Definition of SharedAuth. We define shared authoritative nameservers (abbreviated as SharedAuth) as different nameservers that share a DNS resource record (RR) database or a DNS zone either due to a common underlying DNS infrastructure or through zone transfer. These nameservers may be operated by cloud hosting providers or self-controlled by organizations or companies. In Figure 2, we showcase a schema for SharedAuth. Entity A and B utilize `ns[1-2].entity-a.com` and `ns[1-2].entity-b.com`, respectively, to provide authoritative DNS records for their managed domain names such as `example1.com` and `example2.com`. Despite differences in their NS domains, we consider the nameservers of Entity A and B as SharedAuth, as all DNS RRs for both `example1.com` and `example2.com` are stored in the same DNS RR database.

In this paper, **we highlight the lack of DNS data isolation among entities sharing the same DNS infrastructure in practice**. As per RFC 1034 [39], domain nameservers are authorized to hold zones and provide authoritative answers only for their delegated domain names. For instance, according to the DNS setting in the `.com` zonefile (the top box in Figure 2), `ns[1-2].entity-a.com` should handle queries only for `example1.com`, not `example2.com`. However, the adoption of SharedAuth by both entities compromises these authority boundaries, and there is no restriction for any entity to access resources from the shared DNS database by design. As a result, their nameservers can manage domain names beyond their authorized scope. For example, someone can configure or fetch DNS records for `example2.com` through `ns[1-2].entity-a.com`, as shown by the dashed lines in Figure 2. Due to the lack of proper access control in the shared DNS database, the stored DNS records are vulnerable to poisoning or tampering.

Scenarios for deploying SharedAuth. SharedAuth is often deployed in cloud hosting environments by two or more entities with the following scenarios:

- *Hosting and non-hosting*. Some organizations, like governments and companies, may seek dependable DNS infrastructures from public hosting providers. In this scenario, we observe that many hosting providers offer customization services like vanity DNS [13, 14, 18, 47] and white-label nameservers [9]. They initialize hosting instances from a shared DNS infrastructure, enabling customers to manage their own DNS zones with their self-controlled NS domains. This practice has been adopted by several renowned companies, including *Anon.E*, Canon, and Nike.

- *Hosting and hosting*. Sharing nameservers can also result from business collaborations and service upgrades. First, small hosting providers or intermediaries opt to employ established nameservers of prominent hosting service suppliers instead of constructing brand-new DNS infrastructure. For example, some web hosting providers (e.g., Squarespace) share nameservers with a well-known DNS provider, NSONE. Second, hosting providers may update their DNS infrastructure and change NS domains as part of service enhancements. To ensure seamless migration, old NS domains may continue to be used, with DNS resource records synchronized between the old and new nameservers.

These practices indicate that SharedAuth has been widely adopted. However, ensuring data isolation between different DNS zones is crucial to avoid potential security risks, such as data reuse or alteration, when nameservers are shared. In Section 5.2, we will further explore the prevalence and scenarios of nameserver sharing in the real world.

Types of SharedAuth. To clarify further, let's consider a SharedAuth pool containing two groups of NS domains, NS1 and NS2. Based on their apex domains and IP addresses, all SharedAuth can be classified into four types (see Figure 3):

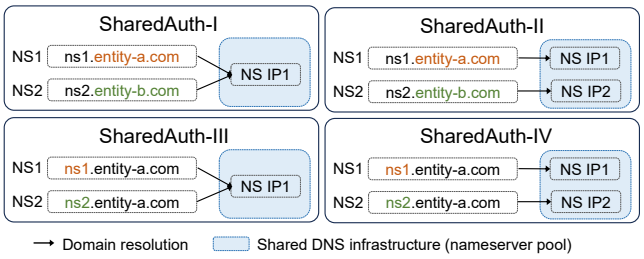

Figure 3: Classification of SharedAuth.

- *SharedAuth-I*. NS1 and NS2 belong to different apex domains but share the same IP address.
- *SharedAuth-II*. NS1 and NS2 belong to different apex domains and have distinct IP addresses. Meanwhile, they facilitate cross-resolution, namely, a domain name hosted on NS2 can be resolved through NS1.
- *SharedAuth-III*. NS1 and NS2 are different subdomains under the same apex domain and share the same IP address.
- *SharedAuth-IV*. NS1 and NS2 are different subdomains under the same apex domain and have different IPs.

Note that our discussion of SharedAuth excludes scenarios where NS domains are configured with canonical names (CNAMEs), because DNS standards prohibit such associations [21]. Furthermore, the identification for these four types of SharedAuth differs. For instance, NS domains in SharedAuth-III and SharedAuth-IV share the same apex domain, making them relatively easy to collect. However, there appears to be no correlation among the NS domains in SharedAuth-I and SharedAuth-II, rendering them more covert and challenging to discover. Moreover, they would result in the exposure of two entities that are unaware of each other to significant security risks. Consequently, we will focus our effort more on SharedAuth-I and SharedAuth-II in Section 4.

