot be distinguished from any other broadcasts. **Right:** a *stalking victim* receives broadcasts from many LTAs including a *stalking LTA* "A". The victim is continuously within range of the stalking device and receives all of its broadcasts, which is enough to enable stalker detection.

1. **Unlinkability:** In order to achieve privacy against tracking adversaries, we require a new *unlinkability* property for secret sharing. Roughly speaking, this guarantees that given a mixed set of shares of different secrets broadcast by multiple dealers, an adversary cannot "link" any of the shares emitted by a dealer to one another as long as the shares comprise an unauthorized set. Note that this is *stronger* than the standard privacy property, which only guarantees that the adversary cannot recover the secret.
2. **MD-Correctness:** In order to detect stalker tags, we require a robust secret recovery mechanism in the presence of *multiple dealers*. In particular, we require that given a set of shares from multiple dealers, a receiver can reconstruct all secrets for which they have an authorized set (i.e., at least a threshold number) of shares. In the context of AROF, this means that a victim can identify potentially multiple stalker tags even in the vicinity of ephemeral tags.

We refer to a secret sharing scheme that satisfies these two properties as *multi-dealer secret sharing* (MDSS). While achieving either of the above two properties is non-trivial, it is especially challenging to achieve them simultaneously. Indeed, in prior uses of secret sharing (e.g., [6, 16, 18]), the problem of robust reconstruction in the presence of noisy shares is addressed by simply *identifying* (or labeling) all shares transmitted by a given dealer to identify which shares correspond to which set. This, however, is *not* an option in our setting since labeling of shares immediately breaks the unlinkability property.

Constructing MDSS. We present two constructions of MDSS. Our first construction is a variant of Shamir secret sharing where instead of using fixed evaluation points (which breaks unlinkability), we sample polynomial evaluation points uniformly at random from a super-polynomial sized field. In order to achieve MD-correctness, we leverage the connection between Shamir's secret sharing and Reed-Solomon (RS) codes [37] and utilize known list decoding algorithms [21] for RS codes. The main disadvantage of this construction is that the parameter restrictions of [21] cap the number of dealers in a way that renders the scheme impractical for our application to AROF.

To achieve better bounds, we employ a variant that uses multiple Shamir polynomials simultaneously, realizing an "interleaved" Reed-Solomon code (IRS) [8]. To achieve MD-correctness, we develop a novel lattice-based list-decoding algorithm building on the work of Cohn and Heninger [14]. This construction achieves provable unlinkability and heuristic correctness guarantees that we justify empirically. Crucially, this approach unlocks significantly better parameters that make efficient decoding achievable on highly-restricted devices. We remark that while efficient decoding algorithms for IRS codes exist in the literature [8, 15], they are defined for the random noise model which does not capture our multi-dealer setting.

Organization. We begin by formalizing the notion of abuse-resistant offline finding protocols in §2. Next, in §3, we give definitions and constructions for our main building block: multi-dealer secret sharing (MDSS). In §4, we show how to use MDSS to construct AROF schemes. In §5 we discuss how to tune MDSS parameters to optimize AROF deployments. In §6 we describe our implementation of MDSS schemes, and in §7, we provide benchmarks of our implementation using our suggested parameters. We discuss some limitations of our approach in §8, related work in §9, and conclude in §10.

2 Abuse-Resistant Offline Finding

An offline finding network, illustrated in Figure 3, is a crowd-sourced system designed to locate lost or stolen devices. In these systems, users purchase *location-tracking accessories* (LTAs) that run a tracking protocol with the network and service provider. Deployed networks typically work as follows: to enroll the device, the user pairs the LTA to a client device

(such as a smartphone or computer) and optionally registers the LTA with a service provider (SP) that controls the network. LTAs typically operate in two modes: in *near-owner mode* the LTA is in range of the owner's device and communicates directly with it. The LTA switches to *separated mode* when it is out of range of the owner device. In this work we focus primarily on the behavior of devices in separated mode, which is the typical setting for stalking attacks.

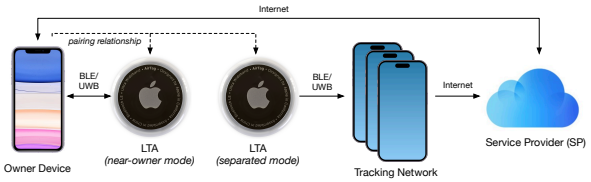

Figure 3: Components of a location-tracking network.

In separated mode, the LTA periodically emits RF-based broadcasts that can be detected by volunteer devices in the offline finding network. These volunteer devices construct *location reports* that combine the LTA broadcast data with the encrypted GPS coordinates of the volunteer device, then upload these reports to the service provider's servers. An owner device with the necessary identifiers (and other credentials) can query the service provider to obtain past and present location reports for a given LTA.

Abuse-Resistant Offline Finding Protocols. The devices in an offline finding network jointly conduct an offline finding protocol. We present algorithmic definitions and security notions for an *abuse-resistant offline finding protocol* that achieves privacy (formalized via a notion of tag indistinguishability) as well as detectability for malicious tags (formalized via a notion of tag detectability). Throughout this section, we use notation inspired by the work of Mayberry *et al.* [29].

While stalking is inherently a malicious activity, the LTA devices used in these attacks are typically *honest*, in the sense that they correctly execute the tracking network protocol. This is due to the fact that many attackers use legitimate (non-counterfeit) devices produced by the original manufacturer. In this work we will focus on the case where all LTAs honestly execute the protocol, and consider extensions to address counterfeit/malicious LTA devices, as well as other concerns, in the full version of the paper.

Definition 2.1. An *abuse-resistant offline-finding protocol* (AROF) is a tuple of algorithms $(\mathsf{KeyGen}, \mathsf{Beacon}, \mathsf{GetTagID}, \mathsf{GenReport}, \mathsf{Detect})$, a protocol $\mathsf{RetrieveReports}$ as specified in Figure 4, and two predicates P_s and P_h.

To use an offline-finding protocol, each LTA executes the KeyGen algorithm with a set of deployment-specific parameters, and shares the resulting key with an owner device. The LTA then initializes an *anonymity epoch* counter that increases monotonically whenever the identifier is to be rotated (we refer to this period as the *epoch duration*.) At the start of each epoch, the LTA executes the Beacon algorithm on the current epoch counter and transmits the output one or more times.[3] Periodically, after a *detectability period* of some number of anonymity epochs, the LTA may re-key so that very old beacons do not contribute to the tag being detectable. Volunteer devices collect the resulting broadcasts and use the $\mathsf{GenReport}$ algorithm to generate location reports for the service provider. An owner device executes the $\mathsf{RetrieveReports}$ protocol with the service provider to obtain reports collected by the network. Victim devices collect all received LTA broadcasts within a *detection window* and then use them in the Detect algorithm to detect the presence of nearby stalking LTAs.

Abuse-resistant Offline Finding Protocol

$\mathsf{KeyGen}(1^\lambda, \mathsf{cfg}) \to k_{\mathsf{tag}}$ given a set of implementation-specific scheme parameters cfg, generates a secret key k_{tag}

$\mathsf{Beacon}(k_{\mathsf{tag}}, i_{\mathsf{epoch}}, \mathsf{aux}) \to B$ on input the tag key, the index of the current *anonymity epoch*, and auxiliary data aux (*e.g.,* battery status), generates a broadcast message B

$\mathsf{GetTagID}(k_{\mathsf{tag}}, i_{\mathsf{epoch}}) \to \mathsf{id}_{\mathsf{tag}}$ is a helper algorithm used by the LTA and owner device to find the current identifier for the LTA.

$\mathsf{GenReport}(B, \mathsf{loc}) \to R$ on input a tag broadcast B and time/GPS coordinates loc, outputs a report R

$\mathsf{Detect}(\mathsf{cfg}, \{(B_1, \mathsf{loc}_1), \ldots, (B_n, \mathsf{loc}_n)\}) \to \{\mathsf{id}_{\mathsf{tag}_i}\}$ on input a set of broadcasts, outputs one or more identifiers $\mathsf{id}_{\mathsf{tag}}$

$\mathsf{RetrieveReports}(\mathsf{Owner}(k_{\mathsf{tag}}, i_{\mathsf{epoch}}), \mathsf{SP}(\mathcal{D}))$ a protocol executed between two parties. Owner provides a tag key k_{tag} and an epoch i_{epoch} and SP uses a database $\mathcal{D}$. The output to Owner is potentially a list of reports and SP's output is $\perp$.

Figure 4: Algorithms for abuse-resistant offline finding protocol.

An abuse-resistant tracking scheme must satisfy correctness and security properties. We first give informal descriptions of the desired properties, followed by the formal definitions. For the purposes of our definitions, we will use the predicates P_s and P_h to describe specific access patterns that determine whether or not a tag should be *detectable* as a potential stalker, or should remain unlinkable, respectively.

Correctness. An authorized Owner should be able to obtain location information on their LTA, provided a volunteer device sees at least one of its emitted broadcasts.

Detectability. A stalking LTA should be detectable by a victim. Even when selected adversarially, any set of received broadcasts satisfying P_s should both reveal the LTA as a stalker, and result in the victim device accurately learning the stalker's unique identifier.

[3] If the broadcast interval is longer than the epoch duration, then the LTA may transmit the same data multiple times.

Tag Indistinguishability. A tracking adversary who receives a broadcast pattern that satisfies P_h should *not* be able to distinguish a given LTA's broadcast from those of other LTAs. We model this as an indistinguishability game, where an adversary may see broadcasts from one of two LTAs, and then must determine which LTA a challenge broadcast belongs to. The advesary wins if it can successfully determine the correct LTA while only having seen broadcast patterns that satisfy P_h.

We can now proceed with the formal definitions.

Definition 2.2 (Correctness)**.** *A privacy preserving tracking protocol satisfies correctness if for all authorized owners* Owner *and compliant service providers* SP, $\forall \mathsf{loc}, \mathsf{aux}$ *and allowed anonymity epochs* i_{epoch}*, and* $\forall \mathcal{D}$ *provided by* SP*,*

$$\Pr\left[\begin{array}{l} k_{\mathsf{tag}} \leftarrow \mathsf{KeyGen}(1^\lambda, \mathsf{cfg}); \\ B \leftarrow \mathsf{Beacon}(\mathsf{cfg}, k_{\mathsf{tag}}, i_{\mathsf{epoch}}, \mathsf{aux}); \\ R \leftarrow \mathsf{GenReport}(B, \mathsf{loc}); \\ \mathcal{D}' := \mathcal{D} \cup \{R\}; \\ \mathsf{out} \leftarrow \mathsf{RetrieveReports}(\mathsf{Owner}(k_{\mathsf{tag}}), \mathsf{SP}(\mathcal{D}')) : \\ \exists m \in \mathsf{out}, m = (\mathsf{loc}, \mathsf{aux}) \end{array}\right] = 1$$

Tag Detectability

Other Properties. Mayberry *et al.* [29] identify some additional properties for an offline finding system. For example, the service provider should not be able to determine the location of LTAs or volunteer devices from the encrypted location reports it receives. Our schemes in §4 achieve this property in much the same way as the constructions of [29]. Since the focus of our work is on the interaction between stalking tags and victims (and due to space limitations) we omit this analysis here.

3 Multi-Dealer Secret Sharing

In a secret sharing scheme [41], a dealer divides a secret into shares such that the secret remains hidden from anyone who holds an "unauthorized" set of shares, but can be recovered from any "authorized" set of shares. These properties are referred to as privacy and correctness, respectively.

In this work, we consider a setting where *multiple* dealers may simultaneously distribute shares of their respective secrets. We put forth a notion of *multi-dealer secret sharing* (MDSS) that achieves *stronger* security and correctness properties in this setting.

3.1 Definition

We study multi-dealer secret sharing for threshold access structures. Such a scheme is parameterized by four variables:

- t_{rec}, the number of shares required to recover a secret.
- t_{priv}, the number of shares one can emit before privacy and unlinkability are broken.
- d, the number of sufficient dealers the scheme is able to tolerate.
- max, the maximum number of shares that can be input to the reconstruction algorithm.

We consider the *ramp* setting of Blakley and Meadows [7], where we allow for a gap between t_{rec} and t_{priv} larger than 1. We now formally define multi-dealer secret sharing.

Definition 3.1 (Multi-dealer secret sharing scheme)**.** A $(t_{rec}, t_{priv}, d, \mathsf{max})$-multi-dealer secret sharing scheme (MDSS) is defined over a secret space $\mathcal{S}$ of values that can be shared and consists of the following algorithms, which are expected to run in polynomial time in a security parameter λ:

- $\mathsf{Share}(s, n; r) \to \{sh_i\}_{i\in[n]}$, takes as input a secret $s \in \mathcal{S}$, an integer n, and some randomness r, and outputs a set of n shares $\mathbf{sh} = \{sh_i\}_{i\in[n]}$.
- $\mathsf{Reconstruct}(\{sh_1, \ldots, sh_w\}) \to \{s_1, \ldots, s_m\}$, takes as input a set of shares $\{sh_1, \ldots, sh_w\}$ where $w \le \mathsf{max}$, and outputs a (potentially empty) set of secrets $\{s_1, \ldots, s_m\}$.

In the above, the tuple $(t_{rec}, t_{priv}, d, \mathsf{max})$ is an implicit input to both algorithms.

An MDSS scheme must satisfy two properties: *unlinkability*, which strengthens the standard notion of privacy (§3.1.1), and *MD-Correctness*, which strengthens the standard notion of correctness (§3.1.2).

In both definitions we will use some notational shorthand for computing a set of shares and then projecting them onto a set of indices. For a secret s, an integer n, and a set of indices $I \subseteq [n]$, define $\mathsf{Proj}(s, n, I)$ as follows:

1. Compute $\{sh_1, \ldots, sh_n\} \leftarrow \mathsf{Share}(s, n)$
2. Return $\{sh_i\}_{i\in I}$

When I is a singleton, we will denote it as $\hat{i}$.

3.1.1 Unlinkability

We propose a new security property for secret sharing that is stronger than the standard notion of privacy. Intuitively, this property requires that given a set of shares from multiple dealers, an adversary cannot associate (i.e., link) any unauthorized subset of shares to a common dealer.

We present two definitions: unlinkability and one-more unlinkability. The first intuitively matches the guarantee we would like to achieve, while the second is simpler and easier to use. We will show that the second definition implies the first (the first will obviously imply the second); therefore one can use the second definition without loss of generality.

Unlinkability. Our first definition is characterized by a security game $\mathsf{ULink}^b_{\mathcal{A}}(\lambda)$ where an adversary $\mathcal{A}$ can receive shares from an arbitrary polynomial number of dealers, each sharing a potentially different secret chosen by the adversary. For every dealer i, the adversary receives $|I_{i,b}|$ number of shares of the corresponding secret for adversarially chosen index sets $I_{i,0}$ and $I_{i,1}$. The adversary wins the game if it correctly predicts the bit b. To disallow trivial attacks, we model security against *admissible* adversaries defined as follows:

Experiment $\mathsf{ULink}^b_{\mathcal{A}}(\lambda)$

$\left\{\left(s_i, n_{i,0}, n_{i,1}, I_{i,0}, I_{i,1}\right)\right\}_{i\in[L]} \leftarrow \mathcal{A}(1^\lambda)$
$\forall i \in [L] : \mathbf{sh}_i \leftarrow \mathsf{Proj}(s_i, n_{i,b}, I_{i,b})$
$\hat{b} \leftarrow \mathcal{A}(\mathbf{sh}_1, \ldots, \mathbf{sh}_L)$
Output $\hat{b}$

Figure 7: Unlinkability

Experiment $\mathsf{OM\text{-}ULink}^b_{\mathcal{A}}(\lambda, t)$

$(s_0, s_1, n_0, n_1, I, \hat{i}) \leftarrow \mathcal{A}(1^\lambda, t)$
$\{sh_1, \ldots, sh_t\} \leftarrow \mathsf{Proj}(s_0, n_0, I)$
$\{sh^*\} \leftarrow \mathsf{Proj}(s_1, n_1, \hat{i})$
If $b = 1$, $sh_t \leftarrow sh^*$
$\hat{b} \leftarrow \mathcal{A}(sh_1, \ldots, sh_t)$
Output $\hat{b}$

Figure 8: One-More Unlinkability

Definition 3.2 (Admissible Adversary)**.** *An adversary $\mathcal{A}$ in experiment $\mathsf{ULink}^b_{\mathcal{A}}(\lambda)$ is said to be admissible iff:*

1. $L \in \mathsf{poly}(\lambda)$
2. $\forall i \in [L], |I_{i,0}| \le t_{priv}, |I_{i,1}| \le t_{priv}$
3. $\sum_i |I_{i,0}| = \sum_i |I_{i,1}|$

The second requirement ensures that all share subsets are unauthorized, while the third requirement ensures that the total number of shares are equal in each experiment. The experiment $\mathsf{ULink}^b_{\mathcal{A}}(\lambda)$ is described in Figure 7.

Definition 3.3 (Unlinkability)**.** *A $(t_{rec}, t_{priv}, d, \mathsf{max})$-MDSS with secret space $\mathcal{S}$ is* ε-unlinkable *if there exists a function $\varepsilon(\cdot)$ such that for all* admissible *adversaries $\mathcal{A}$,*

$$|\Pr[\mathsf{ULink}^0_{\mathcal{A}}(\lambda) = 1] - \Pr[\mathsf{ULink}^1_{\mathcal{A}}(\lambda) = 1]| \le \varepsilon(\lambda)$$

When $\varepsilon(\lambda)$ is negligibly small (resp., zero), we say that the scheme is statistically (resp., perfectly) unlinkable. Computational security can be described as well in the standard way.

One-More Unlinkability. Our second definition considers only *two* dealers. The adversary sees up to t_{priv} shares – either all from the first dealer *or* all but one from the first dealer and one share from the second dealer. We formally model this in the security game $\mathsf{OM\text{-}ULink}^b_{\mathcal{A}}(\lambda, t)$ described in Figure 8.

Definition 3.4 (Admissible Adversary)**.** *An adversary $\mathcal{A}$ in experiment $\mathsf{OM\text{-}ULink}^b_{\mathcal{A}}(\lambda, t)$ is said to be admissible iff $|I| \le t$.*

Definition 3.5 (One-More Unlinkability)**.** *We say that a $(t_{rec}, t_{priv}, d, \mathsf{max})$-MDSS with secret space $\mathcal{S}$ is* ε-one-more

unlinkable *if for every* $t \leq t_{priv}$*, there exists a function* $\varepsilon(\cdot)$ *such that for all* admissable *adversaries* $\mathcal{A}$*,*

$$|\Pr[\mathsf{OM\text{-}ULink}^0_{\mathcal{A}}(\lambda,t)=1]-\Pr[\mathsf{OM\text{-}ULink}^1_{\mathcal{A}}(\lambda,t)=1]| \leq \varepsilon(\lambda)$$

We can define statistical, perfect and computational one-more unlinkability in a similar manner as above.

Relationships between definitions. Our proof that the two definitions of unlinkability are equivalent, along with a proof that unlinkability is stronger than the standard secret-sharing notion privacy, can be found in the full version of the paper.

3.1.2 MD-Correctness

Our correctness definition differs from standard secret sharing in that we must reconstruct secrets given a set of shares from *multiple* dealers. This set may include shares from both sufficient dealers (i.e. those outputting at least t_{rec} shares) and *insufficient* dealers (i.e. those outputting fewer than t_{rec} shares). We require that Reconstruct outputs exactly the set of secrets shared by the sufficient dealers, except with some failure probability ε. Similar to standard secret sharing, we only consider correctness for honestly generated (i.e. via the Share algorithm) sets of shares.

Definition 3.6 (MD-Correctness)**.** [4] *We say that a* $(t_{rec}, t_{priv}, d, \mathsf{max})$*-MDSS is* ε*-correct if for all sets* $\{(s_i, n_i, I_i)\}_{i\in[h]}$ *where* $\forall i,\ I_i \subseteq [n_i]$*, and* $\sum_{i\in h}|I_i| \leq \mathsf{max}$*, and* $\left|\{I_i \text{ s.t. } |I_i| \geq t_{rec}\}\right| \leq d$*:*

$$\Pr\left[\mathsf{Reconstruct}(S) \neq \{s_i \text{ s.t. } |I_i| \geq t_{rec}\} \;\middle|\; S := \bigcup_{i=1}^{h} \mathsf{Proj}(s_i, n_i, I_i)\right] \leq \varepsilon$$

3.2 Constructing MDSS

We present two constructions of MDSS based on variants of Shamir's secret sharing. Our first scheme (§3.2.1) achieves provable MD-correctness for $d < \frac{t_{rec}}{t_{priv}}$ number of dealers and is primarily of theoretical interest. Our second scheme (§3.2.2) achieves heuristic correctness but is able to support both more dealers and a concretely efficient reconstruction algorithm that can be executed on devices with limited capabilities. This forms the basis of our AROF construction presented in the next section.

[4] One could also consider a weakening of this definition where we allow the output of $\mathsf{Reconstruct}(S)$ to contain false positives, namely, some extraneous secrets along with the correct set of secrets. In applications where the extraneous secrets are easily discardable or non-impactful, such a relaxed requirement could be sufficient.

3.2.1 Construction I

Our first scheme is based on a variant of Shamir's secret sharing scheme [41]. Recall that in Shamir's secret sharing, a secret s is an element of a finite field $\mathbb{F}$: to share s, one samples a random polynomial $p \in \mathbb{F}[z]$ with degree t_{priv} with the constraint that $p(0) = s$. The i-th share is simply the pair $(i, p(i))$ where $i \in \mathbb{F} \setminus 0$ is a fixed evaluation point.

This scheme is *not* unlinkable: consider a set of shares where two of the shares (i, y) and (i', y') are such that $i = i'$ (but $y \neq y'$). Given such a set, an adversary can determine with probability 1 that these shares correspond to *different* secrets. To achieve unlinkability, we therefore we allow the share algorithm to sample each evaluation point uniformly at random from $\mathbb{F} \setminus 0$. If $\mathbb{F}$ has size super-polynomial in the security parameter λ, any two evaluation points collide with probability negligible in λ. Crucially, this probability is the same for any two shares, *irrespective of whether they correspond to the same or different secrets*.

To achieve MD-correctness, we start with the observation that a collection of Shamir secret shares can be viewed as a Reed-Solomon codeword [31]. Therefore, recovering a secret from a collection of Shamir secret shares in the presence of noise is equivalent to the problem of Reed-Solomon decoding, and a natural choice for Reconstruct is an algorithm based on a Reed-Solomon decoder. Suppose that a single dealer supplies s shares in a set of size $w \leq \mathsf{max}$, and we would like to know if recovering the secret input of this dealer is possible. From a coding theory perspective, we may consider the set of shares to be a word that is distance $w - s$ away from an equivalent length Reed-Solomon codeword corresponding to the dealer's input. As long as an RS decoder exists which can recover from a fraction of $1 - \frac{s}{w}$ errors, we can recover the dealer's secret.

This, however, is not an easy condition to satisfy for a large numbers of dealers; as one example, for any non-trivial scheme with $d > 1$, we cannot use a unique decoding algorithm. Nevertheless, our problem setting can be mapped onto that of list-decoding, which can tolerate higher error (in the ramp setting) and support recovery of multiple polynomials (with enough evaluations). A well-known list-decoding algorithm for Reed-Solomon codes is the one devised by Guruswami and Sudan (GS) [21], and indeed we can use their algorithm as the principal component of Reconstruct to produce a provably correct scheme. The full descriptions of the scheme can be seen in Figure 9. . We defer the theorems and proofs regarding this construction to the full version of the paper.

Limitations. The GS-decoder comes with a significant limitation: it can only recover from a $1 - \sqrt{R}$ fraction of errors, where R is the message rate. Phrased in terms of MDSS parameters, this means that the construction only guarantees correctness for parameters satisfying $t_{rec} > \sqrt{\mathsf{max} \cdot t_{priv}}$. When we consider that $\mathsf{max} \geq d \cdot t_{rec}$, as each dealer must contribute

Construction I

Share(s,n) :

Sample a polynomial p of degree t_{priv} where $s = p(0)$

Sample n field elements $x_1,\ldots,x_n \xleftarrow{\$} \mathbb{F}$

return $\{(x_i, p(x_i))\}_{i\in[n]}$

Reconstruct$(\{sh_1,\ldots,sh_w\})$:

$p_1,\ldots,p_m \leftarrow \mathsf{GSDecode}(t_{priv}, t_{rec}, \{sh_1,\ldots,sh_w\})$

return $\{p_1(0),\ldots,p_m(0)\}$

Figure 9: MDSS Construction I

MDSS Construction

Share(s,n) :

Sample c polynomials $p_1,\ldots,p_c$ each of degree t_{priv}, where $s = p_1(0)||\ldots||p_c(0)$

Sample n field elements $x_1,\ldots,x_n \xleftarrow{\$} \mathbb{F}$

return $\{(x_i, p_1(x_i),\ldots,p_c(x_i))\}_{i\in n}$

Reconstruct$(\{sh_1,\ldots,sh_w\})$:

return CH*-MDSS$(\{sh_1,\ldots,sh_w\})$

Figure 10: MDSS Construction II.

at least t_{rec} shares, this gives us $\frac{t_{rec}}{d} > t_{priv}$. Therefore, the gap between t_{rec} and t_{priv} degrades linearly with the number of dealers we wish to tolerate. This is undesirable, and our next construction will focus on achieving a better relationship between the gap and the number of tolerable dealers.

Subsequent works have built list-decoders for *folded* Reed-Solomon codes (which contain multiple polynomial evaluation points in each symbol) [20] that can tolerate nearly $(1-R)$ (i.e., optimal) error. However, to achieve our desirable trade-off between t_{priv} and t_{rec} using these decoders requires a share-size that is impractical for our AROF application. Furthermore, to the best of our knowledge, these decoding algorithms are not known to be concretely efficient. We defer further discussion of these and other codes to the full version of the paper.

3.2.2 Construction II

Our second construction is inspired by interleaved Reed-Solomon (IRS) codes, which are known to achieve a good trade-off between message and error rate, and could feasibly result in a scheme with a smaller gap between t_{rec} and t_{priv} [8, 15]. For an IRS code, rather than sampling a single polynomial p, a dealer samples c polynomials $p_1,\ldots,p_c$ with the secret s subdivided across the constant term of each, and shares the values $(r, p_1(r),\ldots,p_c(r))$, where the evaluation points r are sampled uniformly at random as in the first construction.

There are numerous decoding algorithms for interleaved Reed-Solomon codes and other closely related noisy curve reconstruction problems in the literature [36, 44]. Unfortunately, all of these algorithms are only known to work in a random noise model - which would correspond to the single dealer setting for *MDSS* - and most are not efficient enough to operate on limited devices at the parameter sets we require. To address these issues, we devise a concretely efficient, novel decoder that can heuristically decode up to a $\frac{c}{c+1}(1-R)$ fraction of errors, where c is the number of polynomials, when the channel is "semi-honest" The decoder, which we call CH*-MDSS, is based on a dual version of a lattice-based decoding algorithm proposed by Cohn and Heninger [14].

In their prior work, Cohn and Heninger give a general technique for list-decoding variants of Reed-Solomon codes and their siblings: first recover one (or more) multivariate polynomials Q_i which vanish on all polynomials of the appropriate degree that agree with a large fraction of input points, then recover the common roots of the Q_i. The first step is done by constructing a polynomial lattice and finding a reduced basis, while the second is done by computing a Groebner basis over the Q_i to find all common roots or, in the case where $c = 1$, by factoring a single Q_i.

We instead consider the *dual* of that lattice, as it directly contains our polynomials of interest and does not require additionally computing a Groebner basis which could be resource intensive. The full description of the algorithm, which we refer to as CH*-MDSS, can be found in Appendix A.

Putting all the pieces together brings us to our main construction, which can be seen in Figure 10. We defer our theorems and proofs regarding Construction 10 to the full version of the paper.

3.2.3 Optimizations

We now discuss some efficiency optimizations.

Small Fields. A suitable choice of field is required to achieve practical unlinkability and efficiency. If a dealer randomly samples the same evaluation point twice and produces two identical shares, then unlinkability is compromised. While this will occur with negligible probability if fields are large enough, in practice small fields are often best to minimize bandwidth and decoding complexity. We therefore propose a stateful variant of our construction in which dealers keep track of previously sampled evaluation points and emit *noise shares* (comprising random elements in place of the polynomial evaluation) whenever an x-coordinate is repeated. This preserves unlinkability at the cost of decreasing the number of "useful" shares passed to the reconstruction algorithm, and thereby increasing the probability of reconstruction failure.

Collision-Aware PRF. In practice, MDSS users may want to output shares in a *streaming* fashion.This would require

keeping state (all previously sampled x-coordinates), which may be undesirable. As an optimization for this setting, we define a new primitive we call a *Collision-Aware PRF* (CA-PRF). Using a CA-PRF allows an MDSS dealer to sample x-coordinates pseudorandomly while being alerted to potential collisions.

Due to space concerns, we defer a formal treatment of both of the above to the full version of the paper.

4 Construction of AROF Protocols

We now describe our main contribution: an offline finding protocol that achieves strong privacy while also admitting stalker detection.

Protocol intuition. The core algorithms of our protocol are presented in Figure 11. At a basic level, this protocol can be viewed as an extension of the offline finding construction used by Apple's FindMy [1]. Like the Apple construction, our protocol employs a pseudorandom function to derive a fresh "pseudonym" for the LTA at the start of each epoch. Just as in the Apple system, each pseudonym also doubles as a public key for a secure encryption scheme: upon receiving a pseudonym from any nearby LTA, volunteer devices in the tracking network can encrypt their current GPS coordinates and transmit the resulting ciphertext to the service provider. Owner devices can later re-derive a sequence of missed pseudonyms and the corresponding decryption keys, and use the RetrieveReports protocol to query the provider for each missed time period.

Achieving stalker detection. To enable stalker detection, our protocol makes several additions to the basic protocol described above. First, each LTA maintains a *detectability period* consisting of L consecutive time epochs. At the start of each detectability period, the LTA generates a secret tag identifier $\mathsf{id}_{\mathsf{tag}}$. It then secret-shares $\mathsf{id}_{\mathsf{tag}}$ using an MDSS scheme configured with appropriate parameters. With each call to Beacon, the LTA generates the current pseudonym and appends one secret share to be broadcast by the LTA. The MDSS parameters are informed by how long it should take before a stalker is detected, the maximum number of stalkers that should be detected, and the maximum number of beacons that will be within any victim's detection window. We discuss more in depth how these parameters are set in §5.

Critically, volunteer devices in the offline finding network *do not transmit these secret shares to the service provider*: they are kept locally and used only to enable stalker detection. Each device maintains a set of all shares received from nearby LTAs during a time window specified in the deployment parameters. Periodically, the victim device executes the Detect algorithm to perform secret sharing recovery. If this collection contains at least t_{rec} shares emitted by one LTA (or a similar set from multiple LTAs), then the MDSS recovery algorithm will recover each $\mathsf{id}_{\mathsf{tag}}$ for the devices. Each LTA can be configured to respond to interactive connections containing $\mathsf{id}_{\mathsf{tag}}$, which enables the victim to contact and physically locate any stalking LTAs.

We build security for predicates that mostly follow the intuition from the technical overview. If t_{rec} beacons from a tag are seen within a detection window, then it is considered to be a stalking tag. Intuitively, t_{rec} is close to the number of broadcasts made in the detection window, so the victim sees almost all broadcasts emitted by the LTA. Privacy is maintained as long as no party sees more than t_{priv} beacons from any detectability period.

Security. We give here the predicates for which our construction satisfies the properties described in §2. Due to space concerns, we defer the theorems and proofs for our construction to the full version of the paper. Tag indistinguishability and detectability both follow naturally from the unlinkability and correctness properties of the underlying MDSS.

For detectability we will need assumptions on the input to the Detect algorithm that are enforced by the MDSS parameters. In terms of the AROF, these assumptions will correspond to there being less than or equal to the maximum number of stalkers in the vicinity, with small enough noise coming from other tags so that no more than max beacons will be given to the detection algorithm. If these assumptions hold, then any tag that has supplied at least t_{rec} beacons corresponding to the same detectability period will be identified. Below is the precise statement for the predicate.

$$P_s(\mathsf{cfg}, Q, \mathsf{id}) = \text{“}\ \exists\ e \text{ such that } |\{(\mathsf{id}, i) \in Q \mid e = \lfloor \tfrac{i}{L} \rfloor\}| \geq t_{rec},\\ |\{(\mathsf{id}', e) \text{ s.t. } |\{(\mathsf{id}', i) \in Q | e = \lfloor \tfrac{i}{L} \rfloor\}| \geq t_{rec}\}| \leq d,\\ |Q| \leq \mathsf{max}\text{"}$$

For tag indistinguishability, the situation is simpler. Indistinguishability holds as long as no party ever sees more than t_{priv} beacons for either tag within any detectability period.

$$P_h(\mathsf{cfg}, Q) = \text{“ for } \mathsf{id} \in \{0,1\},\\ \forall e \in \mathbb{Z}^+, |\{(\mathsf{id}, i) \in Q \mid e = \lfloor \tfrac{i}{L} \rfloor\}| \leq t_{priv} \text{ and } Q \text{ is not a multi-set"}$$

The condition that Q is not a multi-set is meant to rule out an attack where the adversary queries on the challenge indices i_0^* or i_1^* before the challenge phase: by doing so they can trivially win with an equality check on the challenge beacon.

4.1 Implementation Considerations

We now discuss several implementation considerations related to the AROF construction presented in §4.

De-duplication and filtering. The duration of the anonymity epoch (*i.e.,* the time between identifier changes) is an important deployment consideration in our scheme. A shorter interval is clearly desirable to improve privacy against tracking

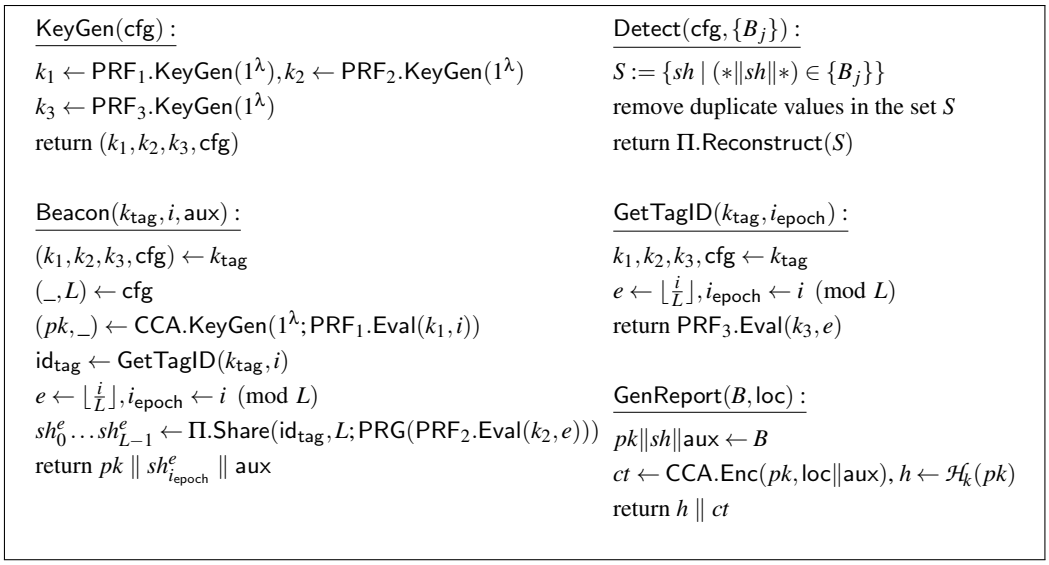

Figure 11: Main construction for abuse-resistant offline finding. This protocol assumes the existence of three pseudorandom functions PRF_i for $i \in [3]$ where the co-domain of $\mathsf{PRF}_1.\mathsf{Eval}$ and $\mathsf{PRF}_2.\mathsf{Eval}$ is $\{0,1\}^\lambda$ and the co-domain of $\mathsf{PRF}_3.\mathsf{Eval}$ is $\mathbb{F}_q$. PRG outputs a sufficient number of bits for the Share algorithm. CCA is a CCA-secure PKE scheme, $\{\mathcal{H}_k\}_{k \in \mathcal{K}}$ a family of collision resistant hash functions and Π a $(t_{rec}, t_{priv}, d, \mathsf{max})$-MDSS sharing scheme. $\|$ denotes concatenation. cfg contains the *MDSS* parameters $t_{priv}, t_{rec}, \mathsf{max}, d$ and a separate parameter L. The RetrieveReports protocol is equivalent to the one in Apple's FindMy [1].

adversaries. However, the duration of the anonymity epoch will also affect the efficiency of stalker detection. To illustrate these considerations we consider two candidate configurations.

Configuration 1: anonymity epoch ≈ broadcast interval. This is our recommended configuration, which maximizes privacy against tracking adversaries by minimizing the duration of the anonymity epoch. Under a 4-second anonymity epoch, this will result in a new pseudonym (via a call to Beacon) every broadcast that the LTA emits.[5] Our implementation transmits twice as much broadcast data at each interval, and so we propose to split each broadcast B into two separate transmissions, each sent at 4-second broadcast interval (see §6), producing 900 hourly unique secret shares from each LTA device.

Configuration 2: anonymity epoch ≫ broadcast rate. Current LTA deployments do not change the pseudonym with each broadcast.[6] This decision is likely motivated by computational costs and battery limitations. In these deployments, the LTA will re-broadcast each pseudonym many times. Applying the same logic to our protocol, these LTAs would also re-broadcast the same secret share.

Since duplicate secret shares do not aid in reconstruction, they are removed (de-duplicated) as part of the Detect algorithm. We note that this de-duplication procedure can produce some counter-intuitive effects on the noise rate. For example, LTAs that remain within range of a victim device for long periods of time (*e.g.,* stalking tags) will see proportionally more duplicate broadcasts removed, as compared to ephemeral LTAs that only briefly enter receive range of a victim device (see Figure 12.) On the positive side, these repeated broadcasts dramatically reduce the impact of erasures caused by RF-layer issues.

Pre-filtering. To compensate for the over-representation of non-stalking LTAs, systems with long-duration anonymity epochs can apply a *pre-filtering* heuristic prior to executing Detect. This heuristic takes advantage of the fact that ephemeral (*non-stalking devices*) are likely to exhibit broadcast behavior that can be recognized and filtered out prior to running Detect. For example, LTAs that remain in close proximity to the victim device for a period of time will transmit many duplicate broadcasts. Focusing detection exclusively on these broadcasts will reduce the number of non-stalker shares processed by the MDSS recovery algorithm.

Secret re-generation and detection window. In our construction, each LTA re-generates its tag identifier and secret-sharing polynomials every L epochs. This mechanism is intended to prevent tracking adversaries from correlating shares sent by the same LTA over longer periods. However, this periodic change of secrets poses a challenge for stalker detection: at boundary epochs where an LTA changes its secret, the victim may not receive a sufficient number of shares to detect a stalker. To address this, we propose two possible deployment options. A first solution is for a device to re-generate

[5] This is based on analysis of Apple's FindMy, where LTAs broadcast every 2 seconds [22, 23].

[6] For example, Apple's Find My rotates the pseudonym every 450 broadcasts (15 minutes) in near-owner mode.

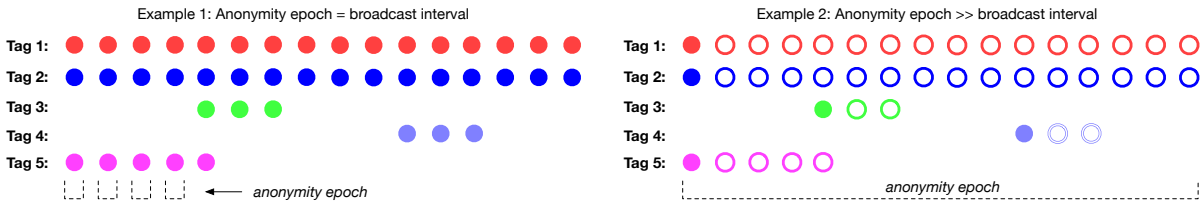

Figure 12: Illustration of the effect of de-duplicating repeated LTA broadcasts: both examples contain the same pattern of transmissions, but use different anonymity epoch durations. Filled circles represent fresh shares, hollow circles represent duplicate shares. **Left:** The anonymity epoch is short: persistent tags (Tag 1, Tag 2) produce the majority (32/43) of the unique broadcasts processed by the Detect algorithm. **Right:** The anonymity epoch is long: once duplicates are removed, the persistent tags (Tag 1, Tag 2) represent a minority (2/5) of the unique broadcasts processed by the decoding algorithm.

secrets relatively rarely. For example, re-generation every 24 hours ensures that such issues will only occur during a small fraction of each day. Second, a device could maintain two identifiers. The LTA would emit shares on both, and stagger their rotation to ensure that detection is always possible.

MAC Address Rotation To deploy with our suggested anonymity epochs would require rotating the LTA's MAC address either every 4 or 60 seconds, which is faster than the minimum rotation period of 15 minutes recommended by the BLE specification [9]. Care should therefore be taken during implementation to ensure that core BLE functionality is preserved. We note that cautious implementers could follow the recommendation and use an anonymity epoch of 15 minutes, which still represents a substantial privacy improvement over the state-of-the-art.

5 Selecting MDSS Parameters

Deploying our main construction of §4 requires us to identify reasonable system parameters for both the AROF and MDSS schemes. The challenge is to optimize privacy while also enabling *efficient* recovery in the face of reasonable noise rates. Our recommended parameters can be seen in Table 1. We now briefly describe the process we used to derive them.

High-level Considerations. We identify five high-level configuration parameters, and for the purposes of our analysis made exemplary choices for each. We note that these can be adjusted for specific deployments. Our identified parameters are:

1. The (minimum) number of minutes of continuous broadcasting after which a victim device must be able to detect a stalker LTA, which we set to 1 hour.
2. The duration of the anonymity epoch (*i.e.,* the time between pseudonym rotation), for which we consider 4 seconds and 1 minute.
3. The frequency of LTA secret/polynomial updates, which we set to 24 hours.
4. The maximum number of LTAs that will be in proximity to a victim device. We assume there will be at most three persistent ("stalker") LTAs at any given time, and at most a number of ephemeral LTAs equal to half the stalking LTA in the aggregate.
5. The bandwidth available for transmitting each secret share, which we derive to be 248 bits, based on available payload space in BLE, and 400 bits for BLEv5.

From these choices, we then optimize our MDSS scheme parameters to provide privacy for the longest period possible, while ensuring $> 99\%$ decoding success in the presence of missed broadcasts. We present two sets of parameter choices in Table 1: a recommended set given current deployment bandwidth limitations (based on widely-deployed versions of BLE), as well as a future recommendation for LTAs that support versions of BLEv5 with higher bandwidth limits. Due to space concerns we defer further description on how we derived these parameters to the full version of the paper.

6 Implementation

We now describe our implementation of our construction in §4, including optimizations and deployment choices.[7]

Implementing the Detect **algorithm.** We implemented the Detect algorithm using SageMath [43], a Python-based computer algebra system that includes fast C implementations for many algorithms. Our decoder for CH*-MDSS is around 400 lines of Python and is the bulk of our Detect algorithm implementation. For each parameter set in Table 1, *e.g.,* $c = 10$ with a field size of 22 bits, the decoding matrix requires less than 10 MB, even for the largest values of max. This is compatible with available application RAM on current smartphones.

Implementing the Beacon **algorithm.** For ease of comparison, we adopt the algorithmic choices of Apple's FindMy scheme: our implementation uses ECIES public keys [4] over the NIST P-224 curve. During each call to Beacon we define a subroutine GeneratePublicKey to pseudorandomly gener-

[7] Our code can be found at https://github.com/becgabri/abuse-resistant-private-lt

Epoch duration	Detect time	Max stalkers	L (= 24 hrs)	$\mathbb{F}_p$ (bits)	c	Share (bits)	Privacy time	t_{rec}	t_{priv}	max
Recommended parameters (compatible with current LTA bandwidth limits):										
4 sec	60 min	3	21,600	22	10	242	39 min	825	591	3150
1 min	60 min	3	1,440	24	9	240	41 min	59	41	210
Future parameters (compatible with BLE v5 bandwidth limits):										
4 sec	60 min	3	21,600	22	17	396	46 min	825	687	3150
1 min	60 min	3	1,440	26	14	390	47 min	59	47	210

Table 1: Recommended and possible future parameters for the MDSS construction of §4, instantiated with CH*-MDSS. Privacy times are rounded to the nearest minute.

Epoch duration	Avg. nearby LTAs	# Unique bxs received	Hardware	Detection runtime (no stalkers)	Detection runtime (stalkers present)	Polynomial recovery (all stalkers)
4 sec	1	1350	MacBook	0.60 sec	1.29 sec	1.37 sec
			RPi 3	8.07 sec	20.42 sec	20.99 sec
	2	2250	MacBook	1.88 sec	5.57 sec	8.74 sec
			RPi 3	25.05 sec	83.91 sec	126.18 sec
	3	3150	MacBook	3.86 sec	24.59 sec	32.96 sec
			RPi 3	51.83 sec	360.95 sec	484.21 sec
60 sec	1	90	MacBook	0.01 sec	0.01 sec	0.01 sec
			RPi 3	0.15 sec	0.27 sec	0.27 sec
	2	150	MacBook	0.02 sec	0.03 sec	0.04 sec
			RPi 3	0.31 sec	0.57 sec	0.73 sec
	3	210	MacBook	0.03 sec	0.08 sec	0.12 sec
			RPi 3	0.48 sec	1.27 sec	2.05 sec

Table 2: Benchmarks for our Detect algorithm (Figure 11) using the CH*-MDSS decoding algorithm with the recommended parameters of Table 1.

ate a new pseudonym *pk* from the master key. We implement this portion of the algorithm in SageMath.

To implement the secret sharing scheme we use the recommended parameters from Table 1, and split the Beacon algorithm into two stateful subroutines. At the beginning of each detection period (every L epochs), we execute GeneratePolynomials to sample polynomials $p_1, \ldots, p_c$, and cache these polynomials during the entire period. The tag password ($\mathsf{id}_{\mathsf{tag}}$) is the concatenation of the constant terms of each polynomial. During every call to Beacon we execute the subroutine GenerateSecretShare to pseudorandomly generate $r \in \mathbb{F}$ and compute a secret share. We implemented these functions in SageMath, as well as in a combination of JavaScript and C in order to run experiments on a low-powered hardware platform. For more information on the hardware used, see §7.

Detection in practice. Since we will be executing detection on resource-constrained devices, we propose that devices should continuously collect shares from the environment into a ring buffer containing the most recent N minutes of shares. The Detect algorithm can then be run every few minutes once the buffer is full. This strategy provides a relatively timely warning of stalking behavior and can be adjusted to account for computational resources. Additionally, once a stalker has been detected, their polynomial can be cached and the shares they emit quickly filtered out. This means that the expensive cases with many persistent LTAs should only occur rarely.

7 Experiments

In this section we evaluate the empirical runtime of our stalker-detection and encoding algorithms. We used three different pieces of hardware to conduct our experiments: a single core of a 2020 MacBook computer with an M1 chip and 16 GB of RAM running MacOS Ventura 13.3.1 (a), a Raspberry Pi 3 Model B running Ubuntu Server 23.04, and a Puck.js, a hardware platform based on the same SoC as the AirTag, running firmware version 2.15.

Stalker detection. To conduct this analysis we ran our CH*-MDSS-based Detect algorithm on simulated broadcasts. We split the experiments into two cases:

1. Decoding when *stalkers are present*, i.e. at least t_{rec} shares originate from the same LTA.
2. Decoding when *no stalkers are present*, the common case for most users, when no single (unknown) LTA contributes t_{rec} shares to the input.

We split these cases further to test two different anonymity epochs: 4 seconds and 60 seconds. More concretely, we performed the following experiment:

Algorithm	t_{priv} (epoch)	Runtime MacBook	Runtime Puck.js
GeneratePublicKey		484 μs	
GeneratePolynomials	591 (4 sec)	6233 μs	11.88 sec
GenerateSecretShare	591 (4 sec)	87 μs	0.26 sec
GeneratePolynomials	41 (60 sec)	451 μs	0.72 sec
GenerateSecretShare	41 (60 sec)	11 μs	0.04 sec

Table 3: Runtime average over 1,000 iterations for the GeneratePublicKey, GenerateSecretShare and GeneratePolynomials subroutines of the Beacon algorithm. Secret sharing uses the 22-bit field with $c = 10$ for the 4 second epoch and the 24-bit field with $c = 9$ for the 60 second epoch.

1. For each anonymity epoch (4 sec, 60 sec), and for each number of stalkers (1, 2, 3), we determine the maximum number of shares our decoder could receive (e.g. for a 4 second epoch and 2 stalkers, the decoder could receive a maximum of $(3600/4) * (2 + 0.5) = 2250$ shares).
2. We then run two experiments: first where that number of shares is generated by a combination of stalkers and ephemeral LTAs, and second where the shares are entirely ephemeral. For the first case we measure both the time to *detection* (i.e. determining the existence of a stalker), and the time to *recovery* (learning the id for all stalkers). We average the runtimes of each experiment over 500 iterations.

For each experiment, we generated the data so that all broadcasts have a unique x-coordinate in order to evaluate a fixed number of points passed to the decoding algorithm and produce an upper bound on the projected runtime. Our decoder was implemented as described in §6 and configured according to Table 1. Table 2 presents our running times, which for common cases take seconds.

Encoding. We benchmarked our encoding algorithms on both the laptop and Puck.js. Table 3 shows the running times of both.

8 Limitations

The AROF scheme proposed in this work comes with some limitations. First, the number of stalking LTAs that the scheme can tolerate must be fixed at the time of deployment. Should a user be stalked by more than the number of LTAs chosen at the outset, they will be unable to detect any of the malicious LTAs. We chose a maximum of three stalking LTAs based on a privacy/cost tradeoff. At the time of writing a four-pack of AirTags costs $99, which is comparable in price to a self-contained GPS tracker. Larger numbers of tolerable stalkers can be chosen at the outset, but would result in lower privacy times than those shown in Table 1. For example, for the 4 second anonymity epoch, tolerating up to 4 stalkers would result in 33 minutes of privacy, 5 stalkers 28 minutes, and 6 stalkers 22 minutes. We note that these numbers were computed assuming the BLE broadcast size is fixed, and as discussed in §5, privacy time can be increased by assuming a larger broadcast.

Additionally, our scheme is weak to large levels of collusion among trackers. We assume that the privacy adversary is not a global adversary. If they are, then the stalking victim no longer has an asymmetry, and passive stalker detection protocols are unlikely to be compatible with privacy.

9 Related Work

Offline finding. Several works have considered the privacy and integrity of the offline finding (tracker) ecosystem. Heinrich, Bittner and Hollick [22] evaluated the anti-stalking mechanism use in FindMy. Heinrich, Stute, Kornhuber and Hollick [23] also considered the privacy of Apple's FindMy protocol. Mayberry *et al.* [30] considered ways to bypass tracking alerts in AirTag devices, and in a separate work Mayberry, Blass and Fenske [29] devised protocols to protect against counterfeit tags. Depres *et al.* [17] develop a method to detect stalking devices with frequently rotating MAC addresses using physical-layer techniques such as RSSI.

Most of the previous works do not consider the attack we attempt to mitigate in this paper: tracking a user via the unchanging identifier of their own LTAs. [23] mentions such a concern, but dismisses it as the authors study only devices which rotate their identifier every 15 minutes. Similar to our work, [17] proposes a stalker-detection mechanism for LTAs with frequently changing identifiers. However, their work focuses on linking broadcasts via physical-layer attributes, whereas our work is entirely on the protocol level. Additionally, our work is the only proposal that prevents the tracking of an LTA until a signficant time in contact with it has passed.

Secret sharing. Many schemes use secret sharing for privacy applications: here we focus on some recent works closely related to ours. The Apple PSI system [6] defines the notion of a *detectable hash function* based on interleaved Reed-Solomon codes [8]. Similarly, the STAR protocol of Davidson *et al.* [16] emits shares of (multiple) secrets for private telemetry reporting: unlike our work, their protocol assumes that the decoder can recognize all shares from a dealer and so noise and unlinkability concerns are not considered. Finally, the literature on robust secret sharing (RSS) and cheater detection is itself robust, and considers many different models (see [10, 12, 34] and references therein). A key difference between the classical RSS setting and our setting is that in RSS there is exactly one dealer; crucially, RSS does not incorporate the notion of unlinkability.

10 Conclusion and Future Work

In this work we considered the problem of constructing privacy-preserving tracking protocols that enable efficient abuse detection. We demonstrate that the use of secret sharing enables privacy-preserving offline finding while also admitting efficient algorithms for detecting stalkers. This work leaves several open questions for future work, including the development of efficient protocols secure against malicious/counterfeit tags, as well as the development of improved multi-dealer secret sharing schemes.

A Full Description of CH*-MDSS

We begin this section by defining polynomial lattices. We then present the problem we need CH*-MDSS to solve in order for our second construction to satisfy MD-Correctness. We end by giving the construction and stating our experimentally-backed heuristic correctness assumption.

Polynomial lattice preliminaries. See [14] for a background on polynomial lattices and lattice reduction. Let $\mathbb{F}[z]$ be the ring of polynomials over variable z with coefficients in $\mathbb{F}$. Let $\mathbb{F}(z)$ be the field of rational functions $u(z)/d(z)$, $u(z), d(z) \in \mathbb{F}[z]$. For a polynomial $f \in \mathbb{F}[z]$, its degree is $\deg(f)$; for a rational function $f(z) = u(z)/d(z)$ in lowest terms, its degree is $\deg(u) - \deg(d)$. Consider a matrix $B \in \mathbb{F}(z)^{n \times n}$ with entries that are rational functions; let the rows of B be n-dimensional vectors $b_i \in \mathbb{F}(z)^n$. The *polynomial lattice* generated by basis B is the set of vectors

$L(B) = \{v \mid v = \sum_{i=1}^{n} a_i b_i, a_i \in \mathbb{F}[z]\}$. That is, the lattice consists of vectors over $\mathbb{F}(z)$ that are $\mathbb{F}[z]$ (polynomial) linear combinations of basis vectors. We define the *length* of a vector $v = (v_1, v_2, \ldots, v_n)$, $v_i \in \mathbb{F}(z)$ to be $|v| = \max_i \deg(v_i)$. Define the determinant $\det L(B) = \det B$. For a full-rank n-dimensional polynomial lattice $L(B)$, there is a polynomial-time algorithm to compute a so-called *reduced* basis B' for $L(B)$ given a basis B [32]. Such a reduced basis is guaranteed to contain a vector of length $|v| \leq (\deg \det L(B))/n$, and (unlike in the case of integer lattices) is guaranteed to contain a shortest vector of the lattice. We will also say that $\lambda_1(B)$ is the length of the shortest vector in $L(B)$. For two vectors $v, w \in \mathbb{F}(z)^n$ define the inner product $\langle v, w \rangle = \sum_i v_i \cdot w_i$. Finally, for any lattice $L(B)$ one can define the *dual* lattice $L^*(B) = \{w \in \mathbb{F}(z)^n \mid \langle w, v \rangle \in \mathbb{F}[z] \forall v \in L(B)\}$. Given a basis B for a full-rank lattice $L(B)$, $(B^{-1})^T$ is an explicit basis for the dual $L(B)^*$.

A note on reduced bases of lattices. While for many applications any reduced basis suffices, we are solely interested in those that are also in *popov form* [25, 35]. It is a direction of future work to determine why such bases are needed for the correctness of our algorithms. For the rest of this paper, we assume $\mathsf{LatticeReduce}(B)$ returns the popov form of B.

Below, we consider the following problem from coding theory which is related to the heuristic assumption that is needed to prove the correctness of our algorithm.

Definition A.1 (Simultaneous Curve Reconstruction Problem [8, 15])**.** *Given n, t, k, c, q, input points $\{(\alpha_i, (\beta_{i,1}, \ldots \beta_{i,c}))\}_{i \in [n]}$, where $\forall i \in [n], j \in [c]$, $\alpha_i, \beta_{i,j} \in \mathbb{F}_q$, each α_i distinct, recover all polynomial sets $P = (p_1, \ldots p_c) \in \mathbb{F}_q[x]^c$ s.t. $\forall i, \deg(p_i) \leq k$ and P agrees with $T \subset [n], |T| \geq t$ points. A polynomial set $P = (p_1 \ldots p_c)$* agrees *with a point $(\alpha, (\beta_1, \ldots \beta_c))$ if $\forall j \in [c], p_j(\alpha) = \beta_j$*

Given a set of input points $\{(\alpha_i, \beta_{i,1}, \ldots, \beta_{i,c})\}_{i=1}^{n}$, $(p_1 \ldots p_c)$ may be called a *solution* or a *solution set* if it agrees with at least t input points.

We briefly make some remarks about this problem from what is known in the literature. First, the difficulty of this problem depends heavily on the distribution of the points $\{(\alpha_i, (\beta_{i,1}, \ldots \beta_{i,c}))\}_{i \in [n]}$. When there is one solution, and all other points are randomly sampled (i.e. $\alpha_i, \beta_{i,j} \xleftarrow{\$} \mathbb{F}_q$) we can *theoretically* recover the solution P with high probability, provided that $t > (nk^c)^{\frac{1}{c+1}} + k + 1$ [15].We know of additional algorithms that are conjectured to achieve the more optimum bound of $t > (nk^c)^{\frac{1}{c+1}}$ [36].

To the best of our knowledge, there are no algorithms in the coding theory literature which solve this problem in a different setting from the random error model.

In our work, we handle a slightly more adversarial channel, where there are multiple solution sets but all solutions (and errors) are independent of one another. We formalize this below.

Input Distribution We begin by introducing two pieces of notational shorthand. First, we define the honest distribution of points that the input to the algorithm will draw from. This distribution is equivalent to sampling points along a collection of polynomials.

Definition A.2 (Honest Distribution)**.** *For a field $\mathbb{F}$, an integer m, and a set of polynomials $P = \{p_1, \ldots, p_c\}$, define the following distribution $D^{\mathbb{F}}_{m,P}$ on $(\mathbb{F}^{c+1})^m$:*

- *For $i \in [m]$, sample $x_i \xleftarrow{\$} \mathbb{F}$ and set $sh_i := (x_i, p_1(x_i), \ldots, p_c(x_i))$*
- *Return $\{sh_1, \ldots, sh_m\}$*

Definition A.3 (Channel Distribution)**.** *Let $\mathbb{F}$ be a field, and let $c, k, \mathsf{max}, m_1, \ldots, m_h$ be integers where $\mathsf{max} = \sum_{i=1}^{h} m_i$, and let $s_1, \ldots, s_h \in \mathbb{F}^c$ be vectors of field elements. Let $\zeta(\mathbb{F}, k, c, s)$ denote the set of all polynomial sets $P = \{p_1, \ldots, p_c\}$ over $\mathbb{F}$ where $\forall i \in [c]$, $\deg(p_i) \leq k$, and $s = (p_1(0), \ldots, p_c(0))$. Then define the following distribution $CD_{c,k,\mathsf{max},\vec{m},\vec{s}}$ on $(\mathbb{F}^{c+1})^{\mathsf{max}}$ where $\vec{m} = m_1, \ldots, m_h$ and $\vec{s} = s_1 \ldots s_h$:*

- *For $i \in [h]$, sample $P_i \xleftarrow{\$} \zeta(\mathbb{F}, k, c, s_i)$*
- *For $i \in [h]$, sample $S_i \leftarrow D^{\mathbb{F}}_{m_i, P_i}$*
- *Return $S := \bigcup_{i \in [h]} S_i$*

Looking ahead, we will need one additional requirement for our algorithm to work: all input points will need to have unique x-coordinates. We define $\mathsf{Unique}(S)$ for a set of points S to be true if all points have a unique x-coordinate, and false otherwise.

A.1 CH*-MDSS

Description of subroutines Briefly we describe all previously undefined subroutines that are needed to give our algorithm description. LagrInterpol simply does lagrangian interpolation of the input points. $\mathsf{Find}(M, d)$ takes as input a matrix M and a degree bound d, and returns all row vectors $\vec{r}$ with $|\vec{r}| \leq d$. $\mathsf{Translate}(\vec{v}, k)$ takes a vector $\vec{v} = (v_0, v_1, \ldots v_c)$ and transforms it into a potential solution polynomial set by unweighting v_0 by k, then dividing $v_1, \ldots v_c$ by v_0. $\mathsf{IsSol}(V, \mathsf{ws}, t, k)$ checks whether the set V agrees with at least t points in the working set ws and if all the entries are actually polynomials of degree less than or equal to k. Finally, $\mathsf{ProcessSol}(P, \mathsf{solns}, \mathsf{ws})$ adds the polynomial set P to solns and removes all agreeing points from ws.

We now give an overview of CH*-MDSS, which is given in Algorithm 1. Recall that this construction is based on the one presented by Cohn and Heninger [14], which creates a lattice for multivariate polynomials Q where a short lattice basis corresponds to low degree Q that have the polynomials of interest as common roots. In particular, we focus our attention on the "linear" version of this decoder, since it corresponds to a relatively small lattice (with dimension growing linearly

with c) and finding the common roots only requires solving a linear system of equations. While this algorithm is a good starting place, it is not ideal, since it still requires a two step procedure, where a lattice reduction is first done to get a short basis before potentially heavy post-processing. We would like to find solutions in one-shot, with minimal additional overhead.

Fortunately, such efficiency gains may be possible by using the dual of the lattice presented in [14]. The dual directly contains our solutions $(p_1 \dots p_c)$ as their dot product with any vector in the primal is a multiple of their syndrome polynomial by construction.[8] We also know these vectors are relatively short because of the degree bounds on the p_i. Thus, we may hope that these solutions show up in a reduced basis.

Constructing this dual lattice, reducing it, and searching for short vectors that correspond to polynomial sets that agree with our input constitutes the first stage of the algorithm (lines 3-7, Algorithm 1).

Experimentally, we found that this first part of the algorithm is capable of finding solutions not only in the random noise setting (which was explored in the past for the primal lattice) but even under our input distribution, with a few caveats:

- Often the reduced basis only contained one solution of interest, the solution agreeing with the most input points
- When there was no single solution agreeing with at least two more points than any other, the short basis contained no solution vector of interest

The former problem can be solved by an iterative solving procedure that removes an input point once a solution has been identified that agrees with it [9]. The second issue is trickier to deal with. To give a high level overview, in these cases we can identify smaller sublattices that contain our solution vectors and then tweak them to allow for a more efficient search of possible solution vectors over this space. A detailed explanation can be found in the full version of this paper. The procedure in lines 15-29 allow us to identify a single solution in the second case, which is enough to give us an iterative algorithm for finding all solutions.

We now state the assumption that must be fulfilled for correctness to hold.

Heuristic Assumption 1. *Let $CD_{c,k,\mathsf{max},\vec{m},\vec{s}}$ be defined as in Definition A.3. Then:*

$$\Pr\left[\mathsf{CH}^*\text{-}\mathsf{MDSS}(S) \neq \left\{ s_i \; s.t. \; m_i \geq \frac{\mathsf{max}+ck}{c+1} \right\} \;\middle|\; \begin{matrix} S \leftarrow CD_{c,k,\mathsf{max},\vec{m},\vec{s}} \\ \mathsf{Unique}(S)=\mathsf{True} \end{matrix} \right] \leq negl(\log|\mathbb{F}|)$$

[8] To be precise, if there is a solution $(p_1 \dots p_c)$, the target vector in the dual will have the form $(z^k E(z), p_1(z)E(z), \dots p_c(z)E(z))$ where $E(z)$ is the error locator polynomial. This is due to scaling the entries in the lattice to be in $\mathbb{F}[z]$

[9] This is only possible because it is very unlikely, given our input distribution, that there will be an input point agreeing on more than one solution

Algorithm 1: CH*-MDSS

Input : $k, t, n, \{(\alpha_i, \beta_{i,1}, \dots, \beta_{i,c})\}_{i=1}^{n}$
Output : a list $\{(p_1^i \dots p_c^i)\}_{i=1}^{z}$ or $\perp$

Abstract

We present a detailed analysis of Samsung's Offline Finding (OF) protocol, which is part of Samsung's Find My Mobile system for locating Samsung mobile devices and Galaxy SmartTags. The OF protocol uses Bluetooth Low Energy (BLE) to broadcast a unique beacon for a lost device. This beacon is then picked up by nearby Samsung phones or tablets (the *helper* devices), which then forward the beacon and the location it was detected at, to a vendor server. The owner of a lost device can then query the server to locate their device. We examine several security and privacy related properties of the OF protocol and its implementation. These include: the feasibility of tracking an OF device through its BLE data, the feasibility of unwanted tracking of a person by exploiting the OF network, the feasibility for the vendor to de-anonymise location reports to determine the locations of the owner or the helper devices, and the feasibility for an attacker to compromise the integrity of the location reports. Our findings suggest that there are privacy risks on all accounts, arising from issues in the design and the implementation of the OF protocol.

1 Introduction

Portable devices such as smart phones and tablets often come with a feature that allows their owner to find those devices when they are lost, typically through the use of a web portal provided by their vendors, such as Google's Find My Device [15], Samsung's Find My Mobile (FMM) [28] and Apple's Find My [2]. A typical requirement for such a feature to work is that the lost device must be connected to the internet so that it can send its location report to a vendor server in the event that its owner flags the device as lost. In recent years, mobile device manufacturers such as Samsung and Apple have extended their lost-device tracking systems with an *offline finding* (OF) feature, which allows a lost mobile device to be found even when it does not have an internet connection. Both Apple and Samsung OF features share two key elements: the use of Bluetooth Low Energy (BLE) for short range transmission of data between devices of a vendor, and crucially, an extensive network of (internet-connected) mobile devices (which we call *helper devices*) that relay location information to a vendor controlled server. We refer to the latter as the *OF network*. The basic idea is quite simple: when a lost device loses its internet connection, it starts broadcasting a unique beacon over BLE, which is then picked up by nearby helper devices participating in the OF network, who then forward the beacon and the location it is found to a vendor server. In this work, we are mainly concerned with Samsung's FMM Offline Finding (OF) feature [29], which was introduced in 2020. An owner can track their devices' locations through Samsung FMM application running in a Samsung mobile device (e.g., a phone or a tablet).

In 2021, Samsung released the Galaxy SmartTag [35], which is a small BLE tracker that can be attached to various items to keep track of their locations. SmartTags are not capable of connecting to the Internet, so they rely on the OF network for long range location tracking (outside the range of BLE). SmartTags are registered and controlled through SmartThings, which is an umbrella control and management platform for a large variety of smart devices and home appliances. OF is also supported for SmartTags using the "SmartThings Find" add-on which works in conjunction with FMM.

Devices in Samsung's OF network can be categorized into three roles: the owner device, the helper device, and the lost device. A mobile device can be registered to the Samsung OF network through the FMM app, while a SmartTag can be registered through Samsung SmartThings app. Each registered device is linked to the owner's account under which it was registered from. When a registered device loses internet connectivity, or in the case of SmartTags, when it is out of the BLE range from its owner device, it broadcasts certain data over BLE periodically. This data contains a rotating identifier, called the *privacy ID*, which is unique to the lost device and which, in theory, can only be linked to its owner by Samsung and the owner device. The helper devices consist of both Samsung devices (phones and tablets), and some third-party devices that support Samsung OF protocol. An active helper device periodically scans for BLE advertisements from nearby

OF devices and reports their locations to a location server. The location reports of the lost devices will be downloaded onto the owner device when the owner queries their locations. The effectiveness of the OF feature depends on the size of its OF network, which in the case of Samsung OF, is estimated to have around 200 million active helper devices [18] in 2022.

In the following, we shall refer to end-user devices, such as mobile phones and SmartTags, that participate in Samsung OF network as OF devices. Our work was driven by the following research questions:

(RQ1) *Identification of an OF device.* Can an OF device be identified through its BLE data?

(RQ2) *Unwanted tracking.* Can Samsung OF network be misused for unwanted tracking of a person or an object by a party other than Samsung?

(RQ3) *End-to-end location privacy.* To what extent does the design of the OF protocol protect the location privacy of the lost devices and the helper devices from the service provider (Samsung)?

(RQ4) *Location report integrity.* Is it possible for an actor (other than the owner and the vendor) to forge a location report of a lost device?

RQ1 concerns the privacy protection of the owner of an OF device against (long term or short term) location tracking through the BLE data emitted by the device by an adversary. RQ2 addresses an attack scenario where a tag is used by its owner to stalk a person without their consent [12]. RQ3 raises the question as to what extent Samsung is aware of the movement of both the owner devices and the helper devices. RQ4 is more of a security (integrity) issue rather than a privacy one and addresses a scenario where the attacker intentionally disrupts the location tracking capability of the OF network through false location reports.

Our main contributions are as follows:

- We provide the first comprehensive reverse-engineering of Samsung OF protocol that allows us to answer definitively the research questions (RQ1 to RQ4) raised above.
- We identified several vulnerabilities that would allow an attacker to link BLE packets observed from a target device over multiple observations, through BLE interactions only, allowing a long term identification of an OF device through its BLE data (RQ1).
- Through our analysis of the OF protocol, we managed to impersonate completely a SmartTag to the OF network. This opens the possibility of creating a custom tracking device that can be tuned to circumvent potential anti-tracking mechanisms by the vendor.
- Our analysis also confirmed that unwanted tracking (RQ2) is possible.
- Our analysis suggests that the vendor does indeed possess the information needed to link an account to a location report (RQ3). Moreover, the vendor server does not appear to check the integrity of the location reports, opening it to manipulation by third parties (RQ4).

Coordinated disclosure. We have reported all the issues we found (see §4) to Samsung and followed an industry-standard of a minimum of 90-day embargo period, prior to the publication of these issues. One of the issues we raised concerns the small pool of privacy IDs being used for FMM BLE packets, which has now been assigned a CVE (CVE-2022-33707, SVE-2022-0126). The more critical security issues that affect the server-side of Samsung OF network, related to SmartTag registration and the location reporting, have been fixed. Section 4.5 provides an update on the status of these issues. Not all the issues we reported have been patched, and in one case, concerning the issue of de-anonymisation through BLE DFU mode (see Section 4.1), the vendor confirmed that they have no plans to issue a fix. However, we believe there is significant public interest in the disclosure of these issues, both from the end user perspective, so that they can make informed decisions on the use of affected devices, and from a scientific perspective, as some of the issues we discovered arise from design choices not specific to a particular vendor.

Related work. The closest to our work is the security and privacy analysis of Apple's FindMy network [21]. Their study uncovered design and implementation flaws that could lead to location correlation attacks and unauthorized access to location histories. They reverse-engineered FindMy protocols and showed that one could create custom tracking devices leveraging on the FindMy network [30].

Several vulnerabilities [11] have been identified in an earlier version of Samsung FMM app, that allow, among others, a malicious app installed in the device to manipulate the URL endpoint accessed by the FMM app and to access unprotected broadcast receivers in the FMM app. This analysis was done prior to the introduction of the offline finding features to FMM, so it did not cover the OF related vulnerabilities.

Both Apple AirTags and Samsung SmartTags use the nRF52 series System on Chips (SoC), which are known to be vulnerable to a power glitching attack. The firmware of both AirTags and SmartTags have been extracted by researchers using this attack [5,27]. While AirTag firmware has been studied extensively [27], we are not aware of any reverse-engineering on the SmartTag firmware prior to our work.

There have been a variety of BLE trackers prior to the introduction of AirTags and SmartTags, such as the Tile tracker. Weller et. al. [34] provides a detailed security and privacy analysis of the security and privacy aspects of these trackers, focusing on their interactions with their associated mobile apps and the backend cloud servers for crowd-sourced location tracking. However, they did not analyze the privacy issues arising from the BLE protocols used in these trackers.

Apple's FindMy network consists of hundreds of millions of active devices, which has raised privacy concerns on whether the network can be abused for malicious tracking. Apple has implemented an anti-tracking framework to detect unknown FindMy trackers for iOS devices. However, Mayberry et al. [25] discovered that Apple's tracking detection mechanism can be defeated through a number of techniques. One technique exploits a "blindspot" in Apple's anti-tracking algorithm that ignores lost mobile devices, focusing only on detecting lost AirTags. As we shall see later, Samsung's anti-tracking feature suffers from a similar oversight.

AirGuard is an anti-tracking application developed by SEEMOO lab to protect Android users from BLE trackers that leverage Apple's FindMy network [20]. It has a higher success rate and lower false positive rate in detecting and reporting trackers compared to Apple's built-in anti-tracking.

A BLE device can be identified by its MAC address. To avoid long-term tracking of a BLE device, vendors often implement anti-tracking mechanisms, such as by randomizing its MAC address. However, issues have been found in implementations of the communication protocols of BLE devices, which can be used to defeat such anti-tracking mechanisms [8–10, 24]. Our own investigations show that many of these issues also affect SmartTags.

Another closely related research area is BLE-based contact-tracing applications, such as Google-Apple Exposure Notification (GAEN) framework [16], DP3T [33], Singapore's TraceTogether and Australia's COVIDSafe [32]. The BLE-related attack surface of these applications, i.e., in relation to RQ1, is similar to our findings, e.g., attacks discussed in [3, 7, 22, 32] show that devices running these applications can be linked through their BLE data. Another similarity is the "wormhole" relay attack demonstrated in [3], which is similar to the relay attack discussed in Section 4.2. There is, however, a crucial difference between an offline location tracking system and a contact-tracing system. In the latter, the "location" information (which takes the form of a list of anonymized user IDs detected in proximity, without any geolocation information) is not sent to users of the applications, but only to a designated health authority. This essentially makes the RQ2, i.e., the possibility of unwanted tracking irrelevant.

Outline. The remainder of the paper is structured as follows: Section 2 gives a brief overview of relevant cryptographic and BLE related concepts. Section 3 presents technical details of the OF protocol that result from our investigations. This section covers the OF operations for SmartTags. The OF operations for FMM devices are a much simplified version of the SmartTag protocol, so its security and privacy issues are subsumed to those of SmartTags. The interested reader can consult Appendix B for details of the FMM protocol. In Section 4, we perform a security and privacy analysis on Samsung OF protocol based on our findings discussed in previous sections. In Section 5 we discuss the broader implication of our findings on the design of offline finding protocols in general. Section 6 concludes the paper. For clarity, our presentation of the OF protocol abstracts away some concrete details such the data format and the BLE interface used, but these details are available in the appendices.

2 Background and methodology

This section gives a very brief overview of the relevant cryptographic functions used in the Samsung OF protocols and some basic concepts related to BLE.

ECDH key exchange and AES block cipher. There are two main cryptographic constructions used in the OF protocol: the Elliptic-curve Diffie-Hellman (ECDH) key exchange protocol and the AES block cipher and its associated encryption modes. We explain briefly each of these constructions. For further details, we refer interested readers to [19] for ECDH and [13] for the AES algorithm.

The ECDH builds on the Diffie-Hellman key exchange protocol [14], where the underlying group operations are defined over an elliptic curve (EC). Samsung's OF implementation of ECDH uses the elliptic curve Curve25519 [4], which was designed to achieve high speeds at computation without compromising the security strength. The Advanced Encryption Standard (AES) algorithm [13] is a symmetric block cipher that is widely used for data encryption, and as a building block for other cryptographic functions. Samsung's FMM and SmartTags implement AES CBC mode cipher with PKCS#7 padding scheme [26] to encrypt/decrypt data for various OF related operations.

Bluetooth Low Energy (BLE) SmartTags uses BLE [17], which is a short-range wireless communication technology, for data transmission. The protocol stack of BLE consists of various layers and profiles, of which, the most relevant ones to this work are the Generic Access Profile (GAP) and the Generic Attribute Profile (GATT). GAP defines the procedures for device discovery and connection establishment. A BLE device can operate in one or more of the following roles:

- Advertiser: a device that sends out BLE data that is available to any nearby Bluetooth capable devices.
- Observer: a device that listens to BLE advertisement data and may process the data from advertisers.
- Central: a device that initiates a connection after receiving advertisement data from an advertiser.
- Peripheral: a device that accepts the incoming connection from a central.

GATT defines the data organization and exchange over connections between BLE devices. GATT uses a hierarchical structure to organize data. A GATT profile may contain multiple services, each contains one or more characteristics. Each characteristic is a container of user data. A characteristic can

be followed by descriptors, which provide additional metadata of the characteristic and its value.

BLE has two ways of transferring data: advertising over BLE and data exchange over connections. Advertising is the process of a BLE device sending out data packets in one-way, while communication over connections allows bidirectional data transfer between the peripheral and the central. Data packets are exchanged through characteristics in the GATT server of the peripheral device. A BLE device is addressed through its MAC address, which is a 48-bit identifier. There are four types of MAC addresses: Public Address, Random Static Address, Random Private Non-Resolvable Address, and Random Private Resolvable Address. A Public Address is registered with IEEE and never changes. A Random Static Address is not registered and remains constant during device runtime. Each Bluetooth-capable device has an *Identity Address*, which is either a Public Address or Random Static Address. The two types of Random Private Addresses (Non-Resolvable, Resolvable) are used for privacy protection purposes. Random Private Non-Resolvable Addresses are generated completely randomly, whereas Random Private Resolvable Addresses (RPAs) are generated using a key-hashed function from a random seed value and a 16-byte key called the Identity Resolving Key (IRK). The possession of the IRK of a device would also allow one to de-anonymize its RPAs.

Pairing is the process by which two BLE devices exchange necessary information so that an encrypted connection can be established. BLE has several pairing modes, which are determined by the authentication requirements and input/output (IO) capabilities of the pairing devices. As part of pairing, the IRKs are exchanged, so the devices can identify their respectives RPAs using the IRKs. BLE supports different pairing methods to authenticate participants in the pairing procedure. The simplest pairing method, called *Just Works*, does not check the authenticitiy of the participants, and has been exploited to steal the IRK of a target device stealthily [32,36,37].

Methodology. A combination of investigation approaches were used to understand the OF protocol for SmartTags and the FMM app. Devices involved in the analysis include a research laptop equipped with a BLE 4.2 adapter running Ubuntu 20.04 LTS, a number of Samsung mobile phones running Android versions 8.0 - 12, and SmartTags with firmware version 1.01.26 and 1.02.06. We used a combination of application and firmware reverse engineering to study the innerworking of various protocols involved in the OF network, analysis of various logs produced by Android systems and applications, and analysis of both BLE and network traffic between devices and vendor servers. The methodology is quite standard for vulnerability research so we omit the details here.

3 The offline finding protocol

This section discusses the key findings on the Samsung offline finding (OF) protocol. Here we discuss only the OF protocol

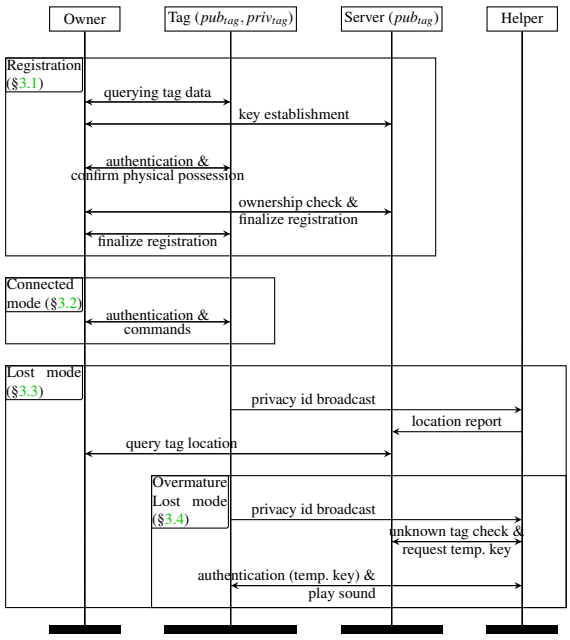

Figure 1: An overview of Samsung OF protocol for SmartTags

for Galaxy SmartTags, but details of the OF protocol for FMM, which is a simplified version of the SmartTag protocol, are available in Appendix B. Our analysis was performed on SmartTags with firmware versions 1.01.26 and 1.02.06, and the FMM app versions prior to version 7.2.24.12.

The OF protocol for SmartTags involves both online interactions (over the Internet) with various vendor servers and offline interactions (over BLE) with nearby tags and mobile devices. We discuss here four important subprotocols, which are summarised in Figure 1. The communication between the devices and the server is done through HTTPS, which we assume to be secure. There are four principals involved: the owner device, the tag, the vendor server and the helper device. The subprotocols are as follows:

1. The registration protocol (§3.1). This protocol involves the owner device, the tag and the server. The owner initiates the protocol by acquiring relevant tag data, such as the serial number, firmware version, etc., and initiates a key establishment protocol with the server, to derive various symmetric keys that will be used in subsequent interactions with the tag.

2. The protocol for tags in the *connected mode* (§3.2). This protocol is executed right after the registration, and whenever the tag is in the proximity of the owner device after having been out of the BLE range. It contains subprotocols for authenticating the owner device to the tag and vice versa. Once authenticated, various commands and data may be exchanged over BLE.

3. The protocol for tags in the *lost mode* (§3.3). This protocol is triggered after the tag has lost its BLE connection to its owner for less than 24 hours. In this state, it broadcasts anonymized rotating *privacy IDs* that trigger nearby helper devices (who are scanning for privacy IDs periodically) to record and report the locations of the recorded privacy IDs to the server.

4. The protocol for tags in the *overmature lost mode* (§3.4). A tag transitions to the *overmature lost mode* after being lost for over 24 hour. A helper device that detected a tag in the overmature lost mode would initiate an anti-stalking detection process. This process aims to enable the helper device to locate a (potentially) tracking tag by playing sound on the tag. To play sound, the helper would need to obtain a temporary key from the server to authenticate itself to the tag.

3.1 SmartTag registration

The SmartTag registration protocol requires interacting with an unregistered tag and the vendor server. For the latter, there are actually multiple servers involved, providing services such as user authentication, application related services such as remote attestation, and services related to storing and retrieving location reports. For simplicity, we shall refer to these servers collectively as the vendor server (or simply "the server") in the following discussion.

The interaction between the owner device and the tag is done through BLE using BLE advertisement and a GATT profile. A SmartTag uses two UUIDs to advertise its presence over BLE: FD59 for non-registered tags, and FD5A for registered tags. SmartTags do not support internet connectivity and thus rely on the owner device (typically a mobile phone) to perform various setups over BLE connections. This is done through its GATT profile, which defines various services and characteristics that the tag and its owner device use to exchange data and commands. In the following, we shall omit the concrete UUID used for each characteristic in the GATT profile, and refer to it using a symbolic name instead. But detailed characteristic UUIDs can be found in Appendix C on arXiv. The SmartTag GATT profile has four primary services which can be summarized as follows:

Authentication Service The Authentication Service uses three characteristics, `NONCE`, `ENONCE` and `SUPPORTED_CIPHER`, for authenticating a connected device over BLE.

DFU Service Service UUID FE59 is a part of the nRF52833 Buttonless Secure DFU service for over-the-air firmware updates. It has a writeable characteristic (`BUTTONLESS_DFU`) that can be used to reboot the tag.

Onboarding Service Service UUID FD59 is used for device onboarding/registration activities. During the registration process, the owner device and the tag exchanges configuration and cryptographic data over various characteristics under this service.

Command Service Service UUID FD5A is primarily used for performing more complicated interactions between the owner device and a tag, such as executing a supported command (e.g., alarm, changing ringtone) on the tag.

A SmartTag registration is initiated by an owner device running the SmartThings app. It involves online interactions with the server, and offline interactions with the tag. The interaction with the server requires a valid user account. In the following discussion, we shall assume that a valid user account has been created and an authenticated session between the owner device and the server has been established. The registration protocol consists of five stages: key establishment, owner-tag authentication, confirmation of physical possession of the tag, tag ownership check, and registration finalisation.

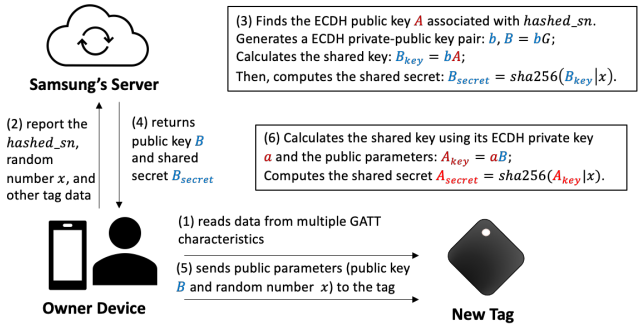

Figure 2: Shared secret establishment protocol

Stage 1: key establishment The first stage of the registration protocol is essentially a key establishment protocol between the tag and the server, mediated by the owner device. Note that since we do not have access to the server code, our analysis of this stage is based on our analysis of the SmartTag firmware and the intercepted traffic between the owner device and the server. Our findings suggest that the tag keeps a pair of private-public ECDH key (a, A_{pub}), which is fixed for the lifetime of the tag and that the server keeps at least the public key of each tag. A tag is identified uniquely via its serial number, which is the identity address of its BLE controller. The public-private key pair of the tag is never sent out from the tag or the server. The shared secret establishment protocol is summarized in Figure 2, which we elaborate below.

Step 1. The owner device obtains the necessary registration data from the tag, through the tag's advertisement payload and Onboarding Service. Among this registration data is a hashed serial number (`hashed_sn`) unique to the tag, which corresponds to the SHA256 digest of the BLE identity address of the tag.

Step 2. The owner device generates a 32-byte random value x, and sends x along with the registration data obtained from Step 1 to the server.

Step 3 & 4. After receiving the request, the server looks up the public key of the tag A_{pub} associated with the `hashed_sn`. The server then generates an ephemeral private-public key pair (b, B_{pub}), and computes the ECDH shared key $B_{key} = bA$. Finally, the shared key is concatenated with the random number x to form the input for the SHA-256 hash function to produce the shared secret: $B_{secret} = SHA256(B_{key}|x)$. The server then sends B_{pub} and B_{secret} to the owner device.

Step 5. The owner receives B_{pub} and B_{secret} from the server, and forwards B_{pub} and x, to the tag.

Step 6. The tag receives B_{pub} and x from the owner device and computes $A_{key} = aB$ and $A_{secret} = SHA256(A_{key}|x)$.

By the property of ECDH, assuming no tampering from an adversary, at the end of Step 6, we should have $A_{secret} = B_{secret}$. That is, all participants now share the same secret B_{secret}. This shared secret will be used next to compute several AES keys that will be used in subsequent protocols.

The first 16 bytes of the shared secret B_{secret} are taken as the `masterSecret`. It is used to derive six 16-byte subkeys for securing communication between the owner device and the tag. Note that Samsung OF protocol does not use any default BLE pairing and authentication mechanisms, so this shared secret is unrelated to BLE Long Term Key (LTK) that is normally exchanged as part of BLE pairing protocols [17].

The subkeys are derived using a key derivation function, given below, that combines the `masterSecret` and a parameter that is used to differentiate subkeys:

$$kdf(k,x) = SHA256(m(k,x))[0:15]$$

where $m(k,x) =$

Bytes 0-15	Bytes 16-19	Bytes 20-
k	00000001	x

.

The following four subkeys are computed by the owner device, the tag and (presumably) the server.

1. **Owner authentication key**: This key is used by the owner to establish an authenticated BLE session with a SmartTag. It is computed by applying :

$$AK_o = kdf(\text{masterSecret}, \text{"bleAuthentication"})$$

2. **Owner GATT key**: This key is used for encrypting the data exchanged in the GATT interactions between the owner and the tag. It is dependent on a nonce and is valid for a single session of interactions with the tag.

$$GK_o(nonce) = kdf(\text{masterSecret}, nonce)$$

Here *nonce* is a 16-byte value received from the SmartTag during each BLE authentication process, see §3.1.

3. **Privacy key** : This key is used for generating unique privacy IDs for a SmartTag (see §3.3).

$$PIDK = kdf(\text{masterSecret}, \text{"privacy"}).$$

4. **Advertisement signing key** : This key is used for signing and validating the integrity of the BLE data broadcasted by a SmartTag:

$$ASK = kdf(\text{masterSecret}, \text{"signing"})$$

Two additional subkeys are derived by a SmartTag and the server, but not the owner device (see §3.4 for details of when and how these keys are used).

- **Non-owner authentication key**. This key is used by a non-owner device to authenticate to the tag.

$$AK_{no} = kdf(\text{masterSecret}, \text{"nonOwner"})$$

- **Non-owner GATT key**. This key is used in a GATT session between a non-owner and the tag for exchanging commands. It is dependent on a nonce that is exchanged during the GATT interaction.

$$GK_{no}(nonce) = kdf(AK_{no}, nonce).$$

Notice that unlike the owner GATT key, the non-owner GATT key is not generated directly from the masterSecret; rather it is derived from the non-owner authentication key.

Stage 2: Owner-tag authentication After computing the `masterSecret` and the AES keys, the owner device initiates a two-way authentication with the tag to establish an authenticated connected session. This protocol is implemented through BLE interaction only, using the Authentication Service of the GATT profile of the tag. In the protocol description below, O denotes the owner device and T denotes the tag. Throughout the remainder of the paper, we shall use the notation $E_k(x,y)$ to denote the AES/CBC/PKCS7 encryption of plaintext y with key k and initialization vector x.

1. $O \rightarrow T$: n_O
2. $T \rightarrow O$: n_T
3. $O \rightarrow T$: $E_{AK_o}(n_T, \text{"smartthings"})$
4. $T \rightarrow O$: $E_{AK_o}(n_O, \text{"smartthings"})$

Here n_O and n_T refer to nonces generated by O and T, respectively. At Step 3, the tag checks that the received ciphertext is indeed the encryption of the text "smartthings"; likewise in Step 4, the owner checks that the received ciphertext is of the expected form. If any of these checks fail, the authentication fails; otherwise the authentication is established, and both the tag and the owner derive an Owner GATT key using n_T, i.e., $gk_o = GK_o(n_T)$. This key acts as a session key that is used to secure data transmission in this authenticated session, until the BLE connection is terminated.

Stage 3: confirming physical possession of the tag. After the owner and the tag have successfully established an authenticated BLE connection and derived the session key gk_o, the next step is to establish the physical presence of the tag. In a normal registration flow, the SmartThings app will ask the user to press the tag button to ensure physical possession of the tag. Pressing the tag button sets the value of the `CONFIRM_STATUS` characteristic on the tag to 0x01 (encrypted using gk_o with IV set to n_T) from the default value 0x00.

$$T \rightarrow O \ : \ E_{gk_o}(n_T, 0x01)$$

The owner's device would only continue the registration flow after validating the value of this characteristic.

Stage 4: tag ownership status check This stage checks the ownership status of the tag to ensure that it is not currently registered to another user. This is done via a simple request to the server, containing the serial number *sn* of the tag. If the server indicates that the tag has already been registered to another account, the registration process will abort.

Stage 5: finalizing tag registration This stage creates an online profile of the tag, associated with the owner's account. The protocol can be described abstractly as follows (a more detailed version can be found in Appendix C on arXiv), where S denotes the server.

1. $O \rightarrow S$: sn, id, B_{secret}
2. $S \rightarrow O$: $deviceId, metadata$
3. $O \rightarrow T$: $E_{gk_o}(n_T, metadata)$
4. $O \rightarrow T$: $E_{gk_o}(n_T, curtime)$
5. $O \rightarrow T$: $E_{gk_o}(n_T, \text{"Finish"})$
6. $T \rightarrow O$: pid
7. $O \rightarrow S$: pid, loc

In Step 1, the owner device sends a record, containing, among others, the tag serial number *sn*, an identifier *id* and the shared secret B_{secret} established in §3.1. Recall that *sn* is used in the ownership status check in the previous stage, to avoid a tag being registered twice. Our observations showed that *sn* and *id* were identical and equal to the tag BLE identity address.

In Step 2, the server returns a unique *deviceId* that is linked to the tag, and a *metadata* record that contains the following fields: the *privacy Id pool size* (*pidsize*), the *privacy Id seed* (*pidseed*) and the *privacy Id IV* (*pidIV*). The owner device keeps a record of these parameters and in Step 3, forwards them (encrypted) to the tag. These parameters are used later by the tag to generate BLE advertisements. The *deviceId* can be used later to lookup the location of the tag.

In Step 4, the owner device sends the current time information (in UTC) to the tag so the tag can synchronize its time with the owner. Finally, the owner sends an encrypted message (`"Finish"`) to indicate the end of the registration process and disconnect from the tag in Step 5.

In Step 6, the tag broadcasts BLE data containing a privacy ID (see §3.3) that the owner device uses to identify it. After discovering its own tag, in Step 7, the owner device reports the current location *loc* and the tag *pid* to the location server. The first location report of a tag made by its owner device creates a device profile on the server, which bonds the tag's ownership status with the owner's Samsung account, preventing others from registering the tag (§3.1). Crucially, the server uses the value *id* as the identity of the tag for the ownership bonding.

3.2 Owner-Tag interaction

A tag may move in and out of the BLE range of its owner device. The owner device (which also acts as a helper device for tags it does not own) periodically scans for tags in its proximity. When a tag is detected in the proximity of its owner, after having been away, the owner (through the SmartThings app) will automatically initiate the owner-tag authentication protocol over BLE, as described in §3.1. Upon successful authentication, the app will show the tag as connected and the owner can perform various supported commands on the tag, such as ringing the tag. SmartThings also allow an option to configure the tag to perform limited actions on the owner device, such as ringing the owner device when a physical button in the tag is pressed. Appendix C on arXiv contains details of some of these commands. Each command is triggered by exchanging encrypted data $E_{gk_o}(n_T, Data)$, where gk_o is the owner GATT key and n_T is the tag's nonce sent during the owner-tag authentication stage (§3.1), and *Data* is an encoding of the command:

$Data =$

Bytes 0-3	4	5-
Counter	Opcode	Argument(s)

The counter value corresponds to the total number of commands successfully sent by O during the current authenticated session. The opcode specifies the command type, as a characteristic may support multiple commands, e.g., opcode 0 for alarm off, 1 for alarm on.

3.3 Location querying and reporting

We now discuss the subprotocols for an owner device to query its lost tags from the location server, and for a helper device to report location information of lost tags to the server. The location querying protocol consists only of simple POST requests to an URL under the `api.samsung.com` domain, so we shall omit the details. In the following, we focus on subprotocols used for location reporting.

SmartTag BLE advertisement data. The helper device identifies nearby (lost) SmartTags through their BLE advertisement data only, so we first present details on the advertisement structure and how it is generated. Figure 3 shows the

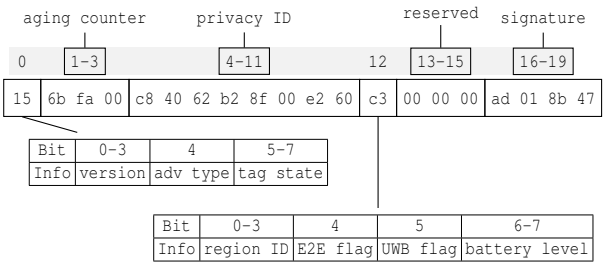

Figure 3: The OF advertisement structure for SmartTags

Bits 5-7	Name
001 (1)	Premature lost mode
010 (2)	Lost mode
011 (3)	Overmature lost mode
100 (4)	Paired with one device
101 (5)	Connected to one device
110 (6)	Connected to two devices

Table 1: Operating states of a SmartTag

OF advertisement structure for SmartTags with the following fields highly relevant to the OF protocol: the *tag state* (byte 0), the *aging counter* (bytes 1-3), the *privacy ID* (bytes 4-11), and the *signature* (bytes 16-19).

The tag state is encoded in bits 5-7 of byte 0 and denotes the operating states of a tag. There are six different tag states, shown in Table 1. The state of a registered tag becomes premature lost once it is disconnected from its owner device or rebooted. After operating in premature lost mode for 15 minutes, the state changes to lost, which informs nearby helper devices that it is considered lost. After 24 hours in lost mode, the state becomes overmature lost, where certain BLE operations slow down for power saving. A helper device that finds a tag in the overmature lost mode will initiate an anti-tracking process (see §3.4).

Bytes 1-3 store the aging counter, a timestamp computed using the tag's time (UTC) and a hardcoded constant: $agingCounter = (tagTime - 1593648000)/900$. The aging counter is universal for all SmartTags in-sync with the server's time and updates periodically.

Bytes 4-11 store an 8-byte privacy ID, which is a unique identifier of a SmartTag. Each registered SmartTag has a set of unique privacy IDs called the privacy ID pool. This set is deterministically generated using the privacy key (*PIDK*) and the privacy ID configurations (*pidsize*, *pidseed*, *pidIV*) that the server sent to the owner during the finalization stage in the registration process (§3.1). The privacy IDs are an essential part of the OF protocol as they associate a tag with its owner's Samsung account. For each $i \in \{1, \ldots, pidsize\}$, the privacy ID pid_i is generated as follows:

$pid_i = E_{PIDK}(pidIV, input_i)$, where $input_i$ is the byte array

Byte 0	Byte 1	Byte 2-9	Byte 10	Byte 11
x_i	y_i	*pidseed*	x_i	y_i

$x_i = (i \gg 8) \wedge 256$ and $y_i = i \wedge 256$. Here, $\gg$ represents right bitshift and $\wedge$ denotes bitwise AND.

The privacy pool size for SmartTags is 1000 when we made our analysis, but the value is controlled by the server so it is not firmware-specific.

The signature field at the end of the advertisement data serves as a cryptographic checksum for the first 16 bytes. Let *blePayload* denote the first 16 bytes of the BLE advertisement data. Then the four signature bytes are obtained from the first 4 bytes of the $fullSignature$ defined below:

$$fullSignature = E_{ASK}(pidIV, blePayload)$$

where *ASK* is the advertisement signing key (see subkey 4). Any changes to the first 16 bytes of the advertisement will likely cause the signature bytes to change correspondingly, which allows the integrity of the BLE data to be validated by parties with the privacy ID configuration and the shared secret of the tag, such as the owner and the server.

A tag rotates its advertisement data periodically. A tag in any non-overmature lost mode updates its privacy ID, aging counter (incremented by 1), and signature every 15 minutes. Under the overmature lost mode, a tag updates the aging counter and signature every 15 minutes. However, the frequency for shuffling the privacy ID reduces from once every 15 minutes to once every 24 hours.

Location reporting A helper device regularly scans for BLE advertisement data from nearby SmartTags. It filters BLE advertisements based on the advertising UUID for SmartTags (FD5A). The helper device stores the privacy IDs of lost devices in a local database that can store up to 1000 entries. Note that these privacy IDs do not necessarily represent distinct devices, as a tag can generate multiple privacy IDs and the (honest) helper device does not have the privacy key (*PIDK*) needed to link these IDs. A privacy ID of a tag is marked as expired if it has not appeared in the BLE scanning for 15 minutes and will be removed from the database. Moreover, the helper device only reports locations of SmartTags in lost or overmature lost mode.

The helper device will report geolocations of lost SmartTags in the database based on estimated locations received from the WiFi or GPS service. Through reverse engineering and runtime analysis on a helper device, we found that each helper device has a pair of RSA 2048-bit private signing key (pk_H) and its corresponding verification key (pub_H) stored in the device, secured using Android keystore. Our analysis shows that these keys are embedded in a native library contained in the FMM apk, so they are likely not unique per device. The public key pub_H is signed by an intermediate CA owned by Samsung. These keys are used in the location report protocol below to certify the originality of the report

(in that it originated from an official Samsung device rather than an unauthorized third party).

To submit a location report, the helper must first obtain an access token from the server. This token request process is re-used again in another protocol (for interacting with an unknown tag), so we describe it separately here.

1. $H \rightarrow S$: REQ
2. $S \rightarrow H$: n_S
3. $H \rightarrow S$: $pub_R, n_S, sig(n_S, pk_H), cert(pub_H)$
4. $S \rightarrow H$: $access\_token$

In Step 1, the helper device generates a pair of private-public key (pk_R, pub_R) and then sends a request for location report to the server S. Concretely this step is done via a simple HTTPS GET request to S. The server responds with a 16-byte nonce, encoded as a hexadecimal string. H extracts the signing key pk_H from its keystore, after having performed an attestation protocol, and uses it to sign the nonce n_S. The helper then sends the nonce n_S, its signature $sig(n_S, pk_H)$, the certified public key $cert(pub_H)$, and pub_R to server. Note that the key pair (pk_R, pub_R) is not used in the location report but will be important later in another protocol. If the server checks the validity of the certificate and verifies the signature and sends a unique access token (which is a JWE token, tied to the nonce n_S) (Step 4) if everything checks out. The access token is then used to authenticate the location report.

$$H \rightarrow S \ : \ access\_token, report$$

where $report$ contains a list of advertisement data and the geolocation they were detected. Each location report allows a maximum of 5 recently found devices ($time_{found} \geq time_{current} - 1$ (minute)) from the local database to be reported. Each access token has a fixed expiry time (around 32 hours, based on our experiments), after which, the token request protocol above must be repeated to obtain a new token.

3.4 Unknown tag detection

The SmartThings app has a feature for detecting nearby overmature lost mode tags for anti-stalking purposes. If such as tag has been detected to be following a helper device, the SmartThings app gives the device owner an option to play sound on the tag to help locating it. Unlike AirTags where any user can issue a command to the tag to play sound [21], a SmartTag only responds to commands from an authenticated device. Since the helper device does not have the authentication key to authenticate to the tag, it would need the vendor server's help.

We assume that the helper device has performed the protocol to request JWE access token (see the location reporting protocol above) and obtained the token. To play sound on the tag, the helper needs to initiate a GATT connection and reads off a nonce from a certain characteristic. In the following, the notation $AE_{pub}(x)$ denotes an asymmetric encryption of plaintext x with public key pub.

1. $H \rightarrow T$: n_H
2. $T \rightarrow H$: n_T
3. $H \rightarrow S$: $access\_token, n_T, pid$
4. $S \rightarrow H$: X, Y
5. $H \rightarrow T$: en_T
6. $T \rightarrow H$: $E_{AK_{no}}(n_H)$
7. $H \rightarrow T$: $E_{gk_{no}}(n_T, command)$

In Step 4, the messages are computed as follows:

$$X = AE_{pub_R}(E_{AK_{no}}(n_T)) \qquad Y = AE_{pub_R}(GK_{no}(n_T))$$

where pub_R is the public key H generated in the access token request protocol. H decrypts these to obtain $en_T = E_{AK_{no}}(n_T)$ and $gk_{no} = GK_{no}(n_T)$ used in the remainder of the protocol. If we omit step 3 and 4, this protocol is similar to the owner-tag authentication protocol, except that the authentication key used is AK_{no}, and the GATT key used to send the command is $GK_{no}(n_T)$. Note that the server never discloses the AK_{no} itself. This request needs to be accompanied by a current access token, and an identifying information from the tag (i.e., its privacy ID pid, and some other information we omit here).

4 Security and privacy analysis

The four research questions guide the construction of our adversary model (Table 2) which we use for our analysis. This model classifies potential threats to the OF system into four categories based on our research objectives, extending the FindMy adversary model proposed in [21]. Firstly, our model subdivides proximity-based threats (A1) into passive (A1.1) and active (A1.2) categories, based on the level of interaction with the SmartTag's BLE interfaces. In line with the FindMy model, we consider network-based (A2) and service operator (A3) threats. Finally, we introduce a new Tag Owner category (A4), acknowledging potential security implications posed by SmartTag owners themselves. The final column indicates the related research questions, highlighting the implications of each threat category.

We now analyze the security and privacy issues affecting Samsung's OF system in alignment with our research questions, each addressed in the following sections: §4.1 (RQ1), §4.2 (RQ4), §4.3 (RQ3), and §4.4 (RQ2). Then, we provide an update on various bugs discussed in Section 4.5.

4.1 Proximity-Based Attack (A1-RQ1)

Attack Scenario By passively eavesdropping on BLE advertisements (A1.1) or actively engaging with the SmartTag's GATT server (A1.2), the attacker could identify and track the presence of the neighbour's FMM device or SmartTag, thereby gaining insights into their daily schedule.

Table 2: Adversary Model for Samsung SmartTags

Model	Assumptions	Capabilities	Impact
Passive Proximity-based (A1.1)	Within BLE communication distance with a tag; Controls a Bluetooth device	Record and replay BLE advertisements	RQ1 (§4.1)
Active Proximity-based (A1.2)		Interact with tag's GATT server	
Network-based (A2)	MITM position between Samsung server and a tag.	Intercept, redirect, or modify network traffic	RQ4 (§4.2)
Service Operator (A3)	Access to backend systems.	Access to all location reports and secret keys for each registered SmartTag.	RQ3 (§4.3)
Tag Owner (A4)	Owns a SmartTag; Controls a Bluetooth device; Direct contact with a victim	Hide the tag/customized tracking device in victim's belongings	RQ2 (§4.4)

Linkability Flaws The privacy ID pool size for OF devices is specified through a parameter sent by the server during the registration phase. For FMM devices, this is 51, while for SmartTags, it is 1000. As the pool size is not hardcoded on the client side, this could change in future updates to the server. As it stands currently, even with 1000 pool size, there is a high probability (due to the birthday theorem) that the same privacy ID could be reused in approximately $\sqrt{n}$ rotations, where n is the pool size. From our experiments, a few days of passive observations of the BLE data would cover all 51 privacy IDs of an FMM device. Recent versions of the FMM app have added a layer of obfuscation to the privacy IDs, keeping the same privacy ID pool size. However, our preliminary finding shows this can be easily de-obfuscated (see Appendix B.2.3). This obfuscation is not implemented in SmartTags.

GATT server leaking sensitive data. A registered SmartTag advertises on RPAs that frequently change. However, we have found that sensitive information leaked by characteristics in SmartTags' GATT profile (Appendix C.1 on arXiv) provides two ways for an attacker to de-anonymize the tag's identity: The `IDENTIFIER` characteristic contains its identity MAC address, and the `HASHED_SERIAL_NUMBER` characteristic contains the SHA256 hash of the identity address. Both values are static and unique for each tag and readable, which can be used by any nearby adversaries to identify the tag.

The `SUPPORTED_CIPHER` characteristic is readable and writable. It contains a default value `"AES128/CBC/PKCS7"` that specifies the cipher being used for BLE authentication. However, we discovered that writing custom values to this characteristic would overwrite the default value until the tag is restarted. Hence, an adversary can identify a registered tag by writing a custom identifier to this characteristic.

DFU device reboot. The Galaxy SmartTag has a DFU (Device Firmware Update) Service for secure over-the-air Firmware updates. We discovered that a SmartTag can be rebooted to the DFU mode by enabling indication on the Buttonless DFU characteristic and writing byte 0x01 to it [31]. This is actually not part of Samsung implementation; rather it is a default service available to nRF52 chipset for firmware updates so this vulnerability is not specific to SmartTags.

In the DFU mode, the tag advertises on a random static MAC address and waits for new firmware packages. If no data is received over a short period (approximately two minutes), the tag will reboot and resume its lost mode BLE operations. Additionally, the DFU mode reveals the identity MAC address of the tag - the MAC address used in the DFU mode ($addr_{DFU}$) equals to the identity MAC address ($addr_{Id}$) plus one [31], e.g., if $addr_{DFU}$ is observed to be 11:22:33:44:55:66, it can be inferred that $addr_{Id}$ is 11:22:33:44:55:65. However, after coming out of the DFU mode, the aging counter in the OF data is reset to 0, making OF tracking unavailable for the tag since the aging counter will be considered as too old and its location will not be accepted by the server.

Unintended pairing with a SmartTag. The update to firmware 1.02.06 introduces a new vulnerability. A SmartTag with this new firmware appears to accept pairing request, using the Just Works association mode, allowing the attacker to obtain the IRK and the identity address of the tag. The IRK can then be used to resolve the RPAs the tag use in BLE advertising. The IRK appears to be persistent across reboot and account switching. So removing the tag from a Samsung account and pairing with another account does not reset the IRK. The possession of the IRK allows a more stealthy tracking of the tag, as the attacker does not need to connect to tag; they simply observe the RPAs used to advertise the payload and de-anonymize them using the IRK.

Unintended Silent Pairing with an Owner Device. It is possible to impersonate a SmartTag and silently pair with its owner device by exploiting the following pairing behavior in the BLE specification: if a central device encounters an "Insufficient Authentication" error when interacting with a characteristic in a peripheral, it will initiate the pairing procedure with the peripheral. This behavior has been exploited in previous work [32, 36, 37] to initiate unintended pairing. As noted in [37], the attacker can influence the association method for the pairing, e.g., force the pairing to use a less secure method, such as Just Works.

In this attack, the attacker acts as the peripheral, while the central device is the owner device. The attacker creates a GATT profile of a SmartTag and replay the latest BLE advertisement from the tag to trick the owner device into initiating the BLE Authentication procedure (§3.1). BLE Authentication starts with the owner device writing to the `NONCE` characteristic of the (impersonated) SmartTag's GATT server. By set-

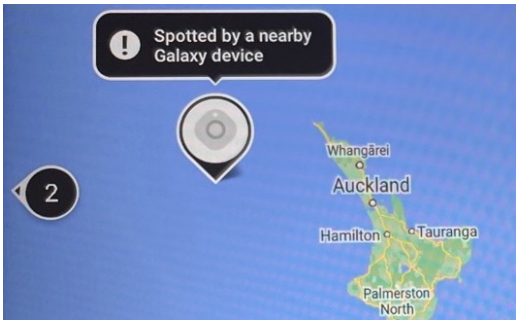

Figure 4: Fake location being updated on the owner device

ting the write permission for the `NONCE` to `encrypted-write`, the "Insufficient Authentication" error will be triggered upon write requests. Prior to the November 2020 patch [1], pairing is performed silently on most Android versions if Just Works is used [32]. Older models of Samsung devices that are not eligible to receive the update, such as Samsung Galaxy 7, remain vulnerable. This attack allows the attacker to obtain the IRK and the identity address of the owner device that can be used for long-term tracking.

4.2 Network-based Attack (A2-RQ4)

Attack Scenario In the context of network-based threats, an attacker stealing a tag (attached to a stolen item) may be able to hide the location of the stolen item by forging location reports using the tag's lost mode advertisement, leading the owner to a false trail.

Forging location reports We found several ways in which the integrity of the location report can be compromised, allowing an attacker to report fake locations of a lost tag.

Relay attack. Recall that the helper device simply forwards the BLE advertisement data of a lost tag or mobile device to the location server. There are no mechanisms for the helper to determine whether the data was indeed broadcasted by a nearby legitimate OF device. This allows a very simple relay attack: two attackers A and B in two different locations can collude by forwarding the BLE advertisement data of a device observed in A's location to B to be replayed at B's location, and vice versa. If there are helper devices in both locations, they will submit conflicting reports. Indeed, our experiments show the location server does not check for the consistency of the location reports, e.g., one device could appear to be detected in two different continents within seconds. This attack is especially effective against FMM devices as their advertisement data has no expiry time and can be replayed indefinitely. In contrast, with SmartTags, the aging counter in the advertisement prevents an indefinite replay. From our observation, we've noticed that advertisement data that is more than 7 days old will be rejected by the server.

Notably, this appears to be a universal issue affecting all crowd-sourced BLE tracking systems, including Apple's FindMy. Potential mitigation will be discussed in §5, such as using a distance-bounding protocol. However, we emphasize that this is a difficult problem that extends beyond the scope of this paper.

The next three attacks exploit the location report protocol itself. They correspond to three different ways in which the attacker can obtain an access token to submit location reports (see §3.3). Recall that the location report will only be accepted by the location server if the reporter has a valid access token. These attacks are more powerful as they do not require any helper devices to be present at all at the target location. For example, we were able to forge a report of an OF device detected in the middle of an ocean, as shown in Figure 4.

Re-using location reporting access token. As it turned out, once the helper device receives an access token from the vendor's server for location reporting, it records the token in its system log. Consequently, an attacker who owns a helper device can extract this token from the log and send fake location reports using it. This process can be easily automated as the report is done through a simple HTTPS POST request to the location server.

Access token renewal through signature replay. We discovered that in the access token request protocol, the server does not check whether the nonce n_S it sent in Step 2 is the same as the n_S it receives in Step 3. This allows an attacker who is in possession of a signed nonce from a previous session to replay it to get another access token. More specifically, suppose the attacker has n'_S and $sig(n'_S, pk_H)$. Then the following is a valid protocol run for token renewal:

1. $H \rightarrow S$: REQ
2. $S \rightarrow H$: n_S
3. $H \rightarrow S$: $pub_R, n'_S, sig(n'_S, pk_H), cert(pub_H)$
4. $S \rightarrow H$: $access\_token$

even when $n_S \neq n'_S$. Note that as all communication between the helper device and the location server are secured via HTTPS, for this attack to be possible, the attacker would need to be able to decrypt the TLS encrypted traffic. In our experiments, this was done by installing a root CA in a rooted helper device, and perform MITM attack between the device and the server. We observed that in recent Samsung phones running Android 10 or later, the location report process involves an attestation protocol before the phone could extract the signing key to sign the nonce. This attestation step would fail if it detects the phone is rooted. We only managed to execute this attack in an older Samsung phone running Android 8.0.

Extracting the signing key. We discovered a flaw that allowed us to extract the signing key itself.[1] This then allowed us to run the entire location reporting protocol outside the

[1] We decide to withhold the details of this flaw as it remains unpatched, to avoid it being exploited.

phone as we now possess all the information to pass the authentication stage to get the access token.

4.3 Service Operator (A3-RQ3)

Attack Scenario Without a strong end-to-end privacy, the service operator may infringe user privacy by inferring social connections through location history analysis.

End-to-end privacy The OF protocol assumes the vendor as the trusted party, since the vendor has the key material needed to compute the privacy IDs for any registered SmartTag. This means that the vendor can de-anonymize the location reports of a lost device. From a privacy standpoint, this is worse than Apple's FindMy network, in which the cryptographic key needed to generate the privacy IDs is not disclosed to the vendor.

A more interesting question is whether the design of Samsung OF protocol protects the privacy of helper devices. From the location reporting protocol in §3.3, we see that the access token can be used to link multiple location reports. Since each access token is assigned to a helper device, its location reports can be linked to plot its trajectory over the validity period of the token. In principle, the access token is not tied to a particular Samsung account. However, under normal operations, such a token request would be accompanied by other requests to Samsung servers that they can potentially be correlated.

4.4 Tag Owner (A4-RQ2)

Attack Scenario Without adequate anti-tracking mechanisms, malicious SmartTag owners could misuse the OF network for stalking purposes, e.g., covertly track a colleague by hiding the tag in their belongings, or create a hard-to-detect customized tracker leveraging Samsung's OF protocol.

OF device emulation. Emulating an OF device helps both in understanding the various sub-protocols involved in the interactions between the devices and vendor's server and in evaluating the feasibility of creating custom trackers to evade Samsung's anti-tracking mechanisms. Emulating FMM mobile devices is straightforward as the (only) secret for generating privacy IDs can be extracted easily from the device log. For SmartTags, this is not possible. To impersonate a SmartTag that can be registered through normal flow, the impersonation would need to successfully pass the finalization stage (see §3.1), to establish a shared secret with the server. Since the private key for deriving the secret is embedded in the hardware of a legitimate tag and is not explicitly exchanged during registration, it cannot be obtained easily without performing a hardware-level attack on the tag. Unlike the case with FMM device, this shared secret is not recorded in the device log of the owner device. However, we managed to obtain the shared secret by setting up a MITM attack between the owner device and the server, and monitor their exchanges. Since this shared secret is sent by the server to the owner device, we sidestep the need for extracting the private-public key of the tag.

Anti tracking feature The FMM version 7.2.25.14 introduces an anti-tracking module for background detection of tracking tags. The OF data advertised by a lost mode SmartTag contains two temporary identifiers: the Non-Resolvable RPA it uses and the privacy ID in the BLE payload. For a lost mode tag, the two change every 15 minutes. For an overmature lost mode tag, the MAC address still randomizes as normal, yet the privacy ID only updates once every 24 hours.

We noticed that the anti-tracking feature could only detect SmartTags in overmature lost mode through initial observations. Reverse-engineering of the FMM app has shown that the tracking detection algorithm uses the privacy ID contained in the BLE advertisement data of a tag as its identifier, then uses two thresholds to determine whether the tag is a tracker: (1) the duration since the tag was first discovered and saved to the local database; (2) the distance traveled while the tag is nearby (according to the geolocations saved to the database). This explains why the algorithm cannot detect tracking tags in lost mode: Since the anti-tracking algorithm uses the privacy ID data as the only identifier of a tag, it cannot correlate a tag before and after its privacy ID changes. Thus, the detected tracking duration is at most 15 minutes for an lost mode tag. While, for an overmature lost mode tag, the privacy ID value only changes once a day, which typically allows both thresholds to eventually satisfy. Another consequence of this is that privacy IDs generated by offline FMM mobile devices are also ignored by the anti-tracking mechanism.

The above allows an attacker to circumvent anti-tracking through a custom BLE tag that either impersonates an offline FMM device, or a SmartTag with fast rotating privacy IDs.

4.5 Updates on the vendor bug fixes

1. Small Privacy ID Pool (§4.1): The pool size remains the same, but an obfuscation process has been introduced to make the privacy IDs appear more unique. However, attackers can de-obfuscate these IDs (Appendix B.2.3).

2. Linkability Flaws (§4.1): In the latest firmware version (1.04.01), the `IDENTIFIER` characteristic only returns the tag's serial number to authenticated devices, the `HASHED_SN` is no longer writable, and the silent pairing (with tag) vulnerability has been fixed. However, the DFU service remains vulnerable.

3. Location Report Protocol: Samsung has implemented a consistency check to secure the nonce used for access token renewal, preventing the signature replay attack from §4.2. Yet, the other two location report vulnerabilities remain.

5 Discussions

We now discuss a broader implication of our findings, in terms of what we think are issues that go beyond the specific implementation we presented in the preceding sections. Again, our discussion here is organised around the four research questions we pose in the introduction, which we think highlight important features of an offline location tracking system. We shall contrast Samsung's OF protocol design and implementation against Apple's Find My (as analyzed in [21]).

Both Apple and Samsung seem to strike a balance in providing privacy to the owner of a tracker (RQ1) while at the same time providing means to detect unwanted tracking (RQ2). The latter seems to be a focus of much public attention, as indicated by articles in major news outlets such as [12], and has prompted an initiative [23] by Apple and Google to jointly develop a standard to ensure that future BLE trackers will have features built-in that allow cross-platform detection of unwanted tracking. On the issue of unlinkability of BLE data, our conclusion, given our findings and many in BLE fingerprinting work [8–10, 24], it seems quite impossible to design a system that would fully enforce unlinkability.

On the issues prompted by RQ2 (unwanted tracking), both Apple and Samsung seem to adopt a similar approach: a lost tracker will transition to a "lost mode", under which its privacy ID rotates infrequently, allowing an easy detection by a victim's phone. The essential difference in their implementations is in terms of how long it takes for a lost tracker to transition into the lost mode. In Samsung's case, it takes 24 hours, which provides ample time for the attacker to achieve its target. However, both Apple [25] and Samsung designs share a similar flaw: their anti-stalking algorithms seem to ignore BLE devices which are not dedicated trackers.

Samsung's protocol design follows a fundamentally different approach to Apple's with respect to end-to-end privacy (RQ3). Apple's design follows a *decentralised* approach, where the cryptographic keys controlling the generation of privacy IDs are controlled by the end users. This guarantees, in principle at least, that Apple cannot de-anonymize a privacy ID without additional information. This is in contrast to Samsung's *centralised* approach, where the cryptographic keys for generating privacy IDs are known and controlled by Samsung server. This fact may come as a surprise to the reader, and as far as we know, it is not something that is well-understood by the public. This centralised approach does, however, have an advantage over the decentralised approach when it comes to identifying a stalking tag. In the case of Apple's AirTags, this identification is done through reading its serial number, which can be linked to the owner's account. But this assumes the victim can locate the tag and access it physically, and that the tag is a genuine AirTag, so not a custom-modified tag (e.g., using the Open Haystack framework [30]). In the case of Samsung's OF system, the server possesses the information to identify a stalking tag through its privacy IDs, without needing physical access to the tag. From a law enforcement perspective, this allows an easier attribution of the attack.

Lastly, concerning the location report integrity (RQ4), there is an inherent difficulty in preventing the relay attack that is not specific to offline location tracking systems. This issue, for example, also manifests in BLE-based contact-tracing systems. A potential solution could be to adopt some sort of distance-bounding protocols [6] to ensure physical proximity, but whether such an approach is practical and whether it will not introduce further vulnerabilities into the system, is something that is beyond the scope of the current paper.

6 Conclusion

In this work, the Offline Finding (OF) and device management protocols for Find My Mobile (FMM) devices and SmartTags have been thoroughly analyzed, and a security and privacy analysis was performed. Our analysis of the protocols' design and implementation has identified several flaws, allowing each of the research questions to be answered definitively.

We have also discovered vulnerabilities outside the scope defined by the proposed research questions, including multiple other flaws related to the GATT server implementation for SmartTags, and the flaw in the registration protocol that allows an attacker to register a SmartTag of someone else without knowing its ECDH private key (Appendix D.2 on arXiv).

Most of the flaws we identified have been fixed in the latest firmware, so some of our findings and analysis results may not apply to devices/tags with higher version numbers. However, our tests show that devices or tags with older firmware/software versions can still participate in the OF network. Existing users of SmartTags and other FMM devices who have the option to upgrade the firmware/apps on their devices are encouraged to do so to mitigate the issues we discuss here.

Among the issues discussed, of great concern is the possibility of unwanted tracking using SmartTags and similar trackers, such as AirTags and Tile, or custom trackers leveraging on these offline finding networks. The current fragmented approach to anti-stalking features leaves a significant number of people vulnerable to unwanted tracking without an effective mean for detecting it. Fortunately, a standardisation effort is on-going, by Apple and Google, to allow a cross-platform detection of unwanted tracking [23]. We hope our analysis would help inform the design choices in such a process. For future work, we plan to investigate ways to detect unwanted tracking that are effective against a variety of OF networks, leveraging on existing efforts such as AirGuard [20].

A Table of Acronyms

Acronym	Full Name
FMM	Find My Mobile
Helper Device	A device that discovers and reports lost FMM devices/SmartTags
Lost Device	An FMM device/a SmartTag operating in lost mode or overmature lost mode
Owner Device	A device signed in with a Samsung account that owns FMM device(s)/SmartTag(s)
OF	Offline Finding
Privacy ID	A unique identifier of an FMM device/a SmartTag

Table 3: Samsung's Offline Finding Protocol Acronyms

Acronym	Full Name
AES	Advanced Encryption Standard
API	Application Programming Interface
APK	Android application Package
BLE	Bluetooth Low Energy
CA	Certificate Authority
DFU	Device Firmware Update
ECDH	Elliptic-curve Diffie–Hellman
GAP	Generic Access Profile
GATT	Generic Attribute Profile
GUI	Graphical User Interface
IRK	Identity Resolving Key
LTK	Long Term Key
MAC	Media Access Control
MITM	Man-in-the-Middle
RPA	Random private address
TLS	Transport Layer Security
URL	Uniform Resource Locator
UUID	Universally Unique Identifier

Table 4: Common Acronyms

B Offline Finding protocol for smartphones

In this section, we discuss our findings in the reverse engineering of offline finding features of the FMM app. The results of this section apply to all versions of FMM app (with the offline finding features) prior to version 7.2.24.12 (July 2022). We have not studied comprehensively the patched FMM app, but some preliminary findings related to how the advertisement payload is generated is given in Appendix B.2.3.

The OF protocol has multiple modes of operations that depend on the functions supported by the devices involved. We outline the main OF protocol that applies to mobile devices, which consists of four main operations: Device/Account Registration, lost (offline) device Operation, helper (online) device Operation, and Device/Account Deregistration. To simplify presentation, we omit the detailed concrete details of various messages exchanged and would refer to some important data symbolically. We also conflate the different servers used in the OF protocol to a single entity, which we simply refer to as "the server".

The protocol can be summarised as follows. Initially, devices must complete the registration process with the server to obtain various parameters that will be used in the offline operation. When a registered device goes offline, it starts advertising a unique payload that identifies itself. This payload is picked up by nearby online (registered) devices which parse the payload extracting the device's identifier. The online device then accesses available location services to find out its own location. It then sends the lost device's identifier and the location through to the server. The owner of the lost device can then access the server to find out its location. Further details of each operation are outlined below.

B.1 Device registration

The Offline Finding (OF) feature can be enabled on Samsung smartphones in the device settings when the device is signed in with a Samsung account. The device will then make an HTTPs request to the `/v1/kms/cf/device/registerDevice` URL of the `samsungdive` server to register itself to the OF network. The request contains the following information:

- Secret key: 16-byte random generated by Java Random.
- Device ID: Base64 encoding of an MD5 hash of the device's IMEI, which is constant and unique for a device.
- User ID: A value associated with the Samsung account logged in.
- Other information such as device type, region code, client version, and device model.

The server then responds with several pieces of information; the most important one (from a security/privacy perspective) is the `PrivateIDConfig`, which consists of a 16-byte secret key, an IV (`PrivacyIV`), and a size parameter (`PrivacyPoolSize`) that will be used to generate BLE advertisements for the OF operations. The IV value is fixed to the same 16-byte value (i.e., `"+IABCfvBZHJYFUek8vp3Gg=="` in base64 encoding) across accounts and devices. The privacy ID pool size determines the amount of possible advertising values the device will generate. This has also been observed to be standard for all devices, taking the value 51. This means that there are only 51 possible advertisement payloads from a lost device.

Registration process details Listing 1 contains the system log produced when enabling the Offline Finding Service on a phone. The Highlighted parts show the information for the device registration request and response. The request contains the account and device information, such as `userId`, `deviceId`, and `email`. The server's response contains the Offline Finding policy, the `privateIdConfig`, and other configuration data.

B.2 Lost device operation

When a OF registered device no longer has an active network connection, it enters 'Lost Mode' and triggers the Offline Finding service to start. The lost device then creates a GATT server profile and starts advertising on the main OF service UUID (FD69). The advertising is the fundamental operation for lost devices as part of the main OF protocol. The GATT server is not directly used by the main OF protocol, however it can be interacted with via BLE and is used as part of secondary OF protocols.

B.2.1 GATT server profile

Table 5: FMM GATT Services

FME	4EBE81F6-B952-465E-9ECE-5CA39D4E8955

The GATT profile of a lost device contains two services: the encryption service and the FME service, as shown in Table 5.

- **Encryption Service** (`ENCRYPTION`). This service is used to implement a challenge-response protocol for authenticating a device that wants to connect to the lost device. It contains three characteristics (see Table 6): The `SUPPORTED_CIPHER` characteristic is readable and contains information about the cipher to be used, which is AES/CBC/PKCS7. The `NONCE` characteristic is readable and returns an IV to be used during encryption. This IV is a random nonce that is generated using Java `SecureRandom` each time a client connects to the server. The `ENONCE` characteristic is writeable and expects to receive an encrypted version of the string "smartthings". This string must be encrypted using the given IV and with the device's secret key (from the `PrivateIDConfig`). Writing the correct ciphertext to the encrypted nonce characteristic completes the handshake between client and server.

SUPPORTED_CIPHER	50F98BFD-158C-4EFA-ADD4-0A70C2F5DF5D

- **FME Service** (`FME`). After completing the handshake, the client is now authenticated and can interact with the characteristics in the FME service. The device's alarm can be set to ring by writing the byte 01 (encrypted using the same cipher) to the `ALARM` characteristic (see Table 7).

B.2.2 BLE operations

Privacy ID generation The lost mode advertisements are the fundamental part of the OF protocol. The lost device generates an advertisement containing a unique identifying payload which is picked up by a helper and reported to Samsung. A key component of the advertisement payload is the *privacy ID* that identifies the device uniquely. A device can generate a number of privacy IDs, depending on the privacy ID pool parameter in `PrivateIDConfig`.

Let k, iv and p denote, respectively, the secret key, IV and the privacy ID pool from the device's `PrivateIDConfig`. To generate a privacy ID, first we compute a 20-byte array:

$x_i =$

Byte 0	Byte 1	Bytes 2-17	Byte 18	Byte 19
00	i	k	00	i

where i is a 1-byte random nonce in $\{1,\ldots,p\}$, i.e., it is a random 1-byte value bounded by the privacy ID pool. From x_i, one then generates a ciphertext: $y_i = E_k(iv, x_i)$, where E denotes the AES/CBC/PKCS7 cipher, initialized with the key k and the initialization vector iv. The privacy ID corresponding to each i is then computed by taking the first 12 bytes of y_i: $pid_i = y_i[0:11]$.

BLE advertisement generation Finally, the advertisement payload is generated from the privacy ID combined with various meta data. Table 8 describes the full advertisement payload; Table 9 provides details of the support info byte.

Table 8: FMM lost mode advertisement structure

Byte	0	1-12	13
Info	operation mode	privacy ID	support info

The first byte describes the operation mode of the OF protocol that is being used by a lost device. In the main OF protocol,

Table 9: Support info byte (byte 13)

Bit	0-3	4	5	6	7
Info	region info	E2E flag	UWB flag	MCF flag	reserved

this byte is always zero. The last byte contains information about the device's region and functionalities supported. This last byte varies depending on the device but stays consistent for all advertisements for a device. If two lost mode devices are advertising in the same area, then this last byte can be used as a quasi-differentiator between the two, provided they do not have the same settings/support.

Once the advertising data has been generated, the lost device starts advertising over BLE on the OF service's UUID FD69. The device will continuously advertise the same data until a timer is triggered that causes it to shuffle the advertising data. This timer is set to trigger every 60 minutes, after which the device generates a new random nonce to be used to generate the advertising data. Since, there are only 51 possible values for the nonce i, and it is the only source of non-determinism, there are also only 51 possible values of the advertising data (for a `PrivateIDConfig`). The lost device repeats this process until it is online again. If an adversary has access to the device's secret key and IV, then it is trivial to generate the 51 possible values.

B.2.3 BLE operations for newer FMM versions

Privacy ID obfuscation Samsung has introduced change to the lost mode advertisement format for Galaxy smart devices with FMM version 7.2.24.12 or above.

Table 10: Payload format for new FMM lost mode advertising

Byte	0	1-12	13	14	15-17	18-19
Info	operating mode	(obfuscated) privacy ID	support info	reserved	aging counter	signature

As shown in Table 10, the key differences for the new FMM advertisement structure include the following:

obfuscated privacy ID an obfuscation method is applied to the privacy ID contained in the BLE data. Details of the obfuscation method will be explained next.

timestamp the added timestamp field is used to store a 3-byte value that represents the time when the advertisement data was computed. It is computed by dividing the current system time by 900 and casting the result to an integer:

$$timestamp = currentTimeSeconds//900$$

signature the added signature field stores a 2-byte value. It is computed using `HMAC-SHA256` with the device's secret key, and first 18 bytes of the advertisement data.

It was observed that the new FMM version still uses a size-51 privacy ID pool as for the older versions, meaning that there will only use 51 unique raw privacy ID for each device. However, an obfuscation algorithm is used to add more randomness to the privacy ID value contained in the advertisement data.

The algorithm uses a universally static obfuscation table and deterministically generated random Bytes to obfuscate each raw privacy ID:

1. First, the FMM app computes a 12-byte raw privacy ID using the same algorithm as in older versions
2. Then, the app computes the current timestamp value and saves it to a variable, which is later used to determine the obfuscation filter being used and the random bytes generated by `java.util.Random`.
3. The obfuscation table is an `ArrayList<String>` object that contains four hex strings as shown in Table 11. For each advertisement data generation process, the FMM app selects the $timestamp \mod 4$th string and convert it to a 12-byte filter.

Table 11: Content of the obfuscation table

Index	Value
0	88DFAF0581FFCEB1429F2200
1	4A2635F7AD0E416906A35CBE
2	19DB724B07DF72B9792511DE
3	7BC79BAB386B8AFEFE63B9B7

4. Then, the app creates a new instance of the `Random` class and uses the $timestamp$ as the seed to generate 12 random bytes deterministically.
5. Finally, the obfuscated privacy ID is computed as follows:

$$privacyID_{obf} = privacyID_{raw} \oplus filter \oplus randomBytes$$

Privacy ID de-obfuscation The obfuscation operation can be easily reversed by an adversary to extract the raw privacy ID from the lost advertisement data observed over BLE:

1. The adversary uses the $timestamp$ value in the BLE data as the seed for `java.util.Random`, which allows $randomBytes'$, the same random bytes used in the obfuscation process, to be generated.
2. Then, the adversary selects $timestamp \mod 4$th string from the universally static obfuscation table as the filter, $filter'$.
3. Finally, the adversary can obtain the raw privacy ID from the following XOR operation:

$$privacyID_{raw} = privacyID_{obf} \oplus filter' \oplus randomBytes'$$

The Decisive Power of Indecision: Low-Variance Risk-Limiting Audits and Election Contestation via Marginal Mark Recording

Benjamin Fuller, Rashmi Pai, Alexander Russell
University of Connecticut – Voting Technology Research Center
{benjamin.fuller,rashmi.pai,alexander.russell}@uconn.edu

Abstract

Risk-limiting audits (RLAs) are techniques for verifying the outcomes of large elections. While they provide rigorous guarantees of correctness, widespread adoption has been impeded by both efficiency concerns and the fact they offer statistical, rather than absolute, conclusions. We attend to both of these difficulties, defining new families of audits that improve efficiency and offer qualitative advances in statistical power.

Our new audits are enabled by revisiting the standard notion of a cast-vote record so that it can declare multiple possible mark interpretations rather than a single decision; this can reflect the presence of marginal marks, which appear regularly on hand-marked ballots. We show that this simple expedient can offer significant efficiency improvements with only minor changes to existing auditing infrastructure. We consider two ways of representing these marks, both yield risk-limiting comparison audits in the formal sense of Fuller, Harrison, and Russell (IEEE Security & Privacy 2023).

We then define a new type of post-election audit we call a *contested audit*. These permit each candidate to provide a cast-vote record table advancing their own claim to victory. We prove that these audits offer remarkable sample efficiency, yielding control of risk with a constant number of samples (that is independent of margin). This is a first for an audit with provable soundness. These results are formulated in a game-based security model that specify quantitative soundness and completeness guarantees. These audits provide a means to handle contestation of election results affirmed by conventional RLAs.

1 Introduction

Risk-limiting audits (RLAs) are methods for verifying the outcome of a large-scale election. Developed by the academic and election community over that last two decades [1], RLAs offer significant efficiency improvements over the burden of a full hand recount while providing rigorous guarantees of correctness. They can also support a variety of social choice functions and election organizations (see Section 1.3). The framework posits reasonable physical assumptions under which elections—involving diverse interactions among multiple untrusted human and electronic processes—can be authoritatively protected from errors or deliberate falsification in tabulation, vote aggregation, and reporting. Finally, the framework supports *public verification*: third-party observers can certify the outcome of the audit [2].

RLAs are only defined in settings with voter-verified ground truth, typically furnished by hand-marked paper ballots.[1] Such marked ballots determine the *ground-truth outcome of the election*; of course, any particular tabulation of the ballots—generally carried out by electronic tabulators—determines a potentially different outcome [1]. RLAs are designed to detect disagreement between the ground-truth outcome and a given tabulated outcome except with a prescribed, concrete failure probability called the "risk" of the audit. The word "outcome" here refers to the winner(s) of the election rather than the exact vote totals.

RLA adoption in large democracies has been uneven. In the United States, RLAs have been advocated by area experts [2], the US Senate, and the 2014 Presidential Commission on Election Administration. However, only a handful of states run such audits, with most adoption occurring in the last few years. A major obstacle to widespread adoption is efficiency: RLAs require manual interpretation of a sampled set of ballots whose size grows as a function of the margin of the race to be audited. Thus, circumstances with small margins may require examination of many thousands of ballots and, unfortunately, election logistics and planning must prepare for such onerous outcomes. (As an example, a conventional ballot polling audit typically requires over 10,000 ballot samples for a 2% margin and 50,000 samples at 1% margin [3].) A related challenge is that high-efficiency RLAs necessarily provide (only) statistical guarantees; common risk values in practice are on the order of 5% (3% in Colorado, 5% in Georgia, 9% in Rhode Island, 10% in Virginia). This invites an immediate criticism:

[1] Verified Voting summarizes the adoption of such methods in the U.S.

a losing candidate whose loss has been reaffirmed by an RLA may argue that a 1-in-20 chance of error is unsatisfactory. We engage with both of these concerns by defining two new families of post-election audits.

1.1 Our Results in Brief

Our new approaches are enabled by revisiting the conventional understanding of a cast-vote record (CVR), a declaration of how a ballot was counted in an election. CVRs are critical elements of standard "comparison" audits, which are the starting points for our new audits. We redefine CVR semantics to include *explicit indication of marginal marks* [4] by either asserting a collection of possible interpretations for a marginal mark or a predicted probability distribution of interpretations. Marginal marks are those for which voter intent is unclear. Aside from partially filled voting targets, this can include "small lines, atypical ink or marker, and marks outside but near the voting target" [4]. We leverage this declaration of indecision to define two new families of audits.

Ballot-comparison risk-limiting audits with reduced variance and improved efficiency. Recording a *predicted probability distribution* for the interpretation of marginal marks in a CVR and reflecting this appropriately in the audit leads to a new family of *Bayesian risk-limiting audits*, which can offer significant efficiency advantages and improved confidence in the audit. In particular, in settings of practical interest this reduces the standard deviation of completion times for standard sequential statistical testing methods and hence reduces the number of ballots that need to be drawn in the first (and typically only) phase of standard multi-phase audits. For margins of 1%, this reduces the number of ballots sampled by over 10%; see Table 2. We also discuss such audits in a less expressive "conservative" setting where the CVR simply lists a set of possible interpretations. (One could consider interpretations with some minimum probability as shown in Figure 1.) These results are articulated in an adaptation of the formal game-based model of Fuller, Harrison, and Russell [5].

Aside from these efficiency improvements, such CVRs provide an improvement in voter confidence and interpretability by explaining discrepancies. Specifically, conventional CVRs will frequently disagree with marginal marks as, of course, there is no authoritative conclusion for such a mark; this can cast doubt on the CVR and the audit. A CVR permitted to assert the ambiguity of a mark provides an immediate means for separating the common circumstances where the mark is ambiguous from more disturbing discrepancies arising from real failures of the audit (see further discussion in Section 2). We remark that Clearballot publishes mark images with predicted probability distributions and allows citizens to search for marginal marks; thus our method makes use of data that is already public in many jurisdictions (Clearballot indicates that 13 US states use their technology).

***Competitive audits* involving multiple CVRs submitted by multiple interested parties, yielding a natural approach to *election contestation*.** We define a novel notion of a "competitive audit," in which multiple parties submit CVRs to substantiate competing claims of victory. We develop a formal cryptographic game-style framework for defining and analyzing such audits. This modeling permits a strong adversary that may prepare all but one CVR, choose which interpretation to return for a marginal mark, and whether to suppress a sampled ballot. We then show that this model leads to an *extraordinarily efficient audit calling for evaluation of a fixed, constant number of ballots*, independent of margin. Such strong efficiency guarantees are impossible for conventional RLAs. This new auditing framework provides an approach to the problem of election contestation, where the results of an RLA are challenged by a third party. We discuss practical considerations for deploying these audits in Section 2.

1.2 A Detailed Survey of the General Framework, Related Work, and Our Results

An RLA is carried out in the context of an election with voter-verified ground truth. For concreteness, our discussion assumes hand-marked paper ballots, which is the most common instantiation in practice. The audit is intended to detect disagreement between the ground-truth outcome of the election, as determined by the ballots themselves, and the *declared* outcome of the election resulting from a tabulation of the ballots; we use the word "declared" throughout to emphasize that the tabulated outcome may be inconsistent with the ground-truth outcome. Such an audit examines a collection of physical ballots, usually drawn at random according to a convention depending on the audit, and either concludes with Consistent, indicating that the sampled ballots appear consistent with the declared outcome, or Inconclusive, indicating that the audit has not amassed sufficient evidence of consistency. An audit is said to have *risk* α (a number in the range $[0,1]$) if the probability that it outputs Consistent is no more than α when the declared outcome contradicts the ground-truth outcome. Inconclusive outcomes usually call for a full hand recount; see the next subsection.

A trivial audit that always outputs Inconclusive has zero risk, but is obviously not useful in practice. This points to the importance of *completeness*—the additional guarantee that the audit outputs Consistent with high probability under favorable circumstances; we discuss this in detail below. A straightforward hand recount of an election is itself a RLA audit with zero risk (modulo any errors in manual interpretation). More sophisticated RLAs randomly draw and inspect a collection of ballots to make statistical conclusions about the outcome. A general feature of such statistical audits is that the number of samples scales with the margin of victory; this reflects the natural intuition that a landslide should be easier to statistically verify than a victory by slim margin. In the most familiar setting of a simple, two-candidate, first-past-the-

Figure 1: Generalization of conventional CVRs to the conservative setting, where multiple interpretations are declared, and the Bayesian setting, where one associates probabilities with each interpretation. Blanks cells in the Bayesian indicate probability 0; for brevity, the "No Vote" columns reflect both the no-mark case and the overvote case (with marks for both candidates).

post election, the empirical mean of the number of votes for a particular candidate among a collection of $\log(2/\alpha)/(2\epsilon^2)$ uniformly sampled ballots is correct to within ϵ with probability $1-\alpha$. This simple procedure—called "ballot polling" in the literature—yields a risk-limiting audit that inspects

$$O\left(\frac{\log(1/\alpha)}{\mu^2}\right) \tag{1}$$

ballots in expectation, where μ is the actual margin [1].

The most efficient known approach for RLAs, known as a *ballot comparison audit* [1, 6–12], requires a detailed tabulation report called a cast-vote record table (CVR). A CVR declares a unique identifier and interpretation (that is, a determination of the cast votes) for each ballot in the election. This ballot-by-ballot record of the election naturally determines a tabulation and outcome. It also enables high-efficiency audits that proceed by iterating the following experiment: (1) The auditor picks a random identifier ι from the CVR table; (2) the auditor finds a physical ballot with identifier ι; (3) the auditor compares the interpretation of the physical ballot against the associated CVR entry. Intuitively, iterations where the physical ballot matches the CVR provide support for this declared record of the election, while disagreements erode that support. Continuing the discussion in the same two-candidate first-past-the-post setting, observe that if the CVR table declares an incorrect outcome for the election, then at least a $\mu/2$ fraction of entries of the CVR table must disagree with the corresponding physical ballot; as above, μ is the scaled margin of ground-truth victory. (The factor of two arises because a single disagreement can both negate a vote for the declared winner and supply a vote for the declared loser.) It follows that after $2/\mu$ samples we expect to observe a discrepancy if the outcomes differ, suggesting that this approach should yield a risk-limiting audit with sample size

$$O\left(\frac{\log(1/\alpha)}{\mu}\right). \tag{2}$$

(The $\log(1/\alpha)$ term increases the number of samples so that the probability of observing an inconsistency is driven to at least $1-\alpha$.) It is instructive to compare this against (1) above. Due to the improved dependence on μ, in circumstances with small margins ballot comparison beats ballot polling.

The completeness challenge. The efficiency landscape is more complicated than the discussion above (and the asymptotic expression (2)) indicates. The complication is the requirement of completeness—that is, that the audit conclude with Consistent when considering an accurate CVR under favorable conditions. In practice, when a post-election RLA concludes with Inconclusive, policy calls for either a complete hand count or an additional stage of auditing (with a smaller risk parameter to avoid significant amplification of risk from the composite audit). See for example, Rhode Island Code 17-19-37-4 and Colorado's fact sheet. Thus a full accounting of efficiency must weigh the costs and likelihood of Inconclusive conclusions in the best-effort settings that arise in practice.

To be more concrete, a ballot-comparison auditor simply wishing to meet a prescribed risk limit α could adopt the framework above with the convention that *any* observed disagreement between the CVR and a physical ballot causes the auditor to immediately terminate the audit and output Inconclusive. If examination of $\log(1/\alpha)/(2\mu)$ ballots indeed exposes no inconsistencies, the audit can safely return Consistent with only an α probability of error, as desired. For margin $\mu = .01$ and risk $\alpha = .05$, for example, this requires inspection of 499 ballots. Now, if this "strict" auditor has the luxury of unambiguous ground truth, a perfectly correct CVR, and consistently accurate ballot interpretations, then it will indeed conclude the audit with Consistent. However, discrepancies between the CVR and physical ballots arise frequently in practice. (For example, the comparison RLA run by the US state of Colorado for the 2020 presidential election generated hundreds of discrepancies [13].) These discrepancies can re-

sult from truly ambiguous voter intent, disagreement among the interpretations of an auditing board, or operational errors such as retrieval of an incorrect ballot. Estimates from prior work (e.g. Stark's audit tools; [14]) suggest discrepancy rates as large as 0.5%, though the actual rate of incidence depends on various features of the election.

These considerations have led to the development and adoption of audits (and associated statistical tests) that can tolerate such anticipated errors. For example, adopting the same parameters (5% risk, 1% margin) but with the introduction of a .01% rate of marks being inadvertently dropped during interpretation, the standard Kaplan-Markov test calls for a sample size of 1220 ballots in order to terminate with probability 95%.[2] This is over twice the sample size arising with no errors (499, as indicated above) and illustrates that even small error rates have a significant impact on required sample size; we remark, additionally, that the incidence of sporadic errors in an otherwise correct CVR or errors in ballot interpretation are the cause of variance in the stopping time for such sequential statistical tests. As audits are typically conducted in phases—drawing a collection of ballots to be inspected at once and calibrated so that each phase is likely to be the last—variance also directly influences efficiency as it forces large phases.

These concerns motivate our exploration of more expressive CVRs. In particular, we note that the party (or tabulator) preparing the CVR can identify marginal marks during tabulation that are likely to lead to errors during a comparison audit. Reflecting these marginal marks on the CVR offers a new dimension of optimization for the auditing rule. As a matter of bookkeeping, we will consider CVRs that may list multiple interpretations for each ballot or a full predicted probability distribution of interpretations. (A traditional CVR corresponds to the case when the size of each set of interpretations is 1.) We apply this to develop both conventional audits with improved efficiency and define a new class of competitive audits, providing both high efficiency and a mechanism for contesting conventional audits.

Enriching CVRs to reflect marginal marks can also improve confidence in the audit, as it can distinguish avoidable discrepancies arising from ambiguity from unexplained auditing failures; see Section 2.

1.2.1 Improved Efficiency Risk-Limiting Audits via Bayesian CVRs

We show how to adapt standard ballot comparison audits to the setting of *Bayesian CVRs* that declare a predicted distribution of ballot interpretations. We indicate how to formulate the standard notions of discrepancy and margin in this setting and observe that this simple change has significant efficiency ramifications. Using discrepancy and marginal rates from practice we show that such audits reduce sample size standard deviation by 14% compared to a traditional audit at a margin of 1% (see Table 2). We also develop a variant of this audit that uses a CVR that merely reflects the *possible* interpretations of each ballot (rather than a full probability distribution). We call this a *conservative CVR*. While this does not provide the full benefits of the Bayesian approach, it may be simpler to deploy in practice since no probability estimation is required. It also considers a stronger adversarial model where the ballot interpretation of the auditor is adversarially controlled.

We adopt to our setting the cryptographic game-style modeling for RLAs developed in [5], and prove that the new audit is risk-limiting. We then carry out simulations to show that the most popular sequential statistical test used for RLAs (the Kaplan-Markov test) can take advantage of the resulting notion of discrepancy to provide more efficient RLAs.

1.2.2 Competitive Audits and Election Contestation

Our second contribution is a new class of post-election audits that we call *competitive RLAs*. In a competitive RLA each candidate has an "advocate" that is allowed to examine ballots (under supervision to ensure ballots are not destroyed or modified). For each candidate $\mathsf{A}_1, \ldots, \mathsf{A}_k$, their advocate produces a CVR that may declare different ballot interpretations and winners; the intent is that the advocate for candidate A files a CVR that is favorable to A. In particular, if A won the election, the CVR (filed by the advocate for A) should establish that; in a weaker sense, even if A did not win, the advocate may wish to file a CVR that prevents other candidates that did not win the election from convincingly claiming that they did. For simplicity, we formulate this audit in the "conservative" setting, where CVRs may list multiple interpretations for each ballot but do not record a probability distribution on these various possible interpretations. (It is certainly possible to formulate this in the setting with a Bayesian CVRs, see end of Section 6.) For elections with very small margins, an interpretation of marginal votes may be necessary to determine which candidate receives the most votes. We are only able to prove results about candidates whose winning and losing status is true regardless of interpretation of marginal marks. Definitionally, an election thus at most one winner, and some candidates may neither win nor lose.

Assuming that at least one submitted CVR only lists interpretations that are consistent with the ballots and the election has a winner, the auditor will identify the correct winner using a constant number of ballots. Furthermore, if some submitted CVR lists the exact list of possible interpretations for each ballot, no losing candidate can be identified as the winner. We emphasize that the number of ballot samples required by this approach is a constant that not scale with the margin. (The constant itself is a function of how robust the audit should be in the face of errors by the advocates.)

[2] This estimate uses McBurnett's tool rlacalc with standard rates of errors in the literature drawn from Lindeman and Stark [1]. These are $o_1, u_1 = .001$ and $o_2, u_2 = .0001$, see discussion in Section 5.

The basic idea of the audit is straightforward: Faced with a pair of contradictory CVRs—cvr_1 and cvr_2—there must be at least one ballot on which these CVRs completely disagree: examining this single ballot then provides an immediate strike against one of CVRs. Indeed, a strict auditor can use a generalization of this approach to settle the competing claims made by a collection of k CVRs with just $k-1$ ballots. (That is, the auditor immediately removes from consideration any CVR found to be inconsistent with an inspected ballot.) Such a stringent auditor will not be appropriate in practice, which must account for a small number of errors on the part of the advocates (and the cvr_i) or the possibility that ballots are lost, say, during the audit. Even accounting for such phenomena, our approach yields audits with remarkable efficiency. (As mentioned earlier, the complexity of the audit scales with the desired robustness in the face of such advocacy errors.)

The most natural and practical instantiation of our techniques is providing an efficient adjudication process for disagreements that result after the parallel scanning of ballots, for example, using the OpenScan system [15]. The idea of the OpenScan system is for advocates to place cameras above a physical scanner and create their own CVRs without having physical access to the ballots. Their system does not have a natural adjudication mechanism. Competitive audits provide that adjudication with a constant query ballot complexity.

Election contestation. Competitive RLAs provide an immediate approach to election contestation. Specifically, consider a situation where a candidate wishes to dispute the conclusions of conventional RLA (that is, the candidate claims that an invalid election was not detected by the RLA). In this case, the candidate (or their advocate) can be permitted to examine the ballots and produce a competing CVR for the election (that, presumably, will claim that the candidate is the victor). The CVR originally produced for the election (and reaffirmed by the original RLA) and the candidate's CVR can then be treated by the competitive audit mechanism. This has a number of notable features: (i.) for some integer t, the audit can rigorously settle the dispute with risk $2^{-\theta(t)}$ after examining only t ballots—thus a small constant number of queries, independent of margin, are sufficient; (ii.) this provides an interesting avenue for election policy: for example, the cost and effort of the audit could be borne by the contesting party. See more discussion in Section 2.

Adversarial modeling. We consider a cryptographic game-based model for analysis. The model places the ballots (and, in conservative and competitive audits, the choice of the returned interpretation) in the hands of an adversarial environment, thus reflecting various adverse circumstances that challenge practical audits. Our treatment universally quantifies over the ground-truth results (and, in particular, the marks appearing on the ballots themselves) and tabulated cast-vote records; in this sense they apply to all elections. We remark that in terms of the formal modeling any universally quantified object can be seen as adversarially controlled.

1.3 Other Related Work

Stark [16] defined RLAs in 2008. The framework was generalized and sharpened over the next decade [1, 17–19] leading to a variety of specific methods, often optimized certain practical settings [1, 7, 16, 20–23]. There are four major directions in current research (1) supporting varied social choice functions [10, 12], (2) managing multiple races [6–9, 24], (3) sharpening risk estimates [8, 11, 16, 20, 21, 25–29] and (4) implementation issues [3, 5, 17–19, 30–33].

The most closely related work to our competitive setting is a recent, independent article of Jones et al. [34]. One can view our competitive audits as an analog of a "multi-prover interactive proof system" consisting of competing and potentially malicious "provers" who are attempting to convince a "verifier" of the truth (or falsity) of a statement (reflecting the complexity-theoretic setting of [35, 36]). Jones et al. were inspired by the "cooperative" version of this same framework in which a collection of cooperating, but potentially malicious, provers attempt to convince a verifier of the truth of a statement; in fact, this cooperative version is far more common in the complexity-theoretic literature (reflecting the standard setting of [37]). Jones et al. develop an auditing approach designed to catch inconsistencies across multiple scans used to create (multiple) CVRs. In our auditing context, their techniques focus on detecting circumstances where at least one of the scans (provers) is dishonest. Our techniques focus on deciding who to trust in a situation where at least one scan is honest. The two approaches can thus naturally compose.

Organization. We discuss practical deployment considerations in Section 2. We then cover notational preliminaries and define CVRs and ballots with multiple interpretations in Section 3, cover Bayesian audits in Section 4, and Conservative audits in Section 4.1. Finally, we evaluate efficiency of the Bayesian and conservative methods in Section 5 and describe competitive audits in Section 6. Proofs are relegated to the online version [38].