3.2 Threat model

Based on the SharedAuth scenario, we introduce a novel domain takeover threat model termed Cross Domain Authority Boundary (XDAuth). It targets prominent domain names delegated to secure nameservers with proper domain ownership validation (DOV). For a clear description, we outline five participants in the XDAuth model (depicted in Figure 4):

- A secure-entity that can be either a hosting provider or a non-hosting organization (e.g., companies, authorities, and government agencies). This entity is responsible for managing all authorized DNS RRs for delegated domain names through carefully maintained nameservers, identified as `ns[1-2].secure.com`. These nameservers either implement stringent DOV strategies or do not offer public hosting services, making them highly resilient to StaleNS attacks [6].

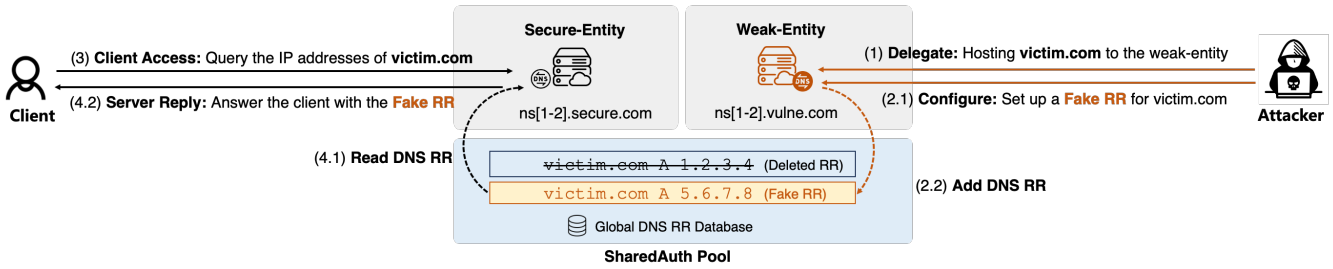

Figure 4: Threat model of Cross Authority-Boundary Attack (XDAuth). Both secure-entity and weak-entity utilize the global DNS database to manage RRs. `victim.com`'s domain owner can configure or delete its DNS RRs, deleting one (with strikethrough) from the database. Meanwhile, the attacker can configure arbitrary RRs in the DNS database to hijack `victim.com`.

- A weak-entity could be a public hosting provider that has security flaws in DOV, which allows the unauthorized claim of arbitrary domain names. It supports authoritative domain resolution services through `ns[1-2].vulne.com` and shares the underlying DNS infrastructure, such as the RR database, with secure-entity.

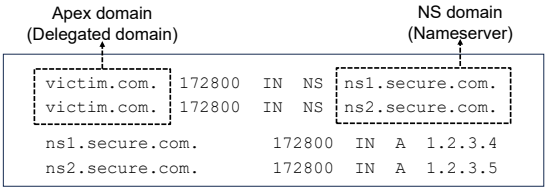
- A victim domain name, `victim.com`, that is delegated to the nameservers controlled by secure-entity, whose nameserver setting is shown in Figure 5. However, these nameservers have stopped the service to it, responding `REFUSED`, which is a common occurrence in the DNS ecosystem [2, 51, 60].

- An attacker can be a legitimate customer of weak-entity and can deploy any domain names on weak-entity without compromising the DNS system or any servers. The attacker aims to covertly hijack `victim.com` by exploiting the SharedAuth pool between weak-entity and secure-entity.

- A client that attempts to access `victim.com`.

To launch an XDAuth attack, attackers are required to follow two requirements. First, they need to uncover the SharedAuth pool that includes the victim domain's nameservers, namely, identifying the nameservers shared with the victim domain. We introduce a black-box testing method to explore nameserver dependencies behind the DNS infrastructure in Section 4. Our results demonstrate that SharedAuth has been utilized by a number of large enterprises on a significant scale. Second, they should gain access to a vulnerable nameserver (e.g., `ns[1-2].vulne.com`) in that SharedAuth pool to configure arbitrary DNS RRs for the victim domain. This condition can be easily achieved by leveraging public DNS hosting services, since previous research [6, 59] demonstrated that most DNS hosting providers lack proper DOV policies, allowing users to claim arbitrary domain names from the providers.

Attack flow. Figure 4 provides a schematic overview of an XDAuth attack. Suppose the domain owner of `victim.com`



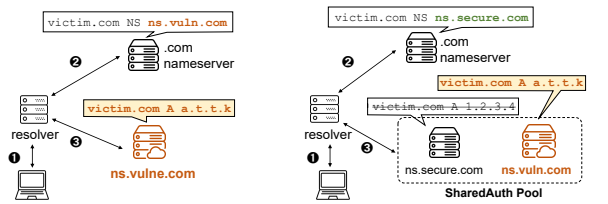


Figure 5: Example of .com TLD zone file information.

(a) StaleNS: The `victim.com` was delegated to `ns.vulne.com`, which **has expired or belongs to a vulnerable hosting provider**. After acquiring `ns.vulne.com`, attackers can take over `victim.com` and configure arbitrary resource records for it, leading the client to `a.t.t.k`.

(b) XDAuth: The `victim.com` was delegated to `ns.secure.com`, which **remains active in use**. However, attackers can inject crafted RRs through `ns.vuln.com` in the SharedAuth pool. In the end, the client will unwittingly access `a.t.t.k` after querying `victim.com`.

Figure 6: Comparison between StaleNS and XDAuth.

cancels its delegation to secure-entity but retains NS records pointing to `ns[1-2].secure.com`, as depicted in Figure 5. Despite this, these NS domains remain active, thwarting the attacker's attempts to take over `victim.com` by registering or controlling secure-entity' nameservers, as done in previous attacks [6, 35]. In this situation, the attacker could host `victim.com` on weak-entity (step 1) and set up a fake RR for it using weak-entity's nameservers (step 2.1). Meanwhile, these fake DNS RRs will be stored (e.g., `5.6.7.8`) in the DNS database shared by weak-entity and secure-entity (step 2.2). If a client queries `victim.com` (step 3), the victim domain's nameservers, `ns[1-2].secure.com`, would retrieve the fake DNS RRs from the shared database (step 4.1) and respond to the client (step 4.2). Consequently, the client may unwittingly access malicious IPs controlled by the attackers.

Comparing threat scenarios of StaleNS and XDAuth. StaleNS attacks (Figure 6a) target victim domains delegated to discontinued nameservers, leaving stale NS records in the TLD zone. These nameservers, either expired NS domains

or those of vulnerable public hosting providers, no longer offer authoritative domain resolution services for the victim domains. Consequently, the attacker can obtain control by re-registering expired NS domains or re-allocating the same NS domains with the victim domains from the hosting provider, using them to take over the victim domain.

Instead, XDAuth attacks (Figure 6b) target victim domains whose nameservers are self-managed by non-hosting organizations or well-managed by public DNS hosting providers. For instance, the domain `victim.com`, delegating to `ns.secure.com` or its subzone `ns.victim.com`, can also be targeted in an XDAuth attack. Unlike StaleNS, the nameservers of the victim domain remain active and are strict in DOV, preventing attackers from acquiring it. XDAuth attackers could exploit nameservers (e.g., `ns.vuln.com`) that share DNS infrastructure with `ns.secure.com` to craft RRs and hijack `victim.com`. In this model, *neither the client nor the domain owner can detect this covert operation, as there are no stale records at either the TLD or SLD levels.*. Thus, it enables offline covert domain hijacking via a novel, previously unreported attack vector.

Discussion. The Internet community has proposed new DNS technologies, such as DNS over HTTPS (DoH), DNS over TLS (DoT), to enhance DNS security, authenticity, and integrity. DoH and DoT only secure the transaction channel, preventing eavesdropping and manipulation in path. However, they cannot prevent XDAuth attacks, as they operate offline from the authoritative nameserver's side by tampering with DNS settings (e.g., SLD zone files) rather than manipulating DNS traffic in transit. Note that a potential limitation of XDAuth is that it primarily affects domain names whose resolutions are suspended, i.e., their nameservers should respond with `REFUSED`. While this condition may seem strict, it is a common scenario in all domain takeover attacks, even in cases of StaleNS. Meanwhile, our analysis reveals such domain names are prevalent, especially among well-known companies (Section 5.3). The inactive domain resolution status and the apparent independence of nameservers may give users a false sense of security, exposing them to XDAuth.

4 Methodology of XDAuth Detection

We introduce **XDAuthChecker**, a framework for evaluating the real-world security implications of XDAuth threats. It aims to (i) detect shared nameservers and potential victim domain names in the wild, and (ii) uncover affected providers and organizations associated with the victim domains. This section provides an overview of the framework's concept and workflow, along with a detailed methodology.

4.1 Overview of XDAuthChecker

Challenges. Designing XDAuthChecker is non-trivial: (C1) The domain name space encompasses over 200M domain names and 2M nameservers, resulting in vast delegation records. Detecting shared nameservers and potential victim domains among this vast pool is overwhelming. (C2) There is no direct evidence for determining the controlling entity of certain nameservers, making it difficult to identify SharedAuth pools based solely on NS domains and NS IPs.