2 Practical Deployment Considerations

Bayesian and conservative audits The deciding factor in adopting RLA modifications is how they impact the balance of trust in the election outcome and auditing effort. The essential trust assumptions of these new audits—that physical ballots faithfully represent voter intent and are available for interrogation—are identical to classical risk-limiting audits. However, we note that Bayesian and conservative audits have the advantage that marginal marks are directly reflected in the cast-vote record, a benefit for public perception and interpretability. For years, Colorado has published a discrepancy report [13] explaining their guess of each nonzero discrepancy to improve public confidence in the audit. In particular, marginal marks which would have resulted in a consistency failure in a conventional audit are now explicitly indicated

and reconciled with ballots; thus they serve to add to public confidence in the audit rather than detract from it. As for public interpretability, conservative audits appear superior to Bayesian audits in the sense that the straightforward role played by a "possible" interpretation in a conservative audit is clearly preferable from the standpoint of intelligibility to the fractional discrepancies arising from "likelihood" estimates. As conservative audits offer most of the statistical improvements of Bayesian audits in our numerical estimates, their relative simplicity may outweigh the small improvements in efficiency. We remark that these new audits can rely on the same statistical tests that underly conventional comparison audits.

As for the challenge of transitioning procedures and equipment to support these audits, the substantive changes pertain to tabulation equipment (responsible for producing the CVRs) and RLA software. In particular, the task of the "audit board" (which evaluates the marks on sampled ballots) is identical to that of a conventional audit: they are still responsible for settling on a single interpretation for each sampled ballot. Both audits demand a richer convention for CVR, and hence changes to tabulator output and RLA administration software. As modern tabulators typically collect full ballots scans, the changes required to generate such CVRs would require only a firmware upgrade (rather than hardware changes). Again, the task here may be simplified by the conservative setting, which requires no explicit likelihood estimation. Changes to RLA administration software are minimal, especially considering that existing statistical tests can be applied. Our simulation [39] builds on Harrison's implementation with minimal changes [40]. We remark that the recent VVSG 2.0 federal voting system guidelines require ballot imprinting, even on voter-facing tabulators. This is an important enabling feature for ballot comparison audits, so adoption of these guidelines will significantly improve the general feasibility of comparison audits in the United States.

Compare the cost of conservative audits against the natural approach that calls for auditors to adjudicate every marginal ballot as a part of the initial tabulation. As an illustrative example, Louisiana is the 25th state by population with roughly 2M votes for president in 2020. Using the .5% marginal mark rate [14], one would have to adjudicate 10K ballots, in addition to what is required for the RLA. At 1% margin ballot comparison requires examining 1K ballots (Table 2).

The competitive setting. Competitive audits have roles and procedures that have no analog in conventional RLAs. Thus, they demand careful consideration before deployment. We outline two different implementations and discuss the trust and efficiency tradeoffs. The first implementation we discuss provides all of the guarantees—including software independence—of a classical RLA while providing an efficient contestation mechanism under two assumptions:

(1) That there is an actual winner (regardless of how marginal marks are interpreted), and
(2) An advocate for the winning party contests an incorrect outcome.

The contestation phase has a risk that reduces exponentially in the number of ballots pulled. We also discuss standalone instances of competitive audits, including an existing framework that supports CVR creation by candidates without directly handling ballots.

Consider the following RLA procedure with an additional contestation phase:

(1) The state's tabulators are run on the ballots, producing $\mathsf{cvr}_{\mathtt{state}}$ that declares candidate W to be the winner.
(2) A conventional ballot comparison RLA is run on $\mathsf{cvr}_{\mathtt{state}}$ with risk α.
(3) If the RLA outputs Inconclusive, existing legal steps are followed such as a recount.
(4) Otherwise, candidates can contest the results of the audit. (Whether such contestations are permitted, or what evidence might be necessary to justify them, is a matter of election law.)
(5) A candidate A permitted to contest the election may inspect the physical ballots (under appropriate supervision to prevent tampering) to assemble $\mathsf{cvr}_{\mathsf{A}}$, an alternate CVR. Various procedures could be used to create $\mathsf{cvr}_{\mathsf{A}}$; for example, (i.) a complete hand count of all ballots, (ii.) use of alternative tabulators trusted by the candidate, (iii.) a hybrid approach, where the candidate uses $\mathsf{cvr}_{\mathtt{state}}$ with the exception of a few precincts of the election that they believe are suspicious; these are hand counted.
(6) Finally, the competitive audit is run on all of the available CVRs (i.e., $\mathsf{cvr}_{\mathtt{state}}$ and $\mathsf{cvr}_{\mathsf{A}}$ for any candidate A that assembled a CVR).

This audit provides the guarantees of a conventional RLA and provides a rigorous approach to contestation. The audit places the vast majority of the work of the competitive audit on the party that believes there is an error and wishes to correct it. The effective risk of the combined audit can be driven to a small constant, e.g., one part in 10,000, with a small number of samples (assuming candidates can create accurate CVRs). We remark that such an audit continues to protect a third party (with only a vested interest in the correct outcome of the election) from an incorrect result with risk α; in particular, when the state's CVR correctly asserts the correct winner, the contestation phase cannot change the outcome. On the other hand, an interested party (wishing to ensure that a candidate of interest is not incorrectly declared a loser of the election) can guarantee risk close to zero. It is a legal matter when to allow a contestation, our method provides a tool to decide when an advocate has gathered sufficient evidence.

One can also consider a standalone competitive RLA. The procedure follows the prescription above without the conventional RLA. (As with the audit above, supervision is required

to protect ballot integrity.) If candidate A is the winner and indeed submits a correct cvr_A, A will win the competitive audit regardless of the procedures or software adopted by other candidates (or state) to assemble their CVRs. We remark that such tabulations significantly change the guarantees offered to a third party with a vested interest only in the correct outcome of the election. With this audit, such a third party can only be guaranteed a correct outcome if the state's tabulation is correct or the true winning candidate participates in the competitive audit.

Such competitive audits provide a rigorous approach to reconciling the results generated by the existing Openscan [15] system. This system permits each candidate to install their own camera over a scanning bed on which each ballot is rested for data collection. Adapting slightly to our framework, advocates do not touch ballots, but can be in the room to ensure each ballot is scanned exactly once. This has the advantage that all data is collected in one pass, and advocates use their own hardware and software to collect and process ballot images. Of course, the state itself may have an installed camera that produces an official outcome. The competitive audit now provides a rigorous guarantee to each candidate: if they won the election (and themselves generate a faithful CVR), they can be guaranteed victory independent of the software used by other candidates or the state. This assumes, of course, that each physical ballot is processed by their camera.

The above deployments require physical access to ballots—this is unavoidable for software-independent guarantees. In either deployment, candidates shoulder auditing responsibilities (borne entirely by the official auditors in a traditional RLA). This is one advantage of the first deployment scenario: it limits candidate effort to only those circumstances where they suspect that a traditional RLA has failed. However, competitive audits introduce a potential inequity: Candidates with fewer financial resources may have less ability to muster a full retabulation for the competitive audit.

Our results assume a low rate of disagreement between the "honest" CVR and the set of interpretations that could be reasonably inferred by an audit board. Preparing a CVR with a low error rate may require knowledge on mark adjudication and audit board behavior.

Audit	Notation	Meaning
All	$\mathbf{b}$	Physical ballot
	$\mathbf{B}$	Ballot family
	$\mathbf{B}_\iota$	Ballots with identifier ι
	S	Number of ballots in election
	C	Candidates in the election
	α	Risk of audit
	γ	Inflation factor of Kaplan-Markov when discrepancy encountered
	E	Election
Bayes.	$\mathcal{T}_\mathbf{b}$	Probability distribution over auditor interpretation of ballot
	$\mathsf{I}_\mathbf{b}$	R.V. with distribution $\mathcal{T}_\mathbf{b}$
	$\mathsf{T}_\mathbf{b}^{\CIRCLE}(\mathsf{A})$	Expected number of votes for ballot $\mathbf{b}$ received by candidate A if audited
	$E^{\CIRCLE}(\mathsf{A})$	Expected number of votes across election received by candidate A if hand counted
	$\mathcal{P}_r$	Predicted distribution of interpretations for ballot with identifier r
	$\mathsf{P}_r^{\CIRCLE}(\mathsf{A})$	Number of votes predicted for candidate A on ballot with identifier r
	$\mu_{\mathsf{A},\mathsf{B}}$	Bayesian diluted margin of A with respect to candidate B
	μ_A	Minimum of Bayesian diluted margin across candidates
	cvr	Cast vote record containing identifiers and predicted interpretations for each ballot
	$\mathsf{cvr}(\mathsf{A})$	Predicted number of votes for A on cvr
	μ_cvr	Bayesian margin declared by cvr
	D_cvr	Discrepancy of cvr with respect to election E
Cons.	$T_\mathbf{b}$	Set of possible interpretations on $\mathbf{b}$
	$T_\mathbf{b}^{\CIRCLE}(\mathsf{A})$	Maximum interpretation for A on $\mathbf{b}$
	$T_\mathbf{b}^{\CIRCLE}(\mathsf{A})$	Minumum interpretation for A on $\mathbf{b}$
	$T^{\CIRCLE}(\mathsf{A})$	Most possible votes for A in election
	$T^{\CIRCLE}(\mathsf{A})$	Least possible votes for A in election
	$\mu^+_{\mathsf{A},\mathsf{B}}$	Conservative diluted margin of A with respect to candidate B
	μ^+_A	Minimum of Conservative diluted margin across candidates
	μ^+_cvr	Conservative diluted margin in cvr^+
	cvr^+	Conservative cvr declaring set of possible interpretations
	$\mathsf{P}_r^{\CIRCLE}(\mathsf{A})$	Minimum predicted interpretation for A
	$\mathsf{P}_r^{\CIRCLE}(\mathsf{A})$	Maximum predicted interpretation for A
	$\mathsf{cvr}^{\CIRCLE}(\mathsf{A})$	Minimum possible votes for A on cvr
	$\mathsf{cvr}^{\CIRCLE}(\mathsf{A})$	Maximum possible votes for A on cvr
	$\mathsf{D}^+_\mathsf{cvr}$	Conservative discrepancy of cvr with respect to election E

Table 1: Summary of Notation

3 Preliminaries; the Bayesian Setting

We use boldface to refer to "physical" objects, such as individual ballots (typically denoted $\mathbf{b}$) or groups of ballots (typically $\mathbf{B}$). For a natural number k, we define $[k] = \{1,\ldots,k\}$ (and $[0] = \emptyset$). We let $\Sigma = [-2,2]$, a set of particular significance as standard single-ballot discrepancy takes values in this set; this is discussed in detail later in the paper. For a set X, let X^* be the set of all finite-length sequences over X; that is, $X^* = \{(x_1,\ldots,x_k) \mid k \geq 0, x_i \in X\}$. In particular, we let $\{0,1\}^*$ denote the collection of finite-length bitstrings. Finally, we define $X^\mathbb{N}$ to be the set of all sequences $\{(x_0,x_1,\ldots) \mid x_i \in X\}$. We typically use script letters, e.g., $\mathcal{P}$, to denote probability distributions. Making multiple interpretations explicit requires many new definitions. A summary is in Table 1.

Formal definitions for ballots, elections, and cast-vote records. For simplicity, we consider only audits of a single first-past-the-post race with a set C of candidates. See Stark [7, 10] for a detailed account of how more complex elections can be reduced to this canonical setting. We now set down the elementary definitions of elections, manifests, and CVRs. **The main definitional change is that a physical ballot induces a probability distribution of possible outcomes;**

this models the important situation where a physical ballot may have ambiguous markings that could reasonably be interpreted in various ways by an auditing board or a tabulation device. We explore two conventions for cast vote records to reflect this uncertainty: the first is the *Bayesian* framework, which associates with each ballot a predicted probability distribution of possible readings (depending on the anticipated reading a particular audit board, say). We then formulate a simpler, *conservative* model that posits a collection of interpretations for each ballot without assigning them probabilities. This reduces the complexity of producing cast-vote records, as one only needs to identify the *possible* interpretations of a ballot rather than a comprehensive probability distribution. In this conservative model, we consider quite strong adversarial behavior that assumes that the audit board always returns the "worst-case" interpretation allowed by the ballot. (In fact, this is equivalent to replacing the probabilities listed on the CVR with a probability of 1 for some interpretation that "minimizes" the margin for a declared winner.) To move as swiftly as possible to our results on conventional audits with marginal marks, we first lay out the definitions for the Bayesian case; we return to the definitions for the conservative case in Section 4.1.

Definition 1 (Interpretations, ballots, and ballot families)**.** *Let C be a set of candidates. An* interpretation *is a function $I : C \to \{0,1\}$; when C is understood from context, we write $\mathcal{I} = \{I : C \to \{0,1\}\}$ for the collection of all interpretations. Such interpretations to indicate the votes appearing for candidates on individual ballots. A* ballot *is a physical object* **b** *with two properties:*

(1) The ballot **b** *is* labeled *with an indelible* identifier $\mathrm{id}_{\mathbf{b}} \in \{0,1\}^*$.
(2) The ballot **b** *determines a "ground truth" probability distribution $\mathcal{T}_{\mathbf{b}}$ on the set of interpretations $\mathcal{I}$. Thus $\mathcal{T}_{\mathbf{b}} : \mathcal{I} \to \mathbb{R}$ is a non-negative function on $\mathcal{I}$ for which $\sum_{I \in \mathcal{I}} \mathcal{T}_{\mathbf{b}}(I) = 1$.*

We let $\mathsf{T}^{\blacklozenge}_{\mathbf{b}} : C \to \mathbb{R}$ denote the expected interpretation over the distribution $\mathcal{T}_{\mathbf{b}}$: that is, for each $\mathsf{A} \in C$, $\mathsf{T}^{\blacklozenge}_{\mathbf{b}}(\mathsf{A}) = \mathbb{E}[\mathrm{I}_{\mathbf{b}}(\mathsf{A})]$, where $\mathrm{I}_{\mathbf{b}}$ is a random variable distributed according to $\mathcal{T}_{\mathbf{b}}$.

A ballot family **B** *is a collection of ballots with the same candidates. We let $\mathbf{B}_\iota = \{\mathbf{b} \in \mathbf{B} \mid \mathrm{id}_{\mathbf{b}} = \iota\}$ denote the subset of ballots with identifier ι. When ballots identifiers are distinct across* **B***, so that $|\mathbf{B}_\iota| \le 1$ for each ι, we say that the family is* uniquely labeled*.*

Ballots are typically intended to have an unambiguous interpretation. This corresponds to the case where the distribution $\mathcal{T}_{\mathbf{b}}$ is supported on a single interpretation (taking the value 1 at that interpretation and zero elsewhere).

Definition 2. *An* election *E is a tuple $(C, \mathbf{B}, \mathsf{S})$ where C is a set of candidates,* **B** *is a ballot family, and $\mathsf{S} = |\mathbf{B}|$ is the total number of ballots.*

Definition 3 (Election winners, losers, and margin)**.** *Let $E = (C, \mathbf{B}, \mathsf{S})$ be an election. For a candidate $\mathsf{A} \in C$, define*

$$E^{\blacklozenge}(\mathsf{A}) = \sum_{\mathbf{b} \in \mathbf{B}} \mathsf{T}^{\blacklozenge}_{\mathbf{b}}(A).$$

The margin of A with respect to B *is defined to be*

$$\mu_{\mathsf{A},\mathsf{B}} = \frac{E^{\blacklozenge}(\mathsf{A}) - E^{\blacklozenge}(\mathsf{B})}{\mathsf{S}}.$$

When we wish to emphasize that this notion of margin is defined with respect to the expected values $\mathsf{T}^{\blacklozenge}_{\mathbf{b}}(\cdot)$ we refer to it as Bayesian margin*. A candidate $\mathsf{W} \in C$ is the* winner *of the election E if $\forall \mathsf{A} \in C \setminus \{\mathsf{W}\}, \mu_{\mathsf{W},\mathsf{A}} > 0$. In this case, we define the* margin*, denoted μ, of the election to be the minimum of these quantities:*

$$\mu_E = \min_{\mathsf{A} \in C \setminus \{\mathsf{W}\}} \mu_{\mathsf{W},\mathsf{A}}.$$

Otherwise, the election does not determine a winner and we define $\mu_E := 0$. If a winner exists it is unique. A candidate L is called a loser *if there is a candidate A for which $E^{\blacklozenge}(\mathsf{L}) < E^{\blacklozenge}(\mathsf{A})$.*

Cast-vote record (CVR). A cast-vote record table (CVR) is an (untrusted) declaration of both the ballots appearing in an election and the interpretations of the ballots.

Definition 4 (Bayesian Cast-Vote Record Table)**.** *Let C be a set of candidates. A* Bayesian Cast-Vote Record table (CVR) *is a sequence of pairs $\mathsf{cvr} = ((\iota_1, \mathcal{P}_1), \ldots, (\iota_t, \mathcal{P}_{\mathsf{S}_{\mathsf{cvr}}}))$ where the ι_r are distinct indetifier bitstrings in $\{0,1\}^*$ and each $\mathcal{P}_r : \mathcal{I} \to \mathbb{R}$ is a probability distribution on $\mathcal{I}$ which we refer to as a "prediction." Intuitively, such a* cvr *declares that, for each row r, the interpretation of the ballot labeled ι_r is given by the distribution $\mathcal{P}_r$.*

For each candidate $\mathsf{A} \in C$ and $r \in \{1, \ldots, \mathsf{S}_{\mathsf{cvr}}\}$, we define $\mathsf{P}^{\blacklozenge}_r(\mathsf{A}) = \mathbb{E}[I(\mathsf{A})]$, the expected value of the vote for A when I is drawn according to the distribution $\mathcal{P}_r$. We then define the total cvr *declaration for candidate A as*

$$\mathsf{cvr}(\mathsf{A}) = \sum_{r=1}^{\mathsf{S}_{\mathsf{cvr}}} \mathsf{P}^{\blacklozenge}_r(\mathsf{A}).$$

Declared winners and losers. *If there is a candidate $\mathsf{A} \in C$ with the property that $\mathsf{cvr}(\mathsf{A}) > \mathsf{cvr}(\mathsf{B})$ for every $\mathsf{B} \in C \setminus \{\mathsf{A}\}$, then we say that A is the* declared winner *according to* cvr*. A candidate A for which there exists some B such that $\mathsf{cvr}(\mathsf{A}) < \mathsf{cvr}(\mathsf{B})$ is called a* declared loser*.*

We use the following general language when referring to CVRs:

(1) The bitstrings ι_r are identifiers *and we let* `Idents`(cvr) *denote this set.*
(2) The number $\mathsf{S}_{\mathsf{cvr}}$ is the size *of the CVR.*
*(3) The r*th row*, denoted $\mathsf{cvr}(r)$, refers to the tuple $(\iota_r, \mathcal{P}_r)$.*

(4) Identifiers appearing in the CVR are distinct, so when convenient we reference $\mathcal{P}_r$ and P_r by identifier rather than row: that is, for an identifier $\iota = \iota_r$ appearing in the CVR, we define $\mathcal{P}_\iota := \mathcal{P}_r$ and $\mathsf{P}^{\blacklozenge}_\iota := \mathsf{P}^{\blacklozenge}_r$.

Definition 5 (Bayesian declared margin)**.** *Let* cvr *be a Bayesian CVR with declared winner* W *and size* $\mathsf{S}_{\mathsf{cvr}}$*. The* declared margin *of* cvr *is the quantity*

$$\mu_{\mathsf{cvr}} := \min_{\mathsf{A} \in C \setminus \mathsf{W}} \frac{\mathsf{cvr}(\mathsf{W}) - \mathsf{cvr}(\mathsf{A})}{\mathsf{S}_{\mathsf{cvr}}} \geq 0.$$

If cvr *has no declared winner, we define* $\mu_{\mathsf{cvr}} := 0$*.*

Definition 6 (Bayesian validity)**.** *Let* $E = (C, \mathbf{B}, \mathsf{S})$ *be an election and* cvr *be a Bayesian CVR. We say that* cvr *is* valid *for* E *if* E *has a winner and* cvr *declares that winner. We say that* cvr *is invalid for* E *if it declares a winner* W *that does not win* E*.*

Discrepancy is a standard measure of how much a CVR overcounts W's margin over other candidates $\mathsf{A} \neq \mathsf{W}$. Discrepancy naturally extends to the Bayesian case by considering the discrepancy of the expected interpretation of the auditor; this is defined precisely below. It is convenient to generalize the notion to yield a default result appropriate for cases when no ballot matches the identifier declared in a CVR; this is the $\perp$ case in the definition below.

Definition 7 (Bayesian discrepancy)**.** *Let* $E = (C, \mathbf{B}, \mathsf{S})$ *be an election and let* $\mathsf{cvr} = ((\iota_1, \mathcal{P}_1), \ldots, (\iota_t, \mathcal{P}_{\mathsf{S}_{\mathsf{cvr}}}))$ *be a Bayesian CVR with declared winner* W*. For a ballot* $\mathbf{b} \in \mathbf{B}$ *and a distribution* $\mathcal{P} : \mathcal{I} \to \mathbb{R}$*, the* discrepancy *is*

$$\mathsf{D}[\mathcal{P}, \mathbf{b}; \mathsf{W}] = \max_{\mathsf{A} \in C \setminus \mathsf{W}} \left((\mathsf{P}^{\blacklozenge}(\mathsf{W}) - \mathsf{P}^{\blacklozenge}(\mathsf{A})) - (\mathsf{T}^{\blacklozenge}_{\mathbf{b}}(\mathsf{W}) - \mathsf{T}^{\blacklozenge}_{\mathbf{b}}(\mathsf{A})) \right)$$

where, as above, $\mathsf{P}^{\blacklozenge}(\mathsf{A}) = \mathbb{E}[I(\mathsf{A})]$ *with* I *distributed according to* $\mathcal{P}$*. We expand this definition to apply, additionally, to a special symbol* $\perp$*:*

$$\mathsf{D}[\mathcal{P}, \perp; \mathsf{W}] = \max_{\mathsf{A} \in C \setminus \mathsf{W}} \left(\mathsf{P}^{\blacklozenge}(\mathsf{W}) - \mathsf{P}^{\blacklozenge}(\mathsf{A}) \right) + 1 \,.$$

For an identifier ι *define*

$$\mathsf{D}_{\mathsf{cvr},\iota} = \begin{cases} \min \{ \mathsf{D}[\mathcal{P}_\iota, \mathbf{b}; \mathsf{W}] \mid \mathbf{b} \in \mathbf{B}_\iota \} & \text{if } \mathbf{B}_\iota \neq \emptyset, \\ \mathsf{D}[\mathcal{P}_\iota, \perp; \mathsf{W}] & \text{otherwise.} \end{cases}$$

The discrepancy of the cast vote record table cvr *is:* $\mathsf{D}_{\mathsf{cvr}} = \sum_{i=1}^{\mathsf{S}_{\mathsf{cvr}}} \mathsf{D}_{\mathsf{cvr},\iota_i}$*.*

We begin by establishing the fundamental relationship between discrepancy and margin for invalid CVRs.

Lemma 1. *Let* $E = (C, \mathbf{B}, \mathsf{S})$ *be an election and let* cvr *be an invalid CVR for* E *with declared winner* W *and size* $\mathsf{S}_{\mathsf{cvr}} = \mathsf{S}$*. Then* $\mathsf{D}_{\mathsf{cvr}} \geq (\mu_{\mathsf{cvr}} + \mu_E) \cdot \mathsf{S} \geq \mu_{\mathsf{cvr}} \cdot \mathsf{S}$*.*

As a reminder, all proofs are deferred to the online version [38].

3.1 Adaptive Statistical Tests

The standard approach for ballot comparison audits determines an experiment that appropriately samples ballots in order to obtain discrepancy samples; the procedure concludes with Inconclusive unless one can statistically reject the hypothesis that discrepancy is at least μ_{cvr}, as this is true for all invalid elections (Lemma 1). Such hypothesis testing requires a one-sided statistical test. In fact, as we consider environments that need not respond independently during each ballot request, we require a slightly richer family of tests, formulated in this setting by [5]. We briefly lay out the definitions here. The parameter δ will ultimately be set to μ in our application.

Definition 8. *[5, Definition 8] A sequence of bounded (real-valued) random variables* $X_1, \ldots$ *are said to be* δ-dominating *if, for each* $t \geq 0$*,* $\mathbb{E}[X_t \mid X_1, \ldots, X_{t-1}] \geq \delta$*. We apply this terminology to the distribution* $\mathcal{D}$ *corresponding to the random variables, writing* $\delta \trianglelefteq \mathcal{D}$*.*

Definition 9. *[5, Definition 9] Let* $\Sigma = [-2, 2]$*. A* stopping time *is a function* $\mathsf{Stop} : \Sigma^* \to \{0, 1\}$ *so that for any sequence* $x_1, x_2, \ldots$ *of values in* Σ *there is a finite prefix* $x_1, \ldots, x_k$ *for which* $\mathsf{Stop}(x_1, \ldots, x_k) = 1$*.*

For a sequence of random variables $X_1, \ldots$ *taking values in* Σ*, let* $\tau_{\mathsf{Stop}}(X_1, \ldots)$ *be the random variable given by the smallest* t *for which* $\mathsf{Stop}(X_1, \ldots, X_t) = 1$*. This naturally determines the random variable* $X_1, \ldots, X_{\tau_{\mathsf{Stop}}}$*, the prefix of the* X_i *given by the first time* $\mathsf{Stop}() = 1$*.*

Definition 10. *[5, Definition 10] An* adaptive audit test*, denoted* $(\mathsf{Stop}, \mathsf{R})$*, is described by two families of functions,* Stop_δ *and* R_δ*. For each* $0 < \delta \leq 1$*,*

(1) Stop_δ *is a stopping time, as in Definition 9, and*
(2) $\mathsf{R}_\delta : \Sigma^* \to \{0, 1\}$ *is the* rejection criterion*.*

Let $\mathcal{D}$ *be a probability distribution on* $\Sigma^{\mathbb{N}}$*; for such a distribution, define* $\alpha_{\delta,\mathcal{D}} = \mathbb{E}[\mathsf{R}_\delta(X_1, \ldots, X_\tau)]$ *where* $X_1, \ldots$ *are random variables distributed according to* $\mathcal{D}$ *and* τ *is determined by* Stop_δ*. The* risk *of the test* $(\mathsf{Stop}, \mathsf{R})$ *is*

$$\alpha = \sup_{\substack{0 < \delta \leq 2 \\ \delta \trianglelefteq \mathcal{D}}} \alpha_{\delta,\mathcal{D}} \,. \tag{3}$$

4 Bayesian Comparison Audits; Leveraging Marginal Marks

We present our auditor and analysis using a cryptographic game between the *auditor* and the *environment*, in the spirit of [5]. The auditor naturally reflects the role played by an auditing team in a conventional audit; as such it is provided with a CVR, the actual size of the election (in real-world settings this is provided by a trusted *ballot manifest*), and the ability to request ballots by identifier in order to carry out the audit. When the auditor has completed the audit, it returns either the

Auditor (MAudit)–Environment (Env) game for election $E = (\mathbf{B}, C, \mathsf{S})$ and CVR cvr

(1) **Setup**.
   (a) **Ballot and tabulation delivery (to Env).** The physical ballots $\mathbf{B}$ is given to Env.
   (b) **Ballot manifest and CVR delivery (to MAudit).** The size S and the cvr are given to the auditor MAudit.

(2) **Audit**. MAudit repeatedly makes a ballot request to Env, or chooses to conclude the audit:
A ballot request. MAudit requests a ballot from Env with identifier $\iota \in \{0,1\}^*$.
Env does one of two things:
   (a) Responds with a ballot $\mathbf{b}$ with identifier ι'; in this case, MAudit is given ι' and I, an interpretation drawn from $\mathcal{T}_{\mathbf{b}}$.
   (b) Responds with **No ballot**; this is forwarded to MAudit.

(3) **Conclusion**. MAudit returns one of the two values: Consistent or Inconclusive.

Figure 2: The $\mathsf{RLA}_{\texttt{MAudit},\texttt{Env}}(E, \mathsf{cvr})$ auditing game for comparison audits with multiple interpretations.

MAudit[Stop, R]($E = (C, \mathbf{B}, \mathsf{S}), \mathsf{cvr}$)

(1) Receive $\mathsf{cvr} = ((\iota_1, \mathcal{P}_1), \ldots, (\iota_t, \mathcal{P}_{\mathsf{S}_{\mathsf{cvr}}}))$.
(2) If cvr has repeated identifiers or $\mathsf{S} \neq \mathsf{S}_{\mathsf{cvr}}$, return Inconclusive.
(3) If cvr declares a winner W, define $\mu := \mu_{\mathsf{cvr}}$; otherwise, return Inconclusive.
(4) Initialize $\mathsf{iter} = 0$.
(5) Repeat
   (a) Increment $\mathsf{iter} := \mathsf{iter} + 1$.
   (b) Perform $\mathsf{D}_{\mathsf{iter}} :=$ BasicExperiment
   until $\mathsf{Stop}_{\mu}(\mathsf{D}_1, \ldots, \mathsf{D}_{\mathsf{iter}}) = 1$
(6) If $\mathsf{R}_{\mu}(\mathsf{D}_1, \ldots, \mathsf{D}_{\mathsf{iter}}) = 1$ return Consistent; otherwise return Inconclusive.

BasicExperiment:

(1) RowSelect: Select a row $r \in [\mathsf{S}]$ uniformly.
(2) Let ι be the identifier in row r; request delivery of ι.
(3) If a ballot $\mathbf{b}$ was delivered with identifier $\iota' = \iota$ and interpretation I^*, return

$$\mathsf{act} := \max_{\mathsf{A} \in C \setminus \mathsf{W}} \left(\mathsf{P}_r^{\mathbf{b}}(\mathsf{W}) - \mathsf{P}_r^{\mathbf{b}}(\mathsf{A}) - (I^*(\mathsf{W}) - I^*(\mathsf{A})) \right).$$

Else, return $\mathsf{act} := \max_{\mathsf{A} \in C \setminus \mathsf{W}} \left(\mathsf{P}_r^{\mathbf{b}}(\mathsf{W}) - \mathsf{P}_r^{\mathbf{b}}(\mathsf{A}) \right) + 1$.

Figure 3: The auditor MAudit[(Stop, R)].

token Inconclusive or Consistent. The environment, on the other hand, is responsible for providing physical ballots when they are requested. Note, in particular, that the auditor's access to ballots is entirely mediated by the environment, which may choose not to return ballots when they are requested, make choices about which ballot to return when multiple ballots share an identifier, etc. The power of this modeling framework is that the critical concept of risk can be defined *in the worst case over all possible behaviors of the environment*. This reflects a wide variety of failures—inadvertent or malicious—that occur in practical audits.

The formal Auditor-Environment game is described in Figure 2. We remark that each ballot "delivered" by the environment in the game generates a single draw from the associated ground truth distribution of interpretations; multiple requests for the same ballot are permitted by the convention, which generate new independent samples from the ground truth distribution (modeling a situation where an audit board evaluates the ballot afresh each time it is sampled).

The formal auditor. The auditor we consider is a standard "comparison auditor" [1] adapted to the setting where discrepancy is computed with respect to the expected value of the predicted distribution in the CVR rather than a single interpretation. Fortunately, once discrepancy is redefined in this way, the remaining analysis of the standard auditor requires no significant changes.

The formal auditor for the Bayesian setting is presented in Figure 3. We now define the risk of a Bayesian audit: this is an upper bound on the probability (taken over all elections and environments) that the audit outputs Consistent if the CVR is in fact invalid.

Definition 11 (Risk of Bayesian audit)**.** *Let* MAudit *be an Auditor. For election E and environment* Env *let* $\mathsf{RLA}_{\texttt{MAudit},\texttt{Env}}(E)$ *denote the random variable equal to the conclusion of the audit as described in Figure 2. An auditor* MAudit *has* α-risk *(or* α-soundness*) if, for all elections E, all invalid* cvr*s and all environments* Env*,*

$$\Pr_{\texttt{MAudit},\texttt{Env}}[\mathsf{RLA}_{\texttt{MAudit},\texttt{Env}}(E, \mathsf{cvr}) = \text{Consistent}] \leq \alpha\,.$$

Theorem 1. *Let E be an election and* cvr *be an invalid CVR. For any environment* Env*, let* $\mathsf{D}^{\mathrm{obs}}_{i,\texttt{Env}}$ *denote the random variable computed in* BasicExperiment *during iteration i; then* $\mathbb{E}[\mathsf{D}^{\mathrm{obs}}_{i,\texttt{Env}}] \geq \mathsf{D}_{\mathsf{cvr}}/\mathsf{S} \geq \mu_{\mathsf{cvr}}$.

Let (Stop, R) *be an adaptive audit test with risk α. Let* MAudit *be as in Figure 3,* MAudit[Stop, R] *has risk α.*

4.1 Conservative Comparison Audits

Our second approach is called a *conservative comparison audit*. At a high level, this can be seen as replacing the probability distribution from the previous section with a set of possible interpretations. For a declared winner W, the auditor runs the audit as though the interpretation that minimizes μ_{W} occurs with probability 1. When accurate prediction of the auditor distribution is possible this model has worse results than Bayesian interpretation but doesn't suffer from the poor

efficiency when one overshoots the probability of the auditor (see results in the next subsection). As a second advantage, for our modeling in the conservative setting, the environment is allowed to choose the interpretation of the ballot selected by the audit board among the possible interpretations of the ballot. This is opposed to the previous section where this interpretation was i.i.d. sampled by the game.

We continue to use the common definitions and terminology for ballots and interpretations. The major change is rather than calling for a ground truth distribution $\mathcal{T}_{\mathbf{b}}$, we merely define a set $T_{\mathbf{b}}$ of *possible interpretations* for this ballot. (That is, interpretations that could reasonably be the conclusion of an audit board's inspection of the ballot.) In the setting with a ground-truth distribution, the set $T_{\mathbf{b}}$ would naturally correspond to the *support* of the distribution $T_{\mathbf{b}} = \{I \in \mathcal{I} \mid \mathcal{T}_{\mathbf{b}}(I) > 0\}$.

Definition 12 (Conservative Interpretation limits)**.** *Let $E = (C, \mathbf{B}, \mathsf{S})$ be an election. For a ballot $\mathbf{b} \in \mathbf{B}$ and a candidate $\mathsf{A} \in C$, define*

$$\mathsf{T}^{\circ}_{\mathbf{b}}(\mathsf{A}) = \min\{I(\mathsf{A}) \mid I \in T_{\mathbf{b}}\},$$
$$\mathsf{T}^{\bullet}_{\mathbf{b}}(\mathsf{A}) = \max\{I(\mathsf{A}) \mid I \in T_{\mathbf{b}}\}.$$

Thus $\mathsf{T}^{\bullet}_{\mathbf{b}}(\mathsf{A})$ and $\mathsf{T}^{\circ}_{\mathbf{b}}(\mathsf{A})$ indicate the most and least favorable interpretations of the ballot for the candidate A. We additionally define

$$E^{\circ}(\mathsf{A}) = \sum_{\mathbf{b} \in \mathbf{B}} \mathsf{T}^{\circ}_{\mathbf{b}}(A), \qquad \text{and} \qquad E^{\bullet}(\mathsf{A}) = \sum_{\mathbf{b} \in \mathbf{B}} \mathsf{T}^{\bullet}_{\mathbf{b}}(A).$$

Definition 13 (Conservative margin and winner)**.** *The* conservative margin of A with respect to B *compares the worst and best case interpretations for two candidates:*

$$\mu^{+}_{\mathsf{A},\mathsf{B}} = \frac{E^{\circ}(\mathsf{A}) - E^{\bullet}(\mathsf{B})}{\mathsf{S}}.$$

We then define $\mu^{+}_{\mathsf{A}} = \min_{\mathsf{B} \in C \setminus \{\mathsf{A}\}} \mu^{+}_{\mathsf{A},\mathsf{B}}$. If there exists some candidate W such that $\mu^{+}_{\mathsf{W}} > 0$ we call this candidate the (conservative) winner and denote this quantity by μ^{+}. If a conservative winner exists, then it is unique. If there is no conservative winner, the election is called indeterminate*. We call a candidate L a conservative loser if there exists some other candidate A such that $\mu^{+}_{\mathsf{L},\mathsf{A}} < 0$.*

Observe that losing candidates may exist even in indeterminate elections and that, in general, a losing candidate candidate cannot tie the election even if every ballot is given the interpretation most favorable to the candidate. As mentioned above, conservative CVRs specify a set of declared interpretations for each ballot.

Definition 14 (Conservative Cast-Vote Record Table (CVR))**.** *Let C be a set of candidates. A* conservative Cast-Vote Record table (CVR) *is a sequence of pairs*

$$\mathsf{cvr}^{+} = ((\iota_1, P_1), \ldots, (\iota_t, P_{\mathsf{S}_{\mathsf{cvr}}})),$$

where the ι_r are distinct bitstrings in $\{0,1\}^*$ and each $P_r \subset \mathcal{I}$ is a subset of interpretations. The CVR declares that for each row r the interpretation of the ballot labeled ι_r lies in the set P_r. For each candidate $\mathsf{A} \in C$, we define

$$\mathsf{P}^{\circ}_r(\mathsf{A}) = \min\{I(A) \mid I \in P_r\},$$
$$\mathsf{P}^{\bullet}_r(\mathsf{A}) = \max\{I(A) \mid I \in P_r\},$$

$$\mathsf{cvr}^{\circ}(\mathsf{A}) = \sum_{r=1}^{\mathsf{S}_{\mathsf{cvr}}} \mathsf{P}^{\circ}_r(\mathsf{A}), \qquad \text{and} \qquad \mathsf{cvr}^{\bullet}(\mathsf{A}) = \sum_{r=1}^{\mathsf{S}_{\mathsf{cvr}}} \mathsf{P}^{\bullet}_r(\mathsf{A}).$$

Definition 15 (Declared winners, losers, and contradictory CVRs.)**.** *If there is a candidate $\mathsf{A} \in C$ with the property that $\mathsf{cvr}^{\circ}(\mathsf{A}) > \mathsf{cvr}^{\bullet}(\mathsf{B})$ for every $\mathsf{B} \in C \setminus \{\mathsf{A}\}$, then we say that A is the* declared conservative winner *according to cvr^{+}. If there is no such candidate, we say that cvr^{+} is* indeterminate*. Any candidate $\mathsf{L} \in C$ for which $\mathsf{cvr}^{\bullet}(\mathsf{L}) < \mathsf{cvr}^{\circ}(\mathsf{A})$ for some candidate $\mathsf{A} \in C$ is a* declared conservative loser*. We adopt the same naming conventions for such conservative CVRs as we do with Bayesian CVRs (that is, for the set of identifiers, size, and treating identifiers as indices for P_r and P_r).*

Finally, we say that two CVRs are contradictory *if there is a candidate declared as a winner in one and a loser in the other.*

An election or CVR can be indeterminate without a tie: e.g., there may be two candidates A and B for which $\mathsf{cvr}^{\bullet}(\mathsf{A}) > \mathsf{cvr}^{\circ}(\mathsf{B})$ and $\mathsf{cvr}^{\bullet}(\mathsf{B}) > \mathsf{cvr}^{\circ}(\mathsf{A})$.

Definition 16 (Conservative Declared Margin)**.** *We call a candidate L a conservative loser if there exists some other candidate A such that $\mu^{+}_{\mathsf{A},\mathsf{L}} > 0$. The* declared margin *of a conservative* cvr *with* declared winner W *is the quantity*

$$\mu^{+}_{\mathsf{cvr}} := \min_{\mathsf{A} \in C \setminus \mathsf{W}} \frac{\mathsf{cvr}^{\circ}(\mathsf{W}) - \mathsf{cvr}^{\bullet}(\mathsf{A})}{\mathsf{S}}.$$

Definition 17 (Conservative discrepancy)**.** *Let $E = (C, \mathbf{B}, \mathsf{S})$ be an election and let $\mathsf{cvr} = ((\iota_1, P_1), \ldots, (\iota_t, P_t))$ be a conservative CVR with declared winner W. For a ballot $\mathbf{b} \in \mathbf{B}$ and interpretation I, the* conservative discrepancy *of I with respect to $\mathbf{b}$ is*

$$\mathsf{D}^{+}[I, \mathbf{b}; \mathsf{W}] = \max_{\mathsf{A} \in C \setminus \mathsf{W}} \left((I(\mathsf{W}) - I(\mathsf{A})) - (T^{\bullet}_{\mathbf{b}}(\mathsf{W}) - T^{\circ}_{\mathbf{b}}(\mathsf{A})) \right).$$

We expand this definition to apply, additionally, to a special symbol $\perp$:

$$\mathsf{D}^{+}[I, \perp; \mathsf{W}] = \max_{\mathsf{A} \in C \setminus \mathsf{W}} (I(\mathsf{W}) - I(\mathsf{A})) + 1.$$

The discrepancy of a cast vote record table cvr *is:*

$$\mathsf{D}^{+}_{\mathsf{cvr}} = \sum_{i=1}^{t} \min\{\mathsf{D}[I, \mathbf{b}; \mathsf{W}] \;\big|\; I \in \mathrm{I}^{\mathsf{cvr}}_i, \mathbf{b} = \perp \text{ or } \mathrm{id}_{\mathbf{b}} = \iota_i\}.$$

Auditor (MAudit)–Environment (Env) game for election $E = (\mathbf{B}, C, \mathsf{S})$ and CVR cvr

(1) **Setup**.
   (a) **Ballot and tabulation delivery (to Env).** The physical ballots $\mathbf{B}$ is given to Env.
   (b) **Ballot manifest and CVR delivery (to MAudit).** The size S and the cvr are given to the auditor MAudit.

(2) **Audit**. MAudit repeatedly makes a ballot request to Env, or chooses to conclude the audit:
   A ballot request. MAudit requests a ballot from Env with identifier $\iota \in \{0,1\}^*$.
   Env either responds a ballot $\mathbf{b}$ with single identifier ι' and **an interpretation** $I \in T_{\mathbf{b}}$ or responds with **No ballot.**

(3) **Conclusion**. MAudit returns one of the two values: Consistent or Inconclusive.

Figure 4: The $\mathsf{RLA}_{\mathtt{MAudit},\mathtt{Env}}(E, \mathsf{cvr})$ auditing game for comparison audits with multiple interpretations.

Definition 18 (Conservative consistency and validity)**.** *A* $\mathsf{cvr}^+ = ((\iota_1, P_1), \ldots, (\iota_t, P_t))$ *is* consistent *with E if the ballots* $\mathbf{B}$ *are uniquely labeled, the identifiers appearing in* cvr *are identical to those appearing on the ballots of E, and for each ballot* $\mathbf{b} \in \mathbf{B}$, $T_{\mathbf{b}} \subset P_{\iota_{\mathbf{b}}}$. *When* $T_{\mathbf{b}} = P_{\mathrm{id}_{\mathbf{b}}}$ *for each ballot, we say that* cvr *is the* canonical *CVR for the election E. We only define these notions for uniquely labeled elections.*

For election E with winner W*, a* cvr *is invalid if it declares a winner other than* W.

4.1.1 Conservative Game and Auditor

We consider the following adaption of the auditing game where the environment is allowed to specify the interpretation returned to the auditor in Figure 4 with the change in boldface. The auditor is identical to that in Figure 3 except the Bayesian cvr margin in Step (3) is replaced with μ^+_{cvr}.

Theorem 2. *Let E be an election and* cvr *be an invalid CVR. For any environment* Env *engaging in Figure 4, let* $\mathsf{D}^{\mathrm{obs}}_{i,\mathtt{Env}}$ *denote the random variable computed in* BasicExperiment *then* $\mathbb{E}[\mathsf{D}^{\mathrm{obs}}_{i,\mathtt{Env}}] \geq \mathsf{D}_{\mathsf{cvr}}/\mathsf{S} \geq \mu$. *where* μ *is the value computed in Step (3).*

Let $(\mathsf{Stop}, \mathsf{R})$ *be an adaptive audit test with risk* α. *Let* MAudit *be as in Figure 3 with* μ_{cvr} *replaced with* μ^+_{cvr}, $\mathtt{MAudit}[\mathsf{Stop}, \mathsf{R}]$ *has risk* α.

5 Completeness of Bayesian and Conservative Audits; Efficiency Analysis

The previous subsection established that one can recover a natural RLA from CVRs that declare multiple interpretations for ballots. In the case when all ballots and CVRs have a single interpretation the audit is a traditional ballot comparison audit. We also note that the auditor receives a single interpretation of the ballot. This models the fact that an audit board has to produce a final adjudication of a ballot. As described above, the purpose of the test is to decide whether $\mathbb{E}[\mathsf{D}_{\mathsf{cvr}}/\mathsf{S}] \geq \mu_{\mathsf{cvr}}$.

Perhaps the most widely deployed test meeting the demands outlined in the previous section is the Kaplan-Markov test (though there are other natural choices [10, 11, 26, 41]); in particular, this is the test featured in the Arlo RLA administration system. The basic Kaplan-Markov test (omitting minimum and maximum sample sizes) is as follows: for a parameter $\gamma > 1$, define the value

$$\mathsf{Risk}^{(\gamma)}_{\delta}(\mathsf{D}_1, \ldots, \mathsf{D}_\ell) = \prod_{\mathrm{iter}=1}^{\ell} \left(\frac{1 - \frac{\delta}{2\gamma}}{1 - \frac{\mathsf{D}_{\mathrm{iter}}}{2\gamma}} \right).$$

Intuitively, the "inflation" parameter γ determines the relationship between the rate of ballot comparison inconsistencies and sample sizes. Common values in the literature are approximately 1.1, see RLACalc. Moreover, the stopping time for risk limit α is determined by the test $\mathsf{Risk}_{\delta} \overset{?}{\leq} \alpha$; when this occurs, the test rejects the hypothesis (that the mean is larger than μ) and, in our setting, the auditor would output Consistent.

Simulation parameters. We consider a two candidate election with 100,000 ballots with $m = .5\%$ marginal ballots and underlying error rates of $o_1 = .1\%$, $u_1 = .1\%$, $o_2 = .01\%$, and $u_2 = .01\%$ [1]; Errors o_1 and o_2 represent ballots with discrepancies of $+1$ and $+2$ respectively. If the CVR lists a vote for the winner W and the actual ballot shows a vote for a loser this is an o_2 error. The actual ballot showing no vote results in an o_1, this is called an undervote. The errors u_1 and u_2 are defined similarly for discrepancies of $-1, -2$. For marginal ballots, we assume there are two possible interpretations: an interpretation for W and an interpretation of an undervote. Throughout the simulations, we assign a discrepancy of 1 and 0 with equal probability in these cases. For the math, the important thing is the distribution of discrepancy, not the votes appearing on the ballots. We compare three approaches in Table 2:

(1) In the *Baseline* approach, half of the marginal ballots are counted as votes for the reported winner on the CVR. When a marginal ballot is selected for audit it is determined as a vote for W with probability 50%. Note this can result in discrepancy values of $\{-1, 0, 1\}$.
(2) In the *Bayesian* approach, the margin receives $\mathsf{P}^{\mathsf{Q}}_r(\mathsf{W}) = .5$ "votes" for each marginal ballot. As above, when a marginal ballot is selected for audit it is determined as a vote for W with probability 50%. However, since $\mathsf{P}^{\mathsf{Q}}_r(\mathsf{A}) = .5$ the possible discrepancy values are $\{-.5, .5\}$
(3) In the *Conservative* approach, no marginal ballots are included in the margin and only negative discrepancy values are possible if the auditor interprets the ballot as a vote for W.

All results perform 5000 simulations for each parameter setting. A simulation pulls a uniform ballot until the risk limit is met. Each time a marginal ballot is pulled its interpretation is independently sampled (50% probability of vote for W and 50% of blank). RLAs require the most work for small margins which is where our improvement is evident. We report on the mean, standard deviation, median, and 95% threshold of ballots retrieved in Table 2. In practice, the 95% mark is most relevant; this reflects the fact that the work to conduct an additional round of an RLA is often prohibitive—requiring a distributed process across a whole region—so termination within the specified sample size with high probability is desirable. The Bayesian approach reduces the 95% percentile of ballots sampled by roughly 10.5%. Roughly, this improvement arises because the variance of discrepancy for "marginal" ballots is reduced from $1/2$ using the baseline approach to $1/4$ using the Bayesian approach.

In the above, both the ground truth (observed by the auditor) and CVR prediction probability of a marginal mark being interpreted as a mark is $p_m = .5$. This is the setting that has the largest improvement on the variance of discrepancy. However, for varying values of p_m the approach still provides efficiency improvements over the baseline approach. This is shown in Table 3. Note for $p_m \in \{0, 1\}$ the baseline and Bayesian approach are identical as marginal ballots never result in nonzero discrepancy. In Table 4, we consider two separate parameters for the probability that the CVR marks each marginal ballot as a vote for W, denoted p_{cvr} and the probability that the auditor does the same denoted $p_{\texttt{MAudit}}$. Interestingly, the baseline approach outperforms the Bayesian approach when $p_{\mathsf{cvr}} > p_{\texttt{MAudit}}$ by $\approx 20\%$; however Bayesian can outperform Baseline by $\approx 30\%$ when $p_{\mathsf{cvr}} < p_{\texttt{MAudit}}$. This is part of the reason we introduce the conservative approach where one does not have to estimate probabilities.

6 Election Contestation and Competitive Ballot Comparison Audits

We consider a new class of post-election audits we call *competitive audits*. These audits can efficiently distinguish CVRs that are consistent with the ballots from invalid CVRs and, more generally, reconcile competing claims of victory made by two CVRs. This novel auditing technique also provides, as described earlier, a direct approach to handling election contestation.

To simplify our treatment of these audits, we focus on the conservative setting, in which CVRs declare, for each ballot, a subset of possible interpretations without assigning a probability distribution to the interpretations in the subset.

An intuitive survey of the framework. After an election, we assume that each candidate $\mathsf{A} \in C$ is represented by an *advocate*. In a preliminary "rescan phase," the advocate for the candidate A may inspect the ballots **B** and submit to the audit a conservative CVR, denoted cvr_A; the idea is that the advocate will submit a CVR that is favorable for the candidate. If the declared conservative winner of cvr_A is A, we say that this is a "declaration of victory." (Advocates may also be allowed to announce the presence of duplicate ballot labels in the election, which can then be corrected by the audit. For simplicity, however, we simply treat **B** as uniquely labeled in this setting.) Following this, the audit commences with the "judgment phase:" after considering some of the ballots, the audit either declares the audit to be Inconclusive or, for some candidate $\mathsf{A} \in C$, declares that "A is the winner."

The judgment phase; reconciling disagreements among the CVRs. If no pair of the submitted CVRs are contradictory, the audit concludes without considering any ballots. In this non-contradictory case, if any CVR declares victory the associated candidate is declared to be the winner of the audit; if, alternatively, no CVR declares a winner, the audit concludes with Inconclusive.

Otherwise, if two submitted CVRs are contradictory, the audit must settle the contradictory claims made by various submitted CVRs. In this case, some candidate A must be a declared winner according to one CVR and a declared loser according to another. We will see that there must then exist an identifier ι on which the two CVRs make contradictory assertions. Intuitively, one of these contradictory CVRs can then be removed from consideration by fetching the ballot with this identifier, if it exists, and relying on this ballot to settle the contradictory claims made by the two CVRs.

The natural procedure is complicated by three issues:

(1) two contradictory CVRs may declare different sets of identifiers rather than disagreeing on the interpretation of specific ballots;
(2) the audit should provide suitable protection against an imperfect or malicious environment that may not always respond with a given ballot, even when it exists; and
(3) the audit should withstand a small collection of errors in the creation of CVRs by advocates to reflect the practical difficulty of producing a perfect CVR, even by a well-intentioned advocate.

We remark that the second issue above forces the audit to treat "positive evidence" and "negative evidence" differently: for example, while the delivery of a ballot that disagrees with a particular CVR, either by possessing an identifier that is not declared in the CVR or having an interpretation that is inconsistent with those declared in the CVR, is considered evidence against the CVR, the failure of the environment to produce a ballot declared in a particular CVR is not. This cautious convention prevents a malicious environment from misleading the auditor. An environment that can refuse to retrieve ballots can always cause the audit to output Inconclusive.

Ultimately, we will prove two facts about the audit.

- If one of the submitted CVRs is consistent with the ballots and ballots are faithfully returned to the auditor dur-

	Baseline				Conservative				Bayesian			
μ	Mean	Stdev	Median	95%	Mean	Stdev	Median	95%	Mean	Stdev	Median	95%

Table 3: Number of ballots across p_m, $\alpha = .05, \gamma = 1.1, \mu = .01$.

ing the judgment phase, then—except with small probability that can be explicitly bounded as a function of the number of samples—the auditor will correctly conclude the audit with "W is the winner." Thus, if the advocate for W indeed acts in W's best interests, W can be confident that the audit will conclude favorably.

- If one of the submitted CVRs is consistent with the ballots and an alternate CVR declares that a losing candidate L won the election, the audit will not conclude that "L is the winner." Furthermore, this guarantee is robust against ballot suppression—it does not require that ballots are correctly returned when requested.

Taken together, we see that if a candidate's advocate submits a consistent CVR, the candidate can be assured a victory if no ballots are lost or suppressed, and can be assured that no losing candidate is declared the victor even in the face of ballot suppression.

6.1 Modeling Competitive Audits

Formally, we model a competitive audit with two parties, the *auditor* (denoted Judge) and the *environment* (denoted Env). The auditor is responsible for analyzing submitted conservative CVRs, requesting ballots to carry out the audit, and arriving at a final conclusion. The environment is responsible for servicing requests by the auditor for individual ballots: in particular, the environment is in possession of the ballots and, for each request for a ballot by the auditor, decides which ballot (if any) will be returned to the auditor and, moreover, how that ballot is to be interpreted (that is, which possible interpretation is to be adopted).

As mentioned above, this two party modeling of the audit reflects the fact that even a well-designed auditor may have to contend with such complexities as loss of ballots, potential malicious suppression of ballots, and the final choice of an "auditing board" in the interpretation of a ballot. These decisions are in the hands of the environment.

Definition 19 (Competitive auditor; competitive environments; honest environments)**.** *A* competitive auditor Judge *is a randomized procedure for carrying out a competitive audit. In the context of an election $E = (C, \mathbf{B}, \mathsf{S})$ with conservative ballots $\mathbf{B}$, the auditor is invoked with:*

(1) the set of candidates C,
(2) the size S of the election, and
(3) a list of conservative CVRs $\mathsf{cvr}_1^+, \ldots, \mathsf{cvr}_k^+$.

The audit proceeds in rounds, each round being an opportunity for the auditor to request delivery of a ballot (specified by an identifier) along with an interpretation of the ballot. After a sequence of requests, the auditor concludes the audit, resulting in either the statement Inconclusive*, or "A is the winner" for some candidate $\mathsf{A} \in C$.*

Ballot requests are handled by a second randomized procedure called the environment*. The environment is invoked with $(C, \mathbf{B}, \mathsf{cvr}_1^+, \ldots, \mathsf{cvr}_k^+)$. To each (identifier) request ι made by the auditor, the environment either responds with a ballot $\mathbf{b} \in \mathbf{B}$ and a single interpretation $I \in T_{\mathbf{b}}$ or a "no ballot" symbol $\perp$. While the environment may choose not to return a ballot when a matching ballot exists in $\mathbf{B}$, any ballot it does return is assumed to match the requested identifier: $\iota_{\mathbf{b}} = \iota$.*[3]

[3]These conventions are a convenience: the auditor can check the identifier of a returned ballot to ensure that it matches the request and, additionally, ensure that the returned interpretation is among those associated with the ballot; if either of these verifications fail, the auditor treats this ballot response as a $\perp$.

p_{cvr}	$p_{\texttt{MAudit}} = p_{\text{cvr}} + .4$			$p_{\texttt{MAudit}} = p_{\text{cvr}} + .2$			$p_{\texttt{MAudit}} = p_{\text{cvr}}$			$p_{\texttt{MAudit}} = p_{\text{cvr}} - .2$			$p_{\texttt{MAudit}} = p_{\text{cvr}} - .4$

Table 4: 95% of number of ballots for Kaplan-Markov comparison audit, $\alpha = .05, \gamma = 1.1, \mu = .01$.

An environment is honest *if it responds to any requested identifier with a matching ballot* $\mathbf{b}$ *and an interpretation* $I^* \in \mathtt{I}_{\mathbf{b}}$ *when such a ballot exists.*

Definition 20. *Let* $E = (C, \mathbf{B}, \mathsf{S})$ *be an election. For a competitive auditor,* Judge*, environment* Env*, and a sequence of conservative CVR tables* $\mathsf{cvr}_1^+, \ldots, \mathsf{cvr}_k^+$*, define*

$$\mathsf{CompeteA}[\mathtt{Judge}, \mathtt{Env}; E; \mathsf{cvr}_1^+, \ldots, \mathsf{cvr}_k^+]$$

to be the result of the audit (returned by Judge*) described in Figure 5. As both the auditor and the environment may be randomized procedures, this is a random variable taking values in the set* $C \cup \{\textsc{Inconclusive}\}$.

Definition 21 (Disagreement Set)**.** *Define the Omission Set as* $\mathtt{Omission}(\mathsf{cvr}_A, \mathsf{cvr}_B) = \mathtt{Idents}(\mathsf{cvr}_A) \setminus \mathtt{Idents}(\mathsf{cvr}_B)$.

Define the Conflict Set as $\mathtt{Conflict}(\mathsf{cvr}_A, \mathsf{cvr}_B) = \{\iota \mid \iota \in \mathtt{Idents}(\mathsf{cvr}_A) \cap \mathtt{Idents}(\mathsf{cvr}_B)$ *and* $P_{\mathsf{cvr}_A,\iota} \cap P_{\mathsf{cvr}_B,\iota} = \emptyset\}$

The disagreement set is the set

$$\mathtt{Disagree}(\mathsf{cvr}_A, \mathsf{cvr}_B) = \begin{smallmatrix}\mathtt{Omission}(\mathsf{cvr}_A, \mathsf{cvr}_B) \cup \\ \mathtt{Conflict}(\mathsf{cvr}_A, \mathsf{cvr}_B)\end{smallmatrix}$$

The identifiers ι *in the disagreement set are those for which* cvr_A *makes a claim about a ballot in* $\mathbf{B}$ *that is inconsistent with* cvr_B*, in the sense that either*

(1) cvr_B *does not recognize that the ballot exists at all* $(\mathtt{Omission}(\mathsf{cvr}_i, \mathsf{cvr}_j))$ *or*
(2) cvr_A *and* cvr_B *make contradictory claims about ballot interpretation* $(\mathtt{Conflict}(\mathsf{cvr}_A, \mathsf{cvr}_B))$.

Intuitively, a CVR cvr_B will be disqualified if a ballot $\mathbf{b}$ is found during the judgment phase with either i) an identifier ι that was not reported on cvr_B or ii) an interpretation I^* that was not in the set of possible interpretations $P_{\mathsf{cvr}_A,\iota}$.

Definition 22. *(Disqualification Function) Define function* $\mathtt{Disqual} : \Sigma^* \to \{0,1\}$ *that takes in an identifier,* ι*, an interpretation,* I^**, and a CVR,* cvr.

$$\mathtt{Disqual}(\iota, I^*, \mathsf{cvr}) = \begin{cases} 1 & \iota \notin \mathtt{Idents}(\mathsf{cvr}) \vee I^* \notin P_{\mathsf{cvr},\iota}, \\ 0 & \textit{otherwise.} \end{cases}$$

The intuition is that Disqual looks up the identifier ι in cvr and outputs a disqualification vote if the provided interpretation I^* is not present on the row $\mathsf{cvr}(\iota)$.

We now analyze the competitive auditor $\mathtt{Judge}^t$ in Figure 6. The parameter t is a positive integer that calibrates the robustness of the audit to possible interpretation errors on the part of the advocates; see Theorems 5 and 6.

6.2 Analysis of the Competitive Auditor $\mathtt{Judge}^t$

In this section, we make two claims arguing about the completeness and soundness of Judge. We first consider these claims in the case that an "honest" party makes no errors and then consider the setting with errors in the next subsection.

Theorem 3 shows that if there is an election winner W and some cvr_W is consistent with the physical ballots, then W will be the output of Judge. This theorem assumes an honest environment. Recall that (i.) the consistency of a CVR means that for each ballot, the CVR submits a superset of the actual interpretations for that ballot and (ii.) a candidate is an election winner only if it wins regardless of the interpretation of ballots with multiple interpretations.

Theorem 4 shows that if a candidate is an election loser L and one of the submitted cvrs is canonical, then L will never be the output of Judge. This theorem does not require an honest environment. Recall that a CVR is canonical if for every ballot it declares exactly the set of interpretations on the physical ballots. Intuitively, since a loser loses no matter the interpretation declared by the environment, a canonical CVR is never disqualified by Judge and L can never be the output.

The main requirement for both theorems is that some advocate asserts the full set of interpretations for each physical ballot on the CVR; this may be either a superset or the exact set, depending on the circumstances. An advocate is disqualified when a ballot is delivered with a ground-truth interpretation that does not appear in the advocate's CVR. Note that any ballot for which no ground-truth interpretation appears on the CVR is sure to disqualify the advocate and, in fact, the

Competitive auditor (Judge)–Environment (Env) game

$$\mathsf{CompeteA}[\mathtt{Judge},\mathtt{Env};\mathbf{B},C,\mathsf{S}].$$

(1) **Advocate CVR generation**. For each candidate $\mathsf{A} \in C$, an advocate for A—with access to the full candidate set C and the physical ballots $\mathbf{B}$—generates a cast-vote record table, $\mathsf{cvr}_{\mathsf{A}}^{+}$.

(2) **Setup**.

  (a) **Candidates, ballots, and CVR delivery (to Env).** $(C, \mathbf{B}, \{\mathsf{cvr}_{\mathsf{A}}^{+} \mid \mathsf{A} \in C\})$ are given to the environment Env.

  (b) **Candidate list, ballot manifest, and CVR delivery (to Judge).** $(C, \mathsf{S}, \{\mathsf{cvr}_{\mathsf{A}}^{+} \mid \mathsf{A} \in C\})$ are given to the auditor Judge.

(3) **Audit**. Judge repeatedly makes a request to Env, or chooses to conclude the audit:

- **A ballot request**. Judge requests a ballot from Env with identifier $\iota \in \{0,1\}^*$.
  (a) Env either responds either with an interpretation I where $I \in T_{\mathbf{b}}$ for some ballot $\mathbf{b}$ for which $\iota = \iota_{\mathbf{b}}$ or responds with $\perp$ (meaning **No ballot**).

(4) **Conclusion**. Judge either returns:

A **is the winner** meaning "The audit is consistent with victory by candidate A," or

INCONCLUSIVE meaning "Audit inconclusive."

Figure 5: The competitive auditing game CompeteA with auditor Judge, environment Env, election E, and advocate CVRs $\{\mathsf{cvr}_{\mathsf{A}}^{+} \mid \mathsf{A} \in C\}$.

analysis only requires this weaker statement.

Theorem 3 (Competitive completeness)**.** *Let* $\mathtt{Judge}^t$ *be the competitive auditor with sample parameter* $t \in \mathbb{Z}^+$*. Let* $E = (C, \mathbf{B}, \mathsf{S})$ *be an election with winner* $\mathsf{W} \in C$*. Let* cvr_* *be consistent with* E *and declare* W *to be the winner. Let* $\mathsf{cvr}_1, \ldots, \mathsf{cvr}_{k-1}$ *be any collection of CVRs. Then*

$$\mathsf{CompeteA}[\mathtt{Judge}^t, \mathtt{Env}; E; \mathsf{cvr}_*, \mathsf{cvr}_1, \ldots, \mathsf{cvr}_{k-1}] = \mathsf{W},$$

for any honest environment Env*. Furthermore,* $\mathtt{Judge}^t$ *completes the audit with no more than* $tk(k-1)$ *ballot samples.*

We remark that the conclusion of the Theorem holds even for $t = 1$, in which case that auditor only draws $k(k-1)$ ballots. Larger values of t are relevant for managing interpretation errors; see the next subsection.

Theorem 4 (Competitive soundness)**.** *Let* $\mathtt{Judge}^t$ *be the competitive auditor with integer sample parameter* $t > 0$*. Let* $E = (C, \mathbf{B}, \mathsf{S})$ *be an election with loser* $\mathsf{L} \in C$*. Let* cvr_* *be the canonical CVR for* E*. Let* $\mathsf{cvr}_1, \ldots, \mathsf{cvr}_{k-1}$ *be any collection of CVRs. Then*

$$\Pr[\mathsf{CompeteA}[\mathtt{Judge}, \mathtt{Env}; E; \mathsf{cvr}_*, \mathsf{cvr}_1, \ldots, \mathsf{cvr}_{k-1}] = \mathsf{L}] = 0,$$

Competitive auditor $\mathtt{Judge}^t[C, \mathsf{S}; \mathsf{cvr}_1, \ldots, \mathsf{cvr}_k]$;

The $\mathtt{Judge}^t$ immediately outputs INCONCLUSIVE if any advocate announces duplicate labels. For each submitted CVR $\mathsf{cvr}_{\mathsf{A}}$, define $\mathtt{Idents}_{\mathsf{A}} := \mathtt{Idents}(\mathsf{cvr}_{\mathsf{A}}) = \{\iota \mid$ the identifier ι appears in $\mathsf{cvr}_{\mathsf{A}}\}$ and, for an identifier $\iota \in \mathtt{Idents}_{\mathsf{A}}$, let $\mathsf{P}_{\mathsf{A},\iota}$ denote the set of interpretations associated with ι in $\mathsf{cvr}_{\mathsf{A}}$.

(1) Remove from consideration any CVRs that do not have size S.

(2) For each ordered pair (A, B) for which the (remaining) CVRs $\mathsf{cvr}_{\mathsf{A}}$ and $\mathsf{cvr}_{\mathsf{B}}$ are contradictory:

- Let $\iota^{(1)}, \ldots, \iota^{(t)}$ be independent and uniformly random elements of $\mathtt{Disagree}(\mathsf{cvr}_{\mathsf{A}}^{+}, \mathsf{cvr}_{\mathsf{B}}^{+})$. For each $s \in \{1, \ldots, t\}$, request the ballot matching $\iota^{(s)}$. Let $I^{(1)}, \ldots, I^{(t)}$ denote the sequence of returned identifiers (including $\perp$).
- For each request s, we define the sequence $\mathtt{Disqual}_s = \mathtt{Disqual}(\iota^{(s)}, I^{(s)}, \mathsf{cvr}_{\mathsf{B}}^{+})$.
- Finally, if $\sum_{s=1}^{t} \mathtt{Disqual}_s > t/2$, disqualify $\mathsf{cvr}_{\mathsf{B}}^{+}$.

(3) Remove all disqualified CVRs from consideration.

(4) If there remains any pair of contradictory CVRs, or no remaining CVR declares victory, the audit concludes with INCONCLUSIVE.

(5) Otherwise, a winner W is declared by a remaining CVR that is not contradicted by any other remaining CVR and the audit concludes with "W is the winner."

Figure 6: The competitive auditor $\mathtt{Judge}^t$, with input C, S, and advocate CVRs $\{\mathsf{cvr}_{\mathsf{A}}^{+} \mid \mathsf{A} \in C\}$ where there are k submitted CVRs. The parameter t determines the number of ballot samples collected by the auditor: in particular, the auditor requests no more than $tk(k-1)$ ballots.

6.3 Handling Advocacy Errors

As producing cast-vote records is a process involving manipulation and interpretation of physical ballots, it may be unrealistic to demand that even a well-intentioned auditor can produce a perfectly consistent (or canonical) CVR. Occasional mistakes may occur during ballot interpretation, there may be some uncertainty about establishing a set I that necessarily contains all interpretations that an auditing board may assign to a ballot, and ballots may be overlooked. As we insist in our setting that CVRs have size consistent with the election, we note that an advocate can always pad out a CVR by adding invented identifiers that do not correspond to any ballot. All told, these considerations lead us to consider CVRs that are "nearly" consistent, defined formally below.

Theorems 5 and 6 extend these theorems to the case when "honest" parties make a small fraction of errors.

Definition 23. *Let $E = (C, \mathsf{S}, \mathbf{B})$ be an election. We say that a* cvr *(over C) is $(1-\epsilon)$-consistent if the size of the CVR is* S *and there is a subset C of* $\texttt{Idents}(\mathsf{cvr})$ *of size at least $(1-\epsilon)\mathsf{S}$ on which* cvr *is consistent, which is to say that for each $\iota \in C$, there is a ballot $\mathbf{b} \in \mathbf{B}$ for which $\iota = \iota_{\mathbf{b}}$ and $\mathtt{I}_{\mathbf{b}} \subset \mathtt{I}_{\iota}$ (where $\mathtt{I}_{\iota}$ is the set of interpretations declared by* cvr *for ι). Define a $(1-\epsilon)$-canonical* cvr *analogously.*

Let $Bin[\gamma, t; t/2]$ denotes the tail of the binomial distribution: specifically, if $X_1, \ldots, X_t$ are independent Bernoulli random variables for which $\Pr[X_i = 1] = \gamma$, then $Bin[\gamma, t; t/2]$ is the probability that $\sum_i X_i \geq t/2$.

Theorem 5 (Competitive completeness with imperfect advocacy)**.** *Let* $\mathtt{Judge}^t$ *be the competitive auditor with integer sample parameter $t > 0$. Let $E = (C, \mathbf{B}, \mathsf{S})$ be an election with winner $\mathsf{W} \in C$. Let cvr_* be $(1-\epsilon)$-consistent with E and declare W to be the winner with margin $\mu_{\mathsf{cvr}_*} > 4\epsilon$. Let $\mathsf{cvr}_1, \ldots, \mathsf{cvr}_{k-1}$ be any collection of CVRs and let* $\mathtt{Env}$ *be an honest environment. Then*

$$\Pr[\mathsf{CompeteA}[\mathtt{Judge}^t, \mathtt{Env}; E; \mathsf{cvr}_*, \mathsf{cvr}_1, \ldots, \mathsf{cvr}_{k-1}] = \mathsf{W}] \geq 1 - 2(k-1)Bin[2\epsilon/\mu_{\mathsf{cvr}_*}, t; t/2].$$

For $\gamma < 1/2$ (guaranteed above by $4\epsilon < \mu_{\mathsf{cvr}_*}$), the quantity $Bin[\gamma, t; t/2] = \exp(-\omega(t))$. Under the mild assumption that $\epsilon < \mu_{\mathsf{cvr}_*}/6$, say, the number of samples required by such an audit to achieve any particular risk limit is independent of μ_{cvr_*}. An advocate may reduce μ_{cvr_*} in an effort to be consistent with the underlying ballots.

Theorem 6 (Competitive soundness)**.** *Let* $\mathtt{Judge}^t$ *be the competitive auditor with integer sample parameter $t > 0$. Let $E = (C, \mathbf{B}, \mathsf{S})$ be an election with loser $\mathsf{L} \in C$. Let cvr_* be a $(1-\epsilon)$-canonical CVR for E. Define*

$$\mu_{\mathsf{cvr}_*} = \frac{\max_{\mathsf{A} \in C \setminus \mathsf{L}} (\mathsf{cvr}_*^-(\mathsf{A}) - \mathsf{cvr}_*^+(\mathsf{L}))}{\mathsf{S}}.$$

Let $\mathsf{cvr}_1, \ldots, \mathsf{cvr}_{k-1}$ be any collection of CVRs. Then

$$\Pr[\mathsf{CompeteA}[\mathtt{Judge}^t, \mathtt{Env}; E; \mathsf{cvr}_*, \mathsf{cvr}_1, \ldots, \mathsf{cvr}_{k-1}] = \mathsf{L}] \leq 2(k-1)Bin[2\epsilon/\mu, t; t/2]$$

for any environment $\mathtt{Env}$*. Furthermore,* $\mathtt{Judge}^t$ *completes the audit with no more than $tk(k-1)$ ballot samples.*

6.4 Remarks on Bayesian competitive audits

While we do not present any details, we make a few remarks about competitive audits in the Bayesian case. This calls for each advocate to submit a Bayesian CVR. Now we note that identification of a collection of ballots D on which the two CVRs substantively disagree permits us to define two different probability distributions on this set of ballots: (i.) select a ballot at random from D, and (ii.) output an interpretation given by the CVR in question. Then the classical sequential probability ratio test provides a statistical test for distinguishing the two models [42]. This can serve as the statistical mechanism for selecting between contradictory CVRs.

ElectionGuard: a Cryptographic Toolkit to Enable Verifiable Elections

Dan S. Wallach*
Rice University

Abstract

ElectionGuard is a flexible set of open-source tools that—when used with traditional election systems—can produce end-to-end verifiable elections whose integrity can be verified by observers, candidates, media, and even voters themselves. ElectionGuard has been integrated into a variety of systems and used in actual public U.S. elections in Wisconsin, California, Idaho, Utah, and Maryland as well as in caucus elections in the U.S. Congress. It has also been used for civic voting in the Paris suburb of Neuilly-sur-Seine and for an online election by a Switzerland/Denmark-based organization.

The principal innovation of ElectionGuard is the separation of the cryptographic tools from the core mechanics and user interfaces of voting systems. This separation allows the cryptography to be designed and built by security experts without having to re-invent and replace the existing infrastructure. Indeed, in its preferred deployment, ElectionGuard does not replace the existing vote counting infrastructure but instead runs alongside and produces its own independently-verifiable tallies. Although much of the cryptography in ElectionGuard is, by design, not novel, some significant innovations are introduced which greatly simplify the process of verification.

This paper describes the design of ElectionGuard, its innovations, and many of the learnings from its implementation and growing number of real-world deployments.

1 Introduction

The ElectionGuard project was initiated by Microsoft in 2018 and announced publicly in 2019. The project intends to help support democratic institutions by building and deploying free, open-source tools that enable so-called, *end-to-end (E2E) verifiable* elections [8]—that is, elections in which voters and observers can confirm the accuracy of the results without having to trust the election software, hardware, or personnel outside of their control. ElectionGuard deters disinformation about election results by providing publicly-verifiable evidence that reported election outcomes are accurate.

One of the principal novelties of ElectionGuard is that it is *not* yet another static verifiable election system. Instead, it is a flexible set of tools that can be used by election equipment vendors within their own systems and processes. ElectionGuard encapsulates the cryptographic functionality and provides simple interfaces that can be used without cryptographic expertise. Broadly, the ElectionGuard tools support three phases of an election.

Key Generation and Set Up. In this phase, designated *guardians* engage, with the assistance of an *administrator*, in a protocol to jointly establish a public encryption key which will be used to encrypt all votes in one or possibly several elections. Additionally, a detailed manifest is provided to describe specifics of an election such as the contests, candidates, and voting rules. The resulting key and manifest will be incorporated into an ElectionGuard application that will run on devices used by voters to cast their votes during the election.

Ballot Encryption. In the course of an election, each time an enabled device used by a voter receives a voter's selections, it calls its embedded copy of the ElectionGuard application. ElectionGuard encrypts the ballot contents and returns back to the calling application a *confirmation code* in the form of a cryptographic hash of the voter's encrypted selections and other data. In most scenarios, the intent is that this confirmation code be given to the voter, and enables voters to confirm that their votes have been recorded without any change for inclusion in the tally. The systems that capture voter selections and call the ElectionGuard application can vary widely—including fully electronic voting interfaces, scanners which can read hand-marked and/or machine-marked ballots, ballots transmitted by physical mail, and even ballots cast online. Indeed, ElectionGuard is compatible with most existing modes of casting votes.

*Dr. Dan Wallach's contributions to this work were made while he was at Rice University and partially funded by DARPA prior to his becoming a DARPA program manager. The views, opinions, and/or findings expressed are those of the authors and should not be interpreted as representing the official views or policies of the Department of Defense or the U.S. Government.

Tally Decryption. In this final phase, the guardians reassemble together with the administrator to decrypt the election tallies and produce a verifiable record for publication. Voters can inspect this published *election record* to ensure that their encrypted votes are present, and the integrity of this election record can be verified by independent applications that can be written by any interested parties.

In addition to the encrypted votes, the election record produced by ElectionGuard includes numerous artifacts that together constitute a proof of the election's integrity—including the correctness of the announced election tallies. The integrity of an election record can be verified by applications written by voters, observers, or any other interested parties.

One of the guiding principles of ElectionGuard is to make independent verification as easy as possible. The desire is to promote the growth of an ecosystem of independent election verifiers by making the writing of a verifier a reasonable project for a first class in programming. Voters and observers can run verifiers from a variety of sources on the record of any election.

The first deployments of ElectionGuard were in 2020 in public elections in Wisconsin and California and then in the U.S. House Democratic caucus to elect its leadership. In 2021, civic votes using ElectionGuard began being conducted in Neuilly-sur-Seine, France. Using the learnings from these early deployments, work commenced on a version 2 of ElectionGuard which offered many advantages and simplifications. Some of these improvements were included in subsequent deployments in Idaho, Utah, and Maryland (detailed in Section 6).

While there have been a signficant number of implementations of various E2E-verifiable election designs in the past that have been used to cast millions of votes, none have followed this approach of building tools which can be incorporated into existing election equipment, and none have achieved anywhere close to this breadth of usage in different scenarios, including in-person voting on ballot marking devices, in-person voting with scanned hand-marked paper ballots, risk limiting audits, and Internet voting – see discussion in Section 6.

The remainder of this paper will describe the cryptographic design of the ElectionGuard protocol and the introduced innovations, some remarks and learnings about implementations of ElectionGuard, and details about various deployments within the U.S.

2 Cryptographic Design

The cryptographic design of ElectionGuard is largely inspired by the 1985 work of Cohen (now Benaloh) and Fischer [17] and the 1997 voting protocol by Cramer, Gennaro and Schoenmakers [20] that have also been adopted in systems like VoteBox [40], Helios 2.0 [1], STAR-Vote [4], and Belenios [18].

The two protocols [17, 20] support elections that compute the tally by adding the number of votes that each candidate received, including elections in which voters either pick a single candidate, a limited number, or as many candidates on the ballot as desired. The winner is determined by the number of votes each candidate received. This so-called homomorphic tallying approach is usually not suitable for voting methods like Instant-Runoff Voting (IRV) or Single Transferable Vote (STV) in which candidates are ranked and eliminated in multiple rounds: the simple addition of votes may not be sufficient to tally such elections. Techniques based on verifiable mixnets [39] are often more appropriate for such voting methods and have also been adopted in many systems, but they are more cumbersome to deploy.

A future variant of ElectionGuard may support mixnet methods, but the philosophy of ElectionGuard has been to cover the majority of scenarios with an approach that is as simple as possible to understand and verify. We have also found that the ability to assert to election administrators that cast ballots encrypted by ElectionGuard will *never* be (individually) decrypted has been a powerful tool to assuage concerns. For these reasons, we have started with homomorphic tallying, but a mixnet alternative (probably using elliptic curve groups) is definitely on the ElectionGuard road map.

2.1 Roles

ElectionGuard describes the various steps that a set of actors can take to obtain a verifiable election. These actors assume the following roles:

- *Guardians* $G_1, \ldots, G_n$ are jointly responsible for maintaining the privacy of the votes.
- *Voters* cast their ballots and may verify that they have been properly recorded.
- An election *administrator* facilitates protocols and procedures and also populates and publishes the election records.
- *Verifiers* verify the election records to confirm an election's integrity and, to some extent, ballot privacy.

It is important to note that the verifiers do not have a direct role in elections, and no assumptions are placed upon them. Instead, anyone—voter, candidate, observer, or other party—can choose at any time after the completion of an election to use their own means to verify the results of an election. There is no need for a verifier to register in any way or to inform anyone about performing this function.

2.2 Election Records

ElectionGuard makes the assumption that the election records are publicly accessible and that everyone has an identical view

of them. This is a standard assumption for any election as there is always a central election authority that provides an authoritative list of voters, fixes the ballot contents, sets the voting times and locations, and announces the election tally.

As such, ElectionGuard assumes that the election administrator can set up a broadcast channel with similar properties and uses it to disseminate the ElectionGuard election records or, and this may be preferred, that the administrator uses an existing channel for this purpose.

In many verifiable election systems, it is assumed that a public bulletin board exists for publishing these records. In practice, it has most often taken the form of a simple web page,[1] as it is also common to publish the records of risk limiting audits [35] that may take place. Sometimes, this bulletin board can be implemented in the form of a more sophisticated distributed system [13, 30, 41]. A permissionless blockchain may be more problematic than helpful in this context: we only seek to authenticate a single authority that publishes a small number of records, not to encourage unidentified actors to replicate and compete on the views of these records.[2]

Digitally signing election records may or may not help depending on the context: signatures may offer means to authenticate records and confront a rogue administrator if inconsistent records are signed. However, a signature may not be beneficial if authenticating the legitimacy of a signature verification key is just as complicated as authenticating the legitimacy of the election records.[3] External mechanisms may be useful for that purpose.

As a complement, candidates may be invited to acknowledge, and possibly replicate, the election records through their own communication channels, just as it is customary that candidates publicly acknowledge the election outcome.

2.3 Election Parameters

This section describes the parameters that define an election and the logical structure for the ElectionGuard software as well as the cryptographic parameters used to implement the protocol components.

2.3.1 Election Manifest

Each election that uses ElectionGuard must have an *election manifest* that defines the election. It must at least contain a unique election label and a list of contests and selectable options for each contest, together with limits on the number of options that a voter can select within a contest (referred to as *contest selection limits*). It must also contain a list of ballot styles that indicate all subsets of contests that may be displayed to voters.[4] The election manifest may also contain various optional data fields, including details about voting devices, software versions, time information, etc.

The election manifest serves to guarantee that all actors have a common view of an election and makes it possible for the ElectionGuard software to record ballots properly.

2.3.2 Cryptographic Parameters

ElectionGuard uses ElGamal encryption in the multiplicative group $\mathbb{Z}_p^*$ of the ring of integers modulo a large prime p. In order to tally contests by relying on an additive homomorphism between the plaintexts and ciphertexts, choices are encoded exponentially as follows. A vote v (usually $v \in \{0,1\}$, but in some cases a larger v is possible) is mapped to the ElGamal group as g^v for some fixed group element $g \in \mathbb{Z}_p^*$. Multiplying two such powers of g together adds the exponents, as desired, and the discrete logarithm extraction needed to perform the inverse mapping remains efficient in practice since the exponent is bounded by the number of votes that a candidate can receive. An encryption of the vote v then is an ElGamal encryption of g^v and the multiplicative homomorphism inherent in the ElGamal encryption scheme through componentwise multiplication translates to an additive homomorphism.

The use of exponential ElGamal prompts for performing ElGamal encryption in a "small" subgroup of $\mathbb{Z}_p^*$. ElectionGuard uses a 4096-bit prime p and works in a cyclic subgroup of $\mathbb{Z}_p^*$ of order q, which is of size 256 bits.[5] This choice leads to more efficient group exponentiations compared to the standard group construction using safe primes without substantially reducing the security against best-known attacks.[6] For the latter, exponentiations are computed in the group of quadratic residues modulo p and are much more costly.

While ElectionGuard could be instantiated with an elliptic curve group, the decision to use integer groups instead was guided by making verifying the integrity of an election as easy as possible. Ideally, writing a verifier should be simple enough to be repeated many times and should not require intricate knowledge of elliptic curve implementations. Integer groups are a conceptually simpler choice with a hopefully lower barrier for implementing them.

On various occasions, ElectionGuard needs to hash values to $\mathbb{Z}_q$. Hashing thus requires some caution because outputs of hash functions are bit strings, so their interpretation as integers modulo q may not be uniformly distributed values in $\mathbb{Z}_q$. In some protocols, this discrepancy can create security issues [15]. There are standard solutions to this problem: for

[1] See, for instance: https://app.enhancedvoting.com/results/public/cc/CollegePark/nov23.

[2] For a discussion of the use of blockchains in voting systems, see pp. 103–105 of the U.S. National Academies report at https://nap.nationalacademies.org/catalog/25120

[3] In either case this could come down to checking a hash value.

[4] For instance, some contests may be available to all voters in an election while others may depend on the district in which a voter resides.

[5] The ElectionGuard specification [6] more generally describes how this p is to be computed for any desired size. But in practice, having verifiers check that a particular prime p is being used relieves them of the complex computational burden of confirming that p has been correctly computed.

[6] This choice also appears in the FIPS PUB 186-4 standard for instance https://csrc.nist.gov/pubs/fips/186-4/final.

instance, one can hash to bit strings substantially longer than q, so that their reductions modulo q are distributed statistically close to uniform. ElectionGuard takes a different approach by selecting $q = 2^{256} - 189$ which is the largest prime below 2^{256}. Hashing to 256-bit strings, converting them to integers, and reducing modulo q then provides values that are almost uniform modulo q when the hash function is modeled as a random oracle. In practice, no 256-bit hash value larger than q will ever occur, and the hash results taken modulo q will be indistinguishable from uniform.

As for the choice of p, ElectionGuard selects a 4096-bit prime such that its binary representation starts and ends with 256 bits set to one, is such that q divides $p-1$ and that $(p-1)/2q$ is also prime. The 3584 middle bits of p are determined as the bits corresponding to the smallest integer larger than the integer given by the first 3584 bits of $\ln(2)$ (the natural logarithm of 2) that make the resulting p compatible with the above constraints. The bits set to one support faster modular reduction, while the middle bits are chosen to prevent an effective use of SNFS [29]. Following this process that is determined by efficiency and security considerations leads to a unique prime p. The standard group generator g is simply chosen as $g = 2^{(p-1)/q} \bmod p$, which is different from 1 and therefore generates the group of order q.

Further cryptographic parameters are the number of guardians n and the quorum value k. The small integer n denotes the number of guardians that collaborate to generate the election public key used to encrypt all votes. To decrypt the election tallies that have been computed by homomorphic addition of encrypted votes, at least $k \leq n$ guardians are required to participate. The quorum can be chosen to be smaller then n to enable decryption even if some of the original guardians become unavailable or uncooperative.

2.4 Keeping track of the context

All cryptographic data produced by ElectionGuard are kept within a clear context. The fixed cryptographic public parameters are tied to all cryptographic operations, starting with key generation. As soon as the election context is known through the election manifest, it is additionally tied to all the election related operations, in order to prevent data reuse across elections. And, within an election, every cryptographic element is unambiguously labeled in order to prevent any internal reuse.

In order to offer public verifiability, ElectionGuard makes an abundant use of zero-knowledge (ZK) proofs that are traditional sigma protocols made non-interactive through the Fiat-Shamir heuristic [26]. The random oracle instance used to implement the Fiat-Shamir heuristic is used to tie all cryptographic data in the election records to their context.

In ElectionGuard, the random oracle is instantiated with HMAC-SHA-256, which is believed to offer a good option when used with keys of a fixed length smaller than the underlying hash function input block size [23]. Notation for the random oracle is $H(\cdot;\cdot)$, where the first input is passed to HMAC-SHA-256 as the key and the second as its input. In ElectionGuard, all HMAC-SHA-256 keys have a fixed length of 32 bytes. For hashing into $\mathbb{Z}_q$, the ouput of H is interpreted as an integer and reduced modulo q. This hash function is denoted $H_q(\cdot;\cdot) = H(\cdot;\cdot) \bmod q$.

As an illustration of this process, the first hash that is computed, the parameter hash $\mathrm{H}_P = H(\texttt{ver};\texttt{0x00}, p, q, g, n, k)$ sets the cryptographic public parameters, where `ver` is the ElectionGuard specification version number that is used, padded to 32 bytes. From H_P and the election manifest, an election base hash is computed as $\mathrm{H}_B = H(\mathrm{H}_P;\texttt{0x01},\texttt{manifest})$, where `manifest` is a file containing the election manifest. The parameter hash H_P is used in the key generation process, which ElectionGuard does not link to a specific election.

After election public keys K and $\hat{K}$ have been generated, an extended base hash is computed as $\mathrm{H}_E = H(\mathrm{H}_B;\texttt{0x14}, K, \hat{K})$.

When a new ballot is encrypted, a random 32-byte selection encryption identifier id_B is chosen and an identifier hash is computed as $\mathrm{H}_I = H(\mathrm{H}_E;\texttt{0x20},\mathrm{id}_B)$, which is then used in all proofs of validity of that ballot. The extended base hash H_E is also used in every decryption proof produced during the tallying operations.

All these hashes guarantee the soundness of the ZK proofs [10], and prevent carrying election data from one election to another, mixing data from different ballots, and, more generally, reusing cryptographic data in an unintended context.

2.5 Key Generation

ElectionGuard's key generation process uses a variant of Pedersen's distributed key generation (DKG) protocol [38] supporting a dishonest majority at the price of reduced robustness. The key generation ceremony runs between publicly identified parties, and there is little benefit for a malicious participant in introducing errors in the protocol execution if these errors are detected before the keys are actually used to encrypt sensitive material. Therefore, we assume that guardians abort key generation as soon as one of them detects an error, that they investigate the error out-of-band, and restart the protocol from scratch, possibly replacing guardians that are identified as acting maliciously.

Although distributed key generation has become relatively common, it can be quite challenging to get all of the details right, and many other efforts have missing or incorrect proofs.[7]

The election administrator publishes a quorum $k \leq n$ in the election record, which means that at least k guardians are needed to compute the election tally. It also means that ballot privacy will depend on the assumption that fewer than

[7] For example, the widely-used Belenios system references an incorrect proof [7].

k guardians are compromised—verifiability does not depend on the number of honest guardians. Pedersen's original protocol [38] was only designed to support $k < n/2$, which guarantees a majority of players are honest such that the protocol terminates and ciphertexts can always be decrypted. Our concern here is that corrupted guardians might want to decrypt individual votes that they should not decrypt, rather than that they refuse to decrypt ballots they are supposed to decrypt. Allowing a quorum less than n accommodates emergency situations on behalf of one or a few guardians, but it needs to be kept high enough to protect from curious guardians.

The protocol starts with each guardian G_i selecting a random polynomial $P_i(x) = \sum_{j=0}^{k-1} a_{i,j}x^j$ and publishing commitments $K_{i,j} = g^{a_{i,j}}$ for $0 \leq j < k$ in the election records, following Feldman's verifiable secret sharing (VSS) protocol [25]. Each guardian G_i also selects a random secret share encryption key ζ_i and publishes the corresponding public key $\kappa_i = g^{\zeta_i}$. Additionally, each guardian publishes Schnorr proofs [42] that it knows how to open the commitments it posts. Afterwards, each guardian G_i sends the value $P_i(j)$ to guardian G_j, encrypted with G_j's public share encryption key κ_j, for every $0 < j \leq n$. Then, each guardian G_j checks the validity of all posted Schnorr proofs, and verifies that $g^{P_i(j)} = \prod_{\ell=0}^{k-1}(K_{i,\ell})^{j^\ell}$ for $0 < i \leq n$. Finally, the public vote encryption key is set to $K = \prod_{i=1}^{n} K_{i,0}$ and each guardian G_i sets its private key share to $P(i) = \sum_{j=1}^{n} P_j(i)$.

The above key generation protocol is run a second time, either in parallel or sequentially, to generate a second public key $\hat{K}$ (together with commitments $\hat{K}_{i,j}$ and corresponding Schnorr proofs). This key is used for encrypting ballot data other than numerical votes, which is done with a different encryption mode.

At the end of this protocol execution, each guardian's software[8] displays a hash of its view of the public key generation protocol transcript records, including all the election parameters, K, $\hat{K}$ and all the $K_{i,j}$, $\hat{K}_{i,j}$, and κ_i. Each guardian compares that view with the one that appears in the election record. If this or any of the previous verification steps fail, the guardian complains and an out-of-band investigation is started before the protocol restarts from scratch, possibly with one or more new guardians. If no guardian complains, the content of the election record up to that point is validated and called the *guardian record*. The goal of these verification steps is to prevent a malicious election administrator from impersonating guardians or even to simply throw away the key generation transcript and to replace it by another fully simulated one—there is no public-key infrastructure (PKI) in ElectionGuard, so guardian messages are not signed.

As noted above, this protocol follows the general structure of Pedersen's [38] by producing a key computed as a sum of individual keys generated by guardians that are shared using a verifiable secret sharing (VSS) protocol. The differences with Pedersen's protocol are that (i) ElectionGuard does not start with a round during which every guardian commits to $K_{i,0}$ ($\hat{K}_{i,0}$) and then opens it, (ii) ElectionGuard adds Schnorr proofs for the $K_{i,j}$ ($\hat{K}_{i,j}$), and (iii) ElectionGuard relies on guardians checking authentic election records instead of signing their key shares.

The vast majority of proposed DKG protocols, including [12, 14, 28, 31, 33, 38] for instance, focus on the honest majority case, which offers robustness. The dishonest majority case has been considered in the context of threshold signatures [24, 32, 34], and ElectionGuard's DKG may be closest to the one proposed by Komlo and Goldberg for FROST [32]. In the following theorem, we claim the IND-CPA security of ElGamal encryption based on keys produced with the ElectionGuard DKG—we refer to the combined scheme as ElectionGuard ElGamal.

Theorem 1. ElectionGuard *ElGamal encryption is IND-CPA secure under static corruption of up to $k-1$ guardians ($1 \leq k \leq n$) if standard ElGamal encryption (performed with the standard single-party key generation) is IND-CPA secure with the same public parameters.*

The proof of this theorem follows the strategy from Braun et al. [12], adapted to the dishonest majority case.

Proof. Let k and n be fixed and define $C = \{1, \ldots, k-1\}$ and $H = \{k, \ldots, n\}$. Assume, w.l.o.g., that the guardians in the set $\{G_i\}_{i \in C}$ are corrupted, while the others are honest. We design an adversary $\mathcal{B}$ against standard ElGamal encryption that wins the IND-CPA game with a probability equal, up to a negligible difference, to the probability that an adversary $\mathcal{A}$ controlling the corrupted guardians breaks the IND-CPA security of the ElectionGuard ElGamal encryption.

Given $\mathcal{A}$, we design $\mathcal{B}$ as follows: when $\mathcal{B}$ receives the ElGamal public parameters $(\mathbb{Z}_p^*, q, g)$ and the public key K^* from the standard ElGamal challenger, it forwards the public parameters to $\mathcal{A}$. $\mathcal{B}$ honestly plays the role of all honest guardians, except for G_n. For emulating G_n, it simulates a share of the discrete logarithm of $K_{n,0} = K^*$ by picking $P_n(i)$ as a random element of $\mathbb{Z}_q$ for every $i \in C$. It then derives $\{K_{n,i}\}_{i \in C}$ so that $g^{P_n(i)} = \prod_{j=0}^{k-1}(K_{n,j})^{i^j}$ for every $i \in C$, by Lagrange interpolation "in the exponent". $\mathcal{B}$ also submits simulated Schnorr proofs for every $K_{n,i}$ with $i \in \{0\} \cup C$. The view of $\mathcal{A}$ is distributed in a way that is identical to what it would be in a normal execution of the ElectionGuard ElGamal key generation.

$\mathcal{B}$ then verifies the guardian records: it checks that all the expected $K_{i,j}$ values appear in the records, that the share verification succeeds for all the values submitted by $\mathcal{A}$, and that the Schnorr proofs are valid. If any of this fails, $\mathcal{B}$ aborts and $\mathcal{A}$ loses. If the verification succeeds, $\mathcal{B}$ extracts the discrete logarithms of the $K_{i,0}$ keys for $i \in C$ by rewinding $\mathcal{A}$ appropriately—this can be performed efficiently since it is a single round of extraction.

[8] Ideally, each guardian will use its own software obtained from a source of its own choosing.

Eventually, when $\mathcal{A}$ asks for the encryption of a pair of messages (m_0, m_1), $\mathcal{B}$ forwards it to the ElGamal challenger, who returns a ciphertext $(c_0, c_1) = (g^r, m_b(K^*)^r)$. $\mathcal{B}$ then submits to $\mathcal{A}$ the ciphertext $(c_0, c_1(c_0)^{\sum_{i=1}^{n-1} s_i}) = (g^r, m_b(\prod_{i=1}^{n} K_{i,0})^r)$ where each s_i is the discrete logarithm of $K_{i,0}$, which has either been extracted from the Schnorr proofs or has been selected by $\mathcal{B}$. When $\mathcal{A}$ outputs a guess b' on b, $\mathcal{B}$ forwards that guess to the ElGamal challenger. The probability that $b = b'$ is exactly the one that $\mathcal{A}$ makes a correct guess in the ElectionGuard ElGamal IND-CPA security game. The only possible discrepancy comes from the potential failure to extract a Schnorr proof, which can be made negligible. □

This protocol works for any quorum k. If a quorum $k = n$ is chosen, the VSS phase of the protocol could be avoided and the DKG could be as simple as asking each guardian to publish its public key together with a Schnorr proof that it knows the corresponding private key, as is done in the Helios voting system for instance [1]. In such a case, each guardian only needs to check that the election public key is indeed the product of a list of public keys that includes its own. In particular, no communication between guardians is needed, which may simplify the key generation ceremony by removing guardian coordination requirements. ElectionGuard chooses to offer a single key generation protocol to keep its specification and election verification as simple and uniform as possible.

2.6 Ballot Preparation

A typical ElectionGuard ballot consists of a sequence of ElGamal encryptions—usually of either 0 or 1, encoded in exponential form to support an additive homomorphism, together with ZK proofs that these encryptions are indeed encryptions of bits. There is one ciphertext per choice on the ballot, and, for most election types, it encrypts 1 if and only if the voter supports the corresponding choice.[9] The encrypted tally is computed by multiplying together all ciphertexts corresponding to the same choice across all cast ballots.

ElectionGuard also supports more general option selection limits and contest selection limits: the former allow a voter to assign a value in a given range to a specific option on the ballot (enabling systems like cumulative voting, range voting, and score voting), and the latter allow the number of options selected by a voter within a specific contest to lie in a specific range (enabling voters to select more than one option in a contest).

Again, ElectionGuard largely follows Cramer et al. [20], but makes some important tweaks and additions.

[9] A blank vote in a contest would be represented by an encryption of 0 for every option.

2.6.1 The ballot nonce

For each ballot B, a secret random nonce ξ_B is chosen in addition to the public random selection encryption identifier id_B. As discussed above, id_B is used to derive the ballot identifier hash H_I, which also incorporates the information related to the election public key and to the election manifest.

This identifier hash is used, together with the secret ballot nonce ξ_B, to derive the randomness $\xi_{i,j}$ used to encrypt the voter's choice for option j of contest i on the ballot:

$$\xi_{i,j} = H_q(\mathrm{H}_I; \texttt{0x21}, i, j, \xi_B).$$

This approach is useful in several use cases.

- Some ElectionGuard-enabled systems can take advantage of this nonce to efficiently challenge an encryption operation performed by an untrusted device. In such systems, the device is required to publish a ballot confirmation code, essentially a hash of all the ciphertexts on that ballot (we will discuss this further below), before the voter decides to cast the ballot. The voter may then choose to challenge the device, in which case the device only needs to provide the 32-byte ballot nonce ξ_B, which can then be used to re-derive, on a personal device, all the $\xi_{i,j}$ values, recompute all the ciphertexts on the ballot, and verify that the ballot confirmation code is actually consistent with the voter's choices. If a ballot is cast instead of being challenged, the ballot nonce is permanently erased.

- Some systems may use an offline ballot marking device (BMD) to print a human readable ballot with the voter's choices, and to compute and print the ballot confirmation code that the voter takes home. As the BMD is offline, there may be no way to transmit the full ciphertexts to the server that publishes the encrypted ballots for verification and in support of the tallying operations. When the paper ballots are anonymous (because they are dropped in a ballot box, for instance), a solution might be to print an encrypted version of ξ_B on the ballot so that, after scanning and decryption, an election server can recompute all ciphertexts on the ballot with the same randomness as the BMD, supporting the election verification steps.

2.6.2 Encryption

The encryption of a selection σ made by a voter, using randomness ξ derived as explained above, is computed as $(\alpha, \beta) = (g^\xi, K^{\xi+\sigma})$. Each ElGamal ciphertext is accompanied by a proof that it really encrypts a selection $\sigma \in \{0, 1\}$ (or, when allowed, in a specified larger domain), which is computed as a disjunctive version of the Chaum-Pedersen protocol [16, 19], following a most common choice in voting

systems [1, 4, 18, 20, 40]. The proof is generated by first computing a commitment consisting of two ciphertexts $(a_0, b_0) = (g^{u_0}, K^{u_0+\sigma c_0})$ and $(a_1, b_1) = (g^{u_1}, K^{u_1+(\sigma-1)c_1})$ for random choices of u_0, u_1, c_0, c_1 in $\mathbb{Z}_q$. Then, a global challenge is computed[10] as $c = H_q(\mathrm{H}_I; \texttt{0x24}, \alpha, \beta, a_0, b_0, a_1, b_1)$ and the selection challenge is updated to $c_\sigma = c - c_{1-\sigma}$. Observe that c_σ did not play any role in the computation of the commitment. Eventually, responses are computed as $v_0 = u_0 - c_0\xi$ and $v_1 = u_1 - c_1\xi$. The proof consists of (c_0, c_1, v_0, v_1) and is verified by checking that (α, β) are elements of the expected subgroup of $\mathbb{Z}_q$, recomputing the commitment, recomputing c using H, and verifying that c is the sum of c_0 and c_1.

The ElectionGuard encryption process differs from the traditional encryption method where ciphertexts are computed as $(g^\xi, g^\sigma K^\xi)$ [1, 4, 18, 20, 40]: this modification has no impact on security but reduces the cost of computing the ZK proof from 5 to 4 exponentiations, following an observation by Devillez et al. [22]. The recent literature offers numerous other options for computing these 0-1 encryption proofs, and these often lead to more compact and faster ways to compute proofs—several such methods are also described and compared by Devillez et al. [22]. ElectionGuard aims at keeping the programming of an election verifier as simple as possible, and therefore keeps these disjunctive Chaum-Pedersen proofs. In terms of proof size, a proof only takes 1024 bits compared to ciphertexts of 8192 bits, so the relative benefits of smaller proofs appear to be marginal. Furthermore, as will be described in the implementation section, the computation process can also be made fast enough for practical deployments by relying on other simple techniques, including fixed-base exponentiation methods.

2.6.3 Encryption of more sophisticated ballots

The encryption process just described can be used for traditional election methods and approval voting, i.e., contests in which voters can select as many options as they like. ElectionGuard supports several other types of contests:

- ElectionGuard includes range proofs, which are immediate extensions of the disjunctive proof technique used to demonstrate that a ciphertext encrypts a 0 or a 1. These can be used to prove that a single selection ciphertext is within an arbitrary range $[a, b]$, hence offering support to other types of voting methods, including cumulative voting and Borda count. These can also be used to prove that the product of the selection encryptions of a single contest is within a range, hence proving that a voter selected exactly or at most x options in that contest for instance.

- ElectionGuard supports contest write-in data, where a voter can enter text in a write-in field instead of selecting a listed option. Here, an extra counter is encrypted for the write-in, and the text itself is encrypted using the secondary ElGamal public key $\hat{K}$ in the threshold version of Signed ElGamal mode [43], hence offering NM-CPA security just as the security mode used to encrypt selections [10]. The counter is used to count the number of voters who used the write-in option and, when that number is low enough to guarantee that no write-in candidate could win (which is expected in most cases), the text of the write-ins is simply ignored and never decrypted. Otherwise, these write-in ciphertexts may be decrypted, providing that they offer sufficient anonymity guarantees.

[10] ElectionGuard often hashes more context inputs like contest and selection indices that are omitted here for simplicity.

2.6.4 Confirmation Codes

After all selections on a ballot have been encrypted, a *confirmation code* is prepared and, in most common use cases, given to the voter. The code is a hash value computed from the sequence of ciphertexts that constitute the encrypted ballot as follows. First, for each contest on the ballot, a *contest hash* is computed. Specifically, if (α_i, β_i) is the ciphertext encrypting the i-th selection of the l-th contest (with m options) on the ballot, the contest hash is

$$\chi_l = H(\mathrm{H}_I; \texttt{0x28}, \mathtt{ind_c}(\Lambda_l), \alpha_1, \beta_1, \alpha_2, \beta_2, \ldots, \alpha_m, \beta_m),$$

where $\mathtt{ind_c}(\Lambda_l)$ is the unique contest index for the index with label Λ_l specified by the election manifest. Ciphertexts are hashed in the order specified by the election manifest.

All contest hashes are then hashed in the order specified by the election manifest to obtain the confirmation code (assuming there are m_B contests on the ballot) as

$$\mathrm{H}_C = H(\mathrm{H}_I; \texttt{0x29}, \chi_1, \chi_2, \ldots, \chi_{m_B}, \mathrm{B}_C).$$

The last input B_C is the chaining field byte array that determines the ballot chaining mode and the additional input for ballot chaining.

ElectionGuard offers the option to chain ballots together via dependencies of their confirmation codes. A simple chaining mode would include the confirmation code of the previous ballot that was encrypted on the same device into the computation of the current confirmation code. The chaining field B_C is a fixed-length byte array that consists of a chaining mode identifier and the previous confirmation code. This means, the j-th confirmation code computed on a device is

$$\mathrm{H}_j = H(\mathrm{H}_I; \texttt{0x29}, \chi_1, \chi_2, \ldots, \chi_{m_B}, \mathrm{B}_{C,j}),$$

where $\mathrm{B}_{C,j} = i_C \,\|\, \mathrm{H}_{j-1}$ is the concatenation of the chaining mode identifier i_C and the confirmation code H_{j-1} of the previous ballot computed on the same device. The first ballot encludes an initial hash value that is derived from device information.

The goal of this chaining process is similar to that of the one proposed by Sandler and Wallach [41]: to make it easier to detect a modification to any ballot. When ballots are chained, any change in a ciphertext that appears on a ballot would require adapting all subsequent elements of the chain in order to keep the chain consistent and valid. As a result, any voter who verifies a confirmation code linked to a ballot appearing in the original chain after the modified ciphertext was included, would detect the modification. This makes detection more likely than in the absence of chaining: without chaining, only the voter holding the confirmation code of the modified ballot is able to detect the modification.

The ElectionGuard hashing process to compute confirmation codes does not include ZK proofs as inputs, which differs from other systems [1, 18]. Including only the ciphertexts is sufficient to commit to the content of the votes and, in some applications, it is convenient to be able to delay the computation of ballot validity proofs to a subsequent step in the election process.

Regardless of the chaining mode, the most a typical voter would do is check an election record to ensure that the expected confirmation code is present. The computations to confirm that confirmation codes are correct are more commonly delegated to election verifiers who, as part of the process of verifying the integrity of an election record, will confirm that each confirmation code in the record is correctly computed. Of course, anyone – including voters – can verify any or all of the contents of an election record.

A component of an election verifier can be a single ballot verifier which takes as its input all data used to generate a confirmation code (including, when appropriate, the chaining variable) and confirms the correct computation of a confirmation code. A single ballot verifier can be particularly useful when instant verification of challenges is offered to voters (for instance, at a poll site). In this scenario, a voter who challenges a ballot would receive information that would allow an app (perhaps installed on a mobile device) to check that the confirmation code is consistent with the selection made by the voter.

It is important to emphasize that since confirmation codes are derived entirely from encryptions of votes, their being given to voters and even their publication in properly deployed in-person applications does not in any way compromise voter privacy or enable coercion or vote-selling.

2.7 Tally

2.7.1 Update of the Election Record

Once voting has concluded, all encrypted ballots consisting of encrypted selections and corresponding ZK proofs of ballot well-formedness are added to the election record, with a clear mark indicating whether each ballot is intended to be included in the tally or is challenged, in which case it is not included in the tally and needs to be individually decrypted. The election record is committed to by the election administrator, and made available for everyone to check, in particular to the guardians who can compare their views of these election records. Again, requiring the administrator to sign the records may help to identify a rogue administrator who would distribute different views of the records to different parties.

2.7.2 Homomorphic tally computation

All ZK proofs of well-formedness are verified, the uniqueness of the selection encryption identifiers is verified, and the encrypted ballots that are intended to be tallied are aggregated to obtain the encrypted tallies. These are computed via the additive homomorphism of the exponentially encoded ElGamal encryption, that is, they are the componentwise products of all selection encryptions that correspond to the same option across all encrypted ballots containing that contest.

2.7.3 Decryption

When all encrypted tallies are available, at least k guardians reconvene together with the election administrator and jointly decrypt every tally for every selection in every contest of the election. Each available guardian G_i uses its private key share $P(i)$ to compute a partial decryption $M_i = A^{P(i)}$ of each given tally ciphertext (A,B). The available partial decryptions are combined to obtain the value $M = \prod_{i\in U}(M_i)^{w_i}$, where $U \subseteq \{1,2,\ldots,n\}$ is the set of indices of the available guardians, and the w_i for $i \in U$ are the corresponding Lagrange coefficients used to reconstruct the shared secret. The value M is therefore the value that would have been obtained by decrypting with the secret key corresponding to the election public key K. This secret key remains implicit in all ElectionGuard computations and is never explicitly reconstructed.

The value M allows decryption of the tally t via $K^t = BM^{-1}$ through the computation of a small discrete logarithm that can be computed efficiently (for example using a precomputed table) because tally values are typically bounded by the number of votes cast, a relatively small number.[11]

2.7.4 Proof of correct decryption

To enable verifiable decryption, the available guardians collaborate to produce a Chaum-Pedersen proof of correct decryption with the secret key corresponding to K. This proof can be computed in a way that is reminiscent of threshold signatures.

We suppose that a set $U \subseteq \{1,\ldots,n\}$ of guardians is available for performing the decryption of a ciphertext (A,B) and that $|U| \geq k$. Each guardian G_i, $i \in U$ starts by committing to

[11] In voting methods that allow a voter to place more than one vote on a candidate, the discrete logarithms may be slightly larger, but they are still easily computed.

the commitment of an individual Chaum-Pedersen proof, by selecting a random $u_i \leftarrow \mathbb{Z}_q$, computing $(a_i, b_i) = (g^{u_i}, A^{u_i})$, and sending $d_i = H(\mathrm{H}_E; \texttt{0x30}, i, A, B, a_i, b_i, M, U)$.

When G_i has received a d_j value from every other guardian G_j, $j \in U$, it sends the pair (a_i, b_i). After receiving the (a_j, b_j) from the other guardians, it then checks that d_j was computed correctly for all $j \in U$ and halts if any of these verification steps fail. This round of commit-reveal guarantees that corrupted guardians are unable to select their (a_i, b_i) pairs as a function of the pairs of the honest guardians, and that the product $(a, b) = (\prod_{i \in U} a_i, \prod_{i \in U} b_i)$ is uniformly distributed as long as one of the guardians G_i, $i \in U$ is honest.

After these verification steps, the proof challenge is computed as $c = H_q(\mathrm{H}_E; \texttt{0x31}, A, B, a, b, M)$. Each guardian G_i ($i \in U$) can then use the i-th Lagrange coefficient w_i to compute an adjusted challenge $c_i = c \cdot w_i \bmod q$ and an individual response $v_i = u_i - c_i P(i) \bmod q$. The final response is computed as $v = \sum_{i \in U} v_i \bmod q$, and the decryption proof is the pair (c, v). Note that $v = \sum_{i \in U} u_i - c \sum_{i \in U} w_i P(i) = \sum_{i \in U} u_i - c \cdot s \bmod q$, but again, the secret election key s has not been explicitly reconstructed to compute this proof.

If the proof is valid, that is, if $v \in \mathbb{Z}_q$ and if c can be correctly recomputed as above, using $a = g^v K^c$ and $b = A^v M^c$, then it is published in the election record.

It would have been more direct for each guardian to publish an independent Chaum-Pedersen proof that it computed its partial decryption accurately. However, as ElectionGuard aims at making election verification as simple as possible, the present protocol, which is more complex for the guardians, offers the central benefit of making the role and identity of the participating guardians completely invisible to an election verifier. From the verifier perspective, the decryption proof is one single Chaum-Pedersen proof.

It can be observed that this protocol is very similar to the Sparkle threshold signature protocol [21]. Its security analysis partly follows similar arguments. First, we can observe that the protocol is sound: since it produces valid Chaum-Pedersen proofs, it follows that it has the same special soundness property and that obtaining two executions with the same commitments but two different challenges and valid responses makes it possible to extract the unique value s such that $K = g^s$ and $M = A^s$. We can also show that honest guardians do not reveal any information by computing the Chaum-Pedersen proof as described above.

We believe this approach of combining zero-knowledge proofs of partial decryptions into a single zero-knowledge proof of complete decryption to be novel. It is especially valuable under threshold conditions where some partial decryptions may not be available, and it completely removes one of the greatest challenges for verifiers, which is the handling of missing guardians and the associated Lagrange coefficients. This approach may have application outside of the domain of elections.

Theorem 2. *Let $U \subseteq \{1, 2, \ldots, n\}$ be the set of indices of the guardians participating when computing the decryption proof as described above. Let V be a non-empty subset of U containing the indices of the honest guardians. There exists a simulator S that, on inputs (A, B), M_i ($i \in V$) and $K_{i,j}$ for $1 \leq i \leq n$ and $0 \leq j < k$, produces an interaction with the corrupted guardians with index in $U \setminus V$ that is statistically indistinguishable from an interaction in a real execution of the protocol. We let S control the function H, modeled as a random oracle.*

Proof. S selects a random $c \leftarrow \mathbb{Z}_q$, computes $c_i = cw_i \bmod q$ accordingly, and selects a random response $v_i \leftarrow \mathbb{Z}_q$ for each guardian with index in V. It then sets $a_i = g^{v_i} \left(\prod_{j=1}^{n} \prod_{m=0}^{k-1} K_{j,m}^{i^m} \right)^{c_i}$ and $b_i = A^{v_i} M_i^{c_i}$ for each guardian with index i in V. Note that the double product between the parentheses in the computation of a_i equals $g^{P(i)}$.

S then starts playing the protocol with the corrupted guardians, using the values above. The random choice of the v_i values and their independence from the (a_j, b_j) values of the corrupted guardians ensures that, with overwhelming probability $\geq (1 - t/q^2)$, where t is the number of queries that the corrupted parties make to the random oracle, the query that is made in order to compute the proof challenge will be fresh. S can then program the random oracle to offer c as the answer to that query. The resulting conversation will then be distributed exactly as a real conversation. □

We observe that the commit-reveal round of the protocol is essential to guarantee that the random oracle query made to compute the proof challenge is a fresh query with overwhelming probability.

2.7.5 Decryption of challenged ballots

The election record may also contain a set of challenged ballots, in order to support cast-as-intended verifiability, which will be discussed in Section 2.8.1. Valid challenged ballots are decrypted exactly in the same way as the aggregated ballots that are included in the tally. The verifiable decryption data provided for the challenged ballots is included within the election record.

2.8 Election Verification

ElectionGuard's main objective is to make elections verifiable. The value of a verifiable election is only fully realized, when the election is actually verified, for example by voters, election observers, or news organizations. ElectionGuard supports two central aspects of E2E-verifiability [8]:

1. *Cast-as-intended verifiability* makes it possible for a voter to verify that the selections made by the voter have been properly recorded.

2. *Tallied-as-cast verifiability* makes it possible for a voter to verify that every recorded vote is correctly included in the tally.

Eligibility verifiability, that is, the possibility to verify that ballots have been submitted by eligible voters, is also a desirable feature of an election. However, it typically relies on external voter identification mechanisms that are election dependent. As such, ElectionGuard enables verifying the number of ballots that are included in the tally, but not their origin. When paired with an external list of people who voted, this enables full verifiability of the results by participants and observers.

2.8.1 Cast-as-intended verifiability

The confirmation code of a ballot is the key element supporting cast-as-intended verifiability.

First, it makes it possible for a voter to challenge a ballot. This challenging operation enables a voter to verify that all selections were correctly encrypted and can be implemented in different ways.

- Most often, the encryption process happens after a voter expresses selections. In this case, the encryption device must commit to the ballot confirmation code and offer the choice to either cast or challenge the prepared ballot. The two choices are mutually exclusive, since the challenging operation reveals the selections on the ballot. A challenged ballot can never be cast and a cast ballot cannot be challenged anymore. The challenging process proceeds either by revealing the ballot nonces of the challenged ballots if they are available, or by decrypting the challenged ballots using the normal verifiable decryption process. It is again of crucial importance to verify, before decryption, that the decrypted ballots are valid and have a unique encryption identifier within the election. A ballot nonce can typically be revealed as soon as the ballot is challenged, while a ballot decryption operation will usually happen at tallying time. The voter can then verify that the selections made were correctly reflected in the decrypted ballot.

- ElectionGuard can also be used with pre-encrypted ballots: voters are then provided with vectors of ciphertexts encrypting every possible selection on a ballot, and select the ciphertexts that are claimed to match their selection. This can be useful in some vote-by-mail scenarios or for pre-printed ballots for in-person voting. In such a setting, it is possible to compute a confirmation code that includes hashes of every available encrypted selection, and the challenge process can then be used to verify that these ciphertexts actually encrypt the expected selections. This approach has two advantages: first, the challenging process is independent of any actual selection made by a voter, which is good for privacy and, second, the verification can be performed by anyone and does not depend on a voter accurately reporting selections, which offers accountability.

Whether a ballot is challenged or cast, it is included in the election record. Voters can then check that one or more ballots (a cast ballot and any challenged ballots) with the expected confirmation codes appear in the election records and for challenged ballots, that it shows the correct selections.

2.8.2 Tallied-as-cast verifiability

At the end of the tallying operations, the election records contain all the ballots and decryption proofs. Any voter can then verify that the ballot the voter cast is accurately incorporated in the homomorphic aggregation of the encrypted selections, and that the decryption proof demonstrates the validity of the announced tally with respect to the aggregated encrypted selections. That second verification can also be carried out by any observer, voter or not.

2.8.3 Privacy checks

All the verification steps that we described confirm the correctness of the election results and are independent of the honesty of the guardians: even a coalition of all guardians together with the administrator would not be able to fake the evidence offered on an election tally.

ElectionGuard however relies on the guardians to guarantee that the votes remain secret, and the guardians are expected to perform several verification steps as part of their role. These steps are not sufficient to guarantee that the votes remain secret: a ballot marking device may be corrupted and leak encryption nonces, or just use a broken pseudo-random number generator (PRG), and there is nothing that the guardians can do to prevent that.[12] Nevertheless, guardians should perform certain verifications to prevent ElectionGuard from being used to compromise voter privacy.

We summarize these steps here: their technical description has been provided above.

1. The guardian software must verify that the cryptographic parameters that are used offer the expected security level. This avoids accepting primes that would be too small for instance.

2. Guardians must check the guardian record at the end of the key generation phase: they must be certain that the published view of the key generation process is consistent with their own. This prevents a rogue administrator from replacing a guardian's key, or from subverting a guardian's key by sending malicious messages during the key generation process.

[12] Cryptographic means cannot ensure that there are no cameras hidden behind voters recording their actions.

3. Guardians must check that the ciphertexts they decrypt are those listed for decryption in the election record. This prevents a rogue administrator from asking for the decryption of individual cast ballots for instance. Guardians should also verify that ballots have been aggregated correctly and that all ballots have a unique selection encryption identifier and correct validity proofs. Though the latter task may be delegated to others, it must be verified before guardians engage in any decryption.

2.8.4 Verification software

In order to perform all these verification steps, voters, guardians and observers should use software that offers as much independence as possible. For instance, if the goal is to detect a malicious election administrator, it makes no sense to blindly trust software provided by the election administrator to perform these verification steps. Public code and availability of software from multiple sources are two important features for a meaningful use of ElectionGuard, and the ElectionGuard website[13] offers links to six independent verifiers (as well as one independent port of the full ElectionGuard implementation).

2.9 Trust

With the design described herein, privacy of ballots is dependent upon the cryptographic assumption that standard ElGamal encryption is IND-CPA secure as shown in Theorem 1 together with an assumption that the device on which the ElectionGuard application performing ballot encryption (such as an in-precinct ballot scanner) maintains ballot privacy. These assumptions need to be paired with necessary physical assumptions about any particular use case. Cryptography cannot prevent strategically-placed cameras or key-loggers from learning the inputs of voters.[14] A principal goal of ElectionGuard—as a technology that is intended to augment but not replace existing voting methods—is to add verifiability without materially weakening privacy.

What ElectionGuard achieves is the ability for voters and observers to verify the accuracy of election results with minimal trust—and critically with no trust at all in election administrators or any other specific entities (such as device manufacturers or software implementers). There is a very weak assumption on the collision resistance of the SHA-256 hash function (essentially that an adversarial agent should not be able to produce two distinct votes or ballots with the same hash). Beyond this, voters and observers may proxy their trust as they wish to one or more verifiers of their choosing or they may instead choose to write their own verifiers and confirm the integrity of the results entirely on their own.

[13] https://www.electionguard.vote

[14] It may be possible to use *code voting* to add a layer of indirection so that a voter's inputs do not reveal the voter's selections.

Confidence in an election result requires confidence that the ballots being counted are genuine. A single, digitally-signed election record allows all voters to confirm that their votes are properly included. The discovery of two distinct signed election records immediately implicates the election administrator who published those records as maleficent.

An interesting challenge in some applications is so-called eligibility verification—ensuring that all votes are cast by voters who are eligible to vote and do not vote more often than allowed. In the U.S. and many other countries, the list of voters who cast ballots in any jurisdiction is a matter of public record. Eligibility is thereby achieved entirely through publicly-verifiable processes that are entirely outside the scope of ElectionGuard, and the only intersection is for interested parties to confirm that the number of ballots cast does not exceed the number of voters listed. There is an expectation that interested parties will scrutinize this list for fictitious voters and for voters who are listed as voting but who did not do so. When voting is in-person, observers can simply count the number of voters present. But these measures are beyond the scope of ElectionGuard. When the list of voters is not public, it is very difficult for observers to verify that insiders did not add additional ballots to the count and inflate counts of the number of voters.

3 Preferred Uses

The primary intended use of ElectionGuard is for in-person poll-site voting. But there are many possible designs that are compatible with a wide variety of equipment. Additionally, many elections offer different modes of voting. For example, hand-marked paper ballots for in-person voters together with machine-marked ballots for voters with disabilities that prevent them from marking physical ballots, together with mailed ballots for voters who are not able to vote in person. To be effective, ElectionGuard must enable all of these and other modes of voting in a single election. There are even applications in which voters are not present and ballot contents are encrypted administratively.

In all applications, an election using ElectionGuard begins with a key-generation ceremony in which an election administrator works with guardians to form election keys. Later, usually at the conclusion, the administrator will again work with guardians to produce verifiable tallies. What happens in between, however, can vary widely.

3.1 Precinct Ballot Scanners

An ideal use of ElectionGuard is on precinct-based ballot scanners. An in-person voter can mark a ballot—either by hand or by using a ballot-marking device—and then feed the ballot into a scanner which may read the contents of the ballot, display the contents as it interpreted them, and print a confirmation code for the voter.

Once in possession of the paper confirmation code, the voter can choose to either accept the scanner's interpretation of the ballot contents and cast the ballot or instead challenge the ballot. A challenged ballot is marked as cancelled and the confirmation code is *opened*[15] by the scanner.[16]

A voter who challenges a ballot can then restart the voting process by marking a fresh ballot. Both cast and challenged ballots will be part of the election record.

3.2 Electronic Ballot Markers

ElectionGuard could instead be hosted by ballot marking devices. In one flow, a voter could make selections directly on an electronic (usually touch-screen) device which would then print a confirmation code and allow a voter to either cast the ballot or challenge the ballot and restart.

In another flow, a ballot marking device which can neither store ballot encryptions nor transmit them within a LAN could use the ballots themselves to convey encryptions by printing an encoding of the encryption directly onto a paper ballot.[17]

3.3 Vote by Mail

Pre-encrypted ElectionGuard ballots could be mailed to voters using the STROBE paradigm [3]. These paper ballots would have short codes printed beside each possible selection and voters could record short codes associated with their selections and check later to ensure that they appear correctly in the election record.

Unreturned ballots could serve as challenge ballots and would be opened to show that their short codes and associated confirmation codes are correct.

3.4 Internet Voting

Although not recommended for public elections[18], ElectionGuard could be used for Internet voting in a manner very similar to Helios [1]. Voters would make their selections online, receive confirmation codes, and then choose to either cast or open their ballots. The Helios model allows voters to prepare as many ballots as they wish—with only the last cast ballot counting.

3.5 Risk-Limiting Audits

ElectionGuard can also be used to protect voter privacy in risk-limiting audits (RLAs).

The most efficient post-election RLAs are *ballot-comparison audits* which operate as follows. The contents of each ballot are published together with ballot identifiers that match identifiers on corresponding paper ballots. Ballots are randomly selected from the published record and matched against the stored paper ballots to show that the stored ballots are consistent with announced tallies.

A major problem with ballot-comparison audits is that publication of ballot contents can compromise voter privacy. Voters can be coerced or sell their votes by completing a less important part of their ballots according to unusual predetermined patterns that are likely to be unique within a voting precinct. This allows each ballot—including the remaining selections—to be associated with specific voters.

Following the VAULT paradigm of [9], ElectionGuard can be used to post encrypted versions of all ballots cast and to prove that these encrypted ballots are consistent with announced tallies. Randomly-selected ballots are decrypted and matched with corresponding paper ballots. These decryptions do not compromise voter privacy since coerced voters can simply claim that their assigned patterns did not appear because they were not among those that happened to be selected for audit.

In this application, ballots are encrypted administratively, and confirmation codes are not needed.

3.6 Other Uses

The above examples are just a sample of the wide variety of ways in which ElectionGuard can be used. The flexibility of ElectionGuard is novel and is one of its primary benefits.

It is important to note, however, that merely using the ElectionGuard tools does *not* ensure that an election's results will be publicly verifiable. There have, for example, been instances where users have sought to require voters to announce in advance when they intended to challenge a ballot or to even eliminate the challenge process entirely.

For at least the near future, it is important to include experts in the process of deciding how ElectionGuard will be used in any new deployments.

4 Implementations

Since its original specification in 2019 [6], there have been several implementations of ElectionGuard that have been used in various applications and pilot elections. Early implementations by various contributors included a Python reference implementation of the full ElectionGuard 1.0 specification, an encryption engine in C++ with C# bindings, implementations in Haskell, Java, and TypeScript. More recently, we have implemented ElectionGuard 2.0 in Kotlin and Rust.

This section discusses some of the lessons learned from building these implementations.

[15] This is accomplished by providing a verifiable decryption to demonstrate that the confirmation code is consistent with the voter's selections.

[16] It is also possible for challenged confirmation codes to be opened as part of the subsequent tally decryption ceremony.

[17] To save space, a symmetric encryption of a nonce could be recorded onto a paper ballot to allow a full encryption to be regenerated later.

[18] For a discussion of Internet voting, see the U.S. National Academies report at https://nap.nationalacademies.org/catalog/25120

4.1 Performance

Unsurprisingly, the modular exponentiation at the heart of most ElectionGuard operations imposes the highest computational cost among all computations and is the limiting factor in any performance analysis. Using fast libraries for modular arithmetic is crucial to achieve good performance so that latency due to ballot encryption and ZK proof generation does not impact usability in the voting place.

For code running on the Java virtual machine (including Kotlin), or on Android, Java's `BigInteger` class is the obvious choice. For Python, it is straightforward to use GnuMP, which has hand-tuned assembly routines. Inside a browser, modern JavaScript engines have a native `bigint` type which is also very performant. The Kotlin code when targeting "native" code rather than the JVM, uses Microsoft's HACL* [11]—a performant C implementation of a wide variety of cryptographic primitives which have been formally verified for correctness.

Fixed-base modular exponentiation. Most exponentiations in ElectionGuard have a fixed base, either the generator g or the election public key K. It is well-known [36, §14.6.3] that using pre-computed tables of certain powers of these bases makes encryption and proving operations substantially faster, as shown in the election context by Devillez et al. [22]. To compute g^x, one parses x in groups of k bits, e.g., for 8-bit groups, $g^x = g^{x_{0-7}} g^{(x_{8-15}) \ll 8} g^{(x_{16-23}) \ll 16} \ldots$. If x has ℓ bits, a precomputed table with all values $g^{2^{ki} \cdot j}$ for $0 \leq i < \lceil \ell / k \rceil$, $0 \leq j < 2^k$, turns the computation of g^x into a series of table lookups and multiplications. Using larger k leads to larger tables ($O(2^k)$ memory usage), but reduces the number of multiplications.

In the original Python implementation, 8-bit tables yielded a 5.1x performance improvement for encryption. 13-bit tables yielded a 7.4x improvement. 16-bit tables yielded an 8.6x improvement. (Measurements taken on a 2013 MacPro with a 3.5GHz Intel Xeon.) Verification operations do make some use of the generator g, but otherwise have variable bases, so we only see improvements of 1.6x-1.7x.

It is standard practice to use Montgomery multiplication [37] for implementing modular multiplication of large integers. In particular, entries in pre-computed tables should be directly provided in Montgomery form to avoid the costly conversion. HACL* provides the necessary primitives, giving a 2.5x performance improvement.

Using base-K encoded ElGamal encryption. As mentioned above in §2.6.2, using the public election key K as the base to encode voter selections for ElGamal encryption saves one exponentiation when encrypting the selection and generating the ZK proof of well-formedness. In our implementations, we observed a 13% speedup as expected.

Compact Chaum-Pedersen proofs. To keep memory requirements for the ZK proofs low, it is important to use the compact representation for proofs consisting of challenge and response values instead of including the commitments as well. Commitments have a large size of 512 bytes (4096-bit values), but they do not need to be stored as they can be recomputed from the challenge and response values, which only are 32 bytes in size each.

Side-channel attacks. Side-channel attacks on cryptographic operations are generally less of a threat for voting devices than with other applications. A poll site presents many more direct opportunities for an attacker to obtain a voter's selections. Nevertheless, implementations should be made side-channel resistant whenever practical.

4.2 Latency

Voter-perceived latency certainly needs to be considered, particularly if the voting device has a slow CPU. Luckily, beyond the optimizations discussed above, there are a variety of other options to hide this latency. For example, we also enable a precomputation approach since most of the computation for encrypting selections and generating the ZK proofs is independent of the voter's selections.

4.3 Compatibility

Every implementation of the ElectionGuard specification should be compatible with other implementations. The design specification only specifies the cryptographic operations in detail. In particular early on, the lack of a concrete implementation specification meant that implementation specifics were developed dynamically while several implementation efforts were underway. This naturally lead to challenges for agreeing on the specifics of data serialization into the JSON format. For example, the Python implementation initially used a base-64 encoding of cryptographic values into JSON strings, which was problematic for the C++ implementation. This lead to a less efficient hexadecimal encoding. Later on, the Kotlin implementation supported Google's Protocol Buffers, for an efficient binary representation, while the Rust code supported MongoDB's BSON (a binary variant of JSON).

The initial under-specification of how inputs to the cryptographic hash function should be serialized in the original version 1.0 specification has created unnecessary complications for achieving compatible implementations.

4.4 Scalability

The original definition of ElectionGuard specified a singular JSON election record. This was a problem for the VotingWorks implementation of VAULT [5], which was meant to read the tabular output of a plain paper ballot scanner and

produce a public bulletin board with as many as a million encrypted ballots. Getting the necessary throughput required running on about 1000 CPU cores.

Fundamentally, ElectionGuard encryption is a CPU-bound operation. It is easy to express the encryption of a million ballots in any sort of data-parallel (e.g., MapReduce) paradigm, and as such, it is straightforward to scale the encryption throughput across multiple cores or multiple machines. The challenges come afterward. Before we had all the optimizations described above, each encrypted ballot was roughly 1MB of JSON data, so a million ballots required a terabyte of storage. On a cloud storage system like AWS S3, scalable read or write performance can only be achieved if your data is spread across multiple separate subdirectories, due to the way these systems do sharding. We ultimately settled on a design using one file per ballot, and building a Merkle tree into the directory structure, so any individual ballot can be verified without needing to read the full terabyte of data. This is what was used in the Inyo County pilot (see Section 6.2).

It will be necessary to allow for bulk storage and for efficient verification operations (e.g., voters, given receipts with the hashes of their ciphertext and knowledge of the root hash of the entire election, should be able to verify their ballots' correct representation in the election record without needing to read and process a terabyte of data).

5 In-Person Voting

While ElectionGuard has proven to be very flexible and usable in a wide variety of voting scenarios (e.g., in-person, mail-in, and Internet), the primary intent is for it to be used for in-person poll-site voting.

Even within the in-person setting, ElectionGuard can be used in many different ways: with hand-marked and/or machine-marked ballots, on ballot scanners, on ballot printers, or on ballot-marking devices. We describe in detail here a preferred scenario which matches the use of ElectionGuard in some of the deployments listed in section 6.

In an ideal setting, the ElectionGuard ballot encryption software can be housed on a ballot scanner located in a voting precinct. The use of precinct-based scanners has become common in the U.S. because of their reliability and flexibility (they can generally read either hand-marked or machine-marked ballots or a combination). Both the Idaho and Maryland deployments described in section 6 used the Hart Intercivic Verity ballot scanner which included both a display and a thermal printer.

Upon completing a paper ballot—either by hand or using a ballot-marking device—a voter feeds the paper ballot into the ballot scanner. After reading the contents of the ballot, the scanner displays its interpretation of the ballot contents and also calls the embedded ElectionGuard application with these same ballot contents. The ElectionGuard application encrypts these contents and returns a confirmation code which is printed for the voter. (N.b., the confirmation code is derived from the encryption of the voter selections and in no way reveals the selections themselves.) The voter collects the paper confirmation code and reviews the selections displayed on the screen. The voter may either indicate approval of the ballot—in which case the paper ballot is mechanically dropped into a bin beneath the scanner—or cancel the ballot—which causes the paper ballot to be returned to the voter. If the ballot is cancelled, the voter may make changes directly on the paper ballot or visit a poll-worker to obtain a fresh blank ballot or authorization to start again on a ballot-marking device.

Confirmation codes from cancelled ballots will be opened and serve to ensure correctness of the system as in [2]. The contents of cancelled ballots will be published in the election record together with additional data to enable verifiers to confirm that they match the given confirmation codes. It is also possible for voters to use personal apps from sources of their choosing together with supplemental data provided when a ballot is cancelled to instantly confirm that the confirmation code matches the voter's selections.[19]

6 Deployments and Other Use Cases

One of the principal benefits of the ElectionGuard toolkit model is its flexibility. This is shown by the variety of use cases seen in the deployments described in this section.

6.1 Wisconsin

The first use of ElectionGuard in a public election occurred in February of 2020 in the town of Fulton, Wisconsin. In Fulton, Microsoft partnered with VotingWorks[20] to deploy a system with five ballot-marking devices, a single ballot printer that was controlled by a laptop which also hosted the ElectionGuard vote encryption tools, and a ballot scanner.

Voters made their selections using one of the touchscreen ballot-marking devices and each voter's selections were written onto a smart card. Upon completing the selection process, a voter would take the smartcard to the printing station which would process the selections, call the ElectionGuard software, and print an ordinary ballot with the voter's selections and, on a separate yellow sheet, an ElectionGuard confirmation code. The voter would then have the option of either scanning the printed ballot or taking it to a poll worker to challenge the ballot and restart the voting process. In either case, the yellow sheets containing confirmation codes could be retained by the voters.

In Fulton, 398 voters cast ballots, and 4 ballots were challenged. After the ElectionGuard tallies were computed and released, a hand count of the paper ballots was initiated to confirm the results. The hand counted tally differed by 1 vote

[19] This instant verification feature was not available in recent deployments in Idaho and Maryland.

[20] https://www.voting.works/

from the ElectionGuard tally. But after a hand recount, it was discovered that one of the paper ballots had been put in the wrong pile, and once this was corrected, the results matched perfectly.

6.2 California

The next use of ElectionGuard in a public election was in November of 2020 in Inyo County, California [5]. But, unlike in Wisconsin, it was not part of the voting but instead part of the auditing process. California requires post-election audits of paper ballots to confirm that they are consistent with any machine counts that may have been done. The best modern audits, ballot-comparison *Risk-Limiting Audits (RLAs)* [35], typically begin by publishing the contents of every ballot and then perform random sampling to show that the published contents match the paper ballots.

The concern about ballot-comparison audits is that publication of ballot contents—even without any indication of the voters who cast each ballot—can compromise voter privacy.[21] The work in [9] shows how the tools used to achieve E2E-verifiability can also be used to conduct a ballot-comparison RLA without revealing raw ballot contents.

In Inyo County, California, ballot contents were encrypted by VotingWorks using ElectionGuard, and these encryptions were published instead of raw ballot contents. An election record was published to show that these encrypted ballots matched the announced tallies, and any ballot selected for auditing was decrypted and matched against the corresponding paper ballot.[22]

6.3 U.S. Congress

Shortly after the November 2020 U.S. general election, the respective political parties in the U.S. Senate and House of Representatives met to elect their leadership. At that time, the COVID-19 pandemic was a great concern, and discussions began between the U.S. House Democratic caucus and Microsoft about enabling leadership elections to be held remotely. While Congressional votes are public, the internal caucus elections are held by secret ballot, and ElectionGuard therefore provided a possible solution.

Internet voting poses many challenges, and although E2E-verifiability can mitigate many of these challenges, it does not offer a solution that is suitable for public elections [27] – it does nothing to protect the voting servers from large scale attacks for instance. Microsoft did a careful analysis of this scenario and concluded that for various reasons—including the small number of voters, the opportunity for direct voter education, the secondary channel available to each voter to confirm vote receipt, and, most importantly, the centrally managed mobile phones held by each voter—that this was an appropriate use of the ElectionGuard technology and partnered with Markup[23] to build a customized solution for the U.S. House Democratic caucus.[24]

House members downloaded a custom application onto their managed mobile devices which they used to make their selections of candidates for offices such as Speaker, Majority Leader, and Whip. Upon making their selections, each House member received a confirmation code and could choose to either cast the ballot or challenge it to verify that it reflected the selections that were made. After each round of voting, the lists of candidates were shortened and a new vote was conducted until a single winner was determined for each leadership position. The record of each round of voting was made available internally to House members and their staffs to enable verification.

6.4 Idaho

Starting in 2021, Microsoft partnered with election vendor Hart InterCivic[25] to integrate ElectionGuard into their voting equipment. The first public use of the Hart equipment with ElectionGuard took place in Preston, Idaho in the general election of November of 2022. Although the design was unchanged, numerous efficiency improvements were made to accommodate the Hart requirements, and new capabilities were added to meet their particular needs. MITRE Corporation[26] built its own independent verifier of the election record and took it to Preston to perform an immediate verification of the election record.

Voters had the choice to use ballot marking devices (which print paper ballots marked according to voter selections) or to fill out paper ballots by hand. Voters then had the option to insert their paper ballots into a traditional ballot scanner or a ballot scanner enhanced with ElectionGuard which provided a confirmation code for each vote on thermal paper. In either case, voters had an opportunity to review the scanners' interpretations of the selections on their ballots and could choose at that time to challenge their ballots and have the paper ballot returned. Voters could take challenged ballots to a poll worker and restart the voting process. In all, 111 voters in Preston chose to cast their votes on the ballot scanner enhanced with ElectionGuard.

[21] On a ballot with many contests and questions (as is typical in California), a voter can be instructed to make a very specific set of selections which is likely to be unique amongst all ballots cast within a precinct or jurisdiction. If the contents of each ballot are published, a coercer or vote-buyer can inspect the list of published ballot contents to ensure that a ballot matching the specific instructions is present.

[22] It is important to note that the small number of ballots that were decrypted and revealed do not enable coercion since a coerced voter can simply assert that the instructed ballot contents did not appear amongst the set of published raw votes because that ballot was, evidently, not amongst the audited ballots.

6.5 Utah

Utah statute has allowed some voters to return ballots electronically since 2006. In the November 2023 general election, Enhanced Voting[27] used ElectionGuard to add integrity to this process in a Congressional special election and several local elections. Ballots that were electronically transmitted were also encrypted and tallied with ElectionGuard to verify that the tally had not been altered. 514 ballots across the state were processed with ElectionGuard.

6.6 Maryland

In November of 2023, ElectionGuard was used for municipal elections in College Park Maryland. Hart conducted this election with similar equipment to that used in Preston, Idaho. Although by this time, most, but not all, of the ElectionGuard version 2 features had been implemented. MITRE corporation revised their independent verifier to match the new features of this version and again ran their verifier immediately after the election. All 1468 voters in this election had their votes encrypted with ElectionGuard.

6.7 Neuilly-sur-Seine

Since late 2021, ElectionGuard has been used by Electis[28] for civic voting in the Paris suburb of Neuilly-sur-Seine.[29] This is a blockchain-based voting system of a kind explicitly recommended against by sources like the U.S. National Academies report.[30] However, ElectionGuard is open-source and may be used by anyone without payment or permission, and its use here demonstrates its broad applicability.

6.8 Concordium

Concordium[31] is a blockchain company based in Switzerland and Denmark. Its June 2024 internal elections[32] used its own Rust implementation of ElectionGuard. Here, the fact that an independent company did its own implementation demonstrates both the applicability and appeal of the ElectionGuard design.

6.9 Lessons

User surveys were conduced at the end of several ElectionGuard deployments.[33] These deployments happened in very different contexts, and were often accompanied by other important changes in the elections, like the introduction of electronic voting. As a result, it is hard to draw strong lessons, and more surveys in similar settings are needed.

At this stage, surveys showed that voters and poll workers expressed a strong increase in confidence in the accuracy of the election results when using ElectionGuard. In the eyes of technical experts observing the deployments, the key management by the guardians appears to be a central aspect that should motivate further research: the current deployments had guardians essentially blindly follow instructions provided by the election organizers, using software and hardware provided by these same organizers. Better ways of achieving independence in practice are needed.

7 Conclusions

As can be seen from the wide variety of scenarios described above, ElectionGuard has proven to be a very versatile design. When used in its primary application, ElectionGuard gives voters the ability to confirm on their own that their votes have been accurately counted—whether cast in-person, by mail, or online—without having to trust anyone or anything out of their control. ElectionGuard can also be used to protect voter privacy in post-election risk-limiting audits.

ElectionGuard also introduces new cryptographic approaches of independent interest that make ElectionGuard a flexible, efficient, and easy to use toolkit with numerous applications.

Acknowledgements

A great many people and organizations have contributed to the design, development, and deployment of ElectionGuard since its inception by Microsoft six years ago. There is not space here to properly thank everyone, but many are noted on the ElectionGuard website at https://www.electionguard.vote and in the ElectionGuard specification at https://www.electionguard.vote/spec/.

The authors do want to call out a few individuals whose help has been invaluable to this paper including John Caron, Henri Devillez, Moses Liskov, Arash Mirzaei, Thomas Peters, John Ramsdell, Marsh Ray, and Vanessa Teague.

The authors would also like to express deep thanks to the anonymous reviewers who made many valuable suggestions which greatly improved the quality of this work.

A High Coverage Cybersecurity Scale Predictive of User Behavior

Abstract

Psychometric security scales can enable various crucial tasks (e.g., measuring changes in user behavior over time), but, unfortunately, they often fail to accurately predict actual user behavior. We hypothesize that one can enhance prediction accuracy via more comprehensive scales measuring a wider range of security-related factors. To test this hypothesis, we ran a series of four online studies with a total of 1,471 participants. First, we developed the extended security behavior scale (ESBS), a high-coverage scale containing substantially more items than prior ones, and collected responses to characterize its underlying structure. Then, we conducted a follow-up study to confirm ESBS's structural validity and reliability. Finally, over the course of two studies, we elicited user responses to our scale and prior ones while measuring three security behaviors reflected by Internet browser data. Then, we constructed predictive machine-learning models and found that ESBS can predict these behaviors with statistically significantly higher accuracy than prior scales (6.17%–8.53% ROC AUC), thus supporting our hypothesis.

1 Introduction

Billions of people worldwide regularly spend a significant amount of their time online or interacting with technological devices. In fact, a recent report shows that the average Internet user spend more than six hours per day online [21]. During this time, users constantly face decisions that directly impact their security and privacy, ranging from configuring permissions to allow or prevent newly installed apps from accessing certain information to selecting options to control who can view their activities on social media.

Researchers have attempted to develop a rigorous understanding of users' privacy attitudes, behaviors, concerns, and preferences to help design systems that serve users best. Among different approaches, psychometric scales such as the Privacy Concerns Scale (PCS) [6], Internet Users' Information Privacy Concerns (IUIPC) [27], the Westin Index [25], and the Security Behavior Intentions Scale (SeBIS) [11] have been proposed as affordable and scalable means to learn about users' security and privacy attitudes, concerns, and behaviors. Conceptually, these scales can be useful for various goals, including enabling us to configure systems to safe defaults respecting users' preferences (e.g., configuring sharing policies on social media [50]); bootstrapping personalized defenses to usable states (e.g., ones to automatically enable or block tracking per user preferences [30]); raising users' privacy awareness (e.g., when they underestimate certain risks [15]); or measuring changes in users' behaviors and concerns over time (e.g., due to interventions such as user education or the implementation of new security and privacy features [9, 12]).

However, unfortunately, *prior scales are often found to be poor predictors of actual behavior*. For example, Woodruff et al. found no correlation between the Westin Index and respondents' privacy behavior in certain scenarios, such as ones probing whether they would be willing to sell their medical records for a certain fee [51]. Similarly, Tan et al. found that two of three IUIPC sub-scales do not explain users' likelihood to share their private data, while the third had markedly weaker explanatory power than other factors (e.g., the party with whom the data is shared) [48].

A seeming counterexample is the work of Egelman et al. who showed that scores on SeBIS—a 16-item scale composed of four sub-scales measuring dimensions related to proactive awareness, password generation, updating, and device securement—are correlated with users' security-related behavior [10]. For example, they showed that study participants who scored highly on proactive awareness were less likely to be deceived by phishing than others. Still, the correlation was far from being perfect. Furthermore, prior work found that while SeBIS responses could predict users' exposure to malicious websites, they were significantly less accurate than behavioral features at doing so ($\sim$20% lower area under the receiver operating characteristic curve) [43]. Thus, while scales such as SeBIS constitute easy-to-use instruments to learn about users, there remains significant room for improving their accuracy at predicting actual behavior.

We hypothesize that the omission of critical factors that may directly impact users' security behavior may harm scales' ability to predict actual behavior. Said differently, we expect that *scales that cover a more comprehensive set of security-related factors can predict users' behavior more accurately*. To test this hypothesis, we developed the *extended security behavior scale (ESBS)*, a scale covering a wider range of items and factors than SeBIS. To develop ESBS, we started with a comprehensive list of 374 security advice items [38], of which we selected 45 to construct the initial questions according to a well-defined, objective criteria. Following standard practices [7], we recruited 299 participants to refine the scale and discover its underlying structure. Subsequently, we remained with a scale consisting of 20 questions and five sub-scales (i.e., factors), measuring behavior related to data securement, proactive awareness, anti-virus usage, updating behavior, and password creation. In a follow-up study, we recruited another batch of 500 participants and validated the structure and reliability of ESBS. Besides being more comprehensive than SeBIS (e.g., containing 20 vs. 16 items and five vs. four factors), ESBS also allows respondents to select N/A as answers with the aim of eliciting more detailed information from them and facilitating more accurate predictions.

Following scale construction, we tested how accurately ESBS can predict users' security behavior and contrasted it with SeBIS. In particular, over the course of two studies, we recruited 672 participants, collecting their browsing history and user-agent information, and measured three behaviors: *(1)* whether they clear their browsing history;*(2)* whether they compartmentalize their browsing activities across browsers or browser profiles; and *(3)* whether they keep their operating system up-to-date. Following standard psychometric techniques—namely, factor analysis [7] and item response theory [13]—we scored ESBS by linearly combining sub-scale responses while giving equal weights to items (as in SeBIS), or by combining sub-scales responses non-linearly, scoring items per the mean and variance in participant responses. Then, we trained and evaluated predictive models relying on scale scores, the number of N/As, and demographics as independent variables. For all three security behaviors, we found that ESBS scored linearly leads to more accurate predictions than SeBIS (6.17%–8.53% higher mean receiver operating characteristic area under curve) and that accounting for N/As can help improve prediction accuracy.

In a nutshell, this work makes the following contributions:

- We propose ESBS, a high-coverage psychometric security scale containing more items and factors than SeBIS, and validate its structure and reliability.
- We found that ESBS can predict three different security behaviors more accurately than SeBIS.
- We found that including N/As can aid in improving prediction accuracy, demonstrating the utility of including them in psychometric scales as potential responses.
- We discovered that simple, linear scale scoring surpasses elaborate non-linear scoring in prediction accuracy.

The paper proceeds as follows. Next, we cover related work and background (§2) and introduce an overview of our methodology (§3). Then, we present ESBS's construction and validation processes and results (§4) before we demonstrate its improved behavior-prediction capacity (§5). We close the paper with a discussion (§6) and a conclusion (§7).

2 Background and Related Work

This section will present standard scale-development procedures, existing security and privacy scales, and work on security and privacy predictive analytics.

2.1 Psychometric Scale Development

Of many scale-development procedures proposed in prior work (e.g., [4, 7, 18, 31, 33]), the processes defined by Carpenter [7] and Netemeyer et al. [33] are of the most widely employed. At a high level, the processes start by composing a list of concrete statements, also known as scale items, to be used for capturing and measuring the different aspects of latent concepts of interest (e.g., privacy attitudes or security intentions). Then, *exploratory factor analysis (EFA)* is typically used to assess correlations between statements, and identify the structure of underlying latent constructs (i.e., sub-scales) behind the main concept. After this step, we usually remain with a subset of initial statements, each assigned to a different sub-scale. Finally, *confirmatory factor analysis (CFA)* is conducted to confirm the structure identified by EFA on a distinct sample of responses. In line with prior work (e.g., [11]), we follow a similar procedure to construct our scale.

Traditional approaches relying on factor analysis leverage linear scaling to measure humans on different sub-scales. In other words, a sub-scale identified via factor analysis is usually scored via the sum or average of responses to its corresponding statements. However, such approach does not account for the varied difficulties of items (i.e., mean response) and the variance between respondents. To this end, certain psychometric approaches, such as the notable *item response theory (IRT)* [13], aim to account of inter-statement differences, scoring respondents differently on each statement, depending on its difficulty and the variance within the population. However, IRT models are rarely used to score scales, potentially due to their complexity and limited support by open-source tools [22]. In this work, we evaluate whether (non-linear) IRT-based scaling can enable more accurate behavior predictions.

2.2 Security and Privacy Scales

Researchers have designed several privacy scales in past decades (e.g., [6,17,25,27]). Considered as one of the longest-

standing scales, the Westin Index helps categorize respondents as privacy fundamentalists, pragmatists, or unconcerned depending on their level of privacy concerns reflected by answers to three statements [25]. The Internet Users' Information Privacy Concerns (IUIPC) scale contains three sub-scales—control, awareness, and collection—for gauging users' privacy concerns [27]. Lastly, the Privacy Concerns Scale (PCS) is a one-dimensional scale commonly used for measuring privacy attitudes [6]. Differently from these efforts, we aim to develop a security scale geared toward assessing and predicting security-related behavior.

By contrast to privacy scales, the development of psychometric security scales mostly dates back to the last decade (e.g., [10, 14, 34, 41, 46, 49]). Notably, to our knowledge, the Security Behavior Intentions Scale (SeBIS) was the first composite scales aiming to assess user intentions to adopt a range recommended security behaviors [10]. SeBIS contains 16 items and four sub-scales gauging intentions to secure devices (e.g., via locking), generate strong passwords, update software, and proactively avoiding risks through awareness (e.g., via verifying links before clicking on them). Faklaris et al. proposed SA-6, a one-dimensional six-item scale, for assessing users' security attitudes [14]. While it seeks to measure attitudes rather than behavior intentions, Faklaris et al. found that SA-6 strongly correlates with SeBIS. In this work, we compare our scale with SeBIS, as it aims to gauge behavior more directly and is more comprehensive than alternatives.

2.3 Predictive Analytics

Researchers working on security and privacy predictive analytics have demonstrated the feasibility of forecasting security behavior and incidents through observations and measurements made earlier in time (e.g., [26, 40, 43, 45]). Many predictive analytics systems rely on system logs and other costly, time-consuming, and potentially invasive system measurements to enable predictions. For instance, Soska and Christin collected information about content-management system versions and installed plugins to forecast whether web servers will be compromised within a year from data collection [45]. As another example, Sharif et al. gathered HTTP logs and related Internet browsing data (e.g., website categories and amount of bytes downloaded or uploaded) to predict user exposure to malicious content [43].

Arguably, scales constitute one of the simplest and least invasive means to acquire information for predictive analytics. Indeed, prior work has shown responses to scales are somewhat predictive of actual user behavior. For instance, Egelman et al. have shown that study participants who scored higher on SeBIS's proactive awareness, updating, device securement, and password generation sub-scales also tended to detect phishing attempts more successfully, applied software updates in a more timely manner, used smartphone-locking mechanisms more often, and generated harder-to-guess passwords, respectively. Still, users' scale scores often do not correlate with their real-world behavior or leave significant room for improvement. For instance, facing the so-called privacy-paradox phenomenon, Woodruff et al. found that participants reporting high privacy concerns on the Westin Index (i.e., privacy fundamentalists) were roughly as likely as others to share sensitive data about themselves (e.g., medical records) for a certain fee [51]. Mayer et al. found that SA-6 scores were not predictive of password-meter adoption [28], while Smullen et al. discovered they were unable to forecast whether users will opt-out from online tracking [44]. Tan et al. reported that two of three IUIPC sub-scales do not explain users' likelihood to share their private data, while the third had markedly weaker explanatory power than other factors (e.g., the party with whom the data is shared) [48]. Similarly, Sharif et al. found that although SeBIS responses could predict users' exposure to malicious websites with certain accuracy, they were significantly less accurate than behavioral features at doing so ($\sim$20% lower area under the receiver operating characteristic (ROC) curve) [43]. This work explores the possibility of enhancing security scales' accuracy at predicting user behavior by making them more comprehensive.

3 Methodology Overview

Here we provide an overview of our methodology before we lay out the details and the results in the following sections. Our methodology consists of three primary stages, involving scale development, scale validation, and user-behavior prediction. In each of the first two stages we ran an online user study, while in the last stage we administered two studies, resulting in four studies overall. To avoid learning effects and ensure internal validity, we recruited independent samples across the four studies. Fig. 1 summarizes our methodology.

Scale Development We initiated our work by composing the initial items to be included in our scale. We composed the items' statements by selecting appropriate security advice from Redmiles et al.'s comprehensive set of 374 advice items [38]. In particular, we selected advice that was deemed accurate, useful, of high priority, and widely relevant, as elaborated in §4.1. For each resulting item, scale respondents were given the option to respond on a 5-point Likert scale denoting the frequency in which they follow the advice, or alternately select N/A, in case they felt the statement did not apply to them or they did not understand the statement.

After composing the initial version of our scale, we conducted an online user study to refine it and identify its latent structure. We designed and ran an online user study to collect responses to the initial scale items. After collecting the responses, we removed unhelpful items (e.g., ones exhibiting ceiling or floor effects) and ran EFA to identify the sub-scales forming our primary scale, ending with ESBS_{FA}, a security-behavior scale containing five sub-scales and 20

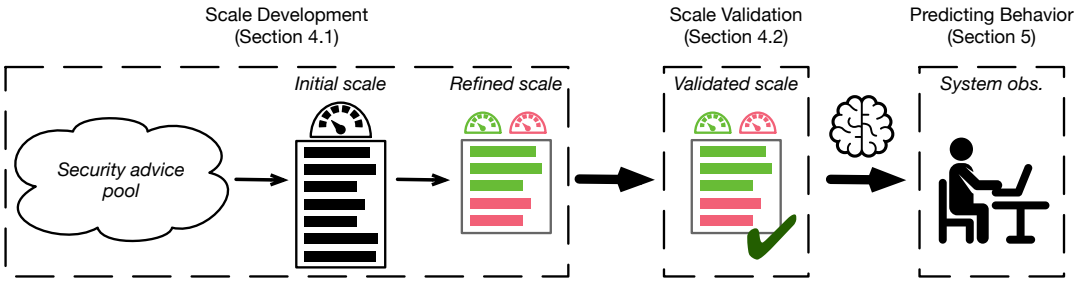

Figure 1: A high-level overview of our methodology. We started by developing the scale, first compiling an initial scale by selecting and rephrasing appropriate security advice, collecting responses via an online study, and refining the scale by running EFA to identify the sub-scales that emerge and select the items to maintain. Subsequently, we collected additional responses and validate the scale's structure (via CFA) and validity. Lastly, we ran studies, this time also collecting system-level behavioral observations, and built machine-learning models to measure the scale's accuracy when predicting behavior.

items. Additionally, we analyzed the responses with an adequate IRT model, and ended with $ESBS_{IRT}$, a scale with five equivalent sub-scales based on the same 20 items as $ESBS_{FA}$ but is scored non-linearly.

Scale Validation Next, we ran another online study to assess the scale's reliability and validity. High reliability indicates that the scale and its corresponding sub-scales' items measure the same constructs, whereas high validity denotes that the same underlying construct holds on independently collected samples. After collecting another sample of responses, we ran standard reliability and validity tests and ensured that scale and the underlying structure we identified in the first stage were reliable and valid.

Predicting Behavior Finally, we conducted two online studies to measure whether ESBS can predict security behavior and put out hypothesis—i.e., scales with higher coverage are able to predict behavior more accurately—to the test. In these studies, besides collecting responses to ESBS's and SeBIS's items and demographic questions, we also collected participants' browsing history or their user agent strings, to gauge whether they follow recommended security behaviors (namely, isolating browsing sessions across profiles or browsers, clearing browsing history, and frequently applying operating-system updates). Subsequently, we trained machine-learning models to predict behavior based on scale scores and demographics, and compared the prediction performance across scales and scoring techniques (i.e., via FA or IRT).

All of our user studies have been reviewed and approved by our Institutional Review Board (IRB).

4 Higher Coverage Security Scale

This section presents the process we followed to develop ESBS, our scale with higher coverage, and the process for refining and validating it. We also contrast ESBS with SeBIS to highlight their similarities and differences.

4.1 Scale Development

4.1.1 Methodology

Composing Initial Items Similarly to SeBIS [11], we based our scale's questions on widely recommended security advice to measure end-users' compliance intentions. Yet, unlike SeBIS, which started from 30 advised behaviors, we used a richer, more exhaustive pool. Specifically, we built on Redmiles et al.'s work [38] to form an initial comprehensive set of advice. Their work analyzed >2,000 documents containing security and privacy advice, and identified 374 advice items that are often suggested to users. These items pertain to twelve categories, ranging from account security to network security, and from password creation and management to antiviruses. The categories are mostly mutually exclusive, except for four advice items that appear in two categories each. Redmiles et al. surveyed 41 security and privacy experts to assess the advice items' accuracy (i.e., whether following them is conducive to security and privacy) and perceived utility (i.e., the expected risk reduction due to compliance with the advice). Furthermore, they asked experts to prioritize items, only to find out that there is no widely acceptable prioritization among experts—more than 50% of advice appeared at least once in experts' top-ten most recommended advice items.

While comprehensive, basing the scale's items on all 374 advice items would result in a long, impractical questionnaire: it would be prohibitive to complete the questionnaire in a reasonable amount of time, and participants are likely to become less engaged and drop out in the middle, thus harming data quality [2]. Therefore, we sought to select a subset of advice to include in our questionnaire. Particularly, we applied the following criteria for advice selection:

1. **High accuracy**: We ensured that all experts surveyed agreed that the advice items are accurate.
2. **High utility**: The advice selected had high perceived risk reduction. Specifically, we picked items whose per-

ceived risk reduction was ≥40%—the median perceived reduction among all advice.

3. **High priority**: We excluded low-priority advice items, only keeping items in the 50th percentile.

4. **Security relevance and wide applicability**: Two researchers manually and independently examined the remaining advice items and the documents originally presenting them to identify ones that are *1)* related to personal security (e.g., excluding items concerning giving advice to others); and *2)* applicable to a wide range of users (e.g., not only ones raising kids or employed by tech enterprises). Overall, they found 30 items that do not satisfy the criteria, narrowing down the advice-item list to 83. The coders had substantial inter-coder agreement (Cohen κ=0.69) [29], and resolved disagreements manually by discussing and agreeing on definitions.

5. **Non-redundant**: As a final step, we identified and removed redundant advice. Over two consecutive meetings, two researchers clustered the advice items together according to their similarity, and picked a representative item for each cluster.

Applying criteria 1–3 resulted in a marked decrease in the number of advice items, with 103 items surviving the selection process. After applying all criteria, we remained with 45 initial advice items to include in our scale. Interestingly, these items covered 15 of the 16 advice items originally included in SeBIS. As a final step, in line with SeBIS, we rephrased the advice items to statements assessing frequency at which respondents follow recommended advice. Accordingly, responses to the scale are reported on a 5-point Likert scale: *Never (1), Rarely (2), Sometimes (3), Often (4), and Always (5)*. Additionally, we allow respondents to select N/A to indicate they do not understand the statement or feel it does not apply to them. When scoring the respondents, we treat N/As as never, since the respondent do not follow the describe behavior in practice. Moreover, in our experiments, we evaluate whether the additional information gained from N/As (e.g., that the participant lacks basic understanding regarding a certain behavior) can be leveraged to enhance prediction accuracy. Tab. 6 in App. B presents the initial 45 items.

Refinement and Sub-scale Identification Following the recommended steps for scale development of Carpenter [7] and Netemeyer et al. [33], and SeBIS's development procedure, we designed an online user study to collect responses on our initial scale, refine it, and explore its latent construct via EFA. We asked participants in our study to fill out a survey composed of three primary parts. The first part presented the initial scale's questions, assessing the participants' propensity to follow the 45 recommended advice items initially selected. We were concerned that participants' responses were influenced by their desire to appear more socially acceptable [8]. Therefore, in the second part, we measured social desirability to test whether participants' willingness to appear more socially acceptable correlated with their answers to our survey questions. Particularly, to measure social desirability, we asked participants to complete a conventional 13-item version of the Marlowe-Crowne social desirability scale [8, 39]. Finally, we asked participants basic demographic questions. The detailed study protocol is presented in App. A.1.

We took several measures to maintain internal and external validity, and ensure data quality. To mitigate ordering effects, we presented the questions of the first and second parts in a randomized order. Additionally, to avoid selection bias, we advertised our study as one exploring technology perceptions, similarly to Abrokwa et al. [1]. Finally, following Egelman and Peer [11], we began the study with attention questions, notified participants that failed them once, and precluded participants that failed them twice from completing the study.

Data Analysis We followed standard processes to analyze the collected data [7]. First, we examined how often questions received N/A responses. After noticing the no question stood out as widely non-applicable, we mapped N/A responses to "Never" (i.e., 1), following the intuition that if a respondent reports security advice as non-applicable, then they never follow it. As an alternative approach, we also ran an identical analysis while employing the so-called imputations technique—treating N/As as missing values, and replacing them with most likely estimates based on other participant responses [32]. This approach led to consistent findings.

Secondly, we removed items exhibiting ceiling (μ>4.0) or floor (μ<2.0) effects, or low variance (σ<1.0), as these have low utility in a scale due to not differentiating between respondents. We also removed items that did not exhibit high Spearman correlation (≥0.3) with other items, as they fail to measure the same construct as other items [7].

Thirdly, we verified the factorability of the data by running Bartlett's test of sphericity, the Kaiser-Meyer-Olkin test of sampling adequacy, and inspecting the inter-item correlation matrix. We then tested whether all statistics lay within the recommended ranges [7].

Then, we performed EFA, using maximum-likelihood estimation and Oblimin rotation [7]. In line with prior work [19, 36], we followed an iterative EFA procedure. Specifically, after selecting the number of factors via the standard eigenvalue criterion (i.e., factors whose eigenvalue are above one) [7], we examined per-item factor loadings and removed items whose largest loadings were low (<0.32). The rationale behind removing those items is that they are unable to reliably measure a single latent construct [7]. We repeated this process until no items were removed, remaining with the refined scale and corresponding sub-scales.

Lastly, we analyzed the participants' responses using a multidimensional IRT model called the multidimensional graded response model (MGRM), a model applicable for analyzing polytomously scored items (e.g., on a Likert scale, akin to ours) and discovering latent dimensions (i.e., sub-scales) [24].

MGRM assumes that each person has a certain ability that cannot be observed directly, but can be estimated from their observed responses to a psychometric scale. The MGRM model assigns each item k-1 thresholds where k is the number of response levels per item (e.g., k=5 for a 5-point Likert scale). The i^{th} threshold denotes the ability score the respondent need to surpass to increase their likelihood of selecting the $i+1^{\text{th}}$ response level or higher for the given item. Moreover, MGRM assigns each item a discrimination parameter per dimension. The higher is the discrimination score, the more the item varies between individuals as their ability changes along the dimension. We estimated the MGRM model's parameters with an increasing number of dimensions, selecting the model with the lowest Bayesian information criterion (BIC) as long as increasing the number of dimensions (i.e., model complexity) markedly decreased the BIC (by $>$5), as is standard [42]. Once the model's threshold and discrimination parameters were found, we could use them to estimate the participants' latent ability scores per sub-scale from their responses through maximum *a posteriori* likelihood estimation. We used the GIRTH Python package[1] for parameter estimation.

4.1.2 Participants

We recruited participants via Prolific,[2] an online crowdsourcing platform. We opened our study to participants from the United States who are at least 18 years old. Additionally, we used Prolific's functionality to collect data from a population-representative sample, resulting in a sample whose ethnicity, gender, and age distribution reflects the general United States population's. A total of 307 participants started the study, and eight dropped out due to failing the attention question. Thus, overall, 299 participants completed our study, leading to $>$5:1 response-to-item ratio, as recommended [7]. The average participant's age was 45.6 ($\pm$16.0) years and 47.8% of the participants reported themselves as males. It took participants an average of 9.3 minutes to complete the survey, and they were compensated 1.6 GBP ($\approx$2.0 USD) for participating.

4.1.3 Results

The number of N/A responses received for each of the 45 initial items was relatively low, leading us to initially keep all items. However, we later excluded 19 items due to ceiling effects (10), low variance (11), or low total-item correlation (2), leaving us with 26 items. Tab. 6 presents detailed statistics for all items. For the remaining items, we found that Bartlett's test of sphericity (χ^2=2730.0, p-value<0.001), Kaiser-Meyer-Olkin test of sampling adequacy (0.91), and the inter-item correlation values (0.28 on average), all laid in the recommended ranges [7, 35]. We highlight that none of the items, including those removed, were correlated with the social desirability measures, indicating that participants' responses were not influenced by a social desirability bias.

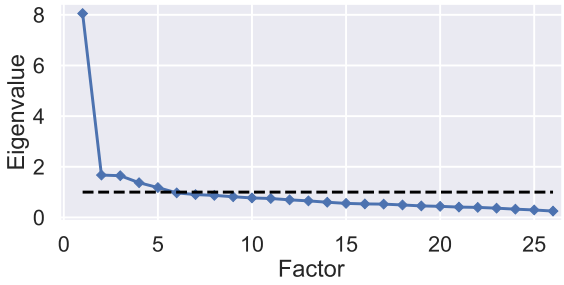

Figure 2: Eigenvalues attained from EFA. We selected five factors, as the eigenvalues of remaining factors were $<$1.

For EFA, we selected five factors according to the eigenvalue criterion (Fig. 2) [7]. We ran EFA for three iterations, removing a total of six items in the first two iterations, and none in the third. Hence, overall, we remained with 20 items in our scale. Tab. 1 presents the factors and their corresponding items, while Tab. 2 lists the factor loadings on each factor, per item. Two researchers met and named the sub-scales according to the themes of their respective items. The first factor (DS) gauges behaviors related to data securement (e.g., validating the digital certificates of HTTPS websites); the second factor (PA) assesses proactive awareness (e.g., verifying the extensions of downloaded files); the third factor (AV) measures whether individuals install and use security programs (namely, anti-viruses); the fourth factor (UP) elicits whether individuals keep their devices up-to-date; and the last factor (PW) checks whether they select strong and unique passwords. We refer to each of these identified sub-scales by ESBS^{*}_{FA}, where $*$ stands to the sub-scale's name (e.g., ESBS^{DS}_{FA} to the data securement sub-scale identified via factor analysis and scored via summing the relevant items' responses).

The IRT analysis also resulted in five dimensions, all of which heavily align with the factors found by EFA. Tab. 2 presents the dimensions and items' discrimination-score estimates. It can be immediately seen that items typically contribute the most to the dimension corresponding to the related factor from EFA. In other words, the highest factor loadings and discrimination scores of most items are assigned to the same dimensions. Accordingly, we refer to the IRT sub-scales by ESBS^{*}_{IRT}, where $*$ stands for the related factor's name. A chief difference between the IRT and EFA models is that, in the case of EFA, the sub-scale scores are computed by linearly combining the scores of specific sets of items via summation, whereas, in the case of IRT, all items contribute non-linearly to all sub-scale scores (a.k.a., the ability scores), and the item contributions to each ability score are non-uniform, varying based on the thresholds and discrimination parameters.

#	Factor 1: Data Securement (DS; 15.0% of variance explained; λ=3.00)	μ	σ
1.1	I encrypt my email contents when sending sensitive information (e.g., banking and health information or social security number)	2.52	1.56
1.2	I validate the digital certificates on the websites I visit	2.64	1.38
1.3	I review the validity of my root certificates	2.12	1.40
1.4	I validate the digital signatures files before opening them	2.68	1.46
1.5	I physically destroy drives I am done using and wish to erase	2.60	1.68
1.6	I encrypt my devices' disks to keep my data confidential	2.38	1.48
1.7	I safely store my private key for email encryption	2.60	1.68
#	**Factor 2: Proactive Awareness (PA; 11.0% of variance explained; λ=2.19)**	μ	σ
2.1	I verify whom I communicate with online (via email or online messaging apps) is really the person I intend to	3.92	1.18
2.2	I verify links (e.g., in the URL bar or by mouseover) to ensure that I am accessing intended websites	3.83	1.19
2.3	I check the extensions (e.g., .exe, .pdf) of files I download	3.93	1.25
2.4	I turn on download notifications in my browsers	3.69	1.45
2.5	When possible, I use two- or multi-factor authentication	3.83	1.11
2.6	I disable auto-run to prevent potentially malicious downloaded programs from running	3.61	1.55
#	**Factor 3: Anti-virus (AV; 7.7% of variance explained; λ=1.55)**	μ	σ
3.1	I scan attachments for viruses before downloading or opening them	3.51	1.43
3.2	I verify that my anti-virus software is up-to-date	3.77	1.30
3.3	I install anti-virus software when setting up my devices	3.91	1.31
#	**Factor 4: Updates (UP; 5.9% of variance explained; λ=1.17)**	μ	σ
4.1	I turn on automatic updates for devices and applications upon installation	3.56	1.22
4.2	When I am prompted about a device or software update, I immediately install it	3.30	1.13
#	**Factor 5: Passwords (PW; 3.8% of variance explained; λ=0.77)**	μ	σ
5.1	I select hard-to-guess passwords (with multiple character types, without dictionary words, etc.)	3.99	1.11
5.2	I select different passwords for different accounts and devices	3.93	1.09

Table 1: The final items included in our scale and the related factors (i.e., sub-scales) uncovered by EFA and IRT. For each item, we report the mean (μ) and standard deviation (σ), where responses were collected on a 5-points Likert scale. We assign each factor and acronym, and report the percentage of variance explained and associated eigenvalue from factor analysis.

4.2 Scale Validation

4.2.1 Methodology

Study Design We validated the scale by eliciting responses on the ESBS from new participants. This time, we asked the participants to respond to the ESBS's questions followed by demographics questions. Again, to ensure data quality we introduced an attention question, warned participants who failed it once, and disqualified those who erred twice. We also randomly ordered the ESBS's items to prevent ordering effects. Moreover, we advertised the study as one exploring technology perceptions to alleviate selection bias. The complete study protocol is available in App. A.2.

Data Analysis We validated ESBS by testing its overall reliability, as well as the reliability of each of its sub-scales. Additionally, we tested the validity of the structure discovered in §4.1.3—i.e., checking whether the same latent structure generalizes across samples. To assess reliability, we used Cronbach's α, and checked whether it lays in the desirable range of $\geq$0.6 [3]. To check structural validity, we used a battery of goodness of fit measures and tested whether they fall within their respective recommended ranges. Specifically, we tested that the Root Mean Square Error of Approximation (RMSEA) falls below the recommended cutoff of 0.06 [20]; the Standardized Root Mean Square Residual (SRMR) lays below the suggested 0.08 [20]; the Comparative Fit Index (CFI) is above the recommended 0.9 [33]; and the Tucker-Lewis Index (TLI) falls above 0.9 [33].

4.2.2 Participants

We recruited participants via Prolific. We opened our study to participants from the United States who are at least 18 years old. Additionally, we collected data from a population-representative sample, resulting in a sample whose ethnicity, gender, and age distribution reflects the general United States population's. We also ensured the participants were distinct of those recruited for the first study. A total of 509 partici-

Table 2: A summary of the EFA and IRT results. For EFA, we report the per-item factor loadings on the identified five factors. We also report Cronbach's Alpha (α) for each factor. The scale's overall α is 0.882. For IRT, we report the discrimination values per dimension for each of the items. The maximum factor loading and discrimination value for each item are in boldface.

pants started the study, and nine dropped out due to failing the attention question or quitting our study. Thus, overall, 500 participants completed our study. The average participant's age was 45.4 (±16.3) years and 47.6% of the participants reported themselves as males. It took participants an average of 5.1 minutes to complete the survey, and they were compensated 0.82 GBP (≈1.0 USD) for participating.

4.2.3 Results

Tab. 3 presents the reliability and validity metrics we calculated. The results show that all metrics fall within the ranges recommended in the literature. Hence, we can conclude that ESBS and each of its sub-scales are reliable, and that the scale's structural validity holds.

	Metric	Value	Recommended
Reliability	α(DS)	**0.83**	≥0.60
	α(PA)	**0.71**	
	α(AV)	**0.80**	
	α(UP)	**0.64**	
	α(PW)	**0.71**	
	α(Overall)	**0.88**	
Validity	CFI	**0.93**	≥0.90
	TLI	**0.91**	≥0.90
	RMSEA	**0.05**	≤0.06
	SRMR	**0.05**	≤0.08

Table 3: Reliability and validity measures and their recommended ranges. All lay within recommended ranges.

4.3 Comparison With SeBIS

It is instructive to contrast ESBS with SeBIS. Two members of the research independently coded each of the SeBIS and ESBS items according to whether they are included in the other scale. The researchers agreed on 13 of the 16 SeBIS items and resolved differences by accepting one of the researchers' codes. Eight of the SeBIS items were not included in ESBS due to exhibiting ceiling effects of low factor loadings. Of the eight SeBIS items that were included in ESBS, two overlapped with a single ESBS item. Hence, 13 ESBS

items were not covered by SeBIS. Specifically, these included ESBS items 1.1, 1.3–1.7, 2.1, 2.3–2.6, 3.1, and 3.3 (see Tab. 1). These items cover a wide range of critical security behavior, including the encryption and protection of sensitive information users send online, the verification of parties they communicate with via email and messaging applications, the use of multi-factor authentication, and the deployment of anti-viruses [38]. By including these items, ESBS covers a wider range of behaviors than SeBIS. In what follows, we verify whether this higher coverage translates to higher prediction accuracy of actual user behavior.

5 Behavior Prediction

After developing ESBS and validating it, we ran two studies to test whether it can predict user behavior and compare its prediction accuracy with that of SeBIS. In one study, we collected Internet-browsing data and attempted to predict whether participants isolate browsing sessions across different profiles or browsers, and whether they frequently clean their browsing history. In the other study, we sought to predict whether users keep their operating systems up-to-date.

5.1 Browsing-Behavior Study

5.1.1 Methodology

Study Design We administered a user study to gather responses to ESBS and SeBIS, and collect browsing data. In this study, we presented participants with ESBS and SeBIS questionnaires. As in the studies above, additionally to the 5-point Likert scales, study participants could also respond with N/A to ESBS items. Subsequently, participants were asked to install a Chrome extension to share their browsing history with the researchers. We selected Chrome as it is the browser with the largest market share—62.85% of Internet users set Chrome as their default browser [47]. To ameliorate privacy concerns, we limited the data collection to the last three months of browsing history, collecting only first-party websites and fully qualified domains visited (instead of full URLs). Furthermore, we allowed study participants to remove domains they preferred not to share before uploading the data. For each domain shared by participants, we also included the timestamp of the visit. After completing the upload, participants were presented with demographic questions, asking about their age, gender, education, occupation, and income. In the absence of automatic means to collect data about participant behavior via the extension—i.e., test if they clear their browsing history or compartmentalize browsing sessions—we resorted to collecting self-reported data. However, we later verified that the reported data were consistent with the logged browsing histories (§5.1.3). Specifically, we asked participants whether they use unique profiles or browsers for participating in online study, separating their study-taking activities from everyday browsing. Such compartmentalization would indicate that the participants are security- and privacy-aware, as isolating browsing sessions is a recommended behavior to help circumvent online tracking and protect one's data when engaging risky activities [38]. Moreover, we asked participants about whether they have cleared their browsing history, fully or partially, within the past three months. Participants could answer affirmatively, negatively, or most likely. Again, clearing the browsing history is a recommended security and privacy behavior [38], as it could, for example, help remove login tokens that could be (mis)used by adversaries to impersonate the user. App. A.3 contains the study's protocol.

As before, in this study too we used attention questions to ensure data quality. We also presented the SeBIS and ESBS questionnaires and their respective items in random order to mitigate ordering and learning effects. To comply with the study platform's terms of service, we let participants know in advance that they will be asked to install an extension that will share browsing data with researchers. Yet, to alleviate self-selection bias, we avoided listing the study as a security study, advertising it as one aiming to measure technology perception and Internet usage. Furthermore, we limited participation from Chrome browsers, as our extension only supports uploading data from Chrome.

Data Analysis We initiated the analysis by validating the participants' responses, checking that participants who self-reported to compartmentalize browsing activities indeed mostly visited study-taking platforms, while those who self-reported to have cleared their browsing history uploaded records that span shorter time periods than others.

Next, we tested and compared the behavior-prediction accuracy using SeBIS and ESBS. To this end, we built machine-learning models aiming to predict whether participants behave securely based on scale responses and demographics. More concretely, the dependent variable of the models was an indicator variable denoting whether a participant behaves securely (i.e., compartmentalize sessions or clear browsing history) or not. The independent variables primarily included the scores on each sub-scale—four scores in the case of SeBIS and five in the case of ESBS. To compare linear and non-linear scoring, we trained and evaluated models with EFA- and IRT-derived scores for both SeBIS and ESBS. Additionally, to evaluate whether N/As are conducive for predictions, we tested ESBS models with and without an additional independent variable representing the number of N/A responses entered by the participant. I.e., this resulted in six conditions compared per security behavior: linearly scored SeBIS (SeBIS_{FA}), non-linearly scored SeBIS (SeBIS_{IRT}), linearly scored ESBS with or without N/A count (ESBS_{FA} and N/A+ESBS_{FA}), non-linearly scored ESBS with or without N/A count (ESBS_{IRT} and N/A+ESBS_{IRT}). To account for demographics, we also included independent variables for age (in years), and indicators for higher education (Bachelor's or above), high income (75K USD or higher yearly income), gender (female or not), and

technical background. Of different machine-learning models we tested, random forests attained the highest accuracy. Thus, we ran 20 evaluation rounds (90-10 training-test splits), in which we performed a grid-search with three-fold cross-validation to choose the best model hyperparameters per condition, and evaluated performance on the test samples. As the accuracy metric, we used the receiver operating characteristic area under curve (ROC AUC), whose value ranges from 0 to 1, and tends to 1 as the model is more accurate. After finishing the evaluation, we performed a paired t-test to compare the mean AUC with the SeBIS$_{FA}$ condition.

We were also interested in assessing how each independent variable affects prediction accuracy. Therefore, we used the well-established permutation-importance model interpretation technique [5]. Given a trained model, this technique permutes the values of an independent variable across samples and measures the resulting decrease in accuracy. This process is repeated several times, permuting values of one independent variable at a time, and the average decrease in accuracy is eventually emitted as a measure of feature importance—the higher decrease in accuracy due to permutation, the more important is the independent variable for classification, as perturbing it markedly harms classification accuracy. We report the average permutation-importance scores across all evaluation rounds per feature.

5.1.2 Participants

We recruited 228 participants for this study through Prolific, while limiting participation to individuals who are at least 18 years old, are located in the United States, and had not participated in the two previous studies. We recruited a gender-balanced sample, resulting in 111 respondents who identified as females. The average participant age was 40.04 ($\pm$13.12) years. It took participants roughly 12 minutes on average to complete the study. Considering the sensitivity of the browsing data we collected, we increased the compensation compared to the previous studies to 2.48 GBP ($\approx$3.0 USD), after drawing on Tan et al.'s estimate of the cost at which individuals are willing to sell their browsing history [48].

5.1.3 Results

On average, each participants reported 1,279 visits to 18 distinct first-party domains. Most participants submitted their entire available browsing history for the past three months, with only 24 of the 228 participants removing and average of 9.17% of the items from their history. Browsing histories spanned at least two days for $\geq$89.47% of the participants, suggesting that the study did not trigger most participants to (fully) clear their history (arguably, participants who cleared their history before participating may be intuitively deemed security- and privacy-aware). 21.05% of the participants reported using a unique profile or browser to participate in online studies and

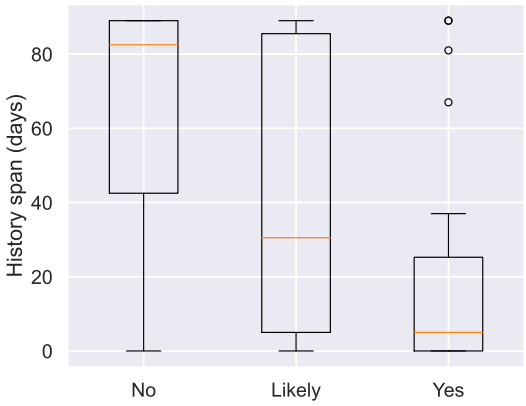

Figure 3: Boxplots depicting the time span covered by the browsing history of participants reporting to have cleared, likely cleared, or not cleared their browsing history.

crowdsourcing tasks. While we cannot fully verify compartmentalization behavior using our data alone, upon examining the domains visited most often by the participants, we found that indeed visits to crowdsourcing domains constituted an overwhelming majority of the total visits in their browsing history—a median of 71.59% of the total visits were to crowdsourcing websites. By contrast, for users reporting not using unique profiles or browsers to partake in studies, a median of only 42.54% of their total visits were to crowdsourcing domains. These self-reports were reliable, thus we used them to label participants according to whether they compartmentalize their browsing activity, separating their study-taking activities from everyday browsing. The boxplots in Fig. 3 depicts the time span covered by browsing histories of participants reporting clearing, likely clearing, or not clearing their browsing history in the three months prior to uploading their data. It can be seen that participants reporting clearing their browsing history shared histories spanning markedly shorter time spans than others, with all spanning 39 days or fewer when excluding the three outliers. Still, some participants reporting clearing or likely clearing their history shared data spanning roughly three months. Hence, when labeling our data, we avoided using potentially unreliable self-reports, and instead treated participants who shared data spanning $<$39 days as ones who clean their history. Three participants reported clearing their browsing history but shared browsing data spanning $>$39 days. We categorized those participants as ones who have not cleared their history. Labeling them as ones who have cleared their browsing history did not impact our takeaways.

Tab. 4 presents the ROC AUC mean and standard deviation per condition. The results highlight that ESBS$_{FA}$ led to higher prediction accuracy (1.70%–6.48% higher mean AUC) than SeBIS, when scores via linearly (FA) or non-linearly (IRT). These differences were statistically significant. Furthermore,

Dependent variable: Compartmentalization		
Condition	**AUC**	**(±std)**
$SeBIS_{FA}$	57.04%	(±15.35%)
$SeBIS_{IRT}$	63.87%	(±11.99%)
$ESBS_{FA}$	65.57%	(±12.33%)
$ESBS_{IRT}$	58.03%	(±12.98%)
$N/A+ESBS_{FA}$	69.60%	(±10.60%)
$N/A+ESBS_{IRT}$	61.08%	(±12.54%)
Dependent variable: Clearing history		
Condition	**AUC**	**(±std)**
$SeBIS_{FA}$	62.57%	(±10.70%)
$SeBIS_{IRT}$	59.42%	(±10.88%)
$ESBS_{FA}$	69.05%	(±12.47%)
$ESBS_{IRT}$	63.17%	(±13.94%)
$N/A+ESBS_{FA}$	68.76%	(±11.22%)
$N/A+ESBS_{IRT}$	65.47%	(±11.91%)

Table 4: ROC AUCs of predicting dependent variables derived from participants' browsing histories (i.e., compartmentalization and clearing history) using scale responses, demographics, and (sometimes) number of N/As. For each condition, we report the mean and standard deviation (std) of the AUC. Underlined values denote mean AUCs statistically significantly larger than those achieved by $SeBIS_{FA}$ (p-value<0.05).

incorporating the number of N/As as an independent variable either preserved prediction accuracy (for clearing history) or led to a statistically significant increase in prediction accuracy (4.03% higher AUC for compartmentalization in condition $N/A+ESBS_{FA}$ compared to $ESBS_{FA}$). Finally, it can be seen that non-linear scoring with IRT generally led to lower prediction accuracy than linear scoring with FA.

We also tested whether incorporating $SeBIS_{FA}$ scores alongside $N/A+ESBS_{FA}$ could increase prediction accuracy. The models we built using both scales as independent variables attained 66.40%±12.11% and 68.70%±11.73% mean AUC for compartmentalization and clearing history, respectively, failing to improve the accuracy achieved via $N/A+ESBS_{FA}$ alone. This finding further supports our analysis in §4.3, showing that informative SeBIS items are covered by ESBS. Hence, combining scores on both scales is unlikely to introduce additional information boosting prediction accuracy.

Figs. 4–5 present the feature importance scores assigned to the independent variables in the $N/A+ESBS_{FA}$ condition. Age was the most predictive independent variable both when predicting whether the participants compartmentalize browsing activities or clear their history, leading to a drop of roughly 5.91–7.54% in mean AUC when permuted. Closely behind are the ESBS sub-scales. When predicting compartmentalization, the data-securement ($ESBS^{DS}_{FA}$) and proactive-awareness ($ESBS^{PA}_{FA}$) sub-scales received high scores—2.55% and 2.88% reduction in AUC when permuted, respectively. This result supports the intuition that users reflecting high

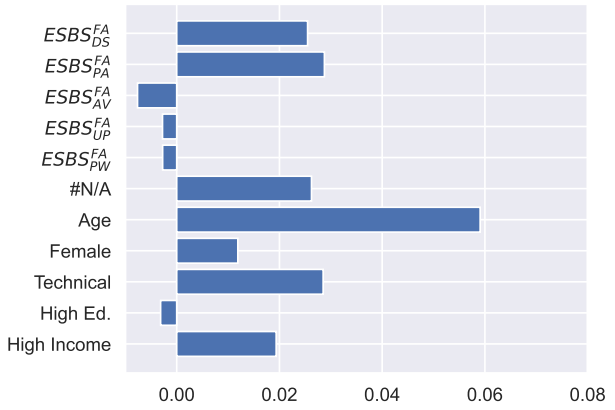

Figure 4: Mean importance of the independent variables when predicting browsing-activity compartmentalization, as calculated by the permutation test.

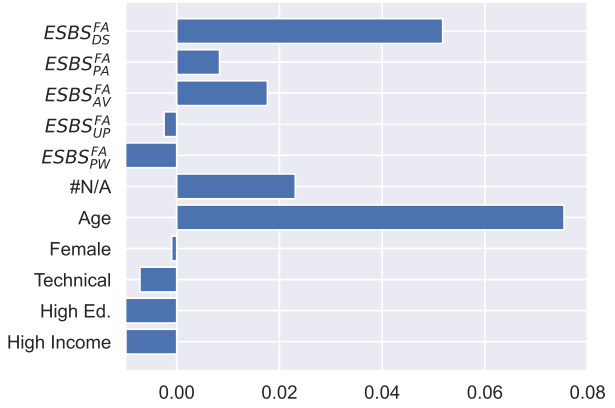

Figure 5: Mean importance of the independent variables when predicting whether users clear their browsing history, as calculated by the permutation test.

data securement and awareness intentions are more likely to compartmentalize their browsing than others. When predicting whether participants clear history, the data-securement sub-scale ($ESBS^{DS}_{FA}$) received the highest importance score amongst all sub-scales, again supporting intuition.

5.2 Updating-Behavior Study

5.2.1 Methodology

Study Design In the last study, following prior work [10], and given the recent release of MacOS Ventura [23], we elected to investigate whether ESBS responses can enable accurate prediction of MacOS updates. More specifically, we sought to test whether ESBS can predict whether participants' MacOS versions are eligible for security updates. Intuitively, as participants whose MacOS version is more than three versions old do not receive security updates, they are more vulnerable to at-

tacks than others. Hence, a desirable user behavior is that they update their MacOS version to receive security updates. We limited participation in the study to MacOS users. We asked participants to answer the ESBS and SeBIS questionnaires, followed by demographic questions. Lastly, we asked participants to self-report their MacOS version from a drop-down list, giving them instructions for how to find the exact version in case they were uncertain about it. In the background, similarly to prior work [10], we also collected the user-agent string to further confirm the MacOS version. The complete study protocol is available in App. A.4. Here too, we avoided ordering effects by presenting the SeBIS and ESBS questionnaires and their respective items in a random order. We also advertised the study as a technology-perceptions study to minimize selection bias.

Data Analysis Except for the validation of the self-reported MacOS versions and the derivation of the dependent variable in the machine-learning model, our analysis was similar to the previous study. Specifically, as the user-agent string can be misleading (e.g., it can be altered by certain browser extensions [16]) and participants may misreport their MacOS version, we compared self-reports with user-agent strings, removing inconsistent responses, to ensure data validity. Our dependent variable denoted whether the user's MacOS version is still eligible for security updates (i.e., version 11 or above [23]) or not.

5.2.2 Participants

We recruited a set of new participants, distinct of those included in the studies previously presented, via Prolific. We opened our study to participants from the United States who are at least 18 years old, using Prolific's functionality to recruit a gender-balanced sample. A total of 558 participants started the study, and 57 of them dropped out due to failing the attention question (7), quitting the study (4), or disqualifying because they did not use MacOS (46). Overall, 501 participants completed our study. The average participant's age was 36.1 ($\pm$13.2) years and 49.3% of the participants self-identified as males. It took participants 5.1 minutes on average to complete the study, and they were compensated 0.82 GBP ($\approx$1.0 USD) for participating.

5.2.3 Results

Of the 501 participants, the self-reports of 57 were inconsistent with the user-agents, leaving us with 444 participants to train models and evaluate prediction accuracy. Tab. 5 presents the prediction mean ROC AUC for different conditions. Here too, ESBS_{FA} had statistically significantly higher mean AUC than SeBIS_{FA} (+6.17% mean AUC). Non-linear scoring of SeBIS (SeBIS_{IRT}), increased prediction's mean AUC by 3.41% compared to linear scoring (SeBIS_{FA}), however, the mean AUC did not surpass that of predictions with ESBS_{FA}.

Dependent variable: MacOS updating		
Condition	**AUC**	**($\pm$std)**
SeBIS_{FA}	51.13%	($\pm$10.59%)
SeBIS_{IRT}	54.54%	($\pm$8.75%)
ESBS_{FA}	<u>57.30%</u>	($\pm$9.82%)
ESBS_{IRT}	54.50%	($\pm$9.86%)
N/A+ESBS_{FA}	<u>56.09%</u>	($\pm$12.51%)
N/A+ESBS_{IRT}	54.15%	($\pm$12.39%)

Table 5: ROC AUCs of predicting MacOS updates using responses, demographics, and (sometimes) number of N/As. For each condition, we report the mean and standard deviation (std) of the AUC. Underlined values denote mean AUCs statistically significantly larger than those achieved by SeBIS_{FA} (p-value$<$0.05).

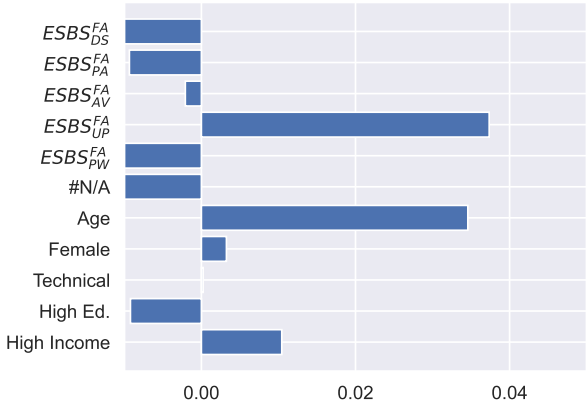

Figure 6: Mean importance of the independent variables when predicting whether participants keep their MacOS up-to-date, as calculated by the permutation test.

Incorporating the number of N/As alongside ESBS_{FA} decreased the mean AUC by 1.21%, but the decrease was statistically insignificant.

Fig. 6 presents the feature importance scores assigned to the independent variables in the N/A+ESBS_{FA} condition. As anticipated, the updating sub-scale (ESBS^{UP}_{FA}) was most predictive of whether the participants had an up-to-date MacOS version, leading to a 3.74% decrease in mean AUC when permuted. As for other security behavior, the participants' age was again a strong predictor of actual updating behavior with a 3.46% importance score.

6 Discussion

Limitations Several limitations should be taken into consideration when interpreting our work. First, our participants, all of whom are located in the United States, were recruited through Prolific. It is well-known that Prolific users are younger and

more educated than the general public. Hence, while the participants represent a non-negligible fraction of Internet users, the extent to which our results generalize to the general Internet-user population, across cultures, ages, and education levels remains to be tested. Second, we showed that ESBS can help predict three security behaviors more accurately than SeBIS. The validation of the result across three behaviors is indeed encouraging. Nonetheless, it would be worthwhile to test whether the result generalizes across more behaviors. Particularly, behaviors related to the security of popular computing platforms not covered in this work (e.g., mobile and cloud) would be intriguing to study. Third, participants' self-reported behaviors could be inaccurate. We, however, ensured that self-reports were consistent with logged data, indicating that they were of high quality. Thus, inaccuracies, if any, are expected to be minimal. Lastly, we evaluated a finite set of machine-learning models. While we identified and used the best performing model type (i.e., random forests), it is conceivable that their might exist another model that could outperform it. Still, we believe our findings are informative, as they hold across the most commonly used models in practice.

Means to Leverage ESBS Similarly to prior scales [10], ESBS can serve both researchers and practitioners. Researchers can employ ESBS as an inexpensive and non-invasive means to explore how user behavior differs across cultures [41] or evolves over time, for instance, due to changes in technological norms or user exposure to advice or education material. Practitioners, on the other hand, can exploit ESBS's predictive power to enable effective, personalized interventions. For instance, employers surveying their employees can target security advice and education material to employees anticipated to be at certain risk (e.g., due to not separating personal browsing activities from those related to work). One may also seek to leverage ESBS to tailor defenses to users. For instance, if a user is expected to avoid timely updates, aggressive interventions targeting them, such as blocking or throttling access to the employer systems, may help encourage them to update their system.

The ESBS sub-scales can be used together or separately. Although individual sub-scales may be more helpful than others for predicting specific behaviors (Figs. 4–6), we recommend using the full scale if maximizing prediction accuracy is a primary objective. For example, our experiments showed that the ESBS_{FA} and N/A+ESBS_{FA} conditions incur up to 5% ROC AUC loss when relying only on the most important sub-scale per Fig. 5 (i.e., data securement) instead of all sub-scales to predict whether participants clear their browsing history.

Trade-offs Between SeBIS and ESBS Due to including more questions, ESBS has higher time overhead than SeBIS. A rough estimate based on our data shows it took participants ∼54 seconds on average to respond to SeBIS compared to ∼68 seconds needed for the ESBS. While the additional time imposed by ESBS could increase dropout rates, we have not observed such an increase—the incompletion rates due to quitting in the middle or failing attention checks were low (<3%) regardless of whether we asked participants to fill out only the ESBS questionnaire (§4.2) or both ESBS and SeBIS (§5). Hence, the higher predictive accuracy of ESBS may justify the minimal overhead compared to SeBIS, primarily when ESBS is employed in settings where accuracy is critical (e.g., studying user behavior over time).

Future Work To maximize the utility of ESBS, it is crucial to ensure that it is widely accessible. To this end, we intend to conduct cognitive and readability studies (e.g., employing measures such as Smart Cloze [37]) to assess the scale's accessibility, compare it with prior scales, and identify means to improve it. Furthermore, we plan to run cross-cultural studies to adapt ESBS to different cultures, with a primary focus on under-studied populations that are not western, educated, industrialized, rich, and democratic (WEIRD) [41].

7 Conclusion

This paper offers the extended security behavior scale (ESBS), a high-coverage security scale consisting of 20 questions and five sub-scales. We developed ESBS through a rigorous process and validated its structural validity and reliability through an independent study. Furthermore, we showed that ESBS can predict a variety of security behaviors at a higher accuracy than commonly used prior scales. In particular, we measured three user behaviors, including compartmentalization of browsing activities, clearing browsing history, and updating operating systems, and showed that ESBS can predict whether users follow these behaviors with 6.17%–8.53% higher ROC AUC than SeBIS [11]. Among others, we also found that N/As can help boost prediction accuracy, and that linear scoring of scales typically leads to better predictions than elaborate non-linear scoring.

A Study Protocols

A.1 Scale development

A.1.1 This study requires you to voice your opinion using the scales below. It is important that you take the time to read all instructions and that you read questions carefully before you answer them. Previous research on preferences has found that some people do not take the time to read everything that is displayed in the questionnaire. The questions below serve to test whether you actually take the time to do so. Therefore, if you read this, please answer 'three' on the first question, add three to that number and use the result as the answer on the second question. Thank you for participating and taking the time to read all instructions.

- I would prefer to live in a large city rather than a small city.
  - [Seven-levels Likert scale: Strongly disagree; Disagree; Weakly disagree; Neutral; Weekly agree; Agree; Strongly agree.]
- I would prefer to live in a city with many cultural opportunities, even if the cost of living was higher.
  - [Seven-levels Likert scale, from strongly disagree to strongly agree.]

A.1.2 Please answer the following questions by selecting the Likert-scale option that best describes how often you follow the described behavior (i.e., Never, Rarely, Sometimes, Often, Always). Alternately, if you are unfamiliar with the described behavior or believe it is inapplicable to you, please select the N/A option.

- [Initial 45 questions (i.e., all items); see Tab. 6]

A.1.3 Listed below are a number of statements concerning personal attitudes and traits. Please read each item and decide how it pertains to you. Please respond to each item by either TRUE (T) or FALSE (F). Indicate your response by selecting the appropriate answer next to the item.

- [Marlowe-Crowne's social desirability questions [39].]

A.1.4 What is your age in years?

A.1.5 What is your gender?

- [Options: Male; Female; Non-binary / third gender; Prefer not to say.]

A.1.6 Which of the following best describes your highest achieved education level?

- [Options: Some high school; High school graduate; Some college, no degree; Associates degree; Bachelor's degree; Master's degree; Doctorate (PhD, MD, or similar); Other; Prefer not to answer.]

A.1.7 Which of the following best describes your primary occupation?

- [Options: Administrative support (e.g., secretary, assistant); Art, writing, or journalism (e.g., author, reporter, sculptor); Business, management, or financial (e.g., manager, accountant, banker); Education or science (e.g., teacher, professor); Legal (e.g., lawyer); Medical (e.g., doctor, nurse, dentist); Computer engineer or IT professional (e.g., programmer, IT consultant); Engineer in another field (e.g., civil or bio-engineer); Service (e.g., retail clerk, server); Unemployed; Retired; College student; Graduate student; Crowdsourcing worker (e.g., Mechanical Turk worker); Prefer not to answer.]

A.1.8 What is your household's income?

- [Options: Less than $15,000/year; $15,000/year-$24,999/year; $25,000/year-$34,999/year; $35,000/year-$49,999/year; $50,000/year-$74,999/year; $75,000/year-$99,999/year; $100,000/year-$149,999/year; $150,000/year-$199,999/year; $200,000/year or above; Prefer not to answer.]

A.1.9 Which device types do you use? Please select all applicable types.

- [Options: Smartphone - Android; Smartphone - iPhone; Smartphone - Others; Laptop - MacOS; Laptop - PC/Windows; Laptop - Other; Desktop - MacOS; Desktop - PC/Windows; Desktop - Other; Tablet - Android; Tablet - iPad; Tablet - Windows; Tablet - Other.]

A.2 Scale Validation

A.2.1 [Attention check, same as App. A.1.1.]

A.2.2 Please answer the following questions by selecting the Likert-scale option that best describes how often you follow the described behavior (i.e., Never, Rarely, Sometimes, Often, Always). Alternately, if you are unfamiliar with the described behavior or believe it is inapplicable to you, please select the N/A option.

- [ESBS questions; see Tab. 6]

[Six demographic questions; same as Apps. A.1.4–A.1.9.]

A.3 Predicting Behavior (Browsing-Behavior)

A.3.1 [Attention check; same as App. A.1.1.]

A.3.2 [ESBS question; same as App. A.2.2.]

A.3.3 [SeBIS questions; same as Egelman et al. [11].]

A.3.4 [Direct study participants to install Chrome extension and upload their browsing history.]

[Six demographic questions; same as Apps. A.1.4–A.1.9.]

A.4 Predicting Behavior (MacOS updating)

A.4.1 [Attention check; same as App. A.1.1.]
A.4.2 [ESBS question; same as App. A.2.2.]
A.4.3 [SeBIS questions; same as Egelman et al. [11].]
[Six demographic questions; same as Apps. A.1.4–A.1.9.]
A.4.4 Which macOS version are you currently using? If unsure, please check the macOS version by selecting the Apple logo in the menu bar followed by "About This Mac."

- [Options: Ventura (13); Monterey (12); Big Sur (11); Catalina (10.15); Mojave (10.14); High Sierra (10.13); Sierra (10.12); El Capitan (10.11); Yosemite (10.10); Mavericks (10.9); Mountain Lion (10.8); Lion (10.7); Snow Leopard (10.6); Leopard (10.5); Tiger (10.4); Panther (10.3); Jaguar (10.2); Puma (10.1); Cheetah (10.0).]

[The user-agent string is logged in the background, without user interaction.]

B All Initial Items

Tab. 6 presents all 45 items initially considered for inclusion in ESBS and reports the reason why certain items were eventually excluded.

#	Description	μ	σ	N/As	Corr.	Removed
1	I verify that recipients are reputable before sharing sensitive information	4.33	0.97	0.02	-	μ,σ
2	I verify whom I communicate with online (via email or online messaging apps) is really the person I intend to	3.92	1.18	0.03	2	
3	I share my email address in return for free samples and products	2.45	1.10	0.01	0	C
4	I scan attachments for viruses before downloading or opening them	3.51	1.43	0.03	16	
5	I carefully handle suspicious emails even if the sender address appears trustworthy	4.43	0.82	0.01	-	μ,σ
6	I encrypt my email contents when sending sensitive information (e.g., banking and health information or social security number)	2.52	1.56	0.14	13	
7	I verify that my anti-virus software is up-to-date	3.77	1.30	0.03	14	
8	I turn on automatic updates for devices and applications upon installation	3.56	1.22	0.00	1	
9	When I am prompted about a device or software update, I immediately install it	3.30	1.13	0.00	1	
10	I install anti-virus software when setting up my devices	3.91	1.31	0.02	6	
11	I use browsers that protect against phishing	4.00	1.21	0.04	14	F
12	I am careful about following email links that ask me to provide sensitive information	4.71	0.66	0.00	-	μ,σ
13	I verify links (e.g., in the URL bar or by mouseover) to ensure that I am accessing intended websites	3.83	1.19	0.02	16	
14	I avoid clicking on ads while browsing the Internet	4.32	0.88	0.00	-	μ,σ
15	I abstain from entering sensitive information on websites not using HTTPS	4.07	1.20	0.03	-	μ
16	I validate the digital certificates on the websites I visit	2.64	1.38	0.09	16	
17	I review the validity of my root certificates	2.12	1.40	0.21	7	
18	I avoid downloading and installing untrusted programs I may not be looking for	4.69	0.56	0.00	-	μ,σ
19	I validate the digital signatures files before opening them	2.68	1.46	0.15	17	
20	I check the extensions (e.g., .exe, .pdf) of files I download	3.93	1.25	0.02	11	
21	I turn on download notifications in my browsers	3.69	1.45	0.05	4	
22	I physically destroy drives I am done using and wish to erase	2.60	1.68	0.13	5

24	I avoid storing data that I do not need	3.71	1.12	0.01	2	F
25	I back up the data on my devices	3.68	1.18	0.01	8	F
26	I securely lock my devices with passcodes or biometrics (e.g., touch ID)	4.21	1.18	0.02	-	μ
27	I lock my computer when I am away from it	3.75	1.43	0.02	3	F
28	I avoid accessing online banking on public computers	4.48	1.13	0.04	-	μ
29	I select the strictest security settings (e.g., app permissions or browser options) that are practical	3.68	1.08	0.01	16	F
30	I am wary of popups and requests, even from known sources	4.39	0.85	0.01	-	μ,σ
31	I suspect offers that seem too good to be true	4.67	0.67	0.00	-	μ,σ
32	I safely store my private key for email encryption	2.60	1.68	0.27	9	
33	I report account breaches or losses to the appropriate people	3.45	1.57	0.12	8	F
34	I use a password to protect my Wi-Fi network	4.80	0.69	0.02	-	μ,σ
35	I avoid using open Wi-Fi networks for sensitive tasks (business, banking, shopping, etc.)	4.09	1.16	0.01	-	μ
36	I select hard-to-guess passwords (with multiple character types, without dictionary words, etc.)	3.99	1.11	0.00	11	
37	I select different passwords for different accounts and devices	3.93	1.09	0.00	3	
38	If accounts are compromised, I change their passwords and security questions	4.57	0.83	0.02	-	μ,σ
39	I avoid storing passwords in ways that make them accessible to others (e.g., writing them down on notes or in files)	4.05	1.22	0.00	-	μ
40	I use a password manager to create and store passwords	2.95	1.60	0.02	0	C
41	When possible, I use two- or multi-factor authentication	3.83	1.11	0.01	14	
42	When setting up new devices or joining new services, I change their default passwords	4.35	1.02	0.01	-	μ
43	I remove programs that I do not need or use	3.93	0.92	0.00	-	σ
44	I use a virtual machine when opening suspicious files or websites	1.75	1.17	0.24	-	μ
45	I disable auto-run to prevent potentially malicious downloaded programs from running	3.61	1.55	0.09	10	

Table 6: All items initially considered to construct ESBS. For each item, we report the mean (μ) and standard deviation (σ) of response, the fraction of N/A responses, and the number of the items that exihibit high Spearman correlation ($\geq$0.3) with each item after removing items due to ceiling and floor effects. For removed items, we denote whether they were removed due to ceiling or floor effects (μ), low standard deviation (σ), weak correlation with the other items(C), or insignificant factor loadings (F).

Biosignal Authentication Considered Harmful Today

Abstract

User authentication systems based on cardiovascular biosignals have gained prominence in recent years, as these signals are presumed to be difficult to forge. We challenge this assumption by showing that an observer who has access to one type of cardiac data – such as a user's pulse waveform, readily obtainable from video and commercial smartwatches – can design a spoofing attack strong enough to fool authentication systems based on other cardiovascular biosignals. We present *BioForge*, an approach that leverages a cycle-consistent generative adversarial network to synthesize realistic physiological signals for a given user without relying on simultaneously collected supervision data. We evaluate BioForge on multiple open-access datasets and an array of verification systems, many of which can be fooled over 50% of the time in 10 or fewer attempts. Notably, we are able to fool systems that rely not just on heart rate and peak locations but also on the morphology of the waveforms. We additionally showcase how BioForge can be used to spoof authentication systems from biosignal data extracted from video clips of a target user. Our work demonstrates that authentication systems should not rely on the secrecy of cardiovascular biosignals.

1 Introduction

Recent advances in biosensing and health monitoring have spurred interest in using physiological data as the basis for user authentication systems. In particular, commercial interest in cardiovascular monitoring has stimulated research in authentication systems based on cardiovascular biosignals. Many commercially available wearables (*e.g.,* smartwatches, fitness trackers) advertise the ability to monitor a user's cardiovascular data: small, inexpensive, and high-quality sensors allow for the collection of electrocardiograms (ECGs), photoplethysmograms (pulse waveforms or PPGs), seismocardiograms (SCGs), and ballistocardiograms (BCGs) for cardiovascular health monitoring.

Leveraging these sensors to design authentication systems has gained traction for three main reasons. First, the known disadvantages of current authentication methods have motivated the study of other, more seamless input modalities [9, 21, 59]. Secondly, state-of-the-art machine learning methods have demonstrated remarkable effectiveness in extracting information from physiological time-series data. Traditional authentication systems based on cardiovascular biosignals tend to rely heavily on manual features (*e.g.,* heartbeat segmentation, peak-to-peak distances, spectral analysis); recent deep-learning methods not only perform better but also reduce or eliminate the need for manual feature selection [30, 37, 47]. These advancements have enabled the development of "end-to-end" authentication systems that extract relevant features for user identity prediction along with training the system.

Third, biosignals are assumed to be confidential: an observer cannot easily obtain a user's physiological data and masquerade as that user [30, 37]. Previous work [15] has shown that biometric devices can be compromised if an adversary has access to similar recordings of a target user's biosignal: the BrokenHearted attack demonstrated this vulnerability in 2017 against the Nymi band, a commercially available ECG authentication device in trials at the time with MasterCard [15]. However, system designers assume that physiological signals are difficult to obtain since measurements typically require physical contact with the user. Recent work in video-based, remote estimation of PPG data has chipped away at this assumption [36, 38]. This, however, has still not impeded new research on biosignal-based authentication, with hundreds of mentions of ECG and PPG authentication have been published each year over the past decade with no signs of slowing down; see Figure 2.

In this paper, we show that the key assumption of confidentiality for biosignals is false and that the uniquely identifying features found in a user's cardiovascular signal, such as the ECG, can be consistently leaked from other types of cardiovascular signals from that user. We design black-box spoofing attacks on a wide array of biosignal-based authentication systems to demonstrate that an observer who has some physiological information (obtainable through compromised devices, a leaked database, or even videos of a user) can synthesize a target biosignal to masquerade as the given user. We refer to

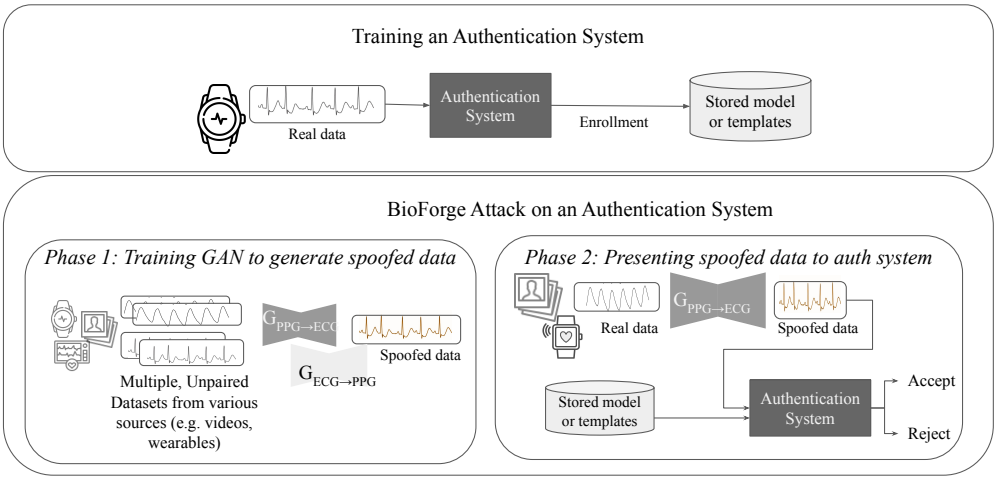

Figure 1: Overview of our BioForge approach. Top: We assume that a user authentication system has been trained on measured biosignal data (*e.g.,* ECGs). Reference templates (or the entire trained model) are stored for retrieval the next time users wish to authenticate themselves. Bottom: Our attack methodology comprises two stages. First, a biosignal generator is trained for a given pair of modalities (*e.g.,* source: PPG, target: ECG). This data is obtained from public datasets or leaked data, such as from health wearables or video clips, and does not need to contain examples from the intended victim. Then, the adversary acquires some true source data from the victim user (again from videos or a data leak), generates spoofed target data using the trained model, and presents the spoofed data to the trained authentication system. The stored templates or model are retrieved for the system to compare against the spoofed data to either accept or reject the attempt.

our overall approach as *BioForge*.

Our approach is comprised of three parts: First, we develop a generative model to synthesize fake, but realistic, biosignal data from another biosignal modality. We call these *target* and *source* signals, respectively. This approach is *system-agnostic*: we do not require details of the target authentication system, and it uses *unpaired* data, *i.e.,* we do not require simultaneously-recorded source-target biosignals. In particular, our model builds on the CycleGAN architecture for unsupervised image-to-image translation [53, 64], which we extend with a contrastive loss term to favor the learning of similar neural representations for biosignals coming from the same user.

Secondly, we implement a wide array of authentication systems published over the past five years and evaluate the success of the forged biosignals created using our generative model in fooling the state-of-the-art authentication techniques. The (offline) user enrollment and the two phases of the attack are illustrated in Figure 1. We primarily focus our evaluation on ECG-based authentication systems because of their popularity due to both the richness of the ECG signal and the wide availability of single-lead ECG sensors in commercial wearables. We also consider systems based on PPGs: pulse waveforms obtained from sensors in many wearable devices with heart monitoring features. To demonstrate the universality of our approach, we additionally evaluate systems based on SCG and BCG signals obtained from accelerometers. We find that spoofed data is able to fool most of these systems within 10 or fewer attempts at authentication.

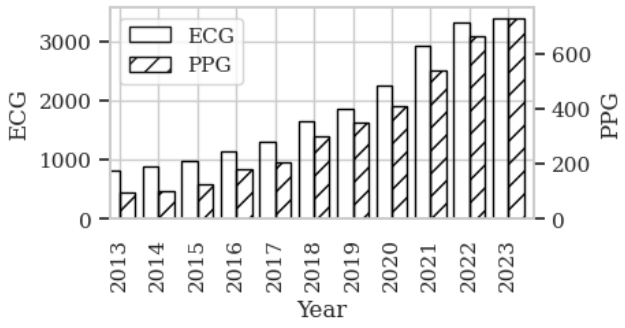

Figure 2: New papers published each year on Google Scholar that mention "authentication" along with either "ECG" (left bars) or "PPG" (right bars)

Finally, we showcase how BioForge can leverage video data to break biosignal authentication systems. We extract remote PPG (rPPG) traces from videos of target users and train BioForge to generate spoofed ECGs from the video-derived traces. We show how these spoofed signals can successfully compromise various authentication systems. Our evaluations illustrate the inherent weakness of biosignal-based authentication systems to spoofing attacks and serve as a warning against the use of these systems in real-world applications.

In summary, our contributions are as follows:

1. We develop a generative model that can synthesize realistic target biosignals from a different cardiovascular biosignal modality in an unsupervised manner.
2. We demonstrate that synthesized ECG traces from PPGs can fool an array of state-of-the-art ECG-based authentication systems.
3. We show the potential for this architecture to generate realistic PPG, BCG, and SCG traces that can fool the corresponding authentication systems.
4. We demonstrate an end-to-end attack that, starting solely from video clips of target users, successfully breaks an array of ECG-based authentication systems.

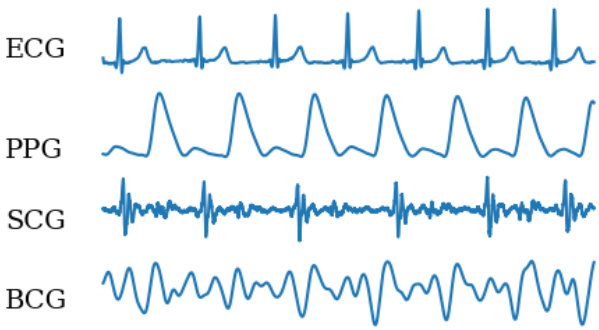

Figure 3: Example traces of each biosignal modality

2 Background

In this section, we provide an overview of the cardiovascular signals of interest and existing techniques for leveraging their statistical properties to develop authentication systems.

2.1 Cardiovascular Biosignals

Cardiovascular biosignals are physiological time-series measurements of cardiac activity. These measurements can be taken from a variety of sensors, on or near the body, and can relay information about heart rate, blood pressure, pulse volume, oxygen saturation, and the general cardiovascular health of the subject. The most recognizable biosignals are electrocardiograms (ECGs internationally; EKGs in the U.S.) and photoplethysmograms (pulse waves, or PPGs). Latif *et al.* [35] and Rathore *et al.* [50] outline the relationships among at least eight types of measurements. For our study, we narrow our focus to the most commonly studied waveforms that have a well-understood morphology, ease of collection, and generally accepted definition: ECG, PPG, SCG (seismocardiogram), and BCG (ballistocardiogram). ECGs are measured via electrodes, PPGs via light reflection or absorbance, and SCGs and BCGs via accelerometers. These four kinds of waveforms are illustrated in Figure 3.

ECG (Electrocardiogram) is a measurement of the heart's electrical activity via recording action potentials from electrodes placed on the skin. The ECG is sufficiently rich to capture the full cardiac cycle, composed of muscle depolarization and repolarization and, as such, it is considered a gold standard for diagnosing cardiovascular diseases in clinical settings. While medical ECG devices consist of 12 leads, an increasing number of wearable devices feature 1-lead ECG sensors. These require at least two points of contact to complete the electrical circuit (e.g., for wrist-worn devices, typically the user needs to touch a sensor with the other hand).

PPG (Photoplethsmogram) is a recording of the changes in blood volume and content, typically obtained by an LED and photodiode pair used to measure the reflection or absorption of light by various components in peripheral blood. The PPG signal is most often used to determine oxygen saturation and heart rate. Conventional sensors (aka pulse oximeters) obtain this measurement at the fingertip, but other common sensor placements include the wrist (for smartwatches), ear, and foot. When PPG is derived from video, we refer to the biosignal as "remote" PPG, or *rPPG*. An rPPG signal is an approximation of PPG derived by tracking the slight fluctuation of red channel values in segments of an individual's face from full-color video recordings.

SCG (Seismocardiogram) is a recording of the vibrations of the chest induced by a heartbeat, typically obtained via an accelerometer placed on the chest.

BSC (Ballistocardiogram) also uses an accelerometer to sense hearbeat-induced vibrations. In contrast to the SCG, the BCG is intended to capture the response at the body's center of mass. Accelerometers for BCG are integrated into chairs, beds, or flat plate scales intended for a user to stand on, and a typical BCG trace is aggregated from multiple sensors.

2.2 Biosignal-based Authentication

Biosignal-based authentication systems leverage the unique statistical properties of physiological waveforms to identify or verify users. A wealth of literature over the past two decades has explored techniques for extracting features from cardiac biosignals [30, 47]. Proposed systems typically consist of the following components in a pipeline: sensing, filtering, segmentation, feature extraction, and template matching. In short, signals are first filtered and then segmented to isolate information about individual cardiac cycles. Features relevant to authentication are subsequently extracted from the segments. During the so-called *enrollment* phase (illustrated in the top half of Figure 1), the extracted features are aggregated to form a user template, which is then stored in a database. When the user later attempts to authenticate themselves, the same process for sensing, filtering, segmentation, and feature extraction is used to build a "test template" to compare against the reference template. A matching algorithm is then used to determine whether the test and reference templates are similar enough to authenticate the user.

Surveys by Li *et al.* [37], Odinaka *et al.* [47] , Ingale *et al.* [30], and Melzi *et al.* [44] have detailed the state-of-art in sensing and signal-processing techniques for designing authentication systems based on PPGs and ECGs. Of particular note is the evidence in support of using single-lead biosignals, which facilitates systems built around wearable devices. Additionally, these surveys enumerate the various segmentation and feature extraction techniques from cardiovascular data, most of which focus on determining significant (*fiducial*) points of the cardiac cycle. Recent end-to-end deep learning approaches learn unique features from the entire morphology of the waveform, rather than relying on manual annotations.

Identification vs. Verification Some systems are primarily designed to perform closed-set user *identification*: a known set of users is fixed, and the system is responsible for predicting the identity of the test subject. These models perform multi-class prediction: given a new test sample, the model is expected to output the known user index most closely associated with

the presented sample. A different approach, termed *verification*, seeks to determine whether the test sample belongs to the intended subject. As such, verification systems output a binary prediction rather than the user index. Verification can be realized through recognition, *i.e.,* checking whether or not the test sample and a stored reference sample belong to the same subject, or through one-vs-all identification, where we use a closed-set identification model and check whether the predicted identity corresponds to the intended one. Our work is suited to both types of systems.

3 BioForge

We design a spoofing attack on biosignal-based biometric authentication systems, assuming access to a signal of a different modality. Figure 1 presents the workflow of the attack, which occurs in two stages: training and presentation. First, a generative model is trained on unpaired segments of source and target biosignals using a Contrastive CycleGAN architecture. Then, at attack time, a user's synthetic target biosignal is generated and presented to the authentication system. For concision, Figure 1 only illustrates spoofing ECG (target modality) from PPG (source modality). Our evaluation, however, explores spoofing multiple cardiovascular signal modalities (various target and source types). We detail our threat model in Section 3.1 and the generative model in Section 3.2.

3.1 Threat Model

We assume that a user authentication system has been trained on biosignal data, and we seek to synthesize data that can fool the system. This process is shown in Figure 1. We make the following assumptions about the adversary:

1. The adversary has black-box access to the authentication system, with solely the ability to present synthesized traces from an arbitrary waveform generator as input to the system. Note that in our evaluation, we re-implemented the authentication systems only to evaluate them; no information about the systems is used to generate the spoofed samples.
2. The adversary has access to datasets of source and target cardiovascular samples to train the CycleGAN models. For better generalization, these datasets should contain samples from a variety of subjects (with subject identifier labels[1]), but the biosignals do not need to be simultaneously recorded. Also, source and target data do not need to originate from the same sets of users nor from recorded signals. As we discuss in Section 4.1, such datasets are widely available online.
3. The adversary has access to some type of cardiovascular biosignal from the target user (a signal of a different modality than what is used by the authentication system). In this study, we evaluate scenarios where the adversary has access to either PPG, ECG, SCG, or BCG as source data. We believe that this assumption is realistic. Data leakages in the healthcare sector are alarmingly common and on the rise. Between 2009-2023, healthcare organizations suffered more than 5,000 data breaches, affecting more than 400 million medical records [6]. Recently reported leaks of biosignal data from devices by Fitbit and Apple [16, 42] demonstrate a significant likelihood that an attacker obtains access to some type of cardiovascular data. The situation is exacerbated by a rapidly growing market for commercial health devices, including many products with less rigorous security than those from major brands. Moreover, as discussed in Section 2, the attacker can acquire PPG signals even remotely from video data, and such signals can be directly used by our method.

[1] This is required by our contrastive loss update.

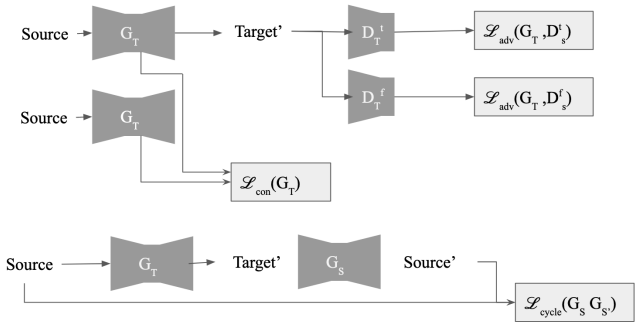

Figure 4: Overview of one half of the signal generation model. The components shown involve translating a Source signal to a Target form using a Generator network G_T. The discriminator networks D_T^t and D_T^f are trained at the same time to distinguish between real and synthetic data. We simultaneously train the inverse mapping: G_S, D_S^t and D_S^f for translating from Target to Source modalities. The loss functions associating with the inverse are $\mathcal{L}_{adv}(G_S, D_T^t)$, $\mathcal{L}_{adv}(G_S, D_T^t)$, $\mathcal{L}_{cycle}(G_T, G_{T'})$, and $\mathcal{L}_{con}(G_S)$.

3.2 Biosignal Generation Model

The proposed biosignal generation model is based on the CardioGAN model [53] with an additional contrastive loss component [34]. CardioGAN leverages the CycleGAN architecture [64] to translate signals between different modalities in an unsupervised manner (*i.e.,* with unpaired data), which in turn builds on the popular GAN model [20].

A GAN is comprised of a generator and a discriminator network, which are trained simultaneously in a competitive scheme. The generator aims to improve its ability to generate realistic data to fool the discriminator, and the discriminator aims to improve its ability to distinguish between real and generated data. The two models are updated in an alternating fashion. After training, only the generator is used to synthesize data. A CycleGAN network consists of two (conditional) GANs that are trained in tandem to enforce a condition of cyclical consistency (in addition to the usual GAN discriminator loss). These generators are $G_T : S \rightarrow T$, the generator that translates source data into target data, and $G_S : T \rightarrow S$, the generator that translates target data into source data. Cycle consistency imposes that a source signal s should be close to $G_S(G_T(s))$, i.e., when s is translated into the target modality

through G_T, and then back to the source modality with G_S, the resulting signal should be close to the original signal s. The same condition is enforced for a target signal t and its cycle-translation $G_T(G_S(t))$. This two-step process allows training generators without requiring pairs of supervised training data, which may not be available (as in our case). We show one half of the model (relative to the S-to-T translation) in Figure 4.

Each generator is based on the CardioGAN design [53], which combines elements of a U-Net with self-attention mechanisms [48] to encourage the network to focus on critical sections of the waveforms. Each generator follows an encoder-decoder architecture consisting of multiple convolutional downsampling, attention, and upsampling layers. CardioGAN introduces two discriminators (instead of one) to preserve time- and frequency-domain information of the generated signals. In particular, the generator G_T (G_S) is paired with two discriminators D_T^t and D_T^f (D_S^t and D_S^f): the former works in the time domain and is trained to distinguish between true signals t (s) and synthetic ones $G_T(s)$ ($G_S(t)$); the latter operates in the frequency domain and discriminates between $DFT(t)$ ($DFT(s)$) and $DFT(G_T(s))$ ($DFT(G_S(t))$), where $DFT(\cdot)$ is the discrete Fourier transform.

Each discriminator's architecture consists of the same downsampling convolutional layers used for the encoder portion of the generators. The discriminator's output represents the probability that the given input comes from real data. Generators and discriminators are updated using three loss functions, defined below only for the half involving G_T, D_T^t and D_T^f. These are the GAN loss relative to the time domain, $\mathcal{L}_{adv}(G_T, D_s^t)$, the GAN loss relative to the frequency domain, $\mathcal{L}_{adv}(G_T, D_s^f)$, and the cycle-consistency loss (involving only the time domain), $\mathcal{L}_{cyclic}(G_T, G_S)$:

$$\begin{aligned}\mathcal{L}_{adv}(G_T, D_T^t) &= \mathbb{E}_t[\log(D_T^t(t))] \\ &\quad + \mathbb{E}_s[\log(1 - D_T^t(G_T(s)))] \qquad (1)\\ \mathcal{L}_{adv}(G_T, D_T^f) &= \mathbb{E}_t[\log(D_T^f(t))] \\ &\quad + \mathbb{E}_s[\log(1 - D_T^f(G_T(s)))] \qquad (2)\\ \mathcal{L}_{cyclic}(G_T, G_S) &= \mathbb{E}_s[\|G_S(G_T(s)) - s\|_1] \qquad (3)\end{aligned}$$

where $\|\cdot\|_1$ is the L1-norm. Loss functions for the inverse mapping are defined analogously. We denote with $\mathcal{L}_{adv}(G_T, D_T^t, \mathcal{S}, \mathcal{T})$, $\mathcal{L}_{adv}(G_T, D_T^f, \mathcal{S}, \mathcal{T})$, and $\mathcal{L}_{cyclic}(G_T, G_S, \mathcal{S})$ the empirical approximations of the above expectations via unpaired batches of source signals $\mathcal{S}$ and target signals $\mathcal{T}$.

On top of the CardioGAN model, we additionally adopt a supervised contrastive loss component. Its purpose is to ensure that the latent features of the generators (*i.e.,* the bottlenecks) are similar for signals coming from the same patient. In doing so, we condition the network to extract a representation of the subject that remains (close to) invariant despite signal variability. This invariant representation can be seen as a proxy for a subject's identifying features; *i.e.,* if two signals have similar latent features, then they likely belong to the same subject. The same principle is applied in popular biometrics and face recognition architectures such as Hadsell *et al.* [22] and Schroff *et al.* [55].

In particular, we consider the SupCon loss from [34] (using the implementation by [45]) for its ability to handle an arbitrary number of positive and negative pairs in a batch of signals. Given a batch of signals $\mathcal{D}$ and a signal $x \in \mathcal{D}$, we denote with $[x] \subseteq \mathcal{D} \setminus \{x\}$ the set of signals other than x but that belong to the same subject as x. For a signal x and generator G, we denote with $z_G(x)$ the latent representation associated with $G(x)$. Then, the contrastive loss relative to G and $\mathcal{D}$ is given by

$$\mathcal{L}_{con}(G, \mathcal{D}) = -\sum_{x \in \mathcal{D}} \frac{1}{[x]} \sum_{p \in [x]} \log \left[\frac{\exp \frac{z_G(x) \cdot z_G(p)}{\tau}}{\sum_{x' \in \mathcal{D} \setminus \{x\}} \exp \frac{z_G(x) \cdot z_G(x')}{\tau}} \right] \qquad (4)$$

where $z_G(x) \cdot z_G(p)$ denotes the dot product between vectors and $z_G(x)$ and $z_G(p)$ and is used as a similarity measure. Hence, the softmax argument of the log function represents a smooth approximation of whether p has the highest similarity to x across all signals in the batch. The temperature $\tau > 0$ controls such smoothness (larger τ, less smooth). We set $\tau = 0.1$ in our evaluation. It is clear to see that minimizing (4) corresponds, for each $x \in \mathcal{D}$, to maximizing the (dot-product) similarity between the representations of x and all signals in $[x]$, consequently minimizing the similarity with signals not in $[x]$ (thanks to the softmax term).

Finally, we update the networks' weights in two separate steps to avoid interference between different loss functions: first, in the direction of the GAN and cyclic losses to improve the quality of the generated signals (see Equation 5 below), then, in that of the contrastive loss to capture key identifying information (see Equation 6). For batches of source and target signals $\mathcal{S}$ and $\mathcal{T}$, the final losses become:

$$\begin{aligned}\mathcal{L}_{GAN} &= \alpha(\mathcal{L}_{adv}(G_T, D_S^t, \mathcal{S}, \mathcal{T}) + \mathcal{L}_{adv}(G_S, D_S^t, \mathcal{T}, \mathcal{S})) \\ &\quad + \beta(\mathcal{L}_{adv}(G_T, D_T^f, \mathcal{S}, \mathcal{T}) + \mathcal{L}_{adv}(G_S, D_S^f, \mathcal{T}, \mathcal{S})) \\ &\quad + \gamma(\mathcal{L}_{cyclic}(G_T, G_S, \mathcal{S}) + \mathcal{L}_{cyclic}(G_S, G_T, \mathcal{T})) \qquad (5)\end{aligned}$$

and

$$\mathcal{L}_{con} = \mathcal{L}_{con}(G_S, \mathcal{S}) + \mathcal{L}_{con}(G_T, \mathcal{T}) \qquad (6)$$

where $\alpha, \beta, \gamma > 0$ are hyper-parameters for combining the individual loss components in the first update.

4 Evaluation

In this section, we present the results of our evaluation. We first describe the open-access datasets and authentication systems chosen to demonstrate our approach in Section 4.1 and 4.2, along with performance on true data. Section 4.3 presents details on the training and performance of the CycleGAN model. Next, we present our comprehensive evaluation of the BioForge approach in Section 4.4-4.6. Finally, Section 4.7 presents our findings from a study using PPG traces extracted from video clips.

4.1 Datasets

We performed our primary evaluation on four publicly available datasets that contain simultaneous measurements of multiple cardiovascular signals. These datasets represent collections from a variety of device types (clinical vs wrist-worn wearables), sampling frequencies (64Hz to 5000Hz), and participants (varied in age and gender). We note that we do not need paired (simultaneously recorded) data to train our generative model and run the attack, but we do need paired recordings to understand and evaluate the performance of our approach. We use data from one modality (*e.g.,* ECG) to train the authentication systems and data from a second modality (*e.g.,* PPG) as a source to generate forged data to present to the trained system. We include four datasets for ECG/PPG translation, one dataset for ECG/SCG translation, and one dataset for ECG/PPG/BCG translation. We additionally evaluated the ability for BioForge to succeed using a biosignal extracted solely from video clips of a target user. For this purpose, we use the MANHOB-HCITagging dataset [57], which includes video/ECG pairings.

BIDMC [19, 49] contains clinical PPG and ECG readings from 53 ICU patients. Each recording is 8 minutes long, and both PPG and ECG are sampled at 125 Hz. BIDMC is a subset of the larger MIMIC II matched waveform database, which contains thousands of vital sign recordings collected bedside in adult and neonatal ICUs.

CAPNO [33] contains clinical PPG and ECG readings from 42 hospitalized children and adults. Each recording is 8 minutes long and all traces are sampled at 300Hz. This is a subset of the larger CapnoBASE benchmark dataset, used to develop algorithms for monitoring CO2 breath saturation and respiratory rate.

DALIA [51] contains PPG and ECG signals from 15 people wearing portable devices. ECGs are obtained from a chest-worn device (RespiBAN[2]) and PPGs were obtained from a wrist-worn device (Empatica E4[3]). Each recording is about 2 hours. PPG was recorded at 64Hz and ECG was recorded at 700Hz.

WESAD [54] contains PPG and ECG signals from 15 people wearing the same ECG and PPG devices used for the DALIA dataset. Each recording is about 1 hour long.

CEBSDB [17, 19] contains SCG and ECG signals for 20 participants in a lab environment recorded using the Biopac MP36 system[4]. Each recording is about 5 minutes. The SCG data is an aggregation of measurements obtained from a triaxial accelerometer and filtered between 0.5Hz and 100Hz. All data was recorded at 5000Hz.

BedBased [23] contains simultaneous BCG, ECG, and PPG recordings from 40 participants in a lab environment. BCGs were collected from a custom bed comprised of four electromechanical films and four load cells. We average the four load cells to obtain a single BCG signal. Each recording is about 7 minutes long and sampled at 1000Hz.

MAHNOB-HCITagging [57] contains data originally collected for studying emotion and affect recognition and includes numerous sessions of video and ECG recordings from 27 participants. ECGs were monitored at 256Hz, and videos were recorded at 60Hz with a resolution of 780x580 pixels. We used all available ECG traces and only videos recorded in color.

4.2 Authentication Systems

We evaluated the ability of our generated biosignal traces to spoof a range of published authentication systems. We looked for systems proposed within the past five years with comparatively high citation counts as representative of state-of-the-art techniques. We selected more ECG-based systems than other modalities due to the abundance of research on ECG systems and the richness of the signal. We also gave preference to publications that made their code publicly available. For training the authentication systems, we followed, where possible, the individual systems' procedures for processing data and hyperparameter selection. We additionally resampled, detrended, standardized, and rescaled data as needed.

4.2.1 Performance Metrics

We first report each system's EER (Equal Error Rate) on true (non-spoofed) data. EER is a preferred evaluation metric for authentication systems, as accuracy can be misleading if the number of samples from each user varies. If we see an authentication system as a function that outputs the likelihood that the given signal is from the intended user, then the EER is obtained by finding the decision threshold for the said likelihood that yields equal rates of false acceptances (FAR) and false rejections (FRR). This threshold is found using a held-out set of calibration signals.

There is a natural tradeoff between FAR and FRR, and the EER is the position on this tradeoff curve where the two are equal (or closest) as the decision threshold is changed. An EER of 0 indicates perfect performance. The FAR and FRR rates can be derived from the empirical counts of False Positives (FP), False Negatives (FN), True Positives (TP), and True Negatives (TN) as follows: $\text{FAR} = \frac{\text{FP}}{\text{FP+TN}}$ and $\text{FRR} = \frac{\text{FN}}{\text{FN+TP}}$.

We note that the EERs obtained in our evaluation do not necessary align with those reported in the respective original studies. This is because we take a different approach to splitting data for training and testing. Most studies shuffle all available data segments and randomly assign them to training and test sets. We instead split our data over the time dimension to mimic a realistic scenario: the systems are trained on the earliest section of available data (by time), tested on the next section to obtain EERs and associated EER thresholds, and evaluation of spoofed data is performed on the last section in time. Also, we remark that most systems present approaches highly tuned to their collected data, and thus we should ex-

Table 1: Performance of ECG-based authentication systems. Equal Error Rates (%) are presented for true (non-spoofed) ECG traces.

System Name	System Description	BIDMC	CAPNO	DALIA	WESAD
KeyToHeart [52]	Support Vector Machine on 25 principal components from ECG segments	35.35%	35.36%	31.19%	29.13%
Deep-ECG [14]	CNN on 8 consecutive QRS complexes	8.00%	8.00%	17.0%	11.80%
EDITH [28]	CNN feature extractor and FFNN siamese network on segmented QRS complexes	2.85%	3.51%	10.59%	1.00%
ECGXtractor [44]	Autoencoder feature extractor and CNN siamese network from a consensus of segmented QRS complexes	7.68%	10.62%	15.95%	14.6%

Table 2: Performance of PPG-based authentication systems. Equal Error Rates (%) presented for true PPG traces.

System Name	System Description	BIDMC	CAPNO	DALIA	WESAD
Hwang2020 [27]	CNN and LSTM on single-pulse segments transformed via FFT, dynamic time warping, and wavelet transforms	7.12%	15.35%	43.45%	42.03%
CorNet [7]	CNN with dual heads to predict both heart rate and identity	3.75%	1.49%	20.25%	29.18%

Table 3: Performance of SCG-based authentication systems on CEBSDB dataset. Equal Error Rates (%) presented for true SCG traces.

System Name	System Description	EER
WaveletTransform [26]	Template matching from wavelet-transformed segments	23.48%
MotionResilient [25]	Support Vector Machine classification on segments	13.29%

Table 4: Performance of BCG-based authentication systems on BEDBASED dataset. Equal Error Rates (%) presented for true BCG traces.

System Name	System Description	EER
HebertCNN [23]	CNN on 3-sec rolling windows	23.48%
ZhangRNN [62]	RNN on segments centered around corresponding ECG R-peaks	13.29%
ZhangRNN+ECG [62]	RNN on concatenated BCG and ECG segments centered around corresponding ECG R-peaks	13.29%

pect performance to deviate when these systems are applied to different datasets (as we do).

4.2.2 ECG Authentication

The performance of the following four ECG-based authentication systems is reported in Table 1.

KeyToYourHeart [52] is a proof-of-concept system for user identification and verification using a commercially-available "pocket" ECG sensor: the KardiaMobile device by AliveCor. [5] The system extracts the top 25 principal components of ECG segments to obtain template features. Classification is performed on these templates using a support vector machine with a radial basis function in a binary one-vs-all scheme. We based our implementation on a codebase provided by the authors.

Deep-ECG [14] by Labati *et al.* is one of the first end-to-end approaches that leverage deep convolutional networks for ECG-based identification and verification. They use a deep CNN trained on QRS complexes (the portion of the ECG cycle closely surrounding the highest peak) and evaluate closed-set identification, identity verification, and periodic re-authentication across time.

EDITH [28] by Ibtehaz *et al.* present a sophisticated deep learning system with two components: a convolutional neural network (with multi-resolution blocks and spatial pooling layers) to learn a feature embedding from segmented QRS complexes, and a Siamese network to train the identification/verification model. The authors released their implementation on GitHub.[6]

ECGXtractor [44] by Melzi *et al.* surveys existing literature to identify the best combination of signal processing methods for single- and multi-session user authentication. They implement a two-step approach for feature extraction and identity recognition. They train an autoencoder with multiple convolutional layers to learn a feature embedding from segmented QRS complexes, and the bottleneck of the autoencoder is then used as inputs for a Siamese model that performs user verification. The authors of ECGXtractor released their implementation and some pre-trained models on GitHub.[7] We use their pre-trained autoencoder and train separate Siamese networks on our individual datasets.

We report that ECG systems based on deep learning models attain low EERs, no larger than 17%, while we see a consistent performance degradation in the only "non-deep" system (KeyToYourHeart).

4.2.3 PPG Authentication

The performance of the following PPG-based systems is reported in Table 2. We acknowledge the high error rates of the DALIA and WESAD datasets, which we explain by the different nature of the datasets. The Hwang2020 system [27] was developed on clinical PPG waveforms that have clear dicrotic notches and follow diastolic peaks. Their proposed data transforms take advantage of the clear peaks and troughs of the signals. The data in DALIA and WESAD were collected from wrist-worn bands (rather than clinical pulse oximeters) and their PPG traces generally do not have pronounced dicrotic notches. Nonetheless, we decided to include Hwang2020 as their work is among the most highly referenced recent efforts on PPG authentication, and the authors made their code avail-

[5] https://store.kardia.com/products/kardiamobile
[6] https://github.com/nibtehaz/EDITH
[7] https://github.com/BiDAlab/ECGXtractor

able for further research.

Hwang2020 [27] by Hwang *et al.* stacks the results of multiple data transforms (in both time and frequency domains) on segmented pulse waves to achieve a standard signal length before feeding the data into a CNN+LSTM for user identification and authentication. The authors released an example of their approach on GitHub. [8]

CorNET [7] by Biswas *et al.* presents a deep learning approach to perform PPG-based identification by leveraging two loss functions: one for closed-set user identification (cross-entropy) and another (mean squared error) for heart rate estimation. The network consists of 2 CNN layers and 2 LSTM layers, with two final dense layers for predicting identity and HR, independently.

4.2.4 SCG Authentication

The performance of the following SCG-based authentication systems is reported in Table 3.

WaveletTransform [26] explores a variety of wavelet-transformed signals, feature extraction, and matching techniques to perform authentication on SCGs. While many of their models achieve similar performance, we selected the Morse Wavelet and L2-norm distance for matching.

MotionResilient [25] The approach consists of averaging five one-second segments of SCG data centered around the ECG's R-peaks for motion artifact removal and then using a Support Vector Machine classifier to predict a user's identity. We implement their approach as a one-vs-all scheme for each user.

4.2.5 BCG Authentication

The performance of the following BCG-based authentication systems is reported in Table 4.

ZhangRNN [62] explored BCG traces of various lengths and a few types of recurrent neural networks. Of their proposals, we adopted the system that concatenated 15 segmented heartbeats to feed as input to a single-layer LSTM network. However, their heartbeat segmentation relies on having an ECG source for R-peak detection. Because of the assumption that ECG is available, they also explored a multimodal approach: they concatenated ECG and BCG traces for increased identification accuracy.

HebertCNN [23] explored BCG-based authentication from a head-mounted wearable device (the Google Glass). They trained a convolutional network on BCG data from independent sensor streams split into 3-second segments for each user, using a one-vs-all identification scheme.

4.3 BioForge Signal Generation Performance

In this subsection, we detail the training process of the BioForge generation model and describe its performance in synthesizing realistic biosignals.

[8] https://github.com/eoduself/PPG-Verification-System

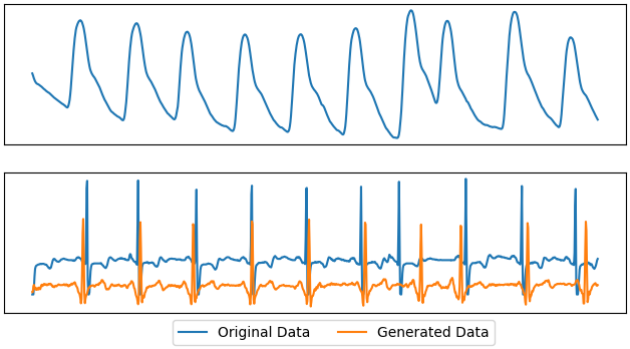

Figure 5: Example original and generated traces of True PPG (blue, top), True ECG (blue, bottom), and BioForge generated ECG (orange, bottom). The generated ECG appears to capture the inter-peak interval morphology of the true ECG well, in addition to reproducing R-peak locations. We observe that the generated data carries over inaccuracies from the source: the true PPG contains an inaccurate extra waveform (the 8th PPG peak), and that extra peak is reflected in the generated ECG.

Data Preparation. A portion of data from the BIDMC, CAPNO, DALIA, and WESAD datasets were used to train the BioForge model for translating between ECG and PPG traces. For translating between ECG and SCG, only the CEBSDB dataset was used. For translating among ECG, PPG, and BCG, only the BedBased dataset was used. We split traces in time and used the first half of each trace to train and test the BioForge model, and the second for training and evaluating the authentication systems. After combining the datasets and segmenting traces into overlapping segments, all segments were shuffled to break relationships among users and datasets. In this way, we prevent the model from memorizing mappings between signals of different modalities for the same user, and between signals of different modalities for a given dataset. We implemented the same signal processing pipeline of CardioGAN [53], which includes resampling all data to 128Hz (or 512Hz for SCG), filtering, standardizing, and shuffling segments to break pairs between simultaneously recorded data.

Training settings. The BioForge models were trained for 25 epochs for the ECG/PPG targets, and 50 epochs for the SCG/BCG targets. We used a total of four Adam optimizers (one for both generators and the GAN loss, one for both generators and the contrastive loss, and one for each discriminator). For all Adam optimizers, we set $\beta_1 = 0.5$ and $\beta_2 = 0.999$ (i.e., the momentum parameters for the gradient and its square) and a learning rate of 10^{-4}, which kept constant for 10 epochs and then decays to 10^{-6} linearly (as done in the CardioGAN paper). We set the GAN loss weights to $\alpha = 3, \beta = 1, \gamma = 100$, as recommended in [53].

Performance. The CardioGAN authors report the accuracy of generated traces in terms of the difference in estimated heart rate (in beats per minute, or BPM) between the generated ECG and ground truth. While we are interested in more than just accurate heart rate estimation, this metric provides an intuitive interpretation of the performance of the models. We observe that

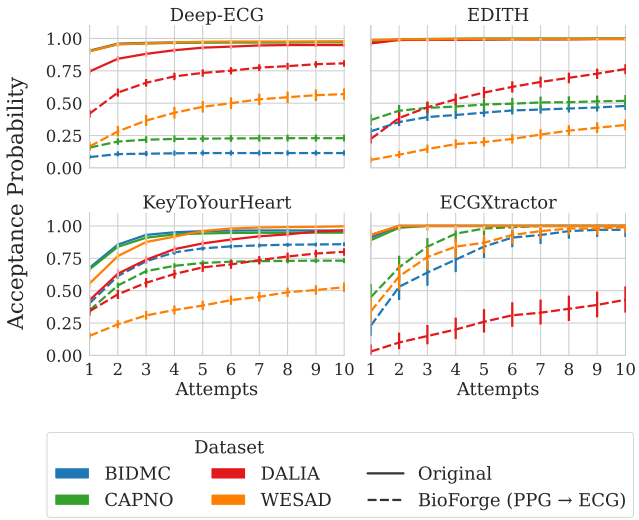

Figure 6: Accumulating probability of accepting an ECG trace, up to 10 attempts. The solid lines show the true probability of acceptance on original ECG traces from the intended user (True Positive Rate, TPR, on true data over time). Corresponding dashed lines indicate the acceptance of spoofed data for the intended user (FPR over time from synthesized data). We observe that for most systems and datasets, the spoofed data was accepted over 50% of the time after 10 attempts.

the mean absolute error (MAE) in heart rate for samples generated by our model is comparable with CardioGAN results. MAE between true and generated ECG ranges from 0.80 BPM to 8.39 BPM across datasets for 60-second traces from a test set.

4.4 Spoofing Success over Attack Attempts

We evaluate the False Acceptance Rate (FAR) of spoofed data in comparison to the True Positive Rates of each system. We report our findings as an accumulating rate of success over 10 attempts at authentication. Typically, a system will allow for multiple authentication attempts before limiting or blocking the user. We chose 10 as the maximum number of tries because many systems, including Apple iOS devices, lock users out permanently after 10 attempts [56]. Results are reported with 95% confidence intervals.

We first focus our attention on ECG-based systems. Figure 6 presents the acceptance rate of true ECG data (solid lines) and spoofed data synthesized from PPG for the four datasets used to train the generation model. We additionally demonstrate the performance of spoofed PPG (from ECG) over the selected PPG-based authentication systems, in Figure 7. Lastly, the performances of spoofed BCG and SCG data are displayed in Figure 8 and Figure 9.

Across all datasets and modalities, we observe that over multiple attempts, the likelihood of a spoofed trace being falsely accepted often surpasses 50%, approaching the authentication performance of true data in multiple settings. Moreover, while some systems (*e.g.,* Deep-ECG) seem to be robust to spoofed data from some datasets, the chance of falsely accepting spoofed data over 10 attempts still often exceeds the reported

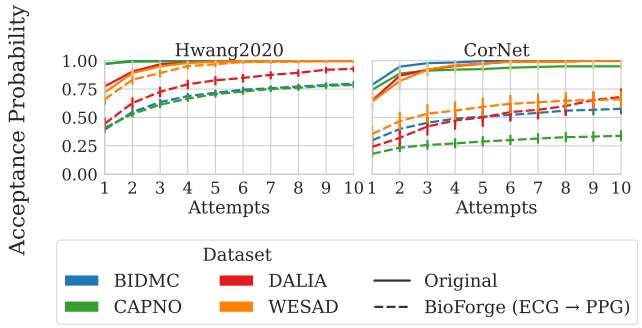

Figure 7: Accumulating probability of accepting a PPG trace, up to 10 attempts. The solid lines show the true probability of acceptance on true PPG (true positive rate), and the dashed lines show the probability of acceptance on spoofed PPG (false positive rate from spoofed data). Similar to ECG results shown in Figure 6, we observe that the spoofed FAR is often higher than expected from reported EERs.

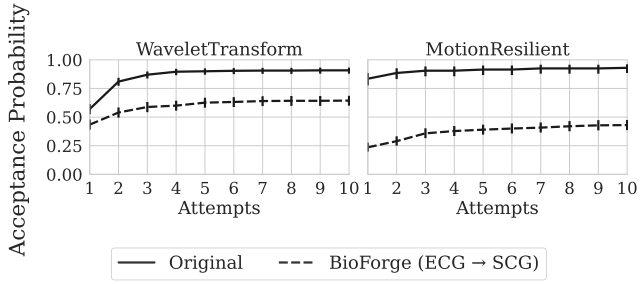

Figure 8: Performance of original and spoofed data from the CEBSDB dataset on SCG based authentication systems. Solid lines represent the True Positive rates from true data, and dashed lines represent the acceptance rates of spoofed data.

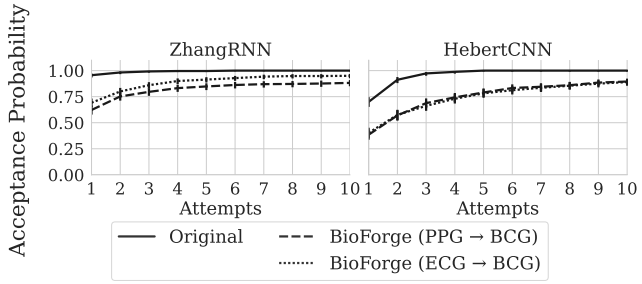

Figure 9: Performance of original and spoofed data on BCG based authentication systems. Solid lines represent the True Positive rates from true data, and dashed lines represent the acceptance rates of spoofed data. The dataset from which BCG is sourced (BEDBASED) contains simulatneous ECG and PPG recordings as well, so we are able to spoof BCG from either source.

test EER. Moreover, a low EER doesn't necessarily provide any information about robustness against spoofed data: both Deep-ECG and ECGXtractor reported similarly low EERs on our datasets, yet spoofed attempt successes differed greatly.

4.5 Multi-modal Setting (ECG+BCG)

A common defense against potential spoofing attacks is to incorporate multiple modalities of physiological data to temper the effects of one tampered data source. However, with our BioForge approach, if an attacker has access to one of these

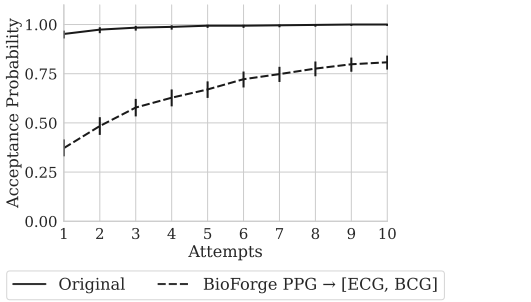

Figure 10: Case study of a multimodal authentication system. The ZhangRNN system considers concatenated ECG and BCG traces. We show that BioForge can spoof both ECG and BCG data sufficiently well from PPG.

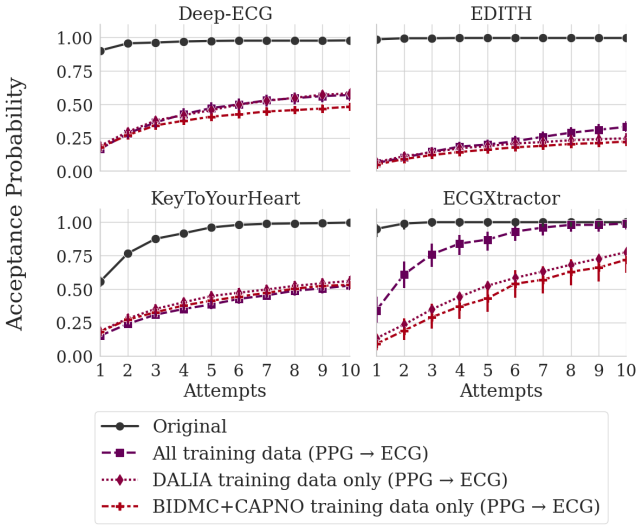

Figure 11: BioForge performance on WESAD dataset for ECG-based system, using various sources of data for training the CycleGAN. The solid lines refer to the original performance of true ECG data on each system. The remaining dashed lines represent various trained models, relying on data from all datasets (■), from just a similar dataset (⧫), and from different datasets (+).

multiple modalities, they can generate signals for the other ones, which renders this particular defense helpless. We evaluate the ability of spoofed data to fool systems that are multimodal by design: we choose to investigate the ZhangCNN BCG system, as the authors propose a version that explicitly operates on a combination of ECG and BCG traces, generating spoofed data from a different source modality (PPG). As shown in Figure 10, the performance of this attack achieves a significant success rate (80%) after 10 attempts. Note that we do not consider here multi-modal systems that simply aggregate predictions from separately trained uni-modal systems, as the performance of these can be trivially obtained by combining the results from the individual models.

4.6 Cross-dataset Transfer

In all previous experiments, our BioForge generative model was trained on an aggregation of data across multiple datasets. Here, we explore the potential of our model trained solely on one dataset to produce realistic traces for a different dataset.

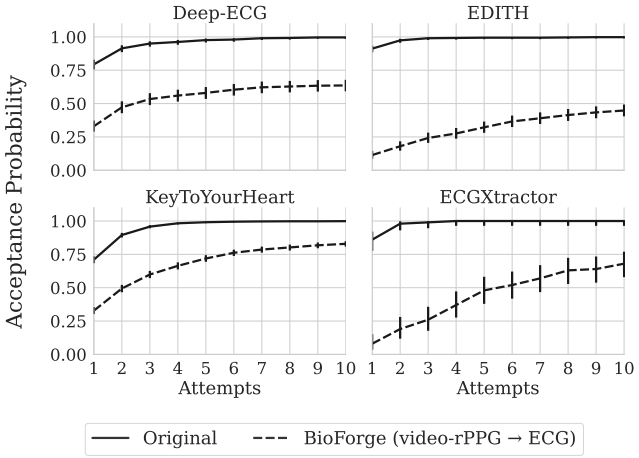

Figure 12: ECG Spoofing results for HCITagging dataset using video as starting point. rPPG traces were extracted from video clips, and the BioForge model was trained on pairs of rPPG and ECG to generate synthetic, spoofed ECG.

Figure 11 shows False Acceptance Rates for various systems trained on WESAD data. The Combined Training Set lines (square markers) correspond to the results shown earlier, where all datasets are used to train the CycleGAN. Next, we examine the attack performance when the generative model is trained only on DALIA data. DALIA and WESAD datasets were collected using the same devices (chest- and wrist-worn wearables). Lastly, we show how a model trained on purposefully different data – BIDMC and CAPNO, which are clinical datasets – can generate data that can still fool the authentication systems. Spoofed data generated using just DALIA performed similarly to that generated from BIDMC and CAPNO, which indicates that there is sufficient similarity among biosignals obtained from different devices to facilitate transfer attacks.

4.7 Video-derived source biosignal

In Section 3.1, we noted that emerging work on remote physiological data sensing would facilitate access to leaked biosignal data. In this section, we demonstrate the feasibility of an end-to-end attack that starts solely with video data rather than a leaked biosignal. We showcase this performance using the MAHNOB-HCITagging dataset, which contains video and ECG recordings from participants. From these videos, we leverage recent advances in remote physiological sensing to extract an *rPPG* pulse trace. For this purpose, we use the CHROM method [13] from the rPPG-Toolbox [41]. [9] An advantage of CHROM is that, unlike other PPG extraction methods, it does not require examples of true PPGs or any other physiological information to train the extraction model. After extracting rPPG from videos, we train our BioForge generative model on shuffled pairs of rPPG and ECG. We compare the performance of the array of ECG-based authentication systems using the true ECG and the spoofed data, shown in Figure 12.

We do not directly calculate the extent to which the video-

[9] https://github.com/ubicomplab/rPPG-Toolbox

derived PPG degrades the performance of BioForge, because the HCITagging dataset does not contain true PPG data. To the best of our knowledge, no large public research dataset exists that contains video, PPG, and ECG recordings from the same participants.[10] Even though the attack employs a video-derived approximation of the true PPG, we observe that most systems accept such spoofed data over 50% of the time after 10 attempts, which is comparable with the results on the other datasets starting with the true PPG.

5 Discussion and Countermeasures

Our evaluations illustrate that biosignal authentication systems cannot solely rely on a presumption of biosignal secrecy: synthesized data can compromise an array of authentication systems that operate on various cardiovascular biosignals. Nonetheless, this work prompts further lines of research regarding safeguards and potential countermeasures:

5.1 Countermeasures

Multi-modal authentication systems These systems can combine information from multiple sources to build a more comprehensive profile of someone's identity. Our experiments illustrate that practitioners should be careful to avoid using solely cardiac biosignal data for all modalities – one compromised modality can be used to synthesize others and serve as a single point of failure. Multi-modal systems that combine data from clearly independent sources might offer a path forward.

Obfuscating physiological information in video While preventing large-scale data leaks is a pressing area of concern for healthcare security in general, our video-based attacks in Section 4.7 demonstrate that keeping physiological data private remains a challenge. We used a method for rPPG extraction which requires nothing but videos of the victim. As methods for remote physiological sensing advance (see Section 6.1 for more details), we can expect the quality of rPPG and subsequent other cardiovascular data only to improve. However, recent research shows that it is possible to remove physiological information from videos to preserve privacy without altering the videos in noticeable ways [10, 12, 58].

Adversarial training to improve authentication systems Our work prompts a line of defensive strategies that actively uses spoofed data to improve the robustness of the authentication systems at training time. One could include synthetic data as negative examples to encourage models to differentiate between true and fake data. Alternatively, these systems could include a liveness test or an initial signal filter to identify anomalous or synthesized traces before allowing an authentication attempt. Nonetheless, we argue that BioForge produces synthetic data that is remarkably similar to true data (along time and frequency domains), and detection of synthetic data is likely a difficult challenge. Moreover, even if a system can detect spoofed data generated using BioForge, future generations of models for synthesizing biosignals might be able to evade detection.

[10] The OBF database [39] did include all three; however, it is no longer available due to GDPR concerns.

5.2 Ethical Considerations

To the best of our knowledge, no commercial devices that use biosignal authentication are available off-the-shelf to consumers. The lone device that uses ECG for authentication (*i.e.,* Nymi Band [29]) does so in conjunction with fingerprint authentication for the purpose of continuous authentication. While our work reveals a fundamental limitation in the design of biosignal authentication systems in general, we do not develop an exploit to compromise the Nymi Band. However, we have initiated contact with Nymi to make them aware of this potential vulnerability. We hope our paper serves as a forewarning to future system designers to seriously consider the threat model associated with spoofed data when using such systems. All our experiments were conducted on publicly available datasets and open-source biosignal authentication systems.

6 Related Work

Our approach involves synthesizing biosignals for spoofing authentication systems, and builds on related work in both biosignal synthesis and spoofing attacks.

6.1 Synthesis of Cardiovascular Biosignals

There exists a wealth of literature on synthesizing physiological data, with the goal of strengthening medical diagnosing. Much of this work has focused on synthesizing ECGs, as clinical interpretation of high-quality ECG recordings is considered the gold standard for diagnosing heart failure. An early popular approach generated ECG signals as the sum of Gaussian curves parameterized with time-domain features manually extracted from the patient's ECG [43]. Current state-of-the-art approaches avoid relying on manual feature selection and mapping, as they instead leverage deep generative models. Various frameworks have been proposed to synthesize ECG, such as the Variational Autoencoder [4] and diffusion models [2]. Notably, Generative Adversarial Nets (GANs) [20] have emerged as a popular framework for the synthesis of ECGs to augment or improve the quality of existing data [1, 5, 61, 61]. For example, multiple works have used GANs to reconstruct a clinical 12-lead ECG recording from a single lead signal for improved arrhythmia diagnosis [3, 31, 63]. Other related approaches consider generating ECG data given another cardiovascular biosignal. The CardioGAN approach by Sarkar *et al.* [53] leverages a GAN framework to generate ECGs from PPG waveforms, and they evaluate the performance of the model in terms of estimated heart rate across a variety of datasets. We base our model on the CardioGAN approach and describe CardioGANs further in Section 3.2. Rather than assessing model performance in terms of heart rate estimation, we evaluate performance in terms of authentication security.

Considerable attention has also been placed on synthesizing PPG data, mainly from remotely-collected data. Traditional

PPG measurement requires physical contact with the user, but recent research has shown that is is possible to estimate a person's PPG waveform from videos [11, 18, 40, 60]. While this is an area of active research, typical approaches involve the detection of regions of interest from videos that correspond to informative areas of the skin, followed by the detection of changes in color intensity within these regions that are correlated with the cardiac cycle. Boccignone *et al.* [8] and Liu *et al.* [40] provide open-source Python toolkits for studying methods of pulse-rate estimation and PPG reconstruction using remote methods.

While less attention has been focused on SCG and BCG biosignals, recent work has considered the synthesis of whole-body BCG signals for data augmentation and from chest SCG measurements [24, 46].

6.2 Spoofing Authentication Systems

Three related lines of research have addressed the threat of spoofing attacks against biosignal authentication. In 2017, [15] demonstrated the first practical spoofing attack against an ECG authentication system. The authors targeted the Nymi band, a commercially available ECG wristband that advertised the ability to facilitate user authentication. They developed models that could translate ECG recordings collected from a portable ECG monitor ("sufficiently close" to the Nymi band) to the form collected by the band. They demonstrated how an adversary could compromise the wristband and present the spoofed data, masquerading as a victim user.

Karimian *et al.* [32] added to this threat by demonstrating various techniques to synthesize a target user's ECG trace, including using another subject's (i.e., an adversary's) ECG from the same device, or by converting a small segment of the victim user's ECG into longer traces. They moreover simulated several types of spoofing attacks against ECG authentication systems that generate victim traces which could pass verification. While promising, these attacks rely on access to supervised training data that include samples of the target user's ECG. This assumption limits its practical threat to authentication systems: if an adversary has access to a sample of the subject's ECG data to train the model, they might be able to replay that sample directly.

Other closely related work focuses on spoofing PPG-based authentication systems using other forms of PPG or remote PPG (rPPG). Karimian et al. developed a method to convert a PPG signal obtained from an arbitrary sensor location to one that looks like it was measured by a target device used for authentication; the resulting signal was then able to spoof the system [32]. Again, this requires pairs of PPG recordings from a target subject for training the translation model. More recently, attention has moved to leveraging remote PPG measurements; rPPG techniques transform a video of a subject (focused on the face or a small section of a finger) into reliable PPG waveforms. While these techniques are still an area of active research, Li *et al.* showed that rPPG data obtained from recordings of participants' faces can be used to spoof an authentication system [36, 38] trained on their regular PPGs. Li's studies were the first to show that PPG-based systems are vulnerable to remote attacks, but so far the attack has only been demonstrated for one dataset and against one example system that relies heavily on fiducial point detection (for heartbeat segmentation). Their work contributes to discrediting the security of PPG-based authentication; however, the extent of this threat to various physiological signals and forms of authentication systems has yet to be shown.

7 Conclusion

Biosignal-based authentication systems are extensively studied as a potential form of biometric authentication. In this paper, we challenge the prevailing assumption that cardiovascular biosignals are confidential and illustrate that spoofed biosignals can fool existing state-of-the-art authentication systems. Our BioForge method shows that spoofed biosignals can be generated both from video of the target and from other biosignal modalities that are plausible for an adversary to obtain from data leaks. Moreover, we show that generating fake biosignals does not require access to simultaneously recorded supervision data. We also illustrate how multimodal authentication, a commonly proposed defense, is similarly vulnerable to spoofing attacks if these multiple modalities include only cardiovascular signals. We anticipate a growing risk landscape on this front as database leaks become more likely, wearable monitoring devices become more widespread, and the performance of generative models continues to advance in the coming years. Our results highlight the inherent weakness of biosignal-based authentication systems to spoofing attacks and the need for strengthened security analysis in the design of future biometric authentication systems.

Availability

We have made our system and evaluation code available at `https://github.com/Ethos-lab/biosignal-auth-harmful` to foster future research.

GlobalConfusion: TrustZone Trusted Application 0-Days by Design

Marcel Busch Philipp Mao Mathias Payer
EPFL, Lausanne, Switzerland

Abstract

Trusted Execution Environments form the backbone of mobile device security architectures. The *GlobalPlatform Internal Core API* is the de-facto standard that unites the fragmented landscape of real-world implementations, providing compatibility between different TEEs.

Unfortunately, our research reveals that this API standard is prone to a design weakness. Manifestations of this weakness result in critical type-confusion bugs in real-world user-space applications of the TEE, called Trusted Applications (TAs). At its core, the design weakness consists of a fail-open design leaving an optional type check for untrusted data to TA developers. The API does not mandate this easily forgettable check that in most cases results in arbitrary read-and-write exploitation primitives. To detect instances of these type-confusion bugs, we design and implement GPCheck, a static binary analysis system capable of vetting real-world TAs. We employ GPCheck to analyze 14,777 TAs deployed on widely used TEEs to investigate the prevalence of the issue. We reconfirm known bugs that fit this pattern and discover unknown instances of the issue in the wild. In total, we confirmed 9 known bugs, found 10 instances of silently-fixed bugs, and discovered a surprising amount of 14 critical 0-day vulnerabilities using our GPCheck prototype. Our findings affect mobile devices currently in use by billions of users. We responsibly disclosed these findings, already received 12,000 USD as bug bounty, and were assigned four CVEs. Ten of our 14 critical 0-day vulnerabilities are still in the responsible disclosure process. Finally, we propose an extension to the GP Internal Core API specification to enforce a fail-safe mechanism that removes the underlying design weakness. We implement and successfully demonstrate our mitigation on OPTEE, an open-source TEE implementation. We shared our findings with GlobalPlatform and suggested our mitigation as an extension to their specification to secure future TEE implementations.

1 Introduction

The security architecture of modern mobile devices heavily relies on *Trusted Execution Environments (TEEs)* to protect highly sensitive data for use cases such as biometric authentication, secure storage, digital rights management, and mobile payment. These distinct use cases require modularization and isolation. They are therefore typically encapsulated in user-space programs executed within the TEE called *Trusted Applications (TAs)*.

The organic evolution of the mobile ecosystem led to heavy fragmentation and heterogeneity of the software stacks on mobile devices. Depending on OEM (Original Equipment Manufacturer), chipset, and model, several TEEs, including QSEE, Kinibi, TEEGris, Trusty, OPTEE, and BeanPod power the security backend of our devices. Each TEE exposes its unique API that is incompatible with the other TEEs.

To counteract this fragmentation and ensure the compatibility of TAs across different TEE implementations, a non-profit industry association, called GlobalPlatform strives to enable a collaborative and open ecosystem by developing specifications, especially regarding trusted computing technologies and particularly for TEEs. The specification relevant to our work is the GP TEE Internal Core API [22], which defines a common interface that can be used by TAs.

In this work, we take a closer look at the GP TEE Internal Core API design and make an insightful discovery. The design choices of this de-facto standard API led to a class of type-confusion bugs affecting almost all TEE implementations used on production devices. Our analysis reveals that this design weakness affected more TAs than was publicly known and continues to manifest itself as critical vulnerabilities in TAs deployed on mobile phones used by billions of users.

In detail, the design weakness leads to a type-confusion bug where an attacker-controlled value is used as a memory reference. In the majority of these cases, this bug leads to arbitrary read-and-write exploitation primitives in the context of the affected TA and, thus, allows to fully take control over parts of the TEE.

Prior work noticed instances of these bugs in isolation without identifying the design weakness. We are the first to elaborate on the design weakness of the GP Internal Core API and its ecosystem-wide scale. Our discovery connects seemingly unrelated bugs affecting platforms of reputable vendors like Huawei [3,54] and Samsung [43,49], and relates these disclosures back to the GP API design weakness.

We present several findings and contributions. First, we detail and systematize the design weakness in the GP TEE Internal Core API highlighting the severe class of type-confusion bugs this weakness leads to. Next, we aim to study the prevalence of this bug class in the ecosystem. Since the vast majority of real-world TAs are closed-source, we designed and implemented GPCheck, a static binary analysis system that automatically detects instances of the type-confusion bug. In the design of GPCheck, we model this domain-specific class of type-confusion bugs as taint-style vulnerability. The encoding of this vulnerability class is our novel contribution, allowing us to conduct a large-scale study regarding the prevalence of this bug class in practice. In total, we investigate 14,777 TAs deployed on billions of devices by 5 vendors. Our results reconfirm the 9 previously known instances of the bug class. Unfortunately, the scope and impact of this bug class is larger than publicly known. We uncover 10 *unknown* and silently fixed vulnerabilities in old TAs, and 14 critical *0-day* vulnerabilities in the latest versions of TAs. Further, to mitigate the threat of this design weakness and to end this stream of critical type-confusion bugs, we propose an extension to the GP TEE Internal Core API specification. This extension preserves compatibility and adds a fail-safe design feature that will prevent type-confusion bugs in the future. We implemented this design on OPTEE and demonstrate its effectiveness.

In summary, we make the following contributions:

- Discovery of a design weakness in TAs using the GlobalPlatform API specification that leads to a series of critical bugs across vendors.
- Modeling of this TA type-confusion bug class as a taint-style vulnerability, as well as the design and implementation of a static analysis system, GPCheck, capable of detecting instances of this bug class in closed-source TAs.
- Automated static analysis pipeline to conduct a large-scale study to measure the scope and impact of this threat. We analyze 14,777 TAs spanning 5 vendors and demonstrate the scope of this issue that affects the majority of the ecosystem.
- Proposal and implementation of a viable countermeasure based on OPTEE.

The artifacts of our research are publicly available at https://github.com/HexHive/GlobalConfusion. All discovered bugs were responsibly disclosed to the respective vendors. We are in an ongoing responsible disclosure for 10 vulnerabilities, 4 CVEs have been assigned. Additionally, we contacted GlobalPlatform aiming to change the underlying specification to mitigate this bug class once and for all.

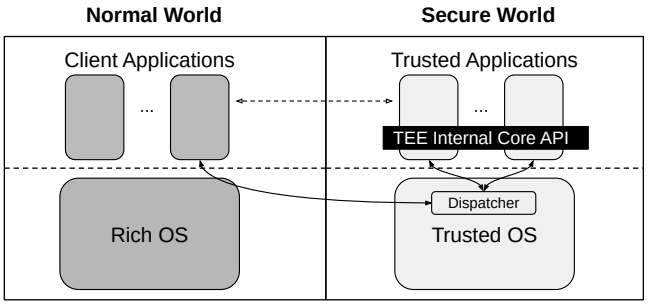

Figure 1: Architecture and communication channels of modern TrustZone-based TEEs. The logical channel of a Client Application–TA interaction (dashed line) is carried out by both OSes that, cooperatively, forward and dispatch requests (solid lines).

2 Background

The basis for almost all TEEs found on modern mobile devices is ARM TrustZone [6]. It allows for partitioning of the System-on-Chip (SoC) into two execution contexts – the Secure World and the Normal World – where code and data from the Secure World cannot be accessed by the Normal World. The idea is to run a feature-rich operating system (the rich OS) and its userland in the Normal World and only execute trusted code in the Secure World. Recent TrutZone-based TEEs split the Secure World into a kernel, the trusted OS, and a userland, which hosts TAs.

For data exchange, a logical communication channel exists between a Client Application and a TA (dashed line in Figure 1). Using this channel, Client Applications can request services from TAs. For example, requesting the generation of an asymmetric key pair, where the private key resides in the TEE, and the Client Application can use the public key [23]. In addition to the key generation, the TA would also provide an API to perform cryptographic operations using the safely stored private key (*e.g.,* sign or decrypt messages).

Technically, the Client Application cannot call a TA directly. It must go through the rich OS that takes care of using a Normal World-Secure World shared memory region for the provided request data and initiates the world switch using a privileged instruction (*e.g.,* `smc`). Then, the trusted OS dispatches the request to the TA. When the TA has processed the request, it writes its output to the shared memory region used for this session, and returns to the trusted OS, which, in turn, initiates the world switch back to the Normal World. Finally, the rich OS returns execution to the Client Application. Figure 1 depicts this communication channel with solid lines.

Vendors of TEEs have an interest in providing a common interface for TAs in order to execute third-party TAs on their platforms. One set of standards that has been adopted by the mobile market is specified by GlobalPlatform (GP). GP is a non-profit organization dedicated to fostering open ecosystems through the development of specifications, with a focus on TEEs. The GP TEE Internal Core API [22] defines a common interface that can be used by TAs (depicted in Figure 1). This API is the de-facto standard for developing TAs that may be deployed on multiple different TEE implementations.

One especially relevant part of the GP TEE Internal Core API is the lifecycle functions that are used from a Client Application's perspective to interact with a TA. The specification defines the following lifecycle functions:

1. `TA_CreateEntryPoint`: This function is the constructor for a TA. It is called only once during the lifetime of the TA when the first session is established.
2. `TA_OpenSessionEntryPoint`: This function is used to establish a session between the Client Application and the TA. It is primarily responsible for authenticating the Client Application and initializating data structures for the session.
3. `TA_InvokeCommandEntryPoint`: This function invokes the actual command handler of the TA. Each TA usually implements multiple commands.
4. `TA_CloseSessionEntryPoint`: This function frees all session-specific state.
5. `TA_DestroyEntryPoint`: This function deallocates all resources reserved in the initial entry point creation.

Both the `TA_OpenSessionEntryPoint` and `TA_InvokeCommandEntryPoint` handle untrusted data passed as arguments. In Section 4, we provide an example of how their *fail-open* design leads to critical type-confusion vulnerabilities.

3 Threat Model

We adopt our threat model based on the standard assurances provided for TrustZone-based Trusted Execution Environments (TEEs), tailoring it to the specific environment of a functional mobile device operating on the Android platform. TEEs leveraging TrustZone offer robust hardware-based isolation, ensuring the integrity and confidentiality of all components within the Secure World. This isolation thwarts the execution of unauthorized code within the TEE, such as loading unsigned or modifying existing code. It also safeguards confidential information, including cryptographic keys and biometric identifiers, from being exposed to the Normal World.

In this threat model, we assume an adversary with the capability to execute code in the context of the rich OS and Client Applications, with access to TEE-exposed interfaces.

```
1 TEE_Result TA_EXPORT TA_OpenSessionEntryPoint(
2     uint32_t paramTypes, [inout] TEE_Param params[4],
3     [out][ctx] void** sessCtx);
4
5 TEE_Result TA_EXPORT TA_InvokeCommandEntryPoint(
6     [ctx] void* sessCtx, uint32_t cmdId,
7     uint32_t paramTypes, [inout] TEE_Param params[4]);
```

Listing 1: The function signatures of the two affected GP API functions.

This attacker model aligns with real-world scenarios on typical Android devices, considering the historical prevalence of privilege escalation exploits targeting the Linux kernel, exemplified by incidents like CVE-2018-9568, CVE-2019-2215, and CVE-2022-0847. Furthermore, the model can be nuanced and weakened, given that a plethora of user-space daemons have access to the TEE driver interface exposed by the kernel. In many cases, access to this interface (limited to individual Client Applications) is sufficient for an attacker to execute the described attacks.

Our specific focus involves an adversary aiming to compromise the integrity and confidentiality of a Trusted Application (TA) and potentially exploit the TA's capabilities to breach the TEE's operating system. Note that achieving the latter only requires an exploitable vulnerability in a single TA, establishing a single point of failure.

4 GlobalConfusion: A Design Weakness in the De-Facto TA API Standard

We discovered a design weakness related to the GlobalPlatform API specification for TAs that proposes a fail-open design for optional, but critical, type checks of untrusted parameters. In the majority of cases, manifestations of this weakness result in an arbitrary read-and-write exploitation primitive and, thus, a complete compromise of the affected TA.

The two affected GP API function signatures are illustrated in Listing 1. In all GP-compliant TAs, these functions are directly exposed to Client Applications and the rich OS which makes them accessible in the context of our threat model described in Section 3. Note that untrusted input is crossing the trust barrier between Normal World and Secure World when these functions are invoked and, thus, all arguments must be properly sanitized.

The `sessCtx` is an opaque pointer that can be set by the TA during session establishment and does not contain untrusted data. Within subsequent command invocations, this pointer is available and used to maintain session-specific data structures. The remaining parameters contain untrusted data and their usage becomes clear by looking at an example.

In Listing 2, we present an echo-TA to demonstrate the usage of GP-compliant TAs and to highlight the type-confusion

```
1  TEE_Result TA_InvokeCommandEntryPoint(
2      void __maybe_unused *sessCtx,
3      uint32_t cmdId, uint32_t paramTypes,
4      TEE_Param params[4])
5  {
6    (void)&sessCtx; // Unused parameter
7
8    switch (cmdId) {
9    case TA_ECHO_CMD_ECHO: {
10     char *in_buf, *out_buf;
11     size_t in_buf_sz, out_buf_sz;
12
13     /*
14     uint32_t exp_paramTypes = TEE_PARAM_TYPES(
15                     TEE_PARAM_TYPE_MEMREF_INPUT,
16                     TEE_PARAM_TYPE_MEMREF_OUTPUT,
17                     TEE_PARAM_TYPE_NONE,
18                     TEE_PARAM_TYPE_NONE);
19
20     if (paramTypes != exp_paramTypes)
21       return TEE_ERROR_BAD_PARAMETERS;
22     */
23
24     in_buf_sz = params[0].memref.size;
25     in_buf = (char*)params[0].memref.buffer;
26     out_buf_sz = params[1].memref.size;
27     out_buf = (char*)params[1].memref.buffer;
28
29     if (in_buf_sz > out_buf_sz)
30       return TEE_ERROR_BAD_PARAMETERS;
31
32     TEE_MemMove((void*)out_buf, in_buf, in_buf_sz);
33
34     return TEE_SUCCESS;
35   }
36   default:
37     return TEE_ERROR_BAD_PARAMETERS;
38   }
39 }
```

Listing 2: The GP TEE Internal Core API specification proposes a weak "fail-open" design to sanitize untrusted input. The type check that distinguishes `memref` from `value` parameters is optional.

problem exposed through the API. In this listing, we can see a simple command handler of an echo-TA. The session context (`sessCtx` in Lines 2 and 6) is not used in this example, and the command handler only implements one command identifier (`TA_ECHO_CMD_ECHO` in Line 9). The implemented echo command uses the first parameter (`params[0]` in Lines 24 and 25) as a reference to an input buffer and the second parameter (`params[1]` in Lines 26 and 27) as a reference to an output buffer. As the name of this TA suggests, the input buffer is copied to the output buffer (Line 32) in this command handler before the TA returns successfully.

Each GP-compliant TA must check the parameter types (`paramTypes`) sent by a client against the expected parameter types (Lines 14 to 21) for the corresponding `cmdId` handler. If the expected types do not match the provided types, the TA is supposed to abort execution and return a `TEE_ERROR_BAD_PARAMETERS` status code to the client. The individual parameters (`params`) are supposed to be passed using either one of two different parameter type classes, `value`

```
1  typedef union {
2    struct {
3      void *buffer;
4      uint32_t size;
5    } memref;
6    struct {
7      uint32_t a;
8      uint32_t b;
9    } value;
10 } TEE_Param;
```

```
1  #define TEE_PARAM_TYPE_NONE          0
2  #define TEE_PARAM_TYPE_VALUE_INPUT   1
3  #define TEE_PARAM_TYPE_VALUE_OUTPUT  2
4  #define TEE_PARAM_TYPE_VALUE_INOUT   3
5  #define TEE_PARAM_TYPE_MEMREF_INPUT  5
6  #define TEE_PARAM_TYPE_MEMREF_OUTPUT 6
7  #define TEE_PARAM_TYPE_MEMREF_INOUT  7
8
9  #define TEE_PARAM_TYPE_GET(t, i) \
10     ((((uint32_t)t) >> ((i)*4)) & 0xF)
```

Listing 3: The parameter type is either a `value` or `memref` struct. Due to the `union`, the two structs overlap in memory. The GP API specifies two classes of parameter types, `value` and `memref`. Each parameter's type is encoded by 4 bits in the `param_types` argument.

or `memref`. Each class can be an input, output, or in-out parameter (Listing 3). Additionally, there is the `none` type indicating that a parameter is not used. Each parameter is implemented as a `union`, `TEE_Param`, consisting of a `memref` and a `value` struct, as illustrated in Listing 3. The `memref`'s first member is an opaque pointer to a buffer, and its second member describes the size of this buffer. The `value`'s members, `a` and `b`, are two 32-bit unsigned integers. Due to the `union`, the two structs overlap, and the same underlying data can be interpreted as either `memref` or `value` type. In a 64-bit environment, the integers `a` and `b` overlap with only the `buffer`.

Design Weakness. In Listing 2, we indicate a forgotten parameter type check in Lines 14 to 21. This type check is essential to prevent type-confusion vulnerabilities. The GlobalPlatform TEE Internal Core API specification proposes an *optional* preprocessor macro-based type check, resulting in a *weak fail-open design*, instead of enforcing the proper sanitization of untrusted input (fail-closed design). Listing 2 demonstrates a manifestation of this weak design when a `value` is used like a `memref`. Assuming an adversary notices the missing type check in any of the commands of any TA (usually there are many commands), it can have severe consequences as we can learn from our example echo-TA. In this case, an attacker can invoke the `TA_ECHO_CMD_ECHO` command and provide the type information used for any of the two used parameters to indicate a `value` type. Since the TA does not check its parameter types, but still interprets them as `memref` types, the attacker provided `a` and `b` values overlap with the `buffer` and `size` fields (in the 32-bit case) and, thus, the attacker has control over the two pointers within the virtual address space of the TA that can be read from or written to. While the prior case can lead to the leakage of confidential data, such as reading export-protected cryptographic keys, the latter case could allow an adversary to manipulate the TA's address space and, in the worst case, lead to code execution.

5 GPCheck Design

Based on the design weakness of the GlobalPlatform Internal Core API as introduced in Section 4, we first surveyed the landscape of existing analysis tools and second, due to their limitations, design a static binary analysis tool to automatically find manifestations of this weakness in proprietary closed-source TAs.

5.1 Prior Art

In our study, we aim for a large-scale analysis of closed-source TAs compiled from C/C++ code. These TAs are shipped as binary blobs in proprietary firmware images and deployed on production devices. They are executed within the TEE of these production devices and do not allow any introspection. Within these TAs, we aim to detect a type-confusion vulnerability as outlined in Section 4. This section reviews prior work related to this class of vulnerabilities. An overview of prior work is summarized in Table 1.

Dynamic Approaches. At its core, manifestations of the GlobalPlatform Internal Core API design weakness materialize as type-confusion vulnerabilities in TAs. Prior research on type-confusion vulnerability detection focuses primarily on dynamic analysis techniques which fundamentally requires concrete executions to trigger the type-confusion. TypeSan [25], HexType [28], BiType [31], EffectiveSan [16], and Uncontained [32] propose several approaches in different domains to instrument target programs during compilation. This instrumentation allows for the detection of type confusions during runtime. In principle, dynamic taint tracking approaches like TaintDroid [18] or TaintArt [56] could also be leveraged to uncover type-confusion vulnerabilities by ensuring that a type check occurs before every access to the variably typed object. There exist similar dynamic approaches targeting type confusions in binaries, including libcrunch [30] and BinTyper [31]. Unfortunately, all of these approaches require recompilation based on source code to extract the necessary type information, require the modification of the target program to add the checks, and/or rely on powerful introspection capabilities into the program state. TAs are closed-source binaries compiled from C/C++. They are vendor-signed and cannot be executed when modified. Additionally, TrustZone TEEs enforce isolation between the Normal World and the TEE, meaning that introspection is prohibited. While emulation-based approaches for TEEs [26] seem promising, they suffer from fidelity issues, require significant engineering efforts to support a wider range of TEE implementations, and existing prototypes are not available to the public. Hence, past approaches leveraging dynamic analysis are inappropriate to support our study of type-confusion bugs in TAs.

Static Approaches. As illustrated in Section 4, the type-confusion bug becomes a vulnerability when a `memref` use is not preceeded by a corresponding type check. In static analysis, this problem falls into the category of *taint-style vulnerabilities*. Analyses aiming to detect taint-style vulnerabilities consist of (i) taint-introducing sources, (ii) taint propagation rules, (iii) taint-removing sanitizers, and (iv) taint-consuming sinks. These analyses raise alerts when a taint can flow from source to sink without being sanitized.

The encoding of these four elements of taint-style vulnerability analyses is highly problem-specific. For instance, Livshits and Lam [38] define a taint-style vulnerability analysis for Java-based web applications. Amongst other encodings, they detect SQL injections when tainted data from an untrusted source flows into an SQL statement interpreted by the database management system without being sanitized. Similarly, Pixy [29] encodes a taint-style vulnerability addressing cross-site scripting vulnerabilities in PHP applications. Their analysis raises an alert when untrusted input is returned to the client without being sanitized.

Different from these domains, our targets are binaries compiled from C/C++. Taint-style vulnerability analyses for binaries were used by Bootstomp [46] and its successor Karonte [47]. Both systems use heuristics, i.e., keywords in strings and `memcpy` functions, to identify sources and sinks. In the scenarios for these systems, sanitizers are not well-defined and it is left to a human analyst to decide if a detected flow leads to unintended behavior. COMfusion [65] is another system leveraging taint-style vulnerability analyses to detect improper usages of unions in the context of Microsoft Component Object Model (COM) code. COMfusion requires Microsoft Interface Definition Language (MIDL) files and uses them to identify union-type parameters of functions. These parameters serve as sources for the inter-procedural taint analysis. The taints are propagated using no further specified "normal data movements". Interestingly, the sinks are identified by a succeeding symbolic execution phase as specific uses of tainted data (i.e., a union is passed as a parameter to `memcpy`). The sanitization check is integrated to the symbolic execution by introducing the type selector (i.e., member of the `struct` containing the union) as symbolic variable and determining its possible values at each sink location. If there are more than one possible values (i.e., multiple types possible), the system reports a type confusion.

The above-mentioned systems propose promising approaches to detect domain-specific taint-style vulnerabilities. However, they are not directly applicable to the type-confusion issues outlined in Section 4. Bootstomp and Karonte do not rely on sanitizers and leave the interpretation of alerts to human analysts. Given the large-scale scope of our study, this approach is infeasible. Further, while COMfusion introduces a taint for one union-typed parameter, our problem (see Section 4) requires tracing the `params` array and continue as a multi-tag taint system whenever the `TEE_Param` union members of this array are propagated. To be precise, we are only interested in the propagation of the first member

Solution	Analysis	Target	Approach
TypeSan [25]	Dynamic	Source (C++)	Runtime Sanitization
HexType [28]	Dynamic	Source (C++)	Runtime Sanitization
BiType [44]	Dynamic	Source (C++)	Runtime Sanitization
Effectivesan [16]	Dynamic	Source (C++)	Runtime Sanitization
Uncontained [32]	Hybrid	Source (C)	Def-Use Chains / Runtime Sanitization
TaintDroid [18]	Dynamic	Bytecode (Dalvik)	Runtime Taint Tracking
TaintArt [56]	Dynamic	Bytecode (Dalvik)	Runtime Taint Tracking
libcrunch [30]	Dynamic	Binary (C++)	Runtime Sanitization
BinTyper [31]	Hybrid	Binary (C++)	Class Recovery / Runtime Sanitization
Bootstomp [46]	Static	Binary (C)	Static Taint Propagation
Karonte [47]	Static	Binary (C)	Static Taint Propagation
COMfusion [65]	Static	Binary (C)	Static Taint Propagation

Table 1: Overview of prior approaches related to type-confusion detection.

(`buffer` or `value`) of `TEE_Param`. COMfusion does not support multiple taints and cannot express these tainting rules with sufficient granularity. Extending COMfusion in these two aspects would be an option, but neither the prototype source code nor any other artifacts of this work are publicly available. In the following sections, we describe our contribution of encoding the type-confusion bug class into a taint-style vulnerability and our system, GPCheck, capable of detecting instances of these vulnerabilities in closed-source TAs.

5.2 Overview

Our system, GPCheck, relies on static analysis to find the type-confusion vulnerabilities as mentioned above. We extend commodity reverse-engineering tools to implement our static analyses. In particular, we require a tool that disassembles the TA's machine code and identifies functions. Further, we aim for an architecture-agnostic analysis by utilizing an intermediate representation (IR) typically provided by reverse engineering tools as a lifter step in the decompilation process. A common feature of these tools is to optimize the IR representation of the code in multiple passes. These optimizations, similar to compiler optimizations, transform the IR into the single static assignment (SSA) form to allow for more advanced data-flow analyses. For instance, SSA facilitates the detection of def-use chains of variables because each variable is defined exactly once. All major reverse-engineering tools provide a scriptable API to query their optimized IR. For instance, IDA Pro lifts machine code to Microcode IR [24], Binary Ninja to BNIL [1], and Ghidra to PCODE [2].

Combining powerful and mature decompilation tools with security-centered static analysis is a promising approach to analyzing proprietary TAs as found within firmware images deployed on production devices.

As illustrated in Section 4, the type-confusion bug becomes a vulnerability when `memref` `TEE_Params` are used without the corresponding preceding `paramTypes` check. The core of our system is an information flow analysis that tracks the flow of data within the program. Using this analysis, we can effectively determine the distinct cases of unchecked `memref`

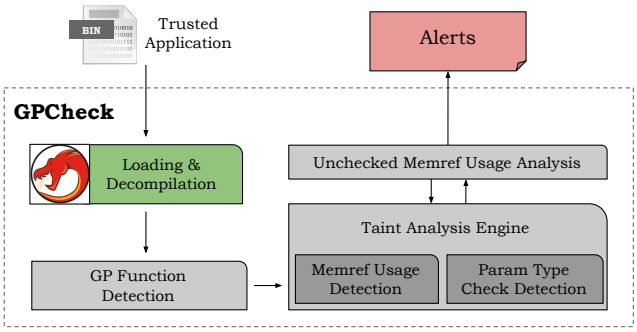

Figure 3: GPCheck consumes closed-source TAs and is based on commodity reverse-engineering tools. First, it detects the relevant GP functions, next it introduces and tracks several taints, and finally combines these information flow analyses to generate alerts for unchecked `memref` usages.

usages and raise an alert for each of these cases. A human analyst can then process these alerts and verify if the reported type-confusion bugs can be exploited.

Our system proceeds in the following steps, as outlined in Figure 3:

1) TA Pre-processing. GPCheck's input is a TA binary. The design choice of supporting binaries enables our system to handle proprietary closed-source TAs. These binaries can directly be obtained from firmware images of devices employing TEEs. We leverage commodity reverse-engineering tools and their decompilation features to obtain control-flow and data-flow information.

2) GP Function Detection. TA binaries are often stripped. Thus, GPCheck needs to identify the two lifecycle entrypoints `TA_InvokeCommandEntryPoint` and `TA_OpenSessionEntryPoint`. Since each TEE implementation uses a different SDK to implement TAs, this detection is TEE-specific and non-trivial. GPCheck identifies these lifecycle entrypoints using a set of effective heuristics that rely on structural patterns of the individual SDKs. The localization of these entrypoints is a prerequisite for our information flow analysis.

3) Memref Usage and Type Check Detection. As explained in Section 4, we are interested in all cases where one of the four `TEE_Params` may be used as a `memref`. In particular, any access (dereference) of the `buffer` member of `memref` can be critical. Hence, GPCheck considers the two relevant lifecycle functions as taint sources and marks their `params` argument as tainted. Further, the system tracks the usages of `params` throughout the CFG and introduces new distinct taint sources for all sinks that access the memory backing any of the up-to-four `memref.buffer` members. In other words, we convert the `params` taint into a multi-tag taint with different propagation rules whenever a potential `memref.buffer` members is created. These `memref.buffer` candidate taints are further propagated and dereferencing ac-

cesses are marked as sinks. Analogously, GPCheck tracks the usages of `paramTypes` and marks all sinks that compare this value. This comparison indicates a parameter type check.

If any taint is propagated to another function, GPCheck properly forwards this information and recursively tracks taints across function boundaries, making this analysis interprocedural.

4) Unchecked Reachability Analysis and Alerting. Having identified `memref` usages and `paramTypes` checks interprocedurally, GPCheck performs a reachability analysis where we determine if a `memref` usage sink is reachable from a source (i.e., entrypoint of a function) without encountering a sanitizing `paramTypes` check in the CFG. In other words, "can we find a path within the CFG that connects a source with a sink without traversing a checker node". GPCheck raises an alert for all unchecked usages and compiles a report for a human analyst containing relevant context information to pinpoint the vulnerability during a manual analysis.

The unchecked reachability analysis also decides if descending into tainted callees is necessary. If the call site is checked, GPCheck does not descend into the callee.

False Positives. Conservative static information flow analyses as the one suggested above have high false-positive rates due to overtainting. GPCheck employs a domain-specific analysis tailored for a fairly narrow class of bugs. Due to the introduction of taints via standardized APIs, we assume a homogeneous handling of the tainted parameters. For instance, it is unusual to encounter `paramTypes` checks more than two callees deep into the callgraph originating from the GP API function. Additionally, we observed a uniform pattern to access the `buffer` members inside of the `params` and did not observe any obfuscation or anti-analysis techniques in in-the-wild TAs. These properties are beneficial for static information flow analysis and result in a false-postive rate of about 10%, as our empirical evaluation in Section 7 shows.

5.3 GP Function Detection

In this section, we describe how we can identify GP API functions in proprietary and stripped binaries.

The GP API defines return codes to indicate certain error conditions. For instance, `0xFFFF000C` indicates an out-of-memory condition, while `0xFFFF0000` indicates a generic error. As a heuristic, GPCheck uses these return codes to identify GP function candidates. Additionally, we use a set of vendor-specific constants and (log) strings that consistently appear within TAs, making use of GP "artifacts" to extend the set of candidates.

Next, we use a set of vendor-specific structural features to first split the result set into `TA_OpenSessionEntryPoint` and `TA_InvokeCommandEntryPoint` candidates, and second uniquely identify the two functions. One structural feature is related to the integration of the GP API lifecycle functions into the binary. All lifecycle functions are only referenced once from one function that implements the lifecycle state machine. Therefore, we filter the result set for candidates having only one caller. Then, we exploit the fact that the lifecycle functions have a common caller and cluster our result set into groups of functions having the same caller. A further cross-vendor structural feature is the parameters used by the two target functions. By considering the parameter count of each function, we can exclude candidates and split each group into `TA_OpenSessionEntryPoint` and `TA_InvokeCommandEntryPoint` candidates. Lastly, we end up with groups of candidates for both functions and use the fact that their common caller passes the same variables (`paramTypes` and `params`) to both functions.

In practice, these heuristics yield reliable results. Depending on the target, the used heuristics can be extended or modified to fit the structural features of other implementations.

5.4 Static Information Flow Analysis

After identifying the two problematic functions as described above and using commodity reverse-engineering tools to obtain control- and data-flow information, the core of our static analysis consists of three elements. First, we identify the CFG nodes that check the parameter types (type check). Second, we identify the CFG nodes accessing the memory backing *memref* buffers (memref usage). Third, we determine if any of the *memref* usages is reachable without traversing a type check.

Tracking `paramTypes`. To intra-procedurally track the `paramTypes`, we taint the corresponding parameter of the taint-introducing function (i.e., `TA_OpenSessionEntryPoint` or `TA_InvokeCommandEntryPoint`). Then, we collect all descendants of the taint by recursively tainting all new definitions that depend on a tainted use. The propagation of the taint is dependent on the expression in which it is used. For instance, copying to a register, casting, or storing to memory introduces new taint flows. The taint can reach two kinds of sinks, a comparison or a function call. A comparison marks the containing CFG node as a type check node. A function call creates an entry in the worklist to later descend into the called function. We generate an alert for unexpected expressions. For instance, we do not expect the `paramTypes` to be used in arithmetic expressions or as a memory location that is written to or read from.

Tracking `params`. The intra-procedural analysis of `params` starts identical to the one performed for the `paramTypes` parameter. The taint is introduced by the corresponding parameter of one of the GP functions and points to an array of four `TEE_Param` unions. When collecting the descendants, we look for sinks that load data from the location of the first member of any of the entries in `params`, meaning a load of either `memref.buffer` or `value.a`. This preparation is typically expressed via (pointer) arithmetic where a

(constant) offset is added to the base of the `params` array. Such a sink allows us to introduce a `param` taint for which we still need to determine if it is ever used as a `memref`. Similar to the `paramTypes` tracking, a usage of `params` as part of a function call creates a new worklist entry to later descend into the callee.

Tracking `param`. Each `param` taint represents a potential buffer. Hence, we collect all descendants for each `param` taint and proceed according to how these descendants are used. We mark a CFG node as `memref` usage sink if we encounter a taint being used as a reference to memory that is read from or written to. We add an item to the worklist containing the `param` taint when we encounter a call site consuming this taint as a parameter. This item will be processed later.

Alerting. Having the current function's CFG annotated with type check nodes and `memref` usage nodes, is a prerequisite to detect unchecked `memref` usages. For each `memref` usage, we determine if it is reachable without traversing a sanitizing type check node. If we can find such a path, GPCheck raises an alert, otherwise the usage is marked as correctly checked.

Inter-procedural Tracking. Similarly, the type check nodes help us to decide if we need to analyze functions contained in the worklist. If we can reach a call site without traversing a type check node, we have to analyze it. If a call site is only reachable by traversing a type check node, we discard the entry. The call-site-based analysis is context sensitive in the sense that the callee is analyzed multiple times depending on the call sites that propagate taints into it.

6 Implementation

We implemented GPCheck on top of Ghidra using the Ghidrathon plugin to enable Python3 support. GPCheck consists of roughly 2,100 lines of Python3 code. GPCheck leverages Ghidra's headless mode and can automatically analyze proprietary TAs of all major TEE implementations.

GPCheck performs a conservative static information flow analysis in the sense that alerts are raised for undetermined taint propagation situations. For instance if a taint is propagated into an external unknown function or an indirectly called function, GPCheck will warn the analyst that the taint can no longer be tracked. Our prototype expects a TA's code to behave well and reports cases of misbehavior. For instance, GPCheck will report if the `uint32_t paramTypes` parameter is used as a memory location. As an optimization, GPCheck maintains a catalog of known functions to shortcut the analysis. For instance, if a `param` taint is passed to a `memcpy()` function as `src` or `dst`, the call site is directly marked as a `memref` usage node instead of descending into the function. All the details of our taint propagation policies can be found in our open-source prototype.

7 GlobalConfusion Prevalence Study

In our evaluation, we aim to answer the following research questions:

RQ 1: GPCheck Effectiveness. Can GPCheck detect type-confusion bugs resulting from the design weakness of the GP Internal Core API specification in closed-source TAs?

RQ 2: Bug Class Prevalence. How prevalent are manifestations of the GP Internal Core API design weakness in contemporary TEE implementations?

RQ 3: Bug Class Severity. How severe is the type-confusion bug in real-world settings?

First, we focus on the effectiveness of GPCheck. We evaluate its GP function detection and type-confusion bug detection capabilities on a ground-truth dataset of proprietary real-world TAs. Next, we employ GPCheck to conduct a large-scale study to understand the prevalence of the type-confusion bug class within the TEE ecosystem. Then, we demonstrate the severity of this bug class by exploiting two discovered vulnerabilities under real-world conditions.

7.1 TA Dataset

We collected a dataset of 545 firmware images from 54 Android devices employing 5 different TEE implementations and spanning from 2016 to 2024. Our dataset is comprised of the top five Android Smartphone vendors covering a market share of over 60% [53]. From these firmware images we extracted 14,777 proprietary TAs (i.e., no open-source TAs), which grouped by their Universally Unique IDentifier (UUID) for each TEE implementation result in 374 TAs. While the TA grouping by UUID and TEE yields insights regarding the distribution and scope of our findings, it does not account for UUIDs being shared across TEEs and vendors assigning different UUIDs for TAs originating from the same code base. A manual data cleansing revealed that TA code is shared across BeanPod, Kinibi, and TEEGRIS on MediaTek chipsets. While the UUID assignment for Kinibi and BeanPod TAs is consistent, we found that it diverges for TEEGRIS. Our interpretation is that Samsung (the only vendor using TEEGris on MediaTek chips) assigned new UUIDs to these TAs. To account for these duplicates, we report the manually deduplicated aggregate number of TAs (#Unique TAs = 336) consistently in our evaluation. Our dataset is summarized in Table 2.

7.2 Ground-truth GP Function Detection

To assess GPCheck's ability to detect GP functions, we select three GP-compliant and three legacy TAs for each TEE implementation, since each of these implementations is using a different TA SDK. We select these TAs by randomly sampling from all TAs grouped by TEE and manually confirm the presence (or abscence) of the `TA_InvokeCommandEntryPoint` function. We conduct this experiment only for MiTEE, Kinibi

TEE	#TAs	#TA UUIDs
BeanPod	1,061	25
MiTEE	13	13
QSEE	7,798	189
Kinibi	1,316	67

and QSEE, because we found that the TAs running on the other TEEs (BeanPod and TEEGRIS) do not strip the `TA_InvokeCommandEntryPoint` symbol. Hence, we do not need the GP function detection step for these TAs. Our results are summarized in Table 3. GPCheck detected the GP API functions in all of the GP-compliant TAs in this evaluation. The detection of GP API functions is a prerequisite for the GP API type-confusion bug detection. Thus, our empirical evaluation partially answers RQ1.

7.3 Ground-truth Type Checking

To assess GPCheck's ability to detect GP API type-confusion bugs, we collected a dataset of known vulnerable TAs. We obtained this information from publicly available advisories and blog posts of security researchers. Note that there are no open-source TAs in our dataset. Table 7 in our Appendix lists the sources for this ground truth.

As our results in Table 4 show, GPCheck is capable of detecting all known type-confusion bugs. Our empirical evaluation suggests that GPCheck is effective in detecting GP API type-confusion bugs in closed-source TAs (RQ1).

7.4 Large-scale Study on Type Checking

In this section, we aim to measure the prevalence of the GP API type-confusion bug class on contemporary TEE implementations. Table 5 summarizes the results of our large-scale study. Overall GPCheck analyzed 14,777 TAs, which are comprised of 374 TAs with distinct UUIDs on five different TEEs (336 after deduplication). GPCheck detected 6,962 GP-compliant TAs mapping to 165 (43%) TAs, or 131 (35%) unique TAs, respectively. All GP-non-compliant TAs are found on Kinibi and QSEE. Kinibi and QSEE support their own proprietary APIs that were in use before the GP APIs were adopted. Thus, many of their legacy TAs continue to use these proprietary APIs.

We analyzed all 6,962 GP-compliant TAs using GPCheck. On average, the analysis of one TA took three minutes. We ran our experiments on a Xeon E5-2680 (56 cores, 256GB RAM) using 46 analysis jobs in parallel. Analyzing all 6,962 GP-compliant TAs takes about seven hours.

GPCheck found 850 vulnerable TAs in total. As a vulnerability deduplication step, we group these TAs by UUID and manually analyze the oldest and newest instances (two TAs per group). Overall this amounts to 86 manually analyzed TAs. We find that 8 TAs are flagged incorrectly as vulnerable by GPCheck (false-positive rate of 9.3%), due to imprecisions in Ghidra's decompilation and taints propagated into indirectly called functions that end up using the taint as `value` parameter. The remaining 78 TAs are true positives, resulting in 39 vulnerable and 33 unique vulnerable TAs. Table 6 shows the involved and affected parties of the vulnerable TAs. Note that about half of the vulnerable TAs in our dataset affect multiple TEE implementations or OEMs.

In total, we found 14 unique zero-day vulnerabilities (affecting the latest versions of TAs, see Table 8 in the Appendix) and 19 unique patched n-day vulnerabilities. Note that only 9 of the total 19 n-day type-confusion bugs are publicly known. The remaining n-day bugs were silently fixed by the vendor,

TEE	#TAs	#GP TAs	#Vuln	#TA UUIDs	#GP TA UUIDs	#Unique Vuln	#n-day	#0-day
BeanPod	1,061	1,061	277	25	25	11	4	7
MiTEE	13	13	1	13	13	1	0	1
QSEE	7,798	676	22	189	19	4	2	2
Kinibi	1,316	623	259	67	28	10	3	7
TEEGRIS	4,589	4,589	291	80	80	17	10	7
Total	14,777	6,962	850	374 (336)*	165 (131)*	39 (33)*	19 (19)*	24 (**14**)*

Table 5: The results of our large-scale study. The GP TAs are TAs that our analyzer has identified as utilizing the GlobalPlatform API. *The numbers in brackets account for TA code shared across TEEs and represent the unique count for these columns.