For (C1), we propose NS Dependency Number (*NS-DN*) as the count of apex domains delegating to an NS. We observe NSs with high *NS-DN*s might belong to hosting providers or organizations controlling large-scale domains. Such NSs are more likely to be part of SharedAuth pools and associated with affected organizations than those with lower *NS-DN*s. So we attempt to discover nameserver seeds by limiting *NS-DN*s in Section 4.2. For (C2), we notice that any nameserver within a SharedAuth pool could handle authoritative responses for all delegated domain names. Thus, in Section 4.3, we propose a cross-resolution method to check whether nameservers belong to the same pool.

XDAuthChecker workflow. As depicted in Figure 7, our framework takes TLD zone files as input and contains three primary processes:

In the first module, we discover NS domains potentially linked with public hosting services. Our focus lies on prominent hosting providers, as the nameservers they assign serve numerous customer domains, potentially leading to widespread security implications if vulnerable. We consider the NS domains of these hosting providers as the nameserver seeds for uncovering additional SharedAuth pools, as they represent potential weak points (i.e., weak-entity) for XDAuth attackers due to inadequate domain ownership verification. Consequently, we prioritize NS domains with high *NS-DN* values in the TLD zone files for analysis.

Based on the nameserver seeds, the second module automatically expands and aggregates the NS domains to uncover SharedAuth pools. This process employs a *cross-resolution verification*d method coupled with a *resolution-task reduction* strategy. The underlying concept is that if two NS groups share the same DNS infrastructure, one NS group can resolve the domains delegated to the other group. Accordingly, XDAuthChecker merges these two NS groups if they successfully support cross-resolution for all delegated domain names.

In the third module, we identify vulnerable entities (i.e., flawed hosting providers and affected organizations) susceptible to the XDAuth threat model, uncovering nameserver dependencies among these entities. We automatically cluster shared nameservers using multifaceted data, including HTTP fingerprints, WHOIS information, and domain label semantics. This refined clustering procedure helps identify the relevant entities responsible for these shared nameservers. Subsequently, we conduct a manual analysis to identify vulnerable entities. Note that any vulnerable entity within a SharedAuth group can impact all nameservers in that group.

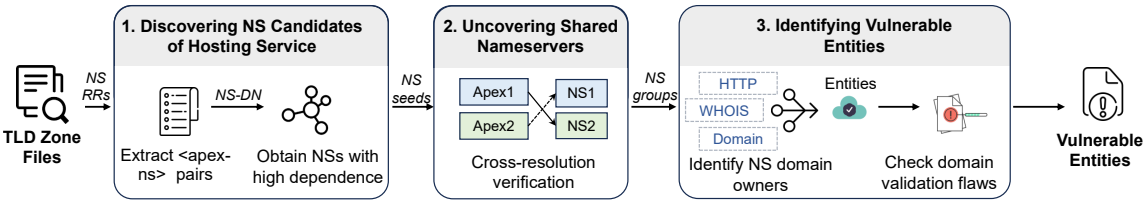

Figure 7: XDAuthChecker: Workflow of XDAuth threat measurement.

4.2 Discovering Hosting Service Nameservers

Our detection starts by discovering the NS domains of public hosting providers to uncover SharedAuth pools, as these domains serve as public entry points for accessing and modifying DNS settings in shared nameservers. However, obtaining a complete list of hosting services and collecting their NS domains is challenging, since they are not publicly released. Additionally, due to the lack of ground truth of nameservers for hosting providers, we can not directly link all NS domains in TLD zone files to their respective controlling entities, such as provider names. To this end, we plan to analyze a selection of representative and influential hosting providers based on two criteria: providers that have garnered high research attention or are widely used with a large user base.

Collecting from public reports. For the first criterion, we review previous research papers, blogs, and hosting provider documentation over the past five years [6,20,30,50,60]. Eventually, we manually curate a list of 72 prominent domain hosting providers (shown in Table 3). This process allows us to obtain the NS domains these providers use to delegate customer domain names. These NS domains serve as the seeds for identifying entities with shared nameservers and help us spot services with potential security risks in DOV.

Exploring from zone files. TLD zone files contain all domain delegation information for registered domains from the perspective of domain registries (as shown in Figure 5), which is more extensive than data derived from passive DNS traffic [60]. We introduce the *NS-DN* to measure the popularity of NS domains based on the zone files. This metric reflects the number of apex domains delegated to an NS domain. An NS domain with a high *NS-DN* suggests its adoption by a public hosting service with many customer domains or a large organization with numerous self-managed domains. Such NS domains deserve further investigation for their security risks.