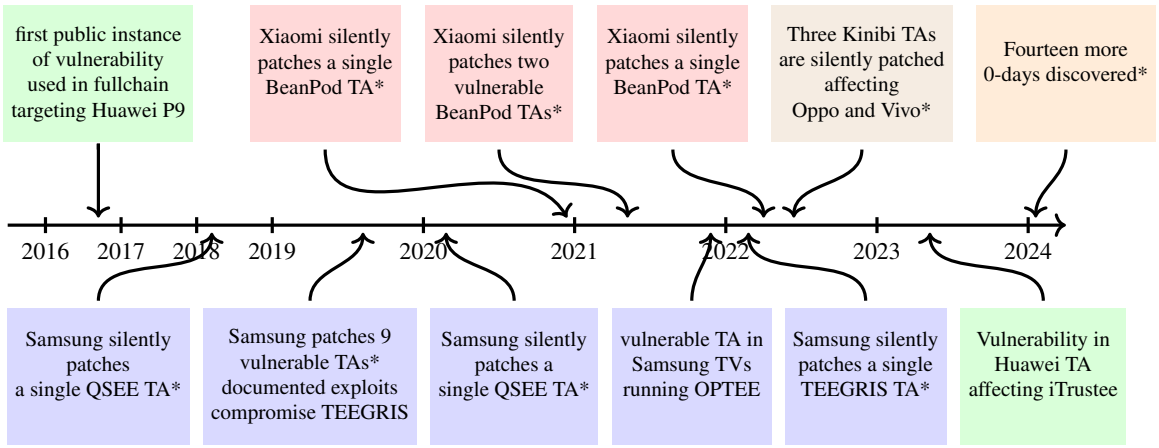

Figure 4: The timeline of known and discovered GP type-confusion bug instances in production TAs. These bugs affect TAs deployed on products by Huawei, Xiaomi, Oppo and Vivo, Samsung, and undisclosed vendors. (*)Type-confusion bugs discovered by GPCheck.

meaning that the affected TAs were vulnerable prior to these silent fixes.

A further aspect of this prevalence study is the perspective of TA developers. Our study reveals that TA developers missed the type check in GP-compliant TAs in 33 out of 131 cases (23%), as indicated in Table 5.

The prevalence of type-confusion vulnerabilities resulting from the GP Internal Core API design weakness systematically occur throughout the history of TAs. We visualize our findings of known, silently fixed, and 0-day vulnerabilities in Figure 4. Over the past seven years, TA developers stepped into the design-weakness trap of this API over and over again. As Table 6 suggests, we see the resulting vulnerabilities in TAs across the major OEMs on the mobile device market, across TEE implementations, and ODMs (Orignal Design Manufacturer). Our results show a wide prevalence of the vulnerabilities in the mobile device ecosystem, which answers RQ2.

7.5 Real-world Exploitation

To show the severity of the type-confusion bug, we exploit two vulnerable TAs that we detected with our static analyzer. We

ODM	OEM	TEEs	#TAs
MediaTek	Samsung,Xiaomi,Oppo,Vivo	TEEGRIS,Kinibi,BeanPod	6
Exynos	Samsung	TEEGRIS	14
MediaTek,Qualcomm	Xiaomi	BeanPod,QSEE,MiTEE	7
MediaTek	Vivo,Oppo	Kinibi	3
MediaTek	Vivo	Kinibi	2
Qualcomm	Samsung	QSEE	1

Table 6: #Unique vulnerable TAs and affected parties.

show how the type-confusion bug can be used to easily leak the memory of a TA and how, under the right circumstances, this bug may be weaponized to get control of the program counter. We exploit these TAs on our rooted Xiaomi Redmi device with the newest firmware version.

TA1449 (`14498ace2a8f11e880c8509a4c146f4c.ta`) was silently patched by Xiaomi in April 2021. Although the TA is outdated we can load it on our fully updated firmware due to missing rollback protection in BeanPod [41]. Listing 4 shows the vulnerable code. In the code that handles the command id `1`, the TA expects a memory reference for the first parameter. It then reads a string from this location and prints it to the kernel log which is accessible from the Normal World context. By supplying arbitrary integers, which are

```
TA_InvokeCommandEntryPoint(void* sessionContext,
    uint32_t commandID, uint32_t paramTypes,
    TEE_Param params[4]) {
  ...
  if(commandID == 1) {
    ...
    char* aaid = (char*)params[0].memref.buffer;
    ...
    ut_pf_log_msg(3,"add Authenticator \
        aaid = %s\n",aaid);
  ...
  }
}
```

Listing 4: Without checking the `paramTypes` the TA dereferences the first entry of the parameters and prints it to the kernel log.

treated as pointers by the TA, an attacker can read the entire content of the TA's memory. This arbitrary read is a problem as the TA relies on the confidentiality of secret keys stored in its memory to authenticate certain commands.

For our second case study, we show how this bug can lead to code execution within the context of the targeted TA. We exploit the `08110000000000000000000000000000.ta` (TA0811) and get control over the TA's program counter. The type-confusion vulnerability in this TA was a 0-day detected by our static analyzer and has been assigned CVE-2023-32835 by MediaTek. It affects Xiaomi, Oppo, and Vivo smartphones with a MediaTek SoC running a firmware version from before November 2023.

Listing 5 shows the relevant vulnerable code executed when the TA is invoked with the command id `1`. The TA assumes, without checking, the first and second parameters to be pointers to shared memory. It subsequently passes the first of these supposed pointers to the `TEE_CheckMemoryAccessRights` function. This function checks if the memory region pointed to by `in` points to readable and writable memory. By setting `in` to an arbitrary value and observing if the TA returns early or executes the `query_drmkey_impl` function, the attacker can leak the location of relevant memory regions, such as the stack. After leaking the stack's location, the attacker can use the functionality in `query_drmkey_impl` to overwrite the return address. This function takes as input the first and second memory reference in `params`. It then writes data from the first parameter to the second parameter. The attacker can set `out` to point to the stack, specifically to the location of the stored return address. The TA then writes the contents in `in`, which are fully under the attacker's control, to the stack. In our exploit, we overwrite the return address with `0xdeadbeef`. After crashing, the TEE conviniently prints a core dump to the kernel log accessible from the Normal World context, indicating that the TA aborted when trying to execute code at `0xdeadbeef`. Note that this control flow hijacking primitive

```
TA_InvokeCommandEntryPoint(void* sessionContext,
    uint32_t commandID, uint32_t paramTypes,
    TEE_Param params[4]) {
  ...
  if(commandID == 1) {
    int* in = (int*)params[0].memref.buffer;
    int inSize = params[1].memref.size;
    int* out = (int*)params[2].memref.buffer;
    r = TEE_CheckMemoryAccessRights(5, in,
                                    inSize);
    if(r==0) {
      query_drmkey_impl(in, out);
    }
  }
  ...
}

query_drmkey_impl(int* in, int* out) {
  int ct = in[17];
  int* src = &in[18];
  int tmpbuf[22];
  int c;
  out[0] = ct;
  int i = 0;
  while(i != ct){
    memcpy(tmpbuf, src, 0x58);
    int offset = tmpbuf[3] + 0x60;
    c = tmpbuf[0];
    out[4*i] = c;
    src = src + offset;
    i++;
  }
  ...
}
```

Listing 5: The vulnerable parts of the code in TA0811. The TA does not check the `paramTypes` and treats entries in the `params` array as pointers. This allows an attacker to enumerate read/writable memory regions using `TEE_CheckMemoryAccessRights`. Furthermore, the attacker can write to arbitrary memory addresses, abusing the TAs `query_drmkey_impl` function.

can easily be converted into arbitrary code execution within the TA context.

These case studies demonstrate that the ability of an attacker to supply arbitrary pointers to a TA provides an extremely powerful exploitation primitive, and answer our RQ3.

8 Mitigation

GPCheck serves two purposes. First, it enabled us to carry out a large-scale study to understand the prevalence of type-confusion bugs resulting from the GP Internal Core API design weakness. Second, we will open-source our prototype and encourage manufacturers to use it as a vetting mechanism for post-production TAs before they are shipped to consumer devices. Given the results of our evaluation in Section 7, show-

ing 14 0-day vulnerabilities, we propose to not only treat the symptoms of these vulnerabilities but also provide a remedy for their root cause.

To mitigate the GP Internal Core API design weakness, we suggest extending the specification and substituting the optional type checking mechanism for a fail-safe alternative. This extension aims at enforcing the currently optional type check before any untrusted parameter reaches the TA. The specification contains two API functions that receive untrusted parameters and their types, namely `TA_OpenSessionEntryPoint` and `TA_InvokeCommandEntryPoint`. Looking at hundreds of proprietary TA samples and those provided by OPTEE yields the insight that the `cmdId`[1] chooses the corresponding handler and, the code of this handler determines how the four `params` are used, namely either as `value` or as `memref`. Consequently, it is the tuple of `cmdId` and `paramTypes` that needs to be fixed and enforced before any untrusted input is supplied to TAs.

From this insight, we propose to deny all `cmdId`s and the invocation of `TA_OpenSessionEntryPoint` by default, and leverage the `TA_CreateEntryPoint` lifecycle function to register command handler-specific `paramTypes`. As discussed in Section 2, `TA_CreateEntryPoint` acts as a constructor and is executed before any untrusted parameters can be sent to the TA. To register the `(cmdId, paramTypes)` tuples, we introduce two new functions to be used in the `TA_CreateEntryPoint` context. Listing 6 illustrates the signatures of `TEE_RegisterCommand`, to register `(cmdId, paramTypes)` tuples for the `TA_InvokeCommandEntryPoint` function, and `TEE_RegisterOpenSession`, to register the `paramTypes` for the single command handler in the `TA_OpenSessionEntryPoint` function. By denying access to any unregistered interface that consumes untrusted data, and enforcing a deliberate registration of `paramTypes` associated with a specific command handler, we change the current fail-open design to a fail-closed one. As a consequence, we prevent any mistakenly forgotten type checks in future implementations, and mitigate the design weakness of the current GP Internal Core API specification.

```
1 TEE_Result TEE_RegisterCommand(
2     uint32_t cmdId, uint32_t paramTypes);
3
4 TEE_Result TEE_RegisterOpenSession(uint32_t paramTypes);
```

Listing 6: We suggest to extend the GP Internal Core API specification with functions to enforce a fail-closed rather than a fail-open design.

[1] `TA_OpenSessionEntryPoint` does not receive this parameter and does not contain any `cmdId`-based switching logic. Hence, we can assume a single fixed set of `paramTypes` for this function.

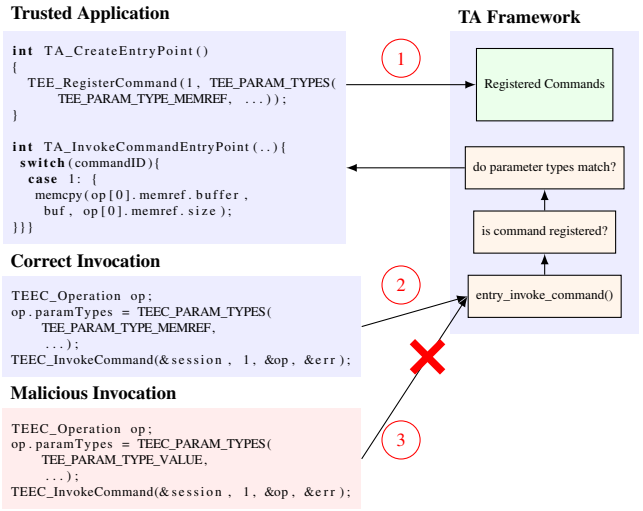

Figure 5: Inner workings of our mitigation.

Figure 5 illustrates the inner workings of our mitigation. First, (1) the TA registers a single command with `cmdId` 1 to have `paramTypes` `TYPE_MEMREF`. After the TA has been loaded, the normal world may invoke the registered commands (2). Such invocations are handled in the TA framework (e.g., `entry_invoke_command` function), which eventually calls the TA's `TA_InvokeCommandEntryPoint` function. However, before the TA framework hands over execution to the TA, it verifies that the `cmdId` was previously registered by the TA and that the `paramTypes` parameter matches the types registered by the TA. An example of the mitigation preventing an attack is shown in Figure 5. In (3), the attacker has manipulated the parameter type to be `TYPE_VALUE` and the TA without checking the `paramTypes` would have treated these values as pointers. However, due to the TA registering the `cmdId` 1 with `TYPE_MEMREF`, the TA framework will deny this API invocation, since the `paramTypes` of the invocation does not match with the expected types.

Compatibility. Our mitigation is backward-compatible with existing TAs in the sense that the exposed TA interface stays untouched. However, changing from a fail-open to a fail-closed design requires TA developers to register `cmdId`s for all existing TAs in a one-time effort. Given the reccuring pattern of bugs within the last seven years, as illustrated in Figure 4, and the 14 0-day vulnerabilities discovered in this research, we argue that this one-time effort is a worthwhile investment to eliminate present and future GP API-based type-confusion bugs once and for all.

Implementation and Evaluation. To demonstrate the effectiveness and practicality of our mitigation, we implement our extension for OPTEE [59], the de-facto reference imple-

mentation for TrustZone-based TEEs. In order to demonstrate the effectiveness of our mitigation, we modify the built-in TA `pkcs11` to remove `paramTypes` checks. Since this TA is using `memref` typed parameters, an attacker can pass arbitrary pointers to the TA and gain powerful read-and-write exploitation primitives when `pkcs11` runs on vanilla OPTEE. In contrast, after enabling our mitigation, passing a wrong combination of `paramTypes` and `cmdId` to the TA results in a `TEE_ERROR_BAD_PARAMETERS` error, effectively preventing the type confusion. We implement the mitigation in 427 lines of code and will open-source our evaluation setup.

9 Limitations

Encrypted TAs. Recent firmware images from vendors like Huawei and Sony are encrypted and cannot directly be processed by our analysis pipeline. Breaking this encryption and, thus, the code confidentiality of encrypted TAs is an orthogonal problem. However, these vendors themselves might be interested to use GPCheck in their integration pipeline, or eager security researchers might break the code confidentiality for individual devices and then use GPCheck.

Decompilation. Compilation is a lossy process. Thus, the inverse process, decompilation, relies on heuristics and inference methods to re-create structures from the original source code. GPCheck relies on commodity reverse-engineering tools and their intermediate representations used in the decompilation process. Consequently, our system inherits the limitations of decompilation, and the specific limitations of Ghidra, since we build GPCheck on top of this reverse-engineering tool. Fortunately, we did not encounter any obfuscation, the dominant programming language to implement TAs is C, and the type checking problem investigated in this study is fairly narrow. These factors contribute to meaningful decompilation results and useful static analysis results.

10 Discussion

In this section, we discuss the findings of our work and contextualize their scope and impact. First, we argue for a fail-safe design in widely adopted TEE-related specifications. Second, we emphasize the impact and threat potential of our findings. Third, we give an outlook regarding the future adoption of the GP Internal Core API specification.

Enforcing Fail-Safe Design. In its current form, the GP Internal Core API specification proposes a weak design that does not enforce type checks of untrusted parameters. The specification suggests an *optional* preprocessor macro-based type check. This lack of "fail-safe" design resulted in 19 n-day vulnerabilities (9 publicly known and 10 silently fixed) and 14 0-day vulnerabilities (found by our system GPCheck) affecting the latest versions of TAs. These numbers underline that especially in a sensitive context like the TEE, fail-safe design principles should be followed, and we must enforce security-critical type checks. In this context, GPCheck serves two purposes. First, it allowed us to assess the prevalence of manifestations of the GP API design weakness, identifying this weakness as a serious threat to the TEE ecosystem. Second, it can serve manufacturers as a post-production vetting tool to catch vulnerable TAs before they are shipped to devices of billions of users. However, instead of treating the symptoms, our backwards-compatible mitigation proposed in Section 8, aims to eliminate the root cause of these vulnerabilities by enforcing type checks and substituting the current weak design for a fail-safe one.

Keeping Promises. In total, we found 39 vulnerable TAs across 5 reputable OEMs affecting 54 recent devices that employ the 5 dominant TEE implementations on the market. Given that OEMs are struggling to deploy effective anti-rollback protection [10] (i.e., preventing to load properly signed but outdated and vulnerable TAs into their TEE), the threat posed by a single vulnerable TA in the history of a device is amplified. Combined with the critical severity [49] of the vulnerabilities resulting from the GP Internal Core API design weakness, the TEE ecosystem must change to keep up their promised confidentiality and integrity guarantees.

Outlook. Our dataset of 336 unique TAs deployed on a representative set of mobile devices in the ecosystem highlights the trend towards GP-compliance. Hence, we believe that the central piece of our discussion, the weak design of the GP Internal Core API, will be adopted by an increasing amount of stakeholders in the future. Further, our study focussed on mobile devices but the scope of this discussion reaches far beyond this device category. For instance, drones [15], TVs [45], tablets [50], and gaming consoles [57] require strong confidentiality and integrity guarantees for specific use cases and are using TrustZone-based TEEs for these purposes. Beyond these ARM-centric device categories, GP's specifications aspire to be architecture-agnostic and we might see them being adopted on other TEE-enabling technologies like Intel SGX, Intel TXT, AMD SEV, and ARM CCA.

11 Related Work

Related work exists across several domains. First, we cover TrustZone-based TEE flaws in general. Second, we highlight approaches to find or prevent memory corruptions in TEEs. Third, we summarize measurement studies in the mobile ecosystem. Finally, we relate to existing work on binary static analysis.

TEE Flaws. Numerous researchers have delved into the exploration and exploitation of vulnerabilities within TrustZone-based Trusted Execution Environments (TEEs). These studies have targeted various TEE implementations, such as Beanpod [41], QSEE [34, 40, 48], TEEGRIS [43, 51, 52], Kinibi [4, 7, 33], TrustedCore [11], and the ARM Trusted Firmware [37]. Furthermore, researchers have scrutinized

software design deficiencies [39, 55] and side-channel vulnerabilities [8, 35, 58, 61]. A comprehensive overview of much of this research has been provided by Cerdeira et al. [12], who summarized and systematized these findings.

Memory Corruption Defenses. The increasing incidence of reported memory corruptions has spurred research efforts towards automated vulnerability discovery within TEEs. TEEzz [9] employs an on-device black-box fuzzing strategy, while PartEmu [26] adopts an emulation-based approach to facilitate coverage-guided fuzzing of TAs. In contrast, Wan et al. endeavor to promote Rust as a memory-safe alternative for TA development [60], rather than focusing on automated memory corruption detection. Our work focuses on a specific vulnerability commonly found in GP-compliant TAs. We propose an effective binary static analysis tool, GPCheck, to find this vulnerability post-production and suggest eliminating the root cause of this issue by updating the GP Internal Core API using our mitigation that enforces a fail-safe design.

Measurement Studies. The widespread adoption of Android has attracted significant attention from security researchers, leading to comprehensive investigations into various facets of its security architecture. Imran et al. [27] measure the usage of TEE-enforced authorization APIs within apps. Farhang et al. [20] scrutinize Android security bulletins issued by different vendors. Numerous studies delve into the application of updates to apps or libraries [5, 14, 42]. Additionally, several investigations have concentrated on identifying and understanding diverse security vulnerabilities present in the Android ecosystem [19, 36]. Finally, Egele et al. [17] conduct an empirical analysis of how developers misuse cryptographic APIs within Android applications. In this paper, we measured the prevalence of type-confusion bugs resulting from a weak API design as proposed by the GP Internal Core API specification. In total, we found 33 unique TAs across all major TEEs that are affected by this critical vulnerability.

Static Analysis. Due to the hardware-enforced isolation of TEEs, vendors effectively lock down their platforms and prevent dynamic analysis approaches like advanced fuzzing provided by LibAFL [21] to discover vulnerabilities in TAs. Further, TAs are distributed as proprietary binary blobs, making them inaccessible for source code-based static analysis approaches as proposed by Yamaguchi et al. [62–64]. Binary static analysis approaches like Bootstomp [46], Bootkeeper [13], and Karonte [47] suggest domain-specific analyses for bootloaders and embedded firmware. These approaches often use additional techniques like dynamic symbolic execution to reduce reported false positives. Our system, GPCheck, concentrates on a well-defined problem in the domain of TAs. We leverage powerful decompilation features of commodity reverse-engineering tools and use the architecture-agnostic and optimized intermediate representation of these tools for our analyses.

12 Conclusions

A design weakness in the GlobalPlatform Internal Core API specification, a specification that serves as the de-facto standard for Trusted Applications, impacts the security of billions of mobile devices. Manifestations of this design weakness lead to critical type-confusion vulnerabilities that threaten the integrity and confidentiality guarantees promised by modern TEEs. After discovering this weakness, we investigate the prevalence of such vulnerabilities and design and implement GPCheck, a static information flow tracking system that is based on commodity reverse-engineering tools. GPCheck allowed us to carry out a large-scale analysis aimed at discovering instances of the type-confusion bug in real-world closed-source TAs that we obtained from firmware images of various popular mobile devices.

In total, we analyzed 14,777 TAs and found 33 instances of the type-confusion issue. 9 out of these bugs are publicly known, 10 were silently fixed by vendors, and 14 bugs were unknown 0-days that we responsibly disclosed to the affected manufacturers. These disclosures resulted in four CVEs and the remaining 10 critical vulnerabilities are still in the responsible disclosure process. Finally, we proposed a mitigation to eliminate the root cause of these type-confusion vulnerabilities. Our backward-compatible mitigation enforces the currently optional type check of untrusted TA parameters and only requires 427 additional lines of code when added to the OPTEE reference implementation for TrustZone-based TEEs. We suggested this mitigation to GlobalPlatform as an extension to the GP Internal Core API to hopefully substitute the design weakness for a fail-safe alternative. As a stop-gap solution, our open-source GPCheck prototype assists manufacturers in vetting their TAs before they are deployed on customer devices and bridges the time gap until our mitigation is adopted to eliminate the issue by design.

Acknowledgments

We thank the anonymous reviewers and our shepherd for their feedback on the paper. This work was supported, in part, the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation program (grant agreement No. 850868), SNSF PCEGP2_186974, and DARPA HR001119S0089-AMP-FP-034.

PointerGuess: Targeted Password Guessing Model Using Pointer Mechanism

Kedong Xiu, Ding Wang
College of Cyber Science, Nankai University, Tianjin, China; {xiukedong, wangding}@nankai.edu.cn
Key Laboratory of Data and Intelligent System Security (NKU), Ministry of Education, Tianjin, China
Tianjin Key Laboratory of Network and Data Security Technology, Nankai University, Tianjin, China

Abstract

Most existing targeted password guessing models view users' reuse behaviors as sequences of edit operations (e.g., insert and delete) performed on old passwords. These atomic edit operations are limited to modifying one character at a time and cannot fully cover users' complex password modification behaviors (e.g., modifying the password structure). This partially leads to a significant gap between the proportion of users' reused passwords and the success rates that existing targeted password models can achieve. To fill this gap, this paper models users' reuse behaviors by focusing on two key components: (1) What they want to copy/keep; (2) What they want to tweak. More specifically, we introduce the pointer mechanism and propose a new targeted guessing model, namely PointerGuess. By hierarchically redefining password reuse from both personal and population-wide perspectives, we can accurately and comprehensively characterize users' password reuse behaviors. Moreover, we propose MS-PointerGuess, which can employ the victim's multiple leaked passwords.

By employing 13 large-scale real-world password datasets, we demonstrate that PointerGuess is effective: (1) When the victim's password at site A (namely pw_A) is known, within 100 guesses, the average success rate of PointerGuess in guessing her password at site B (namely pw_B, $pw_A \neq pw_B$) is 25.21% (for common users) and 12.34% (for security-savvy users), respectively, which is 21.23%∼71.54% (38.37% on average) higher than its foremost counterparts; (2) When not excluding identical password pairs (i.e., pw_A can equal pw_B), within 100 guesses, the average success rate of PointerGuess is 48.30% (for common users) and 28.42% (for security-savvy users), respectively, which is 6.31%∼15.92% higher than its foremost counterparts; (3) Within 100 guesses, the MS-PointerGuess further improves the cracking success rate by 31.21% compared to PointerGuess.

1 Introduction

Textual passwords stubbornly survive as the most prevalent authentication method, and they are unlikely to be replaced in the foreseeable future, because none of their alternatives (e.g., biometric authentication [8, 22], multi-factor authentication [46, 47], and graphical passwords [6]) can compete with textual passwords in terms of simplicity to use, easiness to change and low cost to deploy [9, 10, 30, 37].

Recent research [11, 31, 41] shows that the average user has 80∼107 distinct online accounts, and a large fraction of investigated users (58%∼79% [13, 18, 38, 53]) tend to reuse their passwords across sites, even though 91% of them are aware of the risks associated with password reuse [25]. To address this issue, security experts [12, 43] recommend using password managers to help users create secure passwords and protect users from password guessing attacks. A password manager is designed to store a user's passwords, generate secure passwords, and identify any weak or compromised passwords [29]. However, due to users' lack of trust in password managers and the fact that it is too risky to store all passwords in one place [36, 42, 63], most users still tend to manage their password by themselves. This indicates that users' password reuse behaviors remain a significant security vulnerablity.

On the other hand, unending large-scale password dataset breaches (e.g., [1, 4, 16, 17, 34]) provide attackers with ample training data to conduct targeted guessing attacks. Still, recent studies show that two-thirds of users "modify passwords in a non-trivial way" [56, 57]. This suggests that designing an effective targeted guessing model to accurately characterize users' reuse behaviors is not an easy task.

1.1 Motivations and design challenges

Recent research shows that 58%∼79% of investigated users directly reuse or simply modify their existing passwords [13, 18, 38, 53]. However, the cracking success rates that state-of-the-art targeted password guessing models (i.e., Pass2Edit [57] and Pass2Path [38]) can achieve are much lower than this statistic (e.g., within 1,000 guesses, Pass2Edit [57] achieves a cracking success rate of 52.01% for common users, which is 11.52%∼51.89% lower than the reported statistic). This indicates that existing targeted password models may not effectively characterize users' reuse behaviors, and the threat

of password reuse guessing attacks might be underestimated.

Despite numerous string similarity metrics (e.g., edit distance and cosine similarity), they fail to measure users' password reuse behaviors comprehensively. For instance, while modifying `IloveMacOP` to `MacOP6789`, neither edit distance (employed by Pass2Path [38]) nor cosine similarity (employed by Pass2Edit [57]) can accurately measure their similarity due to overlooking complex reuse behaviors. This highlights a gap in existing research on password reuse, indicating a lack of an appropriate definition for "password reuse". In all, how to accurately characterize users' reuse behaviors given limited guessing attempts (e.g., 100 as recommended by NIST [19]) remains a challenging problem. Here we explain why.

First, characterizing the transformation rules that users employ to modify their passwords is quite subtle. In general, we can view the process of users reusing their old password as involving two major components: (1) Identifying what the user wants to copy from her old password; and (2) Determining what the user wants to tweak or generate based on her old password. However, most existing targeted password models (e.g., Pass2Path [38] and Pass2Edit [57]) focus primarily on the second component. These state-of-the-art models characterize the new password modification process as a sequence of atomic edit operations (i.e., deleting, inserting, or substituting *one character at a time*). Then, they predict the sequence of edit operations in a "password-to-path" task. For example, suppose we modify a user's old password pw_A=`IloveMacOP` to pw_B=`MacOP6789`, then the edit operation sequence from pw_A to pw_B is {`<BOS>`, (`Del`, 0, 'I'), (`Del`, 1, 'l'), (`Del`, 2, 'o'), (`Del`, 3, 'v'), (`Del`, 4, 'e'), (`Ins`, 10, '6'), (`Ins`, 10, '7'), (`Ins`, 10, '8'), (`Ins`, 10, '9'), `<EOS>`}, where (`Del`, 0, 'I') denotes deleting the character 'I' in the first position of pw_A, and `<BOS>`/`<EOS>` represents the start/end of the edit sequence.

To be effective, Pass2Edit [57] and Pass2Path [38] have to define a large number of atomic edit operations (e.g., Pass2Edit [57] defines a total of 1,561 atomic operations). Besides, they filter out "dissimilar" password pairs when training (e.g., Pass2Path [38] only utilizes password pairs with edit distance$\leq$4 for training to avoid the negative impacts of futile/distant password pairs like `yjqqq916198` $\rightarrow$ `916198yj`). This makes it difficult for them to generate long (yet realistic) edit sequences (e.g., edit distance$\geq$5), overlooking users' macroscopic population-wide reuse behaviors (e.g., using popular passwords and substituting long segments). To mitigate this defect, they resort to heuristic approaches to combine a popular password dictionary with the generated guesses.

Second, as 49%$\sim$65% of websites [5, 32] adopt security mechanisms (e.g., account lockout and login throttling as recommended by NIST [60]) to resist online guessing, the guess number allowed is often very small. For instance, the Alexa top-10 websites allow 120$\sim$1,140 attempts per day, i.e., 3,600$\sim$43,200 attempts per month [54]. As the possible password space is large, it is challenging to prioritize password reuse behaviors in a personalized manner under such small guess numbers. In all, building a password reuse-based guessing model that can accurately capture users' comprehensive password reuse behaviors remains a challenging task.

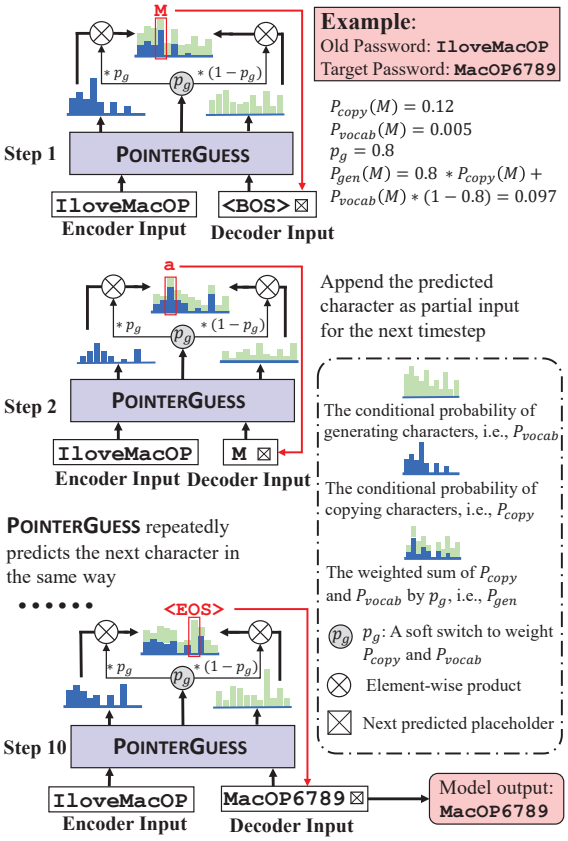

Figure 1: An example of PointerGuess generating guesses. Suppose the old password is `IloveMacOP`, the target password is `MacOP6789`. At each timestep, PointerGuess generates two conditional probabilities, P_{copy} and P_{vocab}, respectively. `<BOS>`/`<EOS>` represents the start/end of the generation.

To address these issues, we propose a new targeted guessing model, PointerGuess (see Fig. 1 for a high-level view), directly taking password characters as input and output, to avoid the need for defining numerous atomic edit operations. Additionally, unlike [38, 57], it trains on the entire dataset without filtering out any distant password pairs. By using the pointer mechanism [50], PointerGuess figures out how likely it is to copy characters from the old password and how likely it is to create new characters, enabling PointerGuess to capture both personal and population-wide reuse behaviors (e.g., using popular passwords and substituting long segments). Particularly, within 100 guesses, PointerGuess achieves a success rate that is 38.18% on average higher than its counterparts. Furthermore, we propose MS-PointerGuess for attack scenarios with the victim's multiple leaked passwords. Experimental results demonstrate that MS-PointerGuess outperforms PointerGuess in practical scenarios.

1.2 Related work

The first targeted guessing algorithm based on password reuse was proposed by Das et al. at NDSS'14 [14]. They introduced

a heuristic algorithm that applies eight transformation rules (e.g., insertion and deletion) to the old password of a victim in a predetermined order to generate guesses. While this algorithm demonstrates superior performance compared to some trawling guessing algorithms like PCFG [59], it remains entirely heuristic in nature. Its fundamental limitation is that it uses the same transformation rules across all users, lacking consideration for personalized rule priority.

At CCS'16, Wang et al. [56] proposed TarGuess-II based on the PCFG algorithm. As the first probabilistic-based targeted password model, its key idea is that the user performs only one operation (e.g., insertion, deletion) on her old password or password structure once at a time. It analyzes the transformation path between the password pairs to learn the probability of the corresponding transformation. It could output guesses in descending order of probability when generating guesses.

At IEEE S&P'19, Pal et al. [38] proposed a password reuse model based on deep learning, named Pass2Path. It utilizes a seq2seq model [49] and conceptualizes its task as predicting the edit-operation path from the old password to the new password. Pass2Path can intuitively predict the edit operations and accurately generate guesses.

One limitation of Pass2Path [38] is that it can not capture the impact between the editing operations and the corresponding editing effects. Accordingly, Wang et al. [57] proposed a new algorithm called Pass2Edit. Unlike Pass2Path, Pass2Edit models the new password generation task as a classification task and uses a multi-step decision-making training mechanism to capture users' reuse behaviors. However, both Pass2Edit and Pass2Path use *atomic* edit operations, once at a time and fiter out "dissimilar" password pairs during training, and thus they can not model transformation operations on long segments effectively.

At USENIX Security'23, Wang et al. [58] introduced RFGuess-reuse, a targeted password guessing model. It represents password prefixes as high-dimensional vectors and employes a random forest classifier to predict each edit operation for each type of string. Results show that RFGuess-reuse performs comparably to TarGuess-II [56] and Pass2Path [38].

1.3 Our contributions

We summarize our main contributions as follows:

- **A new targeted guessing model**. We introduce the pointer mechanism into the password reuse research domain and propose a new targeted password guessing model, PointerGuess. By leveraging the pointer mechanism, PointerGuess can effectively identify what the user wants to copy/keep and what the user wants to tweak from the old password. Furthermore, considering the increasingly realistic scenario of multiple password leakage for common users, we propose a brand-new targeted guessing model, MS-PointerGuess, to assess the threat of attackers using multiple old passwords to compromise the target password. By hierarchically redefining "password reuse" on two levels, we demonstrate the effectiveness of PointerGuess and provide a new angle to understand the performance of existing models.
- **Extensive evaluation**. We demonstrate the effectiveness of PointerGuess on 12 practical attack scenarios by employing 11 large-scale password datasets. More specifically, within 100 guesses, PointerGuess outperforms the state-of-the-art models by 38.17% on average, without counting identical password pairs and mixing an extra popular password dictionary. Furthermore, we demonstrate the superior performance of MS-PointerGuess over our PointerGuess in two practical attack scenarios. More specifically, within 100 guesses, the MS-PointerGuess achieves a success rate 31.21% (on average) higher than PointerGuess.
- **A password reuse-based password strength meter**. We introduce a password reuse-based password strength meter, called PR-PSM, by integrating Zxcvbn [60] with PointerGuess to enhance the evaluation accuracy. Our experiments demonstrate the importance of considering password reuse attacks for improving personalized PSMs, and highlight the importance of avoiding password reuse for security-critical accounts.
- **Some insights**. Our analysis shows that PointerGuess can capture complex password reuse behaviors (e.g., `1991322322` → `1.99132E+12`). These findings enhance our understanding of password reuse and showcase the effectiveness of PointerGuess. Moreover, our results indicate that in multiple old password reuse attack scenarios, the target password is more likely to be found within old passwords, highlighting the increased risk of multiple password compromises against users.

2 Background

2.1 Modeling password guessing probability

There are two approaches for neural network-based models to compute the conditional password probability: (1) directly predicting the targeted password character sequence (e.g., PassTrans [21]); and (2) predicting the atomic edit operation sequence from the old password to the target password (e.g., Pass2Path [38] and Pass2Edit [57]). The first approach focuses on predicting the exact character sequence by modeling conditional probabilities of generating each character, and we can express the conditional probability $P(pw_B|pw_A)$ as

$$\begin{aligned} P(pw_B|pw_A) &= P\left(c_1^{'},c_2^{'},...,c_M^{'}|c_1,c_1,...,c_N\right) \\ &= \prod_{i=1}^{M} P\left(c_i^{'}|pw_A,c_{<i}^{'}\right), \end{aligned} \tag{1}$$

where $c_{<i}^{'} = (c_1^{'},..,c_{i-1}^{'})$ denotes the subsequence of pw_B, and how to model $P\left(c_i^{'}|pw_A,c_{<i}^{'}\right)$ depends on the specific model.

The second approach aims to predict the atomic edit operation sequence needed to transform the old password into

the targeted password. We denote $\tau_{A,B} = (e_1, e_2, ..., e_E)$ as the transformation path from pw_A to pw_B. The conditional probability is modeled to estimate the likelihood of each edit operation given the old password. In this case, we can express the conditional probability $P(pw_B|pw_A)$ as

$$P(pw_B|pw_A) = P(\tau_{A,B}|pw_A) = \prod_{i=1}^{E} P(e_i|pw_A, e_{<i}), \quad (2)$$

where the $e_{<i}$ denotes the subsequence of $\tau_{A,B}$, which is $(e_1, .., e_{i-1})$, and the specific formula of the conditional probability $P(e_i|pw_A, e_{<i})$ depends on the specific model. Most recent targeted password guessing models (e.g., Pass2Path [38] and Pass2Edit [57]) are based on the second approach.

Predicting the atomic edit operation sequence can intuitively capture the transformations in password reuse, providing insights into the specific operations required. However, employing this approach requires defining a substantial number of atomic operations, which limits the model's ability to generate long/complex operation sequences (i.e., giving very low probabilities to such sequences). Thus, PointerGuess employs the first approach to model the conditional password probability in a novel manner. See details in Sec. 3.2.

2.2 Password similarity metrics

Generally, two main types of similarity metrics are commonly used to measure password similarity: syntactic metrics [20, 38, 57] and semantic metrics [14, 52]. Syntactic metrics calculate the "structural distance" (e.g., edit distance and cosine similarity) as a similarity score, while semantic metrics focus on capturing the structural and semantic similarity between passwords. For instance, Wang et al. [52] presented a workflow with eight rules (e.g., leet and reversal) to quantify users' password reuse behaviors.

In this paper, we primarily consider four representative syntactic metrics due to their simplicity and sufficiency for our use in latter sections:

Spatial distance-based metrics. These metrics measure the spatial distance between passwords, considering their structure/character-level differences, such as cosine similarity [57] and edit distance [27]. They primarily focus on the positional and directional differences or equally the number of operations needed to transform one password into another.

Sequence alignment-based metrics. These metrics align the character sequences of two passwords to identify common segments and measure the similarity based on the alignment, such as the Needleman-Wunsch algorithm [35] and the Largest Common Substring algorithm [14], which consider the order and position of characters in the sequences.

Overlap-based metrics. These metrics quantify the overlap or common strings between passwords, providing a similarity score based on the common characters (e.g., the Dice coefficient [15]). They focus on the common elements between passwords rather than their structural differences.

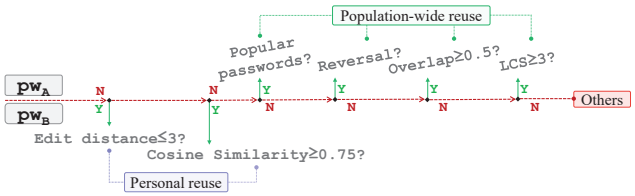

Figure 2: The workflow of detecting password reuse behaviors based on the new password reuse definition. "Others" refers to unmatched password pairs.

Combination metrics. Combination metrics provide a comprehensive measurement of similarities by integrating multiple individual metrics. In the work by Guo et al. [20], a combination of edit distance and cosine similarity is employed to capture both structural and semantic aspects of password similarities. Edit distance focuses on the absolute positional dimension, quantifying the atomic operations (e.g., insertion, deletion, and substitution) needed to transform one password into another, while cosine similarity gauges syntactic resemblance by further considering the angle between vectors representing passwords in a high-dimensional space.

3 PointerGuess: A targeted password reuse guessing model based on pointer mechanism

In this section, first, we introduce a hierarchical definition of "password reuse", which provides a new angle to understand users' password reuse behaviors. Second, we describe our model, PointerGuess, and how to model the conditional password probability using PointerGuess. Third, we detail our model methodology and hyperparameters.

3.1 A new definition of password reuse

As mentioned in Sec. 1.1, existing targeted password guessing models (e.g., Pass2Path [38] and Pass2Edit [57]) have inherent limitations. They prefer to use syntactic metrics (e.g., edit distance [38] and cosine similarity [57]) to measure password similarities and evaluate their effectiveness in characterizing users' password reuse behaviors. To accurately capture users' password reuse behaviors, we propose a new definition of "password reuse" (combining both syntactic and semantic metrics, as depicted in Fig. 2), which hierarchically categorizes users' password reuse behaviors into two distinct levels: personal reuse and population-wide reuse.

Personal reuse refers to the simple modifications that users tend to apply to their old passwords based on their preferences and the characteristics of old passwords. These modifications typically involve a limited number of edit operations, such as adding/deleting the first/last character and/or replacing a character with visually similar alternatives (e.g., replacing `a` with `@`). These new passwords, primarily created through personal reuse, can be easily identified as instances of password reuse using syntactic metrics (e.g., edit distance [38]).

Population-wide reuse refers to some more complex and challenging-to-identify password reuse behaviors. In general, it relates to users' reuse patterns that can be observed across

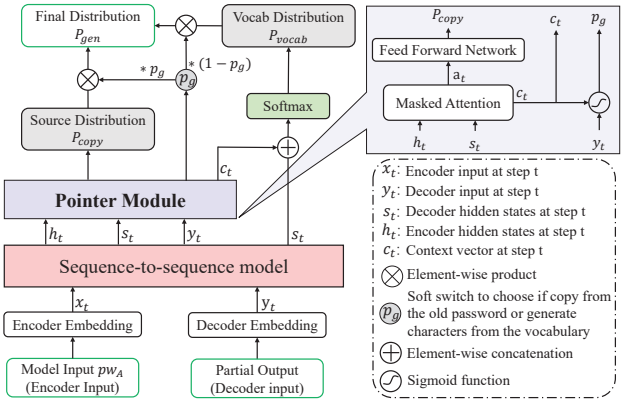

Figure 3: Model architecture of PointerGuess, which is based on [45, 50] and consists of a basic seq2seq model [49] and a pointer module. P_{gen} (i.e., "Final Distribution") denotes the conditional password probability of PointerGuess generating the next character, P_{copy} and P_{vocab} are the conditional probabilities of copying characters from the old password, and of generating new characters from the vocabulary, respectively. PointerGuess employs a soft switch p_g to decide whether to copy characters from the old password or generate new characters from the vocabulary.

the entire dataset, encompassing the reuse of popular passwords (which are frequently chosen by a substantial number of users, e.g., `KeveinMobile` → `password123`). Furthermore, it extends to reusing some specific popular password segments, like `KevinMobile` → `Kevin@gmail.com`.

3.2 Modeling conditional guessing probability

As discussed in Sec. 2.1, we adopt the directly predicting characters approach (i.e., Eq. 1) to address limitations in Pass2Edit [57] and Pass2Path [38]. We start with a basic sequence-to-sequence (seq2seq) model, utilizing it to directly model the similarity between users' target and old passwords. However, the basic seq2seq model may neglect the impact of low-frequency yet crucial characters in a given old password (i.e., the encoder input) on predicting subsequent characters.

For example, as shown in Fig. 1, the basic seq2seq model struggles to generate '`M`' as the first character due to the infrequent occurrence of '`M`' as the first character in the training set. More specifically, at the first step, it assigns an extremely low probability to '`M`' (i.e., $P_{vocab}(\texttt{M}) = 0.005$). This highlights the challenge of modeling the conditional password probability: *How to assign a sufficient likelihood to those crucial characters that appear in the given old password but have low frequency in the training set*.

To address this issue, we introduce the *Pointer Module* to add additional likelihood for those characters appearing in the old password. Our PointerGuess incorporates P_{vocab} (the conditional probability of generating characters from vocabulary, i.e., 95 printable characters) and P_{copy} (the conditional probability of copying from the old password), to model the conditional password probability (P_{gen}). As shown in Fig. 1, after incorporating P_{copy}, the probability of generating '`M`' significantly increases (i.e., $P_{gen}(\texttt{M}) = 0.097 \gg P_{vocab}(\texttt{M}) = 0.005$). In each subsequent step, PointerGuess dynamically adjusts the probabilities of each character through P_{copy} and P_{vocab}, gradually approaching the correct target password (i.e., `MacOP6789`). Below, we formally describe how PointerGuess models the conditional password probability.

As shown in Fig. 3, at each timestep t, PointerGuess uses pw_A as the input to produce encoder input x_t, and uses the previously generated character sequence as decoder input y_t. The basic seq2seq model of PointerGuess outputs encoder hidden states h_t and decoder hidden states s_t. Subsequently, PointerGuess computes the conditional probability of generating characters from the vocabulary, i.e., P_{vocab}, as

$$P_{vocab} = softmax\left(W'\left(W * [s_t, c_t] + b_{out}\right) + b'_{out}\right), \quad (3)$$

where $[s_t, c_t]$ denotes concatenating s_t and c_t, W, W', b_{out}, b'_{out} are learnable parameters, and c_t is the context vector at timestep t. c_t represents the context information learned from the encoder input (i.e., pw_A) at timestep t.

Additionally, PointerGuess employs the *Pointer Module* to capture user-specific patterns and reuse behaviors, producing the conditional probability of copying characters from the old password, i.e., P_{copy}, which can be expressed as

$$P_{copy}(c) = FFN\left(\sum_{j:c_j=c} a^t_j\right), \quad (4)$$

where $FFN(\cdot)$ is a feed-forward network used to rescale the attention vector a^t generated by the pointer module at timestep t. If the input sequence does not contain the token c, then the value of $P_{copy}(c)$ is zero.

To facilitate flexible decision-making on *whether to copy characters from the old password or generate new characters from the vocabulary*, PointerGuess utilizes a soft switch p_g, which is

$$p_g = \sigma(W_c * c_t + W_s * s_t + W_y * y_t + b_g), \quad (5)$$

where W_c, W_s, W_y, b_g are learnable parameters. y_t is the decoder input at timestep t and $\sigma(\cdot)$ is a sigmoid function.

Finally, PointerGuess integrates P_{vocab} and P_{copy} to generate P_{gen}, representing the conditional password probability P_{gen}, which is expressed as

$$P_{gen}(c) = p_g * P_{copy}(c) + (1 - p_g) * P_{vocab}(c). \quad (6)$$

This allows PointerGuess to dynamically decide between copying characters from the old password and generating new characters from the vocabulary.

3.3 Methodology and configuration

As shown in Fig. 4, PointerGuess consists of three phases: Preprocess, training, and generation. We now present the workflow of PointerGuess that tackles model training and guess generation, and detail the preprocess phase in Sec. 4.

Model architecture. As shown in Fig. 3, our PointerGuess mainly consists of a sequence-to-sequence model (with an encoder and a decoder) and an extra *Pointer Module* [50]. The encoder is a 1-layer Bi-LSTM, which is used to capture the

Table 1: Data cleaning of 13 password datasets leaked from various web services ("PWs" stands for passwords).

‡RedMart passwords are in salted-hash, and we use them as real targets in attack scenario #8 (000Webhost → RedMart). See more details in Table 2.

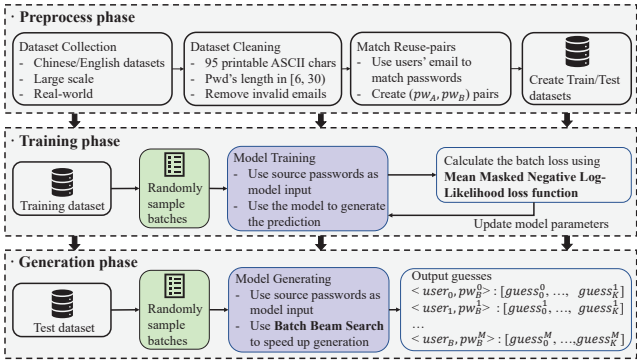

Figure 4: The workflow of PointerGuess. There are three phases: Preprocess, Training, and Generation. Specifically, M and K denote the number of users per batch and Top-K password guesses for each user, respectively.

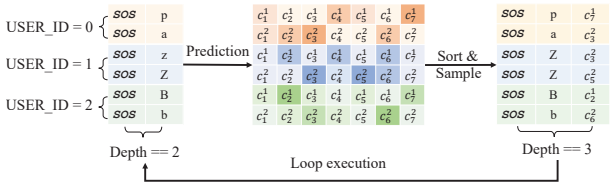

Figure 5: An example of batch-beam search.The batch size is three and beam size is two. ***SOS*** is the start symbol. Darker color means higher probability. For example, the second user (i.e., `USER_ID` = 1) choose c_3^2 and c_5^2 (which denote the predicted characters) due to their high probabilities. Guess generation will continue until all users are completed.

contextual information of the old password. The decoder is a 1-layer Bi-LSTM used to generate conditional guesses based on the captured contextual information from the encoder. We set the hidden dimension of encoder and decoder as 128. We add an extra *reduce layer* to process the output of the encoder and decoder, which is used to aggregate the encoder's output and further improve the performance of our model.

Additionally, we integrate a *Pointer Module* [50] into our PointerGuess, comprising an attention network and a feed-forward network. The attention network highlights relevant parts of the old password during model decoding. It generates the attention vector and employs a sigmoid function to yield the context information vector at each timestep.

Training phase. During this phase, PointerGuess randomly samples batches of password pairs (X_{BS}, Y_{BS}) from the training set, where X_{BS} represents the old passwords, and Y_{BS} represents the corresponding target passwords. Our model inputs the old passwords and generates guesses at the character level, denoted as $\hat{Y}_{BS}$. The training objective involves a loss function, denoted as $\mathcal{L}$, which measures the log probability of $\hat{Y}_{BS}$ being aligned with the ground truth passwords Y_{BS}. The goal of $\mathcal{L}$ is to find the optimized parameters θ^*, which are

$$\theta^* = \arg\min_{\theta} \left(\mathcal{L}_\theta \left(Y_{BS}, \hat{Y}_{BS} \right) \right), \tag{7}$$

where θ denotes model parameters. We use Mean Masked Negative Log-Likelihood as our loss function and the Adam optimizer [23] to optimize parameters based on computed gradients. The training process is repeated over multiple epochs (e.g., set to 50), with shuffling and batch division of the data.

Generation phase. As shown in Fig. 4, PointerGuess generates K guesses for each user using the given old password. Furthermore, we implement the Batch Beam Search algorithm based on [61] to improve efficiency and leverage parallel computing on GPUs. As shown in Fig. 5, the algorithm generates top-K guesses simultaneously for all users (e.g., M users) in a batch, selecting the top candidates based on their probabilities. Password generation process continues until the desired number of guesses is obtained for all users.

Model hyperparameter configuration. During the generation process, we perform log-softmax operations on the conditional probability predicted by the model at each timestep. To ensure the predicted probability is not zero, we select ε=1e-12 as our smoothed value. We denote the vocabulary as Σ, consisting of 95 printable ASCII characters and four special identifiers (i.e., `<EOS>`, `<SOS>`, `<PAD>`, and `<UNK>`), and the vocabulary size $\|\Sigma\|$ is 99. Without loss of generality, we implement Bahdanau et al.'s attention mechanism [7] in our model, and set the learning rate as 0.001 and the number of training epochs as 50. We use the Dropout [48] to alleviate overfitting, and the dropout rate is set to 0.5, which means that there are 50% neurons randomly selected to be invalid and not considered in gradient operations.

4 Experiments and analysis

4.1 Dataset cleaning and ethical consideration

Datasets. We demonstrate the effectiveness of PointerGuess and compare it with other state-of-the-art models based on 11 large-scale real-world datasets, a total of 4.8

Table 2: Setups of 14 different attack scenarios (see detailed results in Fig. 6).[‡]

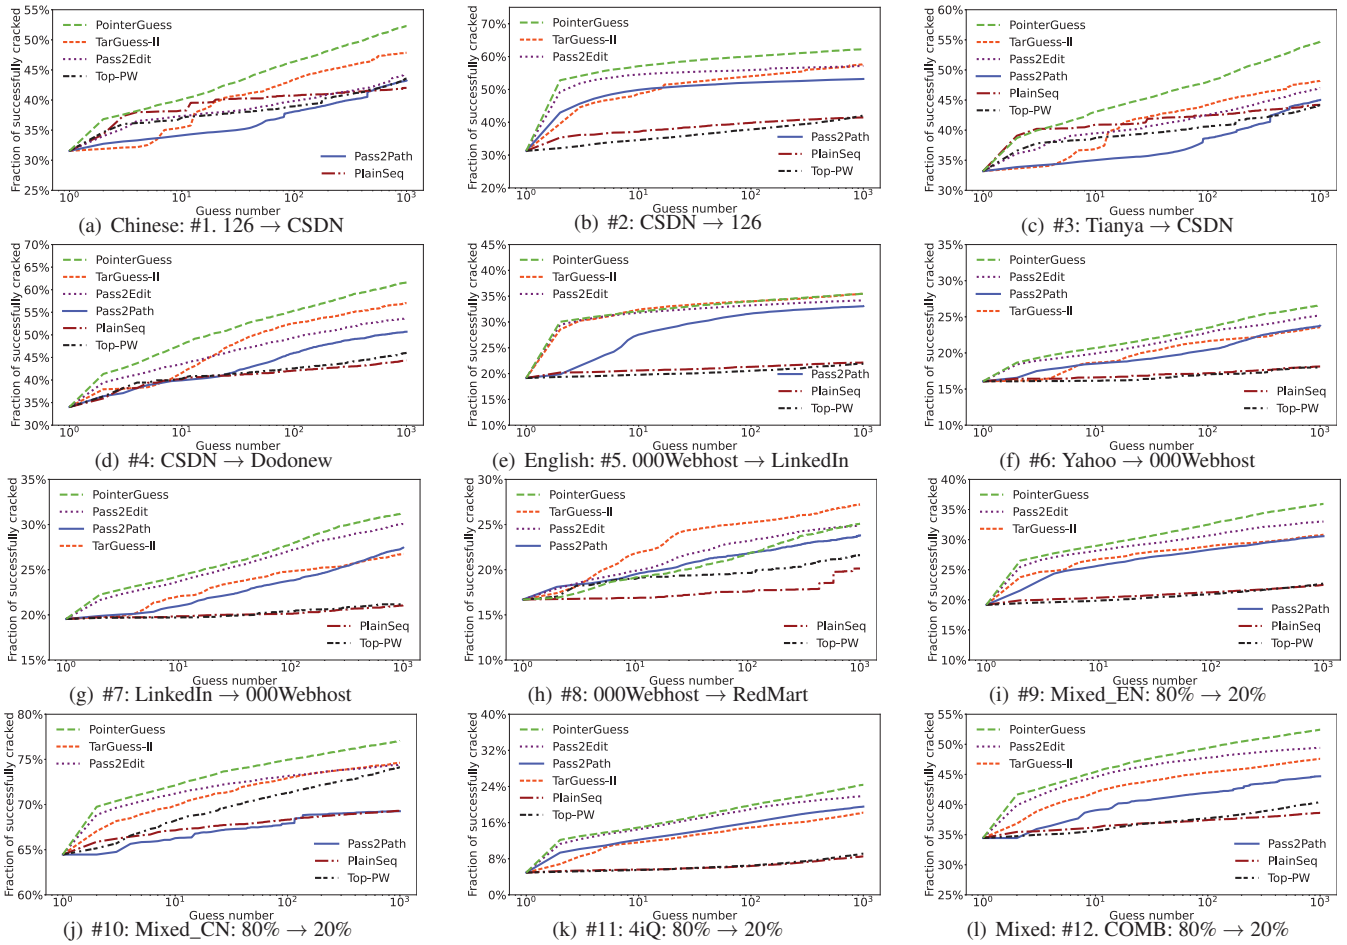
[‡] $A \rightarrow B$ (e.g., #1. 126 → CSDN) means that: A user's password at service A can be used by an attacker to help attack this user's account at service B. Note that for #13A and #14A, we represent the attack scenarios as $A1, A2 \rightarrow B$, which means that a user's passwords at services $A1$ and $A2$ can be used by an attacker to help herself attack the same user's account at service B. The sub-scenarios #13B∼#13C and #14B∼#14C are the sub-scenarios for #13A and #14A, respectively.

[*] The *Union* dataset is built by matching ClixSense, LiveAuctioneers and 4iQ using email. Note that we remove any data item with fewer than three passwords.

[†] The *Basic* strategy (defined in Sec. 4.1) involves the removal of invalid emails and non-human created passwords. Cleaning strategies need to exclusively focus on the site B in the $A \rightarrow B$ pairs. E.g., for Yahoo → LinkedIn and LinkedIn → Yahoo, the initial number of password pairs is identical. However, after applying the LD strategy (which means retaining passwords with at least one letter and one digit) to LinkedIn, its number becomes 40,646, while after applying LD and Len≥6 to Yahoo, its number becomes 40,812. This explains the differences in the number of data items for Yahoo → LinkedIn (LD) and LinkedIn → Yahoo (LD and Len≥6).

billion passwords (see Table 1). To ensure a comprehensive and reliable evaluation of our models and their counterparts, besides four English and five Chinese datasets, we further employ two synthesised large-scale datasets, 4iQ [2] and COMB [3]. All these datasets in Table 1 were leaked and published on the Internet from 2011 to 2021 and are representative of current real users' reuse behavior. Particularly, (1) 4iQ and COMB are two massively mixed datasets [2, 3] consisting of large datasets exposed by previous breaches (e.g., LinkedIn, Netflix); (2) RedMart [4] is an online grocery platform whose servers store all passwords in salted-hash. These passwords serve as *real* targets (as with [57]); (3) 000Webhost is a website used by web administrators, so its users are more likely to have higher security awareness. Thus, the experiments involving 000Webhost in attack scenarios #6 and #7 represent evaluation on security-savvy users (see Table 2).

Ethical consideration. Though ever available on the Internet and dark web (and widely used in the literature [14,38,57,58]), these datasets are private data. Thus, we take three precautionary measures to ensure that there is no additional harm to users: (1) All our datasets are stored and processed on computers not connected to the Internet; (2) Only report the aggregated statistical information and some typical password examples (without PII), i.e., treat each account as confidential, so that using it in our work will not bring new risks to the corresponding victim; (3) Delete all the intermediate sensitive data (e.g., email and datasets of target guesses) once our analysis is completed. These datasets may be exploited by malicious parties for misconduct, while our use is beneficial for the community to understand password strength and for security administrators to make more informed decisions.



Dataset cleaning. First, we remove data items with an empty/invalid email. We also keep passwords that are $Len<30$ and only contain 95 printable ASCII characters. We call this as the *Basic* cleaning strategy. We will adaptively adjust this strategy for different websites according to their password policy (see more details in Table 1).

4.2 Experimental setup

To better evaluate the effectiveness of our PointerGuess, we design 12 practical attack scenarios (see Table 2) by employing datasets described above (see Table 1). More specifically, we use email to match two datasets to create training/test datasets. For instance, 126 → CSDN means matching 126 with CSDN (by using email) and getting 85,206 password pairs. We design attack scenarios #1∼#4 and #5∼#8 for Chinese and English users, respectively. All selected test sets, except for the scenario #8 (where RedMart passwords are in salted-hash), are in plaintext. As 000webhost is mainly used by web administrators, and we design attack scenarios #6 and #7 to simulate attacks on high-security users.

Scenarios #9 and #10 employ mixed datasets within one language, i.e., Mixed_EN and Mixed_CN, which combine multiple English (i.e., 000Webhost, LinkedIn and Yahoo) and Chinese (i.e., Tianya, Dodonew, and CSDN) datasets, respectively. Scenarios #11 and #12 further evaluate users of mixed languages by employing two large-scale synthesized datasets 4iQ and COMB. These four additional evaluation setups are in accord with that of [57].

In Sec. 6, we introduce MS-PointerGuess designed for multiple password reuse attack scenarios. To demonstrate its effectiveness, we design two practical attack scenarios #13 and #14 (see Table 2 for details), with each consisting of a main scenario for MS-PointerGuess and two sub-scenarios for comparison with PointerGuess. We design scenario #13 (#13A∼#13C) for Chinese users, which evaluate the cases when the attacker gets *two* old passwords of the victim. This allows us to fairly compare the effectiveness of

(a) Chinese: #1. 126 → CSDN (b) #2: CSDN → 126 (c) #3: Tianya → CSDN

(d) #4: CSDN → Dodonew (e) English: #5. 000Webhost → LinkedIn (f) #6: Yahoo → 000Webhost

(g) #7: LinkedIn → 000Webhost (h) #8: 000Webhost → RedMart (i) #9: Mixed_EN: 80% → 20%

(j) #10: Mixed_CN: 80% → 20% (k) #11: 4iQ: 80% → 20% (l) Mixed: #12. COMB: 80% → 20%

Figure 6: Experiments for attack scenarios #1∼#12, for each of which the training set is shown in Table 2 and the test set is as the sub-title. Our PointerGuess achieves the highest cracking success rate in 10 of 12 scenarios over its foremost counterparts TarGuess-II [56], Pass2Edit [57] and Pass2Path [38].

PointerGuess with MS-PointerGuess.

We design scenario #14 (#14A∼#14C) for English users. We match ClixSense, LiveAuctioneers, and 4iQ by emails, ensuring a minimum of three passwords for each data item in the matched dataset called *Union*. We randomly select 80% of the *Union* as the training set and the rest 20% as the test set. Additionally, to comprehensively evaluate our models' performance, we construct $Union_{A1}$ and $Union_{A2}$ for scenarios #14B and #14C, based on the source data, respectively.

State-of-the-art models for comparison. We compare our model with three state-of-the-art models (i.e., TarGuess-II [56], Pass2Path [38], and Pass2Edit [57] and their variants), as well as other relevant models (e.g., Top-PW and PlainSeq). To evaluate the impact of the pointer module on model performance, we use a basic seq2seq model, called PlainSeq, *without* utilizing the pointer module. We provide a briefly overview of these models in Appendix A. As CPG [40] and ReSeg-PCFG [51] are tailored for trawling guessing or mask guessing rather than password reuse-based attacks, and RFGuess-reuse achieves comparable performance with TarGuess-II [56] and Pass2Path [38] (see Table 5 in [58] for details), we exclude them from our model comparison.

Experimental environment. We randomly sample 20,000 passwords for test sets exceeding 20,000 as previous studies [38,57] have proved that using over 10,000 password pairs leads to performance convergence. We perform all experiments on a workstation with an Intel Xeon Silver processor and a GPU of NVIDIA RTX 3090 (24GB of VRAM), an experimental environment most attackers can easily build.

4.3 Experimental results

Here we briefly analyze the results of attacking scenarios #1∼#12. As with [14, 38, 57, 58], we use the guess-number graph to evaluate the performance of PointerGuess and its counterparts (see more details about these models in Appendix A). Moreover, we present exact crack rates for specific guess numbers (e.g., 10, 100, and 1,000), which are commonly concerned in password security studies [38, 56, 57] and standard (e.g., NIST [19]). See more detailed results in Appendix G of the full version at https://bit.ly/3wGx9Ke.

Overall analysis. Due to the presence of identical password pairs (i.e., $pw_A = pw_B$) in each test set, we present the experimental results of scenarios #1∼#12 in two cases: one without identical password pairs and the other with.

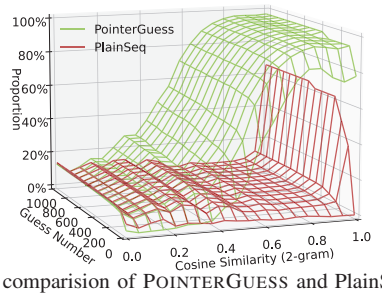


Figure 7: The comparision of PointerGuess and PlainSeq's ability in cracking passwords with different cosine similarity (2-gram) thresholds. Here we take scenario #2 (CSDN → 126) for example.

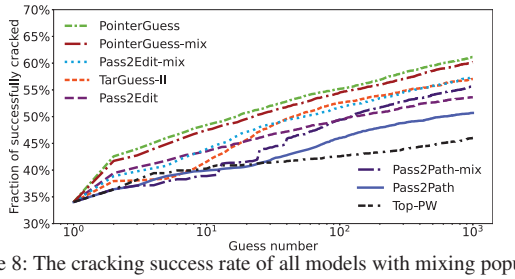

Figure 8: The cracking success rate of all models with mixing popular passwords (using scenario #4: CSDN → Dodonew as an example). A model with the suffix "-mix" means that it is an adjustment to its original model by mixing popular passwords in the same strategy with [57].

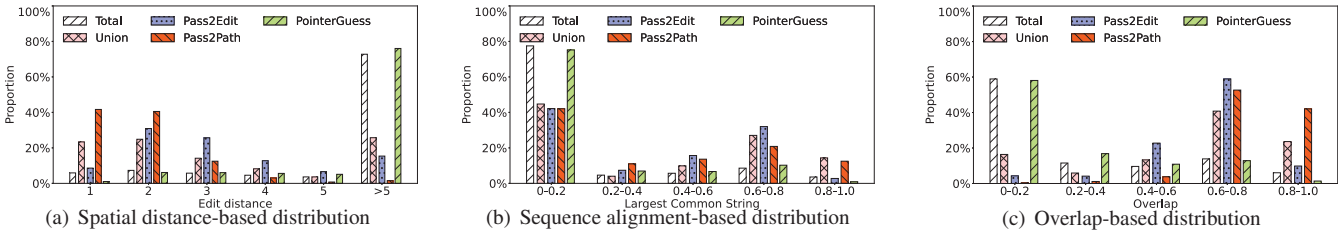
In the former case (i.e., without identical password pairs), as shown in Table 8 of the full version, within 1,000 guesses, the success rates of PointerGuess are 10.08% ∼ 45.00% (avg. 25.85%), while that of Pass2Edit [57], Pass2Path [38], and TarGuess-II [56] are 9.82%∼37.62% (avg. 20.39%), 8.52%∼31.87% (avg. 16.28%), and 8.92%∼38.38% (avg. 20.61%). That is, the guessing success rates of PointerGuess are 21.58%, 52.27%, and 20.61% (on average) higher than Pass2Edit, Pass2Path, and TarGuess-II, respectively.

In the latter case (i.e., with identical password pairs), as shown in Table 9 of the full version, within 1,000 guesses, the success rates of PointerGuess are 24.36% ∼ 77.03% (on average 44.91%), while that of Pass2Edit [57], Pass2Path [38], and TarGuess-II [56] are 21.88%∼74.39% (on average 41.25%), 19.54%∼69.26% (on average 38.64%), and 18.20%∼74.62% (on average 41.25%), respectively. That is, the guessing success rates of PointerGuess are 8.87%, 16.23%, and 8.87% (on average) higher than Pass2Edit, Pass2Path, and TarGuess-II, respectively.

Compare with the baseline (PlainSeq). To better illustrate the role of the pointer mechanism [50], we conduct a further comparison between PointerGuess and the basic seq2seq model [49] without the pointer mechanism [50], i.e., PlainSeq. Fig 7 shows their performance in cracking passwords under different cosine similarity (2-gram) thresholds. Results show that PointerGuess drastically outperforms PlainSeq, especially in cases where the cosine similarity threshold ranges from 0.8 to 1.0. We further analyze the password cracked by PointerGuess, and find that PointerGuess excels in cracking: 1) password pairs whose target passwords are created by adding or deleting uncommon substrings from the old passwords (e.g., `585129wupan` → `585129`); and 2) password pairs whose cosine similarities are large but also with a large edit distance, such as `1000020000` → `100200` whose cosine similarity is 0.91 and edit distance is 4.

The impact of language on performance. We now compare the effectiveness of PointerGuess in Chinese (#1∼#4) and English (#5∼#8) attack scenarios. As shown in Fig. 6, the experimental results demonstrate that PointerGuess outperforms other models in all Chinese scenarios. In English scenarios, our model still achieves higher or comparable performance. Notably, PointerGuess significantly outperforms other models when attacking security-savvy users (see scenarios #6 and #7 that attack 000webhost).



It is worth noting that our PointerGuess shows a much higher success rates in Chinese scenarios than in English ones. This can be largely attributed to the facts that: (1) English scenarios all involve users of 000Webhost, who are web administrators and thus possess a higher level of security awareness than common users [56]; (2) there exist vast differences in structural and semantic characteristics between Chinese and English passwords, and the strength of Chinese passwords is weaker in online guessing scenarios (i.e., when the guess number allowed for the attacker is small [55]).

Mixing with external popular passwords. We explore the impact of mixing external popular passwords on the performance of PointerGuess and other models in attack scenarios #1∼#12. We adopt the same mixing strategy as in [57]. Fig. 8 shows that all models (except for PointerGuess) have a significant increase in crack rates after mixing external popular passwords. Pass2Edit [57] and Pass2Path [38], in particular, improve performance significantly after mixing popular passwords, which is mainly due to their inherent defect of overlooking users' macroscopic population-wide reuse behaviors (see Sec. 1.1). While excluding identical password pairs, within 1,000 guesses, the success rates of PointerGuess-mix are 10.38%∼45.50% (avg. 25.87%), while that of Pass2Edit-mix, Pass2Path-mix are 10.96%∼45.70% (avg. 24.58%) and 8.52%∼31.87% (avg. 16.28%), respectively. That is, the guessing success rates of PointerGuess-mix are 5.25% and 58.91% (on average) higher than Pass2Edit-mix and Pass2Path-mix, respectively.

While not excluding identical password pairs, within 1,000 guesses, the success rates of PointerGuess-mix are 23.95%∼62.55% (avg. 44.94%), while that of Pass2Edit-mix, Pass2Path-mix are 22.96%∼62.68% (avg. 44.04%) and 19.85%∼57.97% (avg. 41.27%). That is, the guessing success rates of PointerGuess-mix are 2.04% and 8.89% (on average) higher than Pass2Edit-mix and Pass2Path-mix.

5 Further analysis

We analyze characteristics of passwords cracked by different models, employing various similarity metrics to explore users' password reuse from both "syntactic" and "semantic" perspectives. To demonstrate models' performance accurately, we adopt a new "password reuse" definition (as discussed in

(a) Spatial distance-based distribution (b) Sequence alignment-based distribution (c) Overlap-based distribution

Figure 9: Syntactic metric distributions of independently cracked password pairs by three major models. Figs. 9(a)∼9(c) show the example of similarity distributions based on spatial-distance metric (i.e., edit distance [27]), sequence-alignment metric (i.e., Largest Common String algorithm [14]) and overlap-based metric (i.e., Overlap [26]), respectively. "Total" represents all password pairs in all test sets and "Union" represents all password pairs cracked by three models.

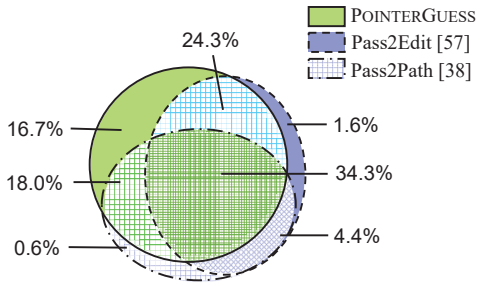


Figure 10: The overlap ratios of cracked password pairs by three models.

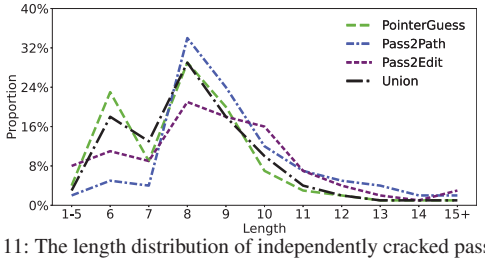

Figure 11: The length distribution of independently cracked passwords.

Sec. 3.1) to measure similarity distributions. Additionally, we investigate existing models' performance and limitations based on similarity distributions of cracked passwords.

5.1 Characteristics of cracked passwords

Overlap. To compare the cracking capabilities of PointerGuess, Pass2Edit [57], and Pass2Path [38], we examine the overlap in *uniquely* cracked password pairs across 12 attack scenarios (i.e., 29,252 of 89,951 all cracked password pairs). Fig. 10 shows a total overlap rate of 34.3% (10,033 of 29,252) among the three models. For *independently* cracked password pairs, PointerGuess has a 16.7% overlap (4,885 of 29,252), while that of Pass2Edit and Pass2Path are 1.6% (468 of 29,252) and 0.6% (176 of 29,252), respectively.

Notably,the overlap between PointerGuess and either Pass2Edit or Pass2Path is significantly higher (i.e., 24.3% = 7,108/29,252, and 18.0% = 5,265/29,252, respectively) compared to the intersection between Pass2Edit and Pass2Path (i.e., 4.4% = 1,287/29,252). This highlights that PointerGuess is good at what Pass2Edit and Pass2Path can do.

Length distribution. Here we use the password pairs *independently* cracked by each of these three models to explore their differences in cracking passwords of varied lengths. Fig. 11 shows that our model primarily focuses on passwords with lengths of 6 and 8∼10 due to the fact that PointerGuess can capture users' macroscopic population-wide reuse behaviors, e.g., using popular passwords (which are typically of length 6 and 8) and substituting long segments (like `yjqqq916198` → `916198yj`). Notably, the length distributions of our model and the union set (denoted as "*Union*" in Fig. 11) exhibit a high degree of similarity (i.e., have two peaks), which highlights that PointerGuess is good at cracking passwords of lengths that Pass2Edit [57] *and/or* Pass2Path [38] are good at.

5.2 Characterize password reuse behaviors

We conduct further evaluations on the performance of different models in characterizing user's password reuse behaviors. We employ various similarity metrics (as we mentioned in Sec. 2.2) to evaluate different models' ability on cracking password pairs with different similarity scores.

First, we employ syntactic metrics to measure the distribution of independently cracked password pairs. As shown in Fig. 9, PointerGuess exhibits superior performance on low-similarity cases, *attributing this to its ability in predicting targeted password character sequences without excluding unsimilar password pairs from the training set.* This allows PointerGuess to generate tweaked passwords with low similarity to the old password, including those with edit distances >5 (see examples in Table 3).

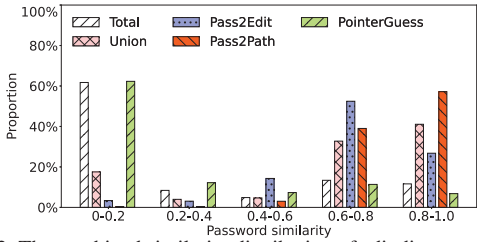

Figure 12: The combined similarity distribution of edit distance and cosine similarity (2-gram) as defined in [20]. Results are similar to Fig. 9.

Fig. 9 illustrates that Pass2Edit [57] and Pass2Path [38] exhibit "overfitting", as the similarity distribution of the cracked password pairs significantly *deviates* from the overall similarity distribution (i.e., "Total" in Fig. 9) of all password pairs in the test sets. This phenomenon implies that Pass2Edit and Pass2Path struggle to model the distribution of entire password reuse behaviors. Particularly, they face challenges in cracking password pairs with excessively long

Table 3: Ten examples of password pairs cracked independently by PointerGuess, Pass2Edit [57] and Pass2Path [38].

Models	PointerGuess		Pass2Edit [57]		Pass2Path [38]

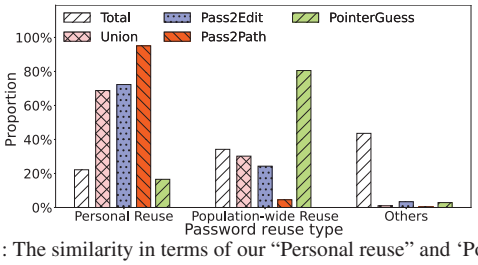
Table 4: The proportion of transformation rules.

Models	Password transformation rules %†							
	Sub.	Leet	Cap.	LCS	Rev.	Leet+LCS	Cap.+Sub.	Others
Union	71.48	0.57	4.31	63.71	0.06	36.48	1.78	9.78
PointerGuess	62.46	0.53	3.35	57.41	0.13	34.94	5.00	20.17
Pass2Edit [57]	76.75	0.60	4.53	68.03	0.01	38.69	7.02	3.13
Pass2Path [38]	78.92	0.59	5.53	68.14	0.00	36.15	8.44	1.92

†The abbreviations "Sub.", "Cap.", "LCS" and "Rev." stand for "Substring", "Capitalization", "Largest Common String" and "Reversal" respectively.



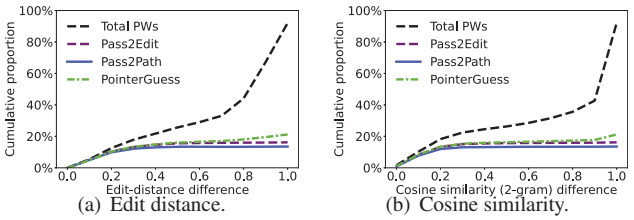


Figure 13: The similarity in terms of our "Personal reuse" and 'Population-wide reuse' and other types of reuse.

editing sequences or low similarity (e.g., `KeveinMobile` → `password123`). As shown in Fig. 12, we combine edit distance and cosine similarity (2-gram) as suggested in [20] for a comprehensive evaluation, yielding similar conclusions to other syntactic metrics.

Second, we employ semantic metrics, following the workflow proposed by Wang et al. [52], to measure the transformation rules of cracked password pairs. Table 4 shows that Pass2Edit [57] and Pass2Path [38] tend to focus on some specific transformation (e.g., "LCS") while overlooking some other complex segment-level transformations (i.e., "Others" in Table 4), e.g., transforming `yjqqq916198` to `916198yj`.

Third, as mentioned in Sec. 3.1, we introduce a hierarchical definition of "password reuse", and propose a workflow that considers both syntactic and semantic metrics (see Fig. 2). More specifically, we use a combination of edit distance and cosine similarity to identify "personal reuse" password pairs, while applying transformation rules to detect "population-wide reuse" patterns for the remaining password pairs. As shown in Fig. 13, nearly 40% of all test passwords are categorized as population-wide reuse, and PointerGuess shows a clear advantage in cracking such password pairs. We can see that another 40% of password pairs still can not be identified as reuse (see "Total" when x-axis="Others") by PointerGuess and other major models. This outlines the need for a more thorough understanding of users' reuse behaviors.

(a) Edit distance. (b) Cosine similarity.

Figure 14: Cumulative Distribution Functions (CDF) of cracking proportion on password similarity difference. Figs. 14(a) and 14(b) show the results of using edit distance and cosine similarity as metrics, respectively.

Table 5: Running time of different attack models.†

Attack model	PointerGuess	Pass2Edit [57]	Pass2Path [38]
Training time	15:14	**09:43**	14:10
Testing time	**00:24**	02:26	01:47
Speed‡ (pw/s)	**9,700∼9,800**	2,100∼2,200	2,900∼3,000
Model size (MB)	**2.26**	11	53.6

†All running time is taken from attack scenario #10, and their format is "hour:minute". All model parameters are consistent with Sec. 3.

‡Speed (of generating guesses) is calculated by dividing the total number by the total testing time, and there may be fluctuations in different scenarios.

5.3 Further exploration on model performance

Limitation of existing models. Existing models tend to lean towards generating passwords that are either "very similar" or involve "fewer edit operations" regarding old passwords. This limits their ability to effectively comprehend and capture password reuse behaviors across the entire password distribution, particularly in cases of population-wide reuse. As a result, there is a notable gap between their cracking performance and the reality of password reuse.

To demonstrate this disparity and delve deeper into the limitations of password reuse-based guessing models, we utilize Cumulative Distribution Function (CDF) curves. As shown in Fig. 14, existing models [38, 57] (that focus on generating highly similar passwords) quickly reach the stable saturation plain. In contrast, PointerGuess can crack password pairs even when the similarity differences are as large as 0.8∼1.0, which corroborates its capability in capturing "population-wide reuse" and provides a new perspective on why PointerGuess achieves higher performance than existing models.

Furthermore, when comparing the proportion cracked by the three models with the whole 89,951 unique test password pairs, a significant gap emerges. As shown in Fig. 14, the CDF curves of proportions cracked by three models deviates significantly from that of overall password pairs when the similarity difference ≥0.5. To address this issue, we intro-

Table 6: Comparison of the cracking success rate of MS-PointerGuess and PointerGuess.*

Experiment setup		Include the identical password pairs			Remove the identical password pairs		
Attack scenario	Guess number	PointerGuess-A1&A2	PointerGuess-A1	PointerGuess-A2	PointerGuess-A1&A2	PointerGuess-A1	PointerGuess-A2
#13: Tianya, 126 → Taobao	10	**43.44%**	32.22%	41.41%	**2.70%**	2.35%	2.14%
	100	**44.82%**	34.18%	43.12%	**5.08%**	4.29%	4.38%
	1,000	**45.97%**	35.62%	44.45%	**7.05%**	5.79%	6.36%
#14: 80%*Union* → 20%*Union*	10	**58.97%**	47.90%	44.30%	**10.34%**	6.07%	9.54%
	100	**61.37%**	49.70%	47.67%	**15.58%**	8.97%	15.00%
	1,000	**63.67%**	52.11%	50.80%	**20.63%**	12.99%	20.32%

*Note that the PointerGuess-A1&A2 represents our MS-PointerGuess. PointerGuess-A1 means that we feed pw_{A1} into PointerGuess and guess pw_B, and similarly for the definition of PointerGuess-A2. PointerGuess-A1&A2 means that we feed both the pw_{A1} and pw_{A2} into the MS-PointerGuess and guess pw_B.

duce our MS-PointerGuess for multiple leaked password scenarios (see details in Sec. 6).

Model attacking efficiency. Here we examine the attacking efficiency of different neural network-based models. Fig. 5 shows that the training time of PointerGuess is slightly longer than Pass2Edit [57] and Pass2Path [38], mainly because existing models need to filter the training set with some similarity threshold (e.g., edit distance<4) and this leads to a smaller training set; As for testing time, our PointerGuess runs the fastest generation speed, which is much higher than other models; Our model's size is only 2.26 MB, which is 5∼25 times smaller than other models, leading to easier local deployment and reducing the risk of information leakage.

Model preferences. Table 3 shows ten examples of password pairs cracked independently by different models. Our PointerGuess demonstrates clear preferences in complex reuse behaviors. First, PointerGuess can characterize users' vulnerable behaviors of reusing popular passwords (e.g., `abc123` in the first example). Second, PointerGuess can generate semantic fragments based on the old password (e.g., email suffixes like `@hotmail.com`), potentially assisting in guessing reused passwords. Third, PointerGuess utilizes extractive generation by identifying key parts of the old password to generate the target password, (see indexes 7∼10 in Table 3). Particularly, our model can generate numbers represented in scientific notation (e.g., `1991322322` → `1.99132E+12`). This reflects the limitations in Pass2Edit [57] and Pass2Path [38], which utilize the old password as a template for transformations (e.g., insert/delete a character) is less effective in identifying reused fragments within the old password.

Potential applications in password protection. We consider two potential applications of PointerGuess: password strength meter (PSM) and compromised credential checking (C3) services. We discuss how to design reuse-based PSM in Sec. 7 and the application in C3 services in Appendix B.

6 Multi-Source PointerGuess

Reports [13, 31] show that most users maintain over 90 accounts on average and prefer to reuse their old passwords, which impairs password security. At IEEE S&P'19, Pal et al. [38] attempted to employ multiple old passwords of a user for targeted guessing attacks by running Pass2Path multiple times and simply "merge the lists by picking one from each list in a round robin manner" [38]. Their ad hoc approach cannot accurately capture the relationships between different old passwords, and we take a principled approach.

6.1 Modeling password generation

In response to the threat posed by a realistic attack scenario involving multiple leaked old passwords, we introduce a new targeted password guessing model, MS-PointerGuess. MS-PointerGuess incorporates a "Multi-Encoder" module into PointerGuess to handle the victim's multiple leaked passwords simultaneously. More specifically, this module empowers the model to extract multiple contexts from each encoder input (i.e., old password), enabling our MS-PointerGuess to effectively characterize users' password reuse behaviors by leveraging multiple contexts.

Note that MS-PointerGuess is highly scalable and can be easily extended to handle multiple old passwords. Here, we use two encoders to briefly describe MS-PointerGuess without losing generality.

In general, the conditional guessing probability that an attacker exploits users' multiple leaked passwords (e.g., pw_A at site A and pw_B at site B) to attack the victim's target password at site C (namely $pw_C = \left(c'_1, ..., c'_M\right)$) can be expressed similarly to Eq. 1, which is

$$P(pw_C|pw_A, pw_B) = \prod_{i=1}^{M} P\left(c'_i|c'_{<i}, pw_A, pw_B\right), \quad (8)$$

where $c'_{<i}$ dentoes the sub-sequence $\left(c'_0, ..., c'_{i-1}\right)$ of pw_C, and $P\left(c'_i|c'_{<i}, pw_A, pw_B\right)$ is the conditional probability of generating the character c'_i at position i in pw_C given the sub-sequence $c'_{<i}$ and the two old passwords pw_A and pw_B.

There are two key research questions (**RQs**) that need to be solved to build an effective targeted password guessing model based on users' multiple leaked passwords:

RQ1: How to evaluate the importance of different leaked passwords on guessing the target password?

RQ2: Does the designed model demonstrate superior performance compared to PointerGuess in practical?

To address **RQ1**, we introduce an *additional softgate layer*, denoted as λ, which serves to evaluate the significance of users' various old passwords and discern their preferences when generating a new password. More specifically, MS-PointerGuess outputs two context vectors, c_t, c'_t, from pw_A

and pw_B, respectively. Then, we can express $\lambda \in [0,1]$ as

$$\lambda = \sigma\left(W_c * c_t + W_{c'} * c'_t + b_\lambda\right), \tag{9}$$

where the σ is a sigmoid function, W_c, $W_{c'}$, b_λ are learnable parameters. Initially, λ is employed to weigh and combine the conditional probabilities of copying characters from pw_A (i.e., P^A_{copy}) and pw_B (i.e., P^B_{copy}), respectively. This yields P_{copy}, the weighted conditional probability of copying characters from pw_A and/or pw_B, can be expressed as:

$$P_{copy}(c) = \lambda * P^A_{copy}(c) + (1-\lambda) * P^B_{copy}(c). \tag{10}$$

Then, we can represent P^A_{copy} and P^B_{copy} similarly to Eq. 4, which are

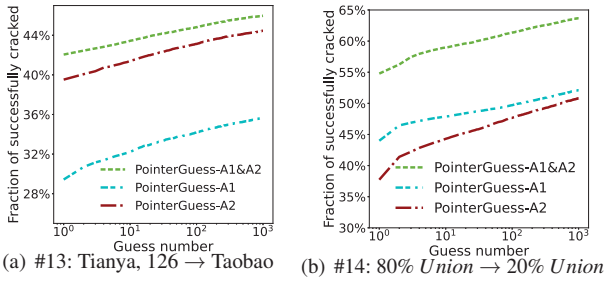
$$P^A_{copy}(c) = FFN\left(\sum_{i:c_i=c} \alpha^t_i\right), \tag{11}$$

and

$$P^B_{copy}(c) = FFN\left(\sum_{i:c'_i=c} \alpha'^t_i\right), \tag{12}$$

where α^t_i and α'^t_j are the attention weights of the two encoders at timestep t and c_i (resp. c'_i) denotes the character at position i in pw_A (reps. pw_B). $FFN(\cdot)$ is a feed-forward network. Note that if character c does not appear in pw_A or pw_B, then the value of $\sum_{i:c_i=c} \alpha^t_i$ or $\sum_{i:c'_i=c} \alpha'^t_i$ will be zero.

Still, we use the pointer mechanism p_g to weigh $P_{copy}(c)$ and $P_{vocab}(c)$, the conditional probability of generating characters from the vocabulary. At each timestep t, our generation probability $p_g \in [0,1]$ can be calculated from two content vectors and current decoder state vector s_t and current decoder input x_t, that is



$$p_g = \sigma\left(W_c * c_t + W_{c'} * c'_t + W_s * s_t + W_x * x_t + b_g\right), \tag{13}$$

where W_c, $W_{c'}$, W_s, W_x, b_g are learnable parameters, and $\sigma(\cdot)$ is a sigmoid function.

Finally, MS-PointerGuess integrates P_{copy} and P_{vocab} to represent $P_{gen}(c)$, the conditional guessing probability of MS-PointerGuess generating the character c, which is

$$P_{gen}(c) = p_g * P_{copy}(c) + (1-p_g) * P_{vocab}(c). \tag{14}$$

Overall, the scalability facilitated by the "Multi-Encoder" module in MS-PointerGuess empowers our model to handle users' multiple leaked passwords simultaneously. This capability enables MS-PointerGuess to extract multiple contexts from various old passwords, facilitating flexible decisions regarding the importance of each old password at every timestep. Moreover, the pointer mechanism [50] ensures that our MS-PointerGuess dynamically determines whether to copy characters from the old passwords or generate new characters directly from the vocabulary.

(a) #13: Tianya, 126 → Taobao (b) #14: 80% *Union* → 20% *Union*

Figure 15: Experiments of attack scenarios for MS-PointerGuess (i.e., #13 and #14) in Table 2. PointerGuess-A1&A2=MS-PointerGuess.

6.2 Experimental results and analysis

Experimental design and results. To address **RQ2**, we conduct two practical attack scenarios (#13 and #14, detailed in Sec. 4.2) to evaluate the performance of MS-PointerGuess. Fig. 15 shows that MS-PointerGuess invariably outperforms PointerGuess across both attack scenarios. For identical password pairs, MS-PointerGuess achieves cracking success rates that are, on average, 17.54% (scenarios #13) and 26.11% (scenarios #14) higher than PointerGuess within 100 guesses, respectively. Even when excluding identical password pairs, MS-PointerGuess maintains its superiority. More specifically, within 100 guesses, it achieves cracking success rates that are, on average, 17.20% (scenarios #13) and 38.78% (scenarios #14) higher than PointerGuess, respectively. See Table 6 for more details and specific results.

This highlights the effectiveness of MS-PointerGuess and the substantial impacts of utilizing different training sets to attack the same test set on PointerGuess' efficiency. As a large proportion of users directly reuse their old passwords (i.e., 20%∼59% [14, 51, 53, 57]) and there are unending catastrophic password leaks [44, 62] (making it more and more likely that users have leaked two or more distinct passwords), password guessing based on multiple old passwords is a rather damaging threat (see the columns 3 and 6 in Table 6).

Further analysis. Overall, our analysis reveals two key findings: (1) The results show that most users have identical old passwords, aligning with recent research findings [13, 18]. As users' leaked passwords increase, the risk of compromising their target passwords also rises. Directly using these identical password pairs in password cracking significantly improves the success rate; (2) MS-PointerGuess effectively leverages multiple old passwords to generate accurate guesses, resulting in higher cracking rates compared to PointerGuess.

7 Targeted Password Strength Meters

Password strength meters (PSMs) offer real-time feedback on password security during user registration, receiving much attention as a useful tool [54]. Among them is the Zxcvbn [60], a widely-used PSM that is renowned for its accuracy, low cost, and user-friendliness. While Zxcvbn performs well under trawling guessing attacks, it does not consider the targeted guessing threat as explored in the previous sections.

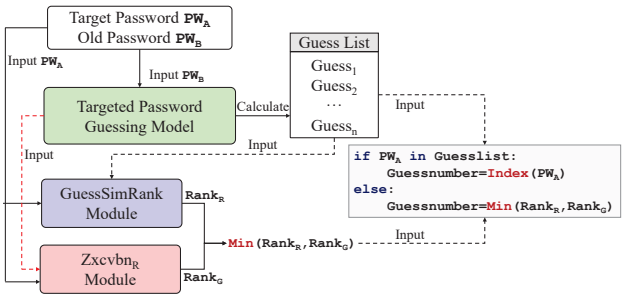


Figure 16: Architecture of PR-PSM. It consists of three primary parts: (1) search the index in the guess list; (2) the $Zxcvbn_R$ module; (3) the *GuessSimRank* module.

To address this limitation, we introduce PR-PSM, a password reuse-based PSM that integrates our PointerGuess with Zxcvbn. As shown in Fig. 16, PR-PSM utilizes users' old passwords to accurately estimate the password strength through a "multi-step evaluation" process. This process includes *GuessSimRank* and $Zxcvbn_R$ modules, to accurately evaluate the password strength of the target password.

7.1 Multi-step evaluation

Fig. 16 shows the architecture of our PR-PSM. We design a two-step evaluation mechanism to evaluate the strength of a given password more accurately.

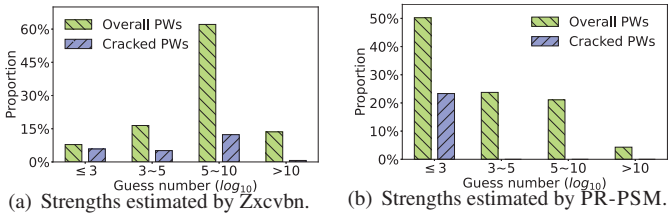
Step 1: Get the index of the target in the guess list. First, we directly input the old password pw_B into the targeted password guessing model (e.g., PointerGuess) and generate Top-K guesses. Then, if pw_A is in the guess list, we use its *index* in the guess list as the guess number, that is

$$GN = Index(pw_A), \tag{15}$$

where GN denotes the guess number (i.e., the *index* of pw_A). If pw_A is not in the guess list, we move into the next step.

Step 2: Get the guess number from two modules. When pw_A is not in the guess list, PR-PSM uses two evaluation modules to assess the strength of the target password. The first module, $Zxcvbn_R$, integrates Zxcvbn [60] and evaluates the strength $Rank_R$ of pw_A using the generated guess list, which can be expressed as

$$Rank_R = Zxcvbn_R(pw_A). \tag{16}$$



The second module, *GuessSimRank*, integrates PointerGuess and Zxcvbn to evaluate the strength $Rank_G$ of pw_A, that is

$$Rank_G = GuessSimRank(pw_A). \tag{17}$$

The final guess number GN is determined as the minimum between $Rank_R$ and $Rank_G$, that is

$$GN = min(Rank_R, Rank_G). \tag{18}$$

Alg. 1 shows the detailed design of PR-PSM. Then we describe how we use $Zxcvbn_R$ and *GuessSimRank* two modules to reevaluate the strength of the target password pw_A.

(a) Strengths estimated by Zxcvbn. (b) Strengths estimated by PR-PSM.

Figure 17: PSM accuracy evaluation by comparing the distribution of cracked passwords with overall test passwords. The smaller the guess number, the weaker the password, and should the higher probability to be cracked. Results show the advantages of PR-PSM in evaluating password strength with users' old passwords over Zxcvbn [60].

Algorithm 1: PR-PSM evaluation

Data: Target password, Targeted password guessing model, K, Index importance distribution
Result: Guess Number GN

$pw_A \leftarrow$ Target password
$Model \leftarrow$ Targeted password guessing model /* input the password and guess number, output guesses. */
$Guesses \leftarrow Model(pw_A, K)$ /* get the guess list, which has K guesses. */
$Index \leftarrow Search(pw_A, Guesses)$ /* search the index of the password in the guess list. */
$dist_{index} \leftarrow$ Index importance distribution
if $Index >= 1$ *and* $Index <= K$ **then**
  $GN \leftarrow Index$
  return GN
$Rank_R \leftarrow Zxcvbn_R(pw_A, Guesses)$ /* use the $Zxcvbn_R$ module to calculate the $Rank_R$. */
$Rank_G \leftarrow GuessSimRank(pw_A, Guesses, dist_{index})$ /* use the *GuessSimRank* module to calculate the $Rank_G$. */
$GN \leftarrow min(Rank_R, Rank_G)$ /* let the minimum value of $Rank_R$ and $Rank_G$ as GN. */
return GN

$Zxcvbn_R$ module utilize the basic Zxcvbn [60] and the guess list generated by PointerGuess. As shown in Fig. 17(a), the basic Zxcvbn is not designed for the target guessing scenarios and overlooks the strength of most passwords if given the old password. We incorporate the guess list based the user's old password to construct a new PSM that offers accurate evaluations in targeted guessing scenarios. More specifically, we employ sentencepiece [24] to extract popular password segments Seg_{top} from the guess list. Then, we input Seg_{top} into Zxcvbn to adjust the guess number evaluated by the basic Zxcvbn. We denote $Zxcvbn_R$ as

$$Zxcvbn_R(pw_A) = Zxcvbn(pw_A, \text{PointerGuess}(pw_A)), \tag{19}$$

where PointerGuess(pw_A) denotes the guess list generated by PointerGuess using pw_A. Alg. 2 shows the detailed design of $Zxcvbn_R$ module.

Algorithm 2: $Zxcvbn_R$ module

Data: Target password, Guess list, Segment count
Result: Guess Number GN

$L \leftarrow$ Segment count
$pw_A \leftarrow$ Target password
$BM \leftarrow$ BPE Method /* trained by sentencepiece [24], use it to split password. */
$Guesses \leftarrow$ Guess list
Define $split$ split password function
Define $sort$ sort segments by frequency function
$zxcvbn$ // Zxcvbn function
$Seg \leftarrow split(BM, Guesses)$ /* split all guesses and statistic all segments. */
$Seg \leftarrow sort(Seg)$ /* sort by descending order of frequency. */
$GN \leftarrow zxcvbn(pw_A, Seg[0:L])$
return GN

Algorithm 3: $GuessSimRank$ module

Data: Target password, Guess list, Index importance distribution
Result: Guess Number GN

$pw_A \leftarrow$ Target password
$MLED$ /* the function of calculating the Minimum Levenshtein Edit Distance */
$Guesses \leftarrow$ Guess list
$zxcvbn$ // Zxcvbn function
$M \leftarrow zxcvbn(pw_A)$
$K \leftarrow \|Guesses\|$
$dist_{index} \leftarrow$ Index importance distribution
$rank \leftarrow 0$
for $i \leftarrow 1$ *to* K **do**
  $score \leftarrow MLED(pw_A, Guesses[i])$ /* calculate the similarity score of target password and a guess */
  $importance \leftarrow dist_{index}[i]$
  $rank \leftarrow rank + importance * SimGuessNum(pw_A, score, i)$ /* $SimGuessNum$ is corresponding to Eq. 21 */
return GN

Then, the $GuessSimRank$ module uses a password similarity method $SimAlg$ (e.g., edit distance) to calculate the similarity sim_i of the i-th guess, $guess_i$, and the target password pw_A. That is $sim_i = SimAlg(pw_A, guess_i)$ Then we denote the guess number $Rank_G$ as

$$GuessSimRank(pw_A) = \sum_{i=1}^{K} W_{guess}(i) * SimGN(pw_A, sim_i, i), \quad (20)$$

where K denotes the number of guesses, and W_{guess} denotes the normalized *importance* distribution of different guesses in the guess list, weighting the impact of each $guess_i$ on $Rank_G$.

Note that the $SimGN(pw_A, sim_i, i)$ denotes that we use sim_i and the guess number i of $guess_i$ to calculate the guess number for pw_A. More specifically, we can express $SimGN(pw_A, sim_i, i)$ as

$$SimGN(pw_A, sim_i, i) = \exp((gn_A - i) * \sigma(sim_i)) + i, \quad (21)$$

where $\sigma(\cdot)$ is a sigmoid function, and gn_A denote the guess number of pw_A directly evaluated by Zxcvbn [60]. Alg. 3 shows the detailed design of $GuessSimRank$ module. The results of the two modules are then compared, and the minimum value is selected as the final guess number GN.

7.2 Results and analysis

Fig. 17 evaluates the effectiveness of PR-PSM by investigating the password strength distributions of all target passwords (in the 89,951 unique test password pairs) with these 29,252 cracked target passwords in 12 scenarios. Fig. 17(a) shows that Zxcvbn [60] estimates the guess number for the majority of overall test passwords to exceed 10^5, with over 15% of target passwords even deemed unguessable (i.e., $\geq 10^{10}$).

Zxcvbn accurately evaluates only a minority of the cracked passwords (i.e., guess number$\leq 10^3$) and overestimates the majority of the cracked passwords to exceed 10^5, with some even exceeding 10^{10}. In contrast, Fig. 17(b) shows that PR-PSM accurately evaluates all the cracked passwords to be within 10^3 guesses, and the majority of overall test target passwords to be less than 10^{10}. This indicates that Zxcvbn overestimates the strength of most passwords in targeted guessing scenarios, and PR-PSM well fixes its defect.

Table 7: Examples of password strengths by Zxcvbn [60] and PR-PSM.

Index	Old password	Target password	GN_Z†	GN_R	*Hit*
1	yanlin19880911	yanlin5201314	10.02	2.45	Yes
2	yyt395746	yyt3957460	10.00	1.08	Yes
3	w564011	5640117aiolia	12.11	8.29	No
4	liu231377	liujian231377	12.53	2.99	No
5	gyhhx970621	gylyx060504	9.16	5.62	No

†GN_Z and GN_R denote the guess number (log_{10}) evaluated by Zxcvbn [60] and PR-PSM, respectively. *Hit* denotes if the target password is cracked or not.

Table 7 presents five password pairs from the *Overall* list, demonstrating the difference in strength evaluations between Zxcvbn [60] and PR-PSM. As shown in Table 7, Zxcvbn seriously overestimates the strength of both cracked and uncracked passwords, while PR-PSM effectively uses the old password to evaluate password strength more accurately and provides a more reasonable evaluation (i.e., guess number). See more results and analysis in Appendix B of the full paper. Our experimental results demonstrate that designing a PSM that integrates the targeted guessing model can more accurately evaluate the strength of given passwords.

8 Conclusion

This paper provides a new technical route to dynamically generate a user's new password through her old password. For the first time, we propose a password reuse guessing model coupled with the pointer mechanism, namely POINTERGUESS. By introducing a hierarchical definition of password reuse, POINTERGUESS can characterize users' password reuse behaviors more accurately. Extensive experiments demonstrate the effectiveness of POINTERGUESS and its applicability to targeted PSMs. Furthermore, we investigate a realistic attack scenario where attackers leverage victims' multiple old passwords to compromise their current passwords, and propose MS-POINTERGUESS. We hope that our new models and accurate characterization of users' password reuse behaviors will help the academic community and web administrators have a better understanding of password security.

A Supplementary details of other models

We now introduce several state-of-the-art models and alternative models that serve as benchmarks for comparison.

TarGuess-II. TarGuess-II was proposed by Wang et al. at CCS'16 [56]. This model is based on PCFG [59] for training a probabilistic structure model. Additionally, it incorporates an n-gram Markov model [33] to generate two n-gram files, one in the original order and the other in reverse. Moreover, TarGuess-II models users' transformation behaviors at segment- and character-level. When generating guesses, TarGuess-II mixes guesses with a popular password dictionary. We denote it as Top_{cn} (for Chinese) and Top_{en} (for English). In this paper, we use CSDN, Dodonew, and 126 to compose Top_{cn} and use 000Webhost, LinkedIn, and Yahoo to compose Top_{en}. Then, we multiply the ranking by the frequency of passwords in the three datasets and chose Top-10^4 as the dictionary. Note that for all parameters of this model, we keep the default settings provided by the authors.

Pass2Path. In their paper presented at IEEE S&P'19, Pal et al. [38] introduced Pass2Path, a targeted guessing model based on seq2seq [49]. Pass2Path is designed to complete the "password-to-path" task (i.e., take character sequence as input and the edit-operation sequence as output) and generate new passwords based on generated operation sequences. The model uses a three-layer RNNs with a hidden dimension of 128 for both the encoder and decoder. They set the learning rate to 0.0003 and the dropout rate to 0.4. We follow the same

configuration for the validation set as with [38]. As Pass2Path is open-source, we used the same model structure and the settings mentioned above as recommended by Pal et al. [38].

PlainSeq. At IEEE S&P'19, Pal et al. [38] also introduced Pass2Pass, a targeted guessing model tailored for the "password-to-password" task. Inspired by their work, we design a similar model, which we refer to as PlainSeq. In this paper, we use PlainSeq to conduct an ablation study to demonstrate the effectiveness of the pointer mechanism. We only keep the basic sequence-to-sequence model. It is worth noting that we did not incorporate the `<key-sequence>` proposed by Pal et al. [38] into PlainSeq. Instead, we used the original password string (i.e., character sequence) as model input to make a fair comparison with our PointerGuess.

Pass2Edit. Wang et al. [57] proposed a new algorithm called Pass2Edit. They redefined the password generation task as a "multi-step decision classification" task. Pass2Edit has a 3-layer GRUs and two fully connected layers. At each timestep, Pass2Edit takes the modified password and the original password (at the character level) as input and predicts one atomic edit operation which will be applied to the modified password. As the source code provided to us by Pass2Edit's authors, we keep the model's default settings and only adjust it on training/test datasets. Note that in [57] Want et al. proposed two models, Pass2Edit-nomix and Pass2Edit-mix. Pass2Edit-nomix is the original model that does not mix an extra popular password dictionary, while Pass2Edit-mix heuristically mixes its guessing list with popular passwords to output the final guessing list. In this paper, we name the model without mixing popular passwords (i.e., Pass2Edit-nomix) as Pass2Edit.

Untargeted dictionary attack (Top-PW). We build two popular password dictionaries based on Chinese (i.e., CSDN, 126, Dodonew) and English (i.e., 000Webhost, LinkedIn, Yahoo) training sets. We first sort these passwords in descending order of frequency. Then we select Top-10^3 as the popular dictionary (as our maximum guess number is 10^3), then we use them to build an untargeted dictionary attack.

Mixing models with an extra popular password dictionary. Note that the models mentioned above refer to the original models that are not mixed with popular passwords, except for TarGuess-II [56]. We investigate how mixing popular passwords with the original model outputs affects each model's performance. We follow the same strategy of mixing popular passwords as proposed in [57], and append "-mix" to the original model's name to denote the model using the mixing strategy. Furthermore, we strive to keep the random seeds used for these neural network-based models consistent with those used in the original paper (e.g., Pass2Edit [57]) to ensure more meaningful and reliable comparisons.

Note that the PG-Pass model proposed by Li et al. [28] is unsuitable for comparison with our PointerGuess, because these two models are initially designed for different attacking scenarios: PG-Pass focuses on PII-based targeted guessing scenarios, while our PointerGuess focuses on password reuse-based targeted guessing scenarios.

B Potential applications

Password protection. Here, we discuss two potential approaches for integrating PointerGuess into compromised credential checking (C3) services, such as MIGP, drawing inspiration from the application of Pass2Path [38] in MIGP [39]. First, we directly apply our PointerGuess to dynamically generate guesses. We denote this approach as "PTG". Second, as the "wEdit" proposed in [39], we explore using PointerGuess to generate a ranked list of tweaks, which can be applied to generate guesses. We denote this approach as "PTG-wEdit". Below we briefly introduce these two approaches.

First, "PTG" involves the real-time execution of PointerGuess within MIGP. Here, the pre-trained PointerGuess model is loaded onto the server's CPU/GPU. When a client submits the target password, the loaded model is immediately utilized to generate a set of password variants. This approach capitalizes on the ability to dynamically generate password variants using a pre-trained model. However, while offering flexibility and on-the-fly variant generation, this method comes with drawbacks such as increased resource consumption and potential speed issues during protocol execution.

Second, we employ a pre-trained PointerGuess to produce a series of password guesses for each user. These guesses are then transformed into the "transformation path" format proposed by Pal et al. [38]. By using a given dataset, PointerGuess generates transformation paths for all password pairs. We tally the occurrence of each transformation path and rank them in descending order based on frequency. While generating n variants of the target password, we apply the first n valid transformation paths from the sorted list. This approach offers the advantage of requiring fewer computational resources and providing faster variant generation. However, it is important to note that it relies solely on a statistically derived list of transformation paths for generating variants.

Overall, our proposed approaches aim to enhance password protection within the MIGP framework by leveraging the capabilities of PointerGuess. The first approach offers dynamic variant generation using a pre-trained model but may demand higher computational resources and raise speed concerns. In contrast, the second approach enables rapid and resource-efficient variant generation based on a statistically derived list of transformation paths. Further exploration and evaluation are necessary to gauge the feasibility and suitability of these approaches, considering the specific requirements and constraints of the MIGP system. Balancing execution speed and accuracy emerges as a critical issue to address in future research endeavors.

FFXE:
Dynamic Control Flow Graph Recovery for Embedded Firmware Binaries

Abstract

Control Flow Graphs (CFG) play a significant role as an intermediary analysis in many advanced static and dynamic software analysis techniques. As firmware security and validation for embedded systems becomes a greater concern, accurate CFGs for embedded firmware binaries are crucial for adapting many valuable software analysis techniques to firmware, which can enable more thorough functionality and security analysis. In this work, we present a portable new dynamic CFG recovery technique based on dynamic forced execution that allows us to resolve indirect branches to registered callback functions, which are dependent on asynchronous changes to volatile memory. Our implementation, the Forced Firmware Execution Engine (FFXE), written in Python using the Unicorn emulation framework, is able to identify 100% of known callback functions in our test set of 36 firmware images, something none of the other techniques we tested against were able to do reliably. Using our results and observations, we compare our engine to 4 other CFG recovery techniques and provide both our thoughts on how this work might enhance other tools, and how it might be further developed. With our contributions, we hope to help enable the application of traditionally software-focused security analysis techniques to the hardware interactions that are integral to embedded system firmware.

1 Introduction

Embedded systems are heavily relied upon in nearly every aspect of our daily lives, from the keyboards we use on a day-to-day basis, to the programmable logic controllers that coordinate complex manufacturing processes, to the medical imaging devices found in our hospitals. For many of these applications, system safety and security are of critical importance. A crucial component of realizing this is firmware verification and vulnerability analysis, which is unfortunately lacking in many modern systems [45]. As a specialized form of software, firmware images can theoretically be analyzed with traditional software analysis techniques. However, this is often difficult in practice due to fundamental differences between firmware and software. Nonetheless, if software analysis techniques can be reliably adapted to firmware, there could be significant improvements in the security, trust, and assurance of embedded systems.

In this paper, we focus on Control Flow Graph (CFG) recovery as an important enabling step for applying more complex software analysis to monolithic bare-metal binary firmware images. We present the Forced Firmware Execution Engine (FFXE), which leverages the original dynamic forced execution algorithm [48] to enable the resolution of indirect branches whose targets are determined asynchronously. Such branches often arise from callback function registration, a programming archetype that occurs ubiquitously in embedded systems development. To accomplish this, we introduce several additional stages to the original technique that allow us to resume execution from instructions that access volatile memory when a potential branch target is written to the same location. Our prototype is implemented as a manager class designed to handle the additional context information needed to track volatile memory accesses, as well as execution thread state. Our code artifacts are publicly available on GitHub. [1]

Our paper is outlined as follows: the rest of this section gives a high-level overview of the motivations for this work and a summary of our contributions; Sections 2 and 3 provide further background on CFG recovery techniques and related work; Section 4 details the design and implementation of our technique; in Sections 5 and 6 we present and discuss our results; and finally in Sections 7 and 8 we discuss future work and make our final remarks.

A CFG is a graph representation of all of the possible execution paths that might be taken through a program [3]. The vertices of a CFG are called basic blocks, which are contiguous sets of sequentially executing instructions that have a single entry point and exit point. Exit points are control flow instructions that can alter the value of the program

[1] https://github.com/rchtsang/ffxe

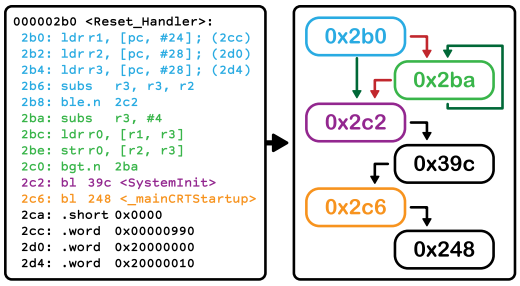

Figure 1: CFG Recovery Example.

counter, typically function calls, function returns, or conditional branches. The edges of the CFG represent the branch targets of the basic block's last instruction and are therefore directed. A small example of a CFG for a single function can be seen in Figure 1. CFGs are valuable structures for program analysis and are used in many applications like verification [5, 8, 15, 18, 23, 47], data flow analysis [2, 43], and malware detection [1, 10, 19, 27, 28, 30, 32]. As embedded and cyber-physical systems continue to grow in ubiquity, such techniques have become increasingly necessary for ensuring the security of the firmware that drives them.

As already mentioned, it is often difficult in practice to apply software analysis techniques to the firmware. This is because, by nature, firmware code is strongly coupled to the hardware that it is written for. While software usually abstracts hardware interactions through the operating system and concerns itself only with application behavior, bare-metal firmware must manage both application and hardware, since hardware dependencies are often directly referenced through memory-mapped input/output (MMIO). Moreover, MMIO references are usually linked to hardware events that have a direct effect on firmware control flow, making execution paths unpredictable based on syntax alone.

In particular, embedded systems tend to interact with the physical environment through hardware peripherals like sensors and actuators. Thus, firmware tends to have a high degree of asynchronicity, as interrupts and interrupt service routines (ISRs) often play critical roles in responding to external events triggered by peripherals. An ISR is typically a programmer-defined function that gets registered to a particular event. When that event occurs, an interrupt is triggered that stops the current thread of execution, switches context to the registered ISR, and executes it. When the ISR thread finishes executing, the processor context is restored to the point of interrupt and continues with the main thread of execution. This complicates many analyses because values can change unpredictably from a given thread's point of view. These values are considered *volatile* and may need to be handled differently depending on their underlying hardware dependency.

These differences between software and firmware limit the effectiveness of existing CFG recovery techniques, as existing techniques are designed primarily for serial software and fail to account for asynchronicity that arises due to hardware dependency in firmware. In this paper, we address some of these challenges by building upon existing techniques to enable greater support for firmware CFG recovery. Our contributions can be summarized as follows:

- We present a portable dynamic algorithm for CFG recovery, designed specifically to handle indirect branches that are affected by interrupt-based asynchronicity (volatile memory).
- We implement and evaluate a prototype of our algorithm, the Forced Firmware Execution Engine (FFXE).
- We demonstrate FFXE's effectiveness at resolving indirect branches whose targets are dependent on asynchronous memory writes (registered callback functions).
- We compare our prototype's performance against several CFG recovery techniques, including a reimplementation of the original dynamic forced execution algorithm.

2 Background

2.1 Control Flow Graph Recovery

Naturally, a complete control flow graph (CFG) can be constructed trivially from the syntax of the program's source code, as all paths are inherently enumerated by the programmer. However, while such CFGs are useful in many cases, due to compiler optimizations in compiled languages, they do not always accurately reflect the actual control flow of the compiled binary. As such, there has been significant research effort given to recovering control flow graphs directly from binaries [16]. This amounts to a graph exploration problem, in which the graph information is embedded in the firmware binary, and graph vertices and edges are only revealed as an exploration algorithm is executed. A toy example of CFG recovery is shown in Figure 1. The figure demonstrates the identification of basic blocks in ARM Thumb disassembly, as well as the edges between those blocks that indicate control flow transfers due to conditional branch or function calls. While straightforward in principle, there are many challenges that make it difficult to recover a complete and accurate CFG. Existing research on CFG recovery deals with many specific issues, but perhaps the most fundamental one is the problem of *indirect jumps*. These are control flow instructions whose branch targets are not fixed–i.e. dependent on the value stored in a register or memory location. Since this information is only known at runtime, it is difficult to guarantee perfect CFG recovery for software that contains indirection.

Since their inception, the most common CFG recovery methods have been largely static, relying purely on the analysis of program disassembly without runtime information like processor or memory state [39]. The typical approach to static CFG recovery is to scan the entire program binary for jump

and branch instructions whose targets can be resolved to begin recovering basic blocks. When a target is found, the recovery engine simply continues to disassemble contiguous instructions until the branch instruction that signifies the end of a block is reached. This is continued until no new blocks can be found [40, 42]. However, fundamentally, static recovery techniques suffer from the problem of indirect jumps—branches that are dependent on memory and register state. Significant efforts have been made to address this problem and many improvements have been applied to static techniques which can help offset this problem [50], but the fundamental limitation remains. By introducing dynamic execution, we can theoretically resolve the indirect jump issue, as runtime information can be extracted to resolve indirect jumps. As such, there have been significant research efforts to build hybrid and fully dynamic recovery engines which can yield more complete, correct, and accurate CFGs [11]. These efforts have ranged in their approach from pure emulation, to symbolic execution. Moreover, the extracted runtime information can be used to enhance other techniques and enable more complete analyses, such as execution frequency annotation, on the resulting CFG [1].

2.2 Dynamic Forced Execution

Introduced by Xu et al. in 2009, forced execution is a dynamic technique for recovering CFGs predicated on the observation that the calculation of indirect jump targets is usually independent of intermediate program states, and postulates that an accurate CFG can be recovered by exploring both directions of every encountered conditional branch [48]. The original optimized algorithm for the Forced Execution Engine (FXE) is presented in Algorithm 1 In FXE, **(1)** the program is initialized in a virtual environment and an empty CFG is instantiated. **(2)** The engine begins executing the program at its entry point and an exit point is inferred from the entry point's value and the code section size. **(3)** Path exploration is directed with a coloring system for conditional branches. When a conditional branch is encountered, its location is saved and uncolored, indicating that neither path has been explored yet. **(4)** The engine then saves the current processor and memory state, as well as the target address of the branch path not taken. **(5)** The engine then colors that branch gray and continues down the execution path that is consistent with the emulated branch condition. **(6)** When the current path terminates, either because the engine has encountered a known basic block, or because the program itself has terminated, the engine restores context to the nearest gray branch, colors it black, and continues down the unexplored path. This results in a depth-first exploration pattern that terminates when all branches have been marked black. However, the original authors implement further optimizations to ensure the timely termination of their algorithm.

In order to avoid long-running or infinite loops, the engine assigns each basic block an execution quota that determines whether it should be skipped or not. On the first encounter, a block is given a quota of 1 and the quota is decremented after execution. If a block is encountered that ends with an indi-

Algorithm 1: Dynamic Forced Execution

```
Output: CFG cfg
Input: Executable exe
cfg = NULL; current = NULL; block = NULL;
  ip = get_instruction_pointer();
  branches = [];

while true do
    while block = get_block(ip) do
        if !(exe.EntryPoint ≤ block.pc < exe.ExitPoint) or (block.quota
          <= 0)) then
            try
                ip = execute_block(block);
            catch (exception)
                error_handler(ip, block, exception);
            continue;
        connect_block(cfg, current, block);
          current = block;
        while inst = get_instruction(block, ip) do
            if (inst.type == ConditionalBranch) and
              (find_branch(inst) == NULL) then
                branch = get_branch(inst);
                if branch_is_taken(branch) then
                    branch.next_ip = ip + inst.length;
                else
                    branch.next_ip = get_target(branch);
                branch.state = gray;
                  save_context(branch);
                  add(branch, branches);

            else if (inst.type == CallBranch) and (find_branch(inst)
              ≠ NULL) then
                branch = get_call_branch(inst);
                    get_return_points(branch, cfg);  // forward
                    reachability
                branch.next_ip = ip + inst.length;
                  branch.state = gray;
                  save_context(branch);
                  add(branch, branches);

            if (inst.type == IndirectBranch) and (find_target(inst) not
              in known_targets(inst)) then
                add_target(inst);
                    increment_quotas(current, cfg);  // backward
                    reachability
            try
                ip = execute_inst(inst);
            catch (exception)
                error_handler(ip, block, exception);
    if branch = get_last_gray_branch() then
        load_context(branch);
          ip = branch.next_ip;
          branch.state = black;
          current = get_branch_block(branch);

        if branch.type == CallBranch then
            add_return_points(branch,current.predecessors);
    else
        break

resolve_blocks(cfg);
  return cfg;
```

rect branch, and the branch target has not been seen before, then after executing it the engine will increment its quota and the quota of every block leading up to it within the current function. A block is thus only executed if it has a non-zero quota, while still allowing for the future discovery of other indirect branch targets. However, an additional consideration needs to be addressed to preserve CFG edge completeness. To circumvent the loss of function fall-through edges–which may occur when a function that has already been explored is called from a new location, resulting in termination before returning–function calls are treated similarly to conditional branches. The call branch is colored gray and added to the branch list with the saved fall-through path context (i.e. the return address). To capture the return edge from the function to the fall-through path, forward reachability analysis is performed on the function to determine the possible return points, which are all added as return edges for the fall-through path. An exception handler is also implemented to allow for graceful recovery from crashes that may arise from exploring the contradictory path at conditional branches.

While the forced execution method appears to be quite effective at recovering CFGs based on coverage results of the reported benchmark, the algorithm does have its drawbacks. Particularly, in its presented form, it has only limited support for recovering unconnected portions of the CFG that do not exist as part of the main thread of execution but may be executed asynchronously, such as those representing interrupt service routines (ISR). The authors rely on manually enumerated instruction patterns in order to detect interrupt handler registration, after which the forced execution engine can be invoked on the registered interrupt [48], where event and interrupt-driven programming is prevalent, the manual enumeration of patterns for handler registration patterns is impractical since there are many ways that an ISR might be registered. Moreover, forced execution neglects the role that volatile memory addresses may play in resolving the indirect jumps, and does not handle cases where indirect jumps targets are contingent on volatile data. In order to adapt forced execution to event-driven firmware, we relax some of the assumptions that FXE makes about the independence of program states, and augment to FXE algorithm to account for volatile memory and interrupt handlers.

3 Related Works

Indirect jump resolution in CFG recovery remains an ongoing topic of research. While many efforts have been made to resolve indirect jumps in a purely static fashion [6, 7, 14, 17, 21, 22, 29, 37, 37, 44], many of the more recent approaches to this problem leverage dynamic analysis techniques [20, 32, 36, 38, 39, 42, 49, 50]. In this section, we outline some of these works, focusing on methods that leverage dynamic analysis techniques.

Nguyen et al. [32] propose a hybrid approach that combines static and dynamic analysis for CFG generation from binaries. Symbolic execution is used in the static analysis phase until an indirect jump or function call is encountered. Test cases are then generated to cover all execution paths, and dynamic analysis is used to execute the test cases to resolve jump targets. Static analysis is then invoked to analyze new targets, and the process is repeated in this alternating manner until no new targets are found.

In a continuation of work on forced execution, Peng et al. [36] introduce *X-Force*, a binary analysis engine that applies forced execution for a small set of conditions to explore paths and expose a binary's behavior. Dynamic binary instrumentation is used to monitor the concrete program state of the target binary. *X-Force* is used for three different applications of CFG recovery, malware analysis, and reverse engineering, thereby demonstrating the potential of force executing binaries for security purposes. However, You et al. note that because *X-Force* is a heavy-weight engine and therefore suffers from scalability issues, it is impractical to use [49]. They improve upon it with PMP, a practical forced-execution engine that instead avoids tracking individual instruction and on-demand allocation using a buffer pre-allocation scheme that prevents pointer dereferencing exceptions and probabilistically avoids state corruption.

A popular framework for dynamic binary analysis, `angr` [42] offers two separate recovery algorithms: *CFGFast* and *CFGEmulated*. *CFGFast* uses static analysis for CFG generation, sacrificing the graph recovery accuracy for speed and coverage, employing standard static recovery techniques such as function prologue matching and recursive disassembly. *CFGEmulated* uses a combination of dynamic forced execution, symbolic execution, and backward slicing, prioritizing completeness in resolving indirect jumps, resulting in a more accurate CFG at the cost of execution time. The first stage of the algorithm uses forced execution to seed further CFG recovery by adding basic blocks and their *direct* jumps only to the CFG under construction. To ensure that *indirect* jumps are resolved correctly, `angr` does not make the assumption that indirect branches are independent of intermediate program states. Thus, all indirect jumps discovered with forced execution are stored for later analysis. `angr` then uses *symbolic execution* on the path to an indirect jump, utilizing a constraint solver to retrieve possible jump targets. Any unresolved jumps are further analyzed in a context-sensitive manner by creating a backward slice of the program starting from the unresolved branch that includes all call contexts. Because `angr` is designed specifically for binary analysis, many of its techniques can be applied to ARM-based firmware out-of-the-box. However, it is fundamentally designed for general-purpose software, making it unclear how effective it is for firmware, which exhibits many non-standard programming patterns.

Recently, Zhu et al. [20] have proposed another hybrid recovery technique for x86 binaries that uses static analysis recover an initial CFG, then employs coverage-based gray-box

fuzzing to generate test cases that are used to resolve indirect jumps. The technique is further developed in a later work using directed gray-box fuzzing [50] on C/C++ programs at the source code level. Hence, while interesting, neither techniques are suitable for binary analysis of firmware images, which are almost never in x86, nor have access to source code.

4 Design and Implementation

At a high level, we propose a forced execution-based algorithm that takes memory accesses into account in order to recover registered callback functions. In our algorithm, we first apply forced execution to each known ISR entry point in order to determine what addresses may be accessed asynchronously. Once this scan is complete, we begin forced execution from the main entry point, watching for memory writes to addresses that overlap with those accessed by ISRs. When such accesses are detected, we restore the corresponding ISR execution state, overwriting the accessed memory location with the value of the write. When the values written are registered function addresses, this allows the emulator to correctly resolve subsequent indirect branches that rely on that value. However, before we discuss our algorithm in depth, it makes sense to first discuss the reimplementation of the original Forced Execution Engine (FXE), as some minor changes to the original algorithm must be made for use with our chosen emulator. As our algorithm relies on portions of the original, these modifications will be carried forward into our algorithm's implementation.

4.1 Reimplementing FXE

As the method of forced execution requires dynamic information, we require an emulator for the instruction set of the target embedded system. For this, the Unicorn emulation framework [13] was an ideal choice, as it provides a more flexible interface to the powerful JIT binary translator used in the Qemu emulator, and is a good platform for adapting forced execution to other architectures. We choose Python to implement the proof of concept, as it is a widely adopted language and easy to work with. Though Python is generally slower and allocates more memory at runtime than other languages, our priority is proof-of-concept, so this is acceptable. We also rely on the Capstone disassembly framework [33] to identify instructions. However, because of some unfortunate bugs in the Capstone and Unicorn frameworks, some of the memory decoding and access checking functionality became unreliable. Thus, decoding crucial memory and branch instructions required custom structures to parse opcodes and parameters.

Since the original forced execution algorithm was implemented using neither Python nor Unicorn, we first reimplement the original forced execution engine (FXE) in Python and Unicorn for later comparisons. Our version of the original includes the block execution quota system, as well as the associated backward and forward reachability steps necessary to deal with the complications that inevitably arise when blocks are not allowed to execute. We do not include a separate construct for error handling, as exceptions can be handled on a case-by-case basis using Python's built-in `try-except` syntax.

Unicorn already encapsulates an emulator and exposes emulator state information primarily through a hook/callback API, so the algorithm could not be implemented in the same form as the original Algorithm 1. We instead implemented FXE piecewise, in separate callback functions for blocks and instructions. These callbacks are executed when the emulator encounters a new Qemu translation block and the next instruction, respectively. Hence, while the forced execution algorithm remains fundamentally the same, different portions of the algorithm must be written into the callback function suitable to the operation being performed. As mentioned, this was further complicated by bugs in the Unicorn and Capstone code base which were leading to the unreliability of hooking memory accesses and decoding of branch and memory instructions. We therefore defined custom `ctypes` structures for each branch, load, and store instruction type to guarantee proper behavior for the algorithm. This was done for the most common types of single load and store instruction, but not all, so there is some chance of incompleteness.

4.2 Implementation

We augment the original FXE algorithm by introducing some platform-aware modifications, specifically targeting ARM-based microprocessors for our prototype, since ARM-based systems hold a large share of embedded systems market. Modern ARM architectures come in 3 variants: Cortex-A for general-purpose computing, Cortex-M for efficient computing in constrained resource environments, and Cortex-R for performance computing with real-time requirements. Of the 3, Cortex-M is most frequently used for embedded systems and microcontrollers, though Cortex-R is not uncommon, and is the successor to older architectures that employed both ARM and Thumb modes of the instruction set architecture (ISA), such as ARM7TDMI. We design our prototype primarily for Cortex-M, though we have also implemented some support for ARM7TDMI and Cortex-A/R, which we discuss in later sections.

4.2.1 Locating ISR Entry Points

Before we can run FFXE on a given firmware, we must first determine its program entry points: the main entry point, and the ISR entry points. The Cortex-M architecture family implements hardware interrupts using the Nested Vector Interrupt Controller [4]. While we will not delve into the details, it suffices to know that hardware events are linked to an entry in the NVIC's vector table, which contains the address of a call-

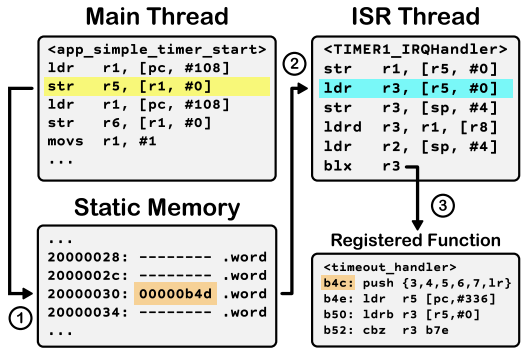

Figure 2: Registered Function Example.
(1) The main thread writes the registered function address `0xb4d` to a static address known to the API callback. (2) In the ISR thread, the API callback reads the registered function address into a register. (3) The API callback then calls the registered function by jumping to the address in the register.

back function. The vector table is a sequence of consecutive words that correspond to the location of a callback function or interrupt service routine (ISR) that will be invoked if its corresponding hardware event occurs. Particularly important is the Reset Handler entry, which is the first entry of the vector table. As defined by the Cortex-M architecture, on cold reset or startup, the processor will always initialize the program counter from the fixed address `0x4`, which is also the default location of the Reset entry of the vector table. While the vector table can be relocated at runtime, `0x4` will still contain a valid pointer, which we can take to be our main entry point if the firmware image base address is still `0x0`. If this is not the case, prior work in FirmXRay [46] has been done on statically locating relocated vector tables, which we can utilize to attempt to locate a valid base address.

In general, the first set of vector table locations are used for exception handling and other privileged use-cases. However, starting from offset `0x40` in the vector table, generic interrupt handlers can be registered [24] per vendor hardware specification. For example, the nRF52 series of microcontrollers maps specific sets of peripherals to each generic ISR entry point [41]. The vector table provides us with entry points for starting forced execution on these handlers, but the quality of the resolved blocks will still be poor if the state of the emulator's volatile memory locations does not accurately reflect the expected state that the handler should operate in. This is due to the fact that these handlers are typically responsible for invoking user-registered callbacks, which means the functions must be registered in the emulator's memory at the time of execution if they are to be recovered. This also means that the state of volatile memory locations must be taken into account to resolve indirect jumps that rely on volatile data.

4.3 Designing for Volatile Memory

As previously stated, volatile memory locations play a prominent role in embedded systems programming. While "volatile" can also refer to the permanence of memory with respect to power cycling. Herein, we use the term to refer to memory locations whose data may be altered asynchronously—the same way the`volatile` C keyword is used. In embedded systems, a volatile memory location typically corresponds to a memory location that is accessed by both the main thread of execution and an interrupt service routine, or to a memory-mapped hardware peripheral register. This is especially relevant for interrupt service routines, as it is a common programming pattern to *register* functions to particular hardware events using an application programming interface (API). Such APIs, like those in the nRF52 software development kit [34], are typically implemented in such a way that some default handler is defined for each possible hardware event, which then invokes a *callback function* that was registered at API initialization. An example of this is shown in Figure 2. This means that there is indirection associated with interrupt events, which poses a significant challenge for CFG recovery, as most static methods will have no way to resolve an indirect jump whose target is determined dynamically in a separate execution thread. This is the primary issue we attempt to tackle in this work.

4.3.1 Modifying Forced Execution

To address the aforementioned challenges, we propose the following algorithm for volatile-aware forced execution:

1. Initialize the emulator's memory state by pre-executing the reset handler, which is responsible for copying pre-initialized global variables into RAM. This is done before forced execution begins because it typically involves a loop that may not be fully executed during forced execution due to the block execution quota system.

2. Do a forced execution pass on each of the ISR function addresses in the vector table, excluding the main entry point. During each of these passes, the engine records each memory access as a volatile memory access.

3. If the volatile memory access was a read, the engine creates a backup of the emulator's CPU and memory context associated with the address and saves the vector table entry that it was descended from. This will allow it to resume execution from that point when the volatile address is written in the main thread of execution.

4. After a pass is conducted on each vector table entry, the quotas on all ISR blocks are reset and the engine begins forced execution at the main entry point. As it executes portions of the original algorithm along the main thread, it also watches for accesses to volatile addresses and logs any memory writes, volatile or otherwise, to a dictionary.

5. Whenever a volatile memory address is written, the engine resumes execution from any reads to the same address that occur in a different thread context, modifying the memory state to reflect that at the time of writing

so that the written value has a chance to influence any indirect jumps that may rely on it.

6. If any new blocks are discovered in an ISR thread, the engine updates its record of volatile memory locations with any additional memory accesses that are encountered, saving and restoring execution contexts as necessary if it is found that a previously written address is now identified as volatile.

7. Additionally and optionally, the engine queues additional forced execution passes on ISR entry points under 2 conditions: **(a)** when it is recognized that interrupts have been enabled for a given peripheral via a memory-mapped register write, and **(b)** when wait-for-interrupt (WFI) or wait-for-event (WFE) instructions are encountered in the main thread. This is done to increase the odds of capturing as many possible memory states that might be valid under preemption, so as to improve the odds of finding valid indirect execution paths.

We acknowledge that our technique exhibits significant coupling with hardware and ISA, particularly with respect to the second and last step in our algorithm. In step 2 we rely on the Cortex-M definition of the vector table to locate ISR entry points; however, the concept of the vector table is not specific to the Cortex-M architecture, and nearly all common architectures for embedded systems implement a similar scheme to facilitate interrupt handling. Moreover, in step 7, we note that the precise memory address that enables interrupts is completely platform dependent, and the WFI and WFE instructions are specific to the ARMv7e-M ISA. However, note that the underlying concept of this step can be generalized to other hardware platforms and architectures. Note further that this step is not integral to the algorithm, as it is included primarily to further cover the search space for indirect execution paths–paths that are contingent on indirect jump targets. The core contribution is the idea of resuming execution from volatile memory accesses in order to resolve indirect jump targets that are contingent on asynchronous writes to those locations.

4.3.2 Edge Cases

In this section, we discuss the various edge cases that have been considered during implementation. As one might expect, there are a significant number of edge cases that arise as a result of forcibly executing indirect jumps from invalid execution states. Moreover, because compiler optimizations can significantly change the layout of the original source code, there are additional edge cases to consider where typical conventions may have been violated. Additionally, the ARMv7e-M instruction set implements some instructions that have unique effects and must be handled specially.

Encountering Invalid Addresses: During the course of forced execution, it is very common that an invalid basic

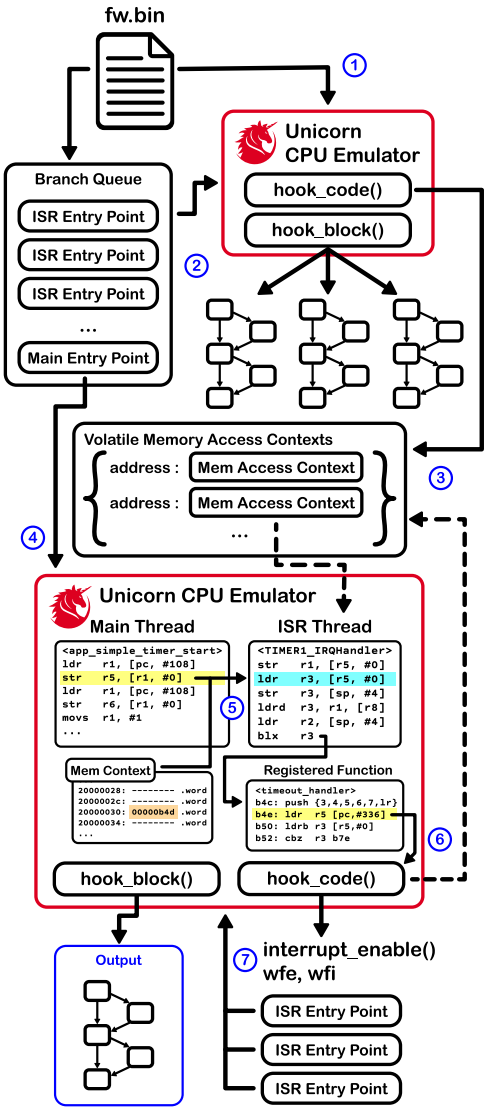

Figure 3: FFXE Algorithm Diagram

block will be encountered as a result of either an indirect jump from an inconsistent processor state or a fall-through edge that does not correspond to an actual function return. We observed that these invalid block locations tend to fall into one of three categories: (1) the 0 address and vector table entries; (2) data that has been interspersed within code sections; and (3) non-instruction regions like separate data sections, empty code regions past the edge of the firmware image, and hardware-mapped memory regions. The first and last categories are typically a result of invalid indirect jumps and are dealt with by halting execution if an address within those ranges is encountered. To deal with invalid attempts to fetch interleaved data, we refer to the memory log to determine if the address has been read from before. If it has, we assume that the address corresponds to data and halt the execution, allowing the engine to continue on to the next path to explore. This category of invalid locations tends to be encountered as

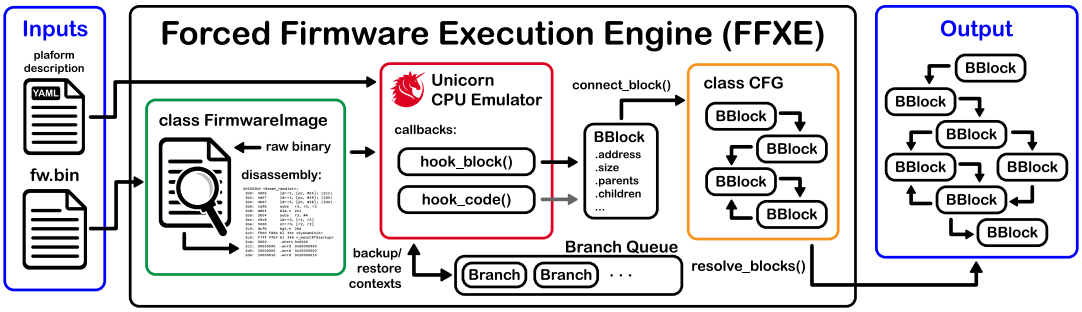

Figure 4: FFXE Software Architecture Diagram.

a result of an invalid fall-through edge, i.e. one that does not correspond to a returning function call, as in the case of tail call optimized functions. In addition, we also check that every instruction in a new translation block can be successfully disassembled, terminating if any invalid instruction is encountered. In each case where we terminate execution, we mark the invalid block for deletion, which occurs alongside the resolution of overlapping blocks at the end of the algorithm. In doing this, we prioritize the validity of our reconstructed CFG, attempting to prune those blocks and edges which we believe do not appear in the true CFG. However, in rare cases, this can remove a block that is actually a known target of a direct jump. In this case, we want to prevent the deletion of the block and edge. Therefore, we also keep track of explicitly defined jump targets and protect them from removal, forcing the engine to explore the defined targets regardless of the address location and preventing over-pruning.

Detecting Inlined Functions: It appears that tail call functions result in more than just invalid fall-through edges. They also complicate the detection of inlined functions, since an inlined function invoked via tail call may violate expectations if it is done without explicitly using a branch-and-link instruction. For instance, this may be done by overwriting the return address of a function address before a `pop` instruction is invoked, calling the next function implicitly similar to return-oriented programming, or making an unconditional branch straight to the inlined function without linking. While it is impossible to guarantee the detection of inlined functions under all circumstances, we are able to guess their presence if they are called more than once from separate locations. Since each block is labeled with the address of the function they are believed to belong to, we can detect if a block has been executed before from a different function context. This is because, in our implementation, blocks inherit their function label unless a branch-and-link instruction gives it a new one or a function return is detected based on the call stack return address. When an existing block's function label mismatches the current context, we assume that it is the start of its own function and relabel it, and any of its successors with the same address. This solution is not formally proven. In particular, the propagation of function labels may be troublesome, but in practice, it does not seem to cause undue pruning.

Thumb IT Instruction: This instruction is used to define conditional blocks for otherwise unconditioned instructions, allowing the programmer to conditionally execute several sequential, individual instructions based on a single condition code [25], this can complicate the forced execution algorithm if taken to be separate control flow paths since it would break the conditional block into several separate basic blocks. It turns out that `Unicorn` treats these blocks as a single translation block, so we are incapable of resolving this aspect of the control flow. Hence, we resign ourselves to dealing with conditional blocks only in the event that they end in a branch instruction, making that a conditional branch that requires a context split.

Table Branch Instructions: The ARMv7e-M ISA also implements the table branch instructions `tbb` and `tbh`, which are essentially the ISA's version of a jump table [25]. These instructions enable PC-relative forward branching based on a table of single-byte or single halfword offsets, respectively. A base register is used to indicate the start of the table, which can be the PC, allowing the table to be interleaved with instructions in the code section. The branch target is twice the value of the table entry. Under forced execution, the natural way to deal with this is to follow every unique branch path in the table, looping through the entries and adding each one to the exploration queue until we reach the end of the table. However, as far as we can tell, there is no hard limit on the size of the table, so we rely on empirical observations and assumptions made in line with Cojocar et al. [12] to decide when to stop adding entries, potentially resulting in long-running loops or lost coverage. We first observe that table branch instructions are almost exclusively compiled from `switch` statements, which results in a short data section inserted between the table branch instruction and the compiled `case` statements. This means that as we loop through the entries if we encounter a memory address that corresponds to a previously calculated branch target, we have hit the end of the table and can terminate the loop. This strategy proves effective in the cases we have observed, but to avoid overestimating the number of jumps, we also introduce termination conditions for several other scenarios: if the target is outside of a valid

Table elements: (# of found edges to registered function)/(# of found registered function entry blocks)/(# of known registered functions).

code region, if the jump target has a null value, and if the jump target cannot be disassembled. These all generally correspond to invalid jump targets, which we assume would indicate the end of the table. According to Cojocar's findings, such scenarios are unlikely to come into play, but we feel it appropriate to include them nonetheless. Note however that `switch` statements do not always translate to table branch instructions and FFXE currently does not handle other compilation patterns.

5 Evaluation and Results

5.1 Registered Function Resolution

As we have discussed at length, our algorithm is designed to resolve indirect jumps in firmware whose targets are dependent on volatile memory locations. Thus, our primary interest is whether our technique is able to resolve functions that are called following a registration pattern. To evaluate this, we consider a set of 8 firmware taken from the nRF52 SDK peripheral examples that are known to use the function registration pattern. We compile each sample using the `arm-none-eabi-gcc` [26] compiler at 4 optimization levels in order to maximize the variation in binaries and effectively bring our test set size up to 32. We execute our algorithm, as well as several others, on each of the samples, then determine each algorithm's success at finding known functions based on the presence of both a function's entry block and a valid control flow edge to that block in the graph. The location and presence of each registered function are determined manually by analyzing the source code and unstripped disassembly. The results of our analysis are listed in Table 1, in which each cell lists the number of known registered functions, the number of function entry blocks found, and the number of edges leading to those blocks from right to left. As can be observed, our algorithm can resolve callback function blocks as well as the edges leading to them, giving us confidence in the technique's ability to resolve volatile-influenced indirect branches. Note that we consider registered functions resolved when both the function entry block and an indirect jump to that block are found. However, the table records only the number of edges that lead to functions, without consideration for the control flow transfer type. We have manually analyzed this and discuss the results further in Section 6.

5.2 Overall Coverage Comparisons

Of secondary interest is how our technique compares to other algorithms overall. The goal of CFG recovery is to obtain a high-quality graph that is as close to the ground truth as possible, where the ground truth is represented by the ideal CFG which contains the set of all reachable basic blocks and all realizable control flow transfer edges. CFG quality is therefore judged on 2 primary criteria: *soundness* and *completeness*. We adopt the definitions of soundness and completeness in alignment with the `angr` authors, who flip the definitions of Xu et al. [48]: the recovered CFG G_R is *sound* with respect to the ideal CFG G_I if all edges in the ideal CFG are in the recovered CFG. Conversely, G_R is complete with respect to G_I if all edges in G_R are in G_I. Thus, a perfectly reconstructed CFG is both sound and complete, neither missing vertices nor edges, nor having non-existent ones, while an empty graph would be considered complete, and a fully-connected graph would be considered sound [42].

In an ideal world, we would evaluate the results of our CFG recovery algorithm against a ground truth CFG. However, short of painstaking manual analysis, it is rather difficult to establish the notion of ground truth when considering CFGs recovered from disassembly [35]. A number of works in the literature note that an ideal CFG might be derived directly from source code, but the resulting CFG does not necessarily map well to binary. Moreover, the accuracy of indirect jump edges resolved this way is not always guaranteed [36,48]. The same works opt to approximate the ground truth CFG by taking the union of observed execution paths from a curated set

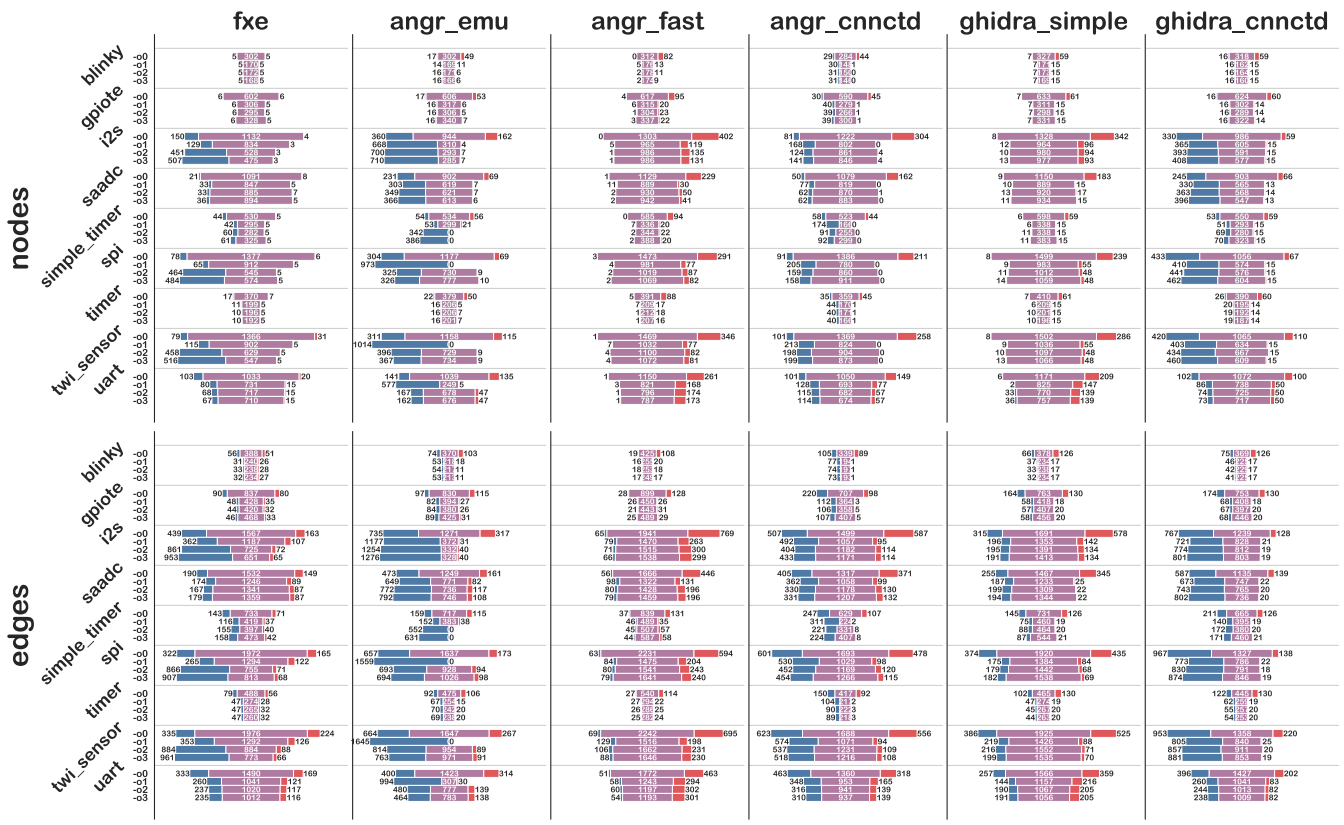

Figure 5: CFG Overlap Between FFXE and other Algorithms (Blue: FFXE only, Red: Column Technique only, Purple: overlap).

of inputs, designed to trigger as many conditions as possible. Unfortunately, designing those inputs for maximum coverage is cumbersome, and while some papers attempt a similar approach via fuzzing [50], the fuzzing of bare-metal firmware is a significantly difficult task. For the same reasons, generally, the union of inputs method is much more difficult to apply to entire firmware images, since firmware inputs typically come from hardware sources and would require significantly more effort to instrument than simply invoking a program with different parameters.

Having established that, short of exacting manual analysis, obtaining an ideal CFG is generally infeasible, we instead adopt the approach taken by other works on CFG recovery [35, 36, 39, 50] and evaluate our method against existing CFG recovery tools by comparing overlap between recovered blocks and edges. In particular, we compare FFXE against our implementation of the original paper's FXE [48], `angr`'s speed-optimized static method and accuracy-optimized dynamic method [42], as well as `Ghidra`'s built-in static CFG recovery technique [31]. We use the same set of firmware binaries compiled in Section 5.1, with the addition of the `blinky` firmware example, for a total of 36 firmware images. The results can be seen in Figure 5, which shows the edge and block overlap between FFXE and the other engines. Specifically, we define an overlapping block as any block in one

engine whose address range is completely covered by one or more blocks of the other engine. Hence, the blocks found exclusively by one engine in Figure 5 are those blocks that contain addresses not found by the other engine. This is to account for the fact that 2 engines may locate blocks covering the same address range, but with different sizes and boundaries due to differences in edge resolution. Additionally, note that results denoted as `cnnctd` correspond to the *reachable* subgraph of that engine's statically recovered CFG, where only blocks and edges that have a path from a known entry point are kept from the original. We discuss the results in Figure 5 further in Section 6.

In addition to these unit tests, we also run FFXE on a set of real-world firmware samples sourced from 4 commercial

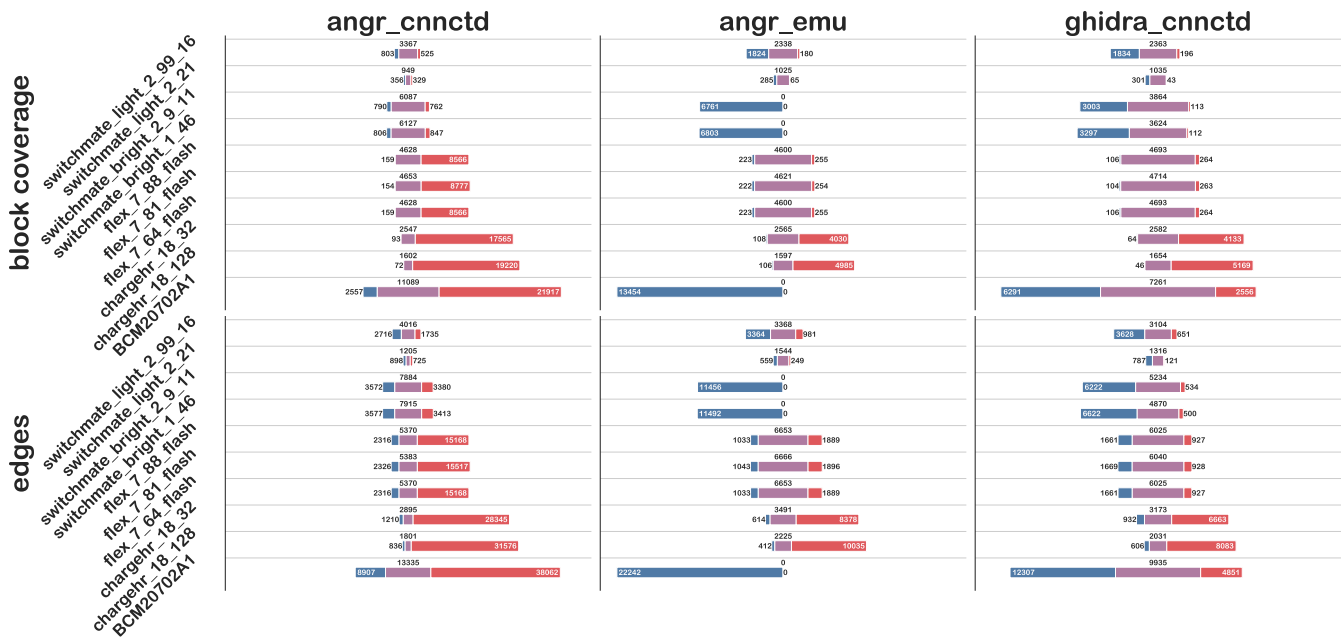

Figure 6: Block Coverage and Edge Overlap Comparison for Real-World Samples (Blue: FFXE only, Red: Column Technique only, Purple: overlap).

products: (1) the FitBit Flex 1 smartwatch, (2) the FitBit Charge HR smartwatch, and (3) the Switchmate Bright and (4) Light smart light switch controllers. The firmware names and processor models can be seen in Table 2, and the CFG coverage comparisons between FFXE and other engines can be seen in Figure 6. Note that in this figure, it is block coverage that is being charted, such the blue bars represent basic blocks found by FFXE that have *no address overlap* with blocks from the other engine. In other words, the exclusive blocks found by either engine would cover address ranges that are not found by other engines. Also note that FFXE is compared to `angr_cnnctd` and `ghidra_cnnctd`, which are the subset of blocks found by the static techniques that are reachable from a known entrypoint.

5.3 Performance Comparisons

While our FFXE implementation is only a prototype and not optimized for execution time, we are nonetheless interested in how its runtime compares to other techniques. As dynamic analysis fundamentally requires longer execution times, for what are likely obvious reasons–an entire CPU must be emulated as opposed to purely examining disassembly–we are inclined to compare FFXE runtime only against that of other dynamic techniques, i.e. the FXE re-implementation and `angr`'s CFGEmulated. To realize this objective, we use the same test set as in Section 5.2. The execution times are listed in Table 3 for the same set of firmware in Section 5.2 and were measured on an Apple M1 Pro processor. We observe that FFXE is considerably faster than `angr`'s emulated method, and somewhat slower than the original implementation. This is about what is expected given the relative complexity of each of the recovery techniques in question. As mentioned before, `angr` has a multi-step recovery process: first lifting the binary to the VEX intermediate representation, running its own symbolic version of dynamic forced execution as a preliminary step, then applying symbolic execution and backward slicing to accurately resolve every encountered indirect branches. Naturally, this translates to longer runtimes, as both symbolic execution and backward slicing involve graph traversal, and symbolic execution must further invoke constraint solving, which has a significant runtime overhead. With respect to the FXE implementation, we find relatively small increases in runtime that likely correspond to the traversal of additional paths. Overall, we are satisfied with the performance of our prototype, as it suggests that the runtime overhead introduced by volatile memory tracking and restoration is relatively modest. Improving the performance of our proposed method is a subject of our future work.

5.4 Case Study: Resolving Complex Data Flows

Our lab collaborates with the health technology startup healthetile.io and they have given their permission for us to conduct a case study on firmware for their We-Be Band, a smartband designed for monitoring vitals like heart rate and blood pressure. They have provided us with a firmware image and graciously allowed us access to their source code so that we can conduct an audit for the presence of vulnerabilities.

Times are recorded in seconds.

While there were a number of potential issues we found in their source code, there was one vulnerability that we found which represents a data-flow path that would otherwise go undetected if only using CFGs recovered with `angr` or Ghidra. Since we were unable to find a plug-and-play automated vulnerability detection tool that employs binary data-flow analysis, we instead identify the data-flow using Ghidra's built-in backward slicing capabilities for decompiled variables and memory referencing capabilities.

This vulnerability can be classified as a potential buffer overflow resulting from a lack of bounds checking for a buffer copy. Because the target buffer is located on the stack, and

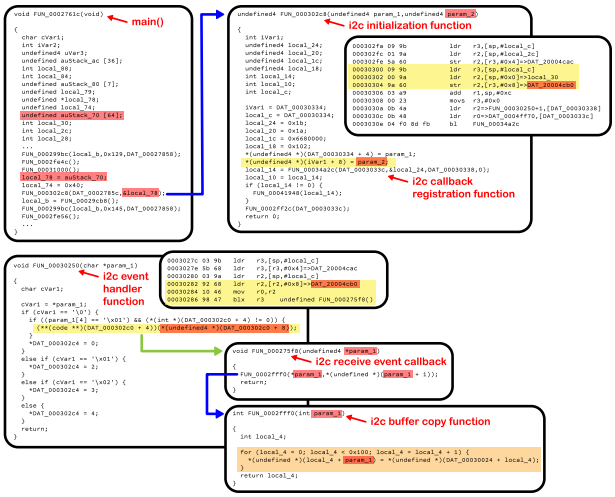

Figure 7: Backward slice of target buffer

the source buffer is read from I2C, the vulnerability is theoretically exploitable. The relevant portions of the backwards slice can be seen in the Figure 7, where we show portions of both the disassembly and decompiled code. We have also verified the decompilation against the source code and confirmed that the decompilation is more or less accurate. From our analysis, it is clear that tracing the affected buffer to assess exploitability was only possible because we were able to resolve calls to registered callback functions using FFXE. The indirect calling edges were not present in static CFGs produced by either Ghidra or angr. Additionally, `angr`'s emulated CFG recovery analysis failed to execute, likely due to lack of implementation details. Yellow highlighted regions map disassembly between decompilation. As can be seen, the first function registers both a callback function, as well as a stack-allocated buffer. In the second set of mapped functions, we can observe the loading of the stack-allocated buffer and its subsequent passing as an argument to an indirect function call, which is presumably a registered callback function. In orange we see the insecure memory copy loop, which copies the entirety of a global I2C buffer to a target buffer without checking the target buffer's length. From the disassembly, we are able to backtrack the target buffer's location to a stack address, passed as a parameter into function FUN_000302c8, which is evidently responsible for registering the callback function to a global structure at 0x20004cb0. Note that the data flow here occurs across threads, since the target buffer is registered in the main thread, but then overwritten in an interrupt context. Because neither Ghidra nor `angr` were able to recover the control flow paths to the callback functions, which is where the overflow occurs, they are unable to trace the target buffer all the way back to its source, which is necessary to determine if the vulnerability is technically exploitable. The presence of the unsafe buffer write alone is not proof that it can be exploited via external input. We have notified our collaborator of the vulnerability and have been informed that it is

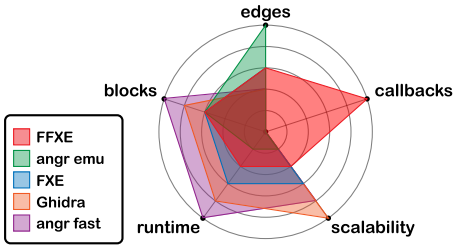

Figure 8: Qualitative Comparison of CFG Recovery Methods.

indeed a bug present in some of the debugging infrastructure that they have implemented. They've informed us that it will be removed. Note that we do not demonstrate the tangible security benefits of FFXE-enhanced CFGs beyond the case study we have presented here, as our focus is primarily on the problem of CFG recovery. This case study is meant to be a proof-of-concept for how FFXE can assist in further analysis.

6 Discussion

This section discusses the results of our evaluation, comparing FFXE to other CFG recovery tools based on our observations. A qualitative comparison of each technique can be found in Figure 8, which ranks orders each technique into 5 categories based on our results and experiences using each tool. Note that in this section, we do not discuss each tool in-depth, but focus on how each tool compares to FFXE.

6.1 Analyzing Identified Registered Function

As mentioned in Section 5.1, we consider a registered function successfully resolved when both the function's entry block, (i.e. the first basic block in the function) and at least one valid edge leading to that block is resolved. Moreover, we have stated that the tabulated edge values had not been validated as actual control flow transfers. Therefore, we must manually analyze each of the cases where blocks and edges are reported found to confirm their validity. We note first that in all test cases for the FFXE, we have fulfilled these conditions and confirmed that each edge does indeed correspond to a valid indirect branch. We can therefore have some confidence in our technique's ability to resolve indirect branches whose targets are written asynchronously to a volatile location. Conversely, we have found that all edges found in other algorithms are fall-through edges, which do not correspond to real control flow transfers. This means that, in general, the entry blocks resolved by the static algorithms–`angr`'s fast method and `Ghidra`'s built-in method–are the result of pattern matching against common function prologues. Hence, in reality, none of the algorithms we compare against are actually capable of resolving volatile memory-dependent indirect branches.

6.2 Considerations for Coverage Comparison

6.2.1 Comparison with Dynamic Techniques

Our coverage results are shown in Figure 5. We can observe improvement over the other dynamic methods, FXE and `angr`'s emulated algorithm, evidenced by the significant number of blocks and edges that were found exclusively by FFXE, as opposed to those found exclusively by the other methods. Furthermore, we demonstrate improvement over the original FXE implementation, in that our recovered CFGs essentially subsume those found by the original, finding nearly all blocks and edges that the original finds, and additionally those part of registered callback functions. This is expected because our modifications to the original algorithm are relatively minor, and do not alter the core mechanisms involved. We are merely adding some functionality to account for asynchronicity. Because the majority of the original algorithm remains intact, we are able to resolve a CFG that is a superset of the original. Hence we can claim that when compared to the original, our enhanced version is able to provide a more sound graph, though this necessarily increases uncertainty about its completeness.

In comparison with `angr`'s emulated recovery method, we observe significantly more coverage, which leads us to claim greater soundness for our recovery technique. We further investigate the underlying causes for the results by conducting an automated analysis on the blocks and edges exclusively found by `angr`. Due to space limitations, the tabulation of our analysis can be found on our Github. [2]

We observe that `angr`'s CFGEmulated algorithm prioritizes accuracy and completeness over coverage, and stores a significant amount of runtime information to enable further analyses like backward slicing. In order to optimize for accuracy and completeness, it makes significant use of value-set analysis as well as constraint solving and symbolic execution when encountering indirect jumps. Because it takes this approach, nearly all basic blocks that it finds are valid, and tends to include all technically possible indirect jumps. The `angr` documentation notes that indirect jumps resolved this way are not guaranteed to be always taken. In our investigation of recovered basic blocks we found an average error rate of approximately 59%, in which the invalid blocks were erroneously disassembled data regions, or corresponded to dead `nop` instructions. Likewise, when considering recovered edges, we found an average rate of error of approximately 19%, in which the edge started at or led to a false address. When we consider the total number of blocks and edges resolved, FFXE almost always outperforms `angr`'s dynamic recovery. Aside from FFXE's ability to resolve registered callback functions, we believe the primary reason for the difference is that FFXE employs concrete execution, while `angr` employs symbolic execution. As a result, `angr` must always

[2] https://github.com/rchtsang/ffxe/tests/analysis

rely on constraint solving, value set analysis, or some other additional method of indirect jump resolution when an indirect jump is encountered, as opposed to having a concrete target by default as FFXE does. While this does afford `angr` some advantages, this puts much more burden on the indirect jump resolution techniques for successful target resolution. If resolution fails, further execution cannot continue down that path. By contrast, because FFXE defaults to a concrete value, it is able to continue exploring. The additional cost also shows up in the form of additional execution time, since relying on constraint solvers for every indirect jump encountered is expensive. For this reason, `angr` also limits the call depth for function re-execution to 1. Our understanding of this is that, after a function has been explored once, if is seen again, it will only execute if calling that function will not increase the depth of the call stack past the limit, further limiting the potential for block resolution.

6.2.2 Comparison with Static Techniques

Comparison against static recovery techniques is not as straightforward as against other dynamic techniques, due to the fact that the underlying mechanisms are significantly different. As we have already discussed in earlier sections, static methods often use pattern matching and fall-through edges for the recognition of basic blocks and are limited in their ability to resolve indirect jumps. This tends to lead to higher block coverage, but diminished completeness, as fall-through edges do not always correspond to valid control flow transfers. We believe that these differences give a partial account for the relative lack of overlap between CFGs resolved by FFXE and those by static methods that appear to be present for both `angr`'s fast static recovery (`angr_fast`) and `Ghidra`'s default recovery (`ghidra_simple`), encoded in the size of the red bars charted in Figure 5.

To understand the differences in resolved blocks and edges between FFXE and static techniques, we have analyzed the blocks and edges found exclusively by `angr` and Ghidra for our unit tests on the nRF52832, since these binaries have corresponding source code and unstripped elf files whose disassembly can act as ground truth in determining whether a block is valid. This allowed us to programmatically determine if a recovered block represented a real block, or was erroneously disassembled data. Likewise for edges, we were also able to filter edges that led to falsely disassembled instructions in data sections or between actual instructions. As expected, for `angr_fast` and `ghidra_simple`, there were significantly more blocks and edges found than FFXE, since static pattern matching strategies are not constrained by actual control flow and, as a result, can pick up dead code or falsely disassemble data. On average, about 62% and 48% of statically recovered blocks, for `angr` and Ghidra respectively, corresponded to erroneously disassembled addresses, and about 32% and 41% of edges either started at or led to a false address, making

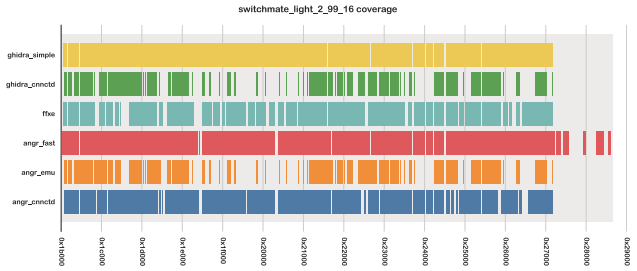

Figure 9: Visualization of coverage across the firmware image

them invalid. As we hoped, this is in line with our goal of producing more accurate CFGs, particularly with regard to completeness.

Additionally, we conducted a random sampling of the statically recovered blocks and edges that were not marked invalid, then performed a manual analysis to identify the reasons why FFXE could not resolve them. We determined that most of the blocks in this category had one of 2 causes for lack of identification: the blocks were part of unreachable dead code regions (about 60% and 59% for `angr` and Ghidra respectively), or the blocks could be traced back to a switch statement compiled as a load-based jump table (35% and 33%), which FFXE does not handle. We also note that the compiler optimization significantly influences this latter statistic, as unoptimized code tends to include many more functions and code sections that would otherwise be optimized away, including the aforementioned load-based jump tables. This appears to account for much of the differences in block resolution between optimized and unoptimized firmware images. As for edges, load-based branch tables (28% `angr` and 44% Ghidra) and dead code (21% and 49%) again played a significant role, with the difference that `angr` appeared to identify more function return edges (39%).

Based on our in-depth analysis of those blocks and edges not found by FFXE, we believe that FFXE provides complementary coverage gains to existing techniques, where existing techniques have a definite edge in resolving load-based branch tables, but fall short in completeness. Indeed, when we strip away the dead code regions in the `cnnctd` graphs, Figure 5 suggests FFXE can markedly improve completeness with the additional resolution of indirect branches. The complete tabulation of our manual analysis can also be found on our Github.

6.3 Effectiveness on Real-World Firmware

The high-level coverage comparisons between FFXE and every other algorithms are included on our Github. As already mentioned, in general, static recovery techniques tend to outperform dynamic techniques in terms of pure coverage. However, when we consider CFG coverage in terms of blocks that are reachable from a known entrypoint, for 8 out

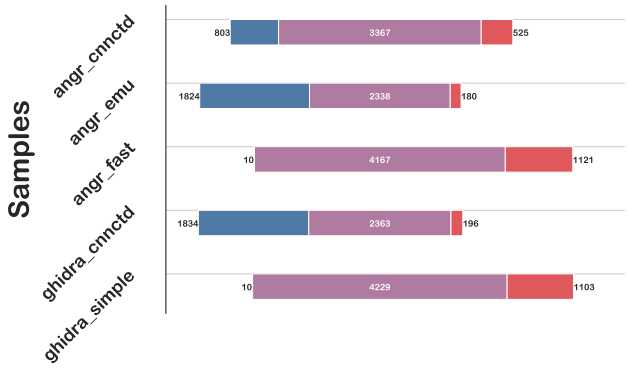

Figure 10: Basic block coverage overlap

of the 10 firmware images, FFXE coverage is comparable or substantially complementary to other techniques. In all cases of coverage comparison, we found that FFXE reports blocks that have non-overlapping coverage with other tools, which implies that FFXE has complementary utility with existing techniques. Note this is especially true of the images for the Switchmate Light and Bright, one sample of which is shown in Figures 9 and 10. Again, note that when compared to static tools, FFXE is helpful for recovering reachable blocks as opposed to sheer coverage of the address space. In the example above, this can be seen when comparing the overlaps to connected ("cnnctd") graphs, which are simply the results of doing a full traversal of the statically recovered CFG from any known entry point. While nearly all of FFXE's blocks are covered by static analysis, when the static CFG (whether from Ghidra or from `angr`) is reduced to only what is reachable from entry points, the coverage is significantly diminished. This is because both `angr` and Ghidra apply a mixture of pattern matching and recursive disassembly when conducting their analysis, which allows them to aggressively identify potential functions for disassembly, but cannot provide the control flow edges that would lead to them. This, as mentioned earlier, can impede automated analyses. Hence, our tests on real-world firmware demonstrate that the complimentary control flow edges that FFXE resolves can benefit analysis algorithms that rely on accurate representations of control flow between blocks.

6.4 Shortcomings

Here we must clarify what we believe to be the current shortcomings of FFXE:

- ***Increased Memory Footprint:*** To restore context upon asynchronous writes to volatile memory, we employ the simple but memory-intensive strategy of making additional backups of the processor and memory state. As this is already a costly task, we potentially exacerbate the problem by keeping these additional backups.
- ***Exploration Cycle Uncertainty:*** In the original forced execution paper, the quota system is introduced to guarantee termination of the depth-first search, and optimizations are made to ensure that enough state information is captured to lead to valid indirect jumps. We leave this system intact in our implementation and do not account for all edge cases that may arise when restoring a state based on a volatile memory write. While we believe that the quota system should handle this without modification, we have conducted no rigorous proof of this claim, and therefore admit uncertainty in the occurrence of infinite loops that may result from improper handling of block quotas in conjunction with cycles in the CFG.
- ***Invalid Processor States:*** The original paper was based on the assumption that indirect branch targets were generally independent of intermediate states. This assumption has been found to be false on multiple occasions [36,42]. While our work discards this assumption implicitly, as the very notion of volatile memory states must necessarily invalidate the assumption, the rest of the algorithm has not been touched, and may therefore still be subject to the shortcomings that accompany the invalid processor states when conditional statements are ignored.
- ***Architecture Dependence:*** Our prototype is currently coupled to a particular hardware platform and ISA. While we have created it with some flexibility and the ability to adapt to other hardware platforms that implement the same ISA, it is still fundamentally tied to the underlying architecture, particularly the Cortex-M interrupt management system. This means that, while not impossible, some implementation effort is necessary to apply this technique to other architectures.
- ***Scalability:*** Given our observations of execution time compared against both angr and the original FXE implementation, the scalability of our technique is not entirely certain. By adding additional context backups and path explorations on top of those needed by the original algorithm, we introduce some overhead in both execution time and memory footprint. However, it is difficult to predict how this overhead scales with firmware size without further analysis.

7 Future Work

Based on our observations in Section 6, we believe there are several practical directions that this research might take. First, because we have observed that our modification to the original forced execution algorithm adds only modest overhead to execution time, we believe that the general concept of volatile-aware forced execution might be incorporated into more mature existing dynamic CFG recovery techniques, like that of `angr`'s emulated method. Doing so could make `angr`'s

already powerful recovery technique much more suitable for firmware analysis. Furthermore, doing so would directly address the aforementioned issue of invalid processor states, as `angr`'s emulated method directly addresses this shortcoming through the use of symbolic execution. Conversely, we can consider enhancing FFXE further by adapting some of `angr`'s techniques and attempting to address the issues of invalid processor states, architecture dependence, and lack of features using intermediate representations and symbolic execution.

Second, we consider further evaluation of our technique by expanding our test set with more real-world examples and comparing against more recovery methods, such as those in IDA Pro [17], CMU's Binary Analysis Platform [9], and other research works like X-Force [36]. Expanding both our test set and comparison space would give us greater confidence in the validity and effectiveness of our technique.

Third, we consider possible enhancements to improve scalability, by addressing performance overheads in execution time and memory. Regarding memory footprint, we can refactor our codebase to utilize a database approach to saving and restoring execution contexts, allowing us to eliminate memory overhead that may arise from unnecessary duplication during backup and restore steps. Regarding execution time, if the quota system can be rigorously re-examined, we may be able to minimize the number of search paths for indirect branches and reduce the total execution time. Additionally, because forced execution is fundamentally a graph traversal, we may also be able to introduce speedup by designing a parallelized version of the algorithm.

Finally, to build upon this work and truly examine its potential impact on broader-scale firmware analysis, we intend to enhance the existing prototype to produce graphs that can be incorporated into more sophisticated techniques, such as binary similarity analysis or data flow analysis. Examining and comparing the results of such techniques when using CFGs generated using various recovery methods can give insight into how firmware analysis might benefit from enhancing intermediate analyses like control flow graph recovery with hardware awareness.

8 Conclusion

In this paper, we have presented FFXE, our prototype for a modified form of forced execution designed to address indirect branches whose targets are dependent on volatile memory by saving and restoring execution contexts on volatile memory accesses. We have tested our prototype on a test set of 36 example images, 32 of which contain manually verified functions that rely on the callback registration pattern. We compared our results against a re-implementation of the original forced execution algorithm, as well as the default CFG recovery methods employed by the popular software analysis frameworks `angr` and `Ghidra`. We find that in all 32 cases, we are able to meaningfully locate the registered callback functions where other techniques fail to do so. This gives us confidence that our implementation of volatile-aware forced execution is a viable solution to this class of indirection, which appears commonly in embedded firmware binaries. We have found that our tool has potential for improvement, but that the underlying algorithm is conceptually simple enough that other tools may benefit from incorporating this technique into their own dynamic recovery algorithms. We hope that our work will enable the application of sophisticated software analysis techniques to firmware and ultimately lead to more secure embedded systems.

Abstract

Firmware running on resource-constrained embedded microcontrollers (MCUs) is critical in this IoT era, yet their security is under-analyzed. At the same time, concolic execution has proven to be a successful program analysis technique on conventional workstation platforms. However, porting it to the MCUs faces challenges, such as incomplete and inaccurate emulation of hardware peripherals, reliance on customized hardware, and low execution speed.

CO3 is a firmware-oriented concolic executor attempting to address these limitations. *CO3* runs the firmware concretely on a real MCU to utilize its fidelity. Unlike previous designs, *CO3* gets rid of the slow or proprietary debugging interfaces for synchronization between the MCU and workstation. Instead, *CO3* instruments the firmware source code to strategically report runtime information via a basic serial port to a workstation where symbolic constraints are constructed and solved. We further combine *CO3* with a semi-hosted firmware fuzzing framework to create a hybrid fuzzer (*SHACO*).

The evaluation shows that *CO3* outperforms state-of-the-art (SoTA) firmware-oriented concolic executors by three orders of magnitude while incurring mild memory and runtime overheads. It is also faster than SymCC, a general concolic executor. When evaluated on the existing benchmark, *SHACO* finds all known bugs in a much shorter time. It also found seven bugs from three new firmware samples. All new bugs have been confirmed and patched responsibly.

1 Introduction

In this era of Internet-of-Things (IoT), firmware running on resource-constrained microcontrollers (MCUs) are fundamental components of the cyberspace infrastructure [5]. MCU-based firmware controls essential facilities like power grids, factory machines, and smart homes. The security of the firmware is of paramount importance [29].

Unfortunately, the security situation for firmware is dire. Attacks exploiting vulnerabilities in firmware have raised serious concerns [36, 41, 44]. This is primarily because firmware runs on constrained devices for efficiency and cost reduction purposes. As a result, they do not have access to the security features (e.g., ASLR) shipped with conventional operating systems (e.g., Linux). MCU devices also lack the necessary hardware support (e.g., MMU) on which many security mechanisms depend. Recent research [59] shows that attack mitigation techniques on MCUs are significantly lagging compared to their desktop counterparts. Consequently, detecting bugs in the firmware before deployment is imperative to mitigate these security threats.

On the front of vulnerability detection, concolic execution—a prominent software testing technique—has seen tremendous success and demonstrated great edges over traditional symbolic execution in workstation applications (e.g., desktop and server programs), especially in identifying critical security risks [26, 27, 49, 52, 56, 60]. Different from classic symbolic executors (e.g., [10, 55]) which aim to explore all execution paths at the same time, a concolic executor requires an concrete input to bootstrap [26]. Through maintaining both symbolic and concrete states as the program-under-test executes, a concolic executor gains more flexibility in using different states to explore different parts of the program, taking the advantages of both sides. As an example, a majority of program states can be explored concretely (e.g., by a fuzzer) in a cost-effective manner, while the symbolic engine is only engaged to break through "narrowly guarded" conditions. This forms the logical foundation of hybrid fuzzing [56, 60, 63].

Besides this intrinsic synergy with fuzzing, concolic execution also addresses a scalability limitation in classic symbolic execution, modeling the execution environment (e.g., system calls or even hardware). Concolic execution typically uses taint tracking to distinguish symbolic values from concrete ones at runtime. This allows a concolic executor to observe whether interactions through an environment interface are symbolic. If not, there is no need to symbolically model this interface. In comparison, determining this information statically is intractable for classic symbolic executors.

In firmware testing, recent years have seen a plethora of bug detection techniques tailored towards firmware, as evident

by the extensive list of fuzzers [9, 24, 38, 42, 43, 50, 51, 64] and symbolic executors [4, 13, 15, 20, 28, 40, 61]. Due to the resource-constrained nature of MCUs, performing fuzzing or symbolic execution entirely on the MCU is impractical. As a result, recent works tend to *rehost* the firmware from its native environments (i.e., the MCU) to a much more powerful platform (i.e., a workstation) either through emulation [20, 33] or hardware-in-the-loop [4, 13, 17, 35, 45, 61] (HiL). Emulation inherently does not meet the concolic execution's requirement, which requires an authentic execution environment (e.g., the real hardware), while MCU emulators are rarely complete nor accurate in their modeling [23].

On the other hand, while existing HiL approaches [17, 28, 35] engage the real hardware using debugging interfaces, they have not yet formed into a firmware-oriented concolic executor. Specifically, HiL-based symbolic executors are used as a standalone system instead of being combined with fuzzing. Moreover, they rely on versatile yet complex debugging facilities for synchronization between the MCU and workstation. Unfortunately, established research shows that this debugging interface is often the bottleneck of HiL-based systems [17, 35, 61]. This is because a complex procedure is involved to perform simple functionalities. For example, as illustrated in SURROGATES [35], seven steps are typically involved to perform a simple MCU hardware access. Each step further involves multiple gdb messages. As a result, as low as five hardware accesses can be performed per second. Many works strived to crack this bottleneck. One popular theme of solution is to use expensive or even commercially unavailable FPGA-based debugging interfaces [17, 35]. However, the sheer cost and customization required by such approaches deeply undermine their applicability. Besides, HiL approaches cannot support all hardware features available on a MCU. For example, they require halting the MCU's processor for state synchronization. This violates the real-time requirement that firmware commonly relies on.

Instead of accelerating the debugging process, we took a different route: to avoid the debugging interface completely. We designed a system, *CO3*, to reduce the synchronization cost between MCU and workstation, making *CO3* a practical concolic execution for firmware testing. More specifically, *CO3* faithfully executes firmware on the MCU with real hardware but keeps all hardware events local to the MCU without forwarding them. Instead, *CO3* instruments firmware source code strategically which instructs the firmware to *report and only report* concrete execution states that are relevant to symbolic reasoning to the workstation at runtime. The workstation handles resource-demanding tasks such as building and solving symbolic constraints by receiving firmware states from the MCU instead of emulating the firmware. This design combines key features of MCU and workstation, i.e., full-fidelity concrete execution and powerful symbolic reasoning with low communication cost. *CO3* does not need any debugging interface or customized hardware to bridge MCU and workstation; only a basic serial port is sufficient, warranting good applicability.

We evaluate *CO3* as being three orders of magnitude faster than the state-of-the-art (SoTA) HiL approach. It is even faster than SymCC [49], a SoTA workstation concolic executor. We further experimented with hybrid fuzzing, another benefit of concolic execution, through combining with SHiFT, a SoTA semihosted firmware fuzzer. We named this combination *SHACO*. We compare *SHACO* with various bug detection tools for firmware. *SHACO* outperforms all of them in identifying all known bugs in a much shorter time. *SHACO* also found previously unknown bugs, including three undefined behaviors and four buffer overflows in three actively maintained firmware samples, all confirmed and patched by the developer.

In summary, we make the following contributions:

- We introduce a novel design of concolic executor for firmware, *CO3*, which engages the MCU without resorting to debugging interface. While utilizing MCU's hardware, *CO3* greatly outperforms the traditional HiL-based design, achieving workstation-level performance.
- We combined *CO3* with a semi-hosted firmware fuzzer, SHiFT, to build the first hybrid fuzzer for firmware testing (*SHACO*) which outperformed all SoTA works. Additionally, *SHACO* found seven previously unknown bugs in three new firmware samples.
- Artifacts and source code of *CO3* are available at https://github.com/Lawliar/CO3

2 Background

2.1 Architectural Features of the MCUs

MCUs are self-contained and resource-constrained by design for economical and energy-saving reasons [2]. These design goals make them ubiquitous in critical infrastructure such as medical and industrial devices, aerospace, defense, and automotive [1]. Typical MCUs implement a single address space with designated RAM, FLASH, and peripheral areas. The peripherals' blackbox nature and diversity make them hard and tedious to model [23] in an emulated environment. The core processor interacts with these components in three ways: MMIO, interrupts, and DMA [24]. Thus, an ideal firmware concolic executor should support these three channels without modeling the peripherals.

Previous work [46] categorized embedded systems into three types (I, II, and III) according to their software architecture. This paper focuses on firmware running on Type II (i.e., RTOS-based) and Type III (i.e., bare-metal) MCUs. Type I MCUs support general OSes (e.g., Linux) and have more computation power, making running existing concolic executors (e.g., SymCC) on these systems feasible.

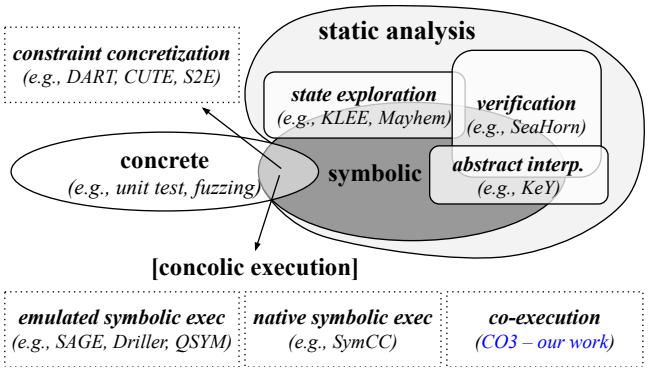

Figure 1: Program analysis techniques that intersect with symbolic and concolic execution and how *CO3* is positioned.

2.2 Symbolic and Concolic Execution

Despite being prominent program analysis techniques, both terms (i.e., symbolic and concolic execution) are overloaded and are sometimes used interchangeably. In this section, we pin down the definition and distinction of these terms for this paper, build a knowledge map on this topic (see Figure 1), and position *CO3* on the map.

The concept of symbolic execution is proposed to differentiate it from concrete execution. In a concrete execution, a program runs on a concrete test case, and a single execution path is explored. In contrast, symbolic execution can simultaneously explore multiple, if not all, paths that a program could take — by marking partial or all inputs as *symbolic*. A symbolic engine follows the program control flow and produces symbolic formulae representing the flow. These symbolic formulae are fed to a solver to answer queries about the program's properties, such as whether the program can take a particular path or reach a specific (buggy) state.

Classic symbolic executors (e.g., KLEE [10], AEG [6], and angr [55]) aim to symbolically track *all* sources of nondeterministic input. This makes them static despite the name "executor". In fact, for classic symbolic execution, its abilities to check property violations on all execution paths create a nice synergy in the domain of software verification and abstract interpretation(e.g., SeaHorn [30], KeY [3]). However, such an exhaustive exploration strategy faces two major challenges: incomplete environment modeling and path explosion. A concolic executor mainly differs from a symbolic one in addressing these two challenges.

A classic symbolic executor needs to soundly model the execution environment to capture the program's interaction with it. This is particularly hard in the MCU as its environment is composed of highly diverse peripherals. Modeling them has been proven to be infeasible [23]. Even worse, for completeness reasons, the modeling is needed even when the interaction with a peripheral rarely involves symbolic input. To ease the manual modeling efforts, DART [26], CUTE [52], and S2E [15] proposed using concrete values, instead of symbolic ones, to interact with the environment. This convenience comes with the expense of potential unsoundness and incompleteness; luckily, the benefit outweighs the cost in practice. Needless to say, concretization requires the availability of environments (e.g., the actual hardware) and faithful interactions with them.

In addressing path explosion, unlike classic symbolic executors that explore a program in a breadth-first manner, a concolic executor uses a depth-first strategy. It collects symbolic constraints along the path dictated by a concrete input and generates new inputs based on that single execution [27, 52]. Doing so enables better synergy with fuzzing [56], arousing extensive research interests [14, 60, 63].

Also, concolic execution is not to be confused with the hybrid execution proposed in Mayhem [11]. Although hybrid execution does use concrete execution to alleviate the workload of symbolic exploration, its main purpose, however, is to approximate path segments instead of being an independent input generator. This makes it less intuitive to combine with fuzzing. And yet, like Driller [56], Mayhem is emulation-based and requires binary rewriting for concrete execution and RPC for communication — features not commonly available and rather limited on the MCU [8, 47].

As highlighted in two concolic executors (i.e., Qsym and SymCC), a major impediment to concolic execution is speed. Qsym [60] shows that symbolic tracking can be accelerated using dynamic binary instrumentation. SymCC [49] further reveals that even dynamic binary instrumentation is slow: the compiler can implant the symbolic tracking logic directly into the binary — enabling symbolic tracking at native speed!

Figure 1 summarizes the flavors of symbolic execution and the evolution of concolic execution. Built upon the power of native symbolic execution enabled by SymCC, *CO3* lifts its reliance on a UNIX-like system for the purpose of placing the concrete execution on the MCU. *CO3* channels concrete execution with symbolic tracking on the workstation through our carefully designed protocol, achieving native execution on both sides (hence the name, co-execution).

2.3 Symbolic Execution for Firmware

Most symbolic executors built for firmware did not improve the symbolic execution itself, e.g., they adopt the same path-exploration, symbolic tracking strategies, etc., as their workstation counterparts. The major efforts in building such a system have been to resolve the hardware dependencies, as they all adopted the *rehosting* method.

As shown in Figure 2, where we summarize all relevant solutions, no matter it is *(a)*, the binary solutions (e.g., Avatar [61], SURROGATES [35], Symbion [28]) where the firmware is rehosted in an emulator or *(b)*, the source code solutions (FIE [20], Inception [17]) where the source code is interpreted in a symbolic engine, they address this problem in

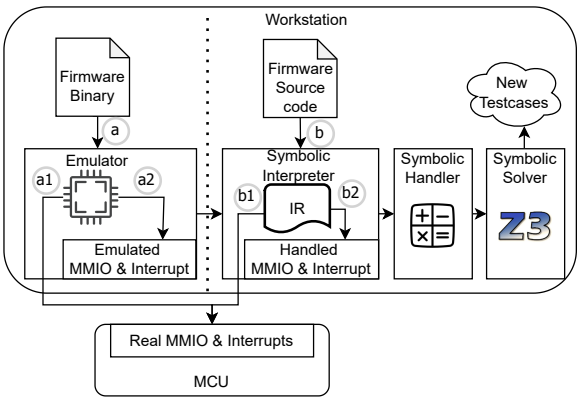

Figure 2: Existing design of symbolic execution for firmware.

the same way. Specifically, they either engage the real hardware through the HiL design (denoted in Figure 2 by *(a1)* and *(b1)*) or emulate the hardware through heuristic-based rules or symbolic values (denoted by *(a2) and* (*b2)*). FIE [20], for example, follows *(b2)*. It symbolically interprets the source code of the firmware and handles its MMIO by symbolizing them while firing interrupts according to a pre-defined specification.

Binary and source code solutions address very different problems. Source code solutions have richer semantics but are dependent on the availability of source code, while binary solutions are, in theory, more universal but have a harder time locating and distinguishing components in MCU's address space. Nonetheless, these works have severe limitations. The HiL approaches require highly customized connectivity interfaces due to outrageous synchronization latency between the MCU and the workstation. For example, SURROGATES [35] and Inception [17] use tailored, commercially unavailable FPGA-based debugging interfaces to connect the MCUs to the workstation. Such expensive customization deeply undermines their applicability. Yet, they are still slow (i.e., slower than KLEE) and fail to support all hardware features (e.g., real-time operation). To use the emulated hardware, the models proposed by the emulation approaches are inaccurate and incomplete. This leads to various problems caused by the lack of fidelity [23]. In contrast, using a better model, or even the real hardware, can prune the symbolic exploration [17] and mitigate state explosion and false positives [43]. In summary, existing solutions are limited in fidelity, speed, or applicability. Hence, these solutions have difficulties finding more, deeper, and real bugs in firmware.

3 Reflection on Hardware-in-the-Loop (HiL)

At the expense of physically engaging the hardware, HiL-based techniques excel over emulation-based approaches in reducing false positives. However, in current HiL designs, hardware is only involved in a very *passive* manner. Specifically, HiL requires a cumbersome procedure to communicate messages and commands with the MCU. For example, to request MMIO data on behalf of the firmware-under-test, the workstation has to: 1) pause the MCU, 2) set a hardware breakpoint at a specific address on the MCU, 3) command to resume the execution, 4) wait for the breakpoint to be hit, and finally, 5) retrieve data from the MCU. This process happens every time a hardware interaction occurs. It relies heavily on debugging protocols and facilities which, even when publicly available, are not intended for speedy testing.

In this paper, we challenge this "intrusive" debugging practice by asking whether we can make the MCU work with the workstation *cooperatively and voluntarily*. Drawing an analogy to hypervisor technology, *CO3* is an experimental solution that transits from full virtualization to paravirtualization for smooth and accelerated analysis on firmware. In the context of concolic execution for firmware, "paravirtualization" means that the firmware running on MCU is fully aware that it is executed concolicly and will proactively report all necessary information for symbolic tracking to the workstation.

This idea is partially inspired by SymCC, which instruments and compiles the target program to implant concolic execution capability into the program itself. The instrumented code allows the program to *actively* taint-track symbolic values and instructions instead of waiting for an interpreter to *passively* single-step it. In *CO3*, we take this concept to the next level by enabling concrete execution on the MCU platform, and channeling it with the symbolic execution on the workstation, realizing native executions on both platforms.

This results in three major benefits:

1. It assures the highest fidelity of all hardware features available on the MCU without having to model them, thanks to the nature of concolic execution.
2. There is no need to forward any hardware event (e.g., MMIO), as they all happen inside the MCU. In doing this, we do not need to host firmware emulation and can directly construct symbolic formulae on the workstation.
3. It takes advantage of the plentiful computing resources on the workstation for heavy symbolic tracking.

However, *CO3* does require source code for instrumentation. For MCU vendors and firmware developers who intend to boost the security assurance of their firmware, source code access is not a limitation. However, we acknowledge that *CO3* is not a solution for blackbox testing for firmware.

Remaining Challenges Although the above concept already shows noticeable advantages over the HiL design (e.g., support all hardware features, no need for firmware emulation and heavy synchronization), two major challenges and questions remain: 1). how does the workstation interact with the MCU and how to minimize the impact of this interaction? 2). how can we symbolize the physical input channels on the MCU due to the lack of a common abstraction layer? The

former is particularly important, as the existing HiL works engage the MCU through a cumbersome debugging protocol which forces them to use prohibitively expensive debugging interfaces. *CO3* needs to come up with a lightweight protocol that can sustain the most commonly available interface—the serial port [43]. In *CO3*, we achieved this via conservative compile-time analysis to extract (1) a skeleton of the symbolic formulae which we termed symbolic value flow graph (SVFG), and (2) as many constants in the formulae as possible.

4 Design

To demonstrate how SVFG works, take Figure 3 as an example. The left side depicts the instrumented firmware running on the MCU in the form of LLVM IR. The right side depicts the symbolic handler on the workstation with the knowledge gained from compile-time analysis of the firmware. Through compile-time static analysis, we already know all symbolic operations to build the symbolic formulae and some values for the operands (i.e., values in green). Reporting these operations and operands is redundant. Instead, the firmware only needs to communicate missing pieces from the MCU to the workstation (i.e., underlined red values), and the firmware should report them at runtime when they are known. Interested readers may refer to Appendix A.1 for a verbose reading of this example.

At *CO3*'s very core is a compiler that can be abstracted into the following interface:

$$\textbf{compile}(src) \rightarrow bin^{*}\,(\text{MCU}) \;+\; SVFGs\,(\text{workstation})$$

Specifically, *CO3* takes in the source code of the firmware and produces two outputs:

- bin^{*}: an executable binary of the firmware for the MCU with instrumented value reporting;
- $SVFGs$: SVFGs on how to build symbolic constraints by consuming reported values from the MCU.

The actual process of a single concolic execution round is distributed across two platforms, as abstracted below:

[on MCU]:
$\textbf{execute}(bin^{*}, input) \rightarrow result \;+\; trace\,(\text{reported on-the-fly})$
[on workstation]
$\textbf{build}(SVFGs, trace) \rightarrow constraints$
$\textbf{solve}(constraints) \rightarrow input$ # send to **execute()** on MCU

Interested readers may also consult Figure 4 for a more complete and graphical overview of this process. The rest of this section focuses on the design details of the SVFG, and symbolizing MCU physical input channels.

4.1 Symbolic Value Flow Graph (SVFG)

In *CO3*, an SVFG is a collection of data-flow slices obtained at compile-time. Each data-flow slice captures how symbolic values flow through a fraction of the firmware execution at runtime. The right side of Figure 3 is a sample SVFG.

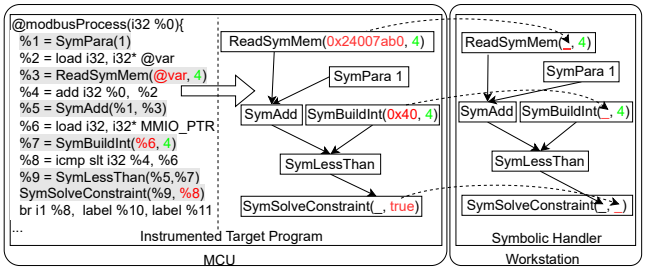

Figure 3: A simplified example of symbolically-instrumented firmware running on the MCU and the SVFG on the workstation. Shaded lines are the instrumentation code in LLVM IR, unshaded lines are the original instructions. Values in green are already known at compile-time. Values in red are unknown until runtime and, thus, need to be reported.

Symbolic value flow stems from three different places, namely, ① constant literals, ② memory reads, and ③ function parameters. These nodes are named *leaf nodes* in an SVFG. Through a series of computations (via *computation nodes* ⊠), these value flows will end up in one of two places: ❶ passing to solver, or ❷ memory write. These two places are known as *root nodes* in an SVFG, and represent how constructed symbolic formulae are ultimately used.

Multiple SVFGs can be connected in two ways: (1) via a memory write then read at the same memory address, or (2) via a function call where the caller passes the value as an argument. On the compiler side, the process of extracting SVFGs is to convert the firmware source code into a static single assignment (SSA) form that encodes the data-flow information. In marking symbolic nodes, the rule of thumb is to treat 1) every memory read (i.e., the `load` instruction in LLVM IR) as a leaf symbolic read, and 2) every memory write (i.e., the `store` instruction) as a root memory write; unless the compiler can decide the values are compile-time constant.

The task on the workstation side is quite straightforward. Information reported by the MCU in real-time instructs which SVFGs to construct together with:

- concrete values for non-symbolic operands in computation and pass-to-solver nodes (e.g., the `true` value in `SymSolveConstraint` in Figure 3).
- memory addresses where the content is symbolic when accessed at runtime to link SVFGs via ❷→② flow. (e.g., address 0x24007ab0 in `ReadSymMem` in Figure 3).
- function calls at runtime to select which SVFGs to build and link SVFGs via function call→③ flow.

The workstation only needs to backtrack the SVFGs from their roots to the leaves to reconstruct the symbolic formula.

4.2 Runtime Operations on MCU

In this part, we focus on how the firmware is instrumented to properly track and report information that the workstation needs to construct symbolic constraints.

① **Constant literals.** It is common to build symbolic formulae containing values already known at compile-time. For this type of leaf node, *CO3* directly embeds their literal values inside the SVFGs stored at the workstation; thus, the MCU does not need to report them.

② **Memory reads and ❷ writes.** MCUs implement a single address space where RAM, FLASH, and MMIO are mapped into different regions that are predetermined per architecture. For example, on ARM Cortex-M, the most popular architecture for MCUs, FLASH is in $[0x00000000, 0x20000000)$, RAM is in $[0x20000000, 0x40000000)$, and MMIO is in $[0x40000000, 0x60000000)$. This allows the firmware to distinguish which memory region its memory access is about by examining the value of the address.

RAM functions like a working memory where the firmware can read and write arbitrary values, including values controllable by user input (i.e., symbolic values) and supplied at runtime by the environment, such as peripherals (i.e., concrete values). As a result, two SVFGs can be connected in two ways:

1. A root node of SVFG_1 writes a *concrete* value to address X and a leaf node on SVFG_2 reads from X.
2. A root node of SVFG_1 writes a *symbolic* value to address X and a leaf node on SVFG_2 reads from X.

Note that case 1) is not interesting to *CO3*. Although it can, the firmware does not need to report the concrete value nor the memory address because they does not involve any symbolic operation. Also this information can be subsumed by a reporting of non-symbolic operands of the computation node. Case 2) on the other hand, is crucial in building the symbolic constraint because this allows two SVFGs to be merged and the continuation of formula building without the need for a symbolic memory model.

In order to track the mapping between memory address and symbolic values, conventional concolic executors use *shadow memory* [49]. The shadow memory essentially stores symbolic values indexed by their corresponding addresses. *CO3* incorporates the same idea, but needs to make one decision: where to host the shadow memory?

Since the MCU is too limited, the expensive shadow memory has to be hosted on the workstation. However, separating the shadow memory from the concrete execution requires the MCU to report the memory address when executing *every* `ReadSymMem` and `WriteSymMem` instruction. In doing so, the workstation is informed with all interactions between the firmware and RAM, and thus can keep its shadow memory up to date as the concrete execution goes on the MCU. However, this approach would incur much traffic since the firmware interacts with RAM intensively. Furthermore, if the user-controlled input is narrowly scoped, most of the reporting would not be interesting to the workstation as they fall into case 1).

Therefore, in *CO3*, we task the MCU to keep track of the *symbolic state* of the RAM. This is done by implanting another *shadow memory* at the MCU side. Instead of storing the real symbolic values of each byte like its workstation counterpart, this shadow memory only stores the symbolic state for them, i.e., each bit in this shadow memory indicates the symbolic state of one byte in the RAM of the MCU. Through the MCU-side shadow memory, we enable the MCU to memorize the symbolic state of every byte on RAM. This allows reporting only for the store and load operations that would affect the shadow memory on the workstation. For example, when *CO3* tries to read from RAM, the MCU can quickly check if this needs to be reported by checking the shadow memory and only report the address when any of the bytes being read is symbolic. This reduces unnecessary traffic significantly.

For ❷ memory writes, the MCU will examine the symbolic state of the value to store and the piece of memory being written. If both are concrete, i.e., writing a concrete value to a concrete memory, no action needs to be taken. However, if any of them is symbolic, the MCU will report to the workstation about the address it is writing to, and update its shadow memory accordingly. The workstation will use this to execute the write operation, and update its shadow as well.

Other memory-mapped regions. For FLASH, due to its read-only nature, no symbolic value will be written to it, and no symbolic value will come from it. Thus, the MCU will always treat its read as *concrete* and do nothing. On the other hand, MMIOs, which the firmware uses to interact with the environment, are complex and hard to model. Thus, *CO3* uses concrete values to interact with the MMIOs to use the real peripheral hardware. In writing to MMIO, the firmware will simply write the concrete runtime values to it; any symbolic taint of that value, if exists, will be lost. The only exception on MMIO handling is the data register (DR) which serves as a source of symbolic input and is discussed in detail in 4.4.

③ **Function Parameters.** Like RAM, the symbolic taints for function parameters and return values must be properly set when executing the call instruction. More specifically, the caller needs to update the symbolic state of the parameters so that they can be correctly referred to in the callee. To that end, we designate another static section of RAM on the MCU to keep track of the symbolic states of the function parameters when executing the call instruction. This is only to properly propagate the symbolic states of the parameters between the caller and the callee; thus, no reporting is needed. The workstation does the same, except it passes the real symbolic values instead of the symbolic states.

X Non-symbolic operands in computation nodes. A major source of reporting is when a computation node involves operands in contrasting symbolic states. To illustrate, consider a `SymAdd` operation that reads its left-hand side (LHS)

operand from RAM and the right-hand side (RHS) operand from MMIO. According to the MCU-side *shadow memory*, the LHS operand is symbolic. And the RHS is concrete. Thus, there is address reporting for the LHS and no address reporting for the RHS. As a result, the workstation will read the symbolic values from its shadow memory for the LHS and mark the RHS as concrete. However, to successfully build this `SymAdd` operation, the concrete value for the RHS also needs to be reported. The instrumented firmware is aware of this situation due to taint tracking. Hence, it will report the concrete value of the RHS to the workstation.

Taint tracking for computation nodes. After establishing the sources of the SVFG, these symbolic values will go through a series of computations. From the MCU's perspective, this process serves merely as the propagation of the symbolic states. Like taint tracking, the result is just a logical disjunction of the taint states of all its operands. Thus, we replace these symbolic operation instructions all with a simple logical disjunction instruction at compile time, reducing the binary size.

Pass-to-solver nodes. This type of node corresponds to a conditional branch that can be toggled to generate new input. In such a case, the MCU will report to the workstation which branch the concrete execution took, and the workstation will negate this formula to pass to the symbolic solver to generate new input that goes to a different branch than the one taken by this concrete execution.

4.3 Complication of the SVFG

Although Figure 3 shows a tree-like structure for SVFG, it is actually a graph because of the existence of ϕ-node in SSA [19]. Code in SSA form uses ϕ-node to choose between different values according to different control flows, and it is common to use ϕ-node on loop boundaries. Regarding the SVFG, a ϕ-node can introduce a back edge to its tree-like structure — making it a graph. For example, depending on whether the control flow comes before the loop (i.e., the first iteration) or inside the loop (i.e., the subsequent iterations), such ϕ-node will take its initial value, which is defined before the loop or the incremented one defined inside the loop. This requires *CO3* to embed control flow information in the SVFG, as we need it to inform which value the ϕ-node chooses on the side of the workstation.

To that end, we group computation nodes by the basic block (BB) they belong to. The naive solution would be for the firmware to report every BB executed. In doing so, we inform all ϕ-nodes on the workstation about which value they should choose, as this can be quickly checked by looking at the immediate preceding BB. Furthermore, the workstation is also informed about the loop, e.g., how many times it has been iterated and which branch it took inside the loop, if any.

Straightforward as this solution might sound, it has a severe drawback: if all operands of a ϕ-node are not symbolic, this reporting is redundant—this is similar to why reporting operands of a `SymAdd` is redundant when both operands are concrete. Reporting those BBs ramps the traffic up but is not interesting to the workstation. Therefore, before reporting it to the workstation, the instrumented firmware needs to check if the BB contains any symbolic operation. To achieve this, *CO3* instruments an instruction in the firmware that aggregates the symbolic states of all nodes within the BB through logical disjunction in compile-time at the end of each BB. The resulting bit indicates if this BB contains any meaningful symbolic operation and should be reported at runtime.

While this fix eliminates the unnecessary traffic, it introduces another problem which we call *symbolic residual*. To illustrate, consider an in-loop BB that contains one read operation from the shadow memory. When it is first executed, this read can be symbolic (i.e., the memory cell contains symbolic value). As a result, such a read and the BB it belongs to will be reported to the workstation. However, when that BB is executed again, the read shifts address, and becomes concrete. Worse still, the other operations within the same BB are also concrete. Neither the read nor the BB would be reported in such a case. Hence, their symbolic states will not be updated on the workstation side. Subsequently, if any formula depends on such a read, it will wrongfully use its symbolic expression that remains on the workstation.

As a result, we also report the BB to the workstation once it switches wholly from symbolic to concrete to eliminate this residual. Note that only the state switch will be reported. If the BB stays concrete, it will not be reported. Although the read is not reported in the previous case, the BB will report a state switch. As a result, the workstation will execute the nodes within the BB again. When it executes the read operation, it will know that the read does not come from a read reporting. Hence, it will know that this read is concrete and mark it as such, keeping it up-to-date. Also, on the MCU side, to memorize the state of the previous execution of every in-loop BB, we allocate one bit per in-loop BB on the function's stack.

After we switch from reporting every BB to only "symbolic" BBs, we cannot inform the ϕ-node on the workstation in the old way, i.e., by checking the immediate preceding BB, as there is no guarantee that either the preceding BB or the BB containing the ϕ-node would be reported. However, following the same idea of reporting only the symbolic BBs, we do not have to report for every ϕ-node, i.e., we only need to report and construct symbolic ones. Thus, what we do instead is to instrument right after each ϕ-node to check which value is chosen and only report when the chosen value is symbolic. Also, the ϕ-node has the same issue of *symbolic residual*, i.e., it switches from symbolic to concrete, but the workstation is unaware. We adopted the same solution as the loop to eliminate its residual.

4.4 MCU Physical Input Channels

As mentioned in Section 2.1, unlike the workstation with well-defined abstracted interfaces (e.g., the POSIX-like API), the MCU uses raw physical channels. MMIO, interrupts, and DMA were identified, summarized, and recognized as physical input channels by previous works [23, 24]. Unlike emulation approaches that use manually crafted heuristics to dynamically identify the input channels, *CO3* can easily locate these channels in the source code based on the insight that the firmware always configures the input channel before using it. To handle these channels, *CO3* introduces a monitor to direct the input from the workstation to the physical channel used by the firmware. This monitor receives input from the workstation, feeds it to the specified physical channel and starts executing the instrumented code. We discuss these three channels in more detail as follows.

Memory-Mapped IOs (MMIOs) The core processor accesses the MMIO region to interact with the peripherals. The data registers (DRs) are the main channel through which raw data flows from peripherals to firmware [24]. To support these DRs, emulation-based fuzzing approaches, such as P2IM, first locate them inside the MMIO region dynamically; then whenever these DRs are read inside the emulator, fuzzer-generated input data is provided.

Following P2IM, *CO3* also directly feeds input data to the DR through the monitor. However, unlike P2IM using pattern matching to identify the DRs, *CO3* automatically locates the DR through a static code scanning and configures the monitor to feed data to it. During online testing, as the workstation sends input to the monitor, the monitor will feed such input to the DR for the firmware to execute upon. Meanwhile, since the workstation also has symbolic memory that needs updating, the firmware must also communicate the DR to the workstation. Specifically, the firmware reports the address and subsequently every read of the DR as it executes. This enables the workstation to feed input data to the DR's address on its end for consumption whenever it receives the message.

Direct Memory Access (DMA) DMA allows data transmission through a DMA controller without the processor's intervention. DICE [42] observes that to use the DMA for receiving inputs, the DMA controller has to be configured with an input source and a destination buffer. After configuration, the DMA controller automatically moves the data from the input source to the destination buffer for consumption.

Following this observation, *CO3* directly symbolizes the destination buffer of the DMA. Specifically, the user first specifies *CO3* to use the DMA channel. Then, *CO3* will automatically locate the destination buffer during symbolic compilation. When the testing starts, the workstation sends input to the monitor; the monitor will feed input data to the configured buffer, symbolize it and start executing the instrumented firmware. To properly update the workstation, the firmware reports the address of the destination buffer. Then, the workstation will know where the input data will be consumed and symbolize it on its end.

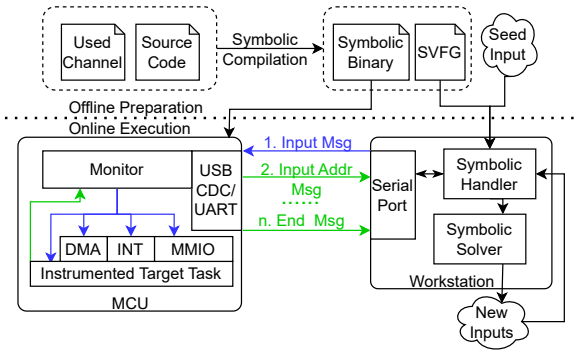

Figure 4: *CO3*'s system overview and communication protocol between the workstation and the MCU in action.

Interrupt Service Routines (ISRs) Firmware follows an interrupt-driven design for efficiency and power-saving purposes. Supporting their service routines is essential [61].

Emulation-based approaches usually fire interrupt according to a pre-defined heuristic due to the inaccessibility of real interrupt-firing information. HiL approaches generally rely on a proxy to broker the triggered interrupt. This turns out to be slow. In *CO3*, since we run firmware directly on the MCU, we only need to instrument the ISRs and let them execute when triggered. The instrumented ISRs behave just like an instrumented function. Meanwhile, since the interrupt can be raised at any time during firmware's execution, it can arrive in the middle of *CO3*'s updating the shadow memory, making it unstable. To solve this problem, *CO3* dynamically disables the interrupt when the firmware enters the *CO3* runtime and re-enables it when the firmware exits it, protecting its integrity.

Designated Buffer Last but not least, to make the *CO3* more flexible, besides supporting all the physical channels mentioned above, we also support the designated buffer as an input source. This is based on our observation that, regardless of what physical channel the firmware uses, it tends to gather them, place them in a buffer, and begin the main processing logic, which is of much testing interest. In contrast, the part of firmware that moves the data from the physical channel to such a buffer is much less interesting. To support such a case, the user just needs to specify which buffer to use before the symbolic compilation. Then, in the testing phase, the monitor will symbolize such a buffer, report its address to the workstation, and start executing the instrumented code. After receiving the address, the workstation will also symbolize the buffer on its end.

Vendor	MCU	CPU	Connectivity	FLASH	RAM
STM32	*F429ZI*	Cortex-M4 @ 180 MHz	UART @ 7.5 Mbauds	2MB	260KB
STM32	*L4R5ZI*	Cortex-M4 @ 120 MHz	USB 2.0 @ 12Mbps	2MB	640KB
STM32	*H743ZI*	Cortex-M7 @ 480 MHz	USB 2.0 @ 12Mbps	2MB	1024KB
NXP	*K66F*	Cortex-M4 @ 180 MHz	USB 2.0 @ 12Mbps	2MB	256KB
Microchip	*SAMD51*	Cortex-M4 @ 120 MHz	USB 2.0 @ 12Mbps	512KB	256KB

Table 1: List of MCU platforms

4.5 MCU-Workstation Communication

To put everything together, we show the overall workflow in Figure 4. First, in the offline phase, the user specifies which input channel the firmware-under-test will use. With this information, *CO3* automatically locates and configures the input channel in the monitor. Meanwhile, *CO3* symbolically instruments the firmware and performs the compile-time analysis to produce the symbolic binary and generate the SVFGs. Then, we feed the SVFG to the workstation and flash the binary on the MCU.

In the online testing phase, the symbolic handler will initiate the *CO3* protocol by sending the seed input. In response, the MCU sends back a message telling how the input is configured. This is followed by all the formulae-building messages, finally ending with an *End* message indicating no more message to send. In parallel with receiving the messages, the workstation constructs the formulae, passing them to the solver to produce new inputs. The newly generated inputs can be fed back to the MCU to continue the symbolic exploration.

5 Implementation

Symbolic Compilation The symbolic compilation is through an LLVM pass based on LLVM-14. Thanks to LLVM's modular design, we only need to instrument at the LLVM IR level, and can then lower the IR into arbitrary architecture supported by LLVM. In this LLVM pass, we first use the user-specified input channel to configure the *CO3* monitor. Then, we conduct use-def chain and loop analysis based on SymCC's instrumentation and output SVFG. We use the DOT language [1] for recording thanks to its flexibility and portability. The whole analysis and SVFG add 2K LoC to the SymCC's compiler. According to our evaluation, the generated SVFGs are typically very small in size, ranging from 60B to 160KB for each function.

MCU Specification As listed in Table 1, we implemented *CO3* on MCUs from STM32 [2], Microchip [3], and NXP [4]. We chose these vendors because they are among the most prominent MCU providers [1].

Note that we use a virtual serial port over USB 2.0 (USB CDC device) or a physical serial port (e.g., UART) as communication channel connecting the MCU and the workstation. Users can easily choose the one that fits their needs. According to a survey in SHiFT [43], these are the two most widely-available communication channels across all surveyed MCUs. We consider this a significant improvement in applicability as the previous HiL works depend on debugging probes that are highly customized or even commercially unavailable.

MCU-side Monitor and Runtime We built the monitor based on FreeRTOS 10.4.2. We chose FreeRTOS because it is arguably the most popular RTOS for Type II devices [5]. Besides, we only use its basic task-scheduling functionalities. Any other RTOS that provides such functionalities is also compatible. For example, we also ported to ChibiOS later in the evaluation.

As shown in Figure 4, the monitor receives inputs from the workstation, feeds them to the specified input channel, and then executes the target program. The instrumented target will then send back messages to the workstation. For this process, we designed 35 messages in total, with each ranging from 2 bytes to 13 bytes in length. We further buffer these messages in a 64-byte data structure on the MCU before sending them to exploit the 64-byte-sized frame that USB 2.0 uses. We developed the runtime functions and monitor from scratch in C. The code comprises only 2.1K LoC in total.

Symbolic Engine *CO3*'s symbolic engine, as shown in Figure 4, renders the SVFGs using the boost library [5]. It then sends and receives messages through the libserialport [6], a cross-platform library for communication between the workstation's symbolic engine and the MCU serial port. Based on the SVFGs and the messages from the MCU, *CO3* calls to the backend of SymCC to construct and solve the symbolic constraints. The symbolic solver is based on Z3. We set the same time-out for the symbolic solver as SymCC to align with the SoTA.

6 Hybrid Fuzz Testing

CO3 explores an firmware program state concolically through generational search [27]. However, for bug-finding purposes, concolic execution alone has two inherent limitations:

- Concolic execution is significantly slower than fuzz testing, especially when exploring easy-to-reach states [56],
- State exploration implies bugs only when there is a bug oracle to decide whether a state is undesired. To illustrate, for conventional desktop/server programs, a bug oracle for out-of-bound (OOB) access can be as simple as page fault (enabled by MMU) or backed by com-

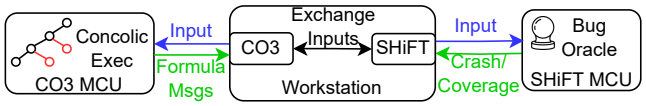

Figure 5: *SHACO*'s overview.

piler instrumentation (e.g., AddressSanitizer [53]). For firmware, however, even OOB might not be observable due to the lack of MMU and kernel support. This lack of observability issue of the MCU has been extensively investigated in wycinwyc [46].

CO3's bug-detection capability can thus be greatly enhanced when combined with a fast fuzzing system that also solves the bug observability issue for the MCU. This is where SHiFT comes in. SHiFT facilities feedback-based fuzz testing (e.g., AFL/AFL++ [25]) natively on the MCU while hosting input mutation on the workstation. It also ported desktop sanitizers to the MCU to address the observability issue. We name this combination *SHACO*, a hybrid fuzzing framework.

As depicted in Figure 5, *SHACO* runs SHiFT on one MCU and *CO3* on another of the same configuration. They both communicate with their workstation component through a serial port. SHiFT is responsible for fast testing and collecting crashes, while *CO3* toggles branches for the inputs deemed interesting by the fuzzer. The input exchange happens on the workstation through a simple file copy. Note that we combine SHiFT and *CO3* in a rather primitive way; as this paper focuses on concolic execution, we leave topics such as a more sophisticated hybrid fuzzer and merging fuzzing and concolic execution to one board for future work.

7 Evaluation

In this section, we evaluate *CO3* to answer the following research questions:

- RQ1: How does *CO3* minimizes the MCU interaction and how does this contribute to the end-to-end performance compared to the SoTA regarding speed and code coverage?
- RQ2: What overhead can a developer expect when using *CO3* for the firmware under development?
- RQ3: How is *SHACO*'s bug detection effectiveness compared to other bug detection works for firmware?

Experiment setup. We perform the evaluation on a workstation with Intel Core i5-7260U CPU, 64 GB of RAM, and Ubuntu 22.04. Details of the MCU used in the evaluation are discussed in Section 5. In fairness, we run all comparison targets using the same workstation, MCU, and communication channel setup. All targets are natively built without patching or modification.

7.1 RQ1: Concolic Execution Performance

Experiment Setup In evaluating RQ1, we select Avatar2 [45], the SoTA multi-target program state transfer framework based on traditional HiL design. Although Avatar2 is not exclusive to testing MCUs, it has built-in support for various debugging probes (e.g., J-Link [7], OpenOCD [8]) commonly used by MCUs. As Avatar2 does not implement fuzz testing nor symbolic execution, we thus compare *CO3* against Symbion [28] which integrates Avatar2 into symbolic execution (i.e., Angr). To be specific, we run both systems against seven real-world firmware samples introduced by P2IM and DICE [42]. These benchmarks are chosen because they have been used extensively by existing works (e.g., Fuzzware, uAFL, and SHIFT). They are *Steering_Control*, *PLC*, *Drone*, *CNC*, *Console* from P2IM; *Midi*, *Modbus* from DICE. For a fair comparison with Symbion, we configured it to perform concolic execution like *CO3* and SymCC. This avoids bias from the path exploration component [9] in angr.

Since *CO3* uses multiple optimizations to minimize the "footprint" of MCU-workstation interaction, we also evaluate how each technique contributes to this reduction. Specifically, *CO3* employs two major techniques: ① replacing a majority of symbolic operations with a logic disjunction instruction on the MCU, and ② MCU-side shadow memory to keep track of the symbolic states of the RAM on the MCU. To see how each technique performs, we have three modes of *CO3*:

- *Report-All*, where the MCU reports every executed instruction without any symbolic states tracking (i.e., disable both ① and ②),
- *Shadowless*, where the MCU performs symbolic state tracking but always treats RAM as symbolic (i.e., disable ②).
- *Full-on*, where both ① and ② are enabled.

Intuitively, *Shadowless* relieves the MCU from having to allocate a piece of RAM as shadow; *Report-ALL* further frees the MCU from keeping any symbolic state. To quantify MCU interactions, we treat the MCU as an IO device and study its impact on the workstation. Specifically, we evaluate 1) how many bytes are transmitted for each run over the wire, and 2) how much time the workstation spends waiting for the MCU to evaluate its impact on the overall performance. These are considered as the "footprint" of an interaction.

Besides the experiment with Symbion, we also compare with SymCC, a SoTA concolic executor. Although SymCC is not designed for firmware, and cannot solve its hardware dependencies like *CO3*, we chose it because both systems follow the compilation-based design. Specifically, SymCC packages symbolic and concrete execution into one binary, while *CO3* further decouples concrete and symbolic execution to heterogeneous platforms and connects them via a serial

[7] https://www.segger.com/downloads/jlink/

[8] https://openocd.org/

[9] Simulation Managers - angr documentation, https://docs.angr.io/en/latest/core-concepts/pathgroups.html#exploration-techniques

port. Comparing with SymCC allows us to assess the value of this decoupling.

In the experiment comparing with SymCC, we use the CGC benchmark with the proof of vulnerability (POV) inputs [48] as seeds. We chose this benchmark because it has been heavily used in SymCC and Qsym for the same evaluation purpose. SymCC and Qsym mentioned many benefits of using CGC programs to evaluate workstation concolic executors. In addition to these benefits, they are also valuable for firmware because of their independence from `libc`, as firmware also typically uses customized `libc` (e.g., `newlib`). We evaluated 5 CGC programs in alphabetical order since these programs need refactoring to run on the MCU and do not represent the real firmware. We consider 5 is enough to understand how *CO3* is compared with SymCC.

Execution Time We measure *CO3*'s execution time between the first *Input Address* message (Figure 4) arriving at the workstation until the last call to the symbolic solver finishes. SymCC measures the time between the start of program execution until the last call to the symbolic solver finishes. Both *CO3* and SymCC use the time measurement module from Qsym. Symbion is slightly different since it relies on the debugger; we measure its time from when the debugger connection is established until all constraints are solved. We continue to loop the generated inputs back as new inputs to the system. We keep running for 24 hours and take the average as results. Although we run all three modes of *CO3* for each experiment, we will focus on *Full-On* mode to compare with SymCC and Symbion while showing data for the other two. We will systematically discuss the differences between different modes in answering RQ2.

In comparing with Symbion, from Figure 6.(2), we can see that without the physical debugging probe, *CO3* outperforms Symbion by three orders of magnitude. The reason for this advantage is three-fold: Firstly, *CO3*'s optimization of traffic. Figure 6.(3) shows that for the tested firmware, Symbion transmits about 150KB per execution, while *CO3* transmits less than 8KB.

Secondly, *CO3* parallelizes MCU-workstation interactions. As mentioned in Section 3, in a traditional debug-based solution (e.g., Symbion), the workstation has to send command, wait for the MCU to take action and send back the result every time a hardware event occurs. The workstation cannot do anything besides waiting in this process. Whereas in *CO3*, the MCU just puts the data on the wire and does not wait for confirmation. This enables the workstation to interact with the MCU in a separate thread. The workstation may process what has been sent by the MCU while waiting for the next message. Figure 6.(6) shows that, in *CO3*, the MCU-workstation interaction has about 1% impact on the end-to-end execution time, resulting in a mere 0.0001s to 0.001s waiting; whereas in Symbion, waiting for MCU has about 23% impact with time ranging from 3s to 7s. From 3-7s to 0.0001-0.001s, *CO3* significantly minimizes the MCU's impact on the workstation.

Lastly, using a debugging protocol to synchronize hardware events is detrimental to performance. This design implicitly requires the firmware to be emulated on the workstation since only the emulator can make use of such hardware events. As a result, the symbolic engine must be placed on top of the emulator. *CO3*, in contrast, instructs the firmware to directly report values for symbolic formulae. This enables us to directly host symbolic engine, removing firmware emulation entirely. As a highlight of the benefits of removing firmware emulation the hardware events forwarding, according to a survey from SHiFT, if used solely to communicate data (e.g., through the `m` and `M` packets[10]), the *GDB* protocol is only about 50% slower than using the raw physical channel [43]. This means that even if we use the *GDB* protocol to implement *CO3*, the result would fetch around 50% throughput of the current *CO3*, which is still significantly faster than the traditional schemes that rely on synchronizing hardware events and firmware emulation.

As for comparing with SymCC, from Figure 6.(1), we can see that *CO3* is even faster than SymCC. This result shows that although *CO3*'s offloading concrete execution onto the MCU incurs extra serial communication overhead and a slowdown on the concrete exeucution, the benefit of this parallelization still outweights the disadvantages.

Conceptual formulation To put the benefits of *CO3*'s design into more perspectives, we formulize all three systems in Figure 7 where we denote A as the cost of *concrete execution and concreteness checking* [49], and B as the cost of *symbolic constraint building and solving*. Then we can formulize SymCC as

$$SymCC = A + B \tag{1}$$

Since *CO3* offloads A to the MCU and incurs serial communication overhead, *CO3* can be formulized as:

$$CO3 = max(xA, B, C) \tag{2}$$

where x is how much a commodity CPU (e.g., Intel-i5) is faster than a MCU (e.g., ARM Cortex-M7) and C is the serial communication overhead. From Eq 2, we can see that, although *CO3* slows down A by x and incurs C, these three components run in parallel, making *CO3* outperform SymCC in most cases. Lastly, we formulize Symbion as

$$Symbion = E(A) + I(B) + C' \tag{3}$$

where $E(A)$ and $I(B)$ represent emulated execution and interpretation-based symbolic execution as compared to native ones and C' denotes the communication cost plus the MCU action time. We can see that, Symbion not only suffers from delayed MCU communication, it also has slower and highly sequential components.

Furthermore, although the execution time of *CO3* shown in this experiment is reasonable, there is still plenty of room for improvement. Interested readers may refer to Appendix A.2

for more information.

Code Coverage To evaluate code coverage, in the above experiments, we also collect all the generated alternative inputs by all systems. We measure control-flow edges covered by these inputs accumulatively by feeding them to an independent edge-reporting binary. The edge coverage follows AFL's algorithm [11].

As we can see from Figure 6.(4) and 6.(5), for all the tested benchmarks, *CO3* covers more edges. This highlights the efficiency of *CO3* for generating high-quality inputs compared to the SoTA given the same amount of time.

7.2 RQ2: Overheads

This subsection systematically evaluates, in using *CO3*, how much runtime and memory overheads a developer can expect based on all 12 firmware (CGC and P2IM firmware) mentioned above. For each firmware, we prepare the original unmodified firmware and apply three modes of *CO3*. We used STM32-H743, NXP-K66F, and Atmel-SAMD51 from Table 1 as MCU platforms. We focus on *CO3* instead of other systems because these traditional HiL approaches run original firmware on the MCU, theoretically imposing no memory and runtime overhead. Thus, we run the unmodified firmware as the baseline. *CO3* adds multiple components to the firmware. The overheads of such components are vital to evaluate the practicability of *CO3* as the MCU is resource-constrained. Based on the overheads, we also evaluate the trade-off between different modes of *CO3*.

Regarding memory, *CO3* introduces instrumentation, runtime, and the monitor into the firmware. The footprint analysis is presented in Figure 8.(1). From the figure we can see that the original firmware has a median FLASH and RAM footprint of 46.1KB and 52.46KB respectively. *Full-On* mode introduces 12.67KB FLASH overhead, a 27% increase; however, its RAM overhead is 66.1KB, a whopping 125% increase. *Shadowless* mode introduces 12.45KB FLASH overhead, also a 27% increase to FLASH; however, since it does not require one-eighth of the whole RAM as shadow, it only has 1.5KB RAM overhead, i.e., 2.9% increase. Lastly, *Report-All* has a 19.65KB FLASH overhead, a 42% increase. This is because, in this mode, we instrument the original symbolic instructions instead of replacing most of them with a simple

[11] AFL-technical_details.txt https://github.com/google/AFL/blob/master/docs/technical_details.txt#L23

logical disjunction instruction, resulting in a bloated binary. Its RAM overhead is consistent with *Shadowless*, a 1.5KB overhead, as it also does not require shadow memory.

Regarding time overhead, the result is presented in Figure 8.(2). From this figure we can see that *Full-On* mode has a 121x time overhead, while *Shadowless* and *Report-All*'s time overheads are 449x and 1324x. We attributed this to our efforts to minimize the traffic, as serial communication is slower than the MCU's processing speed by far. For example, a simple logic disjunction instruction in *Full-On* can be transmitting 3B in *Report-All*. Note that, for all three modes, the MCU is only responsible for reporting data, it does not perform expensive symbolic operations. We consider *Full-On* and *Shadowless* time overhead mild compared to the 1000x slow-down from a normal concolic execution engine [49].

Considering the overheads and performances of all three modes, although *Full-On* has a 66.1KB RAM overhead, all three modes of *CO3* fit into the three MCU platforms that we experimented on. This is partly because we use relatively high-end MCUs as experimental platforms. In practice, we do foresee cases where the one-eighth RAM overhead from the shadow memory can be expensive. For such a case, we recommend *Shadowless* for its mere 1.5KB RAM overhead.

In conclusion: *Full-On* mode has the best speed and edge coverage performances but its RAM overhead can be prohibitive making it not applicable to all MCUs. *Shadowless* has slightly worse speed and edge coverage performance compared to *Full-On*, but its memory overhead makes it generally applicable if a 449x time overhead on the MCU is tolerable. *Report-All* not only has much worse speed and coverage performance compared to the first two, but its memory and time overheads also make it less desirable.

7.3 RQ3: Bug-Detection Capability

In RQ3, we evaluate the bug-detection capability of *SHACO*. The SoTAs in bug detection for firmware are primarily emulation-based. We select Fuzzware [51], P2IM, and DICE as targets systems. Fuzzware and P2IM are chosen for their popularity and bug-finding capability; DICE is chosen for its unique ability to support the DMA feature. Since *SHACO* combines *CO3* with SHiFT, we also evaluate against SHiFT alone to evaluate what *CO3* contributes in addition to SHiFT.

Benchmark We evaluate the bug detection capabilities of the selected targets from two different angles: 1. the ability to detect *known, documented bugs*, and 2. the ability to detect *unknown, new bugs*. For the former, due to the lack of a well-known benchmark (e.g., LAVA [21]) for MCUs, we chose the firmware samples with well-documented bugs that were widely used in the literature. P2IM and DICE, the two seminal emulation-based approaches, suggested such samples with detailed bug reports; these buggy firmware samples have also been used by other works (e.g., uAFL, Fuzzware). Besides, SHiFT provides firmware samples with bugs that emulation-based approaches cannot find [43]. Thus, as Table 2 shows, we select *PLC (4 bugs)* from P2IM, *Modbus (3 bugs)* and *Midi (2 bugs)* from DICE, *Shelly Dimmer (3 bugs)* and *Synthetic (11 bugs)* from SHiFT to make a benchmark. *Modbus* and *Midi* use DMA as the input channel which Fuzzware does not support out-of-the-box. For a fair comparison, we manually identify the static DMA buffer from the binary with debugging information and annotate in fuzzware's config file [12]. We run *CO3* and related works for 24 hours, manually triage all the crashing inputs (**UC** row of Table 2), and measure how long they took to identify **all** the known bugs (**TP** row of Table 2) of each firmware to evaluate their bug-detection capabilities.

In addition to the firmware with known bugs, *SHACO* additionally found new bugs in other firmware. As shown in the *SHACO* column of Table 2, these are: *CANopen*: an open-source firmware of the controller area network (CAN), *Stepper*: a firmware that drives a stepper machine, and *bldc*: a firmware for real-world motor controller. In *CANopen*, *SHACO* finds three undefined behaviors. In *Stepper*, *SHACO* finds two buffer overflows (BOFs). In *bldc*, *SHACO* finds two BOFs. These bugs have all been confirmed and patched by the developers. We also run related works on these firmware to test their ability to find unknown bugs via manually triaging their crashing inputs.

Detecting All Known Bugs With as simple a strategy as exchanging inputs between SHiFT and *CO3*, the time taken to detect all the bugs in the benchmark is reduced significantly. This confirms the effectiveness of *SHACO* in detecting bugs in real-world firmware. In some cases, the improvement is insignificant, such as the 1.9x speedup in *Modbus*. This is due to *Modbus*'s small code base and search space, e.g., only 230 LoC. For such small firmware, fuzzing is usually enough. In *Midi*, *SHACO* is almost identical to SHiFT. This is because *Midi* employs a state-machine-based design. As a result, the execution of an input is dependent on the previously executed inputs. In such a case, the input generated by concolic execution can easily be rendered invalid due to the change of state. We refer interested readers to papers (e.g., SGFuzz [7]) addressing this issue.

However, this is just to compare *SHACO* with SHiFT, as these two approaches both run natively on the MCU and utilize real hardware. The contrast is much sharper when comparing *SHACO* against emulation-based approaches. As shown in Table 2, *SHACO* generally outperforms them by two to three orders of magnitude in terms of bug-detection capability. The emulation approaches not only failed to boot (marked with **NB**) due to the incorrect model (e.g., *Shelly Dimmer* for P2IM) when they did boot, their inaccurate MMIO interaction leads to unauthentic program state (e.g., Fuzzware's MMIO

Table 2: Fuzz testing campaigns of *SHACO* compared to other SoTA. **Time**: How much time it takes for this work to identify all the known bugs. **F**: FreeRTOS. **C**: ChibiOS. **SUF**: *SHACO*'s speedup factor compared to this work. **UC**: # of Unique Crashes. **TP**: # of True Positive bugs. **FP**: # of False Positive bugs. **I**: Incomplete detection, i.e., it does not detect all bugs in 24h. **NB**: No Bootstrap, i.e., the firmware fails to boot.

model returns practically impossible values). This prevents them from finding all the true bugs (marked with **I**). Adding up to the vast false positives, the situation even worsens considering the bug observability issue (i.e., the triggered bugs usually take a long time to observe) they have.

Detecting New Bugs Due to the hardware and software dependency of the newly introduced firmware, we ported *SHACO* to two new MCUs (i.e., stm32l4r5 and stm32f429) and one new RTOS (i.e., ChibiOS). P2IM cannot boot due to poor emulator support for these MCUs [13] [14]. Fuzzware avoids this issue by using Unicorn instead of QEMU as the emulator; however, it still fails to support the FPU [15], which *bldc* configures in assembly.

After the fuzzing campaign, the selected systems exhibit similar behaviors as in the known bugs detection experiment (i.e., *SHACO* outperforms SHiFT three to five times while Fuzzware is trapped by the unauthentic program states and fail to detect the same bugs).

Case Study In *Stepper*, for example, we found an undefined behavior (UB) bug. This UB is inside a callback function triggered from a multiplexed timer's interrupt service routine. Since *CO3* has access to the real timer's hardware, the timer just normally incremented and triggered different multiplexed callback functions as expected. In both P2IM and Fuzzware, however, since they are at the NVIC's level which triggers each interrupt service routine in a round-robin fashion, they are not aware of this multiplexing. As a result, in all of their executions, they failed to execute this callback function.

Also, in *CANopen*, a buffer overflow where a hard-coded offset is indexed into the variable length input buffer was identified. However, in this firmware, the returned value of `HAL_GetTick()` was used as the divisor. In the real-world setting, such a function would never return zero. However, both P2IM and Fuzzware uses a simple incrementing strategy to model the Systick, which starts from zero. This crashed the firmware early on and prevented it from exploring deeper.

8 Discussion

Support for Other Architectures We demonstrate the compatibility of *CO3* with the popular ARM architecture. However, MCUs are well-known for the diverse architectures they use. Hence, supporting as many other different architectures as possible would be desirable. In this regard, similar to what the rehosting works do, i.e., using QEMU's ability to lift various architectures to its own intermediate representation [16], *CO3* relies on LLVM's modular design to lower the LLVM IR into a wide range of architectures supported by LLVM [17]. There is one small exception: *CO3* also needs to dynamically disable/re-enable interrupts to protect its runtime's integrity. This is done by architecture-specific inline assembly code (e.g., `cpsid if` in ARM). Fortunately, such code is usually very small and lightweight by design. Thus, it does not harm the portability of *CO3*.

Support for Other RTOSes In the evaluation, we ported *CO3* to FreeRTOS and ChibiOS. However, compared to the relatively small number of popular desktop OSes, embedded RTOSes are much more diverse. It would be desirable to support these RTOSes too.

Since *CO3* does not have any RTOS-specific reliance, it is viable to support any RTOS or even desktop OS. That is, regardless of what type of interface the RTOS provides (e.g., POSIX-compliant like NuttX, CMSIS-compliant like Zephyr, or even the ones not compliant with any standard like FreeRTOS kernel), they all have APIs that accomplish basic OS primitives. Porting to these RTOSes can be as simple as replacing the APIs with the ones that perform the same OS primitive. For *CO3*, these primitives are task creation/deletion and semaphore. In other words, as long as these primitives are implemented, *CO3* can be RTOS-less (i.e., baremetal).

[17] LLVM Architecture & Platform Information for Compiler Writers, https://llvm.org/docs/CompilerWriterInfo.html

Meanwhile, *CO3* utilizes USB-CDC or UART for data transmission. Different MCU vendors have different hardware and driver implementations for the two peripherals, however, they all follow the USB and UART standard, and they are among the most universal peripherals across all vendors [43]. To use these peripherals for *CO3*, one can simply follow the official source code examples provided by the vendors [18].

Future Works *CO3* makes it much more efficient to symbolically and authentically explore the firmware on the MCU. Going forward, two directions can be further explored to utilize this capability.

The first one is to construct symbolic formulae under *CO3*'s framework not just for toggling the branches but also for bug detection. Many works [18,39,58] tried to symbolically model various types of bugs and pass to the solver to see if the bug-triggering condition can be met. *CO3* has inherent synergy with these works. The second one is to use *CO3* purely as a state explorer. With methods such as generational search [27], *CO3* makes it much more efficient to authentically reach certain points of interest than the traditional HiL works (e.g., Avatar2). After reaching that point, the program state can be transferred to the emulator for more dynamic analysis.

9 Related Work

CO3 improves the SoTA symbolic execution for firmware through the inspiration of recent research advancements in symbolic execution and firmware rehosting.

Symbolic Execution Symbolic execution, as discussed in detail in Section 2.2, has seen success in various aspects of bug detection [12,32,37,39,58,62] and program testing [14,56,60] for desktop programs. *CO3* builds upon the compilation-based design proposed in SymCC [49] and pushes it forward by applying it to the firmware through our co-execution design.

Firmware Rehosting Firmware rehosting is the technique of migrating firmware from its native environment to a usually more powerful environment for better visibility and more computing resources. They can be categorized into 1). pure emulation either through symbolic abstraction [31, 33, 51, 54] which uses symbolic values to model the hardware accesses, or heuristic-based methods [16, 24, 42, 64, 65] which uses heuristic-based rules for the same purpose. 2). HiL [22, 34, 35, 45, 50, 57, 61] where the emulator engages the MCU to utilize its real hardware.

The most related work of *CO3* in this line of research is SHiFT [43], as they both follow the *semihosting* philosophy. *Semihosting* emphasizes that the MCU should actively invoke the resources from the workstation instead of the other way around, which is followed by most HiL-based works. Thus, SHiFT runs most of the fuzzing infrastructure on the MCU and actively consumes the input mutation from the workstation. Similarly, *CO3* runs concrete execution on the MCU and actively consumes the symbolic tracking from the workstation. SHiFT's fuzzing and *CO3*'s concolic execution generate an excellent synergy, which results in *SHACO*.

10 Conclusion

This paper presents *CO3*, a novel concolic executor for firmware. *CO3* features high hardware fidelity, applicability, and performance. Built upon the compilation-based idea from SymCC, *CO3* places the concrete execution on the MCU and channels it with the symbolic execution on the workstation.

Evaluated against the SoTA concolic executors for both the MCUs and the workstations, *CO3* achieved workstation-level performance. In combination with a fuzz testing system, *SHACO* outperformed emulation-based bug detection approaches and found seven new bugs.

A Appendix

A.1 Verbose interpretation of the example

In Figure 3, based on compile-time analysis, *CO3* can statically determine that this symbolic formula reads 4 bytes from RAM; it then adds the read value to the parameter of the function and compares the result with a 4-byte integer from MMIO (as the firmware only concretely interacts with MMIO). The comparison result is then used as a branch condition. In order to build this formula, instead of reporting every executed instruction and its operands, the firmware running on the MCU only needs to fill in the missing pieces, which is known at runtime. Upon receiving the missing pieces, the workstation can construct the symbolic formula and call the symbolic solver. Otherwise, if the MCU does not send any information, this would mean that this formula does not involve any symbolic value. Thus, it will not be built.

A.2 Further Optimizations

Symbolic backends such as Qsym employs instruction pruning (i.e., skipping symbolic construction for repeatedly-executed instructions). Although it is viable to do this at the MCU side to further reduce the USB traffic – which warrants even better performance – doing so would tightly couple the MCU runtime with the symbolic backend on the workstation, making the runtime much less generic. Since the end-to-end performance was evaluated to be satisfactory, we chose not to sacrifice simplicity and generality for performance gains.

Similarly, there are also engineering practices that we can adopt to improve the performance further. For example, we can parallelize the construction of independent symbolic variables (i.e., symbolic variables that have no dependency on each other). We can also use dual buffers on the MCU side for sending messages so that the firmware execution will be less affected by the USB transmission. We chose not to implement these for the same reason of simplicity.

Unveiling IoT Security in Reality: A Firmware-Centric Journey

Abstract

To study the security properties of the Internet of Things (IoT), firmware analysis is crucial. In the past, many works have been focused on analyzing Linux-based firmware. Less known is the security landscape of MCU-based IoT devices, an essential portion of the IoT ecosystem. Existing works on MCU firmware analysis either leverage the companion mobile apps to infer the security properties of the firmware (thus unable to collect low-level properties) or rely on small-scale firmware datasets collected in ad-hoc ways (thus cannot be generalized). To fill this gap, we create a large dataset of MCU firmware for real IoT devices. Our approach statically analyzes how MCU firmware is distributed and then captures the firmware. To reliably recognize the firmware, we develop a firmware signature database, which can match the footprints left in the firmware compilation and packing process. In total, we obtained 8,432 confirmed firmware images (3,692 unique) covering at least 11 chip vendors across 7 known architectures and 2 proprietary architectures. We also conducted a series of static analyses to assess the security properties of this dataset. The result reveals three disconcerting facts: 1) the lack of firmware protection, 2) the existence of N-day vulnerabilities, and 3) the rare adoption of security mitigation.

1 Introduction

The *Internet of Things* (IoT) is an ecosystem of interconnected devices. We are witnessing an increasing number of IoT devices being deployed in various domains, such as smart homes, smart cities, and industrial automation. While IoT makes our lives more convenient, it has also introduced new security vulnerabilities. Exploiting these vulnerabilities allows adversaries to launch large-scale attacks, including data exfiltration [21, 28], remote vehicle hijacking [41], illegal break-in [82], and even disabling medial treatment [58].

Firmware analysis can play a crucial step in understanding the security properties of IoT devices. Previous work has shown promising results in large-scale analysis of firmware, both statically [18, 81] and dynamically [13]. Analysis performed at that scale (e.g., thousands of firmware images) helps us understand the commonalities of security vulnerabilities across different devices and thus suggest effective mitigations. A prerequisite for conducting such research, however, is a huge collection of firmware images. Prior work addresses this challenge by developing vendor-specific crawlers to dump firmware images from top vendors' websites. The resulting datasets mainly comprise firmware for home routers, IP cameras, etc., which are all Linux-based.

Besides Linux-based embedded devices, our IoT space also encompasses a wide range of even smaller gadgets that are based on microcontrollers (MCUs). Due to hardware limitations, these devices do not run a full-fledged OS, but they easily outnumber their Linux-based counterparts. With the small form factor and built-in low-energy wireless communication capability, MCU-based devices have been widely adopted in IoT, such as smart homes, smart cities, and industrial automation. Since these devices do not have direct access to the Internet, they commonly rely on mobile companion apps to communicate with the user and the cloud.

Compared with research on Linux-based firmware analysis, less has been done to MCU-based devices, mainly due to the lack of a large dataset of real-world firmware images. Indeed, we rarely find the public release of firmware images for these devices [14]. To overcome this challenge, most existing works utilize the mobile companion apps to infer the security properties of the our IoT ecosystem, including the device, the remote cloud, and the mobile app itself [31, 32, 63, 78, 86]. For example, by analyzing the library artifacts in mobile companion apps, vulnerabilities in the device firmware can be inferred [78]. By reusing the logic of the mobile app, IoTFuzzer can fuzz the device more effectively [14]. Unfortunately, without access to the firmware, it is difficult, if not impossible, to reveal the low-level security features, such as the adoption of attack mitigations. If a bug is found, it is also hard to tell the root cause.

In this paper, we create a large dataset of firmware for

*Both authors contributed equally to this work.

MCU-based IoT products. This will benefit the IoT community in three aspects. First, this dataset will enrich existing firmware corpus [75], which mainly consists of homemade samples compiled from chip SDKs or only represents IoT devices with the BLE feature [79]. The proposed dataset broadly covers firmware of diverse formats, architectures, chips and application fields, enabling us to uncover common security vulnerabilities of real-world IoT devices and enhance manufacturers' awareness. Second, the dataset can unleash the full power of existing firmware analysis tools. For example, when IoTFuzzer finds a bug, if the firmware is available, we can possibly explain the root cause via binary analysis. Third, it will facilitate future research. For example, it can be used to evaluate the effectiveness of existing firmware testing techniques such as rehosting [62]. When these tools fail, investigation can be done to improve the state of the art. As another example, when common vulnerabilities are found in the dataset, it will push research on defense techniques.

To collect real-world firmware, we leverage the fact that IoT devices commonly rely on a companion mobile app to retrieve the latest firmware. Depending on whether the latest firmware is bundled with the APK release or downloaded from the cloud via over-the-air (OTA) update, we develop two tools to capture firmware. First, we retrofit FirmXray which extracts bundled firmware from APKs. Our tool additionally utilizes a list of firmware-related keywords and extensions, compiled based on our empirical study, to screen a more diverse set of candidate firmware. Second, we develop a static analysis tool called *OTACap* to automatically recover the URLs that point to the firmware update server and use them to crawl potential firmware. *OTACap* relies on Value Set Analysis (VSA) [11] to track down the source values used to construct URLs. However, traditional designs may miss many data flows due to the lack of run-time information and implicit data flow in Android apps. In particular, the URL may contain a substring that is dynamically requested from the device. Observing that although the needed information may not be directly on the data flow of the URL, it is sometimes referred to at other places, e.g., for version comparison. By collecting and solving the constraints of these references, we can infer the possible value range of the missing information. The reconstructed URLs do not always directly point to the firmware. Sometime, they can return an intermediate text file that contains the actual firmware distribution point. Since the text format is unpredictable and sometimes contains credentials associated with the links, we empower our crawler with large language models (LLM) to automatically reason about the text structure and extract firmware links (and associated credentials if any).

The candidate firmware images have a high false positive rate, making them unsuitable for reliable analysis. To confirm a firmware image, we look for the footprints left in the image during firmware compilation and packing. Particularly, we find that the chip architecture, vendor toolchain, and firmware bootloader/packer offer distinctive artifacts, making them excellent choices for firmware signatures. Thus, we manually identify 39 signatures to match 4 categories of firmware artifacts. Applying them to the candidate images, we obtained 8,432 confirmed firmware images, out of which 3,692 are unique. Our dataset contains firmware from at least 11 chip vendors across 7 known architectures and 2 proprietary architectures, offering a diverse firmware dataset.

Our analysis of this dataset reveals several disconcerting findings. First, 99.43% of these images are in plaintext, allowing for reverse engineering. Second, by library matching, we found 14 N-day vulnerabilities that affect 191 firmware images. Lastly, the adoption of security mitigations is rare. For example, the adoption rates of memory protection unit (MPU) and stack canary are only 1.56% and 0.11%, respectively.

In summary, our contributions are as follows:

- We developed *OTACap*, the first static analysis tool to recover URLs used in firmware update from Android apps.
- To fully exploit the recovered URLs, we developed an intelligent crawler to download potential MCU firmware.
- Leveraging the footprints left in the firmware compilation and packing process, we identified 39 signatures to reliably recognize real MCU firmware.
- With the developed tools, we collected 3,692 unique MCU firmware images, representing a diverse dataset of real-world firmware, facilitating future research.
- Our analysis of the dataset reveals several disconcerting findings, suggesting future remediation efforts.

2 Background

MCU-based IoT Device. A vital component of IoT is billions of small interconnected embedded devices that are powered by MCU chips. An MCU integrates a processor, RAM, and other peripheral functions into a single chip, aiming to reduce cost, form factor, and power consumption. The peripherals are memory-mapped into the system address space, and their registers are accessed via normal memory access instructions (i.e., memory-mapped I/O or MMIO). The software that runs on MCUs, named firmware, either runs on the bare-metal or with a real-time operating system (RTOS). To better utilize the limited resources (100+ MHz CPU, ~256 KB SRAM, ~1 MB flash), MCU firmware is typically programmed using the unsafe C/C++ programming languages. Over the past years, we have witnessed numerous vulnerabilities targeting the firmware of IoT devices [30, 33, 34, 44, 65].

An MCU chip typically implements a RISC instruction set architecture (ISA), with Arm being the dominating ISA. The device manufacturers (e.g., Amazon), after finding a suitable MCU chip to implement the designed functionality, assemble parts together, including the PCB, sensors, actuators, and most importantly, the MCU chip. In this process, the ISA vendor is at the top of the supply chain, followed by the chip vendor

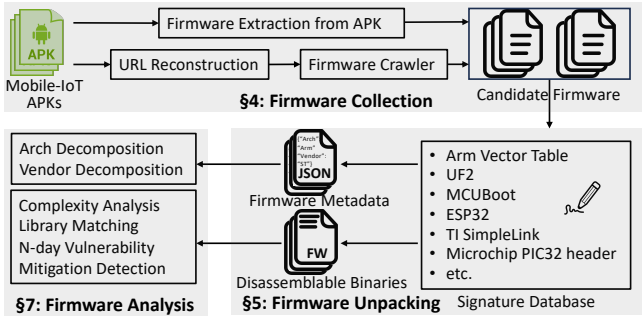

Figure 1: System Overview.

(e.g., Nordic), who fabricates chips that implement an ISA, and then the device manufacturer. While some chip vendors develop their own ISAs (e.g., PIC32 by Microchip), most others, such as NXP and Nordic obtain a license to use a certain ISA. It is worth noting that a chip vendor may offer chips across various series, each employing a different ISA.

Many MCU-based devices run low-energy wireless protocols such as Bluetooth. As such, they rely on companion mobile apps to interact with the user and the cloud.

Over-the-Air Update. To fix software bugs or add new features, many IoT devices support firmware updates. The new firmware can be distributed to the device via two methods. First, the companion app periodically checks for updates from the remote server. If an update is available, the companion app fetches the latest firmware and then pushes it to the device via the low-energy protocol. This process is commonly referred to as OTA update. Second, the firmware can be bundled with the companion app. When the app is updated, the device can also be updated. Different from traditional Linux-based embedded devices such as home routers, the firmware of MCU-based IoT devices is rarely released via vendor websites.

3 Overview

An overview of our system is illustrated in Figure 1. We first design and develop tools to automatically collect firmware images from mobile companion apps (§4). Besides extracting firmware images from APKs, following the method originally proposed in FirmXray [79] (§4.1), we develop an Android static analysis tool (named *OTACap*) to reconstruct URLs that are used to download the firmware via OTA update (§4.2). *OTACap* enhances state-of-the-art string value analysis techniques [63, 86] by incorporating more accurate and effective data flow tracking, such as support for inferring hardware-related fields. Utilizing the reconstructed URLs, our intelligent crawler simulates the OTA update process of real-world mobile-IoT applications to gather firmware images. Throughout this process, we successfully extracted 43,231 candidate firmware images from 40,675 Mobile-IoT APKs.

For the next step, we analyze the collected image files to identify and verify MCU firmware. To facilitate this, we developed a signature-based firmware unpacker. It processes images to detect firmware artifacts present within firmware images (e.g., magic numbers in firmware headers or the architectural metadata essential for firmware execution). This approach not only assists in confirming real MCU firmware but also retrieves metadata for further analysis (§5). In particular, we leverage the collected metadata to decompose the IoT market by major architecture vendors and chip vendors (§7.1). The firmware metadata, which includes information about the instruction set architecture (ISA), load address and entry point, is also crucial in disassembling the firmware and performing binary analysis. This analysis reveals low-level security properties. Specifically, we locate all the recognizable functions, match them with existing IoT libraries, and report whether they contain any known vulnerabilities. Besides, we examine the adoption of security mechanisms such as stack canary in the wild (§7.2).

4 Firmware Collection

Considering the common practice of distributing firmware through mobile apps by device manufacturers, we develop two methods for collecting firmware images: 1) extracting firmware images directly from APKs and 2) reconstructing URLs through APK analysis to collect firmware images during the OTA update process. This step is designed to maximize the collection of firmware images while simultaneously filtering out non-firmware images. We conduct additional verification of the firmware images using various artifacts, as detailed in §5.

4.1 Extracting Firmware from APKs

It has been observed that some IoT device manufacturers bundle firmware images in their companion apps [2, 52]. When the app is updated, the device firmware can also be updated with the latest version that comes with the app. For example, MiBand firmware is typically stored in the `assets` directory of unzipped APKs [52]. This way of firmware distribution has been leveraged by FirmXray [79] to collect firmware of BLE-related devices using Nordic or TI chips. Since our goal is to measure the general IoT security landscape with no bias towards any specific wireless protocol (e.g., BLE) or application field (e.g., home security), we develop general rules to recognize firmware beyond Nordic and TI based on our empirical study of how firmware is stored and named. Concretely, our tool examines the file name, including its path, name, and extension. We use both firmware-related keywords (e.g., "`firmware`" and "`ota`") and self-developed heuristics as filters. For example, we found that many firmware images are named after the hash values of the file content. Therefore, we also include files with

names that are comprised of consecutive hexadecimal digits (e.g., `3f4c38fc366c44d3b399d3951ab719b4.zip`). The list of keywords we use to match file names is provided in Table 11. For the file extension, we follow the common conventions of manufacturers (e.g., `.bin` and `.fw`). The complete list of firmware extensions and their explanations are provided in Table 12. If a file matches any of the rules, it is considered a candidate firmware image.

4.2 Firmware Capture via OTA Update Simulation

Another popular method for distributing firmware images is using OTA updates, where the firmware is downloaded from the server on demand. To tackle this, we develop *OTACap* to reconstruct the URLs for downloading firmware images by statically analyzing Android APKs. In essence, *OTACap* employs Value Set Analysis (VSA) [11] on the string parameters of Android network functions to obtain URLs, and then it applies keyword-based filters to exclude irrelevant links.

In this section, we first introduce the basic string reconstruction solution (§4.2.1). Then we discuss the challenges encountered in applying it to the URL reconstruction problem and propose solutions for a comprehensive and precise analysis of URL-related strings (§4.2.2). Finally, we present an AI-powered crawler that uses the reconstructed URLs to simulate OTA update for firmware downloading (§4.2.3).

4.2.1 String Analysis for Android

VSA is a powerful binary analysis technique to over-approximate the set of values that each data object can hold at each program point [11]. It has been used to analyze strings in Android apps for different purposes [20, 63, 86, 87]. For example, LeakScope [86] recovers URLs from the apps to uncover data leakage in the cloud. IoTFlow [63] analyzes the data flow among the app, the device, and the cloud via internet addresses reconstruction. Many of these works perform static analysis on top of the *Jimple* Intermediate Representation (IR) of the target APK, which simplifies the analysis by exposing to the analysis tools a non-stack-based and non-nested program representation [1]. These tools construct a call graph of the target APK in *Jimple* IR. Then, they perform a backward data flow analysis to trace how a string is constructed. Finally, based on the recorded backward execution trace, a forward simulation is conducted to recover the string. We describe further details on the backward analysis and forward simulation steps of the techniques mentioned above as follows.

Backward Analysis. Starting from the target string parameter, the tool locates the calling method (called a sink) and taints the string parameter, which is termed a `ValuePoint`. Each `ValuePoint` contains information such as the method it is located in, the beginning statement (e.g., the call to the sink method), and the target parameter(s). From this point, the tool moves backward, storing each statement (with its context) that uses or modifies the values of tainted parameters and propagates the taint to relevant variables in the new statements. When the first instruction of a method is reached, the tool finds all its call sites, branches the analysis to each of the callers, and continues backward analysis through each branch sequentially. When the definition of the tainted data (called a source) is reached, the analysis stops. Here, the definition could be an assignment from immediate values, a global variable with default values, or values from Android resource files. If the tool does not find the source and cannot move backward further, it fails to reconstruct the target string.

Forward Simulation. At the end of backward analysis, if the tool finds the sources of the target string, it also maintains a list of execution traces from the source to the sink. The tool then starts from the source, simulates the execution of statements, and updates the register values until the sink is reached. At this point, the tool has reconstructed the target string. Note that since one sink-source pair can have multiple execution traces, the tool may generate multiple values for the target string.

4.2.2 Enhancing Data Flow Tracking

We create a list of Android native or third-party network functions as sinks, focusing on the HTTP GET, FTP and MQTT protocols since they are the most common in OTA update. Important parameters such as URLs, credentials and MQTT topics are tainted, which are to be recovered via the aforementioned string analysis. We initially used the existing implementations of LeakScope [86] and IoTFlow [63]. However, while effective in their respective tasks, we found that they commonly fall short in recovering information needed in OTA update. A significant reason is that they may lose track of essential data flow information due to IoT specificity or incomplete implementation. Below, we present why existing tools fail to capture the intended data flow and how we address them with *OTACap*.

Missing Definition of Hardware-Related Variables. As mentioned before, the backward analysis succeeds when the definition of a tainted value (i.e., the source) is found. However, we found many failed cases where the tainted value cannot be further traced back statically because it is defined by information that is only known at run-time, potentially from the IoT device. We demonstrate such an example in Listing 1, which contains the decompiled Java Code of the app `vstc.vscam.client`. As shown in lines 14-18, part of the URL is a concatenation of three strings in `strArr`. Except for `"firmware"`, both `sFUA.this.language` and `sFUA.this.LocalSysver` are values obtained from the IoT device at run-time. Specifically, the function `"CallBack_CameraStatusParams"` queries the device about its current firmware version and stores it in `sFUA.this.LocalSysver` (line 22). Using the con-

structed URL, `VscamApi.runGet` is called to send the current firmware version to the cloud endpoint and obtain a `JSON` file containing real links to the updated firmware images. Since "`sFUA.this.LocalSysver`" is only available with a real device, it is impossible to recover it statically.

```
1  boolean checkSpecialFirmware(String str){
2      if (str.length() < 11)
3          return false;
4      String[] split = str.split("\\.");
5      if (split.length >= 3 && split[0].equals("48") &&
        split[1].equals("50") && split[2].equals("64") &&
         Integer.parseInt(split[3]) < 49)
6          return true;
7      return false;
8  }
9  void handleMessage(Message message){
10     if (!sFUA.checkSpecialFirmware(sFUA.LocalSysver))
11         return;
12 }
13 void run(){
14     String[] strArr = {"firmware", sFUA.this.
        LocalSysver, sFUA.this.language};
15     StringBuffer buffer = new StringBuffer();
16     for (int i = 0; i < 3; i++)
17         buffer.append(strArr[i]);
18     VscamApi.runGet(connectionURLNew + buffer.toString
        ());
19 }
20 void CallBack_CameraStatusParams(String str, String
        str2, String str3, String str4){
21     ...
22     this.LocalSysver = str2;
23 }
```

Listing 1: URL construction using hardware-related information.

Fortunately, we observe that sometimes these values—while cannot be directly recovered—can be inferred to some extent at other places. For example, the function `checkSpecialFirmware` takes in `LocalSysver` as input and splits it with the delimiter "`\\.`" (line 4). Then, it compares each part with a constant value (line 5). Although this function does not directly influence the value of `LocalSysver`, nor does it determine the execution of `VscamApi.runGet`, we can infer some constraints about it, with which we can guess its possible values. For example, the version number `48.50.64.48` would return `true` while `48.50.64.49` would return `false`.

Solution: For a tainted value whose source is determined at run-time, *OTACap* searches for its references beyond the recovered data flow. From there, *OTACap* performs a symbolic execution to build the constraints along the execution path. Each constraint will be solved to a concrete value, which is used as the source value of the tainted variable. In this example, we would have six constraints and correspondingly six value candidates for `LocalSysver`.

Implicit Data Flow in `AsyncTask`. Firmware downloading usually takes time. Therefore, app developers commonly use a background task to complete it without blocking the UI. In Android, the most popular library to achieve this is `AsyncTask`, which simplifies background task execution and allows updating the UI thread with the task results. `AsyncTask` must be subclassed, and the type information for the parameter of the background task is passed as the first parameter to the constructor of an `AsyncTask`. Then, the `doInBackground` method, which must be overridden, takes an array of parameters of the same type from the `execute` method and performs the background task.

In Listing 2, we show how `AsyncTask` is used in `com.rhodonite.hms_ione_6630` to download firmware. The class `HttpDownload` is a subclass of `AsyncTask`, and the `doInBackground` method takes a string array as download URLs. The type information (i.e., `String`) is specified by the parameter for the `HttpDownload` constructor (line 5). In line 3, the background task is started by calling the `execute` method using `MainActivity.this.file_url + "dir.txt"` as argument, which is passed to the `doInBackground` method (line 6). Unfortunately, the backward analysis does not recognize such implicit data flow since there is no edge in the call graph.

```
1  class BluetoothProcess extends Handler {
2      public void handleMessage(Message msg)
3          new HttpDownload().execute(MainActivity.this.
            file_url + "dir.txt");
4  }
5  class HttpDownload extends AsyncTask<String, ...> {
6      public String doInBackground(String... f_url){
7          URL url = new URL(f_url[0]);
8      }
9  }
```

Listing 2: Firmware Download in Background with `AsyncTask`.

Solution: After the initial call graph is built, we analyze all the `doInBackground` method definitions and look for any sink methods. If so, we ensure the tainted value can be traced back to its parameter. Then, all the invocations to the constructor of this class are located to find the matching `execute` invocations. Finally, an implicit edge is created in the call graph for each pair of `execute` and `doInBackground`.

It is worth mentioning that the `AsyncTask` class has been deprecated since Android API level 30 [29]. Google recommends using the low-level thread control API `java.util.concurrent` to handle asynchronous tasks. Based on our research, using the recommended `Executor` interface, the parameter of the worker thread is explicitly passed from the `createWorker` method. In other words, the recommended API does not need special treatment. Interestingly, our evaluation never encountered the use of recommended API in firmware downloading. We expect more uses of the `Executor` API as `AsyncTask` becomes abandoned entirely.

Additional Challenges. In addition to the aforementioned challenges and our solutions, we also identify further obstacles and describe our strategies to address them. 1) Implicit Call of `toString`: Many primitive types such as `Integer`, `Long`, `Boolean`, `Byte` and `Array` have a `toString` method that is implicitly called when they are concatenated to another string. Existing tools [63, 86] simply ignore these cases, causing incompletely constructed URLs or the premature termination of analysis. Our forward execu-

tion simulates such implicit conversions for common primitive types. 2) String Processing Methods: Neither IoTFlow nor LeakScope provides comprehensive support for string processing methods, leading to incorrect string value recovery. These missing methods such as `relpace` and `split` were frequently encountered during our experiments and are addressed in *OTACap*. 3) Loops: Existing solutions do not support loops. We partially address this by simply unrolling the loop when the number of iterations is statically known. 4) `Intent`: `Intent` is a heavily used *Inter-Component Communication* (ICC) mechanism in Android. Similar to `AsyncTask`, it involves implicit data flow. While IoTFlow [63] handles them, we found some implementation bugs which prevent it from capturing the correct data flow when the "`key`" and "`value`" parameters of `Intent.putExtra` are global variables. 5) URLs in Resource Files: Android apps commonly use resource files to store static content such as bitmaps, layout definitions, user interface strings, etc. Sometimes, resource strings are used as URLs. Although our string analysis supports recovering URLs from resource strings, it may miss some. Therefore, we explicitly include URL-format resource strings in the list of candidate URLs.

4.2.3 Simulating OTA Firmware Downloads

With a list of candidate URLs, we connect to the endpoints via the corresponding protocols (HTTP, FTP or MQTT) to download firmware. A connection may fail for three reasons. First, *OTACap* suffers from accuracy issues as with other static analysis methods. Second, sometimes the HTTP URL needs credential query strings which can only be obtained from a real registration (e.g., `?token=` and `?deviceid=`). Third, the endpoint might be temporarily or permanently down.

For a successful connection, we observe that sometimes it does not directly return a firmware image. Instead, a text-format datastream (e.g., XML, JSON, or even unstructured text) is obtained, pointing to the real OTA URL. The initial URL can be viewed as a permanent distribution point for new firmware, requiring the app to parse and process its dynamic response in a multi-round fashion. For example, when analyzing the app `com.linkiing.firesign`, *OTACap* recovers a URL pointing to a JSON file which in turn contains links to the newest firmware URLs. Emulating the same app logic to download firmware is challenging since it requires accurate static analysis to decide the code slices to run. We therefore approximate the problem to a crawling problem. Specifically, we treat the initial set of URLs as the seeds and recursively crawl the server with the returned new links. To avoid connecting to irrelevant endpoints, in each round, we use the keyword lists in Table 11 and Table 12 to filter the new links.

As aforementioned, the returned text might be unstructured and sometimes contains credentials to make a successful connection. Missing the original app logic to parse the text, we leverage the powerful reasoning capability of LLM to automatically extract the needed information from unforeseen text. In Appendix B, we provide a real example of unstructured text we captured, the prompt we used, and the result.

Table 1: Firmware signatures in groups. The number in the parentheses indicates the number of signatures.

5 Signature-Based Firmware Recognization

Even though we applied filters during firmware collection, a high rate of false positives is expected due to the nature of the crawling process. To further reduce false positives, we implement a signature-based firmware recognition method. The idea is to collect the artifacts that are left to the firmware during the development process and then craft rules to recognize these artifacts. We categorize firmware artifacts into four groups: SDK artifacts, bootloader artifacts, encoding artifacts, and architecture artifacts. These artifacts can not only help us confirm firmware but also play an essential role in firmware analysis due to the firmware metadata contained in it. For example, some firmware headers include fields that indicate the chip information, encryption status, or even the SDK version. We summarize all 39 signatures that we have identified in 4 categories in Table 1. The number in the parentheses indicates the number of signatures for that artifact since a vendor SDK may have multiple versions.

SDK Artifacts. To attract developers, it is common practice that chip vendors provide Software Development Kits (SDKs) to ease the development. Consequently, device manufacturers using these chips often reuse the SDKs shipped with the chip. These SDKs typically include a full toolchain for building firmware images. The use of them leaves diverse footprints in the compiled firmware which are observable via different means. For example, TI designed a firmware update protocol called Over the Air Download (OAD) [71]. When a firmware

image supports OAD, its header must start with the magic string "CC26x2R1", "CC13x2R1", or "OAD IMG". Some chips have unique file extensions (e.g., .cyacd for Cypress), while some organize firmware in specific ways (e.g., Nordic's Device Firmware Update, or DFU image is compressed into a zip file along with some metadata [51]). More generally, a vendor's SDK includes bootstrap code that is commonly shared by all its chips. Since the bootstrap code handles low-level initialization process and has to be written in assembly, the translated machine code—regardless of the compiler being used—can reliably serve as fingerprint of the SDK. To collect SDK artifacts, we manually downloaded and investigated the SDKs of top MCU vendors [54]. Then we summarized the invariances.

Bootloader Artifacts. Beside chip-exclusive firmware formats, we observe a trend of adopting open-source bootloaders to wrap the real firmware. These initiatives will greatly simplify the maintenance and distribution of firmware. Similar to how the U-Boot Image wrapper (uImage) is used to support different OSs (e.g., Linux) that are loaded by U-Boot [64], several bootloaders for MCU firmware are gaining popularity. For example, the USB Flashing Format (UF2) [40] is developed by Microsoft for flashing MCUs over MSC (Mass Storage Class). It has been adopted by the Adafruit community and gains native in-silicon support on the popular Raspberry Pi RP2040 chips. Another example is MCUBoot [35], an open-source secure bootloader for 32-bit MCUs, which can be used in by Zephyr, Mbed OS, RIOT, etc. Finally, the ZigBee alliance also standardized a bootloader for different ZigBee-compatible devices to cooperate with each other with its ZigBee Cluster Library (ZCL) specification [85].

Encoding Artifacts. The firmware conveys binary data that can be understood by the MCU hardware. However, when transmitted or stored, the binary format cannot be easily carried on certain media such as paper tape, punch cards, etc. To address this issue, specially designed encoding schemes are used to represent the binary data in a human-readable ASCII text form. These encodings, as exemplified by Intel HEX [8] and Motorola S-record [43], almost certainly suggest firmware.

Architecture Artifacts. The processor architecture sometimes necessitates specific structures of code or data that can be used as signatures. A classic example is the Arm Cortex-M series's *Nested Vectored Interrupt Controller* (NVIC). According to the Arm architecture manual [7], the NVIC needs a vector table that is mapped at the beginning of the firmware. This table contains the reset value of the stack pointer followed by exception vectors that specify the entry points of the exception handlers, including the reset handler, the entry point of the firmware. Since the stack pointer must point to a valid RAM range, it should be within 0x20000000-0x20200000 and aligned on a word boundary. Besides, each entry in the vector table has to point to a valid address and must be odd since Arm MCUs only support Thumb mode. These simple constraints can quickly screen NVIC vector tables, thus identifying images that are likely to be Arm firmware. To further confirm the result, we ran a chip-generic version of FirmXRay [79], similar to FirmXRay-M used in FirmLine [5], to try to calculate the base address of the firmware. If no meaningful base address can be found, the firmware is discarded. We discuss our improved FirmXRay in §6.1.

6 Firmware Collection Results

6.1 Implementation

The data flow analysis module of *OTACap* is based on IoTFlow [63], which itself is based on LeakScope [86]. The symbolic execution engine reuses the tainting system of data flow analysis and relies on JavaSMT [80] to solve the collected constraints. All the new features were implemented with 2.4k lines of Java code.

Our intelligent crawler is based on Scrapy [88], an open-source web crawling written in Python. We improved it with better FTP support and the integration of the Paho MQTT client [22]. To extract URLs and credentials from unstructured text, our prototype uses a quantized 8B Llama 3 LLM [36] but it can be easily replaced by other more advanced models.

Regarding the firmware signature, our tool now supports 39 firmware signature rules, corresponding 30 SDK artifacts, 4 bootloader artifacts, 4 encoding artifacts, and 1 architecture artifact. We implemented these rules as custom signatures for Binwalk [59], the *de facto* standard of firmware recognition. In particular, the majority of newly developed signatures were written in the libmagic file format. However, when the libmagic is not expressive enough to support a signature (e.g., in the case of Arm vector table recognition), we used the plugin system of Binwalk, which is written in Python. Since the detection of Arm vector table requires FirmXRay [79], our Python plugin also invokes FirmXRay as an external program. FirmXRay was originally implemented for Nordic and TI firmware; however, the idea of using absolute addresses to resolve the base address is general. Our implementation removes all the chip-specific knowledge, similar to FirmLine [5], but retains all the original constraints as much as possible, including indirect calls, string pointers and vector table entries. If all these constraints are found useless during analysis, our tool outputs an invalid base address and discards the firmware. In contrast, the original FirmXray would output a default base value (0x00) since it was built on the assumption that the firmware is either TI for Nordic. Therefore, our modification not only finds the base address for general Arm firmware, but also verifies the Arm signature to reduce false positives. In addition, we fixed some bugs of FirmXRay, which for example might resolve an odd base

address occasionally[1].

To facilitate firmware analysis, we also developed a pipeline to extract firmware metadata from its artifacts and prepare a firmware copy ready to be loaded into Ghidra. If a compressed image is detected, we decompress it using the built-in extraction rules of Binwalk and only analyze the decompressed files. When a candidate image matches a signature, we extract the metadata and store it in a `JSON` file, with entries containing information about firmware architecture, chip vendor/model, base address, entry point, CRC protection, encryption status, etc. Note that not all of these metadata are available on every firmware image. When unsure, the corresponding field is left empty. The text-based firmware (e.g., Intel HEX) is also converted into binary format. The implementation is integrated into Binwalk as extraction rules using an external tool, `srec_cat` [42].

6.2 Dataset

The mobile-IoT Android apps were collected from three sources. In IoTSpotter [32], the authors developed a machine learning-based system that collected a dataset of 37,783 mobile-IoT Android apps to conduct a market-scale security analysis of consumer IoT products. We supplemented this dataset with the APKs used in IoTProfiler [45] (6,208) and another study [47] (455), resulting in a combined dataset of 40,675 unique mobile-IoT APKs. After retrieving the package names of these apps, we downloaded a snapshot of these APKs from Androzoo [6] on July 28, 2023.

6.3 Performance of *OTACap*

As far as we know, there is no prior work that can reconstruct firmware download URLs by analyzing mobile companion apps. The closest work to *OTACap* is IoTFlow [63], which analyzes mobile apps to automatically reveal how the app communicates with IoT devices and remote cloud backends. It, therefore, necessitates reconstructing the Internet addresses of the involved entities, including the cloud backends. In fact, our implementation is based on it. In this section, we evaluate how solving the challenges explained in §4.2.2, including inferring hardware information—a piece of critical information for the OTA protocol—can improve our capability in URL reconstruction. We used the same configuration for both tools to ensure a fair comparison, including the timeout, maximum number of backward iterations/contexts, and the network sinks. These configurations are necessary because they prevent the analysis from spending too much time on a single backward path. No filtering was performed since we focused on evaluating the URL recovery capability instead of the firmware collection capability.

Our experiments ran on a server equipped with two Intel Xeon Silver 4110 CPUs, 46 GB of RAM, and a 14 TB hard disk. The used dataset is a subset of the IoTSpotter dataset, comprising 1,000 randomly selected Mobile-IoT APKs. Since a URL might be incorrectly constructed, we also tested communication via the constructed URLs and checked the status code to verify the result. As shown in Table 2, *OTACap* and IoTFlow are on par regarding the execution speed despite the overhead caused by the symbolic execution engine. There was a high deviation (indicated by standard deviation or SD) in execution time, ranging from five seconds to an hour. The time breakdown indicates that the majority of the time was spent on control flow graph (CFG) construction and backward analysis. *OTACap* found 11,091 more URLs and 422 more reachable URLs compared to IoTFlow. This means *OTACap* can potentially find 25.10% more firmware.

	Time Breakdown in Seconds (mean/SD)				URL #	
	CFG	Backward	Forward	Symbolic	All	Reachable
IoTFlow	152.7 *(253.7)*	283.4 *(597.3)*	4.33 *(7.4)*	–	50,538	1,681
OTACap	155.0 *(253.0)*	297.8 *(628.3)*	4.74 *(8.3)*	20.54 *(45.4)*	61,629	2,103

Table 2: Performance of URL Recovery.

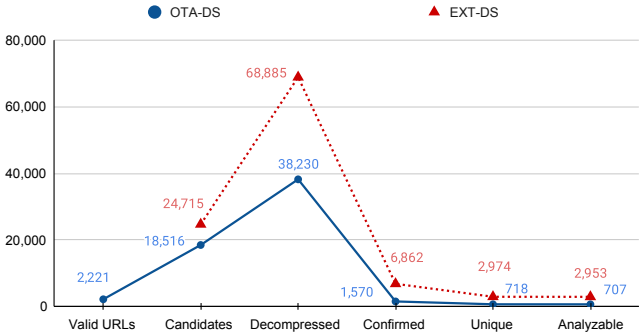

Figure 2: Firmware collection progress.

6.4 Result Summary

Considering the massive number of 40,675 APKs, we threw the workload of *OTACap* to six AWS nodes, each having four CPU cores and 32 GB of RAM. It took six days to complete the URL reconstruction. Other processing steps, including validating the URLs, crawling the firmware images, extracting firmware from APKs, and signature recognition, took negligible time compared with *OTACap*, typically within a few hours. In total, we recovered over 100k URLs after filtering. Among them, 2,221 are valid, with which we crawled 18,516 candidate firmware images. On the contrary, with the APK extraction method, we collected another 24,715 unique candidates. As we will discuss soon, the majority of them are false positives with a `.bin` extension name. We distinguish the two firmware datasets collected via different methods.

- ***OTA-DS*:** Firmware collected via *OTACap*.
- ***EXT-DS*:** Firmware collected via APK extraction.

The majority of the *OTA-DS* dataset consists of firmware from the HTTP GET or FTP protocol. But we did obtain 130

[1] https://github.com/OSUSecLab/FirmXRay/pull/4

images thanks to the 44 valid MQTT endpoints we recovered. Ideally, firmware download should be protected via the unique topic names to subscribe to or additional authentication [76]. However, we found 3 MQTT endpoints that allowed us to connect to the wildcard topic `#` without any authentication, returning trunks of firmware data or the real firmware distribution points. Additionally, one developer used the test broker Mosquitto [23] to send OTA URLs.

Figure 2 shows the progress of processing the candidate firmware. For each dataset, starting with the candidate firmware images (marked as **Candidates** in the figure), we first scanned for zipped files and decompressed them. This leads to a rise in numbers (marked as **Decompressed**). Then, the signature matching was conducted to get the confirmed number of firmware (marked as **Confirmed**). We found that this set of firmware images contains some Linux/Solaris-based images, which were identified by the existing signatures of Binwalk. We excluded them from our dataset since our focus is on MCU firmware. Also, lots of duplications were observed. After excluding Linux/Solaris-based and duplicated images, we obtained the number of unique MCU firmware images (marked as **Unique**). Finally, with the metadata from signature matching, we identified the number of analyzable firmware images to the best of our capability (marked as **Analyzable**). Here, analyzable means that the instruction set of the firmware is known, and the firmware is not encrypted or compressed. Eventually, we obtained 718 and 2,974 unique MCU-based firmware images in *OTA-DS* and *EXT-DS*, respectively.

As shown in the figure, *EXT-DS* includes way more confirmed images than *OTA-DS* (6,862 vs 1,570). We attribute this to two reasons. First, to reduce the cost of maintaining an OTA server, device manufacturers tend to choose bundling firmware within the APKs and rely on Google Play Store to distribute firmware. Second, *OTACap* suffers from the inherent limitation of static analysis (see §8).

We can see a significant drop from **Candidates** to **Confirmed**, indicating the effectiveness of our signature matching mechanism. A high number of `.bin` files were discarded since they are used to store application data instead of code. The developed signatures are extremely accurate. We did not find any false positives in our experiments, as explained in §7.2.

We also found a non-negligible duplication rate in both datasets. The most common reason is shared bootloaders among different devices. For example, the same Nordic SoftDevice firmware image [50], which includes drivers for Nordic radio peripherals, is found multiple times. Some developers release apps with very similar functionality under different names, which in turn lead to duplicated firmware images. For example, both `com.nextys.mobile.powermaster` and `com.nextys.dcu20.mobile.powermaster` are developed by `Nextys`. The two APKs contain identical firmware under `/com/nextys/lib/resources/firmwares/_nef210-bootloader-rel.hex`. Interestingly, we did not find any duplication across the two datasets, indicating that developers tend to stick with one approach of firmware distribution.

Protection	Encrypted or Compressed (High Entropy)	CRC	Not Protected
OTA-DS	10	6	702
EXT-DS	11	157	2,806

Table 3: Firmware protection level.

Regarding the slight drop from **Unique** to **Analyzable**, it is because of encryption or compression that is applied to the firmware or the use of proprietary instruction sets. We found many images with CRC integrity protection (4.41%), but only 0.57% are crypto- or compression-protected (Table 3). This means that at least 99.43% of the collected images are in plaintext and subject to firmware analysis. Moreover, there are 21 images with proprietary instruction sets.

7 Characterizing the IoT Ecosystem

With the large firmware dataset, we conducted two types of analyses. In §7.1, we aim to decompose the IoT market by analyzing the major players in the market. §7.2 is security oriented binary-level analysis. First, we reveal the complexity of firmware datasets, including size and function count. Second, we applied function signature recognition to detect the utilization of IoT libraries and to reveal N-day vulnerabilities. Third, we scanned for the adoption of common attack mitigation. The results are alarming.

7.1 IoT Decomposition

With the signature metadata, we analyze major players in the IoT market by chip vendors and architectures over the **unique** images. Since artifacts follow diverse formats conveying custom information defined by the respective developers, we procured the needed information on a best-effort basis.

By Chip Vendor. Recall that we developed four kinds of firmware artifacts (§5). If an image is recognized by a vendor artifact, it is naturally counted towards that vendor. If a bootloader artifact is used, we examine the fields contained in the bootloader header. Typically, it contains fields indicating the chip information. For example, in the UF2 bootloader, there is a `familyID` field at offset 28, which clearly reveals the device chip information[2]. If an encoding artifact is used, we first convert the firmware into binary format and then try to match it with SDK artifacts and bootloader artifacts. Architecture artifacts typically do not provide vendor information.

We summarize the results in Table 4. The vendor distributions in the two datasets are not consistent. We found more uses of Microchip and Renesas chips in *OTA-DS* while *EXT-DS* has more Nordic, TI, Espressif, and Telink chips. Top Arm MCU vendors such as NXP and STMicroelectronics do not

[2] https://github.com/microsoft/uf2/blob/master/utils/uf2families.json

Vendor	Nordic	TI	Espressif	Telink	Cypress/Infineon	Microchip	Dialog	Qualcomm	Renesas	CSR	Opulinks	Arm*	Total
OTA-DS	16	4	150	1	18	29	6	10	31	1	1	451	718
EXT-DS	875	164	244	450	78	14	24	9	1	1	-	1,114	2,974

Table 4: Firmware distribution by chip vendor (unique images). Arm* means firmware that matches with the general Arm architecture signature but without any vendor signature. This potentially includes other major players such as NXP and STM32.

Arch.	Arm	MIPS	PIC	Xtensa	RISC-V	RX Core	Prop.	Total
OTA-DS	496	18	11	150	1	31	11	718
EXT-DS	2,255	12	2	244	450	1	10	2,974

Table 5: Firmware distribution by architecture (unique images). PIC includes PIC18/24/32. Prop. refers to proprietary.

have an entry in the table since we did not find many reliable artifacts from their SDKs. Instead, we observe a large number of general Arm images in both datasets, which were detected by the architecture artifact. We speculate that a large portion of this group should be attributed to NXP or STM32 chips. Conversely, we also observed some Arm firmware (mainly TI chips) that is not detectable by the Arm architecture artifact.

By Architecture. To get architecture information, we mainly use the chip information. As expected, Arm dominates the market (74.51%), followed by RISC-V and Xtensa. Surprisingly, no TI firmware corresponds to the MSP430 chip, which was popular and runs a proprietary instruction set developed by TI. Xtensa's high share mainly comes from the popularity of ESP32 series chips by Espressif, while RISC-V mainly comes from Telink. Microchip is responsible for the PIC18/23/32 architectures. We also observe 21 images using proprietary architectures. They come from Qualcomm's `CSR102x` chips [55] and the legacy Cambridge Silicon Radio (CSR) BlueCore chips [56]. Both follow a proprietary 16-bit RISC architecture.

7.2 Binary-Level Analysis

To understand the IoT security landscape, unlike previous work that uses the companion apps as the analysis target [14, 31, 32, 63, 86], we directly study the firmware to reveal its binary-level properties, thanks to the large real-world firmware dataset we have collected. Due to their popularity in the market, we selectively conducted static analysis for 2,631 Arm and 394 Xtensa firmware images.

We primarily employed general static analysis techniques to cover a broad range of firmware and identify common properties. While it is feasible to conduct more sophisticated analysis to study a particular firmware property, this requires extensive domain knowledge to properly set up the environment. For instance, techniques like firmware rehosting necessitate an understanding of the device's memory map. If the configuration is wrong, the result might be unreliable. Although this is not done in this paper, domain experts can utilize advanced firmware analysis projects, such as Fuzzware [62] and HEAPSTER [30], to study firmware samples of interest.

	Arm			Xtensa		
	Mean	Median	SD	Mean	Median	SD
Func. #	789.96	539.00	3,317.15	3,799.04	3,106.50	3,337.91
Size (KB)	541.90	85.54	6,912.09	951.82	648.88	863.88

Table 6: Statistics of function count and firmware size.

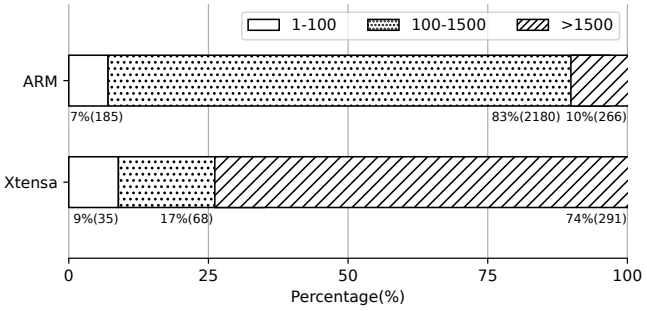

Figure 3: Distribution of function number.

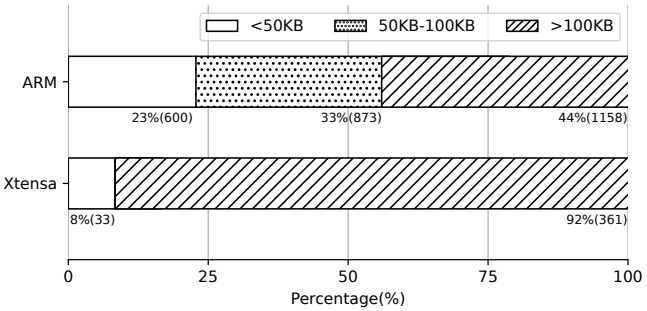

Figure 4: Distribution of firmware size.

7.2.1 Complexity Analysis

We loaded firmware images to Ghidra for automatic analysis and count the firmware size and the number of functions in each image. The distribution of function count in Figure 3 and Figure 4 indicates that Arm-based firmware samples generally have fewer functions and smaller sizes, with more than 90% having less than 1,500 functions. In contrast, over 74% of Xtensa-based firmware images have more than 1,500 functions. We hypothesize that this is because Arm chips are more diverse with customizable peripheral configurations. As a result, many of them are not as powerful as Espressif's ESP32 series chips, which provide a one-stop wireless solution suitable for a wide range of applications. Consequently, firmware running on Xtensa-based ESP32 MCUs often contains more functionalities. Table 6 shows statistics of function count and

firmware size, including mean, median, and standard deviation. We can see that the deviation in Arm-based firmware is more significant than that in Xtensa-based firmware, agreeing with our hypothesis before.

7.2.2 Library Adoption Analysis

To reduce time to market and streamline firmware development, it is common practice for device manufacturers to integrate open-source middleware (e.g., communication protocol libraries), RTOS libraries (e.g., FreeRTOS, Mbed OS), and chip SDKs/BSPs into the firmware stack. By fingerprinting these libraries in our dataset, we can uncover the prevalent libraries used in the IoT ecosystem.

Library Dataset. For Arm, we collected commonly used MCU middleware, RTOS libraries and chip SDKs/BSPs. For Xtensa, we mainly used the Espressif IoT Development Framework (ESP-IDF) [25], which provides a one-stop repository for developing firmware for ESP32 SoCs. Notably, it conveniently maintains not only Espressif's own driver code but custom copies of third-party libraries. We collected all the libraries of latest versions at the time of writing. In total, our dataset includes 1,435,788 Arm functions and 1,239,283 Xtensa functions.

Fingerprinting Libraries. Matching a function is the first step towards library matching. There are two flavors for function matching. The ID-based solution calculates a unique identification signature for each function. For example, Ghidra's Function ID [46] implementation hashes the masked function bytes to generate the ID. Here, masked means that the address information is removed to make the result independent of the function address. The other flavor is based on similarity. That is, for a pair of functions, a similarity score ranging from `0-1` is calculated. Graph isomorphism is widely adopted in this direction, e.g., BinDiff [27].

The Function ID method can be fast and accurate. However, it cannot tolerate trivial differences in library version and compiler selection. That is, to match a library, we would have to build a dataset for all the historical versions using all possible compilers (and options). With the similarity-based method, we can use only the latest library version to potentially match outdated versions. This is particularly relevant for matching functions in IoT firmware, which rarely updates its third-party libraries.

Conducting pairwise similarity-based matching is time-consuming, especially when comparing millions of functions. Inspired by LibMatch [17], we propose SimMatch, a two-step similarity-based function matching approach to overcome the scalability issue. In step 1, we calculate the product of three fundamental metrics for a function: the number of basic blocks, the number of edges in the CFG, and the count of jump instructions. We only proceed to step 2 if the step-1 scores for the two functions are close. In step 2, we compare the context of their basic blocks using the string comparison algorithm based on Ratcliff/Obershelp pattern [12]. We consider two function a match when the similarity score exceeds 95%.

	ARM		Xtensa	
	Function # (%)	Time (hh:mm:ss)	Function # (%)	Time (hh:mm:ss)
SimMatch	99,844 (6.95%)	01:59:56	293,341 (23.67%)	03:10:29
Function ID	72,102 (5.02%)	00:27:45	87,514 (07.06%)	00:15:27

Table 7: Function matching results.

	SDK		Middleware			RTOS
	STM32Cube	Nordic nRF5	Arduino	HARDWARIO	Mbedtls	FreeRTOS
SimMatch	482	615	92	619	8	235
Function ID	366	440	76	380	1	76

Table 8: Library matching results for Arm firmware.

	HAL	lwIP	WiFi	MQTT	BLE	RF	MbedTLS	FreeRTOS
SimMatch	100	343	345	1	144	352	62	266
Function ID	5	195	329	0	86	340	0	79

Table 9: Library matching results for Xtensa firmware.

Results. We ran both SimMatch and Function ID to find matching functions in our firmware datasets and show the results in Table 7. If we consider a library to be matched if two or more library functions are found in the firmware, the library adoption results are shown in Table 8 and Table 9. As expected, Function ID outperforms SimMatch significantly in terms of time consumption. However, it also found less matched libraries because it is more strict and we only used the lasted libraries to perform matching. The gap is bigger for Xtensa firmware. Our investigation shows that the Xtensa compiler tends to generate more diverse machine code even for the same piece of C code, making ID-based solutions more sensitive to little changes.

To understand the false positive rate of both solutions, we manually checked all the Xtensa firmware with matched BLE library. SimMatch incurred 2 false positives out of 144 matches, while Function ID incurred 1 out of 86. The counterintuitive false positive happened in Function ID is because it masks the otherwise different MMIO addresses in `load/store` instructions, leading to a collision. We cannot check false negatives since there is no ground truth about the library adoption.

7.2.3 N-Day Vulnerability Analysis

We identify N-day vulnerabilities using the library adoption information obtained in §7.2.2. If a library has ever had a vulnerable version, it is likely to impact the firmware. Therefore, we first searched for the involved libraries in the CVE database [3] and identified a list of CVEs affecting these libraries. Then, we manually collected the version information of the impacted libraries and the functions involved. Finally, we checked for the presence of vulnerable functions in the firmware.

Since our library datasets were built from the latest releases, we also need to compile the old vulnerable ones to match the function. Fortunately, for Xtensa firmware, the version of the

MPU	TrustZone	Stack Limit	Stack Canary
41 (1.56%)	0 (0.00%)	0 (0.00%)	3 (0.11%)

Table 10: Mitigation features found in Arm firmware.

used ESP-IDF framework is already provided in the firmware header. Therefore, we only need to confirm if the function in firmware is close enough with the one in the latest library.

In total, the Arm dataset contains vulnerable libraries with 2 unique CVEs, while the Xtensa firmware dataset includes 12 unique CVEs. These CVEs were identified twice in 1 Arm firmware image and 552 times across 190 Xtensa firmware images, respectively. The details of these findings are listed in Appendix C. We have reported our findings to 31 manufacturers, and 3 have acknowledged and planned SDK updates.

7.2.4 Mitigation Detection

Modern Arm MCUs enable several security mechanisms to mitigate attacks. We developed Ghidra scripts to search for the adoption rates of these features.

MPU. An *Memory Protection Unit* (MPU) allows programmers to specify the permissions (`R/W/X`) for memory ranges based on the current privilege level. Not using MPU means no data execution protection (DEP) and no isolation between the kernel and user code, allowing code injection, illegal memory access, etc. Since MMIO is the only way to configure MPU on Cortex-M chips, we check whether there exist load/store instructions targeting the memory range of MPUs, i.e., `0xE000ED90 - 0xE000EDBB` for Arm's standard MPU and `0x40000528 - 0x4000060F` for Nordic's simplified MPU (sMPU) [49]. To recover the target addresses in these ranges, the Ghidra plugin finds the base register and offset (register or immediate value) that are known statically. As shown in Table 10, only 1.56% of the images use the MPU feature, agreeing with previous research [16]. There are two limitations of our prototype. First, it does not perform reachability analysis; therefore, the detected MPU code may not be invoked at all. Second, it may miss real MPU accesses due to unavoidable disassemble errors.

TrustZone. Arm announced its Trusted Execution Environment (TEE) solution for MCUs in 2016 [10]. By providing an isolated execution environment, it ensures robust protection even if the normal-world firmware is fully compromised. Nearly eight years following its announcement, we are curious about its real-world adoption. Our tool detects the footprint of TrustZone in the secure-world firmware, since TrustZone implementation details are hidden from the non-secure part. For the secure firmware, we search for the pair of Secure Gateway veneer (i.e., the SG instruction following a branch) and return to the normal world instructions (i.e., `bxns lr`) [9]. We did not obverse any sign of TrustZone usage.

Stack Limit. The stack limit feature introduces two new registers to define the lower limit for the two stacks on Arm. Configured properly, it ensures that stacks do not overrun. Unfortunately, we did not observe any usage of this feature.

Stack Canary. Stack canary is a pure-software mitigation mechanism. It detects stack overflow by checking whether a canary value that is placed by the function prologue is corrupted. We created instruction patterns to match both function prologues and epilogues of canary-enabled functions. Only 0.11% of the images adopt stack canary.

8 Discussion and Future Work

Limitations of *OTACap*. Currently, *EXT-DS* contains much more confirmed images than *OTA-DS*. Besides the fact that APK-bundled firmware distribution is more popular, *OTACap* may also miss a lot of firmware images for three reasons. First, we found many URLs containing a `?token=` or `?deviceid=` query string. These apps typically require user credentials to access the firmware, which is impossible without real user registration. Second, although we tried to infer information about real IoT device to reconstruct URLs as explained in §4.2.2, many apps do not include any clue in the static code. Third, our backward data flow analysis can miss data flows. For example, we cannot unroll loops when the iteration number is unknown.

Threats to Validity. Although we aim to measure the IoT landscape in a general sense, due to the unsoundness and incompleteness of our implementation, bias may exist. 1) We may miss many firmware images due to incomplete keywords/signatures and *OTACap* limitations, thus overrepresenting a specific vendor or architecture. 2) Our measurements presented in §7.1 rely on metadata extracted from known signatures, which may miss some information. For example, we did not find clear signatures for some major Arm vendors, such as NXP. Therefore, we cannot properly decompose the IoT by chip vendors other than roughly putting them to a general Arm group (Table 4). 3) The measurement was conducted over unique images. It does not necessarily reflect the number of chip shipments. 4) Some URLs may become inaccessible over time, leading to reduced firmware.

Future Work. Signature development and identification is largely manual work, which we plan to augment over time. We will also enhance our crawler's user authentication for MQTT and HTTP endpoints. An idea is to emulate user registration using a phantom IoT device, as described in existing work [15, 83]. The main observation is that many device secrets are easily guessable.

More sophisticated firmware analysis tools such as Fuzzware [62] and HEAPSTER [30] can be used to find deeper and even zero-day firmware bugs. Our initial attempt to use Fuzzware to fuzz firmware was not very successful, attributable to three reasons. 1) Some firmware is incomplete, lacking device initialization instructions found in bootloader that is

not part of the OTA update process. 2) Some firmware checks chip information during bootstrapping, which Fuzzware failed to infer. 3) The complex and varied peripheral usage in the firmware cannot be properly modeled. These failed cases will foster new ideas to advance the state of the art.

9 Related Work

Analysis Targeting Firmware. In FirmXray [79], the authors extracted 793 unique firmware from the companion apps. By analyzing this dataset, many BLE-link layer vulnerabilities are identified. In FIoT [84], the authors manually emulated fake IoT devices to capture the OTA update traffic. Then, symbolic execution and fuzzing were adopted to analyze the 318 obtained firmware images. The FirmXRay dataset has been widely used in other firmware analysis research. For example, HEAPSTER [30] runs symbolic execution against the FirmXRay dataset to find the presence of dynamic allocators and uses bounded model checking to find vulnerabilities. Tan et al. [69] systematizes research on Arm MCU firmware. They also analyzed 1,797 Arm firmware samples, which were mainly collected via the FirmXray method and web crawlers to the vendor websites. These works mainly target the Arm instruction set and the results overrepresent devices built on Nordic and TI chips. Our dataset contains more firmware images, covering at least 11 different chip vendors across 7 different architectures. Recently, Firmline [5] proposes a generic pipeline for analyzing non-Linux firmware. An impressive 21,755 samples were obtained from prior research, the Linux firmware repository, Android dumps, and other sources. However, the majority of the samples come from Linux/Android firmware for PC/smartphone peripherals. In contrast, our dataset primarily consists of firmware for consumer IoT devices. Another distinction is that the Firmline analysis pipeline relies on statistical analysis to determine the possible architecture, whereas we leverage firmware signatures to reliably determine the architecture and other metadata.

IoTFuzzer [14], while targeting firmware, relies on analysis of the companion app. It fuzzes device firmware to find memory corruption bugs without having to access the firmware. However, it lacks scalability as real devices are needed. Also, without firmware, it becomes hard to pinpoint the root cause of the bug. By integrating the firmware retrieval capabilities of *OTACap* with the bug detection power of IoTFuzzer, we anticipate more effective tools to combat firmware bugs.

Analysis Targeting Companion Apps. Due to the lack of real firmware, prior work uses mobile IoT companion apps to study the security of the IoT ecosystem on a larger scale. AoT-Scout [31] focuses on finding vulnerabilities involved in the OTA process. The authors analyzed 23 popular IoT devices and corresponding companion apps to locate six popular SDKs with security flaws. Then, they fingerprint each vulnerable SDK in a large dataset of apps, revealing many others that are prone to the same vulnerabilities. However, this approach requires a real device to analyze the APK, thus suffering from the scalability issue. In [78], the authors analyze the library artifacts in mobile companion apps and infer vulnerabilities in the device firmware. IoTSpotter [32] constructs a large IoT-Mobile companion app repository and evaluates the security of each app by analyzing known vulnerabilities in third-party libraries, identifying misuses of cryptographic APIs, and the signing scheme of the APK.

Leakscope [86] finds data leaks from mobile apps to the Internet by reconstructing paths from potentially sensitive sources to network sinks using backward VSA. Similarly, IoTFlow [63] reconstructs the communication of IoT devices with their companion apps and cloud-based backends. BleScope [87] leverages string reconstruction to identify hard-coded UUIDs in the companion app to fingerprint BLE devices. Stringoid [57] reconstructs URLs to analyze Web requests in Android apps. All these tools rely on string analysis. However, they are not specifically engineered towards OTA link recovery, and thus cannot yield the volume of firmware that *OTACap* can. Particularly, *OTACap* outperforms existing tools due to 1) improved VSA accuracy via cross-referencing hardware information and better implicit data flow tracking, and 2) an intelligent crawler that better utilizes the recovered URLs. Moreover, all these works rely on mobile apps to infer the security of the device. They generally cannot get low-level security properties of IoT firmware.

10 Conclusions

We present a novel approach for the large-scale collection, validation, and analysis of MCU-based IoT firmware to improve the understanding of the security landscape of the IoT ecosystem. Specifically, we introduce *OTACap*, a tool designed to automatically extract URLs for OTA firmware update by analyzing companion Android apps. Additionally, we utilize a keyword-based search strategy for rough firmware screening while leveraging a signature-based firmware unpacking pipeline to validate firmware and extract essential information for subsequent analysis.

In our experiments with 40,675 mobile-IoT Android APKs, *OTACap* has successfully extracted over 2,221 valid URLs related to firmware updates, allowing us to download 18,516 candidate firmware images by crawling these URLs. Moreover, we extracted 24,715 unique candidate firmware images directly from APKs that were shipped with the APKs. Using signature matching, we identified 3,692 unique firmware images, and 3,660 of them were analyzable.

Our security analysis indicates a lack of firmware protection, existence of N-day vulnerabilities, and rare adoption of security mitigation in these firmware images. The results presented in this paper establish an extensive, heterogeneous, and annotated dataset of bare-metal firmware currently available.

Acknowledgments

We thank the anonymous reviewers for their valuable comments to improve our paper. This work was partially supported by U.S National Science Foundation (NSF) grants (2238264, 1916500, 2237238, 2329704, 2422242), National Natural Science Foundation of China (NSFC) grant (62202188), and a grant from the University of Georgia Research Foundation, Inc. Opinions, findings, and conclusions or recommendations expressed in this material are those of the authors and do not necessarily reflect the views of any funding agencies

Availability

We have made the source code for our tools available at https://github.com/MCUSec/RealworldFirmware to facilitate the replication of our work. However, releasing the firmware dataset poses potential risks, including copyright infringement and misuse. Despite these concerns, ethical security researchers can leverage the dataset to benefit the IoT community as discussed in §1. To balance these considerations, we will carefully evaluate access requests and share the dataset privately with research teams committed to responsible and ethical practices.

A Lists of Keywords and File Extensions

Table 11 and Table 12 list the firmware-related keywords and file extensions used in *OTACap*.

Keyword	Regular Expression	Description
firmware	(?i)firmware	Firmware
download	(?i)download	Download
release	(?i)release	Release
image	(?i)image	Image
update, upgrade	(?i)update (?i)upgrade	Update
fw	(?i)(?<![a-zA-Z])fw(?![a-zA-Z])	Firmware
ota	(?i)(?<![a-zA-Z])ota(?![a-zA-Z])	Over-The-Air
oad	(?i)(?<![a-zA-Z])oad(?![a-zA-Z])	Over-The-Air Download, mainly TI
dfu	(?i)(?<![a-zA-Z])dfu(?![a-zA-Z])	Device Firmware Update, mainly Nordic
ble	(?i)(?<![a-zA-Z])ble(?![a-zA-Z])	Bluetooth Low Energy
Consecutive hex values	[a-fA-F0-9]{16}	File content hash value as file names

Table 11: Keywords used in firmware collection.

Format	Extensions	Description
Intel HEX	.hex, .mcs, .int, .ihex, .ihe, .ihe, .ihx, .h80,.h86, .a43, .a90, .hxl-.hxh, .h00-.h15, .p00-.pff, .obj, .obl, .obh, .rom,.eep, .bex	Intel hex object file format conveys binary informationin in ASCII text form. Each text line is called a record that represents machine code/data and its address information
Motorola S-Rec	.s19, .s28, .s37, .s1, .s2, .s3, .s, .sx, .srec, .exo, .mot, .mxt	Similar to Intel HEX and created by Motorola
TI-TXT	.txt	Similar to Intel HEX and created by TI
Tektronix	.tek	Similar to Intel HEX and created by Tektronix
Cypress	.cyacd, .cyacd2	Proprietary file format developed by Cypress, now acquired by Infineon
CSR	.csr	The firmware format used in CSR BlueCore bluetoothchips. Developed by Cambridge Silicon Radio and now acquired by Qualcomm
RSU	.rsu	Renesas Secure Update format
UF2	.uf2	A file format developed by Microsoft that is particularly suitable for flashing microcontrollers
MISC.	.bin, .fw, .img, .upg	File extensions generally selected by manufacturers

Table 12: File extensions used in firmware collection.

B An Example of URL Analysis using LLM

When crawling the initial URLs from the app `com.lorexcorp.lorexping`, our crawler captured the following text (actual URL redacted).

CVE	Version	Component	FW #
CVE-2022-35623	v4.2.0-v5.0.0	Mesh	1
CVE-2022-35624	v4.2.0-v5.0.0	Mesh	1
CVE-2019-12588	v2.2.0-v3.1.0	WiFi (Beacon)	45
CVE-2019-12586	v2.0.0-v4.0.0	WiFi (WPA2)	70
CVE-2019-12587	v2.0.0-v4.0.0	WiFi (WPA2)	70
CVE-2020-12638	v4.0.0-v4.2.0	WiFi (WPA2)	74
CVE-2020-13594	v4.0.0-v4.2.0	BLE	13
CVE-2020-13595	v4.0.0-v4.2.0	BLE (HCI)	4
CVE-2020-16146	v2.0.0-v4.0.1*	BLE (Blufi)	3
CVE-2021-28135	v4.0.0-v4.4.0	Bluetooth (LMP)	46
CVE-2021-28136	v4.0.0-v4.4.0	Bluetooth (LMP)	46
CVE-2021-28139	v4.0.0-v4.4.0	Bluetooth (LMP)	46
CVE-2021-33028	v4.0.0-v4.2.0	WiFi (QoS)	94
CVE-2021-34173	v4.0.0-v4.2.0	WiFi (Beacon)	4
		Total (deduplicated)	191

*: v3.1.8, v3.2.4, and v3.3.3 are not subject to the CVE since these minor versions backported the patch released in v4.0.2.

Table 13: Detected N-day Vulnerabilities. Except for the first two CVEs found in nRF5-Mesh [48] and the third found in ESP8266_NONOS_SDK [24], all other CVEs were found in ESP-IDF [25].

```
# FTP tag|FTP server|FTP username|FTP password|
FTP|[redacted]|upgrade|upgrade|
# clientModelID|FW version|FW filename|Config version|Config
filename|
G1|030509|IC717w-gen-030509-n.f|2|g1.cfg|
G2|030418|IC717g-gen-030418-n.f|2|g2.cfg|
...
```

We developed a *system prompt* to extract information.

```
I have some unstructured text. It might contain information about
firmware distribution URLs with credentials. Can you extract such
information, including the protocol, server address, username
and password? If you can, please format your answer in JSON.
Otherwise, just say no.
...
```

LLM returned the following correct result.

```
After analyzing the text, I was able to extract the following
information about firmware distribution URLs with credentials:

```json
[
    {
        "protocol": "FTP",
        "server_address": "[redacted]",
        "username": "upgrade",
        "password": "upgrade"
    }
]
```
```

C List of N-day Vulnerabilities

We identified 14 N-day vulnerabilities across 191 firmware samples. The details including the affected SDKs, versions, and components are shown in Table 13.

Your Firmware Has Arrived: A Study of Firmware Update Vulnerabilities

Abstract

Embedded devices are increasingly ubiquitous in our society. Firmware updates are one of the primary mechanisms to mitigate vulnerabilities in embedded systems. However, the firmware update procedure also introduces new attack surfaces, particularly through vulnerable firmware verification procedures. Unlike memory corruption bugs, numerous vulnerabilities in firmware updates stem from incomplete or incorrect verification steps, to which existing firmware analysis methods are not applicable. To bridge this gap, we propose ChkUp, an approach to Check for firmware Update vulnerabilities. ChkUp can resolve the program execution paths during firmware updates using cross-language inter-process control flow analysis and program slicing. With these paths, ChkUp locates firmware verification procedures, examining and validating their vulnerabilities. We implemented ChkUp and conducted a comprehensive analysis on 12,000 firmware images. Then, we validated the alerts in 150 firmware images from 33 device families, leading to the discovery of both zero-day and n-day vulnerabilities. Our findings were disclosed responsibly, resulting in the assignment of 25 CVE IDs and one PSV ID at the time of writing.

1 Introduction

The rapid increase of embedded devices, ranging from portable devices, such as smartwatches, to large machines like transport vehicles, brings more connectivity and convenience to our lives. The market size of embedded devices is expected to reach 116.2 billion dollars in 2025 [10]. Firmware update plays an important role in fixing vulnerabilities and improving functionalities. However, a poorly implemented firmware update mechanism can diminish the benefit or even introduce new attack surfaces. In fact, vulnerabilities related to software update has been recognized as one of the top five security risks for embedded devices [12].