In experiments, we extract the `NS` records for over 200 million apex domains across 1,090 TLDs' zone files (detailed in Section 5.1). Each `NS` record is converted to an $\langle$`apex,ns`$\rangle$ pair, where `apex` and `ns` represent a delegated domain and its NS domain. All such pairs enable us to calculate the *NS-DN* for every NS domain in the zone files. In Section 4.3, as we need to apply a cross-resolution verification process for these NS domains, the network request demand grows exponentially with the number of NSs. Therefore, we establish a lower-bound *NS-DN* threshold, taking into account our network probe capacity and ethical considerations regarding active network detection. All NS domains exceeding this limit will be screened out as potential public nameserver candidates. Based on our statistical analysis (as detailed in Section 5.1), we observe that nameservers serving more than 500 domains account for 95.20% of DNS delegation relationships. Lowering the threshold would double the experiment cost (as discussed in Section 4.3) with limited additional insights and numbers of discovered vulnerable domains. Thus, we set the threshold at 500, which effectively encompasses the majority of prevalent hosting services. As a result, we obtain 25,310 NS domains as the nameserver seeds.

4.3 Uncovering Shared Nameservers

Recall that shared nameservers are categorized into those sharing the same IPs (SharedAuth-I&III) and those with different IPs (SharedAuth-II&IV). The same-IP nameservers can be easily obtained by checking NS IPs. So we extend all $\langle$`apex,ns`$\rangle$ pairs in the zone files to $\langle$`apex,ns,ip`$\rangle$ by querying IP addresses of the `ns` set, and expand the 25,310 nameserver seeds by grouping the `ip` set.

However, identifying shared nameservers with different IPs requires more effort. As per the definition of a nameserver (Section 2.1), we infer that if two nameservers can provide authorized DNS RRs to all domains delegated to each other, they likely belong to the same SharedAuth pool. Additionally, during our empirical verification, we confirmed that unlike the HTTP Host checking in web scenarios, nameservers lack access isolation for differentiating queries toward different NS domains. This is because resolvers directly query the IPs of the nameservers. Consequently, the stored DNS RRs can be retrieved through any NS domains in the SharedAuth pool.

With this in mind, we classify two NS domains as shared nameservers if they share the same IP addresses or provide authoritative responses for domains delegated by the other. Building upon this assumption, we introduce a novel approach called *cross-resolution verification* to identify shared nameservers efficiently. The detailed methodology is as follows:

Cross-resolution verification. For each nameserver seed, we initially choose three delegated domains at random from the TLD zone files and collect relevant $\langle$`apex,ns,ip`$\rangle$ pairs. If NS domains are associated with the same `ip`, we directly group them together. Otherwise, we conduct a Cartesian product cross-mapping between the `apex` set and the `ns` set, as the sec-

ond process in Figure 7. Based on these mappings, we crossly resolve each apex domain by setting the DNS servers as corresponding nameservers. The cross-resolution allows us to verify the capability of the re-mapped NS domains to handle queries for a specific apex domain. If two nameservers simultaneously respond to the same domain queries, we consider them to share a DNS database and are part of SharedAuth.

An exception is that registrants might configure multiple NS domains, managed by different parties, for a single domain to enhance the robustness of authoritative services. These nameservers are not SharedAuth, though they could answer for the domain. Thus, during the random selection of delegated domains, we only use the `apex` set hosted by one entity to minimize false positives resulting from user configurations. For further domain dependency analysis, we empirically treat different SLDs as controlled by different entities.

Resolution-task reduction. Despite we have narrowed down nameserver seeds by setting a lower *NS-DN* bound in Section 4.2, the query volume during cross-resolution remains substantial. Brute force cross-resolution of all `apex` and `ns` domains would escalate network requests to $3n^2$ (with n being the `ns` number). Only 25k nameserver seeds would generate nearly 1.9 billion domain resolution probes, not to mention analyzing the entire TLD zone file dataset, which includes over 2 million NS domains. To address ethical concerns regarding active probing, we employ a pruning strategy to reduce resolution tasks, mitigating network request load and avoiding overburdening the actual DNS infrastructure. Eventually, we effectively reduced the active query volume by 85.94%. The pruning idea is to minimize n as much as possible:

First, for NS domains under the same NS apex domains (SharedAuth-III&IV), we assume they are owned by the same entity and only select one representative. We validate its rationale by conducting a preliminary experiment, where we perform cross-resolution verification within NSs under the same apex domains and divide them into subgroups. According to our dataset, over 97.88% of NS apexes have no more than 10 FQDNs, resulting in a domain query volume of only 2 million for this experiment. Based on the experiment results, we find the average subgroup number under each NS apex (or possibly each service entity) is 1.84, indicating that only 1.84 NS domains are needed per NS apex domain. As a result, we reduce the NS candidate count (i.e., n) by 58.81%.

Second, for NS domains under various apexes but resolving to the same IP address (SharedAuth-I), we select a representative from these as well. This approach stems from the fact that a single IP address typically hosts one DNS server. Therefore, it is unnecessary to repeatedly verify whether such NS domains are part of SharedAuth pools.

Third, we filter out NS domains with unusual resolution behaviors [59]. Our analysis mainly covers two types of unusual behaviors. Some NSs allow recursive resolution for domains not delegated to them, which falls outside our study focus. Some other NSs respond to arbitrary domain queries with fixed IP addresses (e.g., 127.0.0.1), similar to parking services like iPage, which we also exclude from our analysis.

Experiment considerations. First, we minimize domain resolution overhead by randomly selecting a specific NS IP address from multiple addresses that an NS domain adopts for load-balancing purposes. To assess response consistencies among different NS IP hosts, we conducted a preliminary experiment and found that only 3.4% of NS domains exhibit response variations, primarily due to occasional `SERVFAIL` (DNS Return Code: 2) caused by certain IP hosts. To mitigate this variability, we choose an active IP for cross-resolution tasks instead of relying on the NS domain. This approach helps us circumvent the issues of dynamic DNS IP switching.

Second, we conduct scanning tasks from multiple vantage points (Hong Kong, Dubai, and Virginia) to overcome accessibility issues due to censorship or geographical biases [55]. We take a union of the results from different locations, which ensures a broad data collection and can ensure the accuracy of our results. However, this collection only includes nameservers with perfectly consistent responses, representing a lower bound for all shared nameservers.

4.4 Identifying Vulnerable Entities

Next, we identify the vulnerable entities (i.e., providers or organizations) deploying the shared nameservers. The key challenge lies in accurately mapping nameservers to their managing entities, as no public dataset is available for this purpose. Additionally, even if we know a nameserver's owner, verifying its vulnerability requires complex configuration and manual testing. To address this, we first use information of NS domains to identify their owners. Then, we target the top clusters of shared nameservers and enlist volunteers to verify their vulnerability. If anyone within a cluster is vulnerable, the entire group is affected.

Nameserver owner identification. We utilize multifaceted sources, including HTTP content, WHOIS data, and entity names revealed from domain labels, to identify nameserver owners. See Algorithm 1 for the pseudocode. First, we gather HTTP responses and WHOIS data for the shared nameserver's SLD. Then, we extract owner information from the `Title` and `Copyright` sections in HTTP responses, and from the registrant organization in WHOIS records. This yields 1,867 entities from HTTP and 930 from WHOIS. However, entities may utilize nameservers across various TLDs. For instance, both `azure-dns.com` and `azure-dns.net` are owned by Azure. Thus, we further aggregate the above entities based on domain name labels, resulting in 2,403 identified entities.

Cross-entity inspection. Inspecting cross-entity exploitation requires manual setup, such as registering accounts, delegating domains, and checking DOV processes. With thousands of NS groups and relevant entities, we recruit 10 students working in cybersecurity research to assist in testing the entities within the top 200 NS groups. Note that we only test enti-

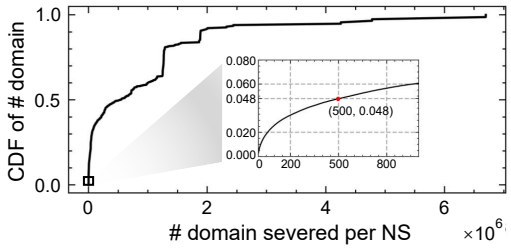

Figure 8: Distribution of delegated domain numbers per NS.

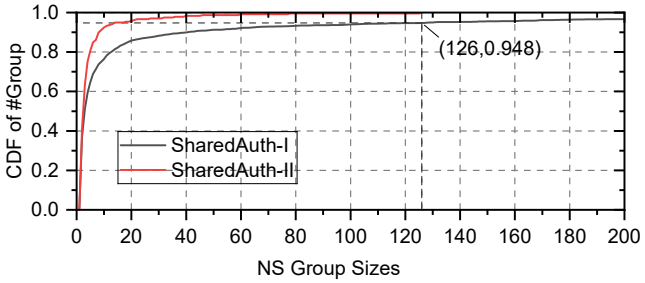

Figure 9: CDF of NS group sizes for SharedAuth-I and SharedAuth-II.

ties offering free or trial public hosting services. For each test group, we prioritize the NS domain serving the most customer domains, which might be a nameserver from providers. For unlabeled NS domains, we manually determine the belonging entities of nameservers using search engines. We conduct *E1* testing for groups with multiple hosting providers and *E2* testing if a group contains only one public provider.