Firmware Update Security. Software or firmware updates are currently one of the most effective techniques against cyber attacks. However, with the increasing connectivity and complexity in modern embedded systems, there is an increasing number of cyber attacks targeting specifically the firmware update procedures, allowing the adversary to execute arbitrary code or roll back the firmware version to expose prior vulnerabilities [21, 70]. Recent vulnerabilities in update mechanisms of Jeep Cherokee [52], Samsung SmartThings Hub [8], and Asus Router [9] have raised significant concerns, highlighting the need for automatic identification of firmware update vulnerabilities. Existing firmware vulnerability detection methods often focus on identifying invocations to unsafe sinks from user-controlled inputs [19, 25, 27, 59, 65] or finding bugs using common vulnerable patterns or deviations from known specifications [24, 33, 49, 50, 64]. However, firmware update vulnerabilities pose a unique challenge as they often arise from a combination of issues across multi-stage update procedures, exacerbated by the absence of comprehensive specifications or systematic categorizations of vulnerable patterns. To gain a better understanding of the landscape of firmware update vulnerabilities, we categorize and systematize firmware update-related CVEs in the past decade. Each type of vulnerability is placed in different abstract phases of a general firmware update procedure, which is detailed in Section 2.

Our Solution - ChkUp. In this paper, we propose ChkUp, a novel approach to Check for firmware Update vulnerabilities, including missing verification (e.g. a lack of version check) and improper verification (e.g., use of MD5 for integrity check). Intuitively, ChkUp extracts the program execution paths for a firmware update procedure and then identifies the chain of verification steps in the update procedure. We then summarize the vulnerable patterns across multiple firmware update phases for vulnerability detection. While working on this, we found that existing implementations of firmware update mechanisms present unique challenges that require new techniques. Specifically, there are three main technical challenges:

C1. Diverse System Components Supporting Firmware Update: In many Linux-based firmware images, various types of

programs such as front-end programs, scripts, and binaries are invoked in the software update execution path that spans both the front end and back end of the web server. Additionally, the diversity of components involved in firmware updates leads to the heterogeneity of inter-process communication (IPC) mechanisms. To tackle these challenges, we develop techniques to generate the inter-process update flow graph (UFG). The entry program is first identified using common code patterns and semantic information that interconnects the front end and the back end in a firmware update procedure. Then, cross-language control flows are extracted by connecting the control flows of individual programs (i.e., front-end programs, scripts, and binaries) and resolving the corresponding IPCs. With such a cross-language cross-program control flow graph, firmware update execution paths are resolved using backward program slicing with firmware update-specific semantics.

C2. Verification Procedure Recognition: A firmware update is a complex procedure that includes a variety of checks and verifications, from the verification of cryptographic signatures to the comparison of versions and device IDs. An update procedure is considered secure only when every verification step (e.g., signature verification or compliance with version update policies) and their composition are properly implemented. However, firmware updates do not have standardized specifications and are often implemented in multiple programming languages. This leads to diverse verification implementations, making it challenging to identify them from numerous functions in execution paths. To tackle this challenge, ChkUp recognizes firmware verification procedures using data flow graph (DFG) isomorphism-based semantic similarity matching. To reduce the overhead of this process, functions in execution paths are first ranked by a similarity score, which is calculated using both syntactic and structural features. Then, functions with higher similarity scores are prioritized for DFG isomorphism-based analysis.

C3. Vulnerability Validation: Static analysis can produce a number of false positives (FP), which require further validation. However, a firmware update procedure often involves a chain of verification steps, each with its unique functions and invocation parameters. To test a step later in the chain, it is necessary to create an input and an environment that are capable of passing the first several steps. To simplify validation, we present a semi-automated dynamic method to validate alerts for emulatable firmware images. Specifically, we employ firmware patching to ensure the execution of potentially vulnerable procedures. The validity of the corresponding alerts is then checked based on the update behaviors after inputting malicious firmware images.

Evaluation and Findings. To gain a deeper understanding of vulnerabilities in the wild, we ran ChkUp[1] on 12,000 firmware images. We found that weak verification algorithms, such as the use of MD5 for integrity verification, were prevalent. Then, we performed vulnerability validation on 150 randomly selected firmware images: For those emulatable firmware images, we performed dynamic validation by creating PoCs; for the remaining firmware images, we conducted manual analysis to validate their alerts. Our results showed a true positive rate (TPR) of 86.7% and a false positive rate (FPR) of 5.3%, leading to the discovery of both zero-day and n-day vulnerabilities in firmware images from 33 device families. These findings were responsibly disclosed, and 25 CVE IDs and one PSV ID have been assigned. Finally, to demonstrate the exploitability of the vulnerabilities, we showcased firmware downgrade and firmware modification attacks.

[1] Our artifacts are available at https://fw-chkup.github.io

Contributions. Our contributions are outlined as follows:

- *A systematization of firmware update security:* We frame general firmware update procedures into four phases and examine security issues in each phase by analyzing and categorizing 381 firmware update-related CVE reports.
- *A new approach for update vulnerability detection:* We propose a new firmware update vulnerability identification approach, ChkUp, which addresses three technical challenges: diverse components in update paths, verification procedure recognition, and vulnerability validation.
- *Vulnerabilities on real-world firmware:* We ran ChkUp on 12,000 firmware images and validated alerts for 150 of them using a combination of proof-of-concept (PoC) generation and manual analysis. The results demonstrate ChkUp's capability to identify zero-day and n-day vulnerabilities. Following responsible disclosure, 25 CVE IDs and one PSV ID have been assigned.

2 Firmware Update Security Systematization

2.1 Challenges of Firmware Updates

To gain a better understanding of the threat landscape, 381 firmware update-related CVEs from the past decade are analyzed and then systemized. While most CVEs stem from vulnerable firmware update mechanisms, others simply have an impact on the security of the update. Figure 1 shows the annual distribution of Common Vulnerability Scoring System (CVSS) v3 metrics since 2015. There is a steady trend of increasing, with the number of CVEs doubling from 2020 to 2021. High and critical vulnerabilities are nearly

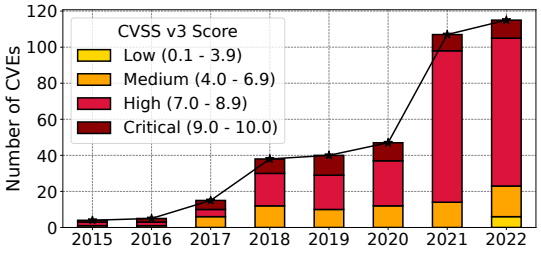

Figure 1: CVSSv3 scores of firmware update-related CVEs.

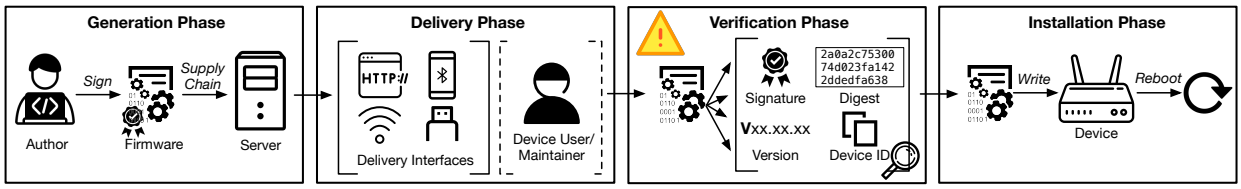

Figure 2: A common firmware update workflow.

four times of low and medium ones. This increase can be attributed to not only the general trend of increasing CVEs but also the newly arising challenges specific to embedded systems [15, 30, 62, 72–74, 84, 86]. These challenges include 1) an expanding attack surface due to increased connectivity, 2) increased complexity of embedded systems, 3) long product life cycle, and 4) limited resources on embedded devices. These factors contribute to diverse firmware update mechanisms and increased vulnerabilities.

2.2 Update Workflow and Vulnerabilities

A typical firmware update workflow has four phases as shown in Figure 2: generation, delivery, verification, and installation.

Generation Phase. The goal of the generation phase is to create firmware images and make them available. Specifically, an author first develops a new firmware image and a manifest. The manifest contains firmware metadata, including the firmware digest, version, and device ID. subsequently, the firmware image and manifest are signed with a digital signature and then transferred to a firmware server through the software supply chain. Usually, the author uploads firmware to the server through trusted parties in the supply chain.

During this phase, external attackers can conduct supply chain attacks to steal certificates and compromise software development tools or infrastructure. The root cause of such attacks is inappropriate access control for critical assets and infrastructures. There has been an increasing number of supply chain-related vulnerabilities reported in recent years, demonstrating their security impact in the real world. Reports indicate that the U.S. Government and more than 30,000 public and private organizations such as Microsoft, Intel, and FireEye suffered from a large-scale software supply chain attack known as the SolarWinds hack in 2020 [55]. Specifically, cybercriminals compromised Orion IT management software and then distributed malicious software updates containing backdoors to users through the supply chain.

Takeaway 1: Supply chain vulnerabilities pose a significant risk, often from inadequate access controls. Without proper on-device verification, compromised firmware can be installed in devices, leading to a loss of control over them.

Delivery Phase. The delivery phase involves transmitting the new firmware image from the server to the target device. A firmware component, known as the *update agent* [46], handles downloading, verifying, and storing the new image in persistent memory. Typically, new firmware can be delivered in three ways: 1) The firmware server directly pushes the firmware and manifest to the device's *update agent*; 2) The *update agent* polls for updates and downloads them when they become available; 3) The firmware server notifies the device user/maintainer, who manually downloads and uploads updates to the *update agent*. In terms of communication channels, common methods include application-layer protocols (e.g., HTTP, FTP), wireless media (e.g., Wi-Fi, Bluetooth Low Energy), and physical interfaces (e.g., USB, removable memory cards). For some low-end, bare-metal devices, companion apps on smartphones can assist with firmware updates. The new firmware can either be bundled within or fetched by the app from the firmware server through application-layer protocols. Then, these apps generally communicate with the device via wireless media for notification, polling, and downloading. It is worth noting that while the apps act as intermediaries for transferring firmware, they may also pre-verify updates. Such early verification can filter out invalid updates, to avoid unnecessary, subsequent on-device processing.

A secure communication channel is important for the confidentiality and integrity of the delivered firmware images. Insecure delivery mainly arises from a lack of cryptographic protocols or the use of hard-coded keys, exposing systems to machine-in-the-middle (MITM) attacks. For example, CVE-2020-9544 involves plain HTTP without authentication, while CVE-2020-25233 derives from the use of a hard-coded RSA key for communication. Mobile apps can also have insecure communication with either firmware servers or devices, as shown by CVE-2018-3928, where insufficient communication security checks can lead to code execution vulnerabilities. Importantly, the primary concern is not just the communication channel but also the lack of proper security verification. For example, even with a leaked communication key, if a robust firmware verification mechanism is in place, malicious firmware replacements during updates can be prevented.

Takeaway 2: Firmware delivery security mainly relies on the communication channel and device user/maintainer. If either is insecure, the device may receive compromised firmware unless proper on-device verification is in place.

Verification Phase. The verification phase ensures the authenticity, integrity, freshness, and compatibility of the received

Table 1: Top ten firmware update-related CWE vulnerability types.

CWE ID	Name	Example	Proportion
CWE-345 ↪CWE-347	Insufficient Verification of Data Authenticity Improper Verification of Cryptographic Signature	CVE-2020-10831, CVE-2020-24395, CVE-2022-36360 CVE-2020-27540, CVE-2021-37160, CVE-2022-21134	5.47% 10.16%
CWE-287 ↪CWE-306 ↪CWE-295	Improper Authentication Missing Authentication for Critical Function Improper Certificate Validation	CVE-2018-6294, CVE-2020-27488, CVE-2022-2503 CVE-2019-16243, CVE-2020-9544, CVE-2020-29379 CVE-2018-15476, CVE-2020-15498, CVE-2021-22909	6.25% 3.91% 3.13%
CWE-20	Improper Input Validation	CVE-2018-3891, CVE-2019-11103, CVE-2021-25437	10.94%
CWE-434	Unrestricted Upload of File with Dangerous Type	CVE-2019-10959, CVE-2021-37160, CVE-2022-28372	5.47%
CWE-798	Use of Hard-coded Credentials	CVE-2019-5158, CVE-2019-14926, CVE-2020-24215	2.34%
CWE-119	Improper Restriction of Operations within the Bounds of a Memory Buffer	CVE-2017-11082, CVE-2017-14444, CVE-2017-14445	1.56%
CWE-639	Improper Neutralization of Special Elements used in an OS Command	CVE-2018-3890, CVE-2019-5157, CVE-2019-15310	0.78%

Note: CWE-347 is the child class of CWE-345; CWE-306 and CWE-395 are the child classes of CWE-287.

firmware. Specifically, the *update agent* performs a series of verification procedures before storing the image in persistent memory: firmware authenticity is ensured by verifying the digital signature of the firmware; firmware integrity is verified by checking the digest contained in the manifest; and the freshness and compatibility are confirmed by examining the metadata, along with version and device ID in the manifest.

Table 1 lists the top ten firmware update-related vulnerabilities in the Common Weakness Enumeration (CWE) category, based on our CVE analysis. The top eight categories, accounting for 47.67%, predominantly involve either *missing verification* or *improper verification* methods for firmware updates. These issues can enable attackers to replace the benign firmware with a malicious one during updates. For instance, the issue with CVE-2018-10988 stems from a lack of digital signature verification in the shell script used for firmware updates. Missing or improper integrity verification may lead to firmware corruption. For example, using easily bypassable internal checksums for firmware integrity checks is problematic (e.g., CVE-2018-5441). Missing or improper freshness verification can lead to firmware downgrade attacks, while inadequate compatibility verification can expose the device to DoS attacks. For instance, the root cause of CVE-2018-3891 is a logic flaw in performing version verification, where integer comparison operators are incorrectly used for string comparison. Similarly, in the case of CVE-2020-10831, arbitrary firmware can be installed due to insufficient verification.

> ***Takeaway 3:*** Either missing or improper implementation of any steps in the verification procedure can lead to the installation of unintended firmware on the embedded device.

Installation Phase. The installation phase is a process of installing and executing the new firmware. After verification, the new firmware is stored in the persistent memory of the device and is activated upon reboot. Specifically, a bootloader first moves the new firmware image to the right offset in the device memory when the device is starting up. Then, the bootloader executes the new firmware image after conducting a firmware inspection. However, this inspection is often incomplete and insecure, commonly relying on internal checksums [46].

Most vulnerabilities in this phase are typical software bugs such as command injection and memory corruption bugs. Specifically, firmware update-related commands executed during this phase may accept parameters from user inputs. If an attacker manipulates these parameters and they are subsequently used by vulnerable functions (e.g., *system*, *strcpy*), it can lead to command injection (e.g., CVE-2019-5155) or memory corruption (e.g., CVE-2021-22675) attacks.

> ***Takeaway 4:*** Incomplete firmware inspection procedures in bootloaders during firmware installation are common, thus making the security of firmware updates dependent on the verification mechanisms in the *update agent*.

Summary. Security vulnerabilities can arise during any phase of the firmware update process. Nevertheless, robust firmware verification mechanisms by the device's *update agent* can mitigate the majority of vulnerabilities originating from other phases. Hence, our research primarily focuses on identifying vulnerabilities within the verification phase.

3 Threat Model and Overview

Threat Model. ChkUp aims to uncover firmware update vulnerabilities in OS-based firmware (integrated with file systems), particularly in the dominant Linux-based firmware [69]. It can detect the most prevalent firmware update vulnerabilities including missing or improper verification of authenticity, integrity, freshness, and compatibility. Aligned with existing research [19, 34, 36, 59, 83], we assume no firmware source code access, making ChkUp a binary-based vulnerability detection approach. Potential users of ChkUp could be security researchers seeking to notify vendors, or end-users trying to obtain additional security information about their devices. Even vendors with access to the source code can benefit, especially in investigating the exploitability of vulnerabilities, since source code analysis can overlook binary and runtime-level details. It is worth noting that, similar to intrusion detection systems or malware detectors, in-depth domain expertise proves valuable in further refining alerts.

Overview of ChkUp. The high-level idea of ChkUp is to statically extract the firmware update program execution paths from the firmware codebase and to pinpoint potential vulnerabilities along these paths based on summarized vulnerability

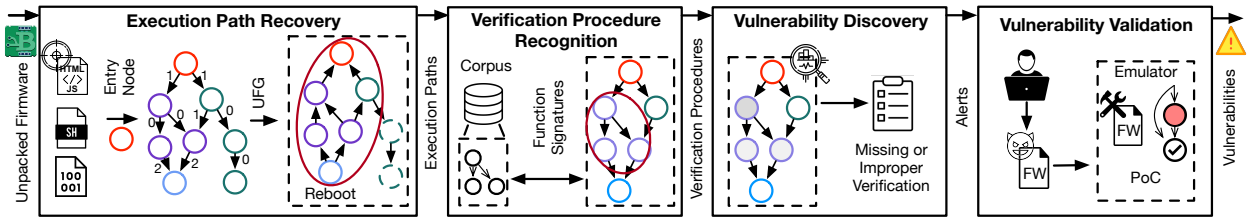

Figure 3: Overview of ChkUp.

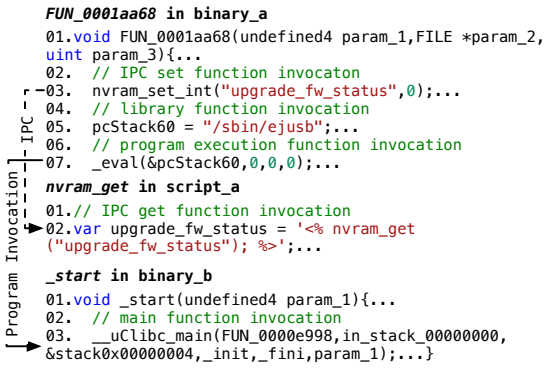
patterns. Then, dynamic vulnerability validation is performed to reduce false alerts. However, as discussed in Section 1, three primary challenges need to be addressed to implement this idea: *C1. Diverse Programs in Update Paths* during the extraction of firmware update execution paths, *C2. Verification Procedure Recognition* for matching vulnerability patterns, and *C3. Vulnerability Validation* to reduce false alerts. To address these challenges, we propose ChkUp (illustrated in Figure 3). Specifically, to address *C1*, we first create a UFG that captures the control flow information across programs written in different programming languages. Next, we perform backward program slicing to determine the firmware update execution paths (Section 4.1). To tackle *C2*, we extract syntactic and structural features for function matching, then employ more sophisticated DFG isomorphism to recognize the verification chains in the firmware update execution paths (Section 4.2). With the execution paths and the associated verification procedures, we examine them to discover vulnerabilities based on defined criteria (Section 4.3). Finally, we address *C3* by a patching-based method where the vulnerable procedure is tested using the generated PoCs after its execution dependencies are bypassed via patching (Section 4.4).



4 Design of ChkUp

4.1 Execution Path Recovery

UFG Definition. The binary dependency graph (BDG) in Karonte [59] can model data dependencies between binaries within firmware images, which is crucial for firmware update vulnerability detection. However, accurate firmware update execution path recovery requires additional information, including control flows, IPCs, and program invocations across programs in various languages to determine the intra- and inter-process control flows of firmware update-related programs. Therefore, building upon BDG, we introduce UFG to accommodate these requirements. A UFG, represented by G, is a directed graph that captures the intra- and inter-process control flow information at the basic block (BB) level of firmware update-related programs. The UFG is defined as $G = (V, E)$, where V is a set of BBs extracted from front-end programs, scripts, and binaries involved in the firmware update procedure. E represents the directed edges between the BBs, and each edge $e \in E$ is represented as $e = ([v_1, p_1], [v_2, p_2], c)$. This indicates that BB v_1 in program p_1 either transfers execution flow or shares data with BB v_2 in program p_2, and c is a flag indicating the type of edge: c is 0 for intra-process control flow edges, c is 1 for IPC relations, and c is 2 for program invocation relations.

Update Entry Finding. Receiving firmware is typically the first step in an update procedure on the device side. Therefore, the entry node in a UFG is the node responsible for this task, and the program that includes this entry node is referred to as the entry program. For firmware containing a web-based update interface, the entry program could be a front-end firmware upload utility. To identify the entry program, we use a static pattern-matching approach. This is non-trivial as firmware update mechanisms vary greatly among different vendors. To address this issue, we manually analyze numerous firmware images (details are provided in Appendix B.2) and identify distinct patterns that differentiate firmware update entry programs from others. Specifically, such an entry program always contains recognizable code patterns. For example, front-end programs to upload firmware images might use the *<input type="file"...>* pattern, while scripts or binaries that download firmware images might use the *wget* ... pattern. Additionally, the entry program often displays prompt messages containing common informative words, as well as function and variable names (e.g., *fw_version* and *fw_upload*) related to firmware updates. Built upon these observations, we identify the program that matches the highest number of predefined patterns as the entry program.

Cross-language Control Flow Analysis. After identifying the entry program, the next step is to locate the programs for processing the received firmware image. These programs can take different forms, such as binaries and shell scripts [48]. To gain complete insight into the control flow of the programs executed during a firmware update, cross-language control flow analysis is necessary. However, current path exploration-based vulnerability detection methods [19, 59] lack this capacity. To address this challenge, we interpret the control flow logic, IPC paradigms, and program invocation paradigms of various program types (i.e., HTML paired with JavaScript, shell script, and binary) commonly used in firmware updates to construct UFGs. Specifically, we build the call graph (CG) and inter-procedure control flow graph (CFG) of the entry

Listing 1: IPC and program invocation examples.

program and identify IPC (i.e., sockets, files, signals, environment variables, NVRAM, and shared memory) and program invocation paradigms in the entry program. Note that the supported program types and IPC paradigms are determined by our preliminary manual firmware analysis, and their generalizability is empirically measured using a large number of firmware images. Then, dependency edges representing control dependencies between the entry program and other related programs are created. The procedure is repeated in a recursive manner, where the CFG of each newly added program is built, and IPC and program invocation paradigms are identified. Listing 1 illustrates the connection of two programs through the discovery of IPC paradigms (*nvram*) and program invocation paradigms (*eval*) between them. The UFG construction is completed once no more update-related programs are found.

Function-level Backward Slicing. With the constructed UFG, the next step is to determine the possible program execution paths for a firmware update procedure using function-level backward program slicing. Typically, a firmware update procedure concludes with a reboot to execute the new firmware. Thus, we locate calls to the reboot function, especially those that trigger the *reboot* binary, in the UFG and set them as the target of backward slicing. The backward slicing follows the inter-procedural control flow within and across programs to determine all possible execution paths starting from the firmware receiving function and ending with the reboot function. These paths represent potential firmware update execution paths. However, as with any path-based exploration analysis, this execution path recovery method may encounter the issues of path explosion and path missing. We tackle path explosion with five strategies, including skipping standard libraries, skipping built-in utilities, using a timeout, filtering paths with prompts, and merging paths. Further details on these strategies can be found in Appendix A.1.

4.2 Verification Procedure Recognition

Two-stage Approach Overview. Key functions are those used in firmware verification, such as hash functions for integrity verification. Our manual analysis reveals that verification procedures often use a similar set of key functions since they all try to accomplish a similar set of functions. Moreover, values from functions, either as return variables or pass-by-reference arguments, often flow into conditional expressions. These expressions then influence which conditional branch is taken. An example can be seen when verifying firmware integrity: the return value of a hash function is used in a conditional expression to determine the verification result, as demonstrated in Listing 2. To identify verification procedures, we construct a corpus of function signatures from common key functions. Next, we recognize verification procedures from the execution paths in two stages: efficient function similarity matching, which quickly filters out irrelevant functions; and verification procedure chain identification, where we use advanced semantic analysis for precise identification.

```
01.int divideUpLoadFile(char *file_name,UPGRADE_FILE_HEADER
*pFileHeader){...
02.iVar2 = md5_verify_digest(fileMd5Checksum,input,uVar4);
03.if (iVar2 == 0){
04.  pcVar5 = "[%s:%d]md5 error\n"; ...}...}
05.
06.int md5_verify_digest(uchar *digest,uchar *input,int len){
07.  int iVar1;
08.  uchar digst [16];
09.  md5_make_digest(digst,input,len);
10.  iVar1 = memcmp(digst,digest,0x10);
11.  return (uint)(iVar1 == 0);}
```

Listing 2: An integrity verification procedure example.

Efficient Function Similarity Matching. The goal of the first stage is to improve the efficiency of the identification of verification procedure chains by ranking functions with syntactic and structural features. Kim et al. [39] show that the use of numeric syntactic and structural features can efficiently achieve comparable accuracy to more complex deep learning-based methods. Therefore, a combination of numeric features (see Table 4 in Appendix A.2) is selected for two reasons: 1) These features can be efficiently extracted without requiring complex semantic code analysis; 2) The combination of these features can achieve high discriminative capability while being robust across different architectures, compiler types, and code stripping. It is worth noting that the impact of compiler optimizations on these features becomes less significant in embedded systems, where stable and industry-standard compiler options are commonly used, thereby ensuring the robustness of features. Specifically, we obtain syntactic features from the intermediate representation (IR) of code, including attributes from its abstract syntax tree (AST) such as the number of function calls and key strings. Structural features come from CFGs, including the number of BBs, edges, and branches. Using these extracted features, similarity scores between functions in execution paths and those in the corpus are calculated based on the relative difference between their feature values [39]. These scores improve efficiency in the second stage by prioritizing functions with higher similarity scores. Function pairs with similarity scores below a specific threshold (0.5 in this work) are filtered due to the low like-

lihood of similarity. More details on the extracted features, mathematical construction of similarity scores, and similarity score threshold determination can be found in Appendix A.2.

Verification Procedure Chain Identification. A data-flow graph (DFG) can represent the relationship between the data and the arithmetic and logical operations, and it is used in cryptographic primitive identification techniques [47, 51]. To further identify key functions with accurate semantics analysis, we employ DFG subgraph isomorphism. In addition to function semantics, the usage pattern of the return variables and pass-by-reference arguments of key functions is also considered to reduce the FPs of verification procedure matching. The insight is that the return variables or arguments from a key function often feed into a conditional expression. This expression then determines the conditional branch to execute and indicates the pass or fail status of the verification procedure. An example can be seen in Listing 2, where the return variable of the function *md5_verify_digest* is used to determine whether the integrity verification has passed.

We search for verification procedure chains from all execution paths. For each execution path, various types of verification procedures are identified successively. To identify verification procedures, such as authenticity verification, we first select a function pair (f, f') with the highest similarity score, where f is from the execution path and f' is a key function for authenticity verification in the corpus. Then, the DFG of the function f is constructed and normalized to preserve its underlying semantics while eliminating variations introduced by developers, compiler optimizations, or machine code translation. With the DFG, we can verify whether the functions f and f' are functionally equivalent by searching for subgraphs in the DFG of f that are isomorphic to the graph signature of f', using Ullmann's algorithm [71]. If a match is found, function f is considered semantically equivalent to function f'. A reaching-definition analysis is then performed on the return variable and pass-by-reference arguments of f to obtain data-flow slices. If the return variable or arguments flow into conditional expressions, the verification procedure is considered identified. The process continues with the next function pair having the next highest similarity score if no match is found unless there are no remaining function pairs exceeding the similarity score threshold. Upon completion of the second stage, verification procedure chains in all execution paths are identified and ready to be further examined.

Corpus Creation. Key functions are either standard library functions or proprietary functions. Functions responsible for authenticity and integrity checks often encapsulate standard cryptographic routines from well-established libraries [85]. To this end, we collect open-source cryptographic functions from libraries commonly used in embedded systems. Though functions used for freshness and capability checks are usually proprietary, they share similarities within the same device family based on our analysis. These are obtained through reverse engineering of firmware images from various major vendors. We categorize all functions into two: those employing proper cryptographic algorithms or assessing protected verification information and those that do not (see Section 4.3 for details). The next stage involves extracting function signatures, which consist of feature vectors and graph representations. The feature vector is derived through syntactic and structural analysis, while the graph representation is generated after constructing, normalizing, and pruning the DFG. Normalization serves to eliminate redundant nodes and edges, followed by pruning to remove elements irrelevant to the verification process. This approach is commonly used in existing research [47, 51, 78], ensuring accurate function matching across a wide array of possible implementations. Specifically, the process requires pinpointing the variables or arguments holding the essential verification data. After setting these as targets, program slicing is executed to maintain all relevant nodes and edges. For more detailed corpus statistics, please refer to Appendix A.3.

4.3 Vulnerability Discovery

Vulnerability Discovery Criteria. We focus on inspecting the implementation deviation of proper verification procedures for the four properties, i.e., authenticity, integrity, freshness, and compatibility. Despite the lack of verification accounts for most verification stage vulnerabilities, improper implementation of the verification procedure can also lead to an insecure or exploitable verification procedure. In our work, the primary concern of improper authenticity verification arises from the use of symmetric cryptographic algorithms (e.g., HMAC, CMAC, Poly1305). Likewise, we identify that the root cause of improper integrity verification often lies in the usage of weak digest verification algorithms such as CRC, SHA1, and MD5. Finally, for freshness and compatibility verification, our work emphasizes that the verification can be insecure when the verification information, including firmware version and compatible device ID, is extracted from unprotected data sources (e.g., filenames of firmware images).

Vulnerability Discovery Process. We identify vulnerabilities by examining both execution paths and associated verification procedures. If a firmware image contains only one execution path, we focus on that path. For firmware with multiple paths, we select the path with the most proper verification procedures, as this often indicates thorough verification. This strategy can reduce FPs, ensuring more conservative vulnerability identification. Next, vulnerability detection is performed on the sole or chosen path based on the previously defined criteria. Specifically, to identify missing verification vulnerabilities, we check for the absence of verification procedures for authenticity, integrity, freshness, or compatibility in the execution path. To detect improper verification vulnerabilities, we examine the use of improper functions in the corresponding verification procedures in the execution path. It is worth

Table 2: Firmware modification or selection for PoCs.

Type		Firmware Modification or Selection Method
Miss.	Auth.*	Select a firmware image without signature from the same vendor
	Integ.	Alter bits in an update firmware image
	Fresh.	Select an outdated firmware image for the same device
	Comp.*	Select an incompatible image from the same device family
Improp.	Auth.	Alter bits in an update image and resign it with the same key
	Integ.*	Alter bits in an update image and replace its digest
	Fresh.	Select an outdated image and alter its version field
	Comp.*	Select an incompatible image and alter its device ID field

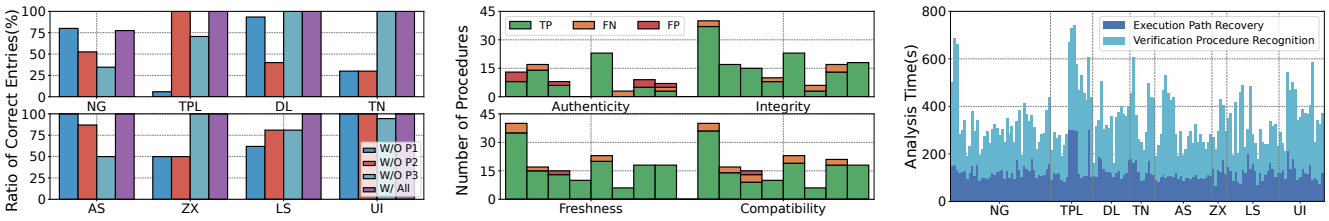
Note: Miss.: Missing; Improp.: Improper; Auth.: Authenticity; Integ.: Integrity; Fresh.: Freshness; Comp.: Compatibility; Vulnerability types marked with an asterisk (*) most likely require patching during test environment generation.

noting that some firmware images perform a quick integrity check using a weak algorithm, followed by a more thorough verification for authenticity and integrity based on digital signature/MAC algorithms. We only report an alert for improper integrity verification when the digest algorithm used in the corresponding digital signature/MAC is also insecure.

4.4 Vulnerability Validation

PoC Creation. We dynamically validate an alert by feeding a PoC input that specifically violates a security property under test and observing whether the firmware update procedure still reaches the reboot stage. If it does, a vulnerability exists; if not, the alert is an FP. The PoC image varies based on alert type, as shown in Table 2. For example, to validate a missing compatibility verification, we replace the benign firmware with an incompatible version from the same device family. However, this process may also alter other properties, complicating root cause analysis. For example, the selected firmware image may also contain an incorrect version number. To mitigate the issue, ChkUp patch and repack the testing firmware to align the execution path of the verification procedure with the property under test.

Patch Generation. We patch to skip verification procedures that may hinder the vulnerability validation of a specific property under test. The patching is conducted either at the source code or binary level, depending on the program type. Typically, we invert conditional expressions without adding extra code, essentially altering comparisons to their opposites (e.g., equal to not equal). Listing 4 in Appendix A.4 presents the disassembly and decompiled code of the compatibility verification procedure of a TP-Link firmware image. This procedure fetches the current product ID using the *getProductVer()* function and extracts the compatible product ID of the new firmware from its file body. The ID comparison is conducted by a *bne* (branch if not equal) instruction. To bypass this verification with the PoC firmware, we can substitute *bne* with a *beq* instruction. Although most verification procedures employ straightforward conditional expressions, some include complex conditions involving various logical operators and multiple variables, some of which are only known at runtime. This complexity makes simple methods like negating comparisons ineffective. To address this, we first conduct a successful firmware update with a benign image and record the values of variables involved in conditional expressions. Next, we perform static value-flow analysis, tracing backward from these variables to identify the instructions where their values are defined. Our investigation indicates that such instructions are typically within the same function, obviating the need for complex control-flow recovery [66]. Finally, with the recorded values and identified instructions, we employ in-place binary rewriting techniques [43] to make use of the previously recorded values, while including conditionals to ensure that the replacement applies only to the firmware execution phase of interest.



5 Implementation

ChkUp is prototyped to support both Linux-based and other embedded OS-based firmware images (equipped with file systems) across various architectures, including ARM, MIPS, and PowerPC. Specifically, the *Execution Path Recovery* module efficiently constructs a UFG for each firmware image within a 300s timeout, representing each UFG as a di-graph using NetworkX [13]. The control flow of various programs is analyzed with tools [22,61,66] like angr [66] for binaries. IPC and program invocation paradigms are identified based on the CPF module from KARONTE [59], extended to support both JavaScript and shell scripts. After constructing UFGs, execution path recovery is conducted using the Simple Paths module of NetworkX at the function level. In the *Verification Procedure Recognition* module, numerical features are extracted from source code (specifically for JavaScript and shell scripts), CFG, and both disassembled and decompiled code (leveraging Ghidra [14]). Upon constructing and normalizing DFGs using the normalization rules by Meijer et al. [51], Ullmann's algorithm is employed for DFG subgraph isomorphism to identify verification procedures. The *Vulnerability Discovery* module is based on the previous two modules and performs vulnerability discovery using the described criteria and process. In the *Vulnerability Validation* module, Firmadyne [18] is initially used for dynamic analysis, and if emulation is unsuccessful, the more advanced FirmAE [42] is employed. Additionally, Ghidra and Firmware-mod-kit [11] are used to patch and repack firmware images.

6 Evaluation

In this section, we evaluated the effectiveness three key modules of ChkUp, i.e., the *Execution Path Recovery* (Section 6.1), *Verification Procedure Recognition* (Section 6.2), and *Vulnerability Validation* (Section 6.3).

Datasets. We collected 157,141 firmware images from the websites of IoT vendors and successfully unpacked 111,958 of them. To enable large-scale analysis, a dataset, D_L, was

(a) Accuracy of update entry identification (b) Metrics of procedure recognition (c) Performance overhead

Figure 4: Evaluation results (NG, TPL, DL, TN, AS, ZX, LS, and UI represent Netgear, TP-Link, D-Link, TRENDnet, Asus, Zyxel, Linksys, and Ubiquiti, respectively).

created by randomly sampling 12,000 firmware images from eight major vendors, including Netgear, TP-Link, D-Link, TRENDnet, Asus, Ubiquiti, Zyxel, and Linksys. To evaluate the effectiveness of ChkUp and validate its alerts, a ground-truth dataset, D_G, was created by sampling from D_L. The construction of the ground truth for the firmware images in D_G was undertaken by four security experts through manual analysis. For details on the dataset construction and manual analysis, refer to Appendix B.1 and Appendix B.2.

Experimental Environment. The evaluation was conducted on a server with an Ubuntu 18.04 LTS OS and an AMD EPYC 7302P CPU with 64GB of RAM.

6.1 Effectiveness of Execution Path Recovery

The effectiveness of the *Execution Path Recovery* module is assessed by the accuracy of the update entry finding as well as the correctness of recovered execution paths.

Accuracy of Update Entry Finding. An update entry program is identified using three types of patterns: prompt message (P1), variable and function name (P2), and common code (P3). To evaluate the effectiveness of each type of pattern, we performed an ablation study, assessing the correctness of the identified entry programs under different settings, specifically, without P1, without P2, without P3, and with all patterns. Evaluation results for firmware from each vendor in D_G are shown in Figure 4a. The highest accuracy is achieved when all patterns are used, and the lowest when only P1 and P3 are employed. This indicates that P2 is the most essential for this process, as its absence often leads to significant performance drops across firmware images from most vendors. The impact of P1 and P3 varies by vendor. For instance, P1 significantly impacts firmware images from TP-Link, TRENDnet, and Zyxel, while P3 is vital for those from Netgear and Asus. Importantly, when using all patterns, the identification demonstrates its robustness by accurately identifying update entry programs of most firmware images. While 9 Netgear firmware images had their update entries misidentified due to limited semantic information, most of these misidentified programs are still related to firmware updates but handle update roles other than firmware delivery.

Correctness of Execution Path Recovery. Upon executing the *Execution Path Recovery* module on firmware images from D_G, ChkUp takes an average of 126.0 seconds for each image (see Figure 4c). As a result, of the 150 generated UFGs, 122 are both firmware update sound and complete. 136 UFGs are sound since since every edge in UFGs represents control flows or IPC paradigms in the update procedures. However, UFGs from 7 Asus, 4 D-Link, and 3 Zyxel firmware images are unsound, yielding unrelated IPC paradigms. 133 UFGs are complete, containing all related control flows and IPC paradigms. However, UFGs from 9 Netgear firmware images are incomplete due to misidentified update entries. Note that the 3 above-mentioned UFGs from Zyxel firmware images are also incomplete due to a mismatch between update entries and back-end handlers. The rest, from 5 TP-Link firmware images, are incomplete due to timeouts during UFG construction.

We found that sound and complete UFGs always lead to the recovery of correct paths, while unsound or incomplete UFGs might introduce incorrect paths or overlook the correct ones during backward slicing. For example, the 3 unsound and incomplete UFGs of Zyxel firmware only contain reboot function invocations that were intended for other device management functionalities (e.g., applying new configurations). Despite this, most incorrect paths do not influence the vulnerability discovery process, as they contain relatively incomplete verification procedures and are filtered out as long as correct paths are also found during the vulnerability discovery. Also, all the overlooked correct paths still contain a reboot step and can be identified once the complete UFGs are constructed.

6.2 Effectiveness of Procedure Recognition

Upon evaluating the *Verification Procedure Recognition* module on D_G, ChkUp recognizes verification procedures for each firmware image in an average of 216.1 seconds (see Figure 4c). The results of recognizing different categories of verification procedures are shown in Figure 4b. Note that the eight columns in each category represent the results of firmware images from Netgear, TP-Link, D-Link, TRENDnet, Asus, Zyxel, Linksys, and Ubiquiti, respectively. In summary, there are 461 true positives (TPs), 45 false negatives (FNs), and 17 FPs. Fewer authenticity verification procedures are recognized because some execution paths indeed lack a firmware authenticity verification procedure, based on our analysis.

ChkUp has the highest integrity verification accuracy, as vendors often use standard functions such as *MD5_Update* with minor or even no customization.

False Result Discussion. The FPs and FNs primarily arise from inaccurate execution paths and misidentification of key functions. Specifically, our analysis reveals that inaccurate execution paths lead to 23 FNs and 6 FPs since either verification procedures are not included or unrelated code is mistakenly identified as verification procedures. For instance, device management functionalities, different from firmware updates, are included in the UFGs of 2 D-Link DAP firmware images and are falsely recognized as authenticity verification procedures. Other FNs and FPs mainly stem from using uncommon key functions or from including functions with similar semantics in execution paths. Notably, 6 FNs arise from deviating from the heuristics guiding the identification of verification procedures: 3 for Zyxel NBG-series images because return variables and arguments of their digest calculation functions do not feed into conditional expressions. A similar issue is seen in the version parsing of Netgear R-series images, resulting in 3 FNs. Further analysis shows that these images display the digests or parsed firmware versions on user interfaces, requiring manual verification. Despite some FNs and FPs, the module remains effective in most cases.

6.3 Effectiveness of Vulnerability Validation

To evaluate the effectiveness of the *Vulnerability Validation module*, we assessed its success rate on D_G and analyzed firmware patching results. Moreover, we measured its scalability on 1,200 additional firmware images from D_L.

Success Rate of Vulnerability Validation. After running the *Vulnerability Discovery* module on D_G, a total of 271 alerts were raised. Of these, 119 alerts were raised for 72 emulatable firmware images in D_G, which are compatible with the *Vulnerability Validation* module. Among the 119 alerts, 90 require patching to create a testing environment for conducting PoCs. Applying the *Vulnerability Validation* module on the corresponding firmware images resulted in 69 successful generations of patched firmware images. Obstacles in creating patched firmware images stem mainly from diverse firmware implementations, including the use of uncommon file systems, which are not supported by the state-of-the-art firmware repacking tool. We then emulated these repacked firmware images and found only 10 failed to run due to violations of runtime firmware signature checks. In total, 88 testing environments from both patched and original firmware images were created successfully. After undertaking PoC creation, 73 PoCs were successfully conducted and the corresponding alerts are considered TPs. Investigation of the failure cases reveals that 6 are indeed FPs and 9 are supposed to be TPs.

Patching Result Analysis. Unsuccessful PoC generation can result from either the alert being an FP or issues encountered during firmware patching. Specifically, patch generation in ChkUp involves three steps: 1) identification of verification procedures to bypass, 2) selection of code segments to modify, and 3) deployment of patched firmware. If the identification of the first step is incorrect, the subsequent patch might not enable further exploration of the program space, leading to an FN. Of the 15 failed PoC cases, 9 were due to this problem. Although not implemented in our current prototype, this issue can be mitigated by monitoring program execution to differentiate between known correct and incorrect running firmware. Even with the correct verification procedure identified, issues like heuristically negating logic in an incorrect code location can arise. Similar to the issue of misidentification, this can be addressed. Yet, we did not encounter any of these cases, likely due to the use of heuristics that work well for known firmware types. Lastly, the deployment of the patched firmware is not always feasible due to challenges with firmware repacking and emulation. A deeper analysis of these challenges is provided later.

Scalability of Vulnerability Validation. The scalability of the *Vulnerability Validation* module is closely tied to its ability to emulate and repack firmware images. To assess this, we analyzed a random sample of 1,200 firmware images, which represent 10% of D_L. Initial emulation tests showed that 44.1% of these images were successfully emulated and thus applicable to this module. Notably, D-Link firmware exhibited the highest emulation success rate, while Ubiquiti firmware had the lowest. For the emulatable images, we achieved a repacking success rate of 72.2%. The most significant factor hindering successful repacking was the presence of file systems that were not as widely supported as common ones like SquashFS and CramFS. Finally, of the repacked firmware images, 82.7% were successfully emulated. The primary reason for most failures was runtime firmware signature checks.

7 Vulnerability Discovery Results

7.1 Alerts on Real-world Firmware

Alert Analysis. We used ChkUp to identify potential vulnerabilities on D_L and analyzed the alert distribution. In terms of performance, ChkUp processed 93.4% of firmware images within 600 seconds each. Timeouts during UFG construction contributed to the extended analysis time observed in 3.4% of the firmware images. ChkUp resolved the execution paths for 10,670 firmware images and generated 15,132 alerts. Figure 5 displays the distribution of alerts by vulnerable verification type for major device types in D_L. Notably, a significant portion of alerts arise from firmware of various network devices (e.g., routers and switches) and cameras due to two primary reasons: 1) Network devices and cameras, which often have publicly accessible firmware images, dominate a substantial share of the IoT market; 2) Many devices reuse vulnerable

Table 3: Vulnerability discovery results of ChkUp on D_G dataset.

Vendor	# FW	Authenticity Verification						Integrity Verification						Freshness Verification						Compatibility Verification					
		Missing			*Improper*			*Missing*			*Improper*			*Missing*			*Improper*			*Missing*			*Improper*

Note: Numbers marked with an asterisk (*) indicate that the TPs correspond to n-day vulnerabilities.

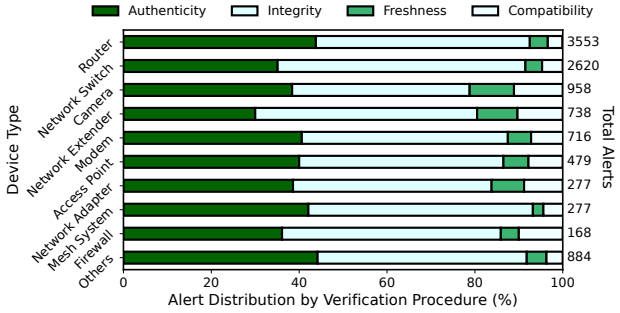

Figure 5: Distribution of alerts for various device types.

code for their firmware foundation and have seen a lack of effective security enhancements, resulting in persistent vulnerabilities across both new and old versions.

The most prevalent security issue reported by ChkUp involved vulnerable integrity verification procedures. For instance, of the alerts for network switch firmware, over half relate to this issue. The majority of these alerts highlight the use of weak algorithms like CRC and MD5. Vulnerable authenticity verification also threatens various device types, notably routers. The primary concern is the lack of verification, but the use of symmetric digital signatures is also widespread. While alerts related to freshness and compatibility verification are less common, cameras and network extenders exhibit more of these alerts than other devices. The most frequent issue involves using unprotected data, such as filenames, to verify versions or device IDs in the firmware update interfaces.

Invalid and Outlier Result Discussion. In the results from ChkUp, the invalid cases primarily consisted of 1,330 firmware images for which ChkUp could not resolve the execution paths. The outlier cases were those 589 firmware images that raised four alerts, which was uncommon as most images typically triggered up to three alerts. We delved deeper into these results by examining a random 10% sample. We found that two primary reasons emerged for the 133 failure cases in execution path recovery: 32.3% of cases stemmed from misidentification of the entry program, and 29.3% from timeouts during UFG construction. The remaining issues were mainly due to unusual IPC implementations or unsupported programming languages, like PHP used for specific firmware update steps. We found no cases where, despite correct UFG construction, the use of reboot functions as slicing targets caused path identification to fail. Moreover, we inspected the verification procedures of 59 firmware images with four alerts to check their validity. Out of these, 39.0% were found to have insecure update mechanisms, while the remaining firmware contained FPs that primarily resulted from misidentified execution paths and verification procedures. Importantly, the key reason for the misidentification of verification procedures was the mismatch of functions between firmware images and the corpus. While most of the procedures that ChkUp overlooked do adhere to the value-to-condition heuristic, some do not. For these outliers that we confirmed as genuine, we provided exceptions, exempting them from the heuristic matching.

7.2 Real-world Vulnerabilities

Validating alerts is both time-consuming and labor-intensive, so our focus was on 150 firmware images from D_G. We employed the *Vulnerability Validation* module for emulatable firmware and manually validated the rest with our ground truth. To pinpoint FNs, all firmware images were assessed using the ground truth. The results are displayed in Table 3. Overall, the TPR is 86.7% and the FPR is 5.3%, demonstrating the effectiveness of ChkUp in detecting vulnerabilities. Most FPs and FNs arose from the *Execution Path Recovery* and *Verification Procedure Recognition* modules as we discussed in our evaluation. TPs for Asus firmware images are n-day vulnerabilities (i.e., CVE-2014-2718, CVE-2020-15498, and CVE-2021-3166), while those for 29 other device families were undisclosed. We have also reported our findings to vendors and received acknowledgment. At the time of writing, 25 CVE IDs and one PSV ID have been assigned. It is worth noting that the majority fall into the categories of CWE-345 and CWE-20. These findings align with our systematization, indicating that these two categories are the most prevalent. More CVE/PSV details are available at our project website [76].

Vulnerability Analysis. Regarding the vulnerability type, improper integrity verification emerged as the most frequent issue, with 39.0% using CRC and 23.8% using MD5. Issues

```
1. upgrade.js
01.function clickUpgrade(form){...
02.  var file_array=file_name.split('-V');...

05.  printf("checksum = 0x%02X, len = %d\n",~uVar5 & 0xff,iVar6);...}
```

Listing 3: Firmware update code in the case studies.

with missing and improper authenticity verification are prevalent. For example, in the firmware from TP-Link WR-series devices, although there exists an RSA signature for authenticity verification in firmware updates, the signature does not protect the firmware header. Moreover, the MD5 sum value is also stored in the header. Therefore, to craft a malicious firmware image that can bypass the verification, an attacker could modify header content and recompute the hash value to replace the original one. Furthermore, fewer vulnerabilities were identified in freshness and compatibility, mostly rooted in the use of unprotected information. For instance, the firmware version verification of D-Link DAP-series devices is to extract the version from the filename of the new firmware image and compare it with the current version. As the filename lacks authenticity and integrity protections, attackers could alter the filename to bypass the verification and introduce vulnerable firmware images to devices.

7.3 Case Studies

Listing 3 shows the firmware verification flows in a firmware image from Netgear WNR-series routers. These devices provide a web interface for manual firmware updates. In the front end of the interface, as seen in line 3 to line 10 of *upgrade.js*, both compatibility and freshness are verified by examining the filename of the uploaded file, a method we have already identified as vulnerable. After passing these verifications, the back-end shell script *webupgrade.sh* proceeds with further verification. From line 2 to line 6 of *webupgrade.sh*, the firmware header is examined to ensure compatibility. Therefore, compatibility can be ensured as long as firmware integrity is ensured. Integrity verification occurs in *webupgrade.sh* (see line 7 to line 10) through the binary *mychecksum*. Upon inspection, *mychecksum* uses the weak CRC algorithm for this verification. Notably, authenticity verification is absent. As a result, these vulnerable verification procedures make the firmware update mechanism susceptible to real-world exploits.

Real-world Exploits. We showcase the exploitability of these vulnerabilities by crafting two exploits, specifically a *firmware downgrade attack* and a *firmware modification attack*, targeting a Netgear WNR-series router. In these attack scenarios, both attackers and the target device share the same network environment. Attackers can either directly access the firmware update interface or sniff the network and initiate MITM attacks, given that the communication for firmware delivery uses unencrypted HTTP. Notably, during our preliminary manual firmware analysis, we found a significant number of public firmware images lack TLS for update interfaces, highlighting the feasibility of these attacks in the real world.

A1. Firmware Downgrade Attack: Since the firmware freshness is determined by checking the filename of the uploaded file, attackers can craft a malicious firmware image using a legacy firmware image by changing its version field in the filename to match a legitimate one. Then, they can either upload the malicious firmware image through the web interface or substitute the benign firmware image through MITM. Subsequently, the firmware is replaced with an insecure legacy version with vulnerabilities, which can be further exploited.

A2. Firmware Modification Attack: As the firmware integrity verification is based on CRC checksum, attackers can create a modified firmware image while keeping the checksum value consistent. However, some fields, such as device ID in the header for compatibility verification, need to remain unchanged to ensure other verification procedures proceed successfully. Attackers can introduce the malicious firmware to the device in the same way mentioned in *firmware downgrade attack*. With this attack, if the malicious firmware is carefully crafted, various further attacks can be introduced, including backdoors, malware, and DoS attacks.

8 Discussion

Security Impacts of Heuristics. Heuristic approaches capture common patterns discovered via manual reverse engineering. While effective for firmware images with similar patterns, they cannot capture the foundational problem that can be generalized across different systems. In the context of ChkUp, our approach that attempts to heuristically identify the entry and end of firmware update paths can fail on customized firmware, preventing the analysis from starting. Furthermore, our heuristic approach that uses information flow from the crypto function to identify the update phase could fail to extract the correct update phase code. From the evaluation, we found that such heuristics can fail on unconventional designs.

Limitations of Static and Dynamic Analysis. There is a trade-off between static analysis and dynamic analysis. However, when used appropriately in combination, they provide a good balance between completeness and soundness of analysis. In the context of ChkUp, a key advantage of static analysis

is the elimination of the need to emulate firmware, which remains an open research challenge. For example, out of 150 firmware images in D_G, only 72 are emulatable using state-of-the-art firmware emulators. The emulation rate is even lower for bare-metal firmware. Another advantage of static analysis is the ability to detect deeper bugs where crafting an input to reach the bug is extremely challenging. For example, 39 firmware images check the cryptographic signature before proceeding to the buggy verification procedures. Yet, static analysis often results in many false alarms. To mitigate this, ChkUp leverages dynamic analysis to attempt to provide a level of validation, albeit a basic one. Besides the challenge of emulation, dynamic analysis only allows the validation of one path at a time, limiting the breadth of exploration. For ChkUp, success also depends on the patching being performed correctly, which is not always true as discussed.

Extensibility of ChkUp. Beyond firmware update vulnerabilities, our techniques can detect vulnerabilities like faulty firmware function implementations (e.g., in cryptographic functions). By adding faulty function signatures to the corpus, we ensure that even if there are correctly implemented counterparts, the vulnerable function will match its signature based on a higher similarity score, enabling us to pinpoint the use of flawed implementations. ChkUp is tailored for multi-architecture Linux and other embedded OS firmware with file systems. While bare-metal firmware analysis poses challenges, like addressing base resolution, most do not require cross-language control/data flow analysis. By incorporating methods from FirmXRay [77] and updating the corpus, ChkUp could handle bare-metal firmware too. Our technique is not vendor-specific; if ChkUp supports the firmware type, it can analyze it. Though FPs can occur, our system can still offer insights like firmware update paths. Extending the corpus can further improve the accuracy of ChkUp.

9 Related Work

Firmware Update Security. Recent studies have revealed security concerns in firmware or software update mechanisms [15, 17, 21, 57, 63, 70]. Notably, the prevalent use of insecure protocols like HTTP can expose update processes to MITM and backdoor attacks [17, 63]. Moreover, there are demonstrated firmware modification attacks by exploiting update procedure weaknesses [21, 70]. Both academics and the Internet Engineering Task Force (IETF) are addressing these concerns by developing secure firmware update strategies [46, 53] and efficient hotpatching solutions [35, 54].

Vulnerability Detection in Firmware. Firmware vulnerability detection is broadly divided into three categories. The first group [37, 40, 68, 77, 82, 87] detects vulnerabilities by identifying discrepancies between specifications and actual implementations. For example, FirmXRay [77] uncovers Bluetooth layer vulnerabilities using specification knowledge. The second category uses methods like taint analysis [19, 27, 59, 83, 85] and symbolic execution [25, 32, 34, 36, 65] to explore vulnerable execution paths. For instance, Karonte [59] targets memory-corruption vulnerabilities by pinpointing unsafe user-controlled input sinks. The third category involves pattern matching [20, 38, 44, 81] and code similarity checks [23, 24, 28, 33, 39, 41, 49, 50, 64, 75, 79, 88], detecting vulnerabilities by matching known patterns or vulnerable code, such as FirmUP [24] that uses procedure similarity. Our research specifically targets firmware update vulnerabilities, which are distinct due to their multi-stage nature and the unique semantics of firmware updates.

Cryptographic Misuse Detection: Cryptographic API misuse detection is a technique for identifying potential vulnerabilities stemming from incorrect usage of cryptographic primitives [16]. The general idea is to verify that parameters passed to cryptographic APIs meet pre-defined rules [26, 29, 31, 45, 56, 58, 67, 85]. ChkUp differs from existing cryptographic misuse detection studies in terms of system goals, security impact and technical standpoints. Regarding security goals, ChkUp focuses on firmware update security, providing a fundamentally distinct focus. Instead of analyzing individual cryptographic vulnerabilities, our approach involves systematizing the firmware update ecosystem and conducting a security analysis to map the attack surface, uncovering a significant amount of non-crypto attack vectors. From the perspective of security impact, ChkUp provides new ways to automate the search for firmware update vulnerabilities, covering both crypto misuses and non-crypto-related vulnerabilities such as downgrade attacks. From the technical perspective, ChkUp tackles new challenges, including identifying long sequences of inter-process invocations as well as discovering and validating firmware update-specific semantic bugs.

10 Conclusion

In this paper, we present ChkUp, a novel approach for detecting firmware update vulnerabilities, including missing and improper verification during updates. Specifically, ChkUp resolves firmware update execution paths through cross-language inter-process control flow analysis and program slicing. Then, firmware verification procedures are identified through syntactic, structural, and semantic program analysis. These procedures along with the corresponding execution paths are further examined based on our defined criteria to detect vulnerabilities. To reduce false positives, alerts for emulatable firmware images are validated dynamically with a patching-based method, while others are validated manually. ChkUp is implemented and employed to analyze 12,000 firmware images, with subsequent validation of alerts for 150 firmware images from 33 device families. The results show that ChkUp can identify zero-day and n-day vulnerabilities, leading to the assignment of 25 CVE IDs and one PSV ID.

A Additional Design Details

A.1 Path Explosion Reduction

Five path explosion reduction strategies are utilized in ChkUp. The initial three are applied during UFGs construction, and the last two during backward slicing. 1) Excluding non-crypto standard libraries: Standard libraries are omitted from UFG construction to reduce complexity, with an exception for cryptographic libraries for vulnerability identification without significantly increasing UFG complexity. 2) Omitting built-in utilities: During firmware updates, known built-in utility programs (e.g., *mtd*, *reboot*) are executed, negating the need for control flow analysis. 3) Implementing a timeout: If UFG generation takes excessive time, a timeout strategy limits UFG complexity and the inclusion of FP paths. 4) Applying path filtering: Execution paths are refined by filtering based on error messages from unsuccessful firmware updates causing device reboots. 5) Path merging: Post backward slicing, paths with identical verification procedures and nodes are merged for their equivalent semantic meanings.

A.2 Function Similarity Matching

Similarity Score Calculation. With extracted features (see details in Table 4), we can calculate the similarity between a function f and a function in the corpus f' based on the relative difference between their feature values [39]. Given

Table 4: Syntactic and structural features of functions.

Category	Feature
Data Constant	# constants, # strings
Instruction	# all instructions, # operands, # each type of instructions[1]
CFG	# BBs, # edges, # loops, avg. # edges per BB, * BBs, * loops
Function Call	# imported calls, # incoming calls, # outgoing calls
Misc.	# arguments, # API callees, # library references, # code references

Note: #: The number of; *: The size of; avg.: average. [1] Instruction type: arithmetic, branch, data transfer, logic, and bit-oriented instructions.

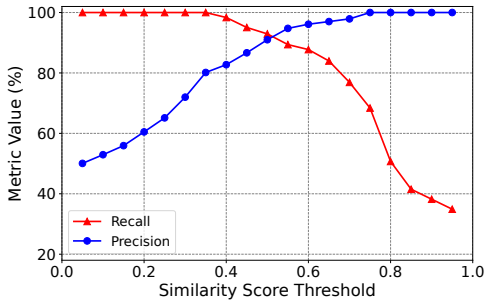

Figure 6: Effect of threshold selection on function matching.

M features, the feature vectors for f and f' are represented as $\mathbf{f} = [x_1, x_2, \cdots, x_M]$ and $\mathbf{f}' = [x'_1, x'_2, \cdots, x'_M]$, respectively. The relative difference δ between x_i and x'_i is

$$\delta(x_i, x'_i) = \frac{|x_i - x'_i|}{Max(|x_i|, |x'_i|)}. \quad (1)$$

From this, the similarity score between the two features is $1 - \delta(x_i, x'_i)$. Then, the overall similarity score of f and f' is defined as the average similarity score for all features by

$$\gamma(\mathbf{f}, \mathbf{f}') = 1 - \frac{1}{M}(\delta(x_1, x'_1) + \delta(x_2, x'_2) + \cdots + \delta(x_M, x'_M)). \quad (2)$$

The value ranges of $\delta(x_i, x'_i)$ and $\gamma(\mathbf{f}, \mathbf{f}')$ are 0 to 1. The higher the $\gamma(\mathbf{f}, \mathbf{f}')$, the more similar f and f' are considered to be.

Based on this similarity score definition, we assess the similarity between each function in the execution paths and each function in the corpus. The corpus contains Q key functions divided into four sets: $\mathbf{S}_n^a$, $\mathbf{S}_n^i$, $\mathbf{S}_n^f$, and $\mathbf{S}_n^c$. Given N recovered execution paths of a firmware image, we calculate four similarity matrices for each path including $\mathbf{S}_n^a$, $\mathbf{S}_n^i$, $\mathbf{S}_n^f$, and $\mathbf{S}_n^c$. Each matrix represents the similarity scores between functions in the n-th path and those in the corpus for a specific verification procedure. For instance, the similarity score matrix $\mathbf{S}_n^a$ for authenticity verification of the n-th path is defined as

$$\mathbf{S}_n^a = \begin{bmatrix} \gamma(\mathbf{f}_1, \mathbf{f}'_1) & \gamma(\mathbf{f}_1, \mathbf{f}'_2) & \cdots & \gamma(\mathbf{f}_1, \mathbf{f}'_Q) \\ \gamma(\mathbf{f}_2, \mathbf{f}'_1) & \gamma(\mathbf{f}_2, \mathbf{f}'_2) & \cdots & \gamma(\mathbf{f}_2, \mathbf{f}'_Q) \\ \vdots & \vdots & \vdots & \vdots \\ \gamma(\mathbf{f}_P, \mathbf{f}'_1) & \gamma(\mathbf{f}_P, \mathbf{f}'_2) & \cdots & \gamma(\mathbf{f}_P, \mathbf{f}'_Q) \end{bmatrix}, \quad (3)$$

where P is the number of functions in the execution path and $\gamma(\mathbf{f}_p, \mathbf{f}'_q)$ is the similarity score between the p-th function in the execution path and the q-th function in the corpus, as calculated using Equation 2. Note that when there is function overlap in the execution paths, the similarity score between each function pair is only calculated once.

Similarity Score Threshold Selection. In the first stage of the *Verification Procedure Recognition*, the similarity score threshold should effectively eliminate a substantial number of irrelevant functions while preserving the majority of essential key functions. This approach can ensure efficient and accurate recognition of the verification procedure in the second stage. To establish this threshold, we calculated numerous similarity scores between key functions found in the firmware images from D_G and their counterparts in the corpus. Moreover, we selected an irrelevant function at random for each key function in every firmware image and calculated its similarity score with the corresponding function in our corpus. In total, we assessed 1,012 functions and generated their respective similarity scores. Subsequently, we defined a range of similarity score thresholds, ranging from 0 to 1 in increments of 0.05, and measured the recall and precision at each threshold. As illustrated in Figure 6, a threshold of approximately 0.5 delivers an optimal balance between precision and recall, with both metrics exceeding 90%. Consequently, we selected a similarity threshold of 0.5.

Table 5: Cryptographic functions in the corpus.

Library	Integrity		Authentication	
	Proper	*Improper*	*Proper*	*Improper*
Libcrypto [2]	SHA256_Update, SHA3_absorb, RIPEMD160_Update, etc.	MD4_Update, MD5_Update, SHA1_Update, etc.	RSA_verify, DSA_verify, ECDSA_do_verify, etc.	HMAC_Update, CMAC_Update, Poly1305_Update, etc.
wolfCrypt [6]	Sha256Update, Sha3_512_Update, RipeMdUpdate, etc.	Md4Update, Md5Update, ShaUpdate, etc.	RsaSSL_Verify, DsaVerify, ecc_verify_hash, etc.	HmacUpdate, CmacUpdate, Poly1305Update, etc.
LibTomCrypt [3]	sha256_process, sha3_process, rmd160_process, etc.	md4_process, md5_process, sha1_process, etc.	rsa_verify_hash, dsa_verify_hash, ecc_verify_hash, etc.	hmac_process, omac_process, poly1305_process, etc.
Mbed Crypto [4]	sha256_update_ret, sha512_process, ripemd160_update_ret, etc.	md4_update_ret, md5_update_ret, sha1_update_ret, etc.	rsa_pkcs1_verify, ecdsa_verify	cipher_cmac_update, md_hmac_update, poly1305_update, etc.
Nettle [5]	sha256_update, sha3_update, ripemd160_update, etc.	md4_update, md5_update, sha1_update, etc.	rsa_sha512_verify, dsa_verify, ecdsa_verify, etc.	hmac_sha1_update, cmac_aes128_update, poly1305_aes_update, etc.

Note: Function names in wolfCrypt, Mbed Crypto, and Nettle are prefixed with *wc_*, *mbedtls_*, and *nettle_*, respectively; Omitted functions implement algorithms from the same family of algorithms implemented by the listed functions, for example, MD2 for improper integrity verification and SHA512 for proper integrity verification.

A.3 Corpus Statistics

Key functions in the corpus include the functions from open-source libraries and proprietary functions obtained during the construction of the ground truth. Overall, the corpus contains 129 functions: 76 from widely used libraries and 53 that are proprietary. Our observations on key functions used for integrity and authentication verification align with previous work [85], showing that executable programs generally utilize either low-level cryptographic APIs from standard libraries or employ self-defined APIs that wrap these low-level APIs. Therefore, our corpus includes common cryptographic functions for digest algorithms (such as SHA family, MD family, and RIPEMD family), digital signature algorithms (such as RSA, DSA, and ECDSA), and MAC algorithms (such as HMAC, CMAC, and Poly1305) from standard libraries, namely *Libcrypto* [2], *wolfCrypt* [6], *LibTomCrypt* [3], *Mbed Crypto* [4], *Nettle* [5]. These functions are further classified into two categories (proper and improper) based on their corresponding algorithms (see Table 5 for details). In addition, non-cryptographic digest functions based on CRC, considered weak for integrity verification, from *zlib* [7] and *LibCRC* [1] are included. All these functions are compiled for ARM (both 32-bit and 64-bit), MIPS (both 32-bit and 64-bit), and PowerPC (both 32-bit and 64-bit) architectures using the GCC compiler with optimization levels ranging from O0 to O3.

Proprietary functions in the corpus include those used for

```
Disassembly Code
01.lw   s0,0x44(s2)
02.jalr  t9=>getProductVer
-03.bne   s0,v0,LAB_004e9c4c
+04.beq   s0,v0,LAB_004e9c4c
05._li   v1,0x4655
06.clear  v1
07.LAB_004e9c4c:
08.lw   ra,local_4(sp)
09.move   v0,v1
10.jr   ra
```

```
Decompiled Code
01.iVar5 = *(int *)(param_1
+ 0x44);
02.iVar1 = getProductVer();
-03.if (iVar5 != iVar1) {
+04.if (iVar5 == iVar1) {
05.    return 0x4655;
06.}
07.return 0;
```

Listing 4: A compatibility verification patch example.

freshness and compatibility verification and developer-defined functions for integrity and/or authenticity that significantly differ from open-source alternatives. These functions were collected through our manual analysis while constructing the ground truth using firmware images from eight different vendors, as outlined in D_G. During this process, we observed that key functions in firmware images from the same device family or vendor tend to be similar. For example, all firmware images from the Asus DSL-N families in D_G feature similar key functions. As a result, the proprietary functions in the corpus can be scaled across numerous firmware images besides their source firmware images. To facilitate vulnerability discovery, all functions are classified into proper and improper categories, based on whether the information used for verification is protected as mentioned in Section 4.3.

A.4 Patching Example

Listing 4 shows the disassembled and decompiled code for the compatibility verification in a TP-Link firmware image. This procedure can be bypassed with our patching method.

B Firmware Collection and Manual Analysis

B.1 Evaluation Datasets

Firmware Collection and Unpacking. We developed a web crawler to collect firmware images primarily from official websites of major vendors in areas like network devices, cameras, and smart home devices [80]. The collected 157,141 firmware images from 204 vendors were then unpacked using Binwalk [60] to extract the file system, kernel, and bootloader, successfully unpacking 111,958 firmware images (statistics can be found in our website [76]). Given the differences in firmware update mechanisms across various vendors, building a ground truth for evaluating ChkUp with firmware images from all vendors demands substantial manual work. Thus, we built a large-scale dataset, D_L, by randomly sampling 12,000 (just over 10%) firmware images consisting of eight leading vendors (i.e., Netgear, TP-Link, D-Link, TRENDnet, Asus, Ubiquiti, Zyxel, and Linksys) from our collection of unpacked firmware images. The eight vendors have significant market share in the embedded device market, notably holding over 60% market share in the wireless router market.

Ground Truth Dataset. Thoroughly evaluating ChkUp and validating its alerts requires manual analysis to establish ground truth, a labor-intensive process even for experts. To establish a ground-truth dataset, D_G, we performed a weighted random sampling of 150 firmware images from D_L, prioritizing those from various device families. These selected images originate from 33 different device families of the eight leading vendors. Then, manual analysis is performed by four security research field experts to build ground truth for D_G (for details, refer to Appendix B.2). With the ground truth, D_G is used to evaluate the effectiveness of ChkUp in Section 6 and validate the generated alerts by ChkUp in Section 7.

B.2 Manual Firmware Analysis

Assumption. Since a ground truth dataset is theoretically impossible to obtain, we have to assume that our manual analysis and cross-validation among different members provide a good approximation to the ground truth.

Approach. A four-member team of experienced security researchers performed the analysis. One team member is a senior computer security researcher with almost 20 years of experience, while the other three members have about 7 years of exposure to computer security. Given a firmware image, the objective is to figure out its firmware update mechanism by resolving all the invoked programs and their execution sequences, as well as all the critical verification procedures. To this end, we use a multi-step, documentation-supported approach. First, we search all the programs suspected of containing firmware update functionalities based on firmware update-related keywords like *firmware update* and *firmware upgrade*. We perform a careful review of any available firmware documentation and README files. These resources are invaluable for validating hypotheses about the function of specific binaries, effectively compensating for the absence of embedded information. For instance, if the screenshots of update interfaces are provided in the documents, the corresponding front-end programs can be easily found.

Secondly, we conduct a control flow analysis to understand the program execution sequence using the binary analysis tool, Ghidra. Data flow analysis, facilitated by angr, reveals how data moves and changes within the programs, providing insights into critical verification procedures. For emulatable firmware images, we also perform emulation to record the firmware update execution paths. Finally, we perform cross-validation to mitigate the limitations in analysis accuracy stemming from the varying experiences of researchers. Specifically, team members independently assess the same binaries and subsequently reconcile their findings. This process depends on internal peer reviews and external documentation to arbitrate discrepancies. Consequently, our approach guarantees a comprehensive examination, establishing a robust foundation for a reliable ground truth.

Abstract

Users' growing concerns about online privacy have led to increased platform support for transparency and consent in the web and mobile ecosystems. To that end, Android recently mandated that developers must disclose what user data their applications collect and share, and that information is made available in Google Play's *Data Safety* section.

In this paper, we provide the first large-scale, in-depth investigation on the veracity of the Data Safety section and its use in the Android application ecosystem. We build an automated analysis framework that dynamically exercises and analyzes applications so as to uncover discrepancies between the applications' behavior and the data practices that have been reported in their Data Safety section. Our study on almost 5K applications uncovers a pervasive trend of incomplete disclosure, as 81% misrepresent their data collection and sharing practices in the Data Safety section. At the same time, 79.4% of the applications with incomplete disclosures do not ask the user to provide consent for the data they collect and share, and 78.6% of those that ask for consent disregard the users' choice. Moreover, while embedded third-party libraries are the most common offender, Data Safety discrepancies can be traced back to the application's core code in 41% of the cases. Crucially, Google's documentation contains various "loopholes" that facilitate incomplete disclosure of data practices. Overall, we find that in its current form, Android's Data Safety section does not effectively achieve its goal of increasing transparency and allowing users to provide *informed* consent. We argue that Android's Data Safety policies require considerable reform, and automated validation mechanisms like our framework are crucial for ensuring the correctness and completeness of applications' Data Safety disclosures.

1 Introduction

Android is the most prevalent mobile operating system, powered by an ecosystem of diverse devices and millions [9] of applications. Throughout its lifetime, Android has undergone major changes aiming to address its underlying security and privacy issues. In particular, one of its most critical components that has received much scrutiny from the research community is the permission system, and a large body of work has explored the permission system's limitations and proposed modifications and countermeasures [46, 69, 74, 76]. This has resulted in Android's permission system evolving significantly over time and deviating from its original design.

While early Android versions required users to accept *confusing blocks of information* (i.e., permissions) prior to installing an application [39], later versions allowed users to accept or reject permission requests at runtime. Prior to installing an app, Android users can access information pertaining to the app's permissions in the Google Play store. This permission list is automatically generated during the app's vetting process by parsing the app's Manifest file. Nonetheless, many users may still not fully grasp how permissions work and what information is collected by a granted permission. In fact, Eling et al. [34] showed that users are more likely to deny a permission request when a detailed description of the accessed personal information is provided. Moreover, a study on the runtime permission model [70] found that misunderstandings are common among users, and that most are unable to accurately infer the resources that are protected and the actions that are permitted by each permission group.

To further simplify permissions, and following Apple's Privacy Nutrition Labels for iOS [61], Google recently introduced the *Data Safety* section which allows applications to disclose the personal data that they collect and share. The Data Safety section, which came into effect in July 2022 [11], requires developers to complete a comprehensive Data Safety form and declare all the data that their application collects or shares. While Google Play's permission list section was removed from the official store [18], considerable pushback from the developer community showed that the permission list is useful and shortly after was reinstated [16]. Currently, both the Data Safety information and permission list remain available in the Google Play store.

Even though the information provided in the Data Safety section can help users better understand how their personal

data is being used, it relies solely on the developer to declare what data the application will collect and share. Essentially, this approach considers developers to be truthful and transparent (which may not always be the case), as well as fully cognizant of the data their app collects. In reality, this can be complicated by embedded third-party libraries, since developers may not be fully aware of the embedded code's functionality and its privacy implications [41]. As developers already spend considerable effort handling third-party libraries' privacy issues [75], being responsible for ensuring the accuracy of the Data Safety section can be challenging.

To make matters worse, the official Data Safety documentation [11] outlines a set of different policies that determine when data collection and sharing should be disclosed in the Data Safety section. We find that these policies are relaxed in many cases and, in general, can be vague and confusing. This not only inhibits users from being informed about the collection and handling of their data, but may also affect developers' ability to accurately declare all relevant information. Importantly, these policies also create "*loopholes*" that allow developers to misuse the system and deliberately avoid declaring certain pieces of information.

Motivated by these observations, we design a methodology and analysis pipeline that searches for discrepancies between the information declared in the Data Safety section on Google Play and the actual information that Android apps collect and share, as well as the extent to which such violations occur. To that end, we develop a framework that collects applications with their metadata and Data Safety sections from the Play Store, and dynamically exercises them to identify the information that each app accesses and shares over the network. Our framework monitors all API methods that lead to sensitive personal information or device data, which we have manually mapped to the corresponding Data Safety labels, and dynamically traverses the apps to trigger these calls. Furthermore, our tool identifies and interacts with in-app consent dialog boxes, and tests them under five different scenarios that explore how apps' data practices are affected by user consent.

Using our framework we conduct the first, to our knowledge, automated analysis of Android's Data Safety section. Our in-depth, longitudinal analysis reveals a multitude of discrepancies and widespread violation of data transparency. We uncover severe inaccuracies in apps' Data Safety sections, with 69.2% of apps not fully disclosing the data they collect and 43.1% the data that they share. Overall, we find that 81% of the tested apps contain at least one discrepancy in their Data Safety section, and that issues persisted for an entire year after the Data Safety section was made mandatory. Furthermore, we find that while in 59% of the cases the discrepancies originate from embedded third-party libraries, app developers are almost equally complicit in not accurately disclosing their own data practices. The implications of our findings are further exacerbated by the fact that applications not only violate Google's Data Safety policies, but also violate Google's policy governing consent requirements. We argue that Google's vague and ambiguous policies can lead to confusion, while also enabling misuse and the surreptitious exfiltration of personal data, thus significantly undermining the potential benefits of the Data Safety section.

The key contributions of our work are the following:

- We analyze the official Data Safety documentation and identify instances of relaxed policies that can confuse users and/or developers, which also enable misuse scenarios with severe ramifications. We then create a mapping of Data Safety labels to the corresponding function calls, which is necessary for analyzing them within the broader context of Android privacy research.
- We develop a dynamic analysis framework and a pipeline that automatically identifies discrepancies between apps' runtime behavior and their Data Safety section, under different user consent scenarios.
- We conduct an extensive longitudinal investigation of Data Safety discrepancies in popular Android apps. Our study uncovers alarming practices and rampant violations of data transparency and user consent. We have disclosed our findings to Google, and will facilitate additional research by publicly sharing our code and data.[1]

2 Background & Motivation

Google Play includes a dedicated section for each app that informs users about the data that the app collects and shares. The Data Safety section consists of three parts, specifically the *Data Collected*, *Data Shared* and *Security Practices* parts. The *Data Collected* part includes information about the data that the respective app collects, while the *Data Shared* part shows which of the collected data is being shared with third parties [11]. Google Play displays the Data Safety section information regarding the data that is collected and shared by using a list of predefined labels (e.g., `Location`, `Contacts`, `Photos or videos`). The *Security Practices* part informs users whether the app uses encryption when transmitting data, if data deletion is possible, and whether the app has been independently reviewed against a global security standard [36]. Moreover, the Data Safety section is mandatory for all apps, and all relevant information needs to be provided by developers when submitting their apps to Google Play, even if no data will be collected or shared.

The Play Console Help [1] provides guidelines for developers, and outlines the policies to be followed for completing an app's Data Safety section. However, our analysis of the policies described in the "User Data" part of the documentation [37], which determine when data collection and sharing should be disclosed, are vague in places and can enable problematic practices. For instance, in the case of *Data Collected*, the documentation specifies that it concerns data transmitted

[1] https://github.com/GiannisArk/USENIX24_DataSafety

off a user's device, with the exception of (i) data that is accessed and only processed locally on the user's device, and (ii) data that is sent off the user's device but is end-to-end encrypted (i.e., messaging apps). A crucial detail is that data that is transmitted off device but only processed "ephemerally" does not need to be disclosed in the Data Safety section.

Moreover, in the case of *Data Shared* policies that concern data transmitted from an app to a third party, the documentation presents several types of data transfers that do not need to be disclosed. These include data transfers to (i) "service providers" that process data on behalf of the developer, (ii) "legal purposes" such as legal obligation or government requests, (iii) "user-initiated action or prominent disclosure and user consent", and (iv) "anonymous data" that can no longer be associated with an individual user.

These policies are overly permissive and potentially unclear, as they rely on complicated terminology and definitions, which may allow apps to exploit "*loopholes*", as was also noted recently by Mozilla [12]. Even more problematic is the policy that allows data transfers based on "user-initiated action or prominent disclosure and user consent" without the need to disclose these transfers. In other words, developers and third-parties can access and transmit user data without declaring it in the Data Safety section if the user consents through the in-app user dialog at runtime. However, prior work has highlighted the use of dark patterns in runtime consent dialogues [72], which can affect users' decision making [52].

In summary, our analysis of Google's policies reveal various opportunities for misinformation and incomplete disclosure of applications' data practices. This motivates our in-depth investigation of Android applications' data practices and their correlation to the corresponding Data Safety section disclosures by app developers. We believe that all data regulated by privacy laws (e.g., GDPR) needs to be declared in the Data Safety section when collected or shared by apps, and Google should not be introducing additional loopholes and exemptions based on arbitrary heuristics. While exemptions to such regulations exist, the well-defined exemption criteria defined by GDPR do not typically cover the nature of the Android apps that we have analyzed, or the specific behaviors that we have uncovered. Throughout the paper we consider as a *discrepancy* any case where data is accessed or shared at runtime without having been disclosed in the app's Data Safety section. Consequently, we use the term data leak, when referring to apps sharing information without disclosing it.

3 System Design and Implementation

Here we describe our methodology for identifying data that is being collected and shared by Android apps, and provide details regarding our framework's implementation. Figure 1 provides an overview of its components and analysis pipeline. Our system consists of several components that allow us to (i) monitor API methods (e.g., framework functions like the

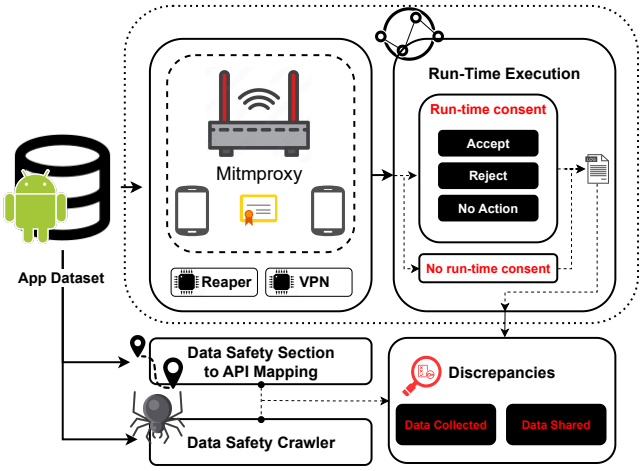

Figure 1: Overview of our framework and analysis pipeline.

Telephony API) and map them to Data Safety labels (i.e., types of information) for identifying discrepancies in the *Data Collected* segment, and (ii) monitor network traffic for identifying discrepancies in the *Data Shared* segment of the Data Safety section. Our framework builds upon existing tools [32], which were modified and extended to match our needs.

Android API monitoring. We monitor API methods by utilizing Reaper [32], a dynamic analysis system that traces permissions requested by apps and non-permission-protected functions that yield Personally Identifiable Information (PII). Since permission mappings do not exist for Android 12 (which was the latest stable version during the time of our experiments), we used the permission mappings provided by DYNAMO [27] for Android 10 as a starting point for constructing our own list of permission-protected functions.

Furthermore, due to the constant evolution of permission-protected APIs and their permission specification, we also followed the methodology employed by APER [77] for identifying any missing or false entries for our target version. Specifically, we traversed all the Java source files for Android 12 and identified all the API methods that have the `@RequiresPermission` annotation tag to specify their permission requirements. Our final list of permission mappings includes all the permission-protected functions of DYNAMO and those that have been identified statically from the source code and the documentation. When encountering differences in the permission annotation of functions between DYNAMO and the permission annotation identified through the Java source files, we used the permission annotation of the latter. Moreover, as apps and third-party libraries are prone to accessing PII from functions that are not permission-protected, our framework also incorporates known PII functions (see Appendix A) from prior work (e.g., [32, 63]).

Data Safety section to API Mapping. The Data Safety section uses predefined labels (e.g., `Location`, `Messages`, `Photos or videos`, `Contacts`) as a high-level, user-

Table 1: Data Safety labels mapped to the functions called by apps in our datasets (coarse- and fine-grained categories).

Category	Sub-categories
App info and performance	Diagnostics, Other app performance data
Location	Approximate location, Precise location
Personal info	Name, Phone number
Photos or videos	Photos
Audio files	Music files
Files and docs	
Contacts	
App activity	
Device or other IDs	

friendly way of describing the information that each Android app can collect and share. Since our system monitors access to function calls (regardless of them being permission-protected or not), we followed a specific process for mapping each function call to the corresponding Data Safety labels that accurately describe the information accessed, thus also indirectly categorizing the collected and shared data. As a first step in this process, we automatically exercised all the apps in our datasets, and out of the 6,955 function calls that our system monitors, we selected 295 functions that were actually accessed by the apps we exercised. This significantly narrowed down the functions that require Data Safety labeling, to only those that were actually accessed by the apps in our datasets. Next, we manually assigned Data Safety labels to these 295 functions and removed any functions that do not require a Data Safety label (e.g., `SystemVibrator.vibrate()`). We took into consideration the relevant permissions and examined the official Data Safety developer guideline documentation [30] and the Java source code of the respective function calls. For example, `getLastKnownLocation()` and `getCurrentLocation()` are mapped to the Location, Precise location and Approximate location labels. Our Data Safety mappings consist of a list of 94 functions that are mapped to 17 different Data Safety labels, with 9 of the labels corresponding to coarse-grained categories and 8 to fine-grained subcategories (e.g., category: App info and performance, with sub-categories: Diagnostics, Other app performance data). All the labels used in our mappings are shown in Table 1. We note that Table 1 does not include labels that relate to personal user identifiers such as name, surname and email, which we detect through network traffic monitoring.

To ensure the accuracy of our manual labeling, this process was performed independently by two of the authors, who subsequently compared their function-label mappings. In cases where the two researchers' mappings did not perfectly align, the two researchers conferred and re-examined the specific cases along with a third co-author. Overall, only a few mismatches occurred between the two labellers and these were cases of assigning labels of a different granularity (e.g., Location and Precise Location). These were all rectified during the re-examination process, based on a majority vote. More specifically, out of the 295 functions examined, the two labellers had a precise agreement (i.e., all assigned labels match) for 242 functions (82.03%). These also include cases where the labellers decided that no Data Safety label is required, and marked it as *NoLabel*. In 8 cases (2.71%) the researchers had assigned some matching labels, but not all labels perfectly matched. For example, for the `getLine1Number()` one researcher assigned the Personal info and Phone number labels, and the other assigned only the Personal info label. After conferring, both labels were assigned to this function. Furthermore, in 44 cases (14.91%) only one of the two labellers assigned a label, while the other one marked them as *NoLabel*. These were cases of uncertainty, and were all discussed and addressed in the presence of a third researcher. Finally, we had a single case of a label category disagreement, for `getDefaultOutgoingPhoneAccount()`, where one labeller assigned the Contacts label and the other the Personal info one. Since this function returns a `PhoneAccount` object we decided that the appropriate label should be Contacts.

Runtime execution. We utilize Reaper's UIHarvester [32] to traverse apps and retrieve all the elements displayed on the device's screen. We have extended UIHarvester to retrieve not only the native Android components but also any web components, since applications may display content inside a WebView element. As stated in the Data Safety's privacy and security practices [36], developers do not need to declare any information in the *Data Shared* part of the Data Safety section if the app requests a runtime user consent (not to be confused with Android's runtime permissions) according to the requirements of Google Play's User Data policy [37].

Our runtime execution methodology takes this policy into consideration and identifies runtime consent elements (e.g., GDPR cookie consent banner) while exercising the app, enabling our subsequent differential analysis. Specifically, our framework identifies any runtime consent elements that exist, and performs two different executions of the app: one for accepting (i.e., providing consent) and one for declining. Additionally, we check whether the accept or reject button has been successfully selected by restarting the app and checking if the runtime consent dialogue persists. In cases where the app does not have a reject button or terminates after the reject button is selected without allowing any further interaction, we terminate the analysis for this app (Figure 1 - No Action). For every execution, we log all the information that the app collects and shares. Interestingly, we found a significant number of apps that contain discrepancies in the Data Safety that also violate the consent requirements of Google Play's User Data policy [37] by collecting and sharing sensitive info even if the user rejects the runtime consent, as we detail in Section 4.

Identifying consent dialogues. Our study analyzes Android apps for data violations and discrepancies in their Data Safety section by taking into consideration the app's request for runtime consent, therefore creating different scenarios for each app execution, based on the user's selection. As such, our system includes a component that identifies *View* and *We-*

bView elements that display runtime consent dialogues, using a string-matching-based approach with a predefined list of keywords. We populated this list of keywords by manually interacting with 100 apps that contain runtime consent dialogues. We verified that our list of keywords is sufficient for identifying runtime consent dialogues by verifying them against a *different* random set of 100 apps. In our manual verification we found that we are able to identify all runtime consent dialogues, even in cases where the app shows a pop-up dialog that informs the user about the data they collect by providing a link to their privacy policy, but without providing an agree or reject button. Moreover, as runtime consent dialogues may require the user to click different checkboxes before being able to press the accept button, we also incorporated this functionality into our module.

Data Safety crawler. We created a Python-based crawler that parses the Google Play web page on a daily basis and logs all the information provided by the Data Safety section for each application in our dataset starting July 29, 2022. Our crawler also logs additional information for each app, such as the developer's name, permissions, and number of downloads.

Discrepancies. Our framework dynamically analyzes apps and logs the data that they collect and share using runtime instrumentation. In our study, we process each app's logs and identify discrepancies between the runtime behavior and the data declared in the Data Safety section. While we crawl each app's Data Safety section on a daily basis, we compare the results of the runtime execution with the information provided in the app's Data Safety section on the day that we downloaded the app's apk file. Furthermore, as we detail in our analysis in Section 4, we find that the same discrepancies tend to persist across different app executions for long periods of time. Overall, we identify *Data Collected* discrepancies by monitoring function calls in the operating system, and *Data Shared* discrepancies by monitoring network traffic.

Testbed configuration. Our experimental setup consists of two Google Pixel devices (Pixel 4a and Pixel 6) running Google's AOSP version 12, and a proxy server using `mitmproxy` [26]. Magisk [78] was used to root the devices and install additional modules. The devices were configured with the LSPosed [51] framework that supports the latest Android versions and is compatible with Reaper's Xposed [2] modules. We intercepted network traffic by configuring the devices with the mitm proxy's root certificate, by installing it into the Android's system store. Moreover, we use Objection [10] to detect and disable SSL Pinning. At runtime, our framework installs and analyzes each application individually (e.g., install, analyze, clear app data, uninstall), and approves all the runtime permissions that the apps may request, using the "`adb install -g`" option. We modified UIHarvester [32] to be compatible with our devices' API and interacted with each app for five minutes using a breadth-first traversal strategy. Finally, we implemented a module for automating the login process by using Google's Single Sign-On whenever possible.

4 Measurements and Investigation

Here we present the findings from our large-scale study of the Data Safety section in the Android ecosystem.

App dataset. We created our application dataset based on free apps downloaded from the official Google Play market. We selected *up to* the top 250 apps (or as many as were available) from 20 different categories. Since our goal is to investigate how developers adhere to Google's Data Safety policies and how the data collected and shared may change over time, we gathered and analyzed four different versions for each app based on the time of download (i.e., September 2022, March/June/September 2023). Overall, we downloaded 4,986 unique apps from Google Play using the Raccoon [3] framework and performed a total of 21,202 executions across the different scenarios and VPN experiments.

The experiments performed in September 2022 were preliminary, aiming for an initial exploration of Data Safety discrepancies, and were performed using a prototype version of our system. These experiments only explored *Data Collected* discrepancies. We decided not to include new apps across datasets for our experiments and findings to remain consistent. Nonetheless, some apps that existed in the `Sep22` dataset were no longer available in the official Google Play Store in March and June 2023, and are not included in the respective datasets. Also, 225 apps have been removed from Google Play in September 2023 (out of which 213 had discrepancies during March's analysis). Therefore, `Sep22` dataset contains 4,986 apps, `Mar23` and `Jun23` datasets contain 4,157 apps and `Sep23` contains 3,953 from the original dataset. While we observe similar behaviors across all four datasets, our analysis here focuses mainly on `Sep23`, as that provides the most up-to-date view of how the Data Safety section is being used.

VPN dataset. We downloaded a subset of 100 apps from our initial dataset and analyzed them in several countries using a VPN service. As differences may exist between versions of an app distributed in different countries due to legislation, for each of these apps we visited the appropriate Google Play market for different countries and downloaded the apk file and crawled the information in the respective Data Safety section. Overall, our VPN-based analysis includes apps distributed in Canada, United States, Brazil, Iceland, Germany, Ukraine, Greece, Estonia, Kenya, Russia and India. Even though apps may be able to detect when a VPN service is used (e.g., GPS coordinates, nearby WiFi access points) and even prevent us from analyzing them (i.e., by geoblocking [45]), we did not detect such constraints for the majority of apps that we analyzed using VPN. Specifically, we only faced geoblocking restrictions in 18 apps (14 apps in Estonia, 2 apps in Iceland, 1 app in India and 1 app in Ukraine). Our VPN experiments took place between April 15 and May 2, 2023.

Data Safety section discrepancies. Table 2 summarizes our findings about apps that contain discrepancies between the run-time execution and their Data Safety section for different

Table 2: Apps with discrepancies for September 2022 (preliminary experiment), March, June and September 2023. *Any Discr* denotes apps with at least one type of discrepancy. *Data Collected* and *Data Shared* denote apps with discrepancies in the respective Data Safety section. Percentages are based on the total number of apps in the corresponding scenario.

Scenario		Preliminary exp.	March 2023			June 2023			September 2023		
		Data Collected (September 2022)	*Any Discr*	*Data Collected*	*Data Shared*	*Any Discr*	*Data Collected*	*Data Shared*	*Any Discr*	*Data Collected*	*Data Shared*
All		2,365 (47.43%)	3,363 (80.89%)	2,871 (69.06%)	1,797 (43.23%)	3,354 (80.68%)	2,878 (69.23%)	1,749 (42.07%)	3,204 (81.46%)	2,731 (69.44%)	1,735 (44.11%)
(i) No runtime consent		2,065 (48.46%)	2,545 (79.18%)	2,169 (67.48%)	1,384 (43.06%)	2,579 (79.11%)	2,209 (67.76%)	1,378 (42.27%)	2,543 (80.02%)	2,156 (67.84%)	1,418 (44.62%)
runtime consent:	***(ii) Accept***	300 (41.37%)	815 (86.42%)	701 (74.33%)	402 (42.63%)	773 (86.17%)	669 (74.58%)	364 (40.58%)	657 (84.77%)	575 (74.19%)	300 (38.71%)
	(iii) Reject	26 (3.58%)	89 (9.44%)	78 (8.27%)	41 (4.34%)	67 (7.47%)	62 (6.91%)	27 (3.01%)	62 (8%)	58 (7.48%)	20 (2.58%)
	(iv) Reject not found	228 (24.07%)	570 (60.44%)	474 (50.26%)	275 (29.16%)	566 (63.1%)	477 (53.17%)	254 (28.31%)	468 (60.38%)	397 (51.22%)	210 (27.1%)
	(v) Reject & app exited	50 (6.89%)	78 (8.27%)	69 (7.31%)	40 (4.24%)	79 (8.8%)	67 (7.47%)	44 (4.9%)	77 (9.93%)	63 (8.13%)	42 (5.42%)

run-time consent scenarios and across three time periods. *All* lists all apps with discrepancies irrespectively of the run-time consent scenario (i.e., we observed discrepancies in at least one of the scenarios). *Any Discr* denotes apps with at least one discrepancy without distinguishing between data being collected or shared, while *Data Collected* and *Data Shared* denote apps with discrepancies in the respective Data Safety section. Overall, we find that 81% ($\sigma = 0.33$) of apps have discrepancies, and that the percentages are high across all datasets (`Mar23`: 80.89% - `Jun23`: 80.68% - `Sep23`: 81.46%). These discrepancies persist for an entire year after Data Safety was made mandatory, highlighting the dire need for an effective automated validation mechanism that will ensure the accuracy and completeness of the Data Safety section.

Level of non-compliance. Figure 2 presents the extent of non-compliance for apps analyzed in March, June and September 2023. For determining compliance we identify which labels each app should have declared in the Data Safety section, based on their run-time behavior, in order to not have any discrepancies. Essentially, this number is calculated by considering both the labels that have been already declared and those that lead to discrepancies. As can be seen, 794 (19.1%), 803 (19.32%) and 729 (18.54%) apps are fully compliant as they do not have any discrepancies, indicating that they declare all the information that they collect and share in the Data Safety section. On the other hand, we found 579 (13.93%), 567 (13.64%) and 504 (12.81%) apps that appear to be entirely non-compliant, across the three datasets, as they do not declare any information, and hence all functions that access or transmit user or device information result in discrepancies. The remaining apps (i.e., 2,784 (66.67%), 2,787 (67.04%) and 2,700 (68.65%) respectively) have declared some information, but are not yet fully compliant as they still have discrepancies. Overall, apps with discrepancies have an average compliance level of 63.9% (`Mar23`: 63.16% - `Jun23`: 63.68% - `Sep23`: 64.85% – $\sigma = 0.71$). Based on these findings we argue that in the majority of cases Android's Data Safety section can not be trusted, as it contains inaccuracies or, one could argue, misinformation that will actively mislead users about what data will be collected and shared. As such, even cautious users may be unable to make truly informed decisions when granting permissions to apps.

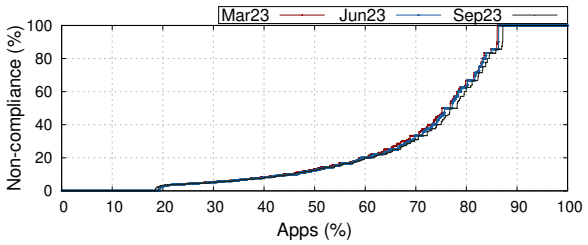

Figure 2: Level of non-compliance for apps in the 3 datasets. Apps in each dataset are sorted in ascending order based on their level of non-compliance.

In-app consent. As apps embed third-party library code and display content from the web, we have also analyzed our datasets with regards to the run-time consent dialogues that the apps present and the possible user options. Overall, our analysis is based on five scenarios, as shown in Table 2. The first scenario refers to (i) apps that do not present any run-time consent dialogue at all, while the remaining four scenarios provide a run-time consent dialogue and consider the respective users' options. Specifically, these scenarios are: (ii) "*Accept*" in the case where the user provides consent, (iii) "*Reject*" when the user declines to provide consent, (iv) "*Reject not found (No action)*" where the reject button was not found in the device's screen and the analysis terminated, and (v) "*Reject & app exited (No action)*" in the case where the reject button was pressed and the application did not allow further interaction. It is worth noting that all apps listed under the scenarios `scenario-iv` and `scenario-v` contain discrepancies and violate Google's policies concerning the user consent and the consent requirements.

We observe that the vast majority of apps (`Mar23`: 79.18% - `Jun23`: 79.11% - `Sep23`: 80.02% – $\mu = 79.43\%$, $\sigma = 0.41$) contain at least one discrepancy in their Data Safety sections and do not have a run-time consent dialogue (`scenario-i`). While our original assessment of Google Play's User Data policies [37] was that they are more permissive than they should be, due to allowing data transfers based on"*user-initiated action or prominent disclosure and user consent*", our analysis reveals that the situation is more problematic than we had expected it to be. Apart from omitting to disclose

in their Data Safety section information regarding the data that they collect and share, these apps do not inform the user about run-time data accesses at all, and do not give them the ability to consent (or deny consent). Specifically, we observe that in all datasets the percentage of apps with discrepancies in *Data Collected* (Mar23: 67.48% - Jun23: 67.76% - Sep23: 67.84% – $\mu = 67.69\%$, $\sigma = 0.15$) and *Data Shared* (Mar23: 43.06% - Jun23: 42.27% - Sep23: 44.62% – $\mu = 43.31\%$, $\sigma = 0.97$) is still significantly high.

For apps that provide a run-time consent dialogue and the user agrees to the consent (scenario-ii), we found that 85.79% of the apps (Mar23: 86.42% - Jun23: 86.17% - Sep23: 84.77% – $\sigma = 0.72$) access and share data not declared in the Data Safety section. While these apps fall in line with Google's policies [11], we believe that such instances of relaxed policies can be abused and mislead users about the data that the app collects and shares, and that this information needs to be disclosed in the appropriate Data Safety section.

For apps that provide a consent dialogue but the user declines the consent (scenario-iii), we found that 8.3% of the apps (Mar23: 9.44% - Jun23: 7.47% - Sep23: 8% – $\sigma = 0.83$) contain a discrepancy in their Data Safety section. We note that apart from having discrepancies between the run-time execution and the Data Safety section, these apps also violate the "*User-initiated action or prominent disclosure and user consent*" policy. We identified 61.31% of apps (Mar23: 60.44% - Jun23: 63.1% - Sep23: 60.38% – $\sigma = 1.26$) in scenario-iv that also violate Google's policy governing consent requirements [37]; this policy states that consent "*must be granted by the user before your app can begin to collect or access the personal and sensitive user data*". These apps present a run-time consent dialogue but they do not display an agree button and, to make matters worse, collect data even if the user does not interact with and exits the app. Finally, we found 9% of apps (Mar23: 8.27% - Jun23: 8.8% - Sep23: 9.93% – $\sigma = 0.69$) in scenario-v that collect data before terminating, after the user has pressed the reject button. These apps contain Data Safety discrepancies and also violate both of the aforementioned consent policies.

Overall, for the three "Reject" scenarios (scenario-iii, scenario-iv, scenario-v), we found that 78.61% ($\sigma = 0.54$) of the apps that present a consent dialogue have discrepancies in their data collection and sharing practices (Mar23: 78.15% - Jun23: 79.37% - Sep23: 78.31%). While apps should always respect users' run-time choice concerning accessing and sharing of their data, our experiments reveal that this is not always the case, thus allowing apps to exploit loopholes in Google's current policies that govern data disclosure.

Data Collected discrepancies. Table 6 in Appendix A breaks down the discrepancies between apps' run-time behavior and their Data Safety labels for every run-time scenario across all datasets, and provides aggregated results for the functions that lead to the discrepancies along with the respective Android permissions. We observe that discrepancies may originate from functions that require "dangerous" permissions, such as ACCESS_(COARSE\FINE)_LOCATION, READ_SMS, READ_PHONE_NUMBERS, READ_EXTERNAL_STORAGE, and READ_PHONE_STATE. Moreover, we observe a large number of apps that access location information without declaring any of the corresponding Data Safety labels: Location, Approximate location, or Precise location. This is also true for 45-69 apps (across datasets) accessing precise location, where the user had no interaction with the app (scenario-iv), and 15-20 apps (across datasets) in which the user declined to provide run-time consent and the app did not allow further interaction yet still collected the location information (scenario-v).

Personal & sensitive data. A large number of apps access sensitive personal information that falls into the Data Safety labels of "Device or other IDs" and "App info and performance" without declaring them. Previous work has shown that this type of data can be used to accurately track users (e.g., [32, 47, 63]). Our experiments show that this behavior became more common between March - September 2023 in apps that do not provide a run-time consent dialogue (scenario-i). Additionally, we found one app that collects and shares the user's contacts in every dataset. We also observe apps accessing functions that yield persistent device identifiers (e.g., IMEI/MEID, IMSI, SIM, build serial), which requires the READ_PRIVILEGED_PHONE_STATE permission in the latest Android versions. Even though this permission can be only granted to apps signed with the platform key and privileged system apps [5] (starting from Android API 29), several persistent identifiers (e.g., IMEI) can still be accessed without this permission if, for example, the app is the default SMS role holder [13]. We did not set apps as the default handler, and in our devices' version these calls are automatically declined and no value is returned; however, this will not be the case for older Android versions. Moreover, we found a small but non-negligible number of apps (i.e., 15) that access extremely sensitive user data such as photos, documents, audio files and contacts without declaring the appropriate labels.

API Methods. We identified and analyzed which functions apps are accessing without declaring the appropriate *Data Collected* labels. Figure 3 shows the number of apps that access functions that resulted in a *Data Collected* discrepancy in the Sep23 dataset across all run-time consent scenarios. We observe that the majority of functions are called by apps that do not have a run-time consent dialog. Some of these functions return device specific identifiers (e.g., getDeviceID(), getIMEI(), getNetworkOperator()) while many apps use functions that reveal the user's location (e.g., getLastknownLocation()). Figure 3(c) shows the aggregated results of apps accessing API methods resulting in Data Safety discrepancies for all run-time scenarios where the consent is rejected (i.e., scenarios iii, iv and v). Surprisingly, we observe that the user's decision concerning the run-time consent (i.e., accept or reject) makes almost no difference to whether the user's data is being collected and not disclosed in the Data Safety section,

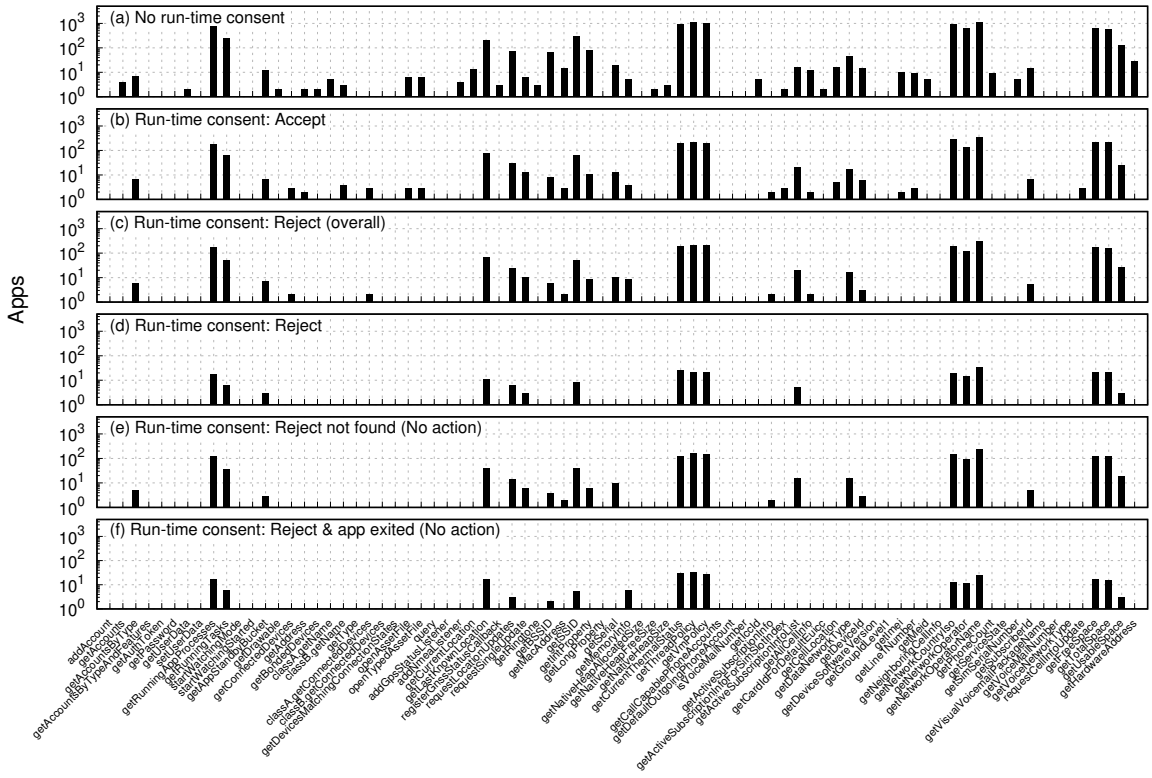

Figure 3: Apps accessing functions that resulted in Data Collected discrepancies for all run-time scenarios for `Sep23`.

as apps ignore the user's reject option (Figure 3(c)). However, for completeness, in Figure 3 we also present apps with discrepancies for all the different reject scenarios (Figure 3(d), Figure 3(e) and Figure 3(f)).

Moreover, we found many apps that use the `getCurrentThermalStatus()` function without declaring the "App info and performance" Data Safety label. This function returns a value that represents the thermal status of the device. Even though similar device characteristics have previously been used for tracking devices (e.g., battery API [59]), verifying whether this is the case here, falls outside the scope of our work. We also observe apps that do not disclose access to the `getSSID()` method which returns the service set identifier of the current WiFi network. Previous work [56] has demonstrated that the list of nearby access points (e.g., the `getScanResults()`) can accurately locate users and, as such, Android protected these functions with the location permission. As mobile devices frequently change access points, third-parties can periodically access this function and gather the list of linked access points in order to locate users. Additionally, we observe apps accessing the BSSID identifier using the `getBSSID()` method, which allows linking devices that share the same access point, thus enabling cross-device tracking [65]. Overall, we identified apps accessing 13,004, 12,860, and 11,645 functions without declaring the respective Data Safety labels in the `Mar23`, `Jun23` and `Sep23` datasets, respectively.

Persistent discrepancies. We investigated whether apps with discrepancies have been corrected between March's and June's version. We found that only 81 apps corrected their discrepancies and are compliant with Data Safety policies. Unfortunately, discrepancies in 3,282 apps remain the same across a period of almost three months. To make matters worse, we identified 72 apps that did not have any discrepancies in March, but had discrepancies in June's analysis. Accordingly, we identified 179 and 270 apps with discrepancies not declaring information in the *Data Collected* and *Data Shared* sections in September 2023 respectively, but having the appropriate labels in March 2023. We believe that these results could indicate confusion amongst developers and the information they are required to disclose. Google should provide better guidelines for completing the Data Safety section and enforce penalties for apps that fail to comply.

Data Shared discrepancies. Our system captures and logs network traffic during the execution of each Android app and identifies *Data Shared* discrepancies following a string-matching based approach that attempts to match device-specific information and keywords to the network traffic logs. For this, we developed a mock application that executes all the functions that we found in our preliminary experiments that can result in *Data Collected* discrepancies, and ran this mock application with both of our testbed devices. We construct a list of device-specific information for our devices (e.g., Ad-

vertising ID, GSF ID), and specifically crafted data values (e.g., email, name, surname), so that our system can detect when these identifiers are being exfiltrated over the network.

Since the values sent over the network can be in an encoded form, our system checks for common transformations during the matching process (e.g., `base64`, `HEX`, `ROT13`, `SHA-1`, `SHA256`, `MD5`, `RIPEMD-160`, `Whirlpool`, and `BLAKE2`). Even though this approach is common for identifying network leaks [23, 31, 58], it is not able to handle all cases of leaked data, as data may be encrypted or heavily obfuscated. As such, our results for *Data Shared* discrepancies present a *lower bound*, and we consider an exhaustive investigation using differential analysis (e.g., following the approach of Continella et al. [25]) as future work. Nevertheless, our experiments still reveal that 42.07% - 44.11% of the apps in our three datasets contain at least one discrepancy in the *Data Shared* section.

Violations. Table 2 shows that many apps share data without declaring it in the Data Safety section. Similar to prior work that found GDPR violations in Android apps [58], we also identified cases of apps leaking data (which has not been declared in the Data Safety section) without the user's consent. We observe that apps violate the Data Safety policies, and also violate and ignore the user's choice for data sharing, resulting in major data leakage without the user's knowledge or consent. To this end, we argue that Google should revise the current Data Safety policies and mandate that any data being collected or shared must be declared without exception.

Data leaks. We identified that apps share without the appropriate disclosure various device characteristics, such as the AdvertisingID, BSSID, BuildNumber, DeviceName, Google Services Framework ID, MCC+MNC and SSID, as well as sensitive user information including Address, Contact Numbers, Email, Latitude, Longitude, Name and Surname, to 16,840 different domains. This information is extremely sensitive as it can be used to accurately track and deanonymize users. On average, apps with *Data Shared* discrepancies leak between two and three PIIs to different domains.

We use McAfee's real-time database [54] to classify all the domains that the apps share data with. Figure 4 shows the number of apps that share undisclosed information to different domain categories. We observe that the majority of apps send data to domains classified as "Internet Services", "Software/ Hardware" and "Content Server". While it is likely that these apps use cloud providers to perform some kind of operation on the data they collect, it is infeasible to actually verify what happens with the data after it has left the user's device. We also found many domains classified as "Web Ads" that may use such data for advertising and retargeted ads. This indicates that embedded third-party ad libraries may be responsible for undisclosed data sharing, as we further elaborate later on. Interestingly, we found 12 apps sending PIIs to 12 domains over HTTP even though their *Data Safety* section states that data is sent over a secure connection.

Origin of discrepancies. Motivated by prior work [24, 32, 69] that differentiated between the permissions requested by the actual app and those requested by third-party libraries, we employed a previously proposed stacktrace-analysis methodology [32,64] to infer which part of the application is responsible for the discrepancies we observe. As the stacktrace reveals the path to the source file and the package name responsible for the function call, we compiled a list of third-party libraries from [20, 48, 68] and distinguished between function calls originating from first-party and third-party functionality. Figure 5 shows the percentage of discrepancies for 2,731 apps in the September 2023 dataset, between the first-party and third-party functionality. We observe that while most of the discrepancies originate from third-party functionality (59%), the percentage of apps with discrepancies originating from first-party functionality (41%) is almost as common. Additionally, we found that for 12.34% of the apps, discrepancies originate only from the first-party functionality, while for 26.62% discrepancies originate only from third parties.

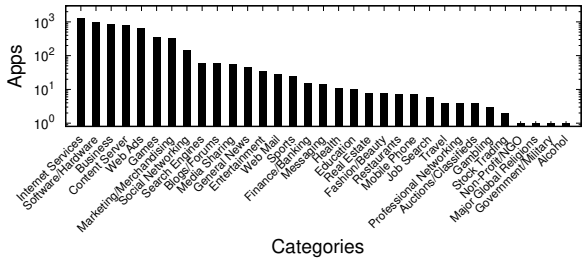

Figure 4: Apps with Data Sharing discrepancies sending data to different domain categories.

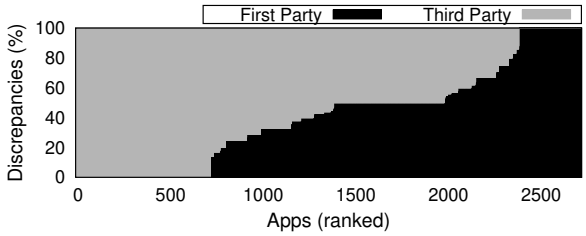

Figure 5: Percentage of discrepancies originating from first-party functionality, for the `Sep23` dataset.

Our analysis shows that 91 libraries are responsible for the discrepancies originating from third-party functionality. The most popular among them is `android.gms` and is used by 1,163 apps, while `facebook`, `applovin` and `unity3d` are used by 828, 678 and 623 apps, respectively. Other popular libraries we found are `ironsource`, `fyber`, `vungle`, `adcolony`, `appsflyer`, `amazon` and `adjust`, all of which are used by more than 100 apps. In total we identified 11,183 function calls that originate from the aforementioned 11 libraries. On the other hand, 58 of the 91 libraries (63.73%) are used by five apps or less, further demonstrating the importance of third-party libraries accurately documenting the

Table 3: Apps with discrepancies across countries.

Country	Data Collected	Data Shared	Country	Data Collected	Data Shared
DEU	80 (80.00%)	81 (81.00%)	CAN	79 (79.00%)	85 (85.00%)
EST	69 (80.23%)	71 (82.56%)	IND	79 (79.80%)	85 (85.86%)
ISL	80 (81.63%)	77 (78.57%)	KEN	79 (79.00%)	83 (83.00%)
UKR	80 (80.81%)	83 (83.84%)	RUS	80 (80.00%)	83 (83.00%)
BRA	80 (80.00%)	82 (82.00%)	USA	79 (79.00%)	82 (82.00%)

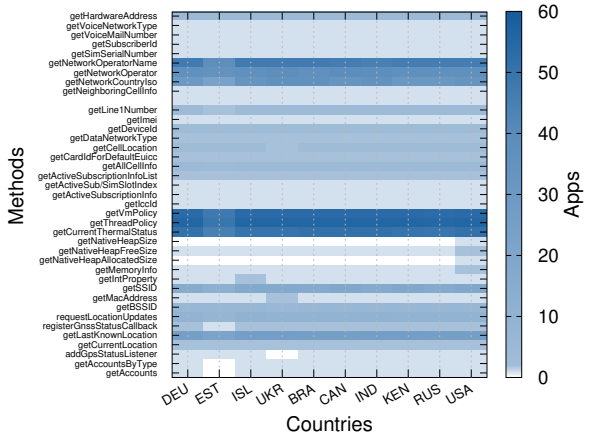

Figure 6: Data Collected discrepancies per country.

information they collect and enabling developers to declare this information appropriately in the Data Safety section.

There has been a long-standing debate regarding the privacy issues that arise form third-party libraries [41, 55, 75] and who is responsible for solving these issues. In that regard, we believe that Google's decision regarding developers being responsible for ensuring the accuracy of the Data Safety section places them in a precarious situation. This has also been argued previously [75] due to developers already struggling with handling the legal requirements for embedded libraries, as they have to invest a lot of time and effort to understand how libraries and ad networks handle privacy issues. Therefore, we believe that third-party libraries should explicitly mention in their documentation the data they collect so they can easily be listed by developers in the Data Safety section. Concerning discrepancies originating from first parties, we observe that developers fail to adhere to Google's policies concerning data transparency in almost half of the cases. As we can not assign (nor disprove) malicious intent, we argue that while developers need to be more vigilant when handling personal data, it is imperative that Google adopts an effective, automated validation mechanism for ensuring the completeness and accuracy of the data disclosed in Data Safety sections.

VPN experiments. Apps served through Google Play across countries contain different app versions based on the regulations and legislation of each country. In this experiment we downloaded and analyzed 100 apps from 10 different countries using a VPN service. The apps were downloaded from the respective Google Play store for each country. Table 3 lists the number of apps with discrepancies analyzed

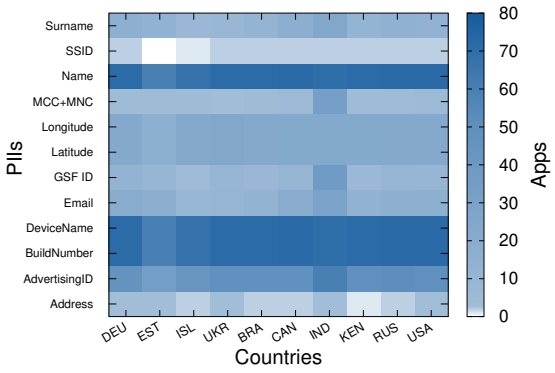

Figure 7: Data Shared discrepancies per country.

in each country. We found that the majority of apps contain discrepancies independent of the geolocation of the device. Furthermore, as apps follow specific policies based on each country's data protection laws (e.g., CCPA, PIPEDA, GDPR) and may have different regulations and enforcement concerning run-time consent, we analyzed the *Data Collected* and *Data Shared* discrepancies for the same set of 100 apps per country. Figure 6 shows the number of apps and the functions that resulted in *Data Collected* discrepancies, while Figure 7 shows the number of apps and the leaked data that resulted in *Data Shared* discrepancies. We observe that apps across all countries access functions that return device characteristics, as well as sensitive personal information such as the user's name, email, contacts and location. Moreover apps in Iceland tend to have more *Data Collected* discrepancies compared to other countries, while apps in Estonia have the least. Finally, we observe that India has the highest percentage of apps with *Data Shared* discrepancies.

4.1 Case studies

Here we further detail notable examples of apps that do not accurately disclose their data practices in the Data Safety.

Popular Apps. Table 4 shows Data Safety discrepancies for popular apps that have more than 500 million downloads, across all three datasets. *Data Collected* denotes the number of Data Safety labels that were not disclosed, and the number of functions that resulted in the discrepancies. *Data Shared* denotes the number of undisclosed Data Safety labels and PIIs that have been sent over the network. We find discrepancies in popular apps from a wide range of categories, including social media (Linkedin, Instagram, Bigo, Lago, TikTok, X, Pinterest), messaging apps (Skype, Telegram, Snapchat), Microsoft Apps (Excel, Word, OneNote), mobile browsers (Chrome, Opera Mini) and games (Free Fire, PUBG MOBILE).

Lago and Bigo are the apps with the most *Data Collected* discrepancies that also leak PIIs without being disclosed in the *Data Shared* section. They access 9 and 13 functions respectively, that return device identifiers and characteristics (e.g.,

Table 4: Discrepancies in popular apps.

⇓ DLs	Application	*Data Collected* (Labels - Methods)			*Data Shared* (Labels - PIIs)

500M+	Uber	1 - 2	1 - 2	1 - 2	1 - 1	0	0

`getMacAddress`, `getDeviceId`, `getSubscriberId`) while also sharing data like the BuildNumber and DeviceName. Microsoft apps (e.g., Word, Excel) leak up to six PIIs including sensitive information such as the Email, Name and Surname. Opera Mini and SHAREit access the `getLastKnownLocation` method without declaring the appropriate Location Data Safety label. Uber fails to disclose the Files and Docs *Data Collected* label. Furthermore, we found that even though several apps do not have *Data Collected* discrepancies, they still share information (e.g., DeviceName, GSF ID, Email, Name and Surname) without disclosing it in the *Data Shared* section. For instance, Skype accesses sensitive information and discloses it in the *Data Collected* section, but fails to declare that the data is also sent over the network. The same applies for all apps that do not have *Data Collected* discrepancies but have *Data Shared* discrepancies. While certain apps may adhere to the relaxed Data Safety policies [11] concerning the requirements for declaring data in the Data Safety section, we strongly believe that such cases not only mislead users but also undermine the Data Safety section's purpose, which is to improve transparency and enable *informed* consent where users can easily understand how their data is being used.

Google Apps. During our March analysis, we identified three Google apps that had discrepancies in their Data Safety section. To further investigate how common this is across apps offered by Google, we manually analyzed all available Google apps [6] during July 2023. Out of 151 Google apps, 44 were not compatible with our device's API, while eight apps could not run on our devices. Out of the remaining 99 Google apps, we found that 47 of them had discrepancies in their *Data Collected* and *Data Shared* sections. Specifically, we found data belonging to 12 Data safety labels (Phone number, Contacts, Device or other IDs, Location, Approximate location, Precise location, Personal info, Files and docs, App info and performance, Other app performance data, Diagnostics, App activity) that were not declared. Such an example is `com.google.android.dialer`, which accesses the user's location using `requestLocationUpdates()` yet fails to declare the appropriate labels. Regarding undeclared data being shared, we found 24 apps sharing data that fall in the category of "Device or other IDs" and include the BuildNumber, Google Services Framework ID, DeviceName, MCC+MNC and AdvertisingID. Interestingly, some of these apps leak data even if the user rejects the run-time consent. Finally, we checked the origin of discrepancies and did not find any that originate from third-party functionality. The list of Google apps with discrepancies can be found here [7]. This further highlights the need for more stringent Data Safety disclosure policies being enforced, and the removal of potential loopholes that enable opaque data collection and sharing practices.

Independent Security Reviewed Apps. Developers can declare in the Data Safety section that their app has been independently validated against a global security standard (i.e., OWASP's MASVS). This is an optional review that is paid by developers and performed by third-party organizations. Google states that the independent security review may not necessarily verify the accuracy and completeness of the Data Safety declarations and that the developer is solely responsible for making complete and accurate declarations [8]. Nonetheless, we checked OWASP's MASVS and found that the MSTG-STORAGE-12 mobile security testing guide describes how to statically or dynamically identify privacy-related information that is being disclosed (or not) [60]. In our analysis we identified only a small number of apps that have gone through an independent security review and some of them still contain discrepancies in their Data Safety section (`Mar23`: 16/34, `Jun23`: 8/26, `Sep23`: 9/27). Interestingly, certain apps showed the independent security review in their Data Safety section in March but no longer listed it in June and/or September.

5 Discussion, Limitations and Future Work

In this section we further discuss our findings and how these issues could be mitigated, and also present the limitations of our dynamic analysis study, some of which are inherited by different components that our framework incorporates.

Mitigation. The Data Safety section has significant potential for enabling more transparent data practices, and Google plans to further incorporate Data Safety's information into certain run-time permission dialogues in their upcoming release of Android [4]. Our experimental findings revealed that 81% of the analyzed apps contain Data Safety discrepancies and many also violate policies governing run-time consent. Moreover, we believe that certain relaxed and vague policies can confuse users and developers alike, while allowing invasive

entities to surreptitiously exfiltrate personal data without the user's knowledge or consent. Our study reveals the extent of Data Safety's misrepresentation of data collection and sharing practices, and highlights the need for reformations that will ensure that all data collected or shared is disclosed without exception. We consider the following directions crucial for improving data transparency in the mobile ecosystem:

Universal standard app disclosure. Android and iOS markets should adopt a universal data privacy disclosure system that accurately, completely, and clearly describes how apps and developers collect and share users' data.

Coherent and comprehensive data policies. All data collected and shared should be disclosed to enhance transparency and protect users from misleading information. Third-party libraries and developers must collaborate to ensure the effectiveness of these policies.

Validation mechanism. Official app markets must not rely solely on the developer's honesty, and must frequently review app's run-time behavior to ensure that it is consistent with the information disclosed in the Data Safety section through automated means. Reports should be publicly available and violations should be penalized by the market. We will open source our framework to facilitate such initiatives and additional research in this space.

Broader implications. The findings of our study are alarming, as they demonstrate to what extent Android applications are collecting and sharing user information without properly disclosing their practices. Surprisingly, this often occurs without the users' knowledge or consent, and in violation of relevant policies and regulations. Our research serves as a cautionary tale to users, aiming to raise awareness about the data Android applications collect and share, as well as the discrepancies that exist in apps' Data Safety disclosures. Overall, we envision that the increased awareness by end users and policy makers will lead to higher demand for transparency in the ecosystem, and hope that it will prompt additional regulations mandating more privacy-preserving practices. This includes Google refining their Data Safety policies, and investing in the deployment of appropriate compliance, review and validation mechanisms. Moreover, we anticipate additional pressure towards developers for properly following the Data Safety disclosure guidelines and accurately reporting the data collected and shared, in compliance with all relevant regulations and policies regarding data collection, disclosure and consent. Our study also sheds light on third-party libraries' questionable practices of incomplete data disclosure, thereby educating app developers about problematic third parties; more widespread awareness about regulatory violations from third-party libraries may facilitate initiatives for better ensuring compliance across the app ecosystem.

Permission mappings. Prior work (e.g., [14, 19, 21, 27] has invested significant effort in providing accurate mappings of permissions to functions. While we used state-of-the-art permission mappings as the starting point for creating the mappings used in our study (since mappings did not exist for version 12 of Android), and further verified them using the methodology employed in [77], it is possible that permission inaccuracies exist due to the limitations employed in their methodology for analyzing the Android framework.

Data Safety label mappings. Our mapping between Data Safety labels and API methods may not be complete, as no official documentation exists that maps the labels to function calls, and our labeling methodology may not be exhaustive. Specifically, we rely on the completeness of the Android Permission Mappings provided by state-of-the-art systems [27, 77]. For non-permission-protected calls to Data Safety labels, we manually identified and labeled such cases using the development guidelines, known PIIs, and by looking at the respective Android classes. Due to the vast amount of API methods that our framework monitors, we only assigned labels to functions that have been accessed during runtime analysis. Finally, our analysis does not include Data Safety labels that do not correspond to an API method, as we cannot monitor such cases (e.g., religious beliefs). Nonetheless, we believe that our mappings are useful to the Android community and are publicly available to facilitate additional research in this space. An alternative approach would be to use NLP techniques for processing API documentation and mapping them to potential labels. While this can be challenging as the documentation may not provide sufficient information, we consider this an interesting future direction.

Encrypted network traffic. We identified data being shared over the network by analyzing HTTPS traffic and using string matching. We searched for values of interest in plaintext format and common encodings. However, we cannot identify shared values that have been encrypted or heavily obfuscated. Differential analysis can be used for identifying leaks even in such cases, by observing deviations in the resulting network traffic [25]. We consider an exhaustive investigation using such techniques as part of our future work.

Consent dialogues. We identify and interact with in-app consent dialogues using a keyword-based approach. While our verification process highlighted the effectiveness of our approach, there may exist cases that cannot be handled by our system (e.g., the decline button being marked with an X).

Stacktraces, libs & obfuscation. Stacktrace-analysis is a common technique, which we use to differentiate Data Safety discrepancies between first and third-party functionality. In our analysis we compiled a comprehensive list of third-party library package names from prior work [20, 48, 68]. However, package names that are not included in our list will be classified as first parties. Furthermore, an obfuscated library package name will be assigned by default to the first party, which may lead to an over-reporting of discrepancies by the first party. While we cannot automatically classify obfuscated package names, such cases are rare [32].

Ethics & disclosure. Our experiments were conducted on our own devices using test accounts; we did not affect actual

users or collect user data. Given the scale of our analysis, we shared our findings with Google as they already have mechanisms in place for auditing and notifying apps. We submitted a report to DDPRP, and they suggested submitting our report directly to the Android security team. Subsequently, we submitted a detailed report of our research, findings and video demonstrations to the security team; they informed us that they will conduct an investigation and share their findings with us. In summary, our work does not inflict any form of harm on users – instead, it has the opportunity to result in major benefits for users as our findings can incentivize and guide changes to the Data Safety section that will further enhance data transparency and user consent.

6 Related Work

The Data Safety section is a relatively recent Android mechanism that has not received sufficient scrutiny from the research community. To the best of our knowledge, this paper presents the first in-depth investigation of the Data Safety section and its use in the Android application ecosystem. We conduct a novel dynamic, large-scale, longitudinal study that uncovers privacy violations by correlating the run-time behavior of apps with the data declared in their Data Safety section. Here, we discuss prior work on the accuracy of privacy labels in the mobile ecosystem, the efficiency of in-app user consent dialogues and the liability for apps' privacy issues.

Data Safety section. In a recent report, Mozilla manually compared the privacy policies and terms-of-service of 40 popular Android apps (20 free, 20 paid) to their Data Safety section. Their comparison showed that the Data Safety section does not match the data practices outlined in the privacy policies and terms-of-service. While their focus is orthogonal to ours, their findings also highlight shortcomings of the Data Safety section. We provide a detailed comparison in Appendix A. In another study, Khandelwal et al. [40] explored how developers' practices evolve over time, using app metadata, by taking Data Safety section snapshots from 1.1M apps. They found that as of May 31, 2023, only 46.8% of the apps had privacy labels. Additionally, they found that developers have difficulties with the new Data Safety mechanism and some of the challenges they face include Google's guidelines being unclear, confusing policies due to frequent changes, and Data Safety form options being too complicated. In regards to the methodology employed, [40] uses static analysis to identify apps that include third-party libraries and, thus, deduces that many apps under-report their data sharing practices. While this approach reaches similar conclusions to ours, it suffers from the inherent limitations of static analysis (e.g., inability to handle encryption, dynamic code loading). They provide statistics based on app metadata and, as such, provide a coarse-grained analysis. On the contrary, our study employs dynamic analysis for detecting data collection and sharing practices on a per function-basis, by utilizing fine-grained and manually-curated mappings between Data Safety labels and function calls. We believe that these prior studies provide an important and complementary view of the Data Safety ecosystem using different methodologies, and contribute to the ongoing body of research pushing for better validation mechanisms being deployed by Google.

iOS privacy labels. Xiao et al. [79] proposed Lalaine, an automated system for iOS that combines dynamic and static analysis, natural language processing and network monitoring to identify inconsistencies between apps' run-time execution and their privacy labels. Their evaluation in 5,102 apps showed that the majority of apps neglect to disclose data, and the incomplete or incorrect guidelines from third-party SDKs may lead to non-compliant labels. While their work presents similarities to our work, significant differences exist between the two studies that stem from the differences between Android and iOS, and the differences between Apple's Privacy Labels and Google's Data Safety section. For instance, their system hooks iOS system APIs and matches the return values to network traffic to identify cases of data collection, since "data collection" refers to transmitting data off the user's device according to Apple [17]. This is in contrast to Google's Data Safety section that distinguishes between *Data Collected* and *Data Shared*. Another major difference between Apple's and Google's policies is that run-time consent does not interfere with Apple's Privacy Labels' disclosure requirements. In contrast, Google's Data Safety decision to incorporate run-time consent complicates the process of validating apps' data practices while also introducing additional obstacles to users being able to make informed decisions.

Koch et al. [43] explored how iOS privacy labels are used and whether developers adhere to the declared labels. They monitored network traffic for 1,687 apps without performing any app interaction and found that several apps contact known trackers, transmit data and violate their labels. They concluded that simply declaring privacy labels is not sufficient for data transparency. ATLAS [38] uses an ensemble-based classifier for predicting privacy labels from the privacy policies. Their study suggests that 88.0% of apps had at least one discrepancy between the privacy policy and labels. Li et al. [50] studied how quickly app developers create and update privacy labels and found that 51.6% of apps do not have a label. In [49] the authors examined the usability and understandability of Apple's privacy nutrition labels and identified confusion amongst developers regarding Apple's documentation. Rodriguez et al. [67] compared Android and iOS privacy labels for 822 apps that exist in both operating systems. They found inconsistencies between privacy labels disclosed across platforms with only 3.2% of the apps being consistent.

Consent violations. A plethora of prior work [22, 44, 53, 58, 62, 71, 80]) has explored run-time consent violation in mobile apps. In [57] the authors showed that apps deceive users into accepting all data sharing and transmit data even when users have opted out, therefore violating GDPR's con-

sent requirements. Reyes et al. [66] found that the majority of the apps and the embedded third-party SDKs contain potential COPPA violations. POLICHECK [15] identifies policy inconsistencies in mobile apps and identifies the entity (first- or third-party) that receives the privacy sensitive data. Koch et al. [42] analyzed privacy consent dialogues in both Android and iOS, and found that apps transmit traffic before the consent and even after rejecting the consent. Additionally, they found that only a small percentage of apps give the user some form of a choice when they are presented with a consent dialog. MOWCHECKER [33] statically identifies data violations from third-party libraries when user's run-time choice is to opt-out from data collection. Subsequently, their study urges that third-party libraries and mobile apps need to collaborate for respecting the users' withdrawal choices.

Privacy responsibilities. While several studies [28, 29, 32, 35, 63, 73] have investigated the excessive permission usage and leakage of private information from third-party libraries, who is responsible for privacy issues has been debated. A recent study [41] showed that libraries are responsible for several privacy issues including ad fraud. On the contrary, Tahaei et al. [75] found that the information presented by ad networks to developers complies with legal regulations and they are responsible for handling privacy regulations.

7 Conclusion

Google's new Data Safety process is an important step towards increased platform support for data transparency that will allow users to easily understand how apps process their data. Unfortunately, in its current implementation, bad practices and relaxed policies can confuse both end-users and developers, while also creating opportunity for abuse and the surreptitious exfiltration of data. In this paper we developed a system that automatically identifies discrepancies between apps' run-time behavior and what data developers disclose in Data Safety. Our system analyzes and identifies discrepancies in applications based on different run-time consent scenarios. Our subsequent in-depth analysis spanning across an entire year demonstrated severe inaccuracies in apps' Data Safety sections. To make matters worse, we uncovered that applications not only violate Google's Data Safety policies, but also violate Google's policy governing consent requirements leading to several alarming findings. Consequently we proposed a set of guidelines that should be adopted towards achieving better data transparency. We hope that our study will facilitate additional research pushing for better validation mechanisms that protect users from misleading information.

A Appendix

Additional Technical Details. Table 5 details the APIs that return Personally Identifiable Information, which are monitored by our framework. Functions may be permission-protected or not depending on the Android version.

Table 5: APIs returning Personally Identifiable Information.

Class	Function
AdvertisingIdClient	getAdvertisingIdInfo
TelephonyManager	getNetworkCountryIso, getNetworkOperator, getNetworkOperatorName
ContentProvider	query
SubscriptionInfo	getCardId, getCarrierId, getCarrierName, getCountryIso, getMcc getDisplayName, getMccString, getMnc, getMncString, getSimOperator
BatteryManager	getIntProperty, getLongProperty

Breakdown of discrepancies. Table 6 shows the discrepancies between apps' run-time behavior and Data Safety labels for every run-time scenario across all datasets, and provides aggregated results for the functions that lead to the discrepancies along with the respective Android permissions.

Comparison to Mozilla's findings. While we cannot directly compare our results to Mozilla's study [12], due to differences in the methodology and the time of their analysis (i.e., we do not have the exact apk version they analyzed or the date of the Data Safety section), we identified their 20 free apps and included them in our analysis. As our main analysis is based on March 2023 and their report was published in February 2023, we found that for three apps we have not found any discrepancies and Mozilla graded these apps as "OK". Furthermore, UC Browser has the most discrepancies and Mozilla could not grade it, due to the app not filling out the form. We found that during March's analysis UC Browser did not declare anything in the Data Safety section. During June's analysis, the app disclosed the labels Device or other IDs and App info and performance in the Data Collected section. We found that the app collects sensitive information from 14 functions and fails to declare the labels Location, Precise location and Phone number in the Data Collected. Moreover, we found that in June's analysis the app does not disclose Data Shared info, but leaks the BuildNumber and the DeviceName that require the label Device or other IDs. We further analyzed the app and found that apart from sharing the BuildNumber and the DeviceName it also shares (without disclosing) the GSF ID and the MCC+MNC. Additionally, for 10 apps that Mozilla graded as "Poor" or "Needs Improvement", in our analysis a month later we did not find any discrepancies. Even though we did not analyze the privacy policies and the terms of use of these apps (as it falls outside the scope of our work), we believe that both studies provide an important and complementary view of the complicated and contentious design of Google's Data Safety mechanism.

Table 6: Breakdown of discrepancies between run-time behavior and the Data Safety section for different run-time scenarios. *API Methods* show the number of methods that yielded the discrepancies. *Apps* show the number of apps with discrepancies.

Scenario	Data Safety Label	API Methods			Permissions	Apps

Abstract

Privacy violations and compliance issues in mobile apps are serious concerns for users, developers, and regulators. With many off-the-shelf tools on Android, prior works extensively studied various privacy issues for Android apps. Privacy risks and compliance issues can be equally expected in iOS apps, but have been little studied. In particular, a prominent recent privacy concern was due to diverse third-party libraries widely integrated into mobile apps whose privacy practices are non-transparent. Such a critical supply chain problem, however, was never systematically studied for iOS apps, at least partially due to the lack of the necessary tools.

This paper presents the first large-scale study, based on our new taint analysis system named *iHunter*, to analyze privacy violations in the iOS software supply chain. *iHunter* performs static taint analysis on iOS SDKs to extract taint traces representing privacy data collection and leakage practices. It is characterized by an innovative iOS-oriented symbolic execution that tackles dynamic features of Objective-C and Swift and an NLP-powered generator for taint sources and taint rules. *iHunter* identified non-compliance in 2,585 SDKs (accounting for 40.4%) out of 6,401 iOS SDKs, signifying a substantial presence of SDKs that fail to adhere to compliance standards. We further found a high proportion (47.2% in 32,478) of popular iOS apps using these SDKs, with practical non-compliance risks violating Apple policies and major privacy laws. These results shed light on the pervasiveness and severity of privacy violations in iOS apps' supply chain. *iHunter* is thoroughly evaluated for its high effectiveness and efficiency. We are responsibly reporting the results to relevant stakeholders.

*The first two authors contributed equally to this work and are ordered alphabetically. Dexin Liu's contribution was made during his research internship at Alibaba Group. Yue Xiao was a Ph.D. student at Indiana University.

†Xiaolong Bai and Luyi Xing are corresponding authors.

1 Introduction

Privacy violations and compliance issues in mobile applications pose serious concerns for users, developers, and regulatory bodies. Prominent issues include those related to data collection transparency and fairness, the right to be forgotten, or various other privacy rights defined by legislation. Comprehensive analyses of these issues have been predominantly Android-focused, utilizing various available tools as demonstrated in prior studies [39, 40, 45, 67, 73, 81, 88]. Conversely, privacy research in iOS applications remains underexplored, despite its stature as a leading mobile platform and Apple's efforts to enforce privacy safeguards, such as mandatory privacy policies [2] and App Store privacy labels [6]. This research gap stems from Apple's closed ecosystem and the absence of off-the-shelf analysis tools. Existing literature has exposed considerable privacy risks within iOS applications [37, 48, 50, 63, 83, 84, 90], including recent findings on widespread non-adherence to privacy labels [84] and reports of extensive app suspensions by Apple for privacy violations in 2021 [4]. Notably, these studies primarily target app-level privacy violations, with less attention given to the influential role of third-party SDKs in perpetuating these issues—a critical aspect that merits deeper investigation in the realm of privacy research.

Modern programs, like mobile applications, heavily rely on third-party software development kits (SDKs) to ease development, reduce costs, and keep up with trends. While enjoying the convenience they bring, apps also have to bear the privacy risk incurred by the SDKs. [17, 47, 70, 74, 77, 80] have demonstrated that SDKs can introduce extra privacy problems to apps. Previous work [46, 47, 57, 67, 70, 71, 74, 77, 78, 79, 80] focused on analyzing and defending against privacy hazards in Android third-party SDKs, including a new kind of privacy violation called Cross Library Data Harvesting (XLDH in short) [80] among Android SDKs. However, no one has studied the problem in iOS SDKs.

Challenges. Several obstacles make it difficult to analyze privacy violations in iOS SDKs:

• **Lack of dataflow analysis tools.** Compared to apps, SDKs are unsuitable for dynamic analysis because they have no entries and cannot be dynamically executed like apps. Existing tools for iOS binaries, such as PiOS [50] and iRiS [48], are limited in their static analysis capabilities, particularly in terms of sophisticated data flow analysis like taint tracking, which is crucial for examining the transmission of privacy data. On the other hand, traditional static dataflow analysis tools [14, 33, 56, 58, 72] for binaries on other platforms cannot handle the semantics of Apple's unique Objective-C and Swift languages. As a result, a static dataflow analysis tool for iOS binaries, which can properly handle Objective-C and Swift semantics, is required to analyze iOS SDKs.

• **Unclear mapping between iOS system APIs and privacy-related data.** System APIs are fundamental sources of user privacy on devices. Yet, a comprehensive and precise list of iOS system APIs that yield privacy-sensitive data, as governed by privacy laws or regulatory frameworks, remains unavailable.

Methodology. We developed an automated static analysis system, *iHunter*, dedicated to performing taint analysis on iOS binaries with flow-sensitive, context-sensitive, and field-sensitive granularity by tackling obstacles imposed by Apple's unique languages. As the foundation of *iHunter*, an innovative iOS-oriented extension to symbolic execution is proposed to handle the dynamic features of Objective-C and Swift and perform taint propagation. Prior works [48, 49, 50, 82] manually defined a limited set of system APIs that return privacy-related data (e.g., device identifier, location, contacts, etc), in which coverage and accuracy cannot be guaranteed. Moreover, the invocation of system APIs, like string operations and array/dictionary manipulation, heavily affect taint propagation, which commonly requires a time-costing cross-binary analysis into the system libraries. To tackle these two challenges and ensure high coverage and efficiency, *iHunter* proposes a fully automatic method to extract sources of privacy data and rules of taint propagation from Apple's high-level system APIs without the need to perform cross-binary analysis. In particular, our system adopts natural language processing (NLP) on Apple's developer documents to automatically extract sources and taint rules from the description of APIs. With taint sources, sinks, and rules, *iHunter* generates taint traces that represent the privacy collection behaviors of SDKs. Our thorough evaluation shows that *iHunter* can extract taint traces effectively and efficiently.

Large-scale analysis and findings. Our approach involves comparing the taint traces, as identified by *iHunter*, against the privacy policies of iOS SDKs procured from their respective websites to scrutinize the adequacy of disclosure regarding their data practices. *iHunter* identified non-compliance in 2,585 SDKs (accounting for 40.4%) out of 6,401 iOS SDKs, signifying a substantial presence of SDKs that fail to adhere to compliance standards. Specifically, we categorized non-compliant SDKs as follows: 2,436 were marked as non-compliance type I, exhibiting data processing activities without any privacy policies; 58 were classified as non-compliance type II, having privacy policies that either neglect to mention or incorrectly represent their data processing activities; and 45 were recognized as non-compliance type III, these SDKs were engaged in data harvesting from other SDKs, violating the Terms of Use of the victim SDKs. We further examined the prevalence of these SDKs in real apps and assessed how these non-compliant SDKs affect the privacy compliance of the apps. We found that 15,336 (47.2%) apps have integrated at least one of the problematic SDKs. Due to non-transparent data practices and improper disclosures of the SDKs, those real apps come with practical risks of privacy noncompliance based on the Apple app store policy. Specifically, Apple app store [6] requires that app vendors should conspicuously disclose (using a privacy policy) all data practices (e.g., collection, sharing) occurring in the app, including those performed by third-party libraries. We characterize the findings with case studies, including the occurrence of XLDH [80], an emerging type of privacy violation previously reported on Android. This has been found in highly popular SDKs such as AppsFlyer [7]. The results of our first large-scale study indicate the prevalence and severity of privacy violations in the iOS apps' supply chain.

Contributions. We summarize key contributions as follows.

• We performed a systematic study on privacy violations in the iOS SDKs. Our results shed light on the prevalence, and seriousness of privacy violations in iOS SDKs.

• We introduced *iHunter*, a comprehensive system designed to systematically scrutinize privacy compliance among iOS SDKs and detect potential violations.

• We conducted a large-scale study of 6,401 iOS SDKs and discovered a high portion (40.4%) of privacy violation behaviors. Moreover, we provide detailed case studies of violations of privacy policies and cross-library data harvesting SDKs affecting real-world iOS apps. This sheds light on the prevalence and severity of privacy violations in the iOS apps' supply chain.

• We plan to release the source code of *iHunter* [36] to facilitate future research on iOS and related datasets in this study.

2 Background

2.1 Programming Languages in iOS

Objective-C [19], the fundamental programming language of iOS apps, offers features such as dynamic typing, messaging, and reflection, enhancing its usability and adaptability. Yet, its unique dynamic features and runtime mechanisms introduce complexities in taint tracking, especially concerning runtime method calls and dynamic types. Objective-C invokes methods by passing function names (selectors) and objects to a standard `objc_msgSend` function. This function dynamically

determines the method implementation at runtime, enhancing program flexibility. However, this dynamism, managed by the Objective-C runtime, complicates taint tracking and data flow analysis, as runtime behavior modifications can alter data flows. Existing literature [48, 50, 82, 84] has explored these challenges in the context of Objective-C binary analysis.

Swift is Apple's new programming language designed for iOS development. It is primarily a statically typed language, known for its emphasis on safety, performance, and user-friendliness. Swift primarily uses static dispatch for function calls, yet it can employ dynamic dispatch by specifically marking a function as 'dynamic.' This change allows the system to decide at runtime which overridden method to execute, rather than making this determination at compile time. In addition, the Swift compiler utilizes name-mangling [60] to generate unique identifiers for each function to be called. Name-mangling is a technique used to produce a distinctive identifier for an object based on its language-level name and type, which can be leveraged by the linker to reference the object. When performing a static taint analysis on Swift binaries, the dynamic dispatch mechanism and the name-mangling scheme used for function names can present significant obstacles in determining which functions in the Swift SDK are being called. This necessitates an in-depth analysis of the runtime behavior of Swift binaries to ascertain the object types and resolve function calls dynamically.

2.2 Taint Analysis and Challenges

Taint analysis can be defined as a graph reachability problem on the program's data flow graph (DFG in short). Given a binary, our goal is to detect the paths from source nodes N_{so}, where privacy data is collected, to sink nodes N_{si}, where privacy data is leaked, within the data flow graph G_d. Commonly, static taint analysis can be summaries with steps as follows:

① Construct the data flow graph $G_d = (N_d, E_d)$ of the whole program. N_d is the node set consisting of registers and memory locations. E_d is the edge set that contains the data flow edges $e_d = (n_1, n_2)$, where data value in n_2 depends on n_1.

② Define and identify source/sink nodes in N_d, and use them to construct N_{so} as the set of initial nodes and N_{si} as the set of terminated nodes.

③ Extract all paths from nodes in N_{so} to nodes in N_{si} within the directed graph G_d, which can be formulated as a graph reachability problem $R = (D_d, N_{so}, N_{si})$.

Challenges. Performing a thorough static taint analysis on iOS app binaries poses several challenges.

• *Dynamic features of unique languages.* As we introduced in § 2.1, the default method invocation mechanism in iOS development is a dynamic dispatch. This mechanism is standard in binaries written in Objective-C and Swift, the two primary programming languages used in iOS development. Resolving the actual targets of dynamic calls serves as the foundation for constructing inter-procedural DFG and enables further taint analysis. To this end, static analysis needs to abstract the high-level semantics of dynamic dispatching functions (e.g., `objc_msgSend` and `dispatch_async`), and analyze along control flow to find out clues deciding the final targets of such dynamic calls. Backward slicing [48, 50], forward propagation [52, 82], and their combination [49] are the most widely adopted approaches to solving this problem in prior works. However, with the rapid and massive growth of the binary size, we need a more efficient method to both solve dynamic calls and perform taint analysis. In *iHunter*, we develop an iOS-oriented symbolic execution engine to tackle the dynamic features of languages, build an accurate DFG, and eventually facilitate taint analysis. This engine, together with other tactics, will be described in § 4.3.

• *Broadly utilized system APIs.* Symbolic execution and related techniques can only help us handle instruction-level taint analysis issues. However, the data flow could be truncated when binaries call external functions implemented outside of the binary, due to the lack of high-level semantics of the external functions. Cross-binary function calls are mainly caused by the invocation of system APIs since iOS SDK vendors seldom compile code into multiple binaries to avoid high integration costs for developers. If we do not handle these API calls properly, the data flow will not be complete. An intuitive method would be performing cross-binary analysis on iOS framework binaries to complement the apps' data flow. However, all iOS system APIs are compiled into a single enormous binary (about 3GB) called `dyld_shared_cache`, which is nearly impossible for a thorough static data flow analysis. In fact, it is not feasible to fully load the binary using static analysis tools (e.g., IDA Pro, Ghidra, Hopper) on commodity hardware (with 32 GB memory and 8-core CPU). To effectively and efficiently address the challenges, we develop an NLP-powered taint rule generation technique for iOS system APIs, to extract and abstract taint propagation semantics from iOS API documentation. Our methodology will be presented in § 4.2.

3 Compliance Criteria for Third-Party SDKs

This section elaborates on the criteria used to consider SDKs as non-compliant, based on their adherence, or lack thereof, to prevalent privacy laws such as the General Data Protection Regulation (GDPR) [35] and the California Consumer Privacy Act (CCPA) [34], or Terms of Service (ToS), as enumerated in Table 5. While adhering to GDPR and related regulations, we consider personal data based on state-of-the-art privacy-data ontologies [39, 40], including categories like "device information", "tracking information", "contact information", "location information", etc. We define data collection practices of SDKs as any data flow that accumulates personal data through sensitive source APIs and then transfers this data

to network or storage APIs. SDKs that conduct data collection practices, including storing, collecting, or transmitting, personal data and meet any of the following conditions are considered non-compliant:

• ***Non-Compliance Type I: Absence of a Privacy Policy.*** SDKs, when processing personal data through actions like collection, sharing, storage, or access under their own means and purpose, act as data controllers. As articulated in Article 12 of the GDPR: "The controller shall take appropriate measures to provide any information referred to in Articles 13 and 14 and any communication under Articles 15 to 22 and 34 relating to processing to the data subject in a concise, transparent, intelligible and easily accessible form, using clear and plain language." Failing to provide a privacy policy detailing this information is a violation of GDPR (i.e., Article 12) and CCPA (i.e., Section 1798.100(b)). In our study, SDKs that engage in data processing activities without providing a privacy policy are categorized as Non-Compliance Type I.

• ***Non-Compliance Type II: Inappropriate Disclosure in Privacy Policies.*** Compliance with privacy laws requires not just providing a privacy policy, but also need to provide a correct and comprehensive declaration of data processing practices in the privacy policy. For example, GDPR (Article 5(1)(a)) requires "Personal data shall be processed lawfully, fairly and in a transparent manner ('lawfulness, fairness, and transparency')." Any inconsistencies between actual practices in code behaviors and those stated in the privacy policy are deemed a violation. We employed the flow-to-policy consistency model as detailed in [40]. Our analysis focuses on two key inconsistencies: omit disclosure and incorrect disclosure, both of which are regarded as violations in previous works [81, 87, 92]: (1) Omit Disclosure arises when data is collected, but there are no statements in the privacy policy that disclose or mention this collection. (2) Incorrect Disclosure is present when data is indeed collected, but the privacy policy conversely states that such a data collection does not occur. We classify the SDKs as Non-Compliance Type II if any above violations are detected.

• ***Non-Compliance Type III: Transgression of ToS Provisions.*** For an SDK that accesses user data from other third-party SDKs, we check whether it violates the ToS policy of the latter. The ToS policy of an SDK may impose different restrictions when another SDK tries to access its specific data, in particular "no third-party access", "requiring user consent", and "complying with regulations" [80]. A violation of the SDK ToS policies is considered Non-Compliance Type III.

4 Design and Implementation of *iHunter*

4.1 Overview

Architecture. Our approach relies on extracting data flow statically from SDK binaries and assessing compliance with

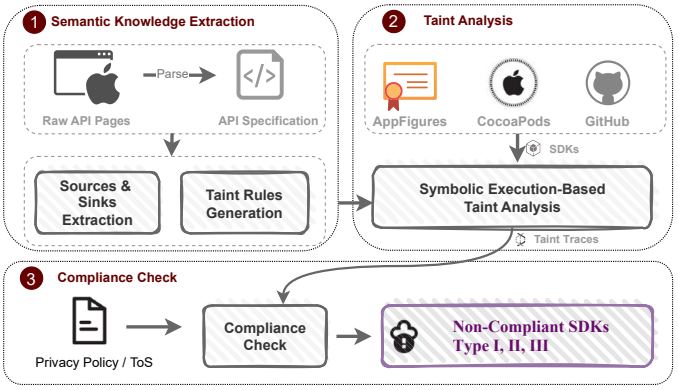

Figure 1: Overview of *iHunter*

their respective privacy disclosures to identify non-compliant SDKs. In particular, the design of *iHunter* includes three major components: Semantic Knowledge Extraction, Taint Analysis, and Compliance check, as outlined in Figure 1.

Component ❶: Semantic Knowledge Extraction § 4.2 Our approach employs NLP techniques to extract semantic knowledge from API documentation, yielding two key elements: (1) taint sources, identified as sensitive APIs that return privacy data, and (2) taint rules applicable among system APIs. Those semantic knowledge are crucial for constructing a data flow graph in subsequent taint analysis. Note that this process is a one-time preparation step, necessitating execution only once for the entire system.