E1: Hosting and hosting. For groups with multiple hosting providers, we register *victim* and *attacker* accounts on two providers (e.g., providers A and B) and conduct the following processes. First, we delegate a test domain using the *victim* account on provider A and then discontinue the service while leaving the NS records unchanged. Second, we claim the test domain using the *attacker* account on provider B and configure a carefully crafted `TXT` record. Then, we verify whether the domain delegation is successful and check if we can query the `TXT` record. A successful outcome demonstrates that the attacker has taken over the test domain.

E2: Hosting and non-hosting. If a group contains only one hosting provider, confirming XDAuth threats is challenging since we cannot host domains to the nameservers of non-hosting entities. To this end, we select domains that delegate to non-hosting nameservers and present `REFUSED` return codes as our test domains. Then, we select two test domains per group and perform cross-entity tests via the hosting provider, i.e., trying to claim the test domain on the hosting provider and set test `TXT` records. If any test domain is vulnerable, we consider the hosting provider allows cross-nameserver queries without XDAuth protections.

Discussion. For minimizing test influences, we only select test domains with low query volume based on passive DNS data from VirusTotal [52], set `TXT` records, and promptly remove the records to restore the domain to `REFUSED` after tests. Additionally, we inform domain owners of our actions and the risks their domains face. Section 6.4 delves into ethical considerations.

5 XDAuth Threat in the Wild

5.1 Dataset Overview

TLD zone files. The input of XDAuthChecker is TLD zone files, which provide comprehensive authoritative DNS records for registered domain names. To explore the real-world domain delegation landscape, we gathered 1,090 authorized zone files through ICANN's Centralized Zone Data Service [29], covering 19 generic TLDs (gTLDs) like `.com` and `.org`, along with 1,071 new gTLDs like `.site` and `.xyz`.

Our study primarily focuses on stable sharing relationships among nameservers, which are less prone to sudden changes, despite TLD zone files being updated daily. Thus, we limited our analysis to a snapshot from September 13, 2023. This dataset comprises 2,648,840 NS domains, spanning over 200M apex domains. Notably, nameservers serving over 500 domain names accounted for 95.20% of the delegations according to Figure 8. Considering the NS popularity as discussed in Section 4.2, we selected 25,310 NS domains that serve over 500 apex domains as our research objects.

5.2 Landscape of Shared Nameservers

Our cross-resolution experiments confirm the pervasive practice among providers of sharing DNS infrastructure. Below, we will explore the landscape of different SharedAuth types.

Understanding SharedAuth-I and SharedAuth-II. We identified 2,134 SharedAuth-I groups and 238 SharedAuth-II groups, comprising 60,974 and 4,800 nameservers, respectively. Additionally, 1,359 nameservers are involved in both types. The group size distributions of these two types are shown in Figure 9, with SharedAuth-I displaying larger NS group sizes. Approximately 5% of nameservers are shared across more than 126 NS domains. Among these, 16 IPs of Bluehost and HostGator serve over 1,000 NS domains each. Instead, within SharedAuth-II, the max group includes 126 NS domains, but 95% of the NS groups have fewer than 18 NS domains.

A wide variety of entity types tend to share DNS infrastructure. They include prominent DNS hosting providers (e.g., Amazon Route 53 and NSONE), web hosting providers (e.g., Squarespace and NationBuilder), domain registrars (e.g., Godaddy and Hichina), as well as renowned corporations (e.g., Nike and McKesson). In addition, this practice is also seen in some governments (e.g., NJ.gov) and famous media websites (e.g., the BBC).

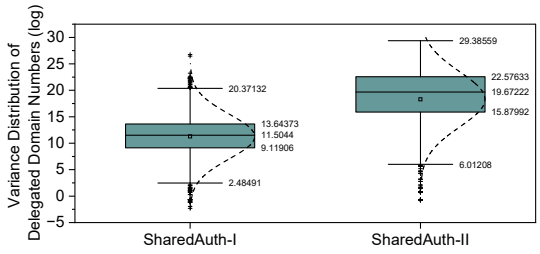

Figure 10: The variance distribution in the delegated domain numbers per NS in each NS group.