Component ❷: Taint Analysis § 4.3 Armed with semantic knowledge outlined in § 4.2, *iHunter* employed under-constrained symbolic execution to construct data flow graph (DFG) and further extract taint traces from sources to sinks within this DFG. Each identified taint trace represents a unique data flow, indicating specific data processing activity, such as accessing, storing, or transmitting privacy data.

Component ❸: Compliance Check § 4.4 After extracting the taint traces, we further compare them with the corresponding privacy disclosures. To achieve this, we employed a set of consistencies model in [40, 80] to detect different types of non-compliance SDKs.

4.2 Semantic Knowledge Extraction

Taint sources, sinks, and rules are crucial for constructing the data flow graph during taint analysis. Previous research depended on manually-curated taint sources (10 in [50] and 150 in [48]), which were neither comprehensive nor scalable, especially considering the existence of nearly 60,000 documented public APIs. Traditional methods, focusing on instruction-level analysis, often miss system-level API taint rules, leading to incomplete call graphs and data flow graphs. Our methodology addresses these gaps by automatically formulating taint

sources and taint rules that span system APIs.

Collect API information. We utilized a crawler to extract semantic data from 60,372 pages of Apple developer documents [29], yielding detailed information on 60,153 public API specifications. This data, encompassing aspects like API names, descriptions, parameters, and return value, enriches our subsequent NLP analysis

Source extraction. To detect data flows involving private data , we initially establish a set of sensitive system APIs to serve as taint sources. Our methodology classifies an API as privacy-sensitive if its return value corresponds to privacy terms within a privacy data ontology as mentioned in [39, 40], which constitutes a graph data structure of privacy terms in legal documentation (e.g., privacy policy/terms of use). To this end, we semantically align the data objects in the API specification to privacy data ontology, facilitated by vector computations using an embedding technique. Specifically, we enhance the skip-gram-based word2vec model in [80], incorporating 60,372 Apple iOS documentation. We classify a system API as a sensitive API if the similarity score between its return value and the privacy terms within the privacy data ontology exceeds 0.885. This similarity threshold was empirically determined by manual examination of a random sample of 500 APIs from the Apple documentation (see evaluation details in § 5.2).

Sink collection. We categorized the potential privacy violation behaviors into two major types: (1) *privacy leakage*, which involves transmitting private data out of devices and storing private data in the file system, and (2) *privacy collection* which contains other activities about related to privacy while not being privacy leakage, e.g., logging by the "NSLog" function. The sink APIs associated with these behaviors are typically defined in the official *Foundation* framework and C-type functions, such as "connect" and "send" in POSIX socket programming. Hence, we conduct a manual investigation of the *Foundaiton* framework and various popular third-party network SDKs. Through this process, we collect 372 APIs from the framework and POSIX, along with 26 APIs from third-party libraries. These included 198 network APIs that handle data transmission out of the device, 138 storage APIs that deal with data stored on the device, and 62 other data-collecting APIs.

Taint rule generation. Taint rules serve as a fundamental component in data taint analysis, providing guidance for tracking the flow of sensitive data as it propagates from system APIs to network or file system APIs. Apple provides detailed specifications for each system API in its document website for developers [29], encompassing elements such as function description, signatures, parameters, and return types. That information can be utilized to infer the trajectory of taint propagation between the parameters and the returned data. For example, consider the API `void NSDecimalCopy(NSDecimal *destination, const NSDecimal *source)`, whose function description is "*Copy the value in source to destination*". From the description, we can infer that the taint rule is from *NSDecimal *destination* to *const NSDecimal *source*. Apple's software ecosystem comprises an extensive 259 frameworks, including over 60,000 APIs. Manual inference of taint rules from such a significant quantity of APIs is undoubtedly a laborious and time-consuming undertaking. To generate taint rules automatically, in our study, we implement a series of Natural Language Processing (NLP) techniques to retrieve semantic information of API in the Apple API documentation.

Table 1: Adpositions associated with propagation direction

Direction	Adpositions List Example
To	in, into, onto, towards
From	with, by, for, at, by, via, through

Taint rules between parameters. API descriptions often use patterns to depict the relationship between parameters and their propagation. For example, the description "Adds data to a compression context" uses the adposition "`to`", marking "*data*" as the taint source and "*compression context*" as the taint sink. Conversely, the adposition "`from`" reverses these roles: in "read the source graph from a specified file", the taint source is "a specified file", and the taint sink is "the source graph". We employed the SpaCy dependency parser [23] for automated extraction of taint rules, identifying the `VERB` and `Adposition` to locate the direct object and adposition object respectively. The direction of propagation was determined by constructing two lists of adpositions signifying distinct directions of propagation, derived from a manual examination of the 650 API documentation, as shown in Table 1. This keyword list guided our determination of whether the direct object or the adposition object functioned as the taint source.

Taint rules from parameters to return value. Regarding propagation from parameters to the return value, our base assumption is that any input parameter propagates to the final return value, given that the API's return value is non-void. This is because iOS SDK APIs often process and transform input parameters, thereby incorporating them into the return value. An exception to this rule arises when dealing with instance methods that do not return a value (void return type), but induce a field change in the instance object. This effect is often a result of taint sources (parameters) influencing the object's fields. In such scenarios, the instance object is treated as the taint sink, and the parameters are considered taint sources.

4.3 Taint Analysis

To tackle the challenges associated with analyzing Mach-O binaries on iOS, particularly their dynamic dispatching feature, *iHunter* employs under-constrained symbolic execution. This allows *iHunter* to accurately resolve the targets of dynamic dispatching functions and construct Data Flow Graphs (DFGs), which serve as the basis for taint analysis. The taint

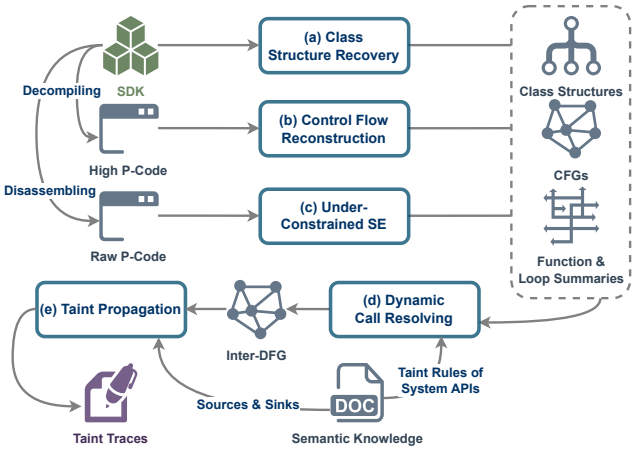

Figure 2: Taint analysis process in *iHunter*

analysis framework in *iHunter* comprises five essential steps, as depicted in Figure 2. These steps are as follows:

(a) Class Structure Recovery. This step is essential for static field-sensitive analysis on binaries compiled from object-oriented languages like Objective-C and Swift. *iHunter* adopts an approach similar to PiOS [50] to parse the header and `__OBJC` segment in the binaries and recover information of classes defined in the binary. The information includes (1) the class inheritance tree, (2) the name, prototype, and address of class methods (3) the name and type of class properties. Additionally, We gather information on dynamically linked libraries in this step to facilitate searching taint sources, i.e., only sensitive APIs defined in linked libraries will be searched before the final taint propagation step.

(b) Control Flow Reconstruction. In *iHunter*, intra-procedural Control Flow Graphs (intra-CFGs) are constructed using basic blocks produced by lifting tools such as *Ghidra*. These basic blocks are then split at each call site to ensure accurate analysis. Loops will present challenges to symbolic execution and type inference in the subsequent analysis. To overcome these challenges, we employ a stack-based topological sorting algorithm during the control flow reconstruction step to identify nested loops and extract essential loop information, including entry points, exit points, and loop levels, which serves as the foundation for generating loop summaries later. Furthermore, in Swift binaries, function names are mangled, which presents a challenge when trying to match these function calls to the APIs in the iOS system SDKs. To overcome this issue, we have developed a demangling tool that can convert these mangled names back into their original function names. The demangling tool achieves this by parsing the mangled names using a finite-state automaton and recovering the encoded type names. The extracted type information is then utilized by *iHunter* to perform an accurate taint analysis in Swift.

(c) Under-Constrained Symbolic Execution. We have developed an under-constrained symbolic execution engine specifically designed for generating Data Flow Graphs (DFGs) in iOS Mach-O binaries. This engine operates under the under-constrained setting, inspired by the approaches in [69, 72], to prevent state exposition during the SE process. The engine is designed to handle various types of variables, including those stored in the stack, registers, or stored in the heap as global variables. In addition, it also collects comprehensive type information to assist in dynamic call resolving during subsequent analysis steps. The SE engine consists of four main stages, including:

Stage ❶: Symbol Initialization. *iHunter* symbolizes all function parameters, stack variables, and heap-allocated variables. This allows us to obtain a more accurate representation of the program's data dependencies and understand the full range of data values used throughout the program.

Stage ❷: Symbolic Execution on Raw p-code In *iHunter*, the symbolic execution process is conducted based on *Ghidra*'s *raw p-code* Intermediate Representation (IR) [13]. *Raw p-code* represents a low-level IR that preserves the original semantics of instructions. To tackle the challenge of context-sensitive taint analysis, we introduce a data structure called the context-switch table to record the call trace of each function encountered during the symbolic execution process. By maintaining this call trace information, *iHunter* can accurately track the flow of tainted data across function boundaries and maintain context sensitivity. Additionally, in *iHunter*, the iOS-oriented symbolic execution engine goes beyond calculating symbolic or concrete values for registers and memory locations. It also propagates type information associated with these values, enabling accurate resolution of the targets of `msgSend` calls. This approach enhances the efficiency of *iHunter* by constructing DFG and collecting information for type resolution in a single pass.

Stage ❸: Loop Summary and Function Summary. Loops and function calls can significantly impact the efficiency of symbolic execution, leading to state explosion and recursive resolving challenges in data flow analysis. To tackle this, *iHunter* generates function and loop summaries by employing symbolic execution within the function or loop during the initial encounter, and subsequently reuses these summaries when encountering them again. Specifically, these summaries include key information such as data flow transmission and symbolic variable type information. When generating function summaries, *iHunter* symbolizes function arguments and explores each path within the function to identify data flows represented as symbolic expressions and variable types. This process accounts for specific side-effects like API calls dependent on particular inputs, discerning specific paths within the function. Similarly, loop summaries are generated by leveraging symbolic execution during the first iteration of the loop, analyzing and tracking symbolic variables within it. Subsequently, during re-entry into the loop (2nd iteration), the symbolic execution finalizes results by identifying any

discrepancies compared to the initial iteration.

Stage ❹: Block Function Processing. Objective-C supports function closure which is compiled into function pointers in designated structures (`NSConcreteGlobalBlock` and `NSConcreteStackBlock`). These structures are frequently used in dispatch functions or as callback parameters of system APIs. *iHunter* traces the data flow associated with the closures, identifies the structures during symbolic execution, and generates a function summary in a specialized format to document the data flow and the type propagation rules for each closure. When the closure structure is transmitted to a dispatcher function, *iHunter* links its context information with the call site and adjusts the symbolic data flow in the generated summaries.

Through symbolic execution, we generate summaries for each function, which can be considered as intra-procedural Data Flow Graphs (intra-DFGs), and form the basis for the subsequent context-sensitivity, flow-sensitivity, and field-sensitivity inter-procedural taint analysis [66].

(d) Resolving Dynamic Calls. *iHunter* resolves the targets of `msgSend` dynamic calls by resolving the type of objects and selector names passed into `msgSend` during this step. As the dynamic dispatching calls are resolved, *iHunter* constructs the data flow in the whole program as the inter-DFG. To this end, *iHunter* employs a two-pass approach. During the first pass, *iHunter* leverage the context-sensitive intra-DFGs generated by SE and taint rules of system APIs extracted from documents. By a rapid backward slicing approach leveraging these data flow summaries, *iHunter* identifies all message-sending sites and endeavors to infer the class type of the message sender, which demonstrates efficiency compared to prior approaches [48, 50, 52]. In the second pass, *iHunter* focuses on refining the resolved dynamic call targets. A worklist algorithm is employed that iteratively updates and refines the dynamic call targets. The refining terminates until both the control flow and data flow stabilize, reaching a fix-point, meaning that the resolving has been carried out to a quite complete level. For other indirect calls in Swift, which can be C++ like function pointers, *iHunter* utilizes dataflow in summaries and tracks addresses stored in memory, as well as the memory block referenced by function pointers. It establishes matching between function pointers and addresses to function to determine the targets of C++ style indirect calls in Swift code.

(e) Taint Propagation. In this final analysis step, *iHunter* extracts all taint traces from the inter-DFG. Considering the propagation efficiency, *iHunter* first simplifies the DFG into a taint graph, which exclusively includes data flows connecting to a source or a sink. Subsequently, it traverses this taint graph using a flooding algorithm to determine reachability from sources to sinks, thus generating the taint trace results.

4.4 Compliance Check

This section details the methodology *iHunter* uses to identify the three types of privacy violations referenced in §§ 3.

Non-Compliance Type I. SDKs processing personal data without an available privacy policy are labeled as Non-Compliance Type I. To determine the privacy policy of an SDK, we leverage the polisis [55] tool, which fetches privacy policies using an SDK's official website URL. Retrieving these official websites varies based on the SDK's source platform: AppFigures, CocoaPods, or GitHub. For SDKs from AppFigures, the platform directly provides the official website URL for each top-ranked SDK listed. CocoaPods-hosted SDKs come with specifications. We analyze these specifications to derive the SDKs' homepage URLs. GitHub, on the other hand, poses a challenge due to the absence of direct links to official websites. To circumvent this issue and prevent overlooking any official websites, we use a semi-automatic approach. First, we extract all URLs located in the SDK's README file. Subsequently, we manually discern the URL that represents the SDK's official website. If no URL is discovered, the SDK is considered as not providing a privacy policy. Given the low frequency of URLs in README files (see details in §§ 6), conducting a manual examination is feasible.

Non-Compliance Type II. SDKs displaying inconsistencies between their code's data collection practices and disclosures in their privacy policy are categorized as Non-Compliance Type II. Specifically, we employed PoliCheck [40] to extract data-action tuples from their policy statements in the privacy policy. Then we utilized the flow-to-policy model of PoliCheck [40] to compare the dataflows that were detected from code with data-action tuples in privacy policy to detect any omit and incorrect disclosure.

Non-Compliance Type III. SDKs that illicitly obtain data from other "victim" SDKs, thereby breaching the Terms of Use (ToS) of these victim SDKs, are designated as Non-Compliance Type III. For any suspected unauthorized data retrieval from a victim SDK, it's imperative to ascertain if the caller SDK breaches the victim SDK's ToS. Using the approach outlined in [80], we extract the conditions under which individual data items are restricted by the ToS and then check whether caller SDK satisfies those requirements. There are two main conditions: (1) *No Access Allowed*: Under this condition, any access to the data by caller SDKs from victim SDKs is a violation. (2) *Regulation Compliance Required*: Violations arise if SDKs inadequately or incorrectly disclose data practices in their privacy policies that contradict regulatory mandates. To validate compliance, similarly, we analyze the caller SDK's privacy policy, ensuring accurate data collection practice disclosures.

4.5 Implementation

The *iHunter* system is implemented based on the Ghidra [14] reverse engineering platform as an analysis plugin, specifically implemented under Ghidra v10.3.1. The entire system is written in Java, Python, and Swift, with a total of about 29,000 lines of code. For the static taint analysis part, *iHunter* leverages two types of IR in Ghidra: *raw p-code* generated from disassembling for symbolic execution and *high p-code* generated by the Sleigh [22] lifter/decompiler for control flow reconstruction. For multiple binaries within a single SDK, *iHunter* treats all of them as components of the SDK and conducts independent analysis on each binary.

5 Evaluation of *iHunter*

In this section, we perform comprehensive evaluations of both the overall system of *iHunter* and the individual components. We aim to assess the effectiveness of each component as well as their combined impact and performance on the system. All evaluations of *iHunter* were conducted on three MacBooks with 16/32 GB memory. Our implementation ensures that the results remain consistent across various MacOS devices.

Evaluation dataset. We established a ground truth dataset named D_g to evaluate the effectiveness of *iHunter*. First, we randomly selected 50, 40, and 40 SDKs from AppFigures, Cocoapods, and GitHub respectively, ensuring the generality of our results. We further employed IDA Pro [56] and Ghidra [14] to reverse-engineer those SDKs, manually tracing the path of privacy data from source APIs to sink APIs (e.g., network transmission or file system storage). In total, we identified 325 taint traces that process privacy data.

5.1 Evaluation of the Entire *iHunter* System

Overall effectiveness of *iHunter*. *iHunter* analyzes SDKs along with their relevant privacy policies or Terms of Service (ToS), identifying and categorizing SDKs into three distinct non-compliance types. To evaluate the overall effectiveness of *iHunter*, we first built a ground-truth SDK dataset (D_g) and conducted a manual check to identify taint traces of privacy data. Subsequently, we assessed the non-compliance of these data practices by (❶) manually searching the SDK's privacy policy, flagging its absence as Non-Compliance Type I; (❷) if a privacy policy was present, manually verifying whether these data practices are appropriately disclosed; and (❸) if the data is harvested from another victim SDK, evaluating whether such practices violate the victim SDK's ToS.

Ultimately, 59 (45.4% in 130) SDKs were deemed non-compliant, with classifications of 49 (83.1%) as Non-Compliance Type I, 10 (16.9%) as Type II, and 4 (6.8%) as Type III, while 3 (5.1%) as both Type I & III and 1 (1.7%) as both Type II & III. On the ground-truth dataset, *iHunter* identified 209 taint traces and classified 179, 25, and 5 as Non-Compliance Type I, II, and III, respectively.

Table 2: Overall effectiveness of *iHunter*. *"#SDKs" refers to the number of non-compliant SDKs detected by iHunter.*

Non-Compliance Type	#SDKs	Precision	Recall	F1
Type I	49	83.7%	74.5%	78.8%
Type II	10	60.0%	66.7%	63.2%
Type III	4	75.0%	100%	85.7%
All types	**59**	**81.4%**	**75.0%**	**78.1%**

• *Results. iHunter* achieve an average F1 score of 78.1%, marked by 81.4% precision and 75.0% recall. As detailed in Table 2, *iHunter* demonstrated a precision of 83.7% and a recall of 74.5% for Non-Compliance Type I, a precision of 60.0% and a recall of 66.7% for Type II, and a precision of 75.0% and a recall of 100% for Type III. *iHunter* exhibits superior detection accuracy for Non-Compliance Type I and III compared to Type II. This discrepancy can be attributed to the incomplete extraction of private data declarations using existing NLP tools (PoliCheck [40] and Polisis [55]), resulting in relatively low precision and recall. To mitigate the potential instability associated with using prior tools, we manually checked and confirmed the results for Non-Compliant SDKs Type II detected by *iHunter* and their corresponding privacy policies, which helps ensure the accuracy and reliability of our measurements (§ 6.1).

• *False positives and negatives analysis.* In addition to the accuracy of the privacy policy extraction tool affecting the results, the rest false positives were mainly caused by inaccurate data flow propagation, such as data transmission in Objective-C collection classes (e.g., `NSArray`, `NSDictionary`). This confusion in data flow introduced wrong crossings between instances and pointers in the containers, which resulted in the generation of non-existing taint traces. On the other hand, false negatives were mostly caused by the limitations in resolving dynamic calls of templated classes and containers, which affected *iHunter*'s ability to identify source API calls.

Performance overhead. The average time consumed to analyze a binary in our datasets with the average size (2.2 MB) is 7.5 min, consisting of 4 minutes of loading and pre-analysis time by *Ghidra* and 3.5 minutes of analysis performed by *iHunter*. To analyze 6,401 SDKs in our three measurement datasets, it took almost two weeks to complete the analysis on our three testing devices. This analysis is efficient considering the measured time starts from when the binary is being loaded into *Ghidra* (which was commonly considered to be time-consuming) to when *iHunter* generates all taint traces. Such high performance is the consequence of a combination of hand-picked techniques like on-demand type inference, one-pass symbolic execution, loop summary, function summary, etc. In our evaluation of *iHunter*, we observed that

the maximum memory usage during the analysis reached 19GB. This was mainly due to the decompilation process performed by the *Sleigh* lifter [22], which requires significant memory resources to execute. Since all of the analyzing stages in *iHunter* are parallelizable, the analyzing process can be significantly accelerated by running *iHunter* on a server parallelly.

5.2 Effectiveness of Individual Components

Effectiveness of source API extraction. To evaluate the performance of source API extraction, we took a random sample of 500 APIs out of the total APIs incorporated from Apple iOS documentation. Through careful examination of the API specifications, we assigned each API a label of being either privacy-sensitive or non-privacy-sensitive. Utilizing our enhanced skip-gram-based word2vec model and a similarity threshold of 0.825 (which was empirically determined), we classified APIs as sensitive or not. This threshold was set to capture the similarity between the return value of an API and the privacy terms within the privacy data ontology. Our methodology proved to be highly effective since it successfully distinguished privacy-sensitive APIs with a precision rate of 88.5% and a recall rate of 92.4% on the manually annotated dataset. In general, our model flagged 2,340 sensitive APIs from the total pool of APIs. Following independent manual verification by two researchers, 1,951 APIs were confirmed as true positives and subsequently incorporated into *iHunter*'s analysis.

Effectiveness of taint rule generation. To gauge the effectiveness of our approach for taint rule extraction, we randomly sampled 500 APIs from a total of over 60,000 APIs that span across Apple's 259 frameworks. These APIs underwent manual analysis to establish ① propagation rules between parameters and ② rules between parameters and return values, serving as the ground truth. Under evaluation, *iHunter* achieved precision/recall rates of 85.9%/79.1% on ① and 89.6%/94.0% on ② respectively. Cumulatively, our methodology identified 1,395 propagation rules between parameters and 21,077 propagation rules between parameters and return values. This assessment further underscores the accuracy and precision of our automated approach in identifying taint propagation rules.

Effectiveness of data flow analysis. To assess the capability of *iHunter* in conducting static data flow analysis on iOS binaries, an evaluation was conducted to evaluate its accuracy and effectiveness in resolving dynamic calls. Specifically, we conducted comparative experiments using IDA Pro v8.3.2 as a baseline. We used IDA Pro and *iHunter* to parse the 41 SDKs in the subset of the ground truth SDK dataset D_g and analyzed the results of resolving dynamic calls using both tools. Of the calls dispatched by message, there were a total of 524,839 call sites for the `objc_msgSend` function or the `dispatch_async` function. Through the two-phase approach described in § 4.3, *iHunter* was able to resolve 480,091 dynamic calls **(91.5%)**, including both object types and selector names. This shows an improvement compared to the static analysis component in PiOS [50] (82%) and iRiS [48] (85%). Compared to the SoTA commercial reverse engineering tool, IDA Pro [56] was able to resolve 393,899 (75.1%) message-sending call sites. In addition, 352,784 (95.2%) of the call sites that could be resolved by both IDA Pro and *iHunter* produced the same resolving results.

As for the dynamic calls that *iHunter* can't resolve, several limitations contribute to this situation: **(a)** Tracking pointers stored in container instances like `NSArray` or `NSDictionary` can be challenging, and inferring their types is not straightforward. **(b)** There are numerous APIs exposed to external apps that are not called within the SDK. It becomes much harder to resolve message sending in these functions when the calls come from a parameter of these functions.

Additionally, we found that there were 20 SDKs written in Swift or partly written in Swift. The recall rate for resolving indirect calls in Swift code is 74.4%, notably lower than in Objective-C programs (91.5%). In Swift, some complex mangled function names and indirect calls through function pointers may not be fully resolved through symbolic execution, leading to this discrepancy. Utilizing *iHunter*'s ability, we were able to identify 7,819 Swift calls of dynamic dispatch to Apple's iOS SDKs. Until this point, other iOS binary analysis tools still lack this feature and Swift support.

Effectiveness of taint propagation. To separately evaluate the accuracy of taint propagation performed on the DFG, we constructed a dataset consisting of 325 manually identified taint traces in D_g. During the evaluation process, the source points and sink points of taint propagation were fixed to the termination points of these manually identified taint traces. Under the evaluation setting described, *iHunter* achieved a successful tracking rate of 85.8%, meaning it accurately traced the propagation of tainted data in 279 out of the total taint traces. The precision of the analysis was measured at 77.7%, so the F1 score was calculated to be 82.4%, affirming the effectiveness of our data flow analysis and taint propagation process.

6 iOS SDK Non-Compliance in the Wild

Running *iHunter* on 6,401 iOS SDKs, we show that the non-compliance of iOS SDKs is prevalent. We conducted a measurement study to understand the landscape of the non-compliant iOS SDKs and assess their real-world privacy implications for end-users and compliance risks of iOS apps that integrated the SDKs.

Measurement dataset. We made a broad collection and sampling from SDK repositories and built several datasets to study the situation of non-compliance privacy collection in the iOS apps' supply chain. As shown in Table 3, our collection comprises (1) 140 SDKs from $D_{AppFigures}$, 2,038 SDKs from D_{GitHub}, and 4,356 SDKs from $D_{CocoaPods}$, specifically

Table 3: Summary of datasets and corpora

Name	Size	Source	Timestamp	Usage
C_{api}	60,372 well-formed document pages	Apple Developer Documentation [29]	202305	Detection
$D_{AppFigures}$	140 SDKs	top SDKs in *AppFigures* [3]	202305	Detection
D_{GitHub}	2,038 SDKs	top-starred in *Github*	202306	Detection
$D_{CocoaPods}$	4,356 SDKs	sampled from *CocoaPods* [10]	202306	Detection
D_{sp}	244 SDKs' privacy policies	websites and repositories	202306	Detection
D_{ToS}	52 SDKs' Terms of Service	websites and repositories	202306	Detection
D_a	32,478 iOS apps	App Store top-popular list	2020-2022	Measurement
D_{ap}	1,358 apps' privacy policies	privacy links in App Store	202307	Measurement
D_{al}	1,040 apps' privacy labels	privacy labels in App Store	202307	Measurement
D_g	130 SDKs	randomly selected SDKs	202303	Evaluation

earmarked for detecting privacy violation behaviors, (2) privacy policies associated with 244 SDKs*, and (3) terms of service (ToS) for 52 designated victim SDKs. Further, to assess their real-world impact within the app ecosystem, we constructed a dataset of 32,478 apps collected from the App Store, denoted as D_{app}. These apps were collected from the App Store in July 2022 and were selected based on their inclusion in the top popular list or the top new list of the App Store or the *AppFigures* website. Among 32,478 apps, 15,336 (47.2%) of them integrated non-compliant SDKs. To assess how non-compliant SDKs lead to apps' privacy violations, we collected 1,358 privacy policies and 1,040 privacy labels from App Store pages.

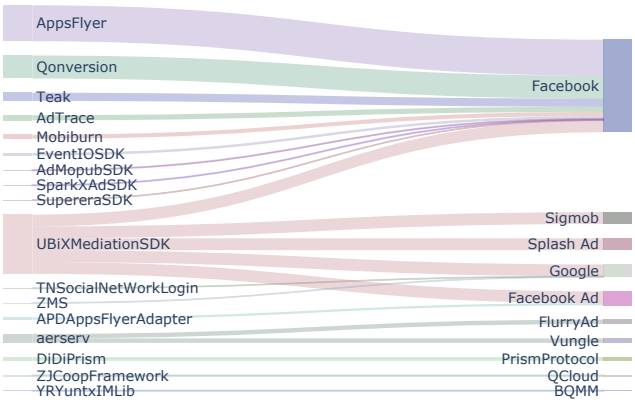

Figure 3: ToS Non-Compliant Flows: Non-Compliant SDKs Type III (left) fetching data from victimized SDKs (right)

6.1 Landscape

iHunter detected 2,585 (40.4%) non-compliant SDKs among a total of 6,401 iOS SDKs, revealing the prevalence of non-compliance. In this section, we perform an in-depth analysis of those non-compliant SDKs, examining their types of non-compliant, distribution sources, and categories.

6.1.1 SDKs of Different Non-Compliance Types

Using the compliance criteria defined in §§ 3, *iHunter* identified 2,436 SDKs with Non-Compliance Type I, 58 with Type II, and 45 with Type III†.

Non-Compliance Type I. In accordance with privacy laws, SDKs that process personal data without a privacy policy are considered Non-Compliance Type I. In our measurement, we extract the official websites of these SDKs and utilize polisis [55] to retrieve their privacy policies. We obtained 41, 110, and 93 privacy policies of SDKs with data collection practices (i.e., the SDKs get data through sensitive APIs, then send the data to the Internet through sink APIs (e.g., network APIs). in $D_{AppFigures}$, D_{GitHub}, and $D_{CocoaPods}$ respectively. Consequently, we identified 27 non-compliant SDKs in $D_{AppFigures}$, 454 non-compliant SDKs in D_{GitHub}, and 1,943 non-compliant SDKs in $D_{CocoaPods}$.

Non-Compliance Type II. *iHunter* initially identified 74 SDKs with Non-Compliance Type II. However, due to the potential imprecision resulting from the adoption of prior NLP tools for data disclosure extraction in the privacy policies of these SDKs (see § 5.1), we conducted a manual verification of the results before using the results for measurement. As a result, we confirmed 58 SDKs with Non-Compliance of Type II across two sub-categories:

• *Omitted Disclosure.* A data flow has an omitted disclosure when there are no policy statements that disclose it. We found 53 SDKs that failed to disclose an average of 102 data harvesting practices. The most commonly omitted data types included system running status, cellular service provider, and apps' active time.

• *Incorrect Disclosure.* A data flow has an incorrect disclosure if a policy statement indicates that the flow will not occur (i.e., a negative sentiment sharing or collection statement) and there is no contradicting positive sentiment statement. On average, 7 SDKs were found to provide incorrect disclosures about their data practices.

Non-Compliance Type III. SDKs that harvest user data from other third-party SDKs are considered with Non-Compliance

*We obtained privacy policies for 2,680 SDKs found to engage in privacy collection activities. However, only 244 were found, while the remaining 2,436 SDKs lacked privacy policies.

†Some SDKs may come with multiple non-compliance types.

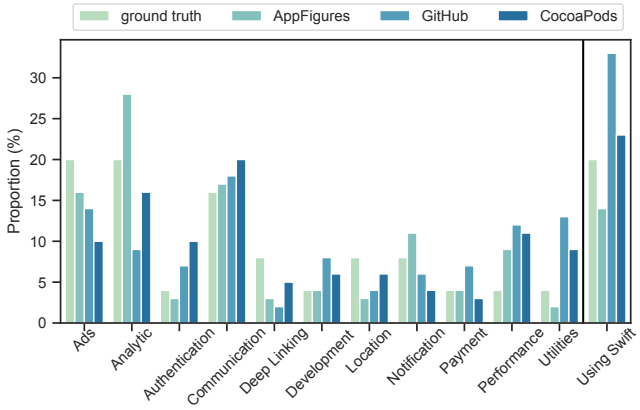

Figure 4: Distribution of non-compliant SDKs across different usage categories

Type III. Our analysis identified 45 SDKs with such non-compliance, which were integrated into 469 apps, targeting 15 victim SDKs. Figure 3 illustrates the victim SDKs and the corresponding number of Non-Compliance Type III that target them. The top 20 non-compliant SDKs, based on the number of apps affected, are considered. It should be noted that over half of these victimized SDKs are categorized as online social networks (OSN) and advertising, indicating that well-known OSN platforms and advertising providers are valuable sources of private user data for harvesting. Our study also uncovers the stealthy collection of advertising tracking tokens and access tokens from Facebook, Google, and WeChat by certain analytic SDKs. These tokens can potentially be exploited to gain unauthorized access to semantically rich personal data.

6.1.2 Distribution Source of Non-Compliant SDKs

During our measurement analysis, *iHunter* detected a total of 2,585 non-compliant SDKs across the three datasets. Specifically, 54 non-compliant SDKs were identified in $D_{AppFigures}$, 482 in D_{GitHub}, and 2,049 in $D_{CocoaPods}$. To understand potential differences in data collection practices among SDK sources, we calculated the average frequency of privacy violations for each dataset. As shown in Figure 6, there is a noticeable variation in the rate of privacy data collection across the datasets. Non-compliant SDKs collected from AppFigures based on AppFigures' statistics have an average of 9.9 practices of non-compliant privacy collection per SDK. In contrast, the top-starred SDKs from GitHub have an average of 2.9 non-compliant practices, while the SDKs randomly sampled from CocoaPods have an average of 4.2 non-compliant practices. Notably, the SDKs with high rankings in AppFigures are usually being widely adopted and favored by app developers — posing potentially high privacy risks.

Table 4: Severity Breakdown for the violations. *"No." refers to the number of privacy violations.*

Data Sensitivity	Data Examples	Non-Compliance Type	No.
Sensitive PII	Biometric Data,	Type I	322
	Health,	Type II	5
	Precise Location	Type III	22
PII	Email Address,	Type I	2,826
	Coarse Location,	Type II	67
	User ID	Type III	32
Non-PII	Crash Data,	Type I	2,388
	Performance Data,	Type II	70
	Diagnostic Data	Type III	7

6.1.3 SDK Categories

As shown in Figure 4, the predominant non-compliant SDKs serve purposes related to advertisement & monetization, analytics, and communication. Those SDKs have inherent motivations to amass a wealth of user data. Their data harvesting behavior is driven not only by their need to facilitate user analytics and cater to various commercial services but also by their significant reliance on advertising revenue and practices of monetizing user data, potentially selling data to external entities such as data brokers. Conversely, the open-source SDKs on GitHub are typically designed to assist with development, such as the Charts SDK [9] for plotting charts in apps. These types of utility SDKs typically may tend not to collect much user data leading to noncompliance.

6.1.4 Severity Breakdown for the Violations

To better characterize the severity of the violations we found, we further categorize data types into three groups: Sensitive PII, PII, and non-PII (based on definitions by the Department of Homeland Security [12]), with each group's relative severity regarding a privacy violation ranging from high to low. In our study, among the overall 5,739 non-compliance violations, we find 349 in Sensitive PII, 2,925 in PII, and 2,465 in non-PII. A detailed breakdown of each non-compliance type, along with their respective sensitivity levels, is presented in Table 4.

6.2 Real-World Impact of Non-Compliant SDKs

iHunter detected 2,585 SDKs as non-compliant, of which 694 (27.9%) contained data transmission out of the device. These SDKs have been integrated into 15,336 apps, which corresponds to 47.2% of our analyzed top-tier apps across 25 categories in the Apple App Store. This highlights substantial privacy risks for end-users. In this section, we study the real-world privacy impact of the non-compliant SDKs by examining their popularity and assessing how their non-compliance leads to non-compliance of iOS apps that integrate the SDKs.

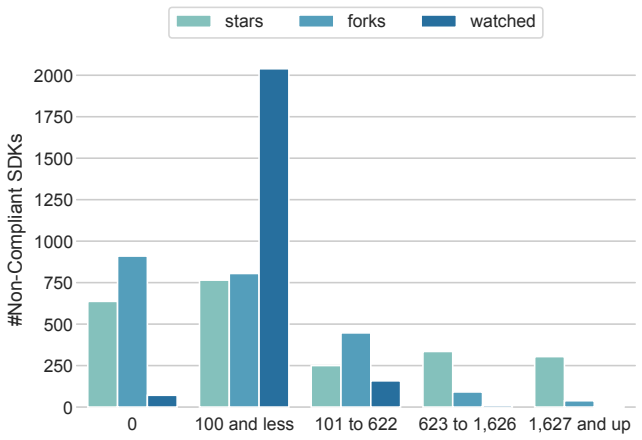

Figure 5: Distribution of GitHub *stars*, *forks*, and *watches* of non-compliant SDKs

6.2.1 Popularity of Non-Compliant SDKs

Assessing the popularity of non-compliant SDKs is crucial as it sheds light on their widespread adoption and potential ramifications in the broader iOS ecosystem. For this assessment, we consider two metrics: (1) engagement metrics on GitHub: *stars*, *forks*, and *watches*; (2) number of real-world integrations of the SDKs in real-world iOS apps.

Engagement on GitHub. For the non-compliant SDKs hosted on GitHub (2,291 in total), we evaluated user interactions by counting primary engagement actions: watching, forking, and starring. These actions elucidate the varying degrees and kinds of user engagement. As shown in Figure 5, a large proportion of non-compliant SDKs, specifically 38.8%, have received more than 100 stars, indicating a relatively high user preference for these SDKs.

Integration within apps. To measure the integration of the non-compliant SDKs in real-world scenarios, we employed a class structure matching algorithm (details in Appendix A) to scrutinize SDK presence within apps, which allows us to understand the prevalence of their adoption and distribution pattern. We found that 47.2% of apps integrated at least one non-compliant SDK.

6.2.2 Propagation of Non-Compliance into iOS Apps

App developers, based on privacy regulations such as the GDPR and Apple app store policies, are obligated to transparently disclose all data handling behaviors, including those performed by third-party libraries. From our dataset, we discerned 14,811 instances of non-compliant data collection across 339 SDKs integrated into 15,336 apps. Among these apps, only 1,358 apps provided links to privacy policies, and 1,040 apps provided privacy labels on the app's Apple app store pages. This section assesses the extent to which non-compliant SDKs integrated into apps led to the app's non-compliance (i.e., the apps' privacy policies or privacy labels did not disclose the data practices of the SDKs).

Non-Compliant privacy policy in apps. When app developers integrate third-party libraries that collect personal data, they remain the primary controller and are thus responsible for ensuring that users are comprehensively informed in the privacy policy, as stipulated by GDPR's Article 13 (i.e., Article 13[‡]). However, data practices performed by SDKs are often opaque to app developers. Without meticulous examination of these practices, non-compliant behaviors from SDKs might inadvertently propagate into apps, posing significant privacy risks to end-users. To evaluate the adequacy of privacy policy disclosures for data practices by SDKs, we collated apps' privacy policies and employed PoliCheck [40] to extract data items and their associated actions from these policies. Subsequently, PoliCheck's consistency model was utilized to verify the comprehensiveness and correctness of these disclosures. In our analysis, *iHunter* identified 6,393 non-compliant data practices across 106 SDKs, encompassing 1,358 apps. Notably, 1,827 (28.6%) of these practices were reflected in apps, inducing non-compliance of apps. Specifically, 279 (20.5%) apps omit to disclose 1,352 data items, most commonly omitting details like location, operating system, and device information. While 105 (7.7%) apps inaccurately claim 475 data collection actions do not occur. The most frequently incorrectly disclosed data items are user identifiers, phone numbers, and purchase history.

Non-Compliant privacy labels in apps. Furthermore, our study explored how non-compliant data practices of SDKs might affect the accuracy of the privacy labels in apps that incorporate them. Apple mandated that app developers must transparently disclose data collection practices throughout their applications, including those carried out by third-party affiliates. Failure to disclose these practices in integrated SDKs would be a violation of Apple's guidelines [32]. Since privacy labels specifically require the disclosure of data that is transmitted off the device, we only focus on non-compliant data transmission practices in SDKs. To examine whether such non-compliant data transmissions in SDKs are propagated to the app's privacy label, we check whether the data is in the app's privacy label, if it is, we regard the app's privacy label as non-compliant. To ascertain their disclosure compliance, we examined 1040 apps' privacy labels and scrutinized the representation of these non-compliant transmissions. We observed that 469 apps omit 593 data in their privacy label disclosure, indicating a significant The data items most frequently omitted include product interaction, payment info, and location.

[‡]When personal data is procured from the data subject (e.g., app user), the controller (app developer/owner) must provide, at the time when personal data is obtained, detailed information about the data processing.

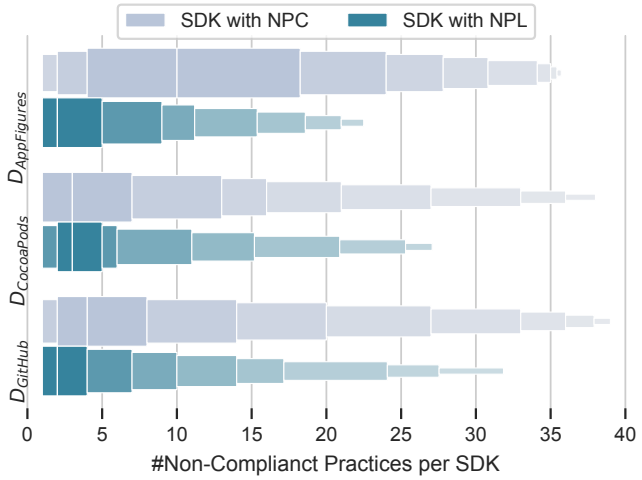

Figure 6: Distribution of Non-Compliant Privacy Collection (NPC) or Leakage (NPL) practices per SDK

6.3 Case Study

Non-Compliance Type I. *iHunter* identified a substantial number of widely used SDKs engaging in the processing of user privacy data without offering a corresponding privacy policy. Notable examples include high-profile SDKs such as SuperPlayer [24], KSPhotoBrowser [15], and LBLaunchImageAd [16], all of which accessed device model and system version information without providing privacy policies. An in-depth examination of the real-world ramifications of these three non-compliant SDKs revealed their presence in 564, 1,147, and 1,560 apps within dataset D_a, respectively. Moreover, we assess the degree to which these SDKs contribute to non-compliance in apps' privacy labels. Our findings revealed that 282, 519, and 741 applications exhibited nonconformity with their privacy labels due to the integration of SuperPlayer [24], KSPhotoBrowser [15], and LBLaunchImageAd [16], respectively, indicating a significant privacy risk posted to end-users by non-compliant SDKs.

Non-Compliance Type II. OpenMediation [18] is a popular SDK that is widely integrated into mobile games for advertising analytics and notifications. According to OpenMediation's privacy policy, the SDK is intended to collect only device information, such as the device model and screen size, solely for user identification purposes. However despite OpenMediation's stated privacy policy, *iHunter* uncovered that the SDK secretly collects additional sensitive data about the phone's running status. This includes information on RAM/storage usage, CPU thermal level, battery level, and precise system boot and app usage times. What is even more concerning is that this collected data is transmitted to OpenMediation's server without the knowledge or consent of the user. Another example of SDKs with discrepancies in their stated data collection practices is Sentry [21] and Buglift [8]. Both SDKs claim to collect only non-personal device information for identification purposes. *iHunter* revealed that Buglift secretly collects location data, which goes beyond the scope of non-personal device information mentioned in its privacy policy. Similarly, Sentry was found to collect data about users' activities, such as CPU time and storage write counts, which again exceeds the explicitly stated data collection purpose.

Non-Compliance Type III. In our case study, we present an example of Cross-Library Data Harvesting on iOS, involving a malicious third-party SDK called Teak [28]. To execute this illicit data harvesting, Teak employs reflection methods to intercept the Facebook user's access token after the login process, and these unlawfully obtained tokens are then sent to a remote server located at `https://gocarrot.com/games/XXX/users.json`. Notably, Teak fails to provide a transparent privacy policy that explicitly outlines this unauthorized data collection and transmission. Significantly, Facebook's terms of use regard access tokens as restricted data items, barring their sharing or transfer to a third party under any circumstances. Compounding the issue, Teak lacks a privacy policy that discloses this data collection behavior. Alarmingly, this SDK is embedded in numerous iOS applications, including those that rank high in popularity in the App Store, posing a significant privacy risk to Facebook users.

7 Discussion

Responsible disclosure. We have reported all our discovered privacy violations to related vendors or developers, including Apple, developers of non-compliant SDKs, and vendors of victim SDKs. The Apple security team told us they are conducting an investigation based on our reports. Some vendors of non-compliant SDKs have confirmed that they are investigating the issues based on our reports, such as Adyen [1], vk-ios-sdk [30], and Countly [11]. For instance, the development team behind the Adyen SDK [1] has informed us that they are in the process of implementing improvements to comply with the regulation requirements set to take effect in Spring 2024. Furthermore, for Type-III violations, some of the victim SDKs have acknowledged our results including Facebook and Twitter; for example, Facebook has taken actions against violating SDKs including Mobiburn [27], Teak [28] and RevMob [20] that collect user data from the Facebook SDK in real iOS apps and send data to their remote servers. Facebook told us that the actions include blocking Facebook Login for iOS apps that integrate the malicious SDKs, which could urge the affected iOS apps to get rid of the violating SDKs. With more vendor responses expected on the way, we will keep updating the results on our website [36].

Usage scenario of *iHunter*. Recently, Apple announced the development of a new mechanism called privacy manifests, aimed at addressing privacy concerns in third-party SDKs. Privacy manifests are files designed to detail the privacy practices of third-party code. Privacy manifests are files that outline the privacy practices of the third-party code. When an app is pre-

pared to be distributed, Apple's official IDE, Xcode [31], will synthesize privacy manifests from all third-party SDKs used by the app into a single report. This comprehensive report can help developers to create privacy labels and complement privacy policies. Privacy collection and leakage behaviors identified by *iHunter*'s taint analysis can greatly help SDK vendors create accurate privacy manifests, which will eventually benefit app developers and users.

8 Related Work

Privacy issues on iOS apps. PiOS [50] examined privacy leakage in iOS apps with a static analysis tool solving the unique indirect `objc_msgSend` calls of Objective-C. iRis [48] then studied the usage of private APIs in iOS apps with a combination of both static and dynamic analysis to improve the ability to resolve `objc_msgSend`. Other works [63, 90] surveyed the usage of private APIs or pursued a source-to-sink analysis using static and dynamic methods on the iOS platform. A crowdsourcing study in [37] indicated that access to users' privacy on devices is widespread in iOS Apps. [83] proposed a fine-grained, application-specific, and user-driven sandboxing for iOS apps to protect user privacy at runtime. Recent studies [59, 84] focused on the impact and compliance of Apple's newly introduced privacy labels. Compared to prior works, *iHunter* is the first to systematically study privacy issues in iOS Apps' supply chain.

Security analysis on iOS apps. Other than privacy analysis in iOS apps, prior works [44, 48, 49, 50, 52, 54, 61, 75, 82] also focused on analyzing the security of iOS apps with static or dynamic approaches, including efforts [48, 50, 52] to deal with dynamic features of Objective-C binaries. Different from PiOS [50] and iRiS [48] leveraging the IR of IDA Pro [56], [52] decompiled and lifted binaries into LLVM IR by the reverse-engineering tool dagger [38], and then performed slicing on the LLVM IR to detect vulnerabilities in iOS. [75] examined vulnerabilities in iOS apps' network services through dynamic vetting in a large number of app collections. Kobold [49] studied the security of IPC channels on iOS with a combination of a static analysis that extracts IPC service interfaces and a dynamic analysis that tests the security of the interfaces. iService [82] performed a top-down static analysis to detect and evaluate the impact of confused deputy problems in macOS Objective-C frameworks. Compared to prior works on iOS, *iHunter* is the first static analysis tool, to the best of our knowledge, to generally handle both Objective-C and Swift binaries.

Privacy issues on Android apps and supply chain. Taintdroid [51] is a system-wide dynamic taint tracking and analysis system capable of tracking privacy leakage on Android. Flowdroid [41] is a static taint analysis framework for Android apps that can be used to examine privacy leakage and security hazards. [86] analyzed transmission of sensitive data in Android apps to privacy leakage that is not related to GUI events. [73] examined privacy policy violations on Android apps and discovered a high portion (341 in 477) of violations.

With these off-the-shelf tools on Android, [39, 40, 45, 67, 73, 81, 88] extensively studied various privacy issues on Android apps. PoliCheck [40] introduces an entity-sensitive consistency model that considers the nature of personal data. PurPliance [43] presents an innovative consistency model, building upon the foundation of PoliCheck [40].

Recent studies [47, 70, 74, 77] have highlighted the alarming prospect of malicious SDKs gaining unauthorized access to users' sensitive data through both host apps and mobile devices. To tackle this issue, researchers conducted both static [67] and dynamic [46, 70] analysis techniques in the measurements of the Android apps' supply chain. This rampant integration and adoption of these SDKs by popular mobile apps have raised serious concerns about potential privacy breaches and data leaks in Android apps' supply chain. To defend or mitigate this threat, prior studies conducted isolation or interdiction approaches [57, 71, 78, 79] on these malicious SDKs.

9 Conclusion

We introduced *iHunter*, a comprehensive system designed to systematically scrutinize privacy compliance among iOS SDKs and detect potential violations. *iHunter* stands out with its unique methodology, utilizing symbolic execution to perform data flow analysis, skillfully analyzing binaries compiled from both Objective-C and Swift. Additionally, it leverages the power of NLP for semantic knowledge extraction, automatically identifying privacy-related taint sources and generating taint rules for iOS system APIs. The system culminates with a compliance check module specifically designed to identify three unique types of non-compliant SDKs. Running on 6,401 iOS SDKs, *iHunter* identified a significant number of non-compliance SDKs (40.4%). Those non-compliant SDKs led to the 15,336 non-compliance apps that integrated them. These results shed light on the pervasiveness and severity of privacy violations in the iOS software supply chain.

Appendix A Setup of Evaluation and Measurement

Building SDK test-bed apps. To perform a taint analysis on the SDKs, we integrated each SDK into an initially empty app to create a test bed, from which we subsequently extracted the compiled binaries. To expedite this process and facilitate batch building, we developed a script that utilizes the `pod install` command to integrate SDKs into the empty app and the `XcodeBuild` command to compile the project. Additionally, we added the `-ObjC` and `-all_load` linker options as compiler parameters to load all code and symbols within the SDKs into the built app:

Analysis of SDK integration. In general, SDKs are commonly integrated into apps through two primary methods: **(a)** static integration into the app's binary or **(b)** dynamic library integration as a *.dylib* file, which is stored in the Frameworks folder of the *.ipa* file. To identify the SDKs used in the apps, we propose a rapid approach that involves analyzing the binary and *.dylib* files of the apps. ***Step ❶:*** We first performed *class-dump* on all apps and SDKs to obtain information about the classes in the binaries, which is similar to the process used in the class structure recovery stage. ***Step ❷:*** Then we generated a hash for every class and recorded the classes defined and used in every binary to an *SQLite* database. ***Step ❸:*** Finally, we conducted a matching process between the classes in each app and the classes in the SDKs and calculated how many classes of each SDK were found in each app. If most of the classes of an SDK were found in an app, we concluded that this app used the SDK. In our evaluation, the threshold ratio for SDK matching could be set to 0.75 since the classes could change with SDK updates.

Compliance criteria. Table 5 lists the pertinent sections to which *iHunter* refers when conducting compliance checks under prominent privacy laws, including GDP, CCAP, as well as Terms of Service (ToS).

Appendix B Other Details of Taint Analysis

Loop extraction. We have implemented a loop detection algorithm based on topological sorting. This algorithm operates on the CFG of every function and employs a stack-based approach to identify nested loops. The topological sorting algorithm sorts the nodes of the CFG in topological order, which means that if node A is before node B in the ordering, then there is no path from B to A in the CFG. This enables the algorithm to identify the loops by detecting back edges in the CFG. To detect nested loops, we use a stack-based approach that helps to maintain the loop hierarchy. Nested

Table 5: Classification of Non-compliances

Non-Compliance Type	Examples of Laws, Regulations or Terms of Use
Absence of Privacy Policy	**Article 12 - GDPR**- Transparent information, communication, and modalities for the exercise of the rights of the data subject: The controller shall take appropriate measures to provide any information referred to in Articles 13 and 14 and any communication under Articles 15 to 22 and 34 relating to processing to the data subject in a concise, transparent, intelligible and easily accessible form, using clear and plain language. **Article 13 - GDPR**- Information to be provided where personal data are collected from the data subject: Where personal data relating to a data subject are collected from the data subject, the controller shall, at the time when personal data are obtained, provide the data subject with all of the following information...
	Section 1798.100(b) - CCPA - Right to Know About Personal Information Collected, Disclosed, or Sold: A business that collects a consumer's personal information shall, at or before the point of collection, inform consumers as to the categories of personal information to be collected and the purposes for which the categories of personal information shall be used. A business shall not collect additional categories of personal information or use personal information collected for additional purposes without providing the consumer with notice consistent with this section. **Section 1798.130(a)(5) - CCPA** - Initial Notice to Consumers: A business that collects personal information about a consumer shall inform consumers as to the categories of personal information to be collected and the purposes for which the categories of personal information shall be used, which shall be provided at or before the point of collection.
Inappropriate Disclosure in Privacy Policy	**Article 5(1)(a) - GDPR**: "Personal data shall be processed lawfully, fairly and in a transparent manner ('lawfulness, fairness, and transparency')."
	Section 1798.100(b) - CCPA "A business shall not collect additional categories of personal information or use personal information collected for additional purposes without providing the consumer with notice consistent with this section."
Transgression of ToS Provisions	**Facebook Terms(3)(2)**: "Prohibition of proxying, requesting, collecting Product usernames, passwords, or misappropriation of access tokens."
	Facebook Terms(2)(1) "Obtain consent from people before publishing content or taking any other action on their behalf."

loops are pushed to the top of the stack and popped when the algorithm finishes analyzing a loop.

Recovery of Swift mangled calls. In Swift binaries, function call names are mangled into unique and indecipherable strings. For example, when initializing a Data instance using the `Foundation.Data.init(referencing:NSData)` function within the Swift Foundation Framework, the corresponding call in the compiled binary is transformed into `s10Foundation4DataV11referencingACSo6NSDataCh_tcfC` after being mangled. To overcome this issue, we developed a Swift function demangling tool capable of extracting all the relevant information about a Swift function call, such as the function name, the indexing path of the function (i.e., module and class name), parameter names, and parameter and return value types. By demangling the name of the `Data` initializer function, we obtained `Foundation.Data.init(referencing: __shared __C.NSData)-> Foundation.Data`, which provides more information than the Objective-C type message-send calling. Furthermore, we can utilize the additional information on the return and parameter types to enhance type inference and assist in resolving message sending in the program.

Taint propagation. During the under-constrained symbolic execution stage, we extract and retain intra-procedural data flow in the summaries. Consequently, propagating taint across the entire iOS binary no longer poses significant challenges. Our approach involves identifying all call sites of each source and sink, marking them as the starting and ending points of taint propagation, and subsequently traversing to construct a taint graph. From this graph, we can extract taint traces by addressing a classical graph reachability problem.

To generate the taint graph, *iHunter* conducts forward propagation within the virtual inter-DFG. This means that propagation occurs within each function's intra-DFG, with context switching when encountering control flow branches or function calls/returns. Propagation starts from the call sites of sources and terminates at the call sites of sinks. To expedite the process, we record all traversed paths and mark them as terminated nodes when traversal concludes. To extract all paths from the taint graph, we employ the flooding algorithm, recording which sources can reach every point and generating all traces for each (n_{source}, n_{sink}) pair.

Is It a Trap? A Large-scale Empirical Study And Comprehensive Assessment of Online Automated Privacy Policy Generators for Mobile Apps

Abstract

Privacy regulations protect and promote the privacy of individuals by requiring mobile apps to provide a privacy policy that explains what personal information is collected and how these apps process this information. However, developers often do not have sufficient legal knowledge to create such privacy policies. Online Automated Privacy Policy Generators (APPGs) can create privacy policies, but their quality and other characteristics can vary. In this paper, we conduct the first large-scale empirical study and comprehensive assessment of APPGs for mobile apps. Specifically, we scrutinize 10 APPGs on multiple dimensions. We further perform the market penetration analysis by collecting 46,472 Android app privacy policies from Google Play, discovering that nearly 20.1% of privacy policies could be generated by existing APPGs. Lastly, we point out that generated policies in our study do not fully comply with GDPR, CCPA, or LGPD. In summary, app developers must carefully select and use the appropriate APPGs with careful consideration to avoid potential pitfalls.

1 Introduction

Mobile phones and apps are now a ubiquitous part of digital life. There is a large variety and volume of data collected and used by mobile apps, which inevitably brings many privacy issues [47, 49, 51, 66, 71]. Privacy policies inform users about what, why, and how their personal data are collected and used. These privacy policies have become an important element of responsible technology in mobile app ecosystems. They also form part of legal agreements for apps and services. Specifically, they are required under regulation in many jurisdictions, such as European General Data Protection Regulation (GDPR) [13], California Consumer Privacy Act (CCPA) [10], Brazilian Law of General Data Protection (LGPD) [9], Australian Privacy Principles (APP) [7], and Chinese Personal Information Protection Law (PIPL) [21]. For example, APP [Art. 1, §1.2] imposes an obligation on organisational entities to *"have a clearly expressed and up-to-date APP Privacy Policy about how the entity manages personal information."* Privacy policies must be consistent with the data collected and functions provided by service providers, and inadequate policies can create significant business and legal problems.

Developing privacy policies is a complex process, demanding both the knowledge of app features and corresponding legal requirements. While larger companies have greater resources and legal expertise to create high-quality privacy policies for their apps, most (citizen) developers do not have legal support and struggle to prepare accurate privacy policies [36, 37, 49, 58]. To develop privacy policies, developers may copy-paste-modify existing privacy policies, ad-hoc. As part of this big picture, app development by non-professional developers is growing quickly, supported by trends of using no-code/low-code automated app development tools [53] and pre-trained Large Language Models (LLMs). To address these needs, Online Automated Privacy Policy Generators (APPGs) can provide more automated solutions and more systematic support for developers to create privacy policies for their apps, rather than through ad-hoc reuse. Figure 1 provides several illustrative examples. Most APPGs are questionnaire-based tools, which work by asking app developers a series of privacy-related questions about the app, and using those answers to generate privacy policies. APPGs can create privacy policies, but their quality and other characteristics can vary and are not yet deeply understood.

As we observe in this paper, many apps fail to provide a privacy policy, perfunctorily provide only a low-quality privacy policy, or provide a privacy policy not in local language. APPGs are becoming an increasingly popular solution used by developers, but developers can be unaware of hidden issues in APPGs [61, 70]. Potential design flaws may reflect in the policies, amplify vulnerabilities, violate users' trust assumptions, and ultimately harm end-users. Thus, a comprehensive and systematic assessment of the capability and limitations of APPGs is necessary. To better understand the scale of po-

tential problems and their broader impact, it is worthwhile to conduct a market penetration analysis on mainstream APPGs. Moreover, by scrutinizing the features of popular APPGs, we can glean insights into the demands and preference of both the market and developers.

Numerous previous studies have analysed privacy policies [33, 47, 48, 51, 52, 56, 61, 64, 65, 71] from various perspectives. However, the majority of existing compliance analyses in relation to privacy regulations lack fine-grained scrutiny of specific clauses and requirements. APPGs often claim the generated policies are compliant with privacy regulations. A more nuanced analysis that hones in on the specific requirements stipulated by privacy regulations is important for a deeper understanding of APPGs' quality. Other issues relate to mobile apps' dependence on device permissions, for instance, *LOCATION* and *CAMERA*, to function normally. Generally, we find users are more vigilant when directly providing personal information, but underestimate the impact brought by device permission requests, which when granted by a user allow apps to continuously collect critical personal information without further user approval or consent. Therefore, it is significant to examine whether developers correctly display the needed device permissions in the generated privacy policies with APPGs for mobile apps. To evaluate current APPGs and their use, we investigate the following research questions:

RQ1: What APPGs exist for mobile apps? What are the differences between them? (Section 2)

RQ2: How many mobile apps' privacy policies could be generated by APPGs? Why are some APPGs more popular? (Section 3)

RQ3: To what extent do APPGs comply with privacy regulations in terms of specific requirements, data rights, device permission disclosure, and self-integrity? (Section 4)

An overview of our methodology is shown in Figure 2. We first collected an initial set of APPGs. After removing duplicates and filtering out irrelevant results, we identified 10 APPGs for mobile apps as our research objects. We conducted an assessment on multiple dimensions, including their features and the recognition of the extent of data use. We then conducted a large-scale market penetration analysis. Based on a random sample of apps from the Google Play app store, we successfully downloaded 46,472 privacy policies (Crawled Privacy Policy Collection) as a large-scale dataset for mobile apps. We found that 15.7% of apps do not provide a privacy policy link, 22.3% of them are low-quality privacy policies, and 20.5% of these privacy policies fail to provide a privacy

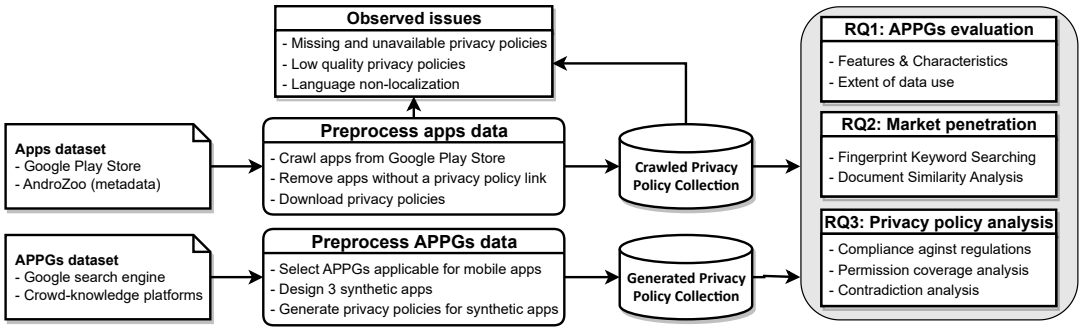

Figure 2: Overview of data flow in the methodology for our empirical study.

policy in English, the first language in the target market. We then generated 30 privacy policies (Generated Privacy Policy Collection) using the 10 APPGs for three synthetic apps and conducted a market penetration analysis. Our results show 20.1% app developers favorably use APPGs to generate their privacy policies, and #2 *App Privacy Policy Generator* is the most popular one, boasting a 72.7% adoption rate. In an effort to more accurately assess compliance with privacy regulations, we scrutinized the generated privacy policies. Our findings revealed a substantial level of noncompliance with privacy laws and a frequent under-claiming of data rights and highly concerning privacy practices, especially the most popular #2. In addition, our results suggest dangerous permissions are commonly missing in the generated policies of APPGs, and inappropriate APPGs selection will hinder developers' capacity to include essential device permissions. Furthermore, we found that APPGs might introduce more privacy policy contradiction issues, undermining the self-integrity.

Contributions. To our knowledge, this is the first large-scale, exhaustive empirical study of automated privacy policy generators for mobile apps. Our observations, findings, and insights will benefit stakeholders beyond just app developers, including APPG providers and privacy regulators from the APPG design perspective and legal perspective. We make the following contributions:

- We perform a systematic empirical analysis of Automated Privacy Policy Generators (APPGs), covering various aspects, such as features, characterizations, and levels of recognition of data use.
- We conduct a systematic analysis of the privacy policies of 99,149 apps in the Google Play Store. Specifically, our dataset includes 46,472 privacy policies extracted from these apps and available at [20].
- We discuss implications for APPG users, APPG providers, and privacy regulators to improve the APPG ecosystem.

2 Online Automated Privacy Policy Generators for Mobile Apps (RQ1)

This section addresses RQ1, describing what APPGs exist for mobile apps and what differences there are between them. We manually collected and identified 10 publicly available online APPGs for mobile apps. We analysed various characteristics and specifically the range of possible data uses in apps.

2.1 Collecting Online APPGs for Mobile Apps

To better understand the current status of APPGs, we identified popular APPGs for mobile apps by using the Google search engine and exploring crowd-knowledge platforms. In detail, we employed the Google search engine to broadly search APPGs for mobile apps. We acted as a hypothetical citizen developer who is trying to generate a privacy policy for their app. We created an initial set of search terms, including "*Apps Privacy Policy Generators*", "*Apps Privacy Policy Generators Online*", "*Privacy Policy Automated Generation*", "*Google Play Store Privacy Policy Generator*", "*GDPR Policy Generators*". For each search keyword, we evaluated all entries on the first result page. In addition to direct results from Google search, we also identified APPGs by using our Google search terms again in app developer crowd-knowledge platforms including Stack Overflow [27], GeeksforGeeks [12], and GitHub [14]. To evaluate search results, we manually identified and read highly related threads, and collected the mentioned APPGs. After collecting an initial set of APPGs and removing duplicates, we filtered out irrelevant APPGs based on the following two criteria: 1) APPGs that only support privacy policy generation for websites; and 2) APPGs that do not actually provide their proposed functions. For example, while some APPGs claim that they are able to generate privacy policies for mobile apps, they do not actually provide such a service.

Table 1 presents 10 identified APPGs in our dataset. "Freeware" represents whether a generator needs monetary investment to use. "Free" means the APPG provides a free version and "Paid" means the APPG provides a premium version that

Table 1: APPGs for mobile apps identified in this study.

#	Name	Freeware	Registration	Mode
1	Iubenda [16]	Free&Paid	Required	User Interface
2	App Privacy Policy Generator [5]	Free only	Not required	Questionnaire
3	Termly [28]	Free&Paid	Required	Questionnaire
4	Privacy Policies [22]	Free&Paid	Required	Questionnaire
5	App Privacy Policy [4]	Free only	Not required	Questionnaire
6	Privacy Policy Online [25]	Free only	Not required	Questionnaire
7	Terms Feed [29]	Free&Paid	Required	Questionnaire
8	Website Policies [31]	Free&Paid	Required	Questionnaire
9	Free Privacy Policy [11]	Free&Paid	Required	Questionnaire
10	Lawpath [18]	Paid only	Required	Document

unlocks more features. "Registration" indicates whether a user needs to register an account to use the APPG. All APPGs we collected are based on question answering and template completion ('boilerplate'), however, they have various different "Modes" to handle information interactions with users as we demonstrated in Figure 1. "User interface"(UI) mode means that users need to select the relative data practices through an integrated UI as à la carte manner, then answer a few other questions about the app's and developers' basic information. "Questionnaire" mode only requires users to complete a long questionnaire that covers all potential data practices and a privacy policy will be generated depending on the answers. This is the most common and popular type of APPGs (8/10). "Document" mode is common in legal consultation websites. Users need to purchase access to a privacy policy document, then answer a series of questions to complete the template. Notably, all analyses of APPGs in this paper include features in both free and paid versions. We conducted all analyses of APPGs in May 2022.

2.2 Characterization

A comprehensive assessment is conducted on identified APPGs along 10 dimensions. The first five (1-5) target practicability, user-friendliness, and convenience from potential APPG users' perspectives. The next three (6-8) cover legal compliance with privacy regulations, according to the tools' claims. The last two (9, 10) focus on the understandability of privacy policies. The results are shown in Table 2. We define these 10 dimensions as follows:

`Extent of Data Recognised (1)`. Mobile apps normally require data from direct user input or device sensors. Some apps may also provide data to third-party services, for revenue or to enhance the user experience. Privacy regulations such as GDPR [Art. 14(1)(d)] and CCPA [§1798.130(a)(5)(B), 1798.110(c), Regs §999.308(c)(1)(d))], can require that app developers include information about all collected or shared data within their privacy policy. However, some APPGs only recognise a limited range of data practices for inclusion in privacy policies. As failing to include all data practices could be regarded as a regulatory violation in some jurisdictions, this is an important characteristic and is discussed in more detail in the next section (Section 2.3). Tentatively, we use (●) to denote that the APPG recognises a wide range of data use, (◐) for a smaller range of data use, and (○) for a few kinds of data use.

`Customizability (2)`. Customizability addresses two concerns: can users add privacy practices that were not originally included in the APPG pipeline, and do users have the freedom to add customized clauses in the generated privacy policy document? The former can help developers to provide a more specific and accurate privacy policy; the latter can more easily accommodate developers who want to address additional concerns about users' privacy. APPGs are denoted as (●), (◐), and (○), as indications that they are positive for both, one, and zero of these questions, respectively.

`User Instruction (3)`. The main target audience of APPGs is expected to be developers with little or no legal knowledge about privacy and data protection. Therefore it is crucial to provide sufficient user instructions to help correctly utilize the APPG. User instructions can be generally categorised into three types: providing further explanation of obscure questions (an example is shown in Figure 1), elaborating terms by listing examples, and supporting users with an interactive help center. APPGs are scored as (○) if they only provide one or nil occurrence of the above user instructions, (◐) for two to five occurrences, and (●) for more than five occurrences. Especially, APPG #1 *Iubenda* also provides an introduction video and comprehensive documentation.

`Complexity (4)`. This dimension indicates the general learning cost for APPG users, and higher complexity reflects a higher cost. For UI-mode APPGs, users have to spend more time getting familiar with the UI and learning operation procedures, therefore, we manually set them as (●). For questionnaire-mode APPGs, we found that the complexity is related to the number of questions that users are asked in the generation process. Based on the "Statistic summary" in Table 3, if the sum of maximum multiple-choice questions and maximum completion is less than 10, the APPG is marked as (○), if it is between 10 to 50, the APPG is marked as (◐); and if it is greater than 50, the APPG is marked as (●). For document-mode APPGs, users only need to select a document from the library and fill up several questions about their basic information, thus, we manually set them as (○).

`Publishing Support (5)`. This dimension reflects how convenient it is to deploy the generated privacy policy. Every APPG provides at least one of the following publishing options: 1) a permanently hosted website link containing the privacy policy; and 2) the generated privacy policy context in editable HTML format. In section 3.3.1, we presented that a large amount of privacy policy links in the market lead to inaccessible websites, and we believe that a permanently hosted website link provided by APPGs can mitigate this

Table 2: The characterization of 10 APPGs on 10 different dimensions.

# and APPG Name	Extent of Data Use	Customizability	User Instruction	Complexity	Publishing Support	GDPR	CCPA	LGPD	Multilingual Support	Readability
#1 Iubenda	●	◐	●	●	●	●	●	●	●	○
#2 App Privacy Policy Generator	◐	○	○	○	◐	○	○	○	○	●
#3 Termly	●	◐	●	●	●	●	●	○	○	●
#4 Privacy Policies	◐	○	○	◐	●	●	●	○	○	○
#5 App Privacy Policy	○	○	○	○	●	○	○	○	○	◐
#6 Privacy Policy Online	○	○	○	○	●	○	○	○	○	◐
#7 Terms Feed	◐	◐	○	◐	●	●	●	○	○	○
#8 Website Policies	●	●	◐	●	●	●	●	○	○	○
#9 Free Privacy Policy	◐	○	○	◐	●	●	●	○	○	○
#10 Lawpath	○	○	●	○	◐	○	○	○	○	◐

○: low level / does not support; ◐: intermediate level / partially support; ●: high level / fully support

problem to some extent. (●) indicates the APPG provides both options and (◐) means APPGs only provide option 2.

`GDPR (6), CCPA (7), and LGPD (8)`. These three dimensions are binary, simply indicating whether the APPG claims that they provide compliance with the corresponding privacy regulations. (●) denotes support and (○) denotes non-support. No APPG claims compliance with other privacy regulations such as APP [7] and PIPL [21].

`Multilingual Support (9)`. In Section 3.3.3, we discuss how current privacy policies suffer from the language localization problems. APPGs that provide multi-language support should benefit both app developers and app users. Additionally, in CCPA [Regs §999.308(a)(2)(d)], it stipulates that online notices should follow generally recognized industry standards, such as the W3C Web Content Accessibility Guidelines [30]. We use (●) to denote that APPG can generate privacy policies in more than one language, otherwise (○).

`Readability (10)`. While a long privacy policy can provide more comprehensive and detailed descriptions of data practices in apps, adding unnecessary information to a privacy policy may lead to information overload [39, 63]. Although APPGs can generate more concise privacy policies that are more specifically tailored to the data and data practices relevant to each app, this does not necessarily mean that those privacy policies are more readable. Some regulations require mobile app developers to use clear and understandable language in privacy statements [46, 62]. Also, W3C Web Content Accessibility Guidelines [§3.1] requires that "make text content readable and understandable". However, those high-level principles do not give details for this requirement. Thus, we adopt the Flesch Reading-Ease Test [44] to evaluate the readability of generated privacy policy context. A higher score indicates the content is easier to read and understand, the score scales from 0 to 100. The average readability score of the privacy policies of 12 leading mobile apps [19], who have over one billion installs, is 46. We use (●) when the readability score is greater than or equal to 46, (◐) for 40 to 46, and (○) for less than 40. Specific readability scores are listed in Appendix Table 10.

Since the assessment of apps in these dimensions involved some subjective judgments, the first two authors assessed the 10 APPGs individually. For any disagreement at the table, they discussed and agreed on the same answer, and if the disagreement persisted, a third author joined the discussion to facilitate a resolution. As shown in Table 2, the level of Complexity is positively associated with the level of Extent of Data Use, Customizability, and User Instruction. Most of the APPGs (8/10) exhibit complete publishing support. As for compliance with privacy regulations, more than half the APPGs (6/10) claim that their privacy policies conform to the GDPR and CCPA, and only #1 *Iubenda* claims compliance with LGPD. Only #1 *Iubenda* supports generating privacy policies in languages other than English. All APPGs' readability scores are between 30 and 50, which indicates that readers should have at least a college-level education background to easily read the policies [44]. #2 *App Privacy Policy Generator* has the highest readability score and is the most frequently used APPG on the current market, as discussed in Section 3.5.

2.3 Extent of Data Use Recognised by APPGs

In this section, we further investigate the extent of data, data use, and data practises recognised by APPGs to support the generation of privacy policies. We identified four major aspects: the app's basic information, users' personal information, device permissions, and third-party services. We carefully gathered all the possible questions and potential options that APPG users might face. If any question or option explicitly pertains to a specific data type, permission, or third-party service, then it is classified as "recognised" (●), otherwise "absent" (○). The specific item enumeration process is available at [20].

`App's basic information`.Apart from user names, providing at least one communication channel to app users

Table 3: The breakdown of APPG's recognition of data use. The first row of each section is the number of APPGs as per Table 1. "Multiple-choice questions" refers to whether developers select options from listed items, and "Completion questions" means developers fill in blanks with plain text. (Selecting a date is also regarded as a completion question.) Since some questions sometimes unlock later questions, we use "Minimum" and "Maximum" to reflect the lower and upper bounds. *If date of birth is included in the APPG, then we consider that Age group can be inferred.

App's basic information	1	2	3	4	5	6	7	8	9	10
Name of the app	●	●	●	●	●	●	●	●	●	●

Maximum completion questions	/	4	76	22	2	3	22	13	22	/

for any potential inquiries is commonly required by privacy protection and regulation laws, and all the APPGs support this with different levels of granularity.

`Users personal information`.We manually separate this into two sub-categories: general personal information, and sensitive personal information. Most APPGs recognise general personal information, and only some APPGs (3/10) explicitly identify sensitive information.

`Device permissions`. According to the Android developer's guide [1], there are nine dangerous permission groups, namely *CALENDAR*, *CAMERA*, *CONTACTS*, *LOCATION*, *MICROPHONE*, *PHONE*, *SENSORS*, *SMS*, and *STORAGE*, on mobile phones. We expect the collection and use of data related to these permissions to be clearly declared in a privacy policy, therefore, they are set as row indices. We found that more than half of the APPGs (6/10) recognise *CAMERA*, *CONTACTS*, and *LOCATION*, and only two APPGs identify all permissions. Failing to correctly state sensor permissions in the privacy policy could lead to serious privacy issues, so we further investigated whether users can correctly utilise the APPG to state all claimed sensor permissions in Section 4.2.

`Third-party services`. Third-party services have become a significant part of mobile apps. Taking into account the diversity of service providers and their popularity, we selected five third-party services as row indices, as most APPGs either fully or partially cover them. Overall, APPGs show decent coverage among these third-party services.

`Statistic summary`. We counted the completion questions and multi-choice questions (examples are illustrated in Figure 1) that users would encounter for the questionnaire-mode APPGs. Although questions may vary dramatically, we take it as a quasi-indicator to approximately reflect users' learning and time cost to use the APPGs.

As it involves intensive manual work, to avoid the effect caused by potential human error, we employ the same strategy as introduced in the previous section. Cohen's Kappa [41] $\kappa = 0.92$ for the initial manual labelling, which is an almost perfect level of agreement. As shown in Table 3, #1, #3, and #8 are the best in terms of the recognised data use, they almost cover every data index listed in the table. #2, #4, #7, and #9 decently cover users' general personal information and third-party services, but only a few or null users' sensitive personal information and device permissions. #5, #6, and #10 merely cover some app's basic information and failed to support the rest of the categories. Above all, users need to carefully select appropriate APPGs, otherwise, the unsupported data use will be missing in the generated privacy policy.

> **Finding 1:** APPGs are a handy solution for developers to draft privacy policies for their apps. They have various features, characterizations, and levels of recognition of data use.

3 Market Penetration of APPGs (RQ2)

The previous section carefully examined various characteristics of APPGs. In this section we consider the questions: How large is the APPG market? And are the seemingly more functional APPGs actually more popular in the market?

3.1 Status Quo of Mobile Apps' Privacy Policy

Privacy policies play an essential role in mobile app ecosystems. An app without a privacy policy is not necessarily malicious, but developers are required to provide privacy policies due to regulations in some jurisdictions. These policies are also increasingly demanded by mobile app users and marketplaces. According to the Apple App Store Developers page [3], a privacy policy is required when submitting new apps or app updates: *"By adding the following links on your product page, you can help users easily access your app's privacy policy and manage their data in your app.* ***Privacy Policy (Required):*** *The URL to your publicly accessible privacy policy."* Additionally, in Google Play Console Help Center [2], developers *"...must include a link to your privacy policy"* to prepare the app for review. Although platform principles regulate the existence and quality of privacy policies, we still discovered some critical problems in the mobile apps market. Other forms of privacy notices, such as privacy nutrition labels (PNLs) [49,54,68,69], focus more on providing succinct information to end users, potentially sacrificing information relevant or required by specific regulations or marketplace requirements.

3.2 Crawled Privacy Policy Dataset

To better understand the status and quality of existing privacy policies, we need a large-scale privacy policy dataset. However, existing datasets suffer from various problems.

The differences between datasets for previous research and our research goals. Existing datasets are either not focused on mobile apps, biased, small, or outdated. First, some prior research focuses on privacy policies across all platforms, including websites and mobile apps [33,50,61], while we only target mobile apps. Since they did not include metadata (e.g., platforms) of the collected policies, we cannot filter them out from other platforms. Second, some research only focuses on apps of certain groups, and their collected datasets are not representative enough for apps in the market. For example, one study [47] manually collected 5,684 "globally popular apps." This selection criterion leads to two critical problems: a) The top overall popular apps appear in a limited set of categories, such as *Social* and *Finance*, which can drive out apps from less popular categories such as *Parenting* or *Libraries & Demo*. b) These globally popular apps do not distribute evenly across various app categories, which may cause potential bias and unrepresentative findings. Third, some existing

datasets are small and can contain potential bias. For example, APP-350 [71] only analysed 350 privacy policies, and another study [51] conducted fine-grained analysis on only 304 privacy policies. Finally, due to the rapid iteration of apps, apps' privacy policies, and APPGs, some prior datasets can quickly become outdated. In summary, to make our findings comprehensive, generalizable, and up-to-date, we needed to collect a current large-scale dataset that can assemble apps of different popularity and from various app categories.

Google Play Store. Android mobile apps are often more transparent and friendly to academic research compared to iOS mobile apps [43,45]. There are many app markets for the Android platform, but Google Play is the largest and the most accessible app market, with over two million apps, according to AppBrain [6]. Thus, we only focus on it in this study. Some Android apps are specially designed for Android smartwatches instead of mobile phones; therefore, we intentionally excluded apps belonging to categories named *Watch apps* and *Watch faces*.

Our dataset. We collected a new large-scale privacy policy dataset from existing apps on the Google Play Store. We also collected app metadata from AndroZoo [32], which is a large-scale and growing Android app collection extracted from multiple sources, including the Google Play app store. We removed duplicates and apps from other app markets and then randomly sampled 268,500 apps as our initial app dataset, which is around 10% of the whole app population. From this initial sample, we observed that some apps are either invalid or not usable. These were mainly dummy apps or student apps with a package size normally less than 10 KB, so we removed invalid apps like these. We further excluded unavailable apps that returned error messages on their Google Play page. Apps can be unavailable for many reasons including geographic differences [47] caused by government censoring, or being removed by Google because of disruptive adware, malware, restricted content, or other reasons. After these exclusions, we were left with 99,194 usable apps and their metadata. We then employed *google play scraper* [15] to obtain app information including privacy policy links, app categories, and required device permissions. Based on the available privacy policy links shown on the app's homepages, we further utilize the *BeautifulSoup* [8] and *Selenium* [26] python packages to download those websites. Eventually, we obtained 46,472 privacy policies, and we refer to this privacy policy dataset as **"Crawled Privacy Policy Collection."** We conducted the above data-gathering process in March 2022.

3.3 Observations on Status Quo

In this section, we report an analysis of app privacy policies and identify three common problems in existing apps: missing/unavailable privacy policies, low-quality privacy policies, and language non-localization problems. Although similar problems were discussed in several previous studies [47,49,71], considering the rapid development of markets, we believe it is worthwhile to revisit those critical issues.

3.3.1 Missing Links and Unavailable Privacy Policies

Providing a privacy policy is essentially required by platform principles and privacy regulations, however, we observed that 15.7% (15,572/99,194) of apps do not provide a privacy policy link on their Google Play homepage. A previous study [71] reported that this statistic was 49.1% in 2019. Seemingly, as more regulation has been introduced, more apps have provided a privacy policy. However, we found that 37.5% (37,150/99,194) of privacy policy links lead to unavailable websites with error messages such as "403 Forbidden" or "404 Not Found." This problem could be caused by potential reasons such as deliberately providing a dummy link, an outage, or the removal of the website server. Hence, in addition to simply requiring app developers to provide the privacy policy, the mobile app market also needs to frequently and regularly verify the validity of provided privacy policy links. Also, a permanent hosted privacy policy link provided by APPGs can help developers to mitigate availability issues to some extent.

3.3.2 Low-Quality Privacy Policies

Several previous studies [51,71] reported that it was not rare that some apps only provide a low-quality privacy policy, and we observe similar issues in our dataset. Firstly, some privacy policies do not contain meaningful privacy-related context, or are just dummy websites. For example, "Bway App" is a free app that provides football results, statistics, trends, and match result predictions, with over 10,000 installs; however, their privacy policy website [23] does not contain any content, and the file size of the crawled privacy policy is close to 0 KB. In addition, some are apparent "homemade" privacy policies that are too general to include essential data practices. For instance, "Easy Communication" is designed to help people with autism, cerebral palsy, dyslexia, intellectual disability, and other special needs to communicate easily. Its privacy policy [24] only has 156 words, and ambiguously mentions required device sensor permissions without any elaborations. Based on our observations and previous work, we empirically set the file size threshold as 2 KB [51], and the document length threshold as 200 words [47]. If a crawled privacy policy does not meet both criteria, it will be regarded as a low-quality privacy policy. In total, we identify 22.3% (10,375/46,472) low-quality privacy policies.

3.3.3 Language non-Localization Problem

Language localization is necessary to promote apps in a global market. Although app UI and content can be translated, app developers may neglect the privacy policy. We employed the Python package *langdetect* [17] to detect the language of the crawled privacy policy documents and found 20.5%

(9,523/46,472) of apps do not provide an English privacy policy, although these apps were released in markets where the primary language is English. Interestingly, the top five non-English languages are Spanish (15.6%), Portuguese (9.7%), German (8.8%), Korean (8.7%), and French (7.6%). This trend might be attributable to the implementation of the European GDPR and Brazilian LGPD. We observed this problem even with top apps from some large companies. For the privacy policies of the top 1,000 most installed apps (all $>$ 500k installs) in our dataset, there are still around 14.1% that do not provide an English privacy policy. APPGs may be a solution to language non-localization problems. Only APPG #1 *Iubenda* supports multilingual generation, but some APPGs (#4, #7, and #9) have included placeholders for future options for language selection.

3.4 Synthetic Apps and Generated Privacy Policy Collection

To identify whether privacy policies could be generated by APPGs, we first need to build the ground truth with self-generated privacy policies for each APPG. As shown in Table 1, seven APPGs require users to register an account to use the service, and six of them also require users to pay subscription fees to unlock all features. We registered as required and paid subscription fees. Synthetic apps are commonly used in similar empirical studies such as [53, 61]. We designed and tailored 3 synthetic apps specifically based on APPGs' features and characteristics as summarised in Table 2 and Table 3. This was so that the boilerplates and pre-defined clauses of every APPG can be fully explored and reflected in the generated privacy policies. The functions and features of these synthetic apps are as follows:

Synthetic App 1. A toy-like app that collects only general personal information and does not need to comply with GDPR, CCPA, or LGPD.

Synthetic App 2. A social app that enables people to interact and communicate with others. Users need to create an account by providing their general personal information, and the app requires all device permissions. The app also accesses third-party services and only needs to comply with GDPR.

Synthetic App 3. A hypothetical omnipotent app that requires users to provide all general and sensitive personal information to function. The app also needs all device permission and access to third-party services. This app needs to meet the requirements of GDPR, CCPA, and LGPD.

These three synthetic apps are various in terms of functionality and sophistication, and they decently cover all data use mentioned in Table 3. Therefore, they are capable of being the boilerplate apps for APPGs' ground truth in the majority of cases. For each APPG, we created the same three custom privacy policies to test whether a privacy policy can be generated by one of analysed APPGs. Given ten APPGs and three synthetic apps, we obtained 30 privacy policies as **"Generated Privacy Policy Collection"** in total. We utilized it and "Crawled Privacy Policy Collection" to conduct the following market penetration analysis.

Table 4: Summary of market use of different APPGs.

Method	Market Occupancy
Fingerprint Keyword Searching	6.6% (3,066)
Document Similarity Comparison	18.1% (8,425)
Intersection	4.4% (2,042)
Union (Total)	**20.1% (9,332)**

3.5 Market Penetration Analysis

We report a market penetration analysis to highlight the extent to which APPGs are used and to provide insights about why some APPGs are more popular. Specifically, we employ two methods to detect whether a privacy policy could be created by one of these APPGs: fingerprint keyword searching and document similarity comparison.

Fingerprint Keyword Searching (FKS). APPGs offer various publishing features, including the provision of a direct link as a permanent website host or an editable HTML document. We observe that to better advertise themselves, APPGs typically embed their company names into the URLs of the generated privacy policy websites or the editable HTML document. Consequently, we construct the fingerprint keyword set grounded in this feature. To cultivate this set, we manually inspected these APPGs and the collection of generated privacy policies. To mitigate the likelihood of false positives, we verified the authenticity of all keywords individually. Specifically, we incorporated a candidate fingerprint keyword into the set only if it appeared consistently across all three ground-truth privacy policies crafted for synthetic apps. All keywords are deliberately sensitive to case and format. The full keyword list is available at [20].

Then, the collected keyword set is employed to perform FKS in the crawled privacy policy collection. For each privacy policy in our collection, if we find a match in either its website link or its document context with one of the fingerprint keywords, the policy is considered to be generated by the corresponding APPG. For example, during the examination of policy website URLs, we use the keyword "iubenda.com" to search URLs like "www.iubenda.com/123abc..." for APPG #1 *Iubenda*. Similarly, while scrutinizing policy HTML documents, identifiable phrases like "iubenda hosts this content" were utilized as markers

Document Similarity Comparison (DSC). As we mention in Section 2.2, some APPGs allow users to customize the content to some extent, and APPG users may also further adapt or polish the initial generated privacy policy in editable HTML format before publishing. Consequently, the fingerprint keywords, even sentence-level segments, are not necessarily included in a generated app privacy policy sometimes,

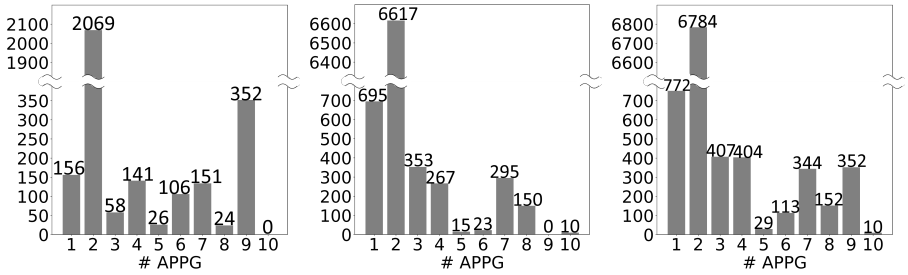

Figure 3: The number of privacy policies generated by APPGs, detected by FKS (left), DSC (mid), and both (right).

and so the searching-based method may not work in those cases. To tackle this problem, we design a semantic-based method with better robustness, called document similarity comparison.

In natural language processing (NLP) tasks, researchers adapt the concept from mathematics by treating documents as vectors, to obtain the similarity between two documents. TF-IDF [57] is a common numerical statistic designed to reflect the relative importance of words in a document corpus, and thus it can be adapted to convert documents into vectors. By doing so, the similarity between two documents can be represented as the similarity of two vectors, and we choose cosine similarity as the most common one. If the average similarity between a crawled privacy policy and three ground-truth generated privacy policies is greater than a threshold β, we consider it a match, i.e., could be created by the current APPG. If a privacy policy matches more than one APPG, we take the one with the highest similarity. To define the value of β, we first calculate the document similarities between the three generated privacy policies of each APPG as an initial value. We then randomly sampled 100 privacy policies that are generated by one of 10 APPGs based on fingerprint keyword searching and evaluate the similarities compared to the three generated privacy policies of each APPG to fine-tune the β. Based on our data, we empirically set $\beta = 0.75$.

Results. We employed the proposed methods to provide an estimation of the market penetration of APPGs. Among 46,472 valid privacy policy documents from apps at the Google Play Store, as shown in Table 4, we found 6.6% (3,066) privacy policies are highly likely generated by one of the APPGs by using fingerprint keyword searching and 18.1% (8,425) by using document similarity comparison. We also checked the intersection size, which is 4.4% (2,042), indicating that these two methods are complementary to each other. The union of the previous two methods is **20.1%** (9,332), indicating an upper bound on possible market occupancy ratio. Overall, the results show that APPGs do play a considerable role in the current mobile app market.

Figure 3 presents the market occupation for each APPG. We can see that APPG #2 *App Privacy Policy Generator* dominates as the most popular APPG, with a 72.7% adoption rate. It could be attributed to its free-of-charge and registration, low complexity, and best readability score. #1 *Iubenda* and #5 *App Privacy Policy* also take decent market shares. #10 *Lawpath* is the least used APPG in our data, perhaps related to its price to use of $199 for one privacy policy document, which is the highest among all APPGs. We notice popular APPGs generally have a low level or partial support on all data practice dimensions, therefore, we conclude that users may prefer to select easy-to-use tools rather than spend extra time learning how to master a sophisticated but more functional APPG. However, the ease of use of APPGs may come at the cost of a potentially-higher risk to breach privacy regulations.

> **Finding 2:** The market occupancy ratio of 10 examined APPGs is around 20.1%, and #2 *App Privacy Policy Generator* is the most popular one, boasting a 72.7% adoption rate. Moreover, users tend to select easy-to-use APPGs even though at the cost of a potentially-higher risk to breach privacy regulations.

4 Assessment of Privacy Policies (RQ3)

Generators are designed to generate compliant privacy policies. This section reports a detailed assessment of generated privacy policies.

4.1 Privacy Compliance Against Regulations

APPGs need to be designed in a way that allows developers to produce compliant privacy policies. Furthermore, they must be updated to reflect evolving laws. In Table 2, six APPGs claim that they are able to generate policies in compliance with CCPA and GDPR, and only #1 *Iubenda* mentions compliance with LGPD. However, their actual compliance with generated policies may be different from what they claim. Zimmeck et al. [70] conducted two studies in May 2020 and January 2021, revealing that some APPGs had significant compliance issues, such as failing to create CCPA-compliant policies. We perform a follow-up inspection in May 2022 based on generated privacy policies by Synthetic App 3, since

Table 5: LGPD privacy policy requirements and APPGs' compliance in May 2022. Numbers indicate APPGs as per Table 1.

LGPD requirement	1	2	3	4	5	6	7	8	9	10
Identify and document the legal bases for processing personal data. [Art. 1, 2]	✓	✗	✓	✓	✗	✗	✓	✓	✓	✓
Disclose, collect and maintain valid proof of consent. [Art. 8 §1-6]	✓	✗	✗	✗	✗	✗	✗	✓	✗	✗
Include required data collection disclosures in the privacy policy in a clear, adequate, and notable manner. [Art. 9]	✓	✓	✓	✓	✗	✗	✓	✓	✓	✓
Disclose the essential data rights to the data subject in a clear, adequate and ostensible manner. [Art. 9, 19]	✓	✗	✓	✓	✗	✗	✓	✓	✓	✗
Appoint a data protection officer (DPO) and publicly disclosed the contact information [Art. 41 §1]	✓	✗	✓	✗	✗	✗	✗	✗	✗	✗
Implement and disclose a security protocol (or such mechanism) to protect personal data. [Art. 46]	✓	✓	✓	✓	✗	✗	✓	✗	✓	✓
State and comply with cross-border data transfer requirements if the data controller conducts international transfer of personal data. [Art. 33]	✓	✗	✓	✓	✗	✗	✓	✗	✓	✓
Disclose the processing of children's data in a specific and highlighted consent, including types of data collected, the way it is used and data rights. [Art. 14]	✓	✓	✗	✓	✓	✓	✓	✓	✓	✗

Table 6: Tallies of the APPGs' compliance against legal requirements in privacy regulations. The individual requirements of LGPD are shown in Table 5. "N.R." stands for "no record". The enforcement date of LGPD is September 2020.

#	**GDPR**			**CCPA**			**LGPD**

5	N.R.	N.R.	0/8	N.R.	N.R.	2/18	1/8
6	N.R.	N.R.	0/8	N.R.	N.R.	2/18	1/8
7	8/8	8/8	8/8	5/18	16/18	16/18	6/8
8	N.R.	N.R.	8/8	N.R.	N.R.	11/18	5/8
9	8/8	8/8	8/8	5/18	16/18	16/18	6/8
10	N.R.	N.R.	2/8	N.R.	N.R.	2/18	4/8

they are supposed to comply with all compliance requirements of GDPR, CCPA, and LGPD.[1] Table 6 shows tallies of generators' compliance with legal requirements in May 2020, January 2021, and May 2022 for GDPR, CCPA, and LGPD.

There is a notable discrepancy between the APPGs' claimed ability to generate policies compliant with specific regulations and their actual compliance levels. In addition, across the table, compliance with GDPR and CCPA requirements improved over time from May 2020 to May 2022 for several APPGs (#3, #4, #7, #9), demonstrating an adaptation to regulatory standards. An encouraging observation is that APPGs (#1, #3, #4, #7, #8, #9) maintained full GDPR and a majority of CCPA compliance since January 2021. This might be due to the fact that GDPR has been in effect since 2018, providing APPGs with more time to adapt their policies accordingly. Given that LGPD came into effect in September 2020, it is not unexpected that compliance levels would be relatively low in the initial stages. The findings underscore the necessity for APPGs to improve their ability to produce compliant privacy policies consistently across all major regulations. The results also call for ongoing monitoring and evaluation of APPGs to ensure they keep pace with evolving laws and maintain transparency with their users regarding their actual capabilities.

APPGs have varying levels of compliance when it comes to data collection practices. For instance, while GDPR emphasises "Categories of personal data concerned", CCPA requires to provide a detailed list of categories of personal information that should be disclosed if collected. APPGs #1, #3, #4, and #7 demonstrate compliance with GDPR's requirements, but when it comes to CCPA's detailed disclosure requirements, only APPGs #3, #7, and #9 comply. As for third-party data-sharing and data-sale practices, CCPA's emphasis is on "List of categories of personal information collected and sold" highlights this; whilst GDPR identifies "Recipients or categories of recipients of the personal data". APPGs #1, #3, #4, and #7 have clear disclosures in line with third-party disclosure, but others like #2 and #5 lag behind. Overall, APPGs #3 and #7 consistently fare well across all three regulations, indicating a comprehensive privacy policy generation. However, APPGs #2, as the most popular, display apparent gaps compared to others.

Data Right Coverage Analysis. Regulations often necessitate data rights to grant sufficient choice and control to the end users over the personal data collected by businesses. Thus, it is important to assess whether the generated policies clearly disclose data rights. For this, following [GDPR Art.13] and

[1]The compliance analysis of GDPR and CCPA of May 2020 and Jan 2021 are directly obtained from [70]. The requirements and compliance checking for GDPR, CCPA, and LGPD are curated in Appendix Table 11, Appendix Table 12 and Table 5, respectively.

[CCPA §1798.130(a)(5)(A)] [2], we extracted and summarised seven fundamental data rights. We manual examined the existence of disclosure for each data right of 10 APPGs. For comparison, we also scrutinized 12 leading mobile apps, which are mentioned in Section 2.2-Readability. These 12 leading apps are in various categories and published by different companies, with over one billion installations. Table 7 shows that almost all leading apps disclose fundamental data rights in their privacy policies. In addition, results validate the respective assertions made by APPGs, regarding their self-claimed compliance with GDPR and CCPA. Notably, #2 as the most popular APPG, does not disclose any of the data rights in the generated policy document.

Table 7: The disclosure existence of seven fundamental data rights. Numbers in the first row indicate APPGs as per Table 1, and "Apps" denotes the tallies of disclosure for 12 leading apps.

Data Right	1	2	3	4	5	6	7	8	9	10	Apps
Right to Know	✓	✗	✓	✓	✗	✗	✓	✓	✓	✓	12/12
Right to Access	✓	✗	✓	✓	✗	✗	✓	✓	✓	✓	12/12
Right to Processing	✓	✗	✓	✓	✗	✗	✓	✓	✓	✗	12/12
Right to Restrict of Processing	✓	✗	✓	✓	✗	✗	✓	✓	✓	✗	12/12
Right to be Forgotten	✓	✗	✓	✓	✗	✗	✓	✓	✓	✓	12/12
Right to Data Transfer	✓	✗	✓	✓	✗	✗	✓	✓	✓	✗	12/12
Right to Lodge a Complaint	✓	✗	✓	✓	✗	✗	✓	✓	✓	✓	12/12

Privacy Practice Disclosure Analysis. In alignment with the principles of data protection and transparency, it is also imperative that privacy policies encompass disclosure of privacy practices. Based on [2] and [60], this study delineates four highly concerning privacy practices. These are: 1) *Data Encryption*: Users' data are encrypted and transferred over a secure connection. 2) *Government Requests*: It refers to the potential for government entities to request access to users' data for various reasons, including national security or criminal investigations. 3) *Data Breach Notification*: In the event of a data breach where users' information is compromised, it is essential to have a mechanism in place to notify affected users promptly. 4) *Changes Notification*: The privacy policy should mention the procedures for notifying users about significant changes to the policy, including how and when users will be informed. Then, we manually scrutinized the existence of disclosure across 10 APPGs and the same 12 leading apps. Table 8 shows that more than half APPGs disclose *Data Encryption* and *Changes Notification*. Five APPGs include *Government Requests* and only #8 includes *Data Breach Notification* in the generated policy document (*"In the event of a data breach, we will make reasonable efforts to notify affected individuals..."*). In addition, #5 and #6 do not include any privacy practice, and #8 includes all items. Furthermore, #2 as the most popular APPG, only include *Data Encryption*.

[2]The specifications are stated in §1798.100, §1798.105, §1798.106, §1798.110, §1798.115, and §1798.125.

Table 8: The disclosure existence of five highly concerning privacy practices. Numbers in the first row indicate APPGs as per Table 1, and "Apps" denotes the tallies of disclosure for 12 leading apps.

Privacy Practice	1	2	3	4	5	6	7	8	9	10	Apps
Data Encryption	✓	✓	✓	✓	✗	✗	✓	✓	✓	✓	8/12
Government Requests	✓	✗	✗	✓	✗	✗	✓	✓	✓	✗	11/12
Data Breach Notification	✗	✗	✗	✗	✗	✗	✗	✓	✗	✗	1/12
Changes Notification	✓	✗	✓	✓	✗	✗	✓	✓	✓	✗	12/12

Finding 3.1: Noncompliance with privacy laws and under-claiming issues indicate potential need for a more stringent evaluation of APPGs' capabilities.

4.2 Permissions Coverage Analysis

Device (sensor) permissions enable features of mobile apps and are normally critical in terms of personal privacy risks. Intuitively and legally, an app's privacy policy should accurately disclose its permission usages; however, it is common that developers do not list all the permissions of their app in the privacy policy [34, 42, 54, 55, 71]. Developers of mobile apps in the Google Play app store are required to clearly list the permissions they intend to obtain on their homepages[3], and we denote them as P_{claimed}. By taking the self-reported device permission usage as the ground-truth, we then assess whether the APPG's provided UIs, questionnaires, or documents can sufficiently allow the APPGs users to enter permission invocation information by their app. Notably, the self-reported device permission usages by developers may not actually reflect the actual privacy behaviour of apps.

To scrutinise how developers translate used device permissions into policies by APPGs, for each permission (*per*), we use it and Synthetic App 1 to generate a privacy policy ($PP_{App1+per}$). By comparing the differences between $PP_{App1+per}$ and PP_{App1}, we can locate and obtain the phrases/sentences each APPG uses to declare each permission in the privacy policy. For each app, by searching and counting the corresponding phrases/sentences in its privacy policy, we obtain the number of permissions displayed and denoted as $P_{\text{displayed}}$. For each app that uses the APPG, its $P_{\text{recognised}}$ is equal to the recognised dangerous permissions enumerated in Table 3. Then, we introduce two metrics for the extent to which APPGs cover claimed permissions in the generated privacy policy, as follows:

$$\text{Recognised Coverage}\,(RC) = \frac{1}{n}\sum_{1}^{n}\frac{P_{\text{displayed}}}{P_{\text{recognised}}}$$

A higher *RC* indicates the app developers use the APPG more

[3]This feature was deprecated as Google launched the new Data Safety after we completed this work.

Table 9: Permissions coverage for APPGs.

#	APPG Name	Mode	User instruction	RC	EC
1	Iubenda	UI	●	15.6%	15.6%
3	Termly	Questionnaire	●	60.3%	60.3%
4	Privacy Policies	Questionnaire	○	85.6%	40.1%
7	Terms Feed	Questionnaire	○	52.7%	25.7%
8	Website Policies	Questionnaire	◐	60.0%	11.8%
9	Free Privacy Policy	Questionnaire	○	64.4%	25.6%

properly, despite APPGs' intrinsic design flaws. And

$$\text{Expected Coverage}\,(EC) = \frac{1}{n}\sum_{1}^{n}\frac{P_{\text{displayed}}}{P_{\text{claimed}}}$$

A higher *EC* reflects the APPG has less intrinsic design flaws about disclosing permissions in generated privacy policies.

We use the intersection of privacy policies identified by both FKS and DSC (2,042 privacy policies) because it is more certain that they are generated by one of the APPGs. Based on our observations in Section 2.3, four APPGs (#2, #5, #6, #10) do not support permission declarations, in other words, $P_{\text{recognised}} = 0$ for every app identified to use those APPGs. In addition, we find that $P_{\text{displayed}} = 0$ for four of those apps, which means that none of the developers realised that the APPG they used did not cover the permissions they claimed.

The results are shown in Table 9. First, for #1 and #3, they both can recognise all nine device permissions involved in this study, so their *RC*s are equal to *EC*s. There is a significant portion of missing permission disclosure for all APPGs, since all *EC*s are much smaller than 100%. The missing disclosure issue is not dependent on users' input, but on the design of APPGs that did not sufficiently accommodate the requirements. Second, compared to #1's and #3's consistency on *RC*s and *EC*s, for #4, #7, #8, and #9, their *EC*s are greatly smaller than *RC*s. The gap shows the importance of APPG selection, because inappropriate APPGs will hinder developers from including self-reported (claimed) permissions in their privacy policies. Third, #1 has the lowest *RC*, but it has high level user instruction; whereas #4, #7, and #9 has the relatively high *RC*s, but low level of user instruction. This counter-intuitive result indicates that current user instructions are not helpful enough to guide developers to correctly include permissions in the generated policies. In addition, #1 is the only UI-mode APPG, with the lowest *RC* (15.6%), and other comparable APPGs, whose *RC* is over 50% are all questionnaire-mode. This observation indicates that UI mode APPGs may be more challenging to be properly used by users.

Finding 3.2: A significant portion of device permissions remain under-claimed, perhaps caused by APPGs' design issues, and questionnaire mode can better guide users to include claimed device permissions compared to UI mode.

4.3 Contradiction Analysis

Previous works have discussed contradictions within a policy [34, 42]. Specifically, if affirmative and negative sentences mention the same or conflicting entities and data types in a policy, then there can be a contradiction. In this section, we compare the APPG-based and non-APPG-based privacy policies, to examine the situation of contradiction issues in both and the effect introduced by APPGs. For non-APPG-based privacy policies, we used the test set from PoliCheck [35] which contains 200 policies randomly sampled from 13K mobile apps. For APPG-based privacy policies, we use 30 policies from the "**Generated Privacy Policy Collection**" and 170 policies that are randomly sampled from the intersection list (indicated as APPG-generated by both FKS and DSC). We employ the state-of-the-art privacy policy analyser, PoliGraph [42], to conduct the following analysis.

We observed 26 contradictions in APPG-based privacy policies and 15 in non-APPG-based policies, indicating a potential tendency for APPGs to introduce more privacy policy contradiction issues. Closer examination revealed that a significant portion of these contradictions in APPG-based policies arise from conflicting statements present in different sections of the document. For example, one section of the policy explicitly states "[A condition], we sell your personal information to third parties", while an assertion in the CCPA section contradicts this by claiming "[The App] has not disclosed or sold any personal information to third parties for a business or commercial purpose in the preceding 12 months.". Therefore, it is imperative for APPG users to exercise caution and meticulously evaluate the coherence and consistency between different sections of generated privacy policies.

Finding 3.3: More privacy policy contradiction issues exist in APPG-based privacy policies.

5 Discussion and Implication

Challenges and opportunities coexist in the current APPG development. Based on our observations and study results, we summarize some findings for various roles or stakeholders in the APPG ecosystem.

App developers/APPG users. While app developers may benefit from using APPGs to create privacy policies more efficiently, they should be aware of APPGs' latent limitations. As illustrated in Section 2, APPGs have different qualities. Some do not directly target specific regulations, such as GDPR and CCPA, and some do not recognise data practices, i.e., the declaration of personal information, device permissions, and third-party services used in their mobile apps. Since app developers must make sure the privacy policies they provide are comprehensive, readable, and compliant, **it is very likely a trap** if they do not select and use appro-

priate APPG with careful consideration.

APPG providers. Our analysis suggests APPG providers should work on improving recognised data use, since the majority of APPGs on the market only provide a very limited scope of personal information and device permissions. The following two requirements are commonly neglected by the APPGs even though they claim to comply with CCPA: **a)** Special requirements for businesses buying, receiving, selling, or sharing personal information of 10,000,000 or more consumers in a calendar year [Regs § 999.308(c)(8), 999.317(g)(1)], and **b)** For online notices, follow generally recognized industry standards [Regs §999.308(a)(2)(d)]. Based on our market penetration analysis, we found that developers would rather use a simpler APPG (e.g., #2) than a correct one. It is worthwhile to consider this trade-off in the design and acquisition of APPGs. Our results indicate that current user instructions are not helpful enough; thus, APPG providers should work to improve user instructions and provide intuitive UIs to guide users to correctly use their tools. We have disclosed our observations and findings to APPG providers [20].

Privacy regulators. We discovered that the privacy policy of 20.1% apps could be generated by existing APPGs, which means APPGs can significantly contribute to reducing policy absence and low quality privacy policies in app markets. However, our results also highlight that the APPGs' design flaws can limit the app developers to include all essential privacy practices, data rights, and device permissions in the policies, which in turn creates a substantial risk of breaching privacy regulations. Regulators should recognize the importance of this issue and be engage with this emerging market trend. One possible approach would be to proactively provide guidance for APPGs developers, to improve compliance with privacy regulation, and to protect apps developers from potential pitfalls. Finally, we hope this study could raise broad attention to inherent design shortcomings and resulting privacy concerns of online low-code/no-code tools such as APPGs, as they are increasingly employed in practice.

6 Related Work

Privacy policy analysis. Privacy policies have been extensively analysed and discussed by the research community [33, 34, 40, 64, 71]. Wilson et al. [64] created a corpus of 115 privacy policies and 23K fine-grained data practise annotations, and revealed users' preferences on privacy policy structure and complexity. Amos et al. [33] reported that privacy compliance and readability were worse in the last 20 years, according to 130k website privacy policies. Andow et al. [34] presented *PolicyLint*, which is a privacy policy analysis tool that can identify privacy contradictions by simultaneously considering negation and varying semantic levels of data objects and entities. Bui et al. [40] proposed an automated system, dubbed *PurPliance*, that detects inconsistencies between the data-usage purposes stated in a privacy policy and the actual behaviours of an Android app.

Code-centric privacy policy auto-generation tools. Yu et al. [66, 67] developed a system named *AutoPPG*, to automatically construct readable descriptions from the source code of mobile apps, to help create privacy policies on Android. Rocky Slavin [59] developed *PoliDriod*, an Android Studio plugin that can be used to detect possible misalignments between Android API methods and privacy policies. Zimmeck et al. [70] proposed a privacy policy generator, named *PrivacyFlash*, which leverages mappings between code signatures and privacy practises expressed in policies for iOS apps. While code-centric generators might better align with apps' actual privacy behaviours compared to online APPGs, they come with significant challenges that hinder their adoption by app developers. First, they cannot ensure compliance with high-level privacy regulations, particularly non-functional requirements. Second, they present a higher entry barrier for developers due to their inherent complexity, whereas online APPGs can be easily accessed, offering a range of user instructions and publishing support as demonstrated in this study. Others [38, 65] also discussed the automated generation of privacy policies using machine learning methods.

7 Conclusion

Online Automated Privacy Policy Generators (APPGs) are broadly used by developers of mobile apps to create privacy policies to respond to regulatory requirements. This paper reports the first large-scale empirical study to comprehensively scrutinize APPGs' various features, characteristics, and extent of recognition of data use. Our market penetration analysis indicates that privacy policies of 20.1% apps could be generated by existing APPGs on the Google Play app store, and that #2 is the most popular APPG, with a 72.7% adoption rate. Our findings underline a substantial level of noncompliance with privacy laws and a frequent under-claiming of data rights and highly concerning privacy practices, especially with the most popular APPG #2. Permissions coverage analysis reveals that existing APPGs have significant issues with including all essential device permissions in the generated privacy policy, and UI mode APPGs could make it worse. Also, more contradiction issues exist in APPG-based privacy policies. In summary, for app developers, selecting and employing APPGs without careful consideration is very likely a trap, creating a substantial risk of breaching privacy regulations.

Appendix

Readability Analysis

The readability score of privacy policies are calculated by the Flesch Reading-ease Test [44]:

$$206.835 - 1.015\left(\frac{\text{total words}}{\text{total sentences}}\right) - 84.6\left(\frac{\text{total syllables}}{\text{total words}}\right)$$

Specific readability scores are listed in the Table 10.

Table 10: Comparison of APPGs' readability scores.

#	APPG Name	Average Readability Score
1	Iubenda	37.3
2	App Privacy Policy Generator	**49.3**
3	Termly	46.0
4	Privacy Policies	37.7
5	App Privacy Policy	43.9
6	Privacy Policy Online	44.0
7	Terms Feed	37.7
8	Website Policies	36.7
9	Free Privacy Policy	37.7
10	Lawpath	41.0
/	12 leading apps	46.0

GDPR and CCPA requirements compliance

The specific requirements and compliance checking for GDPR and CCPA are tallied in Appendix Table 11 and Table 12.

Table 11: GDPR privacy policy requirements and APPGs' compliance in May 2022. Numbers indicate APPGs as per Table 1.

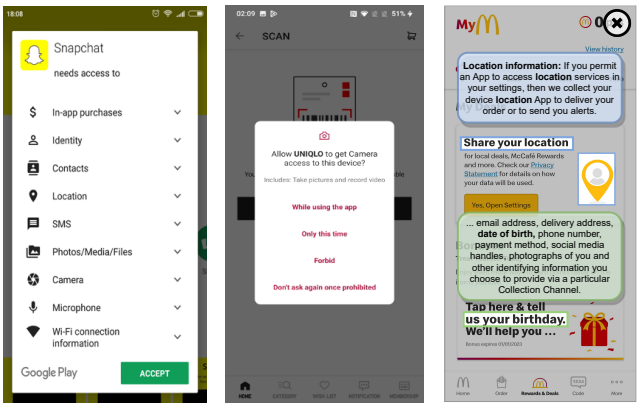
Abstract

Privacy policies have emerged as the predominant approach to conveying privacy notices to mobile application users. In an effort to enhance both readability and user engagement, the concept of contextual privacy policies (CPPs) has been proposed by researchers. The aim of CPPs is to fragment privacy policies into concise snippets, displaying them only within the corresponding contexts within the application's graphical user interfaces (GUIs). In this paper, we first formulate CPP in mobile application scenario, and then present a novel multimodal framework, named **SEEPRIVACY**, specifically designed to automatically generate CPPs for mobile applications. This method uniquely integrates vision-based GUI understanding with privacy policy analysis, achieving 0.88 precision and 0.90 recall to detect contexts, as well as 0.98 precision and 0.96 recall in extracting corresponding policy segments. A human evaluation shows that 77% of the extracted privacy policy segments were perceived as well-aligned with the detected contexts. These findings suggest that SEEPRIVACY could serve as a significant tool for bolstering user interaction with, and understanding of, privacy policies. Furthermore, our solution has the potential to make privacy notices more accessible and inclusive, thus appealing to a broader demographic. A demonstration of our work can be accessed at https://cpp4app.github.io/SeePrivacy/

1 Introduction



Privacy policies have become the most prevalent privacy notice approach for mobile applications, with the aim of protecting users' privacy and digital security [26, 33, 49, 51, 52, 60, 66, 83]. On the contrary, application users often find themselves in a privacy paradox, specifically, *Digital Resignation*. This term refers to a state where users desire to understand and control the information that digital entities own about them, but feel powerless to do so [45]. A study has found that the average length of privacy policies is around 4,000 words for 75 prominent mobile applications and websites, requiring an estimated 16 minutes to read for an average adult [30]. Consequently, according to a survey conducted by Obar and Oeldorf-Hirsch [78], a significant portion of users, approximately 74%, opt for the "quick join" clickwrap option without engaging with privacy policies, primarily due to the lengthy and detailed nature of these documents. These numbers indicate that privacy policies have become increasingly difficult to read and understand in a timely manner, exacerbating the prevalence of digital resignation among users.

In addressing the pressing issue of digital resignation, the contemporary evolution of privacy policies has given rise to the concept of "just-in-time" privacy notices [12]. These notices furnish users with detailed information about data collection at the point of interaction. This practice has been recognized and included in the U.K. General Data Protection Regulation as a recommended approach for crafting privacy policies [12]. However, the dominant application of "just-in-time" notices is primarily limited to the installation phase of applications and first invocation of certain permissions. Figure 1a shows the "install-time" permission reminders that appear when a user installs a new Android app[1], delineating the permissions to be granted. Figure 1b presents another example, which illustrates a camera access reminder triggered at the initial "invoke-time". However, there are inherent limitations to current "just-in-time" notices. For one, while they provide a snapshot of when an app accesses specific data, it doesn't necessarily offer insights into the broader context – how this data might subsequently be transmitted off the device, shared with third parties, stored, or used for other purposes. Furthermore, current implementations of "just-in-time" reminders fall short in terms of efficacy, as security warnings regarding device permissions tend to be isolated from their immediate context, thus failing to adequately engage user awareness [47, 74].

*The author completed most of the research while being a visiting student at Singapore Management University

†Corresponding Author

[1]This feature was essentially deprecated after Android 6.0 (API level 23) since developers must request permissions at runtime.

(a) Install-time (b) Invoke-time (c) Context-aware

Figure 1: Figure 1a represents the install-time reminder of required permissions [20]; Figure 1b corresponds to the invoke-time reminder that appears when permission is first invoked; Figure 1c presents our proposed contextual privacy policy, specifically designed for mobile applications.

To counteract these deficiency, researchers proposed *Contextual Privacy Policies* (CPPs) [48, 94]. This innovative concept aims to deconstruct traditional privacy notices into shorter and digestible segments, displaying them only in relevant contexts in mobile applications. Privacy-related contexts refer to areas in which data practices are directly associated with graphical user interfaces (GUIs). These contexts on the screen are identified and the corresponding privacy policy segments are retrieved and displayed, with key information highlighted. This integration of privacy notices within the GUIs ensures a close and timely alignment with the context, thus conveying precise and succinct privacy information. Windl et al. [94] demonstrated that CPPs have the potential to address the usability issues in privacy policies, thereby enhancing user engagement and awareness of data practices. They also presented a framework for automatically generating CPPs for websites. Studies have shown that users spend 90% of their time using mobile apps rather than websites [5, 32, 62]. However, the prior [94] framework has the following limitations when applied to the mobile app context, all of which are successfully addressed in this work: 1) Their context selection is based on empirical observation of users' behaviour in website browsing scenarios, but lacks connection to privacy regulations and existing standards in practice. 2) The prior context detection method is based on ad-hoc HTML analysis, which has limited internal generalizability, especially for more compact and complicated user interfaces in mobile app platforms. Overall, while the concept of CPP has a great potential, generating accurate CPPs for mobile apps proposes unique challenges that cannot be addressed by the previous automated generation framework.

In this paper, we first formulate the CPPs in the mobile scenario, and then propose a novel multimodal framework, dubbed **SEEPRIVACY**, designed to automatically generate CPPs for mobile applications. Figure 1c presents an example of our CPP in mobile applications. Within this framework, computer vision techniques are incorporated with pre-trained large language models (LLMs) to analyze mobile GUI screenshots, thus pinpointing privacy-related contexts. In addition, natural language processing techniques are used to dissect privacy policy texts, extracting the corresponding policy sections for identified contexts. To quantitatively evaluate performance, we establish our benchmark dataset, named **CPP4APP**, which covers more than 1,200 privacy-related contexts along with their matching privacy policy segments in mobile settings. The quantitative evaluation demonstrates the robust performance of our framework in multiple evaluation metrics. Regarding the identification of privacy-related contexts, SEEPRIVACY achieves accuracy, precision, and recall values of 0.81, 0.88, and 0.90, respectively. Regarding the extraction of the corresponding segments, the framework attains accuracy, precision, and recall rates of 0.94, 0.98, and 0.96, respectively. To further assess the functionality of SEEPRIVACY, we performed a human evaluation with 15 examiners on about 120 CPPs. The results are encouraging: 77% of the extracted privacy policy segments were perceived as elucidating the detected context.

We also discussed the applications, implications, and contributions of CPPs and SEEPRIVACY to the broader community. In the survey, participants display a significantly increased willingness to engage with CPPs, achieving an average score of 4.1 out of 5. In contrast, traditional privacy policies received an average score of just 2 out of 5. This difference suggests SEEPRIVACY could contribute meaningfully to improve user engagement with privacy policies, potentially mitigating the widespread challenge of digital resignation. Additionally, the overall usefulness rating for SEEPRIVACY is 4.53 out of 5, indicating strong user endorsement. Furthermore, we elaborate on two potential application scenarios of SEEPRIVACY: displaying CPPs in app markets and detecting "lack of disclosure" with exact problematic context. Lastly, we discuss how CPPs potentially make the privacy policies more inclusive and allow it to reach a larger audience such as children.

In summary, our proposed framework extends the automated generation of CPPs to mobile applications, which are the digital platforms users spend the majority of time on. The key contributions are:

- To our knowledge, this is the first research to define the concept of contextual privacy policies (CPPs) within mobile application scenarios.
- We have introduced a novel framework, named **SEEPRIVACY**, designed to automatically generate these contextual privacy policies for mobile applications.
- We have constructed the benchmark dataset, named **CPP4APP**, specifically to evaluate contextual privacy policies on mobile platforms and to quantitatively assess the functionality of the SEEPRIVACY framework.

Roadmap. The remainder of this paper is structured as follows: Section 2 introduces the development of transparent privacy notices and privacy-related context identification; Section 3 introduces our benchmark dataset, CPP4APP; Section 4 details the design of our proposed framework, i.e.,SEEPRIVACY; and Section 5 presents the results of evaluating SEEPRIVACY on the benchmark dataset; Section 6 discusses the implications and contributions of our work to the broader community; and Section 7 concludes the paper.

Ethical Considerations and Responsible Disclosure. Ethical approval for this research was secured from our institution's Institutional Review Board (IRB). In conducting our user study, we avoided collecting any personally identifiable information (PII). In line with our commitment to responsible research practices, any privacy discrepancies detected during the course of the study were promptly and transparently disclosed to both the study participants and the corresponding application developers.

2 Background

Mobile applications provide users with unparalleled convenience, multiple entertainment options, and various services. At the same time, they are responsible for the collection and exchange of substantial amounts of personal information, raising concerns surrounding data privacy. In response to the potential risks of privacy violations, the U.S. Department of Health, Education, and Welfare proposed a set of Fair Information Practice Principles (FIPP) in 1973 [9, 63]. Later, the Federal Trade Commission adopted these principles as "*the notice and choice privacy framework*" [78], which is commonly regarded as the foundation for modern privacy regulations such as the European General Data Protection Regulation (GDPR) [10], the California Consumer Privacy Act (CCPA) [6], and the Australian Privacy Principles (APP) [3]. In FIPP, the most fundamental principle is *"notice"* [23]. Consumers should be provided with a clear understanding of an entity's information practices before any personal data is collected from them (e.g., [GDPR Art. 12, GDPR Rectical 58]). In the absence of transparent and understandable notice, it becomes impossible for a consumer to make an informed decision regarding the extent of personal information they choose to disclose.

2.1 Related Work

Research efforts to improve the presentation and readability of privacy policies have been manifold and encompass various approaches. Kelly et al. [57, 58, 59] introduced an innovative method called privacy nutrition labels (PNLs), designed to facilitate consumers' understanding of how their information is collected and utilized in a structured table-like way. By employing this concise and organized framework, PNLs effectively aid in understanding the privacy practices of software applications [40, 68, 70, 81]. In a related vein, Cranor [39] proposed a protocol, i.e., Platform for Privacy Preferences, that allows website organizations to declare their intended use of information collected from website users. Alongside these approaches, there has been a growing focus on visual aids such as privacy icons [46, 53, 54]. These small graphical symbols, symbolizing privacy concepts or practices, serve as visual shorthand, simplifying complex privacy policies. By standardizing these icons across various services and platforms, researchers aim to reduce confusion, thereby making privacy policies more readily accessible to the general populace [54].

The conceptualization of *Contextual Privacy Policies* emerged in 2004, marking a significant change in the approach to the presentation of privacy notices. Bolchini et al. [31] discerned that the conventional reading of privacy policies represented a monolithic block that hindered users from retrieving essential privacy details. In response, they invented a systematic method aimed at reorganizing privacy policies around specific user interaction contexts. Subsequent to this development, Feth [48] extended the concept by introducing *contextual privacy statements*. Rather than using a "one-size-fits-all" privacy policy that must suit every usage scenario, these contextual privacy statements offer precise privacy and data protection information more closely with the user's immediate context. In a recent advancement, Windl et al. [94] proposed the design and architecture of PrivacyInjector, a production AI tool that can automatically generate contextual privacy policies for websites. However, their scope of data practice identification is limited to six website-specific types, such as "Advertising" and "Cookies and Tracking Elements". Their identification procedure primarily considers which date type users are likely to encounter when browsing websites. In contrast, our approach is regulation-driven, examining which data practices should be transparently disclosed in privacy notices. Moreover, their context detection method is intrusive and based on ad-hoc HTML analysis, which is consequently not applicable to mobile applications. In contrast, the source code of mobile applications is typically inaccessible to end-users. This limitation led us to develop a purely vision-based context detection method, tailored to the unique challenges presented by mobile applications. Nonetheless, CPPs have been empirically shown to increase privacy notice transparency, constituting a progressive step toward more user-centric privacy communication [76, 79].

Contrasting with websites, mobile applications represent a unique landscape for personal information collection, often involving multifaceted approaches that include device sensors, user input, and third-party integrations [82]. These complex processes necessitate a precise and transparent articulation of how user information is acquired, employed, and disseminated—an issue of critical concern. Given the expansive and continually growing scale of mobile applications, there exists an emergent need for an automated framework capable

Table 1: Tallies of data types' existence.

of generating CPPs tailored specifically to this domain. In pursuit of this objective, the present work attempts to establish such a framework. As a preliminary step, we recognize the imperative to define clear and comprehensive definitions for privacy-related contexts within the mobile environment, forming the foundation for our proposed framework.

2.2 Empirical Data Practice Identification

According to Windl et al. [94], privacy-related contexts are considered areas on graphical user interfaces (GUIs) where data practices might be applied. To rigorously define these practices, we formulate two guiding questions, each tailored to address a distinct facets of the issue:

1. What data practices should be included in privacy notices by regulations?

2. What data practices are of concern and desire for users?

These questions collectively serve to demarcate the scope of our investigation, guiding our analysis in a manner that encompasses regulatory compliance and user-centric considerations. To our knowledge, there are no existing studies that specifically address the issue of contextual privacy policies within the domain of mobile applications. Specifically, current research appears to be primarily concerned with improving the presentation and readability of privacy policies [37, 39, 57, 58, 59]. Therefore, we perform a rigorous examination of data practices as they relate to privacy regulations and industry market standards (see Table 1). We present each group as follows:

Administration. The administration often functions as the key regulator within the broader ecosystem of data privacy. A report by the United Nations Conference on Trade and Development reveals that 137 of 194 countries and regions have instituted data protection and privacy legislation [16]. To gain insight into the administrative perspective on these matters, we examine five representative privacy regulations, including the GDPR [10], CCPA [6], the California Online Privacy Protection Act (CalOPPA) [8], the Children's Online Privacy Protection Act (COPPA) [7], and APP [3]. These regulations serve as critical touchpoints in our exploration of the administration's stance on data practices.

Industry. Mobile application platforms typically impose particular privacy notice requirements on curated applications within their marketplaces, with special attention to the categories of data involved. For instance, the Google Play app store has delineated 14 primary data categories and 39 subcategories in their data safety reports, which all applications must adhere to [25]. These standards have been formulated through rigorous user studies and market tests, reflecting a comprehensive understanding of user concerns and expectations. Such market standards provide valuable insight into the alignment of privacy requirements with actual user needs and industry practices, thereby serving as a meaningful reference for privacy policy development in the mobile application domain.

2.3 Multimodal Privacy-related Contexts

Privacy-related contexts refer to areas within GUIs where data practices might be applied. In this investigation, we categorize two primary types of GUI components that indicatively collect personal information via human-device interactions: literal texts and graphical icons. Literal texts, often regarded as the foundational information sources in mobile application GUIs, are juxtaposed with graphical icons, which are ingeniously designed to communicate vital information with maximum efficiency. The growing adoption of graphical icons in place of literal texts is due to their concise nature, which provides users with the requisite information instantaneously, thereby substantially minimizing the cognitive effort required to interpret the accompanying textual descriptions [96].

Keyword collection. In the process of analyzing literal texts that describe data types, we snowballed a keyword list tailored to CPPs. This list was compiled by extracting keywords from academic research literature about privacy policies, including content categorization [56, 69, 93, 105], automated generation [89, 100, 106], and compliance analysis [29, 41, 98, 101, 104, 105]. These studies often present unique challenges due to differences in privacy policies, corpus selections, and specific tasks among various topics. Ambiguous terms, such as "address," which could refer to a residential or an email address, were deliberately excluded to

Table 2: Privacy-related contexts.

Data types	Description	Privacy-related keywords lists for textual GUI elements	Related RICO-icon class	Icon examples
Name	How a user refers to themselves	name, first name, last name, full name, real name, surname, family name, given name	n.a.	n.a.
Birthday	A user's birthday	birthday, date of birth, birth date, DOB, birth year	n.a.	n.a.
Address	A user's address	mailing address, physical address, postal address, billing address, shipping address, residential address, residence, personal address	n.a	n.a
Phone	A user's phone number	phone, phone number, mobile phone, mobile number, telephone, call, telephone number	[43] Call	
Email	A user's email address	email, e-mail, email address, e-mail address	[6] Email	
Profile	A user's account information	profile, account	[49] Avatar	
Contacts	A user's contact information, or the access to the contact permission	contacts, phone-book, phone book, device's address book	[68] Group, [3] Follow	
Location	A user's location information, or the access to the location permission	location, locate, geography, geo, geo-location, precision location	[40] Location crosshair, [72] Location	
Photos	A user's photos, videos, or the access to the camera permission	camera, photo, scan, album, picture, gallery, photo library, storage, image, video, scanner, photograph	[42] Photo, [56] Videocam, [82] Wallpaper	
Voices	A user's voices, recordings, or the access to the microphone permission	microphone, voice, mic, speech, talk, audio	[91] Microphone	
Financial info	Information about a user's financial accounts, purchases, or transactions	credit card, company, companies, organization, commercial, organizations, pay, payment, financial, bill, wallet, purchase	[61] Cart	
Social media	A user's social media information, or the access to social media accounts	social media, Facebook, Twitter, socialmedia, share	[77] Facebook, [89] Twitter	

avoid confusion. To further promote unification and consistency across contexts, we rendered the list case-insensitive. Table 2 presents a comprehensive display of the finalized keyword list of each data type.

Icon collection. Icons frequently serve as symbols for specific categories of privacy information. One common example is that the camera-like icons typically correspond to the authorization of camera access by mobile applications or access to the device photo gallery; and a location crosshair icon often represents the access to location permission or users physical location information. Liu et al. [73] developed a comprehensive icon taxonomy, comprising 99 common icon classes in mobile applications. This research effort also yielded one of the largest icon datasets, consisting of over 118,000 distinct icons. Subsequently, we performed a semantic alignment between the RICO-icon classes proposed by Liu et al. and the data types that were identified through our survey. By doing so, the textual information (privacy-related keywords) and visual information (icons) on GUI are well aligned with regulatory requirements (data types), as detailed in Table 2.

3 CPP4APP: The Benchmark Dataset

In our study, the construction of a benchmark dataset is essential to quantitatively assess the efficacy of the proposed framework in generating contextual privacy policies (CPPs). Although existing datasets are available for privacy policy analysis [27, 29, 93, 105], and for understanding mobile graphical user interfaces (GUIs) [34, 42, 64], we identified two major shortcomings within current collections. These limitations, as detailed below, necessitate the compilation of a new dataset.

- **Temporal inconsistency between applications, policies, and GUIs.** With mobile applications undergoing frequent changes in privacy practices, there is a concomitant need to update their corresponding privacy policies. In addition, the GUIs of these apps are subject to rapid evolution. Consequently, it becomes imperative to maintain alignment between the screenshots (representing the GUIs) and their temporally corresponding privacy policies for CPP generation. This alignment ensures the precision and dependability of quantitative evaluations.
- **No annotations about privacy-related contexts in GUIs.** To the best of our knowledge, we are the first to introduce the concept of CPPs specific to mobile applications. For the purpose of evaluating the performance of the automated generation framework, benchmark datasets should ideally incorporate two essential features: 1) the annotated regions (i.e., bounding boxes) representing privacy-related contexts within GUI screenshots, and 2) the mapping relations that connect these privacy-related contexts to corresponding segments of the privacy policy. Unfortunately, as of the time of this study, no existing dataset encompasses both of these vital characteristics.

In the following subsections, we present steps employed to create a benchmark dataset, thereby addressing the aforementioned issues.

3.1 Mobile Apps Selection

The Android platform is often considered transparent and favorable for academic research, with numerous apps markets readily available [67, 92]. Among these, the Google Play app store stands out as the most expansive and accessible, hosting more than two million applications [75, 91]. In particular, Google Play is a leader in requiring mobile applications to

provide a link to their privacy policy on their homepages [19]. As a result, users downloading Android mobile applications from the Google Play app store can directly access the respective privacy policy links.

Consistent with previous research, widely used mobile applications tend to adhere to more stringent privacy practices [61, 71, 105]. In addition, less popular applications often have poorly written privacy policies [81, 82], making it meaningless to generate CPPs for them. In this study, we leveraged market data from AppBrain [24], one of the largest third-party platforms monitoring app statistics for the Google Play app store, to pinpoint the 200 most popular mobile applications. Our study collection method includes four specific strategies. First, recognizing the variations in GUIs, functions, and privacy practices across different application categories (i.e., genre), we endeavored to ensure a diverse representation by selecting the most popular mobile applications from 17 distinct categories. Second, applications published by the same parent company normally share the same privacy policy, so we try to select apps from different developers for better representation. Third, we excluded any mobile applications with privacy policies that were less than 200 words or smaller than 2 KB in size, as these may constitute invalid or insufficient privacy policies [61, 72]. Finally, we limited our selection to those applications that offered privacy policies in English, thus narrowing our candidate pool to 50 mobile applications for subsequent fine-grained annotation.

3.2 Context Annotation Strategy

To create a benchmark dataset, it is imperative to ascertain that vital privacy-related GUI elements are incorporated into our dataset. Therefore, drawing on established guidelines about mobile application GUI design [1, 2], we have systematically gathered specific pages from each selected application. The collection process adheres to the categorizations delineated below:

- *Registration/Login page.* Mobile applications frequently gather user registration information on this page to facilitate account creation. This may encompass both personal and other private details. Certain applications require new users to register before accessing specific features, making it infeasible for these users to circumvent the registration or login process.
- *Home page.* This serves as the initial interface upon accessing a mobile application. It contains essential features and information related to its app's functionality, which may necessitate the provision of personal data or the granting of device permissions. Furthermore, screenshots of adjacent main pages are also collected for analysis.
- *Profile page.* This section may retain users' personal information. For example, some mobile applications might request access to the camera or photo roll to furnish customization options related to public profile appearance.

Table 3: Basic statistic of CPP4APP.

No. Mobile applications & Privacy policies	50
No. Screenshots	402
Screenshots per Mobile application	8.04
No. Privacy-related contexts	1,217
Contexts per Mobile application	24.34
No. Words in Privacy policies	297,010
Words per Privacy policy	5,940

- *Setting page.* Often associated with privacy customization, this page may govern permissions related to device sensors and access to personal information.
- *Onboarding page.* It serves as a tutorial or introduction. Moreover, this page elucidates a mobile application's salient features and benefits.
- *Map page.* Common to various application categories such as travel, posting, food delivery, and shopping, this page is often utilized to amass users' location data.
- *Essential pages for specific categories.* This includes specialized interfaces such as the product card pages in shopping apps, the post-editing interface in forum applications, and the feed page within social media platforms.

We follow these categorizations to systematically collect relevant pages from each selected mobile applications, ensuring that essential privacy-related GUI elements are represented in our dataset. Notably, we have opted for manual collection of GUI pages as opposed to relying on static analysis for several reasons. Accurate static analysis is a challenging task in mobile program analysis, particularly for popular apps that are not only complexly programmed but also commonly employ code obfuscation. Furthermore, iterating through all possible activities to capture their corresponding GUIs is a non-trivial task, and outdated or restricted GUIs may not be accessible through regular user interactions. Manual collection allows us to naturally avoid the aforementioned problems.

After the data collection, the annotators need to manually examine the text in each screenshot, cross-referencing it with our CPP-related keyword list, as mentioned in Table 2. If the text contains any of these CPP-related keywords, it is labeled as the corresponding data type and designated with a bounding box. Subsequently, the annotators are tasked with detecting all icons in the screenshot to determine if any belong to a privacy-related data type. If an icon meets this criterion, it is labeled with the corresponding class and marked with a bounding box. For these purposes, the *OpenCV-Python* [13] library is employed to draw bounding boxes and document coordinates. Two annotators were asked to execute the annotation process independently. For any disagreement, they discussed and agreed on the same opinion, and if the disagreement persisted, a senior annotator joined the discussion to facilitate a resolution. The percent agreement (inter-rater reliability) for initial annotation is about 84%.

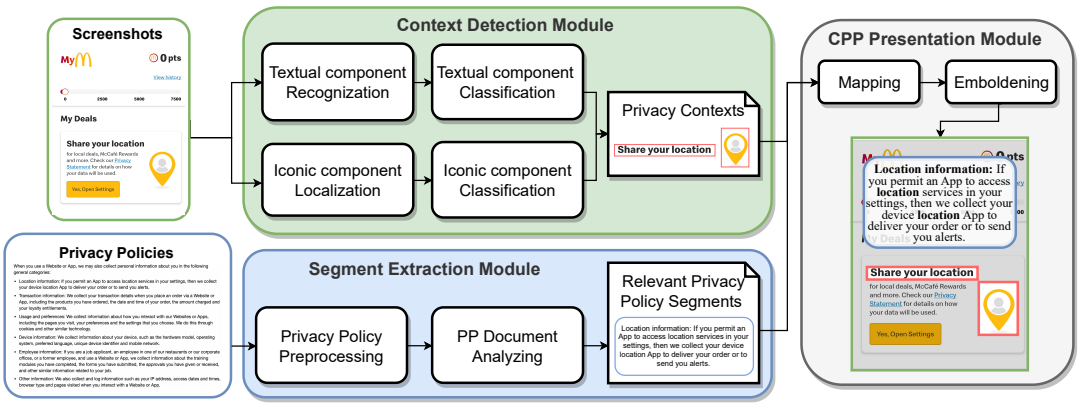

Figure 2: An overview of SEEPRIVACY.

3.3 Segment Annotation Strategy

Initially, if annotators are unfamiliar with the mobile application of the policy they need to annotate, they are mandated to explore and familiarize themselves with its features for a duration of 10 minutes. Then, two annotators independently scrutinize each data privacy-related context within the privacy policies and extract pertinent segments. To ensure the integrity and quality of the annotation process, we establish a reading speed parameter ranging from 250 to 300 words per minute (the reading speed of an average adult [30]) for the annotators, implementing countdown timers in accordance with the policy lengths. If the *segment_sim* (See the Formula 5.1.2) is above 0.8, two annotations are counted as an agreement. The mechanism for resolving disagreements is consistent with the process outlined in the previous paragraph. In cases where both annotators are unable to identify any relevant segments within the privacy policies, the segment is explicitly labeled as "No relative information is found in the privacy policy."

3.4 Setups and Statistics

All annotators involved in this study are research scientists with a minimum of two years of experience in privacy research for mobile applications. To ensure the alignment between the GUIs and privacy policies, an Android mobile phone, i.e., the OnePlus 7 Pro, Android 11, and Hydrogen OS 11.0.9.1.GM21, is employed to download all the selected mobile applications. The corresponding privacy policies are downloaded simultaneously. To preserve the status quo of the apps and policies, the auto-update features within the Google Play app store, individual mobile apps, and the system's general settings on the phone (including auto-update over Wi-Fi) are all deactivated. In total, this effort resulted in the collection of 402 screenshots from 50 diverse mobile apps, accompanied by 1,217 labeled privacy-related contexts, each correlating to specific segments within privacy policies. We have designated this benchmark dataset as CPP4APP, and the statistical analysis is provided in Table 3. As the inaugural dataset of its nature, we are confident that it is sufficient for evaluating our automatic generation framework and positioned to serve as a benchmark for future research in this field.

4 SEEPRIVACY: The Framework

In this section, we introduce our multimodal framework SEEPRIVACY, designed to automatically generate CPPs for a given screenshot and a given privacy policy, as illustrated in Figure 2. The framework accepts privacy policies and screenshots from a given mobile application as input parameters. These inputs are processed through three primary modules within the framework to autonomously build CPPs for the designated mobile application. The three main modules integral to our framework are detailed as follows:

- *Context Detection Module:* This module is designed to identify specific contexts within a mobile application's screenshots where CPPs should be displayed.
- *Segment Extraction Module:* This module focuses on extracting pertinent segments from the privacy policy of the given mobile application.
- *CPPs Presentation Module:* This module is responsible for linking privacy policy segments to their corresponding contexts and articulating the essential information, thereby facilitating the generation of CPPs for mobile applications.

The details of each module are explained in the following subsections.

4.1 Context Detection Module

The source code of mobile apps is typically inaccessible to end-users. This limitation led us to develop a purely vision-based Context Detection Module tailored to the unique challenges presented by mobile apps. Specifically, in our approach to GUI understanding, we opt for visual components as atomic elements rather than function-level GUI widgets. This choice

is driven by the observation that certain widgets (e.g., a navigation bar) may be too coarse-grained to adequately represent a data practice.

Textual GUI components. To detect and localize privacy-related texts from a given screenshot, we apply a state-of-the-art ultra-lightweight OCR system, named PaddlePaddle-OCR (PP-OCR) [65]. After obtaining these texts, we employ a pre-trained large language model, i.e., GPT-3.5[2], to classify their data types. If the answer contains a data type, we will regard the *{detected text}* as relevant to this data type; otherwise, it does not belong to any data type.

Iconic GUI components - Localization. An empirical study [35] demonstrated that rule-based object detection methods on GUIs outperform learning-based methods, such as YOLO [86] series. In addition, rule-based methods have better explainability. To localize iconic GUI components from their screenshots, we adapt previous work [99] and propose an updated set of detection rules to filter out irrelevant objects. Specifically, we have four rules presented as follows: (a) Filtering out elements whose area is greater than 10% of the total area of the screenshot, in order to remove the bounding boxes and large images; (b) Filtering out elements whose area is less than 5% of the total area of the screenshot, aiming to remove the small noises; (c) Removing rectangular elements whose aspect ratio (width to height) is less than 0.6, ruling out control bars and top/bottom banners; (d) Removing elements that area is overlapped with OCR results since some letters in large font-size are also detected as potential icons. By applying these rules to our dataset, we can obtain the position of the iconic GUI components on their screenshots.

Iconic GUI components - Classification. CNN-based neural networks have a strong capability of recognizing patterns on GUIs [36, 73, 95]. In this paper, we train two models to classify the detected graphical icons from the screenshots, including a ViT-based model and a ResNet-based model. ViT stands for Vision Transformer [44]. Specifically, we employ a pre-trained vanilla ViT and fine-tune it on ImageNet [43]. Regarding the ResNet-based model, we employ ResNet-18 as the backbone because of its tiny size and decent efficiency. We further add dropout layers to every ResNet block to enhance its generalizability, preventing the potential over-fitting issue. We then trained both models on the RICO-icon dataset with the default train-test split. We use the ViT-based model as the default for Contextual Detection Model as it achieves the best performance.

4.2 Segment Extraction Module

The objective of this module is to obtain privacy policy segments with their corresponding privacy-related contexts. Mainstream mobile application markets, such as the Google Play app store [19] and the Apple App Store [17], require developers to provide a privacy policy link on the application's homepage. This requirement allows us to access those links based on the name of a mobile application. To capture these privacy policies in HTML format, we leverage two Python libraries, *Selenium* [14] and *BeautifulSoup* [18], which fetch the information via the corresponding privacy policy links. Recognizing the global market trend and the need to cater to multilingual users, we note that an increasing number of privacy policies are available in multiple languages. To maintain consistency and clarity in our analysis, we deploy *langdetect* [21] library to filter out non-English texts in privacy policies. Note that our framework has the flexibility to be easily extended to accommodate other languages.

Previous studies [90, 98] have discussed that only using sentence-level privacy policies processing and analysis can lead to contradictory conclusions, since the same or similar sentences in different sections may have different implications. Therefore, to retrieve the relevant sentence-based segments, we adopt the multi-level privacy policies processing method proposed in [28, 98]. For privacy policy documents whose HTML structure follows the $(\langle\texttt{Heading}\rangle\langle\texttt{Paragraph}\rangle^+)^+$ format, we reuse the pre-trained Bayesian multi-label classifier model [98] to classify privacy policy paragraphs based on their headings since headings usually contain words that can be used as identifiers. The classifier is claimed to achieve 0.85 accuracy and can classify the majority of the documents based on their headings. The paragraphs classified as *Types* are related to the "types of personal data collected by the current app". Those paragraphs are highly related to specific data practices, so we only conduct sentence-level analysis on them. For privacy policy documents whose HTML structure does not follow the $(\langle\texttt{Heading}\rangle\langle\texttt{Paragraph}\rangle^+)^+$ format, we follow previous works [52, 94] to classify paragraphs on specific data practices. Specifically, we train a CNN-based multi-label classification model on a large privacy policy dataset [93] with 23K fine-grained data practice annotations. Note that this dataset contains 12 high-level categories for data practices, including *First-Party Collection/Use* and *Third-Party Sharing/Collection*. The results show that we can achieve a 0.84 top-1 precision for classifying the privacy segments with their related data practices.

After obtaining paragraph-level privacy segments, we tokenize them into sentences using the *stanza* [85] Python library. We then perform a two-stage sentence-level analysis to extract the sentences for each data type. First, we perform a keyword search based on our collected keyword list (see Table 2). If a keyword exists, the sentence will be added to the corresponding privacy policy segments of its data type. Second, for sentences without any keywords, we further employ a Bayesian binary classifier to determine whether the sentence is related to a data type. The classifier is trained on the dataset from [98], reaching an accuracy of 0.98. If yes, we use *SpaCy* [15] Python library to obtain noun chunks from the sentence. A noun chunk is a phrase that includes a noun and

(d) Overall Context Identification

Category	Accuracy	Precision	Recall
Name	0.98	0.98	1.00
Birthday	1.00	1.00	1.00
Address	0.38	0.41	0.86
Phone	0.88	0.91	0.97
Email	0.66	0.96	0.68
Profile	0.70	0.74	0.93
Contacts	0.75	0.94	0.78
Location	0.94	0.97	0.96
Photos	0.86	0.98	0.88
Voices	0.91	0.91	1.00
Financial info	0.81	0.93	0.87
Social media	0.80	0.89	0.89
Average	0.81	0.88	0.90

any connected words such as its adjectives. We calculate the similarity of the phrases *phrase_sim*( ) between noun chunks and keywords as follows:

$$phrase\_sim(p_1, p_2) = \frac{2 \times path\_similarity(p_1, p_2)}{word\_count(p_1) + word\_count(p_2)}$$

where the p_1 and p_2 are a noun chunk and a keyword, respectively; *path_similarity*( ) is the function from WordNet [77], reflecting the similarity based on parsing their semantic constituency trees' structure; *word_count*( ) is to count the number of words. If the similarity between a noun chunk and a keyword is higher than 0.8, an empirically set threshold, then we regard that the sentence that the noun chunk belongs to is the data type of the keyword.

Above all, we obtain the sentence-level policy segments related to each data type and group them as privacy policy segments. We also record the positions of keywords or noun chunks in the resulting sentences. For data types that do not have any match, we simply add "No relative information is found in the privacy policy." to notify users. For less popular applications, such notifications are likely to appear frequently, as they tend not to be stringent to disclosed privacy practices [61, 71, 105].

4.3 CPPs Presentation Module

For each mobile application, privacy policy, and its screenshots, the *segment extraction module* and *context detection module* allow us to obtain the specific privacy policy segments and associated privacy contexts. We further process this information to ensure a more coherent and user-friendly presentation.

Initially, we group the detected contexts of the same data types and map them to their corresponding privacy policy segments. As illustrated in Figure 1c, the SEEPRIVACY framework detects three contexts, including two textual GUI components, i.e., *"Share your location"* and *"use your birthday,"* and one iconic GUI component, such as a location mark icon in the middle right of the screenshot. These are classified into *Location*, *Location*, and *Birthday* data types, respectively. The text *"Share your location"* and the icon of the location mark are coupled with the segment about location information. The text *"use your birthday"* only corresponds to the segment about *Birthday* data type. Drawing on existing research that emphasizes the improvement of readability through the strategic use of typography [80], we render specific keywords or noun phrases within the privacy policy segments in bold font. This design choice, grounded in empirical findings, aims to accentuate essential information and thereby augment user comprehension.

5 Evaluation

In this section, we evaluate SEEPRIVACY both objectively and subjectively. Some visualization examples are displayed in Figure 3.

5.1 Quantitative Evaluation

Our framework, consisting of three integral modules, is systematically evaluated for its performance on our specially curated benchmark dataset, named CPP4APP.

5.1.1 Context Detection Module

In assessing whether a detected GUI component aligns with the ground truth, we utilize Intersection over Union (IoU) [87], a prevalent evaluation metric in object detection models. If the IoU between the ground truth and the detected component area exceeds a threshold β, the match is considered correct. Consistent with standard practice in object detection tasks [84], we empirically establish $\beta = 0.5$.

Textual GUI components. Table 4a presents the results related to the detection of textual GUI components. Our method exhibits a strong capability to recognize and categorize texts within mobile GUI screenshots, achieving an accuracy of 0.82, a precision of 0.87, and a recall of 0.93.

Iconic GUI components. Table 5 shows the comparison of the icon localization capability between our method and previous methods. The results show that our proposed method

Table 5: Performance comparison between iconic GUI components localization methods.

Method	Precision (mislabel)	Recall (missing label)
UIED [99]	0.78	0.44
Liu et al. [73]	0.79	0.86
Ours	**0.84**	**0.88**

Table 6: Performance and efficiency comparison for iconic GUI elements classification on the RICO-icon dataset. "kNN" stands for k-nearest neighbors algorithm, and we use the normalized pixel values of the grayscale icon images as features. "Acc.", "Prec." and "Rec." represents Accuracy, Precision and Recall, respectively. Time(s) denotes the elapsed seconds to process a thousand icons.

Model	Acc.	Prec.	Rec.	Size(MB)	Time(s)
kNN [38]	0.75	0.61	0.52	**0**	6.78
Liu et al. [73]	0.90	**0.90**	0.79	293	5.02
MobileNetV2 [88]	0.86	0.73	0.73	9	0.56
MobileNetV3 [55]	0.79	0.62	0.66	6	0.52
Ours (ViT-based)	**0.97**	**0.90**	**0.90**	328	11.28
Ours (ResNet-based)	0.91	0.80	0.81	43	**0.37**

performs better in identifying the icons curated on GUI screenshots. Table 4b shows the class-wise breakdown for Iconic GUI components, achieving an accuracy of 0.92, a precision of 0.95, and a recall of 0.96. We then compare our icon classification models with several baselines on the RICO-icon dataset. Table 6 shows that our ViT-based model achieves the best performance, but has the largest model size of 328 MB and the slowest time efficiency of 11.28 seconds. The ResNet-based model provides a good balance of performance and efficiency, with the fast time efficiency, decent performance metrics, and a much smaller model size compared to others.

Overall context identification. We further assess the overall performance of our context detection module by considering both textual and iconic GUI components. Table 4d shows the overall context identification results considering textual and iconic GUI components. Specifically, SEEPRIVACY exhibits commendable results, achieving accuracy, precision, and recall rates of 0.81, 0.88, and 0.90, respectively.

5.1.2 Segment Extraction Module

First, to determine whether the retrieval is successful, we introduce a similarity metric, denoted by *segment_sim*( ), which quantifies the similarity between the retrieved segments and the manually annotated ground truth. For a given ground truth s_{gt} and a retrieved segments s_{ret}, our segment similarity

Table 7: Statistic results of our human evaluation. SD stands for standard deviations.

Topic	Mean	Median	SD
Data type & Context	4.22	5	1.14
Data type & Policy segment	3.95	4	1.28
Policy segment & Context	3.75	4	1.40

segment_sim( ) is calculated as follows:

$$segment\_sim(s_{ret}, s_{gt}) = \frac{1}{\text{MIN}(n,m)} \sum_{i=1}^{n} \sum_{j=1}^{m} \overline{lcs}(s_i^{ret}, s_j^{gt})$$

$$\overline{lcs}(s_i^{ret}, s_j^{gt}) = \frac{lcs(s_i^{ret}, s_j^{gt})}{\text{MIN}(\text{LEN}(s_i^{ret}), \text{LEN}(s_j^{gt}))}$$

where *lcs*( ) stands for the function to calculate longest common string; s_j^{ret} are phrases separated by punctuation of retrieved segments and s_i^{gt} are labelled phrases of ground truth segments. If it is greater than 0.8, an empirically set threshold, then the segment pair is regarded as a successful match. Table 4c shows the results of the segment extraction module, SEEPRIVACY achieves 0.94, 0.98, and 0.96 in terms of accuracy, precision, and recall, respectively. There are some categories, such as *Address*, which are more complex than the other categories due to relatively semantically ambiguous keywords. In addition, there are relatively less data for *Voices* and *Contacts*, thus the limited performance of this category could be caused by the randomness.

5.2 Human Evaluation

To further validate the functionality of SEEPRIVACY, we conduct a human evaluation to examine users' perceptions of its capacity for generating accurate CPPs for mobile applications. This investigation seeks to provide empirical evidence on how SEEPRIVACY performs in real-world scenarios from users' perspective, thereby offering insights into its effectiveness and relevance.

5.2.1 Evaluation Study Design

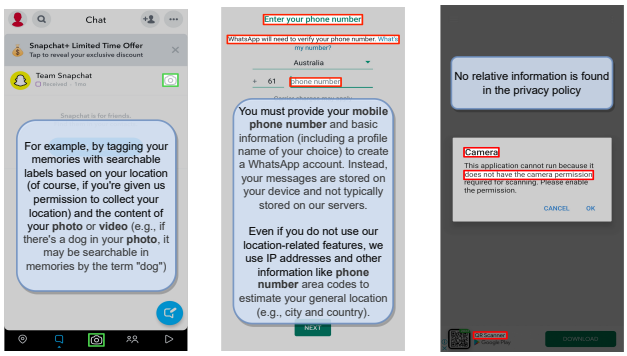
For recruitment, we recruited examiners based on the following criteria: professional fluency in English reading and be capable of using mobile apps without accessibility tools (e.g., VoiceOver on iOS), via mailing lists of authors' institution without offering monetary incentives. For the human evaluation, we randomly sampled 30 screenshots with their privacy policies from the benchmark dataset and employ SEEPRIVACY to generate CPPs. The manual examination involves heavy privacy policy reading and comprehending tasks, and we aim to reduce the session length to keep the examiners focused and increase the result validity. The average duration of

evaluation session is about 30 minutes. To guarantee the validity of evaluation, we then divide the generated CPPs into three folds and compose the questionnaire for each fold, i.e., ten screenshots in each questionnaire. For each CPP, examiners need to rate the following statements:

- The data type matches with the detected context.
- The data type matches with the displayed privacy policy segment.
- The displayed privacy policy segment explains the detected context on the screenshot.

For all the ten allocated screenshots, they are asked to rate the agreement level on a 5-point Likert scale ranging from five (strongly agree) to one (strongly disagree). In addition to providing a general introduction to the user study and obtaining consent, we also provide examiners with detailed descriptions of the data types, explicit instructions, and a concrete example to guide them prior to the beginning of our study.

5.2.2 Evaluation Results



In total, we recruited 15 people for the evaluation (6 females, 8 males, and 1 who preferred not to be mentioned). Each fold of screenshots was evaluated by five different examiners. The average duration for evaluation sessions is about 30 minutes. The results are detailed in Table 7. For the functionality evaluation pertaining to the matching between data types and detected contexts, the ratings were highly favorable, with more than 81% of the responses falling within the categories of "Agree" or "Strongly Agree." The mean and median values for this aspect were also substantial at 4.22 and 5, respectively. Concerning the alignment between data types and privacy policy segments, over 72% of examiners assigned positive ratings, yielding a mean value of 3.95 and a median value of 4. Additionally, more than 77% of examiners concurred that the retrieved privacy policy segments help explain the detected contexts, evidenced by a mean rating of 3.75 and a median rating of 4. Overall, these results demonstrate that SEEPRIVACY successfully fulfills its intended purpose by offering an efficient and effective solution for delivering CPPs to users.

6 Discussion

In this section, we delve into the implications, potential applications, and contributions of our framework, elucidating its significance both for individual mobile application users and the wider community.

6.1 Privacy Concern and Reading Willingness

Before and after the human evaluation, we also asked several questions about privacy concerns and their privacy policy reading habits to examiners. Table 8 lists the specific questions (Q_1 and Q_2 are pre-evaluation; Q_3 and Q_4 are post-evaluation)

(a) Sceenshot 6-1 (b) Screenshot 11-9 (c) Screenshot 16-1

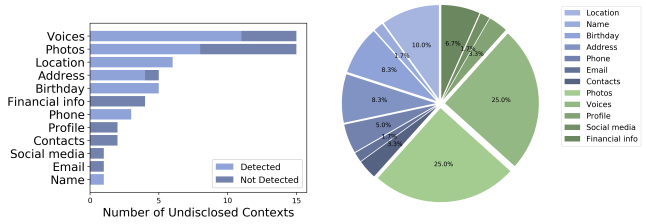
Figure 3: Three examples appeared in the human evaluation.

and results. It is evident that privacy concerns are a prominent issue for users while using mobile applications, with a mean concern rating of 4.13 and a median value of 4 for question Q_1. The utility of SEEPRIVACY in furnishing relevant privacy information for mobile applications was highly acclaimed by the participants. Specifically, 14 out of 15 participants evaluated it as either "Very useful" or "Useful."

In addition, we compare the reading willingness between traditional privacy policies and the CPPs generated by SEEPRIVACY. The results demonstrate a substantial increase in the willingness of participants to engage with CPPs, as reflected by a mean score that surged from 2 to 4.1. Furthermore, among 8 participants who are "very concerned" about their privacy information while using mobile apps, 6 select that they will always read CPPs, and 2 select often read CPPs. These findings collectively underscore the potential of SEEPRIVACY. By enhancing the transparency, accessibility, and digestibility of privacy policies, our proposed framework plays a vital role in engaging users to read privacy statements, potentially mitigating the prevalence of "digital resignation". Although the diversity of participants is slightly under representative, we believe those preliminary findings are still valuable to be reported in this paper.

6.2 Potential Adoption Scenario

6.2.1 CPP in App Market



Our framework has the potential to be applied in various real-world scenarios. One plug-and-play application is displaying CPP in the app market, as illustrated in Figure 4. Research has shown that users' app downloading decisions are often influenced by curated market information such as ratings and reviews [50]. On the apps' homepage (①, ②) in app markets (e.g., the Google Play app store), developers usually curate some showcase screenshots (③) of their apps to exhibit some characteristics. Those screenshots often include the actual GUIs that appear during the users' actual usage. As a privacy policy link (④) is also commonly mandated by app markets,

Table 8: Pre- and post-questions of the functionality evaluation about the general usability of SeePrivacy.

No.	Pre- and post-questions	Scale (5-Likert)	Mean	Median	SD
Q_1	How concerned are you about your privacy information while using mobile apps?	5 for very concerned, 1 for very unconcerned	4.13	4	1.09
Q_2	Do you read mobile app's privacy policies when you encountered?	5 for always read, 1 for never read	2.00	2	1.03
Q_3	What do you think the usefulness of this tool in terms of providing privacy information for mobile apps?	5 for very useful, 1 for very useless	4.53	5	0.62
Q_4	Will you read contextual privacy policies when you encountered in future?	5 for always read, 1 for never read	4.07	4	0.85

Figure 4: An example of the application scenario of our framework. (1) The homepage of the app at the Google Play app store. (2) Basic information of the app. (3) The showcase screenshots provided by the app developer. (4) The link of privacy policy. (5) The CPPs generated by SEEPRIVACY.

(a) Detection Result of Contexts (b) Distribution of Contexts

Figure 5: The left figure shows the detection result of contexts that do not have information in privacy policies. The right figure presents the data type distribution of those contexts.

our framework will be able to generate the CPPs (⑤) by utilizing the showcase screenshots and the corresponding privacy policy on the homepage. By leveraging SEEPRIVACY, users can gain contextualized insights into potential data practices and pertinent policy statements of the mobile application prior to installation. This application allows users to comprehend data practices with real-use scenarios, enabling them to make informative decisions and establish better expectations before downloading the app.

6.2.2 Lack of Disclosure: Contextual Detection

Numerous prior studies [97, 98, 104, 105] have highlighted the inconsistency between statements articulated in privacy policies and an application's actual behaviors. Specifically, the absence of proper disclosure concerning data practices may place users at considerable risk concerning digital security. In the current landscape of privacy policy analysis, we identify two critical shortcomings. First, in the case of essential applications, users often find themselves in a position where they must accept the terms, even if they are made aware of any lack of disclosure within the policies. There is no space to negotiate with developers for specific functions or certain GUI components under the "all-or-nothing" model. Second, existing methodologies fail to link the noted inconsistencies to the real contexts with which users may engage on GUIs. This omission presents a significant gap in understanding how policy misalignment may manifest in a user's interaction with an application. The lack of notice and choice inevitably leads to a digital resignation phenomenon, where users acquiesce to potentially problematic terms out of necessity, rather than informed consent.

To address the aforementioned challenges, SEEPRIVACY is proposed to provide the affected GUI elements, i.e., the context, allowing users to make informed decisions about their interactions. For example, in Figure 3c, SEEPRIVACY detects three contexts related to *"Photos"* in red bounding boxes, but does not obtain any relevant statements in the privacy policy of the app. Therefore, "No relative information is found in the privacy policy" is displayed to warn users about the potential risk. Users can simply choose not to interact with those *"Photos"*-related GUI elements as a band-aid solution, meanwhile "safely" using other features of the app. In total, we found that 60 contexts do not have corresponding privacy policy segments in CPP4APP. The 60 contexts are distributed among 17 mobile applications in CPP4APP and cover all 12 data types. Figure 5 illustrates the specific numbers and the distribution for lack of disclosure. Among the various data

types, *Photos* and *Voices* combined constitute 50% of the data. Interestingly, the *Voices* data type seems to be frequently overlooked. Contexts for this data type typically involve requests to record audio (e.g., a microphone icon), or the conversion of voice to text for search functionality (e.g., a phone icon). In total, SEEPRIVACY successfully identified 63.3% (38/60) lack of disclosure contexts.

6.3 Broader Impacts

Legal Impacts. Privacy regulations frequently stipulate specific requirements regarding the completeness of privacy practices within policies. For instance, GDPR mandates that privacy notices disclose the categories of personal data concerned [GDPR, Art. 14(1)(d)] and recipients or categories of recipients of the personal data [Art. 13(1)(e), 14(1)(e)]. Likewise, the CCPA prescribes that privacy notices should enumerate the categories of personal information collected in the preceding 12 months [CCPA §1798.130(a)(5)(B), §1798.110(c), Regs §999.308(c)(1)(d)]. While such requirements are often adhered to by mobile application developers and can be directly assessed by regulators, **the challenges of formulating best practices to achieve transparency, and evaluating the transparency level of a privacy statement, persist**. In this context, our innovative definition of CPPs within the mobile scenario emerges as a potential metric for evaluating transparency. By linking the stated privacy practices to the actual GUI elements with which users interact, SEEPRIVACY offers an empirical means of ensuring that privacy statements are not only compliant with legal requirements but also meaningfully transparent to end-users. This approach aligns with the broader legal and ethical imperatives of user-centric privacy and could contribute significantly to the development of transparent and accountable privacy practices in the mobile application ecosystem.

Accessibility and Inclusion. By transforming privacy policies into a contextual and understandable format, our approach potentially broadens their accessibility to a more diverse range of users. This includes individuals who may not possess advanced literacy skills as well as those who face challenges related to reading disorders. Such inclusivity not only democratizes the understanding of privacy policies but also aligns with broader societal goals of ensuring that vital information is comprehensible to a wide audience. In this regard, SEEPRIVACY contributes to creating a more equitable digital environment where awareness and control over personal data are not confined to a specific subset of users but are extended to encompass various demographic groups. The potential reach and impact of this approach underscore the need for continued research and innovation in the domain of user-centered privacy communication.

Children and Education. The GDPR Recital 58 (The Principle of Transparency) states "*... any information and communication, where processing is addressed to a child, should be in such a clear and plain language that the child can easily understand.*" This principle acknowledges the unique challenge of making legal and privacy-related texts accessible to young audiences. The SEEPRIVACY framework aligns with this directive by transforming privacy policies into potentially engaging and comprehensible formats to children. By connecting formal legal terms with real privacy use cases, it can facilitate a more straightforward understanding of the implications of online activities. While SEEPRIVACY strives to comply with regulatory requirements, its broader goal is to contribute to the digital literacy of disadvantage groups. This effort seeks to provide them with a basic understanding of online privacy, aiming to equip the next generation with the knowledge needed to approach the digital world with informed caution and responsibility. SEEPRIVACY aligns with the growing emphasis on the creation of tools and resources specifically designed to meet the developmental needs and competencies of young internet users.

6.4 *Notice-and-Choice Privacy Framework* for Mobile Apps: Is This the Way?

The *notice-and-choice* framework for mobile application ecosystem is fundamentally challenged by two critical issues. First, there is a significant disconnection between privacy notices and user-oriented interactions, leading to ineffective engagement of users in meaningful "notice" processes and subsequent privacy decision-making. Second, as illustrated in Figure 1a and 1b, the current designs of privacy controls often present users with an all-or-nothing choice, leaving them without genuine control over their data privacy. Therefore, this imbalance between utility and privacy highlights the need for administrative action through the regulation establishment and enforcement to safeguard consumer privacy rights.

While SEEPRIVACY is not a "panacea" for these challenges, it enlightens "a new hope" in this landscape. It suggests a paradigm shift in the privacy *notice* (what users are agreeing to) and *choice* (to agree or not) from a generic application level to specific functions or certain GUI components. It is critical to proactively elevate privacy considerations from non-functional to functional requirements in software design and development. Our framework aims to actively prompt users with timely and contextually relevant privacy information, enabling the potential for more granular control in future. In addition, exploring the practice of Right to be Forgotten can sufficiently supplement this approach, empowering users with more control over their choices [102, 103].

6.5 Limitations.

Our current human evaluation focuses more on the functionality of SEEPRIVACY, i.e., the level of matching between contexts and retrieved policy segments, thus, all examiners are relatively well-educated in technology. Thus, the preliminary

findings of reading willingness and popularity of CPPs among them may be biased due to the small and non-representative sample. We plan to further conduct a large-scale user study that includes people from diverse backgrounds in the future. In addition, the exploration of fatigue and habituation within human-computer interaction and its impact on interaction design have not been fully developed. These factors may profoundly affect user engagement and interface efficacy. Furthermore, the time and storage efficiency of SEEPRIVACY were evaluated theoretically and may not reflect real-world performance in different application scenarios. Regarding generalizability, our CPP detection is entirely vision-based, allowing for straightforward adaptation to other platforms, such as iOS mobile applications.

7 Conclusion and Future Work

Privacy policies have long been criticized for their complexity and poor readability, leading to a growing interest in contextual privacy policies (CPPs) as user-focused alternatives. In this paper, we introduce the concept of CPPs specifically within the domain of mobile applications and propose a novel framework, SEEPRIVACY, designed to automatically generate these privacy policies. We rigorously evaluated SEEPRIVACY on our benchmark dataset, CPP4APP, which consists of over 1,200 privacy-related contexts and corresponding privacy policy segments. In the quantitative evaluation, our framework demonstrates 0.88 precision and 0.90 recall to detect contexts; as well as 0.98 precision and 0.96 recall to extract corresponding policy segments. Furthermore, a human evaluation was conducted to validate the functionality our approach, reflected by a median score of 4 on a 5-point Likert scale. Our pre- and post-survey revealed that people exhibit much greater willingness to engage with CPPs, scoring 4.1 out of 5, compared to a mere 2 out of 5 for traditional privacy policies. We also discussed the potential adoption scenarios and implications of SEEPRIVACY to the wider community.

Our promising results identify two potential research directions. First, while our current efforts emphasize methodological development and evaluation, we recognize the importance of exploring real-world deployment scenarios. The user experience, particularly how users interact with contextual privacy policies, is vital and could significantly impact the system's effectiveness. Future work may include integrating SEEPRIVACY into specific human-device interactions, such as live applications on smartphones or sandbox environments within which applications operate. Second, although we aim to deliver the original privacy policy content without any modification, we notice that some retrieved policy segments are too long to comprehend in a timely manner. Thereby, it is worthwhile to evaluate how to digest lengthy policy segments with minimum information loss and distortion to maintain their integrity and practicability simultaneously. Overall, we believe this work provides a substantial step forward in delivering transparent privacy notices, paving the way for future research and practical implementation in this crucial area.

Data Availability. Benchmark dataset CPP4APP and the replication package are available at: https://github.com/Cpp4App/Cpp4App.

Abstract

Content Delivery Networks (CDNs) provide high availability, speed up content delivery, and safeguard against DDoS attacks for their hosting websites. To achieve the aforementioned objectives, CDN designs several `back-to-origin` strategies that proactively pre-pull resources and modify HTTP requests and responses. However, our research reveals that these `back-to-origin` strategies prioritize performance over security, which can lead to excessive consumption of the website's bandwidth.

We have proposed a new class of amplification attacks called **Back-to-Origin Amplification (`BtOAmp`)** Attacks. These attacks allow malicious attackers to exploit the `back-to-origin` strategies, triggering the CDN to greedily demand more-than-necessary resources from websites, which finally blows the websites. We evaluated the feasibility and real-world impacts of `BtOAmp` attacks on fourteen popular CDNs. With real-world threat evaluation, our attack threatens all mainstream websites hosted on CDNs. We responsibly disclosed the details of our attack to the affected CDN vendors and proposed possible mitigation solutions.

1 Introduction

Content Delivery Networks (CDNs) play a pivotal role as intermediaries between global clients and website origins. The CDN's primary function is resource caching, a mechanism employed judiciously to optimize content delivery. CDN deploys millions of servers on the Internet backbone to offer services to global websites, working as a critical Internet infrastructure with massive computational, cache, and network resources [1]. Based on the available resources, to seek faster content delivery, CDN designs its `back-to-origin` strategies to arbitrarily and greedily demand more than necessary resources from the website origin (origin server) [2–4].

In this paper, we systematically examine `back-to-origin` strategies and present a novel class of amplification attacks called **Back-to-Origin Amplification (`BtOAmp`)** attacks, which allow attackers to exploit the vulnerabilities of CDN's `back-to-origin` strategies to launch an amplification attack against origin servers. We further classify the attacks into the following four kinds:

`Image Optimization` Attack. We exploit the CDN image optimization feature to launch a maximum 39039-factor amplification attack. It allows an attacker to abuse cropping images to one-pixel images, which can be used to launch an amplification attack against the origin server. We further analyzed the image optimization process and discovered that combining compression and cropping can further increase the amplification factor.

`Request Modification` Attack. We abuse CDN's `back-to-origin` configuration ability to amplify requests to the website origins, with a maximum amplification factor of 93077. CDN's `back-to-origin` strategies encompass the ability to manipulate HTTP headers and URLs. In our study, we analyzed fourteen CDNs and found that eleven of them allow the addition of large HTTP headers and the modification of a thin URL (e.g., "/a") into a much fatter URL (e.g., "/a" * 1024). Attackers can exploit it to exhaust the origin server's bandwidth. Even worse, attackers can cascade two or more CDNs together, leveraging multiple CDNs to achieve a better amplification factor.

`Method Conversion` Attack. We exploit CDN's request method conversion behavior to reach a maximum 53352-factor amplification attack. Through experiments, we discovered that CDNs convert HEAD requests into GET requests. This behavior allows attackers to launch an amplification attack against the origin server by exploiting HEAD-to-GET conversions. Specifically, the attacker sends HEAD requests, triggering the CDN to convert them into GET requests. Consequently, CDN requests all the complete resources from the origin server while returning only HTTP headers to the attacker.

`Connection Decoupling` Attack. As CDN maintains connections with the origin servers even after the client forcefully terminates the TCP connection [5], we exploit this behavior to launch an amplification attack with a 104862 factor.

✉Corresponding authors: snbnix@gmail.com, jianjun@tsinghua.edu.cn

In our research, we came across a few CDNs that terminate the CDN-origin connections when there is a disruption in the client-CDN connections. However, upon further analysis, we found that attackers can use `Transfer-Encoding: chunked` to force CDN to sustain CDN-origin connections, even after the attacker cuts off the client-CDN connections.

Contributions. We make the following contributions in this paper.

- *A Novel Attack.* We have proposed a new class of HTTP amplification attacks, Back-to-Origin Amplification (`BtOAmp`) attacks. These attacks exploit the CDN `back-to-origin` strategies, consuming the victim's incoming and outgoing bandwidth. It leads to network unavailability as well as economic losses.
- *Real-world Evaluations.* We examine the `BtOAmp` attacks on 14 popular CDN vendors and evaluate the feasibility and severity of `BtOAmp` vulnerabilities. We find all examined CDNs are vulnerable to the `BtOAmp` attacks, and the amplification factor is up to 104862 times in some cases.
- *Mitigation and Responsible Disclosure.* We present approaches to mitigate the proposed attacks and responsibly report vulnerabilities to CDN vendors. Notably, five CDN vendors acknowledged the vulnerabilities and took our mitigation solutions to fix them.

Roadmap. We organize the rest of this paper as follows. Section 2 provides the background of CDN and `back-to-origin` strategies. In Section 3 we describe the details of the `BtOAmp` attacks and explore the amplification factors. We also evaluate the feasibility of the `BtOAmp` attacks in Section 4. We discuss mitigation solutions and our responsible disclosure in Section 5. Section 6 elaborates on the related works, including CDN security, and amplification attacks. We conclude in Section 7.

2 Background

2.1 CDN Overview

CDN is a network of server clusters distributed globally, which has become an essential component of the Internet infrastructure. It not only enhances the performance of customer websites but also provides security features such as DDoS protection mechanisms [6]. As shown in Figure 1, CDN acts as a man-in-the-middle between clients and origin servers to decouple traditional client-origin connections into two segments: the client-CDN and the CDN-origin connections.

When a user requests a resource, CDN will attempt to respond from its cache [7]. If the cache is missing, it forwards the request to the origin server to obtain the desired resource and caches the response for subsequent requests. This mechanism efficiently reduces user access latency while relieving the load pressure on the origin server. Besides, CDNs dynamically select edge nodes by load balancing [8, 9]. In a word,

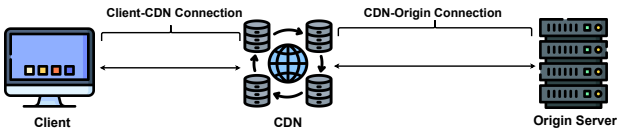

Figure 1: Multiple segments of connectivity in a CDN environment.

CDNs can not only reduce user access delay, but CDNs also serve as an effective DDoS defense for the origin server. To further improve cache hit rates, reduce user access latency, and cater to various user demands, CDNs continuously optimize their `back-to-origin` strategies.

2.2 Back-to-Origin Strategy

CDN `back-to-origin` strategies refer to the methods and rules employed by the CDN when it receives requests from clients and interacts with the origin server to retrieve the required source. The primary objective of the `back-to-origin` strategies is to increase the hit rate of CDN cache, effectively alleviate the load on the origin server, reduce network latency, and ultimately enhance the overall user browsing experience. `Back-to-origin` strategies are critical to CDN services. However, there are no related RFCs or commonly accepted industry standards. Consequently, `back-to-origin` strategies are implementation-dependent and may vary across different CDN vendors. When CDN vendors prioritize performance over security, threats may arise. To our knowledge, no research has systematically analyzed these strategies of various CDNs. In this study, we present the first differential testing of these strategies employed by 14 popular CDN vendors, and we identify five strategies that prioritize performance over security, as shown in Table 1. Additionally, to ensure compatibility with websites of various types, three out of these five strategies can be configured during the CDN service registration process.

Specifically, CDNs provide image optimization strategies that return images in different qualities and sizes based on client requirements. These strategies ensure the best balance of image loading speed and quality across various devices [10]. Additionally, CDNs offer Header Modification and URL Rewriting strategies that permit customers to modify back-to-origin requests and responses to meet specific needs. These strategies help to achieve more precise resource control. Moreover, to improve the CDN cache hit ratio, some CDNs will convert the HEAD requests to GET requests to retrieve more resources from the origin server [11]. Finally, some CDNs provide connection decoupling strategies in which CDNs may maintain the CDN-origin connection even after the client-CDN connection closes, allowing the CDN to continue caching requested resources. The first three strategies improve CDN performance, making it more flexible and adaptable to various user needs. The latter two strategies aim

to increase the cache hit rate, optimizing response time when users subsequently access the same resources.

3 Back-to-Origin Amplification Attacks

To seek service performance and availability, CDNs commonly design and implement `back-to-origin` strategies to retrieve significantly more resources from the origin server than the client requests. However, we find that these strategies result in significant disparities in traffic between the client-CDN side and the CDN-origin side, which leads to an amplification attack.

In this section, we will introduce the threat model of the `BtOAmp` attack. We will then explain how to bypass the CDN cache and exploit these strategies to launch a `BtOAmp` attack. Finally, we will evaluate our techniques on fourteen leading CDN vendors to demonstrate the feasibility of amplification attacks based on different `back-to-origin` strategies.

We selected these fourteen CDN vendors based on CDN market share statistics [12] and from a Google search. Additionally, these fourteen CDN vendors are often studied in previous works as well [13–15]. We found that over 36.5% of websites on the Tranco Top 10,000 list [16] are hosted on these fourteen vendors. As the famous CDN vendors are all affected by the `BtOAmp` attacks, we believe our attacks are also applicable to other CDN vendors.

3.1 Threat Model

When a CDN applies the performance-over-security strategies to demand more than necessary resources from the origin server, we present that it leads to the `BtOAmp` attack. In this study, we assume that attackers possess two limited abilities. First, attackers can send malicious but legal requests to the CDN using a Cloud VPS worldwide or any hacked vantage point. Second, attackers can register accounts with CDN vendors, alter the CDN-offered configuration related to `back-to-origin` strategies, and host the victim website as the origin of the CDN service. Specifically, most CDN vendors currently offer free or free-trial services to potential website customers (including attackers) without robust authentication requirements [17, 18], possibly due to competitive reasons. It makes anonymous assaults feasible at a low cost or even free.

Within this context, grounded in differential testing principles, we systematically examine `back-to-origin` strategies and related configurations, aiming to uncover inconsistencies between the client-CDN side and the CDN-origin side. By leveraging these discrepancies, we delve into how attackers can craft legal requests to trigger CDN behaviors that demand more-than-necessary resources from the origin server (the victim website). Specifically, we investigate these inconsistencies at both the transport and application layers, assessing their amplification effects at the network layer. This analysis reveals that such legal but malicious requests may exhaust the origin server's limited bandwidth, leading to a `BtOAmp` attack on the origin server, as demonstrated in Figure 2.

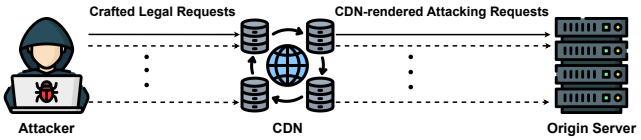

Figure 2: BtOAmp attack against CDN hosted websites.

With comprehensive case analysis, we identify and categorize the `BtOAmp` attack into four types according to the specific `back-to-origin` strategies: `Image Optimization` attack, `Request Modification` attack, `Method Conversion` attack, and `Connection Decoupling` attack, and the detailed attacking procedures are explained in the following subsections. Above all, we find that these fourteen CDN vendors all are vulnerable to the `BtOAmp` attack, and the details are summarized in Table 2.

3.2 Bypassing CDN Cache

To send successive attack requests to the victim, the presence of a CDN cache may prevent forwarding of attack requests to the victim. When attacking a website, the victim may return a cachable HTTP response. It is necessary to detour the CDN cache mechanism to ensure that attacking requests reach the victim rather than hitting the CDN cache.

After exploring the CDN forwarding strategies and working mechanism exhaustively, we conclude several approaches to bypass the CDN cache mechanism and confirm them in the 14 CDN vendors, as listed in Table 3.

CDN vendors cache resources based on HTTP-related parameters such as file extensions, URL paths, or HTTP Header. Attackers can exploit these rules to bypass CDN caching. Besides, we also found that some CDN providers forward

requests with a Cookie or Authorization header to the victim and do not cache their responses.

3.3 Image Optimization Attack

In this section, we introduce a new class of amplification attacks called `Image Optimization` attacks. By exploiting the CDN image optimization features, attackers can create a substantial bandwidth disparity between the optimized client-side image delivery and the actual resource demanded from the origin server. This novel amplification attack targets the inherent functionalities within CDNs designed to enhance client-side image loading speeds, turning these optimizations into vectors for bandwidth exhaustion at the origin server.

3.3.1 Attack Surface

Primer on CDN image optimization. The image optimization feature of CDN is a service that processes and accelerates images at CDN nodes, improving client-side image loading speed and quality while saving bandwidth and costs. It offloads the website's burden to prepare an image with different resolutions to meet the needs of various clients with different screen sizes. Among these, image compression and image cropping are two common image optimization techniques [10, 19].

Image compression is one of the CDN image optimization features, aiming to help clients save bandwidth and costs while improving image loading speed. The fundamental principle of image compression is to reduce the file size of images with image format conversion or image quality adjustment thus improving the efficiency of image transmission [20].

Image cropping functionality is another CDN image optimization feature, aiding websites in adapting to various client-side screens and devices. The principle behind image cropping involves adjusting the image's sizes to accommodate different screens and devices [21]. The dimensions of an image, determined by its width and height, play a pivotal role in determining the overall file size. Larger image sizes result in larger file sizes and crisper display quality, while smaller image sizes reduce file size but may lead to a less clear display.

In summary, CDN's image optimization features assist websites in better managing and displaying images, thereby improving user experiences and website performance.

Attack Principle. The core of the `Image Optimization` attack lies in its ability to exploit the CDN's image optimization functionalities, specifically image compression, and cropping, to exert undue pressure on the origin server's bandwidth. By inducing the CDN to bypass its caching mechanisms for image optimization requests, attackers force the retrieval of lossless, high-resolution images from the origin server. Meanwhile, the CDN's subsequent compression and delivery of these images helps to reduce client-side (also attacker-side) bandwidth consumption, resulting in amplification attacks. This discrepancy is further exacerbated when attackers manipulate image cropping features, compelling the CDN to fetch and process large images only to minimal sizes for delivery, as shown in Figure 3. Such strategies not only inflate the bandwidth demand on the origin server but also underscore the vulnerabilities inherent in CDN image optimization services.

The `Image Optimization` attack demonstrates a clever abuse of CDN's intended optimization functionalities, highlighting the need for enhanced security awareness and measures to reduce potential vulnerabilities within these optimization processes.

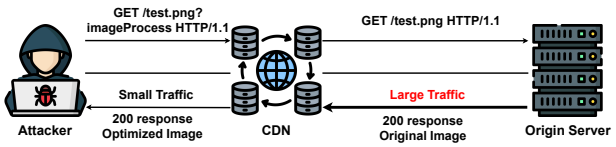

Figure 3: Concept of Image Optimization attack. Step 1: Exploiting CDN edge servers to request original images; Step 2: CDN optimizes images to reduce image size.

3.3.2 Amplification Factor

Image optimization attacks, including image compression and image cropping attacks, are evaluated for their amplification factors through two distinct experiments.

Common Experimental Setup. Both experiments were conducted with an Nginx web server deployed as the origin server across various CDNs. The traffic on both client-CDN and CDN-origin connections was captured using the `tcpdump` [22]. This setup serves as the foundation to assess the impact of image characteristics: the first experiment focused on image formats, while the second concentrated on image resolutions.

The Setup of the First Experiment. For the initial experiment, images in four common formats (PNG, JPG, BMP, and TIFF) were placed on the Nginx server. We sent requests requiring the CDN to fetch and compress these images into WebP format, evaluating the effect of image format on the amplification factor.

Results of the First Experiment. As shown in Table 4, the maximum amplification factor achieved through image compression attacks was 1011. An interesting behavior was observed with Cloudflare's handling of TIFF and BMP formats, where it would return a `415 Unsupported Media Type` response but still fetch the original image, presenting an opportunity for a more potent amplification attack.

Table 4: The amplification factor varies with the format of the image in the Image Optimization attack.

	PNG	JPG	BMP	TIFF
Alibaba†	111	80	126	N/A
Bunny†	136	98	N/A	N/A
ChinaNetCenter†	130	94	156	N/A
Cloudflare†	319	230	1011	1011
CloudFront‡	23	17	N/A	26
Edgio‡	23	17	N/A	26
Fastly†	1.7	1.2	N/A	N/A
G-core†	139	100	N/A	N/A
Qiniu‡	30	21	25	34
UPYun†	139	101	166	149

† These CDNs support lossy compression.
‡ These CDNs support lossless compression.

The Setup of the Second Experiment. The second experiment focused on image resolution. Images of various resolutions, from 720p to 4320p, were evaluated. Requests were crafted to require the CDN to crop these high-resolution images into one pixel, aiming to discern the resolution's impact on amplification.

Results of the Second Experiment. As shown in Figure 4, the amplification factor tended to correlate with the image resolution. However, Alibaba and Edgio were noted to support image optimization only up to a 4096x4096 resolution, directly delivering back the original image for resolutions above this threshold. Additionally, certain CDNs like Alibaba, Qiniu, UPYun, and ChinaNetCenter, when receiving requests with invalid optimization parameters, would issue a `400 Bad Request` response yet still forward the request to fetch the image, thereby still enabling an `BtOAmp` attack.

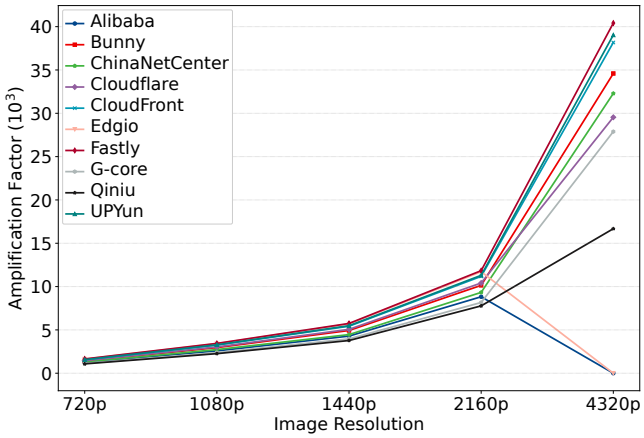

Figure 4: How the amplification factor changes with the resolution of images.

3.4 Request Modification Attack

In this section, we will delve into the Request Modification Attack. This attack leverages CDN infrastructure, which allows for the amplification of attacks by adding HTTP headers and modifying URLs to requests. In contrast to traditional DDoS attacks that rely on massive bots [23–25], this attack is stealthier and harder for CDN to defend against because the crafted requests are legal and are initiated from itself.

3.4.1 Attack Surface

Primer on CDN Modification HTTP Header Behaviors. Chen et al. [17] found that CDNs typically add default headers such as Via and X-Forwarded-For headers when forwarding requests and exploit these automatically added headers to launch amplification attacks against CDNs. However, we found that CDN-offered configurations allow website customers (also the attacker) to add a large number of huge HTTP Headers and rewrite a thin URL (e.g., "/a") into a much fatter URL (e.g., "/a" * 1024) in forwarding requests. Therefore, we present a new class of amplification attacks that attackers can exploit to launch amplification attacks against origin servers.

Table 5: The amplification factor in Request Modification attack.

	Alibaba	Azure	Baidu	Bunny	CDNetworks	ChinaNetCenter	Cloudflare	CloudFront	Edgio	Fastly	G-core	UPYun
Header Name Size	256B	128B	128B	≥1MB	64B	64B	128B	128B	≥100KB	255B	255B	40B
Header Value Size	256B	640B	1000B	≥1MB	63B	64B	512B	768B	≥100KB	≥10KB	512B	400B
Number of Headers	49	99	20	≥10	≥1300	≥800	270	10	15	≥13	49	20
URL Size	≥50KB	512B	1000B	≥50KB	1KB	≥1KB	8KB	256B	10KB	N/A	N/A	400B
Host Header Size	≥512B	128B	64B	≥64B	64B	≥54B	N/A	N/A	≥128B	255B	2048B	≥128B
Amplification Factor	348	367	109	93077	768	481	846	43	5352	590	188	42

The `back-to-origin` strategies empower websites (also the attacker as a malicious CDN customer) with the capability to incorporate bespoke HTTP headers into forwarding requests, thereby catering to specific requirements and affording a higher degree of precision in resource management. When employing CDN to forward client requests, this CDN-provided request modification feature helps websites add various HTTP header fields, such as customized authorization tokens, access controls, and security tokens [26]. As a result, websites can exert a heightened and finely-tuned degree of control over the generated responses. Essentially, this flexibility empowers attackers to finely tune and personalize interactions with the origin server, optimizing the overall content delivery process for improved performance and functionality. However, it is essential to note that CDNs have lenient restrictions on the size and number of HTTP headers when adding them to forwarding requests, as shown in Table 5. As a result, attackers could take advantage of this vulnerability by leveraging CDNs to send requests with large HTTP headers, exhausting the origin server's bandwidth.

Primer on CDN Manipulation of URL Behaviors. It is common for a website to change its resource path on the server, while it requires the website to synchronize all the related URLs in the web pages. To avoid this annoying work, CDNs offer support for URL rewriting when forwarding client requests [27]. It is worth noting that this rewriting does not impact the CDN's internal routing or cache key. Nevertheless, it is crucial to acknowledge that CDNs tend to impose relatively permissive limitations on the length of modified URLs, as shown in Table 5. An attacker can abuse these strategies to make CDNs send requests carrying large URLs, leading to amplification attacks.

Primer on Cascadable CDN Platforms. Chen et al. [17] presented that two or more CDN platforms can be cascaded to make a request forwarding chain, and this cascadable CDN trick has been applied in `RangeAmp Attack` [28] to increase the damage of the attack. A necessary condition for cascading two or more CDN platforms in a chain is that the front-level CDN must forward the request to the next-level CDN, and the next-level CDN treats it as a benign request and continues forwarding it.

Whether the next-level CDN accepts the forwarded requests depends on the Host header. If the front-level CDN platform can modify the Host header in the forwarded requests to match the domain name registered for service on the next-level CDN platform, then the requests can be processed and forwarded by the next-level CDN platform. Our measurements show that thirteen out of fourteen CDN vendors can be cascaded at any level of the CDN chain, as shown in Table 6. However, Cloudflare does not support modifying the Host header as the origin domain name. We can only cascade Cloudflare as the last level in a CDN chain.

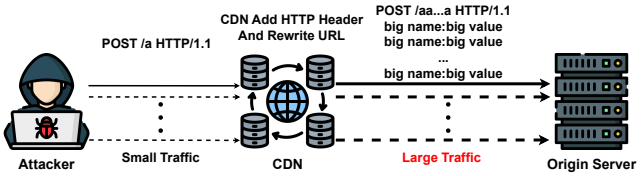

Figure 5: Concept of Request Modification attack. Step 1: Send numerous POST requests to CDN; Step 2: Exploiting CDN to make POST requests to "fat" POST requests and forward them to the origin server.

Attack Principle. With our extensive measurements, CDN `back-to-origin` strategies support the addition of HTTP headers and URL modifications within forwarding requests (Table 1). Hence, we present that attackers can exploit the CDN-provided request modification capability to launch the `Request Modification` attack. As shown in Figure 5, an attacker sends POST requests to the CDN first, then triggers the CDN to append numerous large HTTP headers and modify the URL into a fat URL, creating abnormally large requests that lead to amplification attacks.

Besides, we propose a variant of the `Request Modification` attack called the `Cascade Request Modification` attack. This attack exploits the cascading nature of CDNs to amplify the damage of the `Request Modification` attack. It allows attackers to exploit the cascaded CDNs. Each CDN contributes to the enlargement of requests by adding extensive HTTP headers, increasing the request size at each stage. We will delve into a detailed assessment of the cascadable CDN trick and real-world evaluation of the `Cascade Request Modification` attack in Section 4.

3.4.2 Amplification Factor

The size of the HTTP headers and URL emerges as a pivotal technical factor influencing the amplification factor of

Table 6: Modifiability of "Host" header field on CDNs.

Request Domain	✔	✔	✔	✔	✔	✔	✔	✔	✔	✔	✔	✔	✔	✔
Origin Domain	✔	✔	✔	✔	✔	✔	✔	N/A (Free Plan)	✔	✔	✔	✔	✔	✔
Any Domain	✔	✔	✔	✔		✔	✔	N/A (Free Plan)		✔	✔	✔	✔	✔

the attack. To thoroughly assess its impact, we devised the following experiment.

Experiment Setup. Based on the above measurements of the various CDN `back-to-origin` strategies, we configured the strategies to append the maximum HTTP header and modify the raw URL to its maximum permitted length in forwarding requests. Subsequently, we sent separate POST requests to each CDN, which triggered the CDN to transfer them into large-sized ones. We captured and analyzed all the requests on both the clients and origin servers to determine the amplification factors.

Experiment Result. The most noteworthy experiment result is that twelve CDN vendors are affected by the `Request Modification` attack, as shown in Table 5. Remarkably, CDNs such as Alibaba, Bunny, and Edgio, which permit the addition of substantial, large-sized HTTP headers, exhibited higher amplification factors.

3.5 Method Conversion Attack

Through comprehensive analysis across client-CDN and CDN-origin connections, we've identified a nuanced behavior among CDNs concerning the support and conversion of HEAD requests. Specifically, our investigation into fourteen CDNs revealed that seven exhibit a vulnerability that could be exploited to amplify bandwidth against the origin servers they host.

3.5.1 Attack Surface

Primer on HTTP HEAD Request. The HEAD request aims to only retrieve metadata or header information about a specific web resource [29]. Unlike GET requests, HEAD requests are designed to exclusively retrieve information about the web resource without fetching the actual content. The HEAD request empowers the client to acquire essential information concerning the web resource, encompassing attributes like content length, content type, response status code, and so on, without downloading the complete resource.

The distinctive characteristics of HEAD requests make them exceedingly advantageous for performance optimization, bandwidth management, and cache control [30]. By exclusively obtaining header information and not downloading the whole content, HEAD requests efficiently reduce unnecessary network traffic, improve operational efficiency, and support caching mechanisms, thereby alleviating server and network burdens.

Method Conversion Behavior. While most CDN vendors assert support for HEAD requests to save traffic, a prevalent operational practice involves converting these HEAD requests into GET requests. This conversion aims to prefetch content, improve cache hit rates [11], and minimize response times for subsequent requests. Despite the prevalence of this behavior, there has not been a comprehensive study of its security.

In this experimental setup, we initially configure the origin server to support HEAD requests. Subsequently, we send HEAD requests to the CDNs and capture CDN-origin requests at the origin server using `tcpdump` to explore the CDN's `back-to-origin` strategy of HEAD requests. As shown in Table 7, experiment results have revealed that CDNs support HEAD requests in the client-CDN connection but exclusively use GET requests in the CDN-origin connection, even when the origin server supports HEAD requests.

Table 7: Behavior of CDNs forwarding HEAD requests.

	HTTP Method	
	client-CDN Connection	**CDN-origin Connection**
Alibaba	HEAD	GET
Azure	HEAD	HEAD
Baidu	HEAD	HEAD
Bunny	HEAD	GET
Cachefly	HEAD	GET
CDNetworks	HEAD	GET
ChinaNetCenter	HEAD	GET
Cloudflare	HEAD	GET
CloudFront	HEAD	HEAD
Edgio	HEAD	HEAD
Fastly	HEAD	GET
G-core	HEAD	GET
Qiniu	HEAD	HEAD
UPYun	HEAD	HEAD

Attack Principle. Through the above experiments, we have identified two distinct `back-to-origin` strategies CDNs employ to handle HEAD requests. In one scenario, upon receiving HEAD requests from clients, the CDN directly forwards them to the origin server. In the alternative scenario, the CDN converts HEAD requests into GET requests, fetches more than the required target resources from the origin server, and caches them in the CDN global cache.

As shown in Figure 6, the method conversion strategy results in the CDN retrieving the target resource more than necessary from the origin server and caching it while solely returning HTTP headers to the client. Consequently, it creates an asymmetry in bandwidth consumption between CDN-origin and client-CDN connections, offering attackers an ap-

proach to exhaust the origin server's bandwidth. Upon a HEAD request of a specific resource, the CDN converts it to a GET request and then caches the response for the following HEAD or GET requests of the same resources. However, attackers can use the cache bypass techniques to make each HEAD request not hit the cache and be forwarded to the origin server, thus exhausting the origin server's bandwidth, even when the same resource is requested many times.

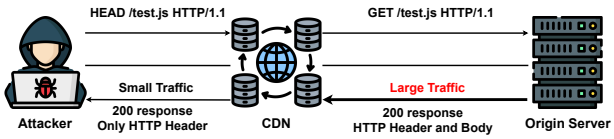

Figure 6: Concept of Method Conversion attack. Exploiting CDN edge servers to convert HEAD requests into GET requests, requesting resources from the origin server but responding with only HTTP headers.

3.5.2 Amplification Factor

We experimented to explore the practicality and amplification factor of the `Method Conversion` attack. This experiment aims to determine which CDNs are vulnerable and the resulting amplification factor.

Experiment Setup. We conduct our experiments under controlled conditions. We send a series of HEAD requests to CDNs to gather information regarding target resources on the origin server. For these experiments, we deployed a website on each CDN and placed target resources of varying sizes on the website origin server.

To determine the impact of the targeted resource size on the amplification factor, we systematically sent HEAD requests to the CDNs for targeted resources ranging from 1MB to 25MB, incrementing by 1MB. We used `tcpdump` to capture traffic on both the client-CDN and CDN-origin connections and calculate the amplification factor.

Experiment Result. As shown in Figure 7, the amplification factor is proportional to the size of the target resource for each CDN except Fastly. For every CDN, we summarize in Table 8 the amplification factor for a targeted resource of different sizes, i.e., 1MB, 10MB, and 25MB.

The `Method Conversion` attack can result in an amplification factor of hundreds of thousands by simply requesting a 10MB resource, which is a common occurrence on the internet. However, Fastly appears to be less affected by this attack. Upon further investigation, we discovered that although Fastly converts HEAD requests to GET requests, it immediately closes the CDN-origin connection after receiving the response header. This unique behavior prevents the amplification factor from increasing with the variations in the size of the target resource, which can act as a mitigation for the attack.

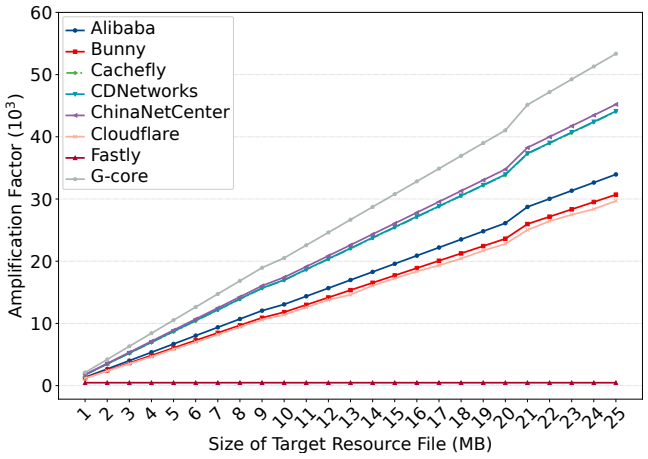

Figure 7: How does the Method Conversion attack amplification factor change with the size of a target resource file.

Table 8: Amplification factors with different target resource sizes of Method Conversion attacks.

	Amplification Factor		
	1MB	**10MB**	**25MB**
Alibaba	1340	13059	33952
Bunny	1212	11808	30702
Cachefly	1738	16940	44044
CDNetworks	1744	16995	44115
ChinaNetCenter	1784	17418	45212
Cloudflare	1170	11385	29698
Fastly	469	469	469
G-core	2106	20520	53352

3.6 Connection Decoupling Attack

It is well-known that CDN, working as a man-in-the-middle, decouples the traditional client-origin connection into two distinct connections: the client-CDN connection and the CDN-origin connection. When the client cuts off the client-CDN connection, no RFCs or industry standards define whether the specific CDN-origin connection should be kept open. In other words, this decoupling connection strategy remains implementation-specific, and some CDNs still maintain CDN-origin connections. Consequently, attackers can exploit this strategy to launch an amplification attack, exhausting the origin server's limited bandwidth.

The `Connection Decoupling` attack leverages the independence of client-CDN and CDN-origin connections. Attackers leverage CDN edge servers to download target resources from the origin server and prevent CDN from responding to these resources, thus consuming the bandwidth resources of the origin server.

3.6.1 Attack Surface

Traditional CDN decoupling attack is unusable. CDNs introduce a division in HTTP communication, delineating it into two discrete segments: the client-CDN connection and the CDN-origin connection. This strategy yields a variety of advantages, notably enhancing the performance and reliability of CDNs. Decoupling these connections and absorbing a substantial influx of flood traffic are common strategies for effectively countering DoS attacks. However, this strategy can give rise to security challenges stemming from potential inconsistencies in TCP states and the asymmetry in bandwidth between client-CDN and CDN-origin connections.

Triukose et al. [31] introduced a new type of DoS attack targeted at CDN-hosted website servers. In this attack, the attacker sends multiple requests directly to various ingress nodes, all requesting the same large file hosted on the website. These requests include a randomly generated query string attached to the URL to bypass the CDN cache. Subsequently, the attacker cuts off all client-CDN connections while the CDN continues to sustain CDN-origin connections, which operate at a significantly higher bandwidth. This results in a bandwidth exhaustion DoS attack against the website. However, during our experiments, we unearthed a noteworthy observation: certain CDNs automatically terminate CDN-origin connections once the Client-origin connection is severed, as shown in Table 9. This mitigation measure renders the traditional CDN decoupling attack outlined in [31] ineffective.

Table 9: Whether CDNs keep CDN-origin connection while an attacker cuts off client-CDN connection.

	CDN-origin Connection	
	Content-Length	**Transfer-Encoding**
Alibaba	Close	Keep
Azure	Close	Keep
Baidu	Close	Keep
Bunny	Keep	Keep
Cachefly	Keep	Keep
CDNetworks	Close	Keep
ChinaNetCenter	Keep	Keep
Cloudflare	Close	Keep
CloudFront	Close	Close
Edgio	Close	Close
Fastly	Close	Close
G-core	Keep	Keep
Qiniu	Close	Close
UPYun	Keep	Keep

Reviving the attack with Transfer-Encoding: Chunked. `Transfer-Encoding: Chunked` constitutes a data transmission technique within the HTTP protocol, wherein data is segmented into small chunks and transmitted sequentially to the client [32]. The principal advantage of this transmission technique lies in its capacity to generate and deliver data in real-time during the transmission process without waiting for the entire content to be ready [33]. This technique fosters not only flexibility but also substantial performance enhancements. For example, in online video conferencing, where real-time communication is vital, the ability to transmit and render data as it becomes available significantly reduces latency [34].

As shown in Table 9, it's important to note that certain CDNs automatically close CDN-origin connections when client-CDN connections are severed. However, we found that using `Transfer-Encoding: Chunked` can force the CDN to sustain CDN-origin connections even after the termination of client-CDN connections. It gives the attacker a new attack vector that revives the CDN decoupling attack. Attackers could still launch an amplification attack that exhausts the origin server's bandwidth.

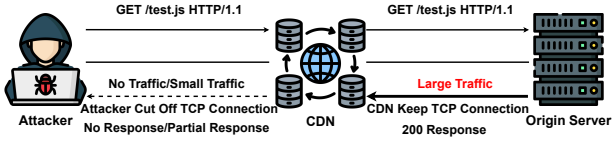

Figure 8: Concept of Connection Decoupling attack. Step 1: The attacker sends requests to CDN nodes; Step 2: The attacker closes the TCP connection and prevents the CDN from responding.

Attack Principle. When an attacker sends GET requests to a CDN and cuts off the attacker-CDN connections, the CDN forwards these requests to the origin server while still maintaining the CDN-origin connections, leading to amplification attacks. As shown in Figure 8, this strategy results in responses traveling only from the origin server to the CDN. It causes the bandwidth consumption on the CDN-origin connections to be significantly higher than the attacker-CDN connections.

3.6.2 Amplification Factor

We speculate that the size of the target resource influences the amplification factor of the `Connection Decoupling` attack. We conducted experiments to explore how the size of the target resource affects the amplification factor.

Experiment Setup. In our experiments, we deploy an Nginx web server on each CDN. We placed target resources of varying sizes on the origin server, ranging from 1MB to 25MB in increments of 1MB. We then used the `tcpdump` tool to capture traffic on client-CDN and CDN-origin connections to calculate the amplification factor. For each CDN, we first sent GET requests for different-sized target resources, then immediately cut off TCP connections to evaluate the impact of resource size on the amplification factor.

Experiment Result. As shown in Figure 9, the amplification factor for each CDN is essentially proportional to the size of the target resource. G-core is an exceptional case, as it differs from the prevalent implementation observed in most

other CDNs. In contrast to the standard behavior, wherein CDNs promptly close the TCP connection upon receipt of a client-sending RST frame requesting connection closure, G-core exhibits a distinctive implementation. This implementation entails a refusal to terminate the TCP connection until it has successfully filled the TCP window. However, it is worth noting that an attacker can still bypass this unique implementation in G-core by setting up a small TCP window to prevent CDN from responding.

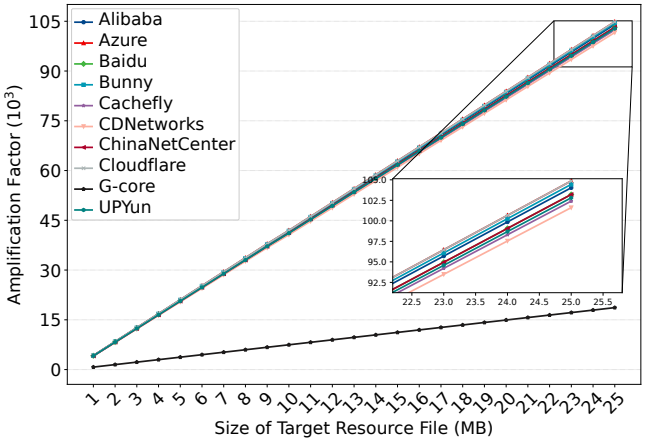

Figure 9: How does the Connection Decoupling attack amplification factor change with the size of a target resource file.

Table 10: Amplification factors with different target resource sizes of Connection Decoupling attacks.

	Amplification Factor		
	1MB	**10MB**	**25MB**
Alibaba	4181	41614	104029
Azure	4216	41948	104862
Baidu	4148	41286	103210
Bunny	4198	41779	104443
Cachefly	4116	40963	102403
CDNetworks	4082	40645	101609
ChinaNetCenter	4129	41284	103207
Cloudflare	4214	41946	104861
G-core	747	7469	18672
UPYun	4131	41124	102805

Table 10 summarizes the amplification factor for a target resource of different sizes (1MB, 10MB, and 25MB). The amplification factor is proportional to the target resource size.

4 Real-world Evaluation

When attack requests reach a website and simultaneously demand the utilization of internal bottleneck resources, such as CPU, memory, and logical queues, a significant influx of requests can persistently overwhelm these resources, leading to more severe DoS disruptions. We first evaluated the real-world amplification factor for all vulnerable CDNs. As shown in Figure 10, all CDNs we tested are vulnerable to at least one specific `BtOAmp` attack, and the `Image Optimization` attacks can attack ten CDN vendors, and it has the most extensive attack surface.

To further demonstrate the real-world impact of `BtOAmp` attacks on bandwidth amplification, we choose one different CDN for each specific `BtOAmp` attack to study the bandwidth of both the attacker and the origin server, results are shown in Figure 11(a) and Figure 11(b).

The Setup of Real-World BtOAmp attacks. We initially set up an HTTP service (2.5GHz/2GB/100Mbps/Nginx 1.21.3) in Silicon Valley as the target victim. Subsequently, we launched the `BtOAmp` attack in a VPS (2.5GHz/2GB/30Mbps) in Singapore. Both servers are located on the backbone network, which greatly reduces the risk of saturating on-path network segments with our attack traffic. To assess the impact of attacks, we monitor the bandwidth consumption of both the attacker (client) and the origin server.

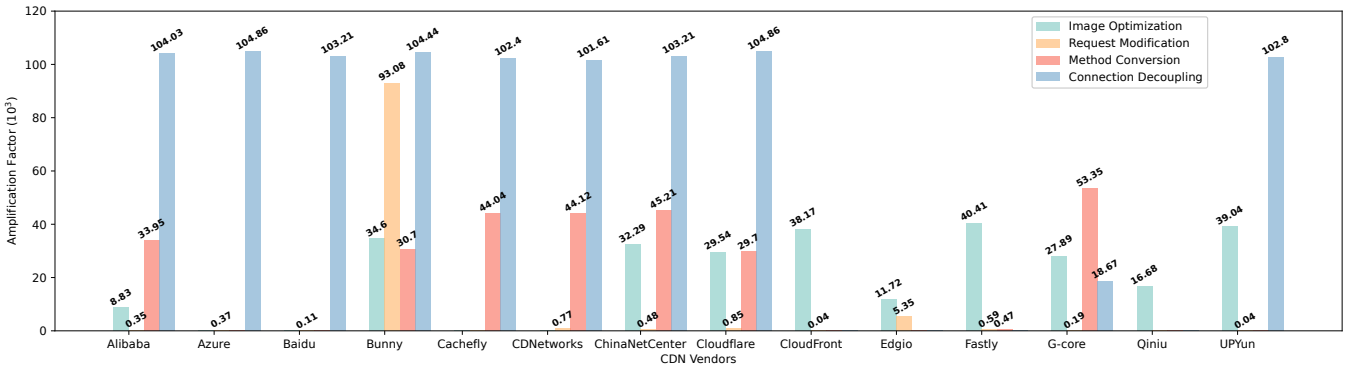
Setting of Image Optimization Attack. Take Fastly as an example, we concurrently send three image optimization requests to Fastly every second, lasting 60 seconds. The resolution of the requested target image on the origin server is 4320 pixels.

Severity Analysis of Image Optimization Attack. Figure 11(a) and Figure 11(b) compare the bandwidth consumption. The attacker sacrifices a bandwidth consumption not exceeding 10Kbps, while the website's bandwidth achieves 100 Mbps at maximum.

Setting of Request Modification Attack. Taking Edgio as an example, we concurrently send 15 POST requests to Edgio per second for 60 seconds. Edgio appends 15 HTTP headers of 200KB each to these requests and rewrites the URL from "/a" to "/a" ten thousand times. Moreover, we also use CDN cascading technology to amplify the threat of `Request Modification` attacks. For example, we cascaded CloudFront and Bunny to evaluate the effectiveness of the `Cascade Request Modification` attack. We simultaneously send 3 POST requests to CloudFront every second for 60 seconds. CloudFront appends 10 HTTP headers, each 896B in size, to these requests and forwards them to Bunny. In addition, Bunny appends 10 HTTP headers of 2MB each to these requests and rewrites the URL from "/a" to "/a" a hundred thousand times.

Severity Analysis of Request Modification Attack. Figure 11(a) and Figure 11(b) demonstrate that an attacker can launch request modification attacks to bring down a victim's 100Mbps bandwidth with just an average 35kbps bandwidth. In addition, an attacker can also use CDN cascading techniques to launch `Cascade Request Modification` attacks, only needing to consume 15kbps bandwidth to paralyze the victim's 100Mbps bandwidth. CDN cascading techniques can greatly increase the threat of `Request Modification` attacks.

Setting of Method Conversion Attack. Taking Cloudflare



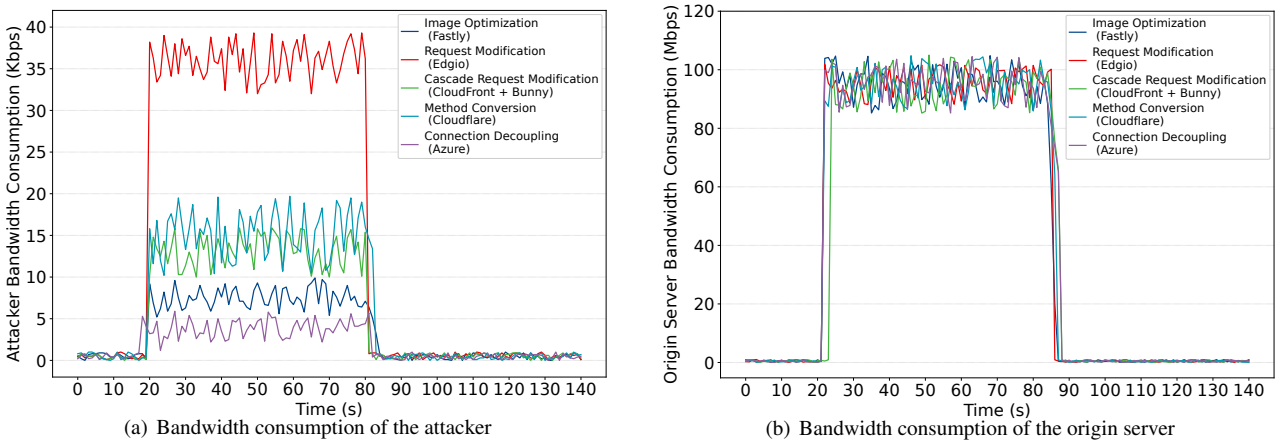


Figure 10: Amplification factor of the BtOAmp attacks on all CDN vendors.

(a) Bandwidth consumption of the attacker

(b) Bandwidth consumption of the origin server

Figure 11: The bandwidth consumption of the attacker and the origin server for BtOAmp attacks.

as an example, we concurrently send 2 HEAD requests per second to Cloudflare, lasting 60 seconds. The target resource size on the origin server is 10MB.

Severity Analysis of Method Conversion Attack. Figure 11(a) and Figure 11(b) show that an attacker can use below 10Kbps bandwidth to launch `Method Conversion` attacks to exhaust the victim's 100 Mbps bandwidth.

Setting of Decoupling Connection Attack. Taking Azure as an example, we concurrently send 2 GET requests to Azure every second, promptly cutting off the TCP connection upon sending the requests, lasting 60 seconds. The target resource size on the origin server is 10MB.

Severity Analysis of Decoupling Connection Attack. Figure 11(a) and Figure 11(b) show that an attacker can launch `Connection Decoupling` attacks by cutting off the TCP connection after the request has been sent. The attacker's bandwidth usage remains below 7Kbps, whereas the website's bandwidth reaches a maximum of 100 Mbps.

The above evaluations show that the `BtOAmp` attack ideally matches the "small spark, big fire" attacking philosophy. Worse, the stealthy nature of a `BtOAmp` attack can also help it to escape DDoS detection.

5 Discussion

5.1 Mitigations

In general, the presence of vulnerabilities is partly due to market competition. CDN vendors naturally aspire to offer more features and maximize compatibility with websites of varying configurations. However, CDNs serve as the backbone of the Internet. Therefore, if there are weaknesses in CDN implementations, they could potentially be exploited, jeopardizing the security of websites and causing a severe threat to the Internet.

Limit parameters in the Back-to-Origin strategies. Currently, all the CDN vendors we tested that support image optimization do not impose any restrictions on parameters. We recommend that CDNs set image cropping parameters to common resolutions in their default configurations, with users having the option to customize as needed. The CDN should cache the original image to reduce the workload on the origin server. Additionally, it is advisable to impose limitations on HTTP header size, HTTP header quantity, and URL size when implementing strategies for adding HTTP headers and rewriting URLs.

Follow RFC standards for request forwarding. We recommend that CDNs by default directly forward HEAD requests rather than automatically converting them into GET requests. If websites want to improve cache hit rates and speed up content loading, they can configure the CDN to forward HEAD requests as GET requests.

Synchronize client-CDN and CDN-origin connections. We recommend that CDNs wait several seconds after the client-CDN connection breaks, allowing the client to reconnect. If the client fails to reconnect, CDN should timely terminate the CDN-origin connection.

Enforce CDN to validate origin ownership. Currently, all fourteen CDNs we tested do not validate the ownership of customer-hosted origin, which allows attackers to register a CDN service and configure targeted websites as the origin [35, 36]. We recommend that CDN providers implement origin ownership validation to prevent abuse, which can narrow the scope of threats only on websites hosted on CDNs.

It's worth noting that both Alibaba and G-core have implemented our proposed solution to mitigate the `Image Optimization` attack. They did this by caching the original image on edge servers, which prevents the `Image Optimization` attack.

5.2 Ethic Consideration

During our study, we aimed to balance real-world severity evaluations with minimizing risks that could impact CDN vendors. We were concerned that higher bandwidth exhaustion during our tests could impair the CDN's network performance and harm other hosted websites. As a result, we took great care to avoid any ethical issues during our experiments.

Firstly, we strategically selected attacker positions with minimal latency to CDN nodes, ensuring our attacks are initiated within the backbone network. This configuration significantly reduced the risk of our attack traffic saturating on-path network segments. Secondly, our attacks targeted our own websites, keeping traffic below the CDN's capacity to avoid service disruption. Thirdly, we limited attack bandwidth to 100Mbps to prevent network overload and protect other CDN services. Fourthly, We only sent three requests to validate the feasibility of Cachefly's `Image Optimization` attack and that there would be no impact on the website's service. These approaches ensure our research minimizes harm while enhancing CDN security.

5.3 Responsible Disclosure

We contacted all 14 CDN vendors to report all vulnerabilities found in our study. We provided them with detailed reports and mitigation solutions to eliminate the detected threats. Most vendors confirmed the vulnerabilities promptly and claimed to fix them as soon as possible. Some vendors have fixed the vulnerabilities, including Alibaba, G-core, and UPYun. The responses from CDN vendors are summarized below:

Alibaba evaluated the problem as a medium-risk vulnerability. They stated that they view it as indeed a problem for the CDN industry, and they would internally assess how to defend against it. They thanked us for our report and provided a reward of ≈$200.

G-core expressed their gratitude for our report and confirmed the vulnerability of their CDN. Subsequently, they have informed us that they have fixed the vulnerabilities.

UPYun thanked us for the report and discussed with us the details of the attack and its potential consequences. They have fixed the vulnerabilities.

Qiniu thanks for this research discovery and acknowledged the issues found in the paper. They would internally assess how to defend against it.

ChinaNetCenter expressed appreciation for our study and informed us that they are investigating to validate the attack scenarios and explore the effectiveness of mitigation already available.

Cachefly thanked us for our work and acknowledged the potential for abuse of these vulnerabilities but said that their denial of service protection mechanism blocks abusive traffic.

CloudFront acknowledged our report and stated that these behaviors align with the CDN's design to facilitate such actions.

Cloudflare thanked us for the report and is evaluating these vulnerabilities. However, they have provided no further response to date.

Azure and Baidu expressed gratitude for the report and acknowledged that the attacks resulted from misconfiguration.

Fastly acknowledged our report, but provided no further comment to date.

So far, we have disclosed the vulnerability reports to Bunny, CDNetworks, and Edgio, but we have not received any response. We are actively seeking further communication with them.

5.4 Anonymity and Cost

One may argue that launching these attacks in the real world is unlikely due to associated costs and the risk of exposing the attacker's identity. However, CDN vendors, presumably for competitive reasons, provide much convenience for their prospective customers (and thus for attackers). Table 11 shows the registration information required to begin using the free or free-trial services of the CDN vendors in our study. Seven out of fourteen CDN vendors require only a valid email address. Azure, Cachefly, and CloudFront require valid credit cards (could be gift cards or stolen). ChinaNetCenter, Qiniu, and UPYun require a valid phone number (could be anonymous). Alibaba requires users to verify their identity through a valid bank card, which takes an attacker more effort to keep anonymous.

Table 11: CDN registration requirements, cost, and origin verification.

	Register Requirements	Price	Origin Verification
Alibaba	C1, C2, C4	Free trial	No Verification
Azure	C1, C3	Free trial	No Verification
Baidu	C1	Free service	No Verification
Bunny	C1	Free trial	No Verification
Cachefly	C1, C3	Free service	No Verification
CDNetworks	C1	Free trial	No Verification
ChinaNetCenter	C1, C2	Free trial	No Verification
Cloudflare	C1	Free service	Domain Blacklist
CloudFront	C1, C3	Free trial	No Verification
Edgio	C1	Free trial	No Verification
Fastly	C1	Free service	No Verification
G-core	C1	Free service	No Verification
Qiniu	C1, C2	Free service	No Verification
UPYun	C1, C2	Free service	No Verification

† C1 means an Email address is required to register an account.
‡ C2 means a Phone number is required to register an account.
‖ C3 means a Credit card is required to register an account.
* C4 means a Bank card is required to register an account.

5.5 Severity Assessment

A severe and widespread practical influence. According to our experimental results, the `Image Optimization`, `Request Modification`, `Method Conversion`, and `Connection Decoupling` are nearly proportional to the size of the target resources, leading to the consumption of the origin server's outgoing bandwidth. Meanwhile, request modification attacks can exhaust the origin server's incoming bandwidth. As detailed in Section 3, the CDNs we tested enjoy global popularity and a high market share. These CDNs host 36.5% of the websites on the Tranco Top 10,000 list. Therefore, many well-known websites are vulnerable to our `BtOAmp` attack.

A low-cost and efficient DDoS attack. Unlike other DDoS attacks that need to control a large scale of botnets [37], the attacker only needs an ordinary laptop to launch the `BtOAmp` attacks. As the CDN nodes are dispersed globally and form a naturally distributed botnet [38, 39], it allows attackers to easily congest the target network and possibly cause a denial of service in seconds for a low cost.

A significant monetary loss to the victims. Most CDNs charge their website customers by traffic consumption, including Alibaba, Azure, Bunny, Baidu, Cloudflare, CloudFront, G-core [40–43]. Attackers can exploit back-to-origin strategies to launch a `BtOAmp` attack against CDN-powered websites, causing a very high CDN service fee and bandwidth fee to the website [44].

A security challenge to anti-DDoS. Traditional DDoS attacks consume bandwidth and primarily target the victim's incoming bandwidth. `BtOAmp` attacks can exhaust both the victim's incoming and outgoing bandwidth. Further, abusing the CDN to launch amplification attacks certainly will pose security challenges for detecting DDoS attacks [45, 46].

5.6 Limitations

There may be some limitations in this study. Our methodology for identifying vulnerabilities cannot guarantee the detection of all possible issues due to the complexity of the HTTP protocol and CDNs. We conducted tests on only 14 CDN vendors, but we believe that other CDN vendors may have similar vulnerabilities. Moreover, as CDNs continue to evolve, new vulnerabilities may emerge that were not previously detected.

6 Related Work

6.1 CDN Security

According to reports [47], nearly one-fifth of Internet traffic is transmitted through CDNs. Therefore, CDN infrastructure is the cornerstone of the Internet, and the security of CDNs has been extensively researched [48]. Due to the DDoS protection provided by CDNs [49, 50], the search for vulnerabilities in CDN architectures or implementations and attacks on CDN-hosted origin servers have been a hot topic in the field of network security.

Previous research has found various vulnerable implementations among CDN vendors. For example, Chen et al. [17] discovered inconsistency of HTTP request handling policies among CDN vendors, where attackers can chain CDN nodes into a loop, causing the malicious request to be processed repeatedly and reducing CDN's availability. Guo et al. [51] identified new architectural weaknesses in CDN infrastructure. Attackers could exploit CDNs to launch pulse attack waves on their hosted origin servers, disrupting their availability. Due to the conflicting nature of CDNs as intermediaries and the end-to-end encryption of HTTPS, previous researchers have explored TLS key management issues on CDN platforms, such as private key sharing and inefficient revocation [52, 53]. Furthermore, attackers can exploit disparities in the interpretation of HTTP header fields between CDNs and origin servers, thereby enabling the misuse of CDN caching mechanisms to initiate cache poisoning attacks [7], cache-poisoned-DoS attacks [54], and web cache deception attacks [55]. Furthermore, CDNs' high reputation and invisibility can be exploited to escape internet censorship, such as domain fronting [56], domain borrowing [57], and domain shadowing [36] that compete with the constantly-evolving censorship systems.

In summary, compared to previous CDN security work, considering the widespread use of CDNs for DDoS attack defense, we have identified implementation vulnerabilities in `back-to-origin` strategies of CDNs, proposed a new class of amplification attacks, and conducted real-world security assessments of fourteen popular CDNs. This research provides a valuable supplement to existing CDN security research.

6.2 Amplification Attacks

Amplification attacks constitute a well-established area of research within the realm of cybersecurity. The UDP protocol has been extensively researched for amplification attacks. Sieklik et al. [58] conducted a further analysis of amplification attacks based on DNSSEC, resulting in amplification factors of up to 44 times. Anagnostopoulos et al. [59] studied TFTP amplification attacks with amplification factors of 60 times. Booth et al. [60] revealed that UDP amplification attacks, recruiting UDP servers on the internet as reflectors, can achieve amplification factors up to 556 times. The TCP protocol can also be abused to launch an amplification attack. Kuhrer et al. [61] proposed that amplification attacks can be launched using the three-way handshake mechanism of the TCP protocol, and application-layer protocols based on the TCP protocol, e.g., FTP, Telnet, and SSH, are vulnerable to these attacks. Unfortunately, even the HTTP protocol has been abused. Li et al. [28] exposed that amplification attacks leveraging the HTTP Range Request mechanism can achieve amplification factors as high as 43000 times. Guo et al. [62] found that the compressed headers can be amplified when HTTP/2 downgrades to HTTP/1, which causes an amplification attack. Triukose et al. [31] proposed an attack that exhausts the origin server bandwidth by quickly disconnecting the client-CDN connection. We evaluated this attack and found that most CDNs mitigate it. However, our decoupled CDN connection attack can bypass this defense to attack the website powered by CDN.

In conclusion, our research reveals that leveraging `back-to-origin` strategies can launch a novel class of amplification attacks against websites hosted on CDNs. More significantly, when the website is hosted by CDN, although the CDN can defend against previously studied amplification attacks, our attacks can penetrate CDN DDoS protection and launch amplification attacks against the CDN-hidden websites.

7 Conclusion

The CDN has undeniably become an indispensable part of the internet landscape, providing several benefits, such as acting as a shield against DDoS attacks for websites hosted on CDN platforms. However, it is crucial to acknowledge that CDN infrastructure, particularly its `back-to-origin` strategies, can also be exploited, undermining the very DDoS protection it is supposed to provide.

We have presented a novel class of amplification attacks and their real-world evaluation of fourteen CDN vendors. This research reveals the flawed trade-off that CDN vendors made between performance and security. Experiment results show that attackers can exploit CDN `back-to-origin` strategies to successfully launch an amplification DoS attack against website servers. We envision our work being able to urge CDNs to raise their security standards and inspire more researchers to explore CDN-related security.

Acknowledgement

We sincerely thank all anonymous reviewers and our shepherd. Their insightful reviews and comments have improved this paper, with a special note of appreciation to our shepherd for their thoughtful and patient guidance. We also acknowledge the prompt response from CDN vendors, notably Alibaba, G-core, UPYun, and Qiniu, in fixing the vulnerabilities we found. This work is supported by the National Key Research and Development Program of China (Grant No. 2021YFB0301100), National Natural Science Foundation of China (No.62072109, No.62272265), and Natural Science Foundation of Fujian Province (No. 2021J06013).

A Appendix

A.1 Details of Image Optimization Attack

To elaborate on how to launch an `Image Optimization` attack, we summarize the parameters for launching an image optimization attack in 12. Taking Fastly as an example, for example, utilizing the parameter "?format=webp" can trigger the CDN to compress the image into webp format. For example, the parameter "?crop=1,1" can trigger the CDN to crop the requested image to one pixel. Moreover, attackers can use the parameter "?crop=1.1&format=webp" to exploit the CDN to compress the image into webp format and crop it to one pixel.

You Can Obfuscate, but You Cannot Hide: CrossPoint Attacks against Network Topology Obfuscation

Abstract

Link-flooding attacks (LFAs) may disrupt Internet connections in targeted areas by flooding specific links. One effective mitigation strategy against these attacks is network topology obfuscation (NTO), which aims to obscure the network map and conceal critical links, preventing attackers from identifying bottleneck links.

However, we argue that the attackers can still discover critical links in the presence of NTO defenses. In this paper, we introduce the CrossPoint attacks to escape the security protections of state-of-the-art NTO defenses by exploiting two network traffic features: *correlated congestion* and *statistical disparities*. Although NTO defenses create a complex and seemingly robust virtual topology, distinct information is still discoverable due to conflicting design objectives and inherent features of the Internet, resulting in novel side channels. Through comprehensive experiments, including a measurement study on the Internet, we demonstrate CrossPoint attacks' high success rate (80%-95%), minor overhead (10%-20%), as well as attack stealthiness and feasibility.

1 Introduction

Large-scale botnet-driven distributed denial of service (DDoS) attacks continue to pose a significant threat to the Internet [2,14,15,31,42]. Despite the prevalence of end-host DDoS defenses, link-flooding attacks (LFAs) remain a substantial threat to the robustness of the Internet [19, 35]. LFAs aim to overwhelm network infrastructure, such as in-line routers and servers, rendering end-host defenses irrelevant. In recent years, LFAs have caused severe damage. For instance, a large-scale LFA in 2013 attacked 4 Internet exchange points between Europe and Asia, leading to numerous sites being offline for several hours [3, 25]. In 2022, Ithaca College's network infrastructure fell victim to an LFA [7]. CloudFlare's statistics from the same year indicated a 109% year-over-year increase in DDoS attacks targeting network infrastructure [2], underscoring the growing concern over such attacks.

To efficiently launch an LFA, the adversary needs to know about the topology of the target network. Without this knowledge, an attacker can only "guess" which flows share a common link, considerably reducing the attack efficiency. Nethide [29] demonstrates that such "guess" attacks require 5 times more flows, rendering them less practical. However, once attackers acquire knowledge of the network topology, they are equipped to disrupt a considerable volume of legitimate communication. For instance, the Crossfire attack [19] demonstrates the potential of topology-probing LFAs against critical infrastructure across US regions, potentially disabling up to 53% of Internet connections in some states. Therefore, LFAs consist of a probing stage followed by an attack stage [19,35]. In the probing stage, attackers use reconnaissance tools to gather knowledge of the network topology and identify bottleneck links that are potential targets. During the attack stage, the attacker coordinates attack flows to flood critical links.

In response, researchers have developed *proactive defenses* against attackers during the probing stage [13,21,22,29], as well as *reactive defenses* to mitigate LFAs during the attacking stage [9,18,25,26,32,34,36,38,39,41,44].

In recent years, *proactive defenses*, also known as automatic moving target defense (AMTD), have gained increasing popularity and attention in academia and industry [28]. According to a Gartner report [28], AMTD is recognized for its potential to significantly bolster security through a "defense in depth" strategy. In the industry, several vendors (*e.g.,* R6security, Dispel) offer AMTD for dynamic reconfiguration of network infrastructure, topology, and configuration to enhance the resilience of networks against various cyber threats [6]. AMTD is also deployed in critical systems [27]. In academia, researchers have proposed dynamic network topology obfuscation (NTO) defenses against LFAs [13,21,22,29]. NTO is an example of AMTD, which manipulates virtual topology to obscure the true network topology and conceal bottleneck links. State-of-the-art (SOTA) NTO techniques, such as NetHide [29] and EqualNet [21], provide strong secu-

*Corresponding author: Kaiping Xue, kpxue@ustc.edu.cn

rity guarantees by reducing the attacker's success rate to less than 1%, even when attackers have substantial resources (2-4 times that of a normal LFA).

Although SOTA NTO defenses [13, 21, 22, 29] can create complex and robust virtual topologies to confuse attackers, it is still possible to break the defenses. One intuitive approach is randomly selecting attack flows, such as blind or bottleneck random attacks [29]. However, these attacks are known to require substantial budgets against recent NTO defenses and have low success rates [29]. Another potential attack is to exploit hardware fingerprints to identify target links [21, 29]. Nevertheless, SOTA defenses are known to defeat similar attacks efficiently [21]. To our best knowledge, there does not exist an attack in the literature that achieves a high success rate with a low cost.

In this paper, we propose CrossPoint attacks that exploit novel side channels to escape SOTA NTO defenses effectively [13, 21, 22, 29]. We argue that some inherent lower-layer features of Internet traffic, such as propagation delay (a static feature) and congestion (a dynamic feature), cannot be completely concealed by higher-layer obfuscation mechanisms. Moreover, the *usability* objective [21, 29] of NTO schemes that require link failures to be correctly located may be employed to compromise link identity. A well-crafted attack may exploit such inherent and robust network features and the *usability* functions to compromise the security promises of NTO defenses and identify critical attack targets.

However, developing such a well-crafted attack is nontrivial. First, since attackers do not have any prior knowledge of the network, they cannot utilize static features, such as propagation delay, to distinguish virtual or physical links. Second, since the congestion probing tools are end-to-end, attackers cannot pinpoint the exact location of congestion and obtain knowledge of physical links by only measuring congestion. In this paper, we demonstrate that attackers can tackle these challenges by introducing statistical and correlation analysis.

First, we present an approach to identifying NTO-crafted virtual links by exploiting lower-layer static network features through *statistical disparities*. Although lower-layer characteristics, such as propagation delay, are difficult to exploit without prior knowledge, we demonstrate that, due to the usability properties of NTO schemes, attackers with sufficient bots can identify features of NTO-crafted links that are inconsistent with their inherent lower-layer characteristics. These inconsistencies allow attackers to pinpoint virtual links that appear more suspicious than others.

Second, we present an approach to discover physical links by analyzing *correlated congestion*. Since NTO defenses do not change underlying routing paths [13, 21, 22, 29], attackers can observe and measure Internet congestion to identify artificially concealed physical links. Figure 1 shows an example of a six-node topology, where link l_{BC} is the attacker's target. We demonstrate Nethide's virtual topology [29] with blue dashed lines, which protects the bottleneck link l_{BC} with two independent routes (A-C-D and E-B-F). When congestion occurs on l_{BC}, highly correlated RTT increases and packet loss indicates that the two parallel virtual paths utilize the same physical link. Nonetheless, the challenge arises because congestion on other links may interfere with the correlation analysis. To tackle this issue, we introduce a *control group* to filter out non-targeted congestion, allowing us to isolate and identify the specific congestion associated with the target link. Subsequently, attackers can calculate the Pearson correlation coefficient (PCC) matrix [10] to measure the similarities among congestion samples and identify the physical target links shared by each unknown path.

Essentially, the CrossPoint attacks exploit two side channels (inherent network features and congestion) to challenge NTO defenses under a black-box network, where the attacker only uses `traceroute` and `ping` as reconnaissance tools. With extensive experiments, we evaluate the performance of the CrossPoint attacks and show that they achieve high success rates (80% - 95%) in identifying bottleneck links at a small extra cost (10%-20%), even though the network is protected by SOTA NTO defenses [21, 29]. Moreover, even though we cannot test this attack on the Internet, we have designed a measurement study to demonstrate the feasibility and stealthiness of the CrossPoint attacks on the Internet. To pave the way for improving NTO defenses, we also discuss countermeasures and future NTO directions.

Contributions To summarize, this paper makes the following contributions:

1. We identify two fundamental weaknesses of the current NTO design: first, the routing compatibility leaks information regarding physical paths, and second, the usability features discover information about virtual links.
2. We present the CrossPoint attacks against NTO defenses. The attacks exploit *usability* with *statistical disparities* to infer virtual links and discover hidden links with *correlated congestion* of physical paths.
3. We demonstrate the effectiveness of CrossPoint attacks against state-of-the-art NTO defenses through comprehensive experiments, which show a high success rate of 80-95% with a low overhead of 10-20%.
4. Our large-scale measurement study demonstrates the feasibility and stealthiness of the CrossPoint attacks.

Ethical Considerations. This research aims to evaluate the effectiveness of SOTA NTO defenses in practice. We never attacked any real-world network infrastructures outside of the lab. Our experiments did not introduce any pressure on any ISP links. We use cloud servers in experiments (Section 6.2) to introduce real Internet noise instead of sending attack flows. Our Internet measurement study (Section 6.5) investigates the feasibility of the CrossPoint attacks with low-rate, benign probes of 0.36 KB/s ICMP flows.

The rest of this paper is structured as follows: Section 2 outlines background and related works. Section 3 contains the

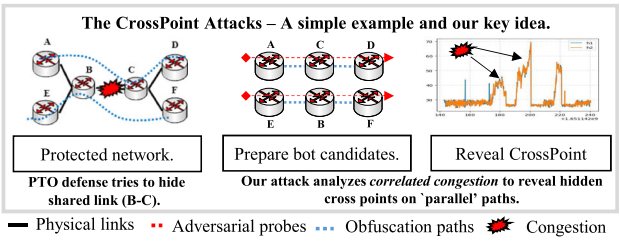

Figure 1: A CrossPoint attacker discovers the hidden shared link by analyzing correlated congestion. We use the same instance with Nethide [29].

threat model and glossary. Section 4 analyzes the weakness of SOTA NTO defenses. Section 5 introduces CrossPoint attacks. Section 6 displays the evaluation results, and Section 7 discusses countermeasures. Section 8 gives discussions. Finally, we conclude in Section 9.

2 Background and Related Works

Link-flooding attacks [19,35] aim to target a limited number of critical links in a network, thereby inflicting substantial damage within a specific network area. For instance, Kang et al. [19] showcased how Crossfire attacks [19] could significantly disrupt over 53% of communication in some states by selecting approximately 20 critical links as targets. Consequently, the selection of critical targets within large-scale networks assumes paramount importance. To this end, Crossfire attacks employ probing tools like `traceroute` to estimate the importance of network links. Attackers calculate the *flow density* of each link by aggregating data from large-scale botnet probes utilizing `traceroute`. The concept of *flow density* is defined as the quantification of bot traffic transmitted through a particular link, which can be used to estimate the link's routing popularity within the network. Notably, links characterized by high flow density are considered prime targets for LFAs [19]. However, Crossfire attacks face limitations when confronted with SOTA NTO defenses.

Network topology obfuscation [13,21,22,29] manipulates `traceroute` responses to obfuscate the link's flow density to prevent attackers from finding profitable targets. This is achieved by strategically manipulating probing responses that present a virtual and resilient topology to potential attackers. In the virtual topology, attackers are left without a clear set of critical links to exploit. In essence, NTO schemes compel LFAs to transition from targeted critical-link attacks to random-target attacks. However, random-target attacks require a substantial budget and offer no guarantees on the effectiveness [29]. Another potential solution countering NTO schemes is exploiting the hardware fingerprints to discern virtual responses from physical ones. However, EqualNet [21] is engineered to produce virtual responses that are indistinguishable from their physical counterparts.

Nevertheless, this paper finds **two fundamental weaknesses** that can be exploited to bypass the obfuscation of SOTA NTO schemes. First, despite a robust virtual map being present, the lower-layer network traffic patterns can not be effectively hidden, allowing attackers to exploit such patterns to distinguish virtual responses. Second, NTO schemes have to provide the *usability* property for benign users, which degrades security when attackers launch statistic analysis. We hope these findings can help enhance the security of NTO schemes in practice.

3 Threat Model and Glossary

Threat model. We use the same threat model as previous attacks and NTO defenses [19,21,29,35]. In detail, the attacker has a limited number of bots located outside the target network to locate and congest at least one bottleneck link within the network. However, the attacker lacks prior knowledge about the network and can only employ limited reconnaissance tools, specifically `traceroute`, `ping`. It is assumed that the network does not prohibit normal ICMP requests and responses that are defined in RFC777 [30].

Most crucially, we assume that the network is protected by SOTA NTO defenses, such as Nethide [29] or EqualNet [21].

Additionally, we assume that at least one congestion event occurs on the target link. However, this assumption is optional and loose. If this condition cannot be satisfied, CrossPoint attacks can still work using only the statistical disparities technique without congestion information. Additionally, our measurement study indicates that most Internet paths experience a large number of congestion events, making it more likely that the bottleneck link will be affected.

Glossary. We give the glossary of definitions in this paper:

- **Paths and links.** A path is a flow route that may consist of multiple links.
- **Bot-path.** A bot can create different flows by altering destinations, and each flow corresponds to a dedicated routing path. In the following, we depict different bot-paths with $(b,p)_A,(b,p)_B,\cdots$. Under a NTO defense, the attacker needs to determine whether a bot-path conceals a profitable link.
- **Link capacity.** We assume that each bot-path sends the same volume of traffic during the attack stage. The link capacity can be represented by the number of available bot-paths passing through the link.
- **Flow density.** Flow density is a link attribute representing the number of bot-paths that pass through it. A link is considered profitable for the attacker if its flow density exceeds its link capacity.
- **Budget.** Budget is the maximum number of bot-paths that the attacker could employ in the attack stage.

The definitions of *link capacity*, *flow density*, and *budget* are the same as Nethide [29]. And the *bot-path* is considered as a

flow in Nethide [29].

4 Security Analysis of NTO Defense

In this Section, we present the fundamental weaknesses of SOTA NTO defenses. Initially, we discuss how the *usability* property leads to a decline in *security*, ultimately resulting in *statistical disparities* in inherent and robust network features that help identify virtual links. Secondly, with unchanged routing paths, the observation of *correlated congestion* can assist in discovering physical links. These two weaknesses enable CrossPoint attackers to expose bottleneck links for flooding. In the following subsections, we delve into the respective root causes of these weaknesses.

4.1 The Statistical Disparities

The *Statistical disparities* refer to the static differential features between virtual and physical networks that higher-layer obfuscations cannot change. Although static features cannot be used to identify virtual or physical links directly, we have discovered a vulnerability stemming from the *usability* property of NTO schemes when attackers have sufficient bots to perform statistical analysis.

Security analysis on Nethide [29]. We briefly summarize the Nethide design detail for the next step of the analysis. Nethide formalizes *usability* as the optimization objective and formalizes *security* as hard constraints, represented by the optimization problem:

$$Max. \sum_{f \in F} (w_1 Acc(f) + w_2 Uti(f))$$
$$s.t. \quad Security\ constraints,$$

where f is a bot-path (a *flow* in Nethide). $Acc(f)$ calculates the similarity between virtual and physical paths, representing the accuracy of using virtual links to make routing decisions, while $Uti(f)$ calculates the probability of correctly locating link failures with virtual paths. The security constraints are solid requirements that some links must be concealed.

In SOTA NTO defenses [21,29], the *security* property takes precedence over *usability*. And the *usability* is achieved as a best-effort function. However, achieving the optimal *usability* objective can lead to undesired outcomes: the *security* is compromised. To comprehend this, it is essential to describe the approach for attaining the highest *usability* objective while ensuring *security*. For example, consider a scenario with three links, A, B, and C, where link B is a bottleneck and must be hidden. Without the *usability* objective, defense schemes are free to conceal any links in A, B, and C, or all of them, to provide good obfuscations. However, when under the objective to maximize the *usability* functions, *i.e.,* $Acc(f)$ and $Uti(f)$, hiding any links leads to these two objective decreases monotonically [29]. That is because removing any physical links in the network leads to inaccuracies in making routing decisions and locating link failures. Therefore, the best choice to maximize the *usability* is to hide link B without A and C, since it maintains the highest accuracy in terms of $Acc(f)$ and $Uti(f)$ for the other two links. To summarize, concealing non-bottleneck links like A and C does not contribute to meeting security constraints but decreases the *usability* objective. Therefore, the solver of the designed model tends to conceal the least number of links to satisfy the *security* constraints. Thus, our first observation is that the *usability* objective results in virtual links having a high probability of concealing bottleneck links, making identifying virtual links crucial in discovering critical targets.

Furthermore, since this design tends to conceal the least number of bottleneck links, an attacker can identify inherent features that show different statistical results from others. In practice, Nethide omits important nodes to offer near-optimal solutions, which means virtual paths appear shorter than physical paths in `traceroute` responses. However, the unchanged propagation delay may discover the actual length of the path. For example, empirical evidence shows that a long propagation delay indicates a long Internet path [5], but the probing results show the long path contains only a few nodes. Consequently, the attacker can guess that the path has been obfuscated. Nonetheless, since the network is a black box, it is challenging to establish the relationship between path length and propagation delay and determine whether the path is virtual or physical.

However, when attackers has sufficient bots to launch statistical analysis, they can identify relatively suspicious virtual links. In the case of path lengths and propagation delay, the attacker calculates *one-hop-delay* defined as $RTT/Hops$, indicating the relationship between propagation delay and the number of nodes along the paths. Even though the attacker does not know the actual relationship between path length and propagation delay in the target network, they can extract paths that are more suspicious than others (long propagation delay but few hops). Figure 2 depicts the statistical results of the $RTT/Hops$ attribute in 47 different topologies with realistic RTT settings (refer to Section 6.1 for details). The left Y-axis denotes the CCDF of $RTT/Hops$ between virtual and physical paths, while the right Y-axis shows the attacker's advantage defined as a Bayes probability $P(link == virtual | X \geq k)$, which increases as $RTT/Hops$ increases. Therefore, it is possible to extract some of the virtual links against Nethide.

Security analysis on EqualNet [21]. Similar to Nethide, EqualNet provides best-effort *usability* to enable benign users to debug link failures within a virtual topology effectively. However, the difference is that EqualNet guarantees accurate link failure within a subnet. To achieve this, EqualNet randomly assigns virtual nodes IP addresses within the same subnet as their physical nodes [21]. Nevertheless, similar to how propagation delay leaks the real path length, subnet-level IP addresses may also unintentionally expose information

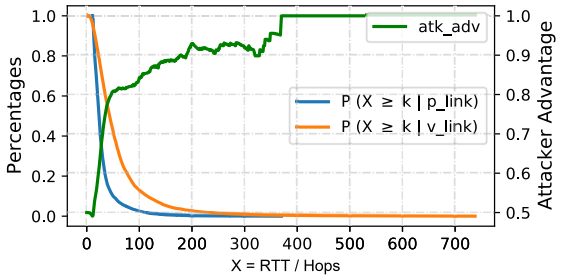

Figure 2: Statistical disparities of the physical propagation delay / virtual path length against Nethide in 47 different topologies. The attacker's advantage is a Bayes probability defined as $P(link == virtual | X \geq k)$.

about virtual links as a static feature. In this case, CrossPoint attackers treat all virtual nodes that have the same subnet prefix as one physical node. While this approach aggregates two physical nodes that share the same subnet prefix erroneously, it is enough to give a coarse-grained identification of virtual nodes and links, which can be used in the next step with *correlated congestion* to discover physical links accurately.

4.2 The Correlated Congestion

As the underlying routing paths remain unchanged under NTO defenses, it is possible to use information from lower-layer routing to identify links [13, 21, 22, 29]. In this study, we leverage correlated congestion to extract physical link information under NTO defenses.

Network congestion occurs when data transmission demands surpass the available bandwidth of a device, leading to significant delays and the possibility of packet loss [8]. It is rare for unrelated congestion events from different network locations to demonstrate similar congestion characteristics, due to the multifaceted nature of typical congestion determinants, such as unpredictable onset times, varying capacities of output queues, the arbitrary magnitude of burst traffic, and the diversity in router buffer sizes. Thus, congestion events with highly similar features observed at two points may indicate a common source, such as the same network device. This phenomenon, known as correlated congestion, serves as a valuable tool in pinpointing bottleneck links within a network. Many congestion control efforts already utilize correlated congestion to enhance performance, such as applications of multipath-TCP [23, 33, 40]. Therefore, it is possible to reveal physical links through correlated congestion events.

5 CrossPoint Attacks

5.1 Attack Overview

We assume an attacker has n bot-paths (defined in the glossary), and the target link's capacity is c, where $c < n$. The classic Crossfire attacks [19] can select sufficient bot-paths passing through the target with `traceroute` reconnaissance in the absence of protections. However, NTO defenses [21, 29] obfuscate the `traceroute` responses to prevent Crossfire attacks. As a result, a Crossfire attacker will find there are only n' ($n' << c$) bot-paths passing through each link, making it impossible to flood any links with sufficient bot-paths. Therefore, the goal of our attack is to identify the remaining $c - n'$ bot-paths passing through the target.

The straightforward method is to randomly select the remaining bot-paths as *blind* or *bottleneck random* attacks [21, 29]. However, they are ineffective due to the protections of NTO defenses [29], achieving less than 1% success rate with 400% of the budget. Another potential method is to utilize hardware fingerprints to identify virtual and physical links. However, state-of-the-art NTO defense [21] can completely defend against such attacks.

CrossPoint attacks identify the remaining $c - n'$ bot-paths with *statistical disparities* and *correlated congestion*. Figure 3 shows an overview of our attacks. First, the attacker collects basic routes and delay information on the virtual map. Second, the attacker makes a coarse-grained classification of bot-paths based on *statistical disparities* to infer virtual bot-paths (*i.e.,* it hides something, potentially the target). Third, the classified virtual bot-paths are used to observe *correlated congestion*. In this step, we introduce *control group* to judge whether congestion happens on the target. If targeted congestion is found, the RTT samples are sent to other bot-paths, and correlations are calculated. A high correlation from a virtual bot-path means that it has a high probability of hiding the target link [23, 33, 40], making it suitable for flooding the target link.

To summarize, CrossPoint attacks have the following steps:

1. **Attack preparation.** The attacker has a bot-path set $S = \{(b,p)_A, (b,p)_B, \cdots\}$. To begin the attack, each bot collects basic information such as propagation delay and routing paths, to construct the (virtual) link map.
2. **Detecting virtual links with statistical disparities.** The attacker utilizes static features and calculates statistical results, then the attacker outputs the virtual bot-path set S_{sort}, where relatively more suspicious bot-paths are prioritized over others.
3. **Identifying physical links with correlated congestion.** The attacker coordinates selective bot-paths in S_{sort} to observe congestion and calculate correlations, clustering the bot-paths that share the same physical links and output the bot-path set S_{attack} for each potential target.

The CrossPoint attacks have two variants: the dedicated use of *statistical disparities* or the *correlated congestion*. The first variant, named the CrossPoint-SD attack, involves steps (1) and (2). This attack utilizes random suspicious bots to launch attacks. On the other hand, the CrossPoint-CC attack involves steps (1) and (3). This attack employs random bots to observe congestion. To achieve optimal performance, the CrossPoint-SD/CC attack combines both the SD and CC side

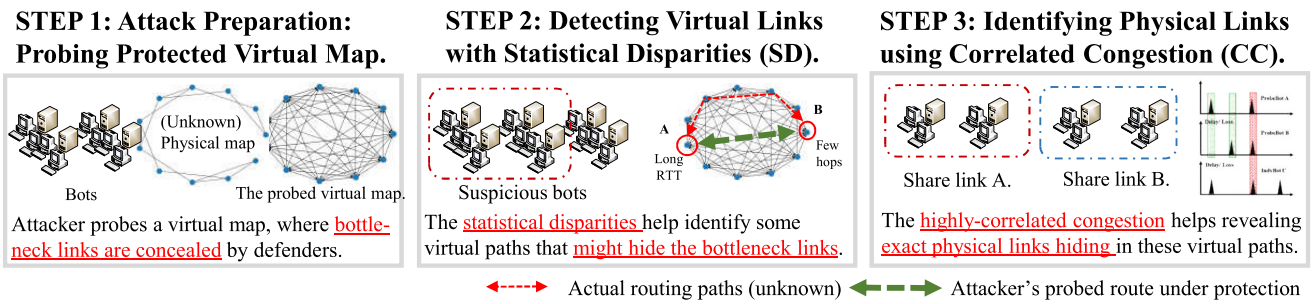

Figure 3: CrossPoint attacks consist of three steps. Firstly, each bot-path collects virtual routing paths and the propagation delay. Then, the attacker performs coarse-grained classification on virtual paths using statistical disparities. Finally, the attacker determines the attack bot-paths using correlated congestion.

channels with steps (1), (2), and (3).

5.2 Step 1: Attack Preparation

This step is the same as the Crossfire attack [19]. During this phase, each bot gathers essential information, including routing data, propagation delays, and available bandwidths, to prepare for attacks. To start this process, each bot sends `traceroute` probes to various potential destinations (other bots or public servers). The `traceroute` results are a series of IP addresses assigned to routers' interfaces, establishing a (virtual) map of network links. For each destination, bots can gather their available bandwidth through tools like `Pathneck` [17]. Next, each bot sends a series of `ping` messages (typically 10-20) to measure the propagation delay of each path. Then, the attacker computes the flow density for each network link and organizes them in descending order of flow density magnitude. Without NTO defenses, attackers can select the top-k critical links with the highest flow densities for their attacks. However, when NTO schemes are in place, the collected link map is virtual, and the top-k links may not be 'critical'. Consequently, CrossPoint attacks proceed to uncover natural critical links through subsequent stages.

5.3 Step 2: Detecting Virtual Links

CrossPoint attacks utilize the inherent features of the Internet (*e.g.* propagation delay, subnet addresses) to identify some virtual links crafted by NTO defenses. Since attackers face an unknown network without any prior knowledge, they cannot determine the value of these features that indicate whether a link is virtual or physical. As discussed in Section 4, CrossPoint attacks extract relatively more suspicious bot-paths with statistical analysis to identify virtual links.

Identify virtual bot-paths against Nethide [29]. For each bot-path denoted as $(b,p)_i$, we have the propagation delay represented as t_i, and the length of the `traceroute` path represented as h_i. As elaborated in Section 4, we employ the concept of the one-hop delay to estimate the relative likelihood of a path being virtual. To compute the one-hop delay for each bot-path, we use the formula t_i/h_i (propagation delay/number of hops). Subsequently, the attacker arranges all bot-paths in a descending order based on the magnitude of their respective one-hop delays. This results in the formation of a sorted set denoted as S_{sort}, where bot-paths with higher one-hop delays are consequently considered more suspicious.

Identify virtual bot-paths against EqualNet [21]. For each bot-path denoted as $(b,p)_i$, we employ the concept of *bot-path IP similarity* as a metric to measure the likelihood of concealing bottlenecks. First, we define *address similarity* as the count of IP addresses with the same subnet. Subsequently, the *bot-path IP similarity* is determined as the maximum *address similarity* observed within the routing paths. Following the computation of IP similarity for all bot-paths, we subsequently arrange the botnet set, denoted as S_{sort}, in a descending order based on their IP similarity values, which furnishes a descending sequence that reflects the likelihood of hiding bottlenecks in the virtual paths.

Finally, the attacker outputs S_{sort}, where the suspicious bot-paths are prioritized over others. Attackers can use these bot-paths in the next step to examine the critical links.

5.4 Step 3: Identifying Physical Links

Once the suspicious bot-paths containing virtual links have been identified, the next step is to identify the hidden physical links. As discussed in Section 4, NTO defenses only manipulate `traceroute` responses without altering the underlying routing paths. Therefore, our attacks utilize congestion in physical routing paths to expose hidden links. Specifically, *correlated congestion* on different paths can indicate that they share a common bottleneck [23,33,40]. As Figure 3 shows, attackers can cluster the unknown bot-paths with the correlation analysis of observed congestion samples.

However, the congestion location is a challenge. First, the `ping` probes are end-to-end, making it difficult to pinpoint the link where congestion occurs. Second, simultaneous congestion could happen on different links, which may pollute the correlation results. Therefore, CrossPoint attacks introduce the concept of *control groups* to help locate congestion.

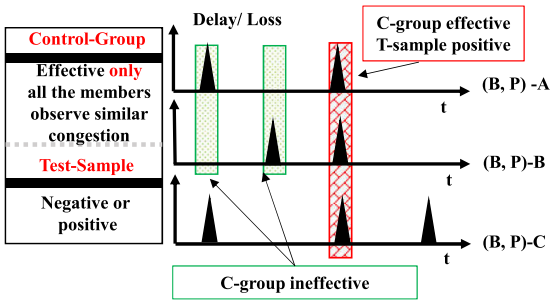

Figure 4: Example of using C-groups to distinguish congestion from a certain link.

Locate the congestion. To address this congestion location problem, we introduce a concept named *control group* comprised of bot-paths that share the minimal number of links necessary to monitor congestion on specific links. Figure 4 illustrates our idea, in which we assume that the routing paths of $(b,p)_A$ and $(b,p)_B$ intersect at a specific link. The objective for attackers is to determine whether the $(b,p)_C$ observed congestion also occurs on this particular link. To achieve this, we leverage $(b,p)_A$ and $(b,p)_B$ to establish a control group, essentially serving as a baseline reference. If congestion occurs on the target link, both $(b,p)_A$ and $(b,p)_B$ should experience the same *correlated congestion*. Consequently, if $(b,p)_C$ likewise observes this correlated congestion, it indicates that $(b,p)_C$ shares the same link with both $(b,p)_A$ and $(b,p)_B$.

In practice, two members in the control group may not be enough. Therefore, the attacker needs to establish a control group with the following rules:

1. Establish a basic control group with two known bot-paths that pass through the target link.
2. Augment the control group by introducing bot-paths that specifically incorporate the target link, to minimize the count of shared links.

Due to the *usability* design, SOTA defenses allow a certain number of bot-paths to retain their physical path, which aids the attacker in constructing control groups using the above-mentioned rules. For instance, Nethide [29] permits $n' < c$ bot-paths to pass through each link, where c is the link capacity, and n' is set to a sufficient value in practice to enhance *usability*. Similarly, EqualNet [21] utilizes virtual IP addresses belonging to the same subnet as their physical nodes, which can also be used to establish C-groups.

Observe the congestion and noise reduction. Since the Internet is noisy, we adopt a noise reduction technique that mitigates the impact of RTT jitters and Internet noise. Specifically, each bot sends `ping` traces at a certain speed (discuss in Section 6.5) and gains RTT traces. Then, we transform the RTT sequences into square waves while preserving critical features. We accomplish this by dividing constant RTT values into discrete buckets, with the lowest value representing propagation delay and the highest indicating packet loss. We define the congestion happening if an RTT sample increases more than 30% of its propagation delay.

Timestamp synchronization. Correctly analyzing congestion correlation necessitates time synchronization of each bot-path. However, the timestamp of the `ping` message is recorded when bot-paths receive ICMP responses, not precisely when congestion occurs. Therefore, we adjust the timestamp using the following correction:

$$t_{correct} = t_{timestamp} - RTT_{whole} + RTT_{target}/2,$$

where RTT_{target} is the delay between the bot and the target. This correction provides a more precise observation of targeted congestion events.

Quantify the correlation. We define *congestion correlation distance* to quantify the correlation between the congestion samples of $(b,p)_A$ and $(b,p)_B$. Specifically, we calculate the Pearson correlation coefficient (PCC) [10] between the two congestion samples, which measures how well the two samples are correlated. If the correlation coefficient is high, then the two samples are more likely to be derived from the same bottleneck.

When attackers observe congestion, they calculate PCC in the following steps. For a C-group containing n bot-paths, we denote the k-th bot-path's RTT sequence of congestion as $\mathbf{bp}_k(t), t \in [t_0, t_m]$. In detail, t_0 is the first RTT of a congestion sample, and t_m is the last. Therefore, all the bot-paths' RTT sequences are:

$$\mathbf{X}(t) = [\mathbf{bp}_1(t), \mathbf{bp}_2(t) \cdots \mathbf{bp}_n(t)]^T.$$

Next, we calculate the self covariance matrix as

$$\mathbf{C_x} = E\{[\mathbf{X}(t) - \mu_x][\mathbf{X}(t) - \mu_x]^T\} = \begin{pmatrix} c_{11} & \cdots & c_{1n} \\ \vdots & \ddots & \vdots \\ c_{n1} & \cdots & c_{nn} \end{pmatrix},$$

where c_{ij} represents the covariance of $\mathbf{bp}_i$ and $\mathbf{bp}_j$, while μ_x is the mean vector of $\mathbf{X}(t)$. Next, we calculate the PCC matrix as:

$$\mathbf{R}_x = \begin{pmatrix} \frac{c_{11}}{\sigma_1^2} & \cdots & \frac{c_{1n}}{\sigma_1\sigma_n} \\ \vdots & \ddots & \vdots \\ \frac{c_{n1}}{\sigma_n\sigma_1} & \cdots & \frac{c_{nn}}{\sigma_n\sigma_n} \end{pmatrix} = \begin{pmatrix} r_{11} & \cdots & r_{1n} \\ \vdots & \ddots & \vdots \\ r_{n1} & \cdots & r_{nn} \end{pmatrix},$$

where σ_i is the standard deviation of $\mathbf{bp_i}$. Each element in $\mathbf{R}_x$ represents two bot-paths' RTT similarity during time t. To find effective congestion, we calculate a distance between the observed congestion and an ideal congestion sample as

$$D = \underset{i,j \le n}{Max} \ (\Delta_x - \mathbf{R}_x)_{ij},$$

where Δ_x is an all-ones matrix that represents all the PCC of each bot-path are 100% similar to each other. We choose

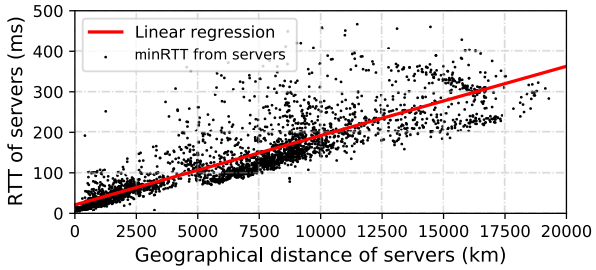

Figure 5: Linear regression of the real-world delay.

the maximum value in $(\Delta_x - \mathbf{R}_x)_{ij}$ as the distance because it describes how dissimilar it is from the ideal one.

Cluster the bot-paths. In determining whether a test sample conceals the target link, the attacker incorporates the test sample into the C-group and recalculates the distance, denoted as D, within the range of $[0,1]$. Subsequently, the attacker employs a threshold to assess the correlation between two instances of congestion. Drawing from the PCC definition [10], where PCC values within $[0,1]$ nearing 1 indicate a strong correlation, while values nearing 0 denote a lack of correlation, we establish a threshold at the midpoint, *i.e.,* 0.5, to determine whether two samples exhibit correlation.

Given that the distance D is inversely proportional to the PCC ($D \approx 1 - \text{PCC}$), if $D < 0.5$, it implies that the test sample traverses the target link. Conversely, if $D > 0.5$, the test sample does not traverse the target link. Given the C-group congestion traces, each bot-path can calculate the distance itself to know whether it passes through the target link. Then, each bot reports its available paths against a certain target to the attacker's command and control (C&C) server.

5.5 Implementation Details

This Section provides the implementation details of the CrossPoint bots and controllers.

Bot behavior. First, each bot sends a series of 10-20 `ping` and `traceroute` messages to determine the propagation delay and the obfuscated `traceroute` route. It then forwards the resulting `<src, dst, delay, route>` structure to the C&C server and waits for instruction. Upon receiving a command to observe congestion, the bot rapidly sends `ping` messages at a fixed rate of 10 packets per second with the shortest package length (36 bytes [30]). For each `ICMP_response` message, the bot extracts `<timestamp, icmp_seq, round_trip_time>` information and records them in a `csv` format file. The difference in `icmp_seq` values allows packet loss detection, while the round-trip-time facilitates congestion measurement. Then, if the bot belongs to a C-group, it transmits fractional `ping` traces containing a few seconds of correlated congestion to the C&C server. If the bot has suspicious paths, it receives fractional traces from C&C server and calculates the correlation. Finally, each bot reports available paths against the target to the C&C server.

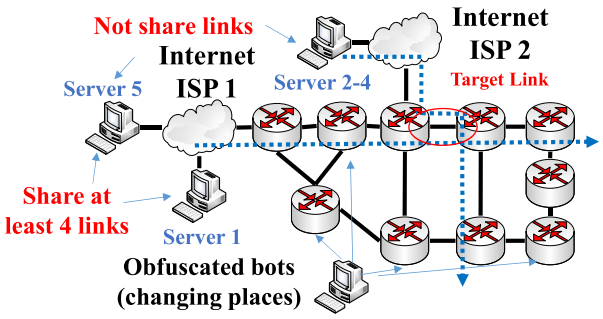

Figure 6: Testbed topology. Five servers from different cities are used to involve noise. Ten bots observe congestion.

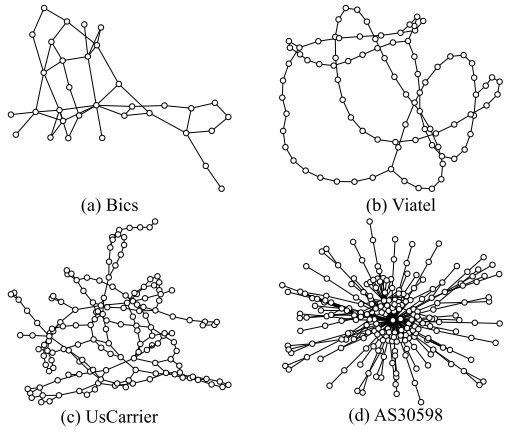

Figure 7: Simulation topologies: (a) Bics comprises 33 nodes and 48 links; (b) Viatel consists of 88 nodes and 92 links; (c) UsCarrier has 158 nodes and 189 links; (d) AS30598 contains 226 nodes and 314 links.

Controller behavior. Like conventional DDoS attacks, CrossPoint attacks are executed via botnets, necessitating C&C servers to coordinate the attack. The C&C server's interaction with the botnet encompasses several critical steps: it first collects probing data from the bots; then, using this data, it identifies the C-group (Section 5.4). Subsequently, the server dispatches the congestion traces from the C-group to each bot and awaits their confirmation on whether the targeted link is accessible. Once confirmation is received, the C&C server gives the final order for the bots to launch the attack.

6 Evaluation

Our evaluations consist of four parts. We assess the dedicated and combined performance of two attack variants and investigate the feasibility of CrossPoint attacks:

1. In Section 6.2, we construct a testbed to evaluate the performance of the *correlated congestion* attack (CrossPoint-CC). This evaluation involves real Internet noise and congestion from 5 servers on 2 continents.
2. In Section 6.3, we assess the single and overall performance of *statistical disparities*, *i.e.,* CrossPoint-SD attack) and CrossPoint-SD/CC attack, with the implemen-

tation of SOTA defenses [21, 29]. This evaluation considers a variety of network topologies, attack budgets, network robustness, and defense parameters.

3. In Section 6.4, we assess the scalability of CrossPoint attacks in different scaled network topologies. This evaluation contains 7 different topologies
4. In Section 6.5, we conduct a large-scale measurement study to investigate whether CrossPoint attacks can remain stealthy and be employed on the Internet.

We compare our attack with Coremelt [35], Crossfire [19], and Crossfire-Random attacks [29], against SOTA defenses including Nethide [29] and EqualNet [21].

6.1 Implementation

Topology. We select representative backbone networks from the Internet Topology Zoo [24] and CAIDA dataset [1], which are widely used in NTO evaluations [29]. The topologies and the corresponding attributes are shown in Figure 7.

Link delay and IP addresses. To emulate realistic link delays, we use the dataset from the Global-Ping-Statistics project [5], containing `ping` data from 247 different servers globally. We employ linear regression to fit the relationship between the geographical distance and the delays from the `ping` dataset, as illustrated in Figure 5. For each link in the testbed and simulations, we extract the longitude and latitude of the nodes, calculate the link delay based on the regression results, and then assign these delays using Linux traffic control in both the testbed and simulations. We assign IP addresses to each node using the CAIDA dataset's ITDK project [1].

Congestion. Congestion occurs when burst traffic exceeds the capacity of network devices [8, 40]. In our experiments, we replicate this process to ensure a realistic reproduction of congestion. To this end, we randomly launch each network node to send burst traffic. At certain times, this burst traffic competes for the bandwidth of the network devices, thereby reproducing short, unpredictable congestion events that mirror real-world congestion processes. Additionally, we also involve real Internet congestion as noise on our testbed by using cloud servers in Section 6.2.

Defenders. We implement Nethide [29] and EqualNet [21] using the OpenVswitch and the Ryu SDN controller to forward and respond to the `traceroute` messages. We use the prevalent shortest-path-first routing policy, in line with Nethide [29] and EqualNet [21].

Nethide [29] employs the optimal solution offered by the ILP solver [4], which promises a gap of less than 2%. We vary Nethide's *flow density reduction factor* parameter, representing different protection levels. EqualNet [21] uses the strictest *obfuscation threshold* ($\tau = 80\%$).

Attacker. In our experiments, the attacker has n^2 candidate attack bot-paths. The bots are uniformly distributed, in line with the Nethide configurations [29], and the defenders fully obfuscate all the bots and their paths. However, in each attack, the attacker can only use a limited number of bots due to budget constraints, which necessitates revealing sufficient bot-path information to counter NTO defenses.

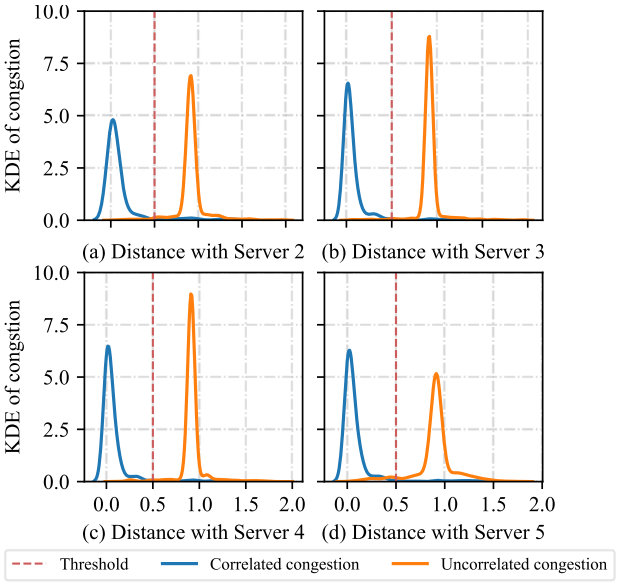

Figure 8: Kernel density estimation of two kinds of congestion on identifying the target link congestion. Figures (a), (b), (c), and (d) show the results of servers 2, 3, 4, and 5.

Table 1: Testbed experiment parameters.

SID*	Date (2022)	Duration	Noise Congestion
1	05-18 — 05-24	120.2 h	10K+
2	05-20 — 05-21	29.15 h	163
3	05-22 — 05-24	29.15 h	955
4	05-22 — 05-23	29.12 h	1384
5	05-18 — 05-19	29.12 h	3053

* SID = Server ID, Server 1 and 5 shares several links.

6.2 CrossPoint-CC Evaluations

Setup. This Section presents the evaluation of the effectiveness of the CrossPoint-CC attack. As depicted in Figure 6, we set up a testbed based on the Abilene topology, which includes several cloud servers and 10 bots for observing congestion. Notably, the cloud servers do not act as bots or generate additional traffic that could affect the ISP links. Table 1 summarizes the key details of our experiments. Specifically, a C-group consists of two servers, a fixed server 1 and a varying server 2-4, located in different regions to involve Internet noise. We also consider a scenario with a non-perfect control group establishment with servers 1 and 5 where overlapped ISP links more than the target are involved.

Performance of identifying shared links. To assess the attackers' effectiveness in identifying shared bottleneck links

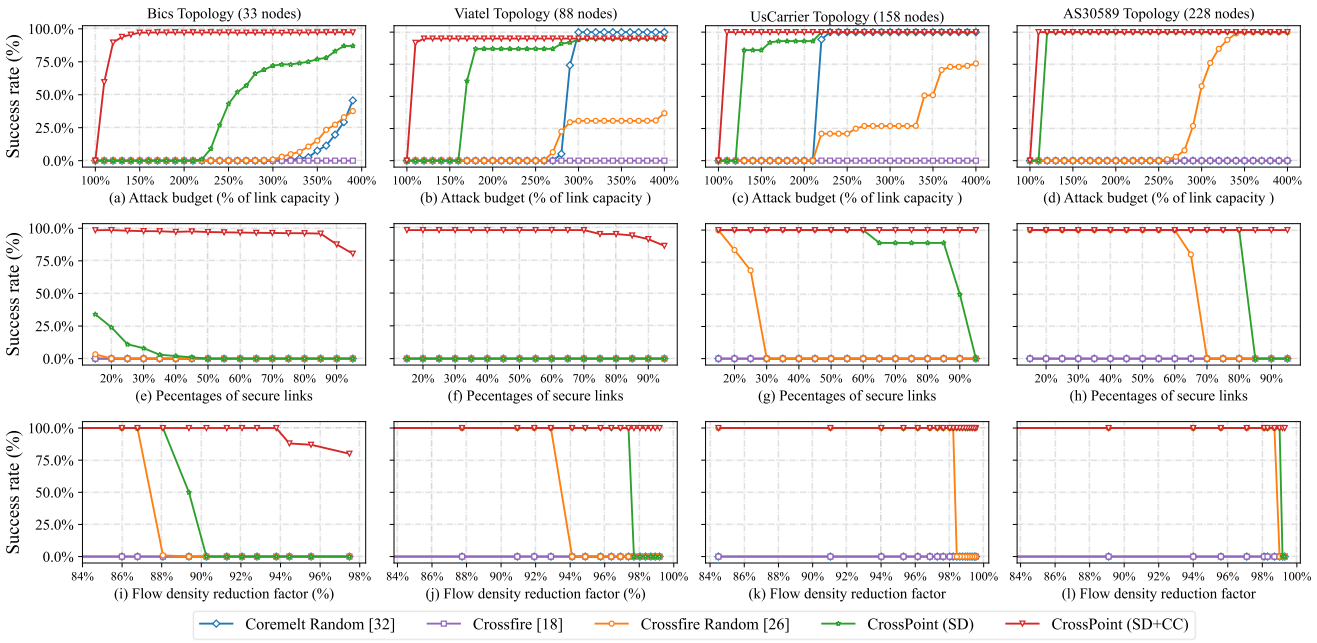

Figure 9: The CrossPoint attacks' effectiveness against Nethide [29] defense mechanism across four network topologies. Subfigures (a)-(d) illustrate the relationship between the attack success rate and the attack budget; subfigures (e)-(h) demonstrate how the success rate of CrossPoint attacks varies with the robustness of the network topology; subfigures (i)-(l) depict the success rate of CrossPoint attacks against varying levels of protection implemented by the Nethide defense.

Table 2: Congestion classification results

Metrics	Accuracy	Precision	Recall	F1 score
Fig.7(a)	96.2%	98.3%	94.4%	96.3%
Fig.7(b)	97.5%	98.4%	96.8%	97.6%
Fig.7(c)	97.7%	98.4%	97.3%	97.8%
Fig.7(d)	95.4%	94.2%	97.3%	95.7%

through correlated congestion, we analyze about 3000 independent data traces collected from a week-long observation of congestion events. Within each data trace, the challenge for attackers is to discern whether the bot-paths have shared bottlenecks amidst the background of Internet noise. Since the problem of whether bottlenecks are shared can be a binary classification problem, we employ Kernel Density Estimation (KDE) to visualize the classification outcomes.

As depicted in Figure 8, the x-axis represents the values of $D = Max_{i,j}\ (\Delta_x - \mathbf{R}x)ij$, which differentiate between two distinct congestion scenarios, while the y-axis indicates their kernel density. In this representation, blue signifies true positives (instances where congestion samples genuinely share bottleneck links), and yellow denotes false positives (instances without shared bottlenecks). The differentiation between the two congestion types is clear, suggesting that a straightforward threshold of 0.5 can effectively classify the samples.

Additionally, we evaluate the classification performance using four key metrics: accuracy, precision, recall, and the F1-score, summarized in Table 2. The results demonstrate that the congestion identification approach presented in this study achieves a minimum performance of 95% across these metrics, validating the practicality of using correlated congestion for bottleneck link identification within the Internet. Notably, the identification method outperforms some recent congestion control studies [40] due to the incorporation of time synchronization and enhanced noise mitigation techniques in our congestion correlation analysis algorithm.

6.3 CrossPoint-SD/CC Evaluations

Setup. In this Section, we focus on the effectiveness of the CrossPoint-SD attack and the CrossPoint-SD/CC attack with comprehensive experiments considering topology, budget, network robustness, and protection parameters.

Metric. To assess the effectiveness of the attack, we employ the attack's *success rate* as our evaluation metric. An attack is considered a *success* if the attackers manage to identify at least c bot-paths traversing a link, where c denotes the link capacity. To ensure reliability, we replicate each experimental condition 1,000 times, contributing to the data presented in Figure 9 and Figure 10.

Experiment 1: attack budget *v.s.* success rate. For LFA adversaries, understanding the correlation between attack budget and success rate is important. To this end, we design an experiment to evaluate the success rates of CrossPoint attacks alongside various other LFAs against NTO mechanisms. In this experimental setup, attackers are constrained to choose a limited number of bot-paths (defined as their budget) from

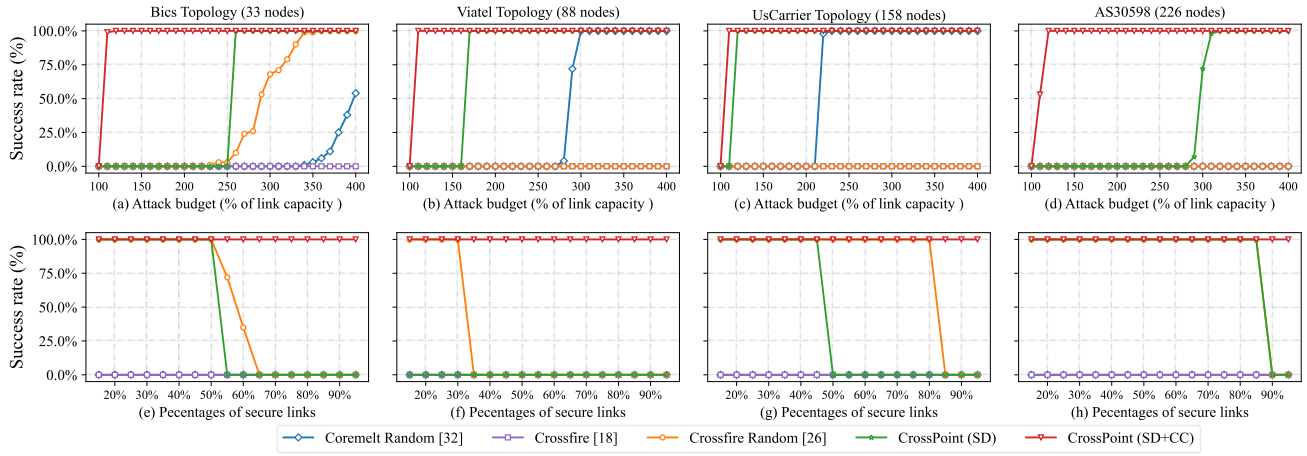

Figure 10: The CrossPoint attacks' effectiveness against EqualNet [21] defense mechanism across four network topologies. Subfigures (a)-(d) illustrate the relationship between the attack success rate and the attack budget; subfigures (e)-(h) demonstrate how the success rate of CrossPoint attacks varies with the robustness of the network topology.

their botnets to initiate attacks, aiming to flood at least one link, which necessitates a critical set of attack flows traversing the targeted link. However, NTO defenses may obscure the physical link information for each bot-path, complicating the attackers' efforts. Under these conditions, the Crossfire attack is unable to pinpoint the target link and its associated attack flows. Conversely, Crossfire+Random and Coremelt+Random strategies employ random bot-paths to mitigate some shortfall, while CrossPoint-SD and CrossPoint-SD/CC attacks leverage statistical disparities and a combination of these with correlated congestion to identify the requisite attack flows.

Figures 9(a)-(d) illustrate the success rates of various LFAs against the Nethide defense and their relationship to budget. Similarly, Figures 9(a)-(d) depict these success rates against the EqualNet defense. In both experiments, the x-axis represents the budget, scaling from 100% to 400% of link capacity, while the y-axis denotes the attack success rate, ranging from 0 to 1. According to the results, the success rates for most attack methodologies (except Crossfire) tend to escalate with an increase in the attacker's budget. Notably, the CrossPoint-SD/CC attack shows a high success rate with a minimal additional budget, significantly surpassing other LFAs, and the CrossPoint-SD method outperforms other random selection-based strategies. Both CrossPoint attacks show good performance because they exploit statistical disparities and correlated congestion, which are challenging for NTO defenses to hide effectively.

Moreover, the success rate of CrossPoint-SD/CC attacks shows consistency across different network topologies, achieving high success rates with an extra budget of 10% to 20%, demonstrating the general applicability of statistical disparities and correlated congestion in CrossPoint strategies. Nevertheless, the CrossPoint approach is not without its limitations. It invariably entails additional budget expenses in the range of 10%-20%. As inferred from the analysis in Section 6.2, this can be attributed to the attacker's approximately 95% accuracy in analyzing correlated congestion, leading to potential minor inaccuracies in flow judgment based on correlated congestion that necessitate a compensatory budget increase. Compared with the higher cost implications of random attack strategies, an extra expense of 10%-20% remains an affordable proposition for attackers.

Experiment 2: Topology robustness *v.s.* success rate. In addition to the budget, the success rate of LFAs is also influenced by network robustness. To understand the relationship between various robustness parameters and LFA performance, we design experiments that vary the link capacity parameters to change network robustness. Given that the flow density on each link is intrinsic to the topology and not readily alterable, adjusting link capacities allows us to control the number of bottleneck links, thereby presenting networks of differing robustness. For instance, a link inherently routing only 10 flows (due to the topology's design) becomes secure to flooding if its capacity is set to 11. We can control the proportion of links susceptible to LFAs by varying the link capacities across different topologies. For example, setting a robustness parameter x = 95% implies that only 5% of the network's links are vulnerable to LFAs, posing a significant challenge for attackers to accurately target one of these susceptible links within the virtual topology.

Figures 9(e)-(h) and 10(e)-(h) depict the relationship between the success rates of LFAs against the Nethide [29] and EqualNet [21] defenses across a spectrum of topological robustness settings. In these trials, we maintained a constant budget parameter at 120%. The x-axis in these figures denotes the topological robustness parameter, which varies from 20% to 95% secure links. As the proportion of secure links grows, the difficulty of achieving a successful LFA correspondingly increases. According to the results, in most scenarios, only the CrossPoint-SD/CC attack consistently maintains a high

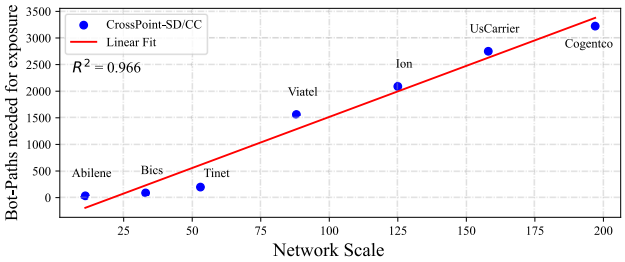

Figure 11: CrossPoint attacks' scalability across different sizes of topologies.

success rate in topologies with high robustness parameters, whereas the efficacy of other attacks reduces as robustness increases. This is because the reduction in vulnerable targets further enhances the defensive advantage, making it difficult to discover the true bottleneck link among the created virtual links. At the same time, the effectiveness of random attack strategies declines due to the increase in the number of invalid flows. Nevertheless, the CrossPoint-SD/CC attack remains largely unaffected, as the congestion information it leverages is independent of the topological robustness.

Experiment 3: Protection levels *v.s.* success rate. The protection levels of defense mechanisms may also influence the effectiveness of LFAs. To explore the impact of different protection level parameters on LFA performance, we conduct experiments that adjust the protection level settings of defensive mechanisms. Specifically, Nethide [29] employs a flow density reduction factor (FR) to vary protection levels across the network topology, depicted as

$$FR = 1 - \frac{Avg.FD_{virtual}}{Avg.FD_{physical}}.$$

The FR value indicates the topology's security level; a higher FR suggests enhanced security, making it increasingly challenging for LFA attackers to accurately discern the intended attack target and select the corresponding attack flows. On the other hand, EqualNet [21] utilizes an obfuscation parameter τ to denote different levels of protection. According to EqualNet, the obfuscation parameter τ can be adjusted up to 80%; hence for EqualNet, our evaluation focuses on the boundary of LFA performance under the strictest condition.

6.4 Scalability

To evaluate the scalability of CrossPoint attacks, we conduct experiments with seven real network topologies (Table 3) from the Internet topology zoo [24].

We explore several evaluation schemes to assess the scalability of CrossPoint attacks. The most intuitive approach is to study the success rate of attacks under different network scales. However, the success rate may not be the most suitable metric for understanding the scalability of attacks. This is because the success rate is closely linked to the attack budget, and maintaining a constant budget for scalability evaluations across varying topological scales makes nonsense. For instance, deploying 1000 bots in a small 10-node network might invariably lead to successful attacks, rendering such experiments on smaller topologies somewhat trivial. Conversely, a limited number of bots might not provide meaningful insights into the effectiveness of attacks on larger networks.

Table 3: Topology used in scalability experiments

Topology	Nodes	Edges	Topology	Nodes	Edges
Abilene	11	14	Ion	125	146
Bics	33	48	UsCarrier	158	189
Tinet	53	89	Cogentco	197	243
Viatel	88	92			

Therefore, our experiment focus shifts towards the required budget to achieve a specific success rate as a measure of scalability. Specifically, we study the number of bot-paths that attackers must reveal against defenders to attain a 90% success rate within different topologies. This approach allows us to better understand the resource demands attackers need to make as network sizes and complexities increase, offering a more practical understanding of attack scalability.

Figure 11 illustrates the number of bot-paths that need to be disclosed by CrossPoint attacks to achieve a 90% success rate across networks of varying scales. With the increase in network scale, there is a corresponding rise in the requisite number of bot-paths for CrossPoint attackers. In particular, the required bot number for CrossPoint-SD/CC attacks appears to grow linearly with the size of the target network. To validate this, we fit the required bot number and the network size into a linear model, as shown in Figure 11, and evaluate the goodness-of-fit with the R^2 coefficient [16]. The R^2 value of 0.966 confirms the linear relationship between the attack resources and the network size.

In practice, the required attack resource also remains affordable to the attackers. For example, attacking a network with about 200 nodes necessitates the disclosure of about 3000 bot-paths. Given the distributed nature of DDoS attacks, 3000 bot-paths is a manageable figure for attackers, especially considering that each bot may handle 100+ paths and report the results to the attackers.

In summary, the proposed CrossPoint attacks are highly scalable in that the required attack resource (bot-paths) increases linearly with the size of the target network. The CrossPoint attacks could pose practical threats to large-scale networks, as long as the attacker has a sufficient budget.

6.5 Measurement study

Setup. We conduct a measurement study on the Internet to understand the feasibility of our attacks. Our study took place from May to November 2022 and utilized 6 senders and 20 public receivers. We observed at least 120 paths and sent

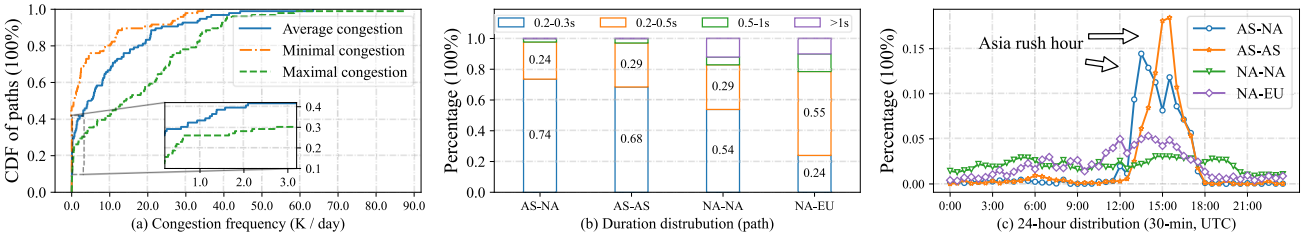

Figure 12: Measurement study of congestion. (a) CDF of the congestion frequency; (b) congestion duration distribution on four path groups; (c) a 24-hour congestion distribution on four path groups. AS = Asia, NA = North America, and EU = Europe.

almost 290 million ping packets, obtaining approximately 100.8 GB of aggregated data. Our senders were located in 6 cities globally, while the receivers consisted of industry and academia, including public DNS servers, universities, and worldwide organizations, on different continents. Each sender sends `ping` probes at a 10 packet-per-second speed, approximately 2.88 Kbps, which will not add pressure to any Internet links and servers.

Separate host-level congestion. Since our study relies on end-to-end delay probing, it's possible that the observed increase in delay might not solely indicate network link congestion but could also include host-level congestion, such as a busy destination server. Therefore, to refine our analysis, we design a method to exclude this host-level congestion. If a correlated delay increase is detected on all sources targeting the same server, this pattern might indicate a server-related slowdown. We examine cases where all sources to a particular destination report correlated congestion and classify these congestion events as host-level issues rather than Internet congestion.

Feasibility of CrossPoint attacks. Figure 12(a) illustrates the aggregated results of the congestion frequency's cumulative density function (CDF) on all paths. Notably, on average, 68% of the paths experience more than 1K congestion events per day. Even on the best days, half of the paths still incur at least 700 congestion events, which indicates an average interval of two minutes between congestion events. Furthermore, the results indicate that about 40% of Internet paths encounter 10K congestion events per day on average. These findings suggest that the Internet provides ample congestion resources that attackers can exploit to conduct CrossPoint attacks. It may take only a few hours to prepare for an attack on most links, even when the network performs optimally. Therefore, in practice, a CrossPoint attacker can launch a 24-hour observation on the Internet to collect sufficient congestion samples of a hidden link in most network paths. It is important to note that this time can be further shortened, as demonstrated in Figure 12(c), where some Internet paths exhibit a specific 'rush hour' around a certain time, during which the attacker can gain more useful congestion data.

Stealthiness of CrossPoint attacks. Given that congestion can occur suddenly, it may be necessary to employ a very high sampling rate to fully capture instances of congestion in real-world scenarios. However, in this study, we demonstrate that even if an attacker uses a lower congestion detection sampling rate to maintain stealth, such as 10 PPS ($\approx$ 2.88 Kbps), they can still observe most network congestion events.

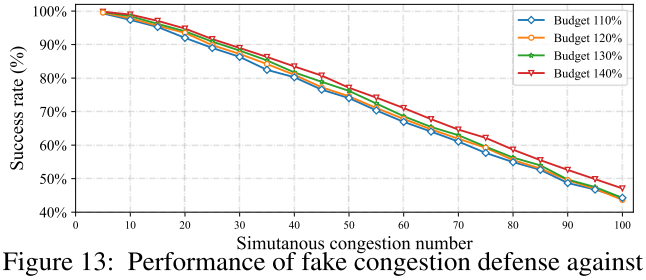

Figure 13: Performance of fake congestion defense against CrossPoint attacks.

As depicted in Figure 12(b), we present four examples of intercontinental link congestion, revealing that most network congestion durations last for more than 0.2 seconds. Consequently, at a sampling rate of 10 PPS, the attacker can differentiate between network noise generated by a single packet and network congestion involving at least two packets.

7 Countermeasure

Since the CrossPoint attacks exploit congestion events to target their attack flows on specific physical links, a conceivable defense strategy is to deflect these attack flows by intentionally creating fake congestion events across various network links simultaneously. For instance, the defenders could craft correlated fake congestion on two distinct network links; bot-paths observing these correlated congestion events might mistakenly believe that they pass through the same physical link and send attack flows to them. However, this misidentified bot-path cannot contribute to attacks against the target, reducing the effectiveness of the attack.

To implement the *fake congestion defense*, the defenders follow three steps: (1) To generate congestion in a specific device, defenders can either delay incoming packets temporarily or inject burst traffic into buffer queues. The latter, injecting burst traffic, is more practical as it reproduces the natural congestion process without necessitating modifications to

network devices. (2) To ensure that the artificial congestion events appear correlated, each network device must have the same bandwidth and receive the same volume of burst traffic simultaneously. Finally, (3) to deceive the attackers, the defenders must strategize on the timing and locations for generating fake congestion. Given the unpredictability of the attacker's target and timing, a practical approach for defenders is to create correlated congestion across random network devices periodically.

In this paper, we evaluate the effectiveness of fake congestion defense against CrossPoint attacks within the AS30598 topology, which comprises 226 nodes and 314 links. The defense strategy involves the use of Nethide [29] to protect the network while simultaneously generating various amounts of fake congestion through burst traffic injection. Figure 13 illustrates the correlation between the attacker's success rate and the number of simultaneous fake congestion events. Our experiment results indicate that as the number of simultaneous fake congestion events increases, the attacker's success rate decreases for all budget levels. This trend suggests that amplifying the number of links involved in fake congestion creation generally boosts defense effectiveness.

While this defense appears to be reasonably effective, however, it comes at a relatively high cost. Implementing this defense requires generating a significant amount of simultaneous fake congestion, which results in substantial burst traffic injection and may impact legitimate users. Firstly, creating short-term congestion on a device requires a considerable volume of burst traffic; for instance, injecting 20 Gb of data into a 40 Gbps queue could only congest the device for about 0.5 seconds. Moreover, achieving simultaneous fake congestion demands the involvement of a large number of network devices. For example, the results suggest that engaging around 90 devices in simultaneous fake congestion generation is necessary to decrease the success rate of CrossPoint attacks by 50%. Secondly, existing congestion control mechanisms are sensitive to congestion [12, 20, 37]; the fake congestion could activate TCP flows' congestion avoidance mechanisms, thereby reducing the throughput for legitimate users. As a result, bridging the gap between the concept of fake congestion defense and its practical implementation remains a challenge.

8 Discussion

Enhancing CrossPoint attacks. In scenarios where congestion events are infrequent or absent, attackers can either exploit existing *statistical disparities* patterns or proactively craft congestion. For instance, they might adopt approaches akin to SDN CrossPath attacks [11], where selected bots are orchestrated to dispatch short-term burst flows to random places while remaining stealthy [43].

Future design of NTO schemes. The CrossPoint attack highlights a fundamental issue in current NTO designs: while NTO strategies can conceal critical information at the upper layer, lower-level network traffic characteristics are inherently difficult to obfuscate, challenging the creation of defenses that align with upper-layer strategies. Nonetheless, introducing lower-level obfuscation mechanisms is possible. For example, fake congestion defense. However, a major challenge associated with fake congestion lies in the trade-off between maintaining benign user throughput and achieving defensive efficacy; a large amount of fake congestion can decrease user throughput, whereas a limited number of fake congestion might fall short of providing robust defense. To tackle this challenge, one potential NTO strategy could integrate upper-layer obfuscation algorithms, network topology, traffic patterns, and other attributes to strategically create fake congestion at key points to minimize the impact on legitimate users. Moreover, other network traffic characteristics that influence security should also be considered. For instance, propagation delay can leak information about path length. Therefore, future NTO schemes should avoid using short virtual paths to substitute long physical paths in detailed obfuscation algorithms. To sum up, future NTO designs should carefully balance the integration of various obfuscation techniques and considerations of network traffic characteristics to enhance security without impacting user experience.

9 Conclusion

Crosspoint attacks exploit inherent Internet features to escape SOTA NTO defenses with a high success rate and a low extra cost. Besides, our measurement study substantiates the practical feasibility and stealthy nature of these attacks. Consequently, although NTO defenses may succeed in obfuscating links, they fall short in concealing the entire network map due to incomplete obfuscation measures on inherent features. To enhance the future security of NTO schemes, we also discuss potential countermeasures. We hope this work could stimulate increased focus on the development of more robust NTO schemes to counteract LFAs effectively.

Abstract

Domain Name System (DNS) establishes clear responsibility boundaries among nameservers for managing DNS records via authoritative delegation. However, the rise of third-party public services has blurred this boundary. In this paper, we uncover a novel attack surface, named *XDAuth*, arising from public authoritative nameserver infrastructure's failure to isolate data across zones adequately. This flaw enables adversaries to inject arbitrary resource records across logical authority boundaries and covertly hijack domain names without authority. Unlike prior research on stale NS records, which concentrated on domain names delegated to expired nameservers or those of hosting service providers, XDAuth targets enterprises that maintain their authoritative domain names. We demonstrate that XDAuth is entirely feasible, and through comprehensive measurements, we identify 12 potential vulnerable providers (e.g., Amazon Route 53, NSONE, and DigiCert DNS), affecting 125,124 domains of notable enterprises, including the World Bank, and the BBC. Moreover, we responsibly disclose the issue to the affected vendors. Some DNS providers and enterprises (e.g., Amazon Route 53) have recognized the issue and are adopting mitigation measures based on our suggestions.

1 Introduction

Domain Name System (DNS), as a fundamental Internet infrastructure, is pivotal for translating domain names to IP addresses, supporting mainstream Internet services like email and CDNs [15, 16, 33]. It organizes the global namespace into distinct zones using a hierarchical structure, with authoritative nameservers maintaining each zone. Once the authoritative nameservers are compromised, all domain names delegated to them will be hijacked, causing serious cybercrimes (e.g., certificate forging, APT attacks) [4, 35, 38, 53]. More and more enterprises are turning to professional DNS hosting services for more robust and secure authoritative services.

✉ Corresponding author.

In recent years, researchers have uncovered security implications of stale domain delegations (StaleNS), identifying cases where domains are pointed to vulnerable DNS hosting providers lacking domain ownership validation (DOV) [6, 42] or their NS domains have expired [2, 35]. To prevent attackers from *claiming or manipulating StaleNS domains*, a series of responsible providers like Amazon Route 53 and Cloudflare have implemented various defensive strategies, such as tracking NS allocation [8] and performing TXT-based DOV [23]. However, given the complexity of cloud hosting scenarios and the diversity of DNS architecture, we wonder about the effectiveness of these measures in ensuring comprehensive protection. *Is it safe if the NS domains have not expired and do not belong to a vulnerable provider?*

The DNS protocol mandates the isolation of data between different zones within authoritative nameservers, ensuring a nameserver cannot exceed its designated authority over domain names. Meanwhile, enterprises expect their DNS zone data on third-party hosting platforms to be inaccessible and can not be tampered with by unauthorized parties. Thus, some enterprises use self-controlled NS domains to establish nameservers via public hosting providers' DNS infrastructures, preventing adversaries from reusing dangling NS. For example, Nike's NS domain is `ns-v#.nike.com`, but its infrastructure relies on Amazon Route 53 DNS infrastructure. However, we observed that *service providers' DNS infrastructures often fail to properly enforce DNS zone isolation for customers*. As a result, both the enterprises' and the providers' nameservers share the same DNS databases, which are called *shared nameservers*. This results in the enterprise's DNS zone not being fully under its control, opening the door for attackers to modify DNS resource records and potentially hijack domains.

Our study. In this paper, we propose a novel threat model named Cross Domain Authority Boundary (XDAuth). An attacker could inject arbitrary resource records covertly for a victim's domain name by exploiting an *out-of-delegation* nameserver. For instance, a customer deploys their authoritative nameserver (e.g., *ns.c1.com*) leveraging a provider's DNS infrastructure. Due to the absence of effective delega-

tion records, unauthorized claims on DNS hosting service providers can only be abused through specific utilization scenarios [59]. Thus, most DNS hosting providers still lack effective domain name ownership verification strategies, allowing legitimate users to claim well-known domain names freely. Moreover, since the lack of DNS zone isolation in the provider, the attacker can manipulate the resource records of domain names delegated to *ns.c1.com* through the nameserver (e.g., *ns.provider.com*) of the provider. Unlike StaleNS, the threat is hard to detect since the exploited nameserver is not expired and is outside the delegation relationship.

We have conducted an empirical study and proved that XDAuth is completely realistic. We successfully implemented cross-authoritative nameserver domain takeover at various leading DNS hosting providers. To evaluate the prevalence of XDAuth, we proposed a semi-automated detection framework, named XDAuthChecker, to uncover XDAuth threats in the wild effectively. We used the framework to explore nameserver dependencies and identify shared nameserver groups systematically. For each group, we examined the existence of vulnerable hosting providers that can be exploited to inject forged DNS records into the shared nameservers. Subsequently, we conducted a large-scale measurement study of the DNS-sharing ecosystem and the enterprises that XDAuth affects.

Findings. We revealed that shared nameservers are indeed *widespread and severe* by running XDAuthChecker on 1,090 gTLD zone files. We identified a total of 2,372 shared nameserver groups, consisting of 60,974 nameservers with identical IP addresses (SharedAuth-I) and 4,800 nameservers with varied NS domains and IP addresses (SharedAuth-II). Upon analyzing these shared groups, we identified 12 potential vulnerable providers, including *Amazon Route 53*, *NSONE*, and *Digicert DNS*. These providers indirectly affect 1,881 other nameservers, with 981 of them ranking in the Tranco top 1M [45], e.g., *ns-v1.nike.com*, highlighting a substantial security threat. After detecting domains delegated to affected nameservers, we found that XDAuth poses security risks to numerous well-known enterprises. As a result, we have discovered 125,124 domains vulnerable to XDAuth attacks, encompassing notable entities like *McKesson*, and *Canon*. The affected entities also include domain management or digital certificate companies, indicating their customer domains are susceptible to domain hijacking. For instance, we confirmed that 184 domains managed by *Sectigo* are affected.

Mitigation and responsible disclosure. We offer feasible suggestions for vulnerable providers, like tracking global domain hosting status in shared nameservers. We have also reported the issues to the affected hosting providers and enterprises. So far, NSONE, *Anon.C* [1], and Amazon Route 53 have acknowledged the issue, with *Anon.C* currently implementing our proposed mitigation. Moreover, *Anon.E* [2] and McKesson have also acknowledged the vulnerability and fixed the affected domains.

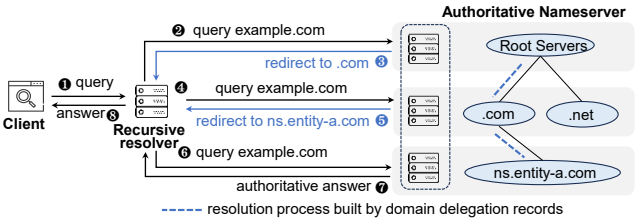

Figure 1: Domain resolution process.

Contributions. We make the following contributions:

- *New attack surface.* We uncover a new attack surface in the DNS infrastructure: shared nameservers infrastructure. To our knowledge, this is the first public disclosure of such a vulnerability, and our extensive measurement reveals that shared authoritative nameservers are highly prevalent.
- *Novel methodology and findings.* We propose XDAuthChecker, a novel approach to discovering shared nameserver threats. Our results demonstrate that XDAuth can circumvent current best protective measures, enabling covert out-delegation domain hijacking and affecting some well-known enterprises.
- *Responsible disclosure.* We responsibly disclose the threat to affected providers and enterprises, provide practical mitigation, and have received their confirmation.

2 Background and Related Work

2.1 Domain Resolution Process

The Domain Name System (DNS) is a hierarchical structure as shown in Figure 1. The authoritative DNS servers (also named nameservers or NS) of parent domains maintain the delegation records for their subordinate domains. For example, root servers hold `NS` records for all Top-Level Domains (TLDs), and nameservers for `.com` maintain `NS` records for all Second-Level Domains (SLDs, commonly referred to as apex domains) under `.com`, such as the NS domain `ns.entity-a.com` for `example.com`. To obtain a domain's IP address, a client initiates a domain query to recursive resolvers (step ❶). The recursive resolvers fetch the domain delegation information (`NS` and `glue` records[3]) from nameservers at different levels, constructing the domain resolution path (step ❷ ∼ ❼). Finally, an authoritative response is obtained from the nameservers of the queried domain (step ❼).

The authoritative nameserver is designed to offer authorized resolution services only for the domains delegated to it

[1] According to the company's requirements, we do not disclose the company's name here. Throughout this paper, it will be referred to by the *Anon.C*.

[2] A Fortune 500 company has asked us not to disclose any of their information. Throughout this paper, it will be referred to by the *Anon.E*.

[3] A `glue` record provides the IP address of a nameserver at a domain name registry.

(domain delegation) [39, 58]. Therefore, even though there may be multiple IPs behind a nameserver, the resolution path of a domain name is visible from a namespace perspective. The fact we can determine is that `ns.entity-a.com` can provide authoritative responses for `example.com`, while other nameservers cannot. However, with the prevalence of DNS hosting services, the boundary between authoritative nameservers is no longer clear. When different authoritative nameservers are combined into a large service platform, the resolution path of a domain name may become unpredictable.

2.2 Nameserver-based Domain Hijacking

Authoritative nameservers maintain all resource records (RRs) of authorized domain names. By controlling a nameserver, an attacker can manipulate or inject RRs for a domain name. Previous work has shown some domain hijacking threats by controlling the victim domain's nameservers.

DNS infrastructure tampering. A common scenario involves an adversary compromising a victim domain holder's account at their registrar or the registrar platform, gaining the ability to manipulate the domain's DNS settings [11]. Such an attack became widely known through reports by Cisco Talos [56] and FireEye's Mandiant [41]. This led the US DHS to issue an emergency directive for implementing mitigation measures in government systems. Researchers have leveraged the behavioral patterns and historical data of domain names to identify authoritative servers that are no longer under proper control [4, 36]. While this type of attack poses a significant threat, compromising a well-managed authoritative nameserver remains challenging.

StaleNS threats. StaleNS occurs when a domain's nameserver stops providing authoritative services for it. Prior work mainly focused on scenarios where domain names are delegated to either *expired NS domains* or nameservers of hosting services that have been discontinued (*discontinued hosting*). Liu et al. [35] showed that attackers could take over domain names by registering expired NS domains if domain owners forget to remove stale NS records. This vulnerability extends to TLDs as well [2, 12, 20, 38, 61]. Additionally, Akiwate et al. [3] illustrated that expired NS domains could also result from the improper operations of domain registrars.

Domain name configuration has become increasingly complex with the advent of DNS hosting services. Registrants are at increased risk of misconfigurations, like failing to update authoritative nameservers after canceling domain hosting. In this scenario, attackers could hijack dehosted customer domains with unchanged delegations by rehosting them [30, 37, 50, 60]. Even if registrants have removed stale NS records at the TLD level, NS records may still remain on the nameservers of SLDs, which could result in ZAW attacks [6]. In addition to hijacking customer domains, the implementation flaws in DNS hosting providers also enable an attacker to take over the providers' domains [49].

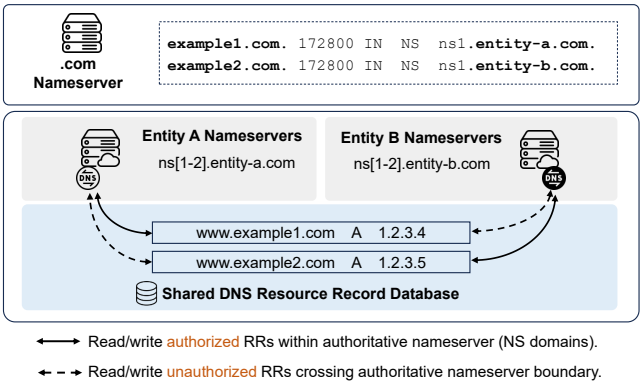

Figure 2: SharedAuth: **Shared Auth**oritative nameserver.

In response to such issues, service providers like Amazon Route 53 have initiated mitigation strategies, such as randomizing NS allocations and preventing the reuse of NS for the same domain, thwarting potential domain takeovers [8].

Comparison with previous threats. Similar to StaleNS, XDAuth aims to hijack prominent domain names and manipulate their resolution results. However, XDAuth involves scenarios where attackers can not take control of the victim domain's nameservers, which *remain unexpired and under the active management of the victim enterprise itself*. XDAuth hijacks the victim domain by injecting crafted DNS records for the domain into the shared nameserver infrastructure, instead of directly controlling the domain's nameservers.

Prior research on StaleNS, notably [6] and [60], focuses on domain names delegated to hosting providers' NS domains, overlooking scenarios where enterprises maintain their own NSs. XDAuth fills this gap by showing that domains with NS that can not be allocated via hosting providers and remains active also face the risk of takeover.

3 Overview of XDAuth Attack

3.1 Shared Authoritative Nameservers