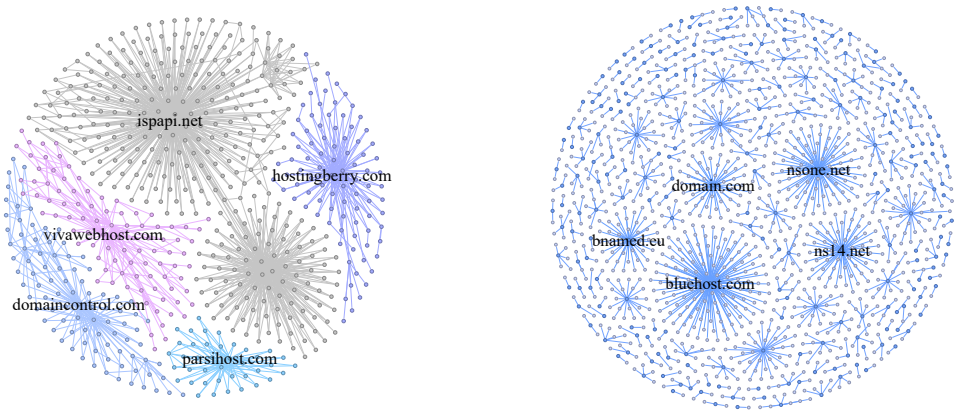
Entities within each group may have notable variations in delegated domain numbers and service types. For instance, a hosting provider (e.g., Cloudflare) typically delegates more domain names than a specific enterprise (e.g., McKesson) that establishes nameservers primarily for its own websites. Figure 10 displays the variance distribution of delegated domain numbers per NS domain within each NS group. It highlights that nameservers might be shared by various types of entities with differing popularity. For example, the popular domain registrar Whois.com manages an NS domain, ns1.whois.com, which shares an NS IP with over 1,679 other NS domains. These NS domains belong to registrars like Regway and BigRock, web hosting providers like BanaHosting, and specific businesses like Waycomp Solutions.



Relationships among entities under SharedAuth-I and SharedAuth-II. In examining the sharing relationships of NS SLDs among different entities, we observed distinct converging clusters formed by the identified NS groups, as depicted in Figure 11. We find that *if any nameserver in an NS group is vulnerable, it could potentially affect all other organizations in that group.* For SharedAuth-I, we showcase the top five NS groups with the most shared nameservers in Figure 11a. The top two prominent groups are `ispapi.net` and `domaincontrol.com`. They are managed by two domain registrars, Hexonet and GoDaddy, respectively. In addition, Figure 11b displays the sharing relationships within the SharedAuth-II category. The two largest groups originate from Bluehost and NSONE[4]. NSONE, in particular, offers authoritative DNS services to a wide range of customers, encompassing web hosting providers like Squarespace, domain management services such as ComLaude, and notable corporations like Porsche and McKesson.

Zooming into the organization level, we investigated the relationships between entities sharing DNS infrastructure, uncovering the motivations behind such deployment. We found that nameserver sharing is often influenced by business practices and partnerships. Overall, we identified four common scenarios (depicted in Appendix B) where different entities tend to share nameservers: (i) *Enterprises subscribe to public DNS hosting services.* Many organizations choose public hosting services when establishing their authoritative nameservers. For example, BBC deploys its nameservers through a public DNS hosting service, NSONE. Its NS domains, ns{#}.bbcdns.net., are pointed to the IP pool controlled by NSONE, as shown in Figure 14a. (ii) *Service providers migrate their DNS infrastructures.* As services need upgrading, providers may change their authoritative nameservers, both in terms of NS domains and IPs. Figure 14b demonstrates how GoDaddy has transitioned its NS domains over time. To maintain service continuity, the old nameserver hosts are integrated into the new ones, ensuring that domains using the previous nameservers remain resolvable. (iii) *Consolidation of DNS infrastructure after company mergers and acquisitions.* A case in Figure 14c is the merger between DigiCert and DNSMadeEasy. Post-acquisition, their DNS hosting services were unified, leading to the consolidation of ns{#}.dnsmadeeasy.com (formerly used by DNSMadeEasy) and ns{#}.digicertdns.com (now employed by DigiCert). (iv) *Different services within a single corporation share a common nameserver pool.* Take the case of 1984.is, which provides both DNS hosting (through ns{#}.1984.is) and web hosting (via ns{#}.1984hosting.is) services. The nameservers of both services utilize the same underlying DNS infrastructure, as shown in Figure 14d.

Understanding SharedAuth-III and SharedAuth-IV. These two categories, encompassing NS domains under the same apex domain, refer to nameservers shared by multiple services within the same providers. Prior research [59, 60] has revealed that providers adopt diverse strategies to assign NS domains to different services. To methodically explore these practices, we delved into the SharedAuth pools at the provider level. Following a thorough cross-resolution verification process as discussed in Section 4.3, we identified 10,426 shared groups under these two categories, enabling us to analyze the deployment strategies within a single provider. From these NS groups, we observed the following practices:

First, significant variations exist in NS deployment strategies among different service providers, with some approaches exhibiting vulnerabilities. Figure 12 depicts a comparative representation of each provider's SharedAuth group number against its NS domain number. For instance, GoDaddy (operating NS domains under domaincontrol.com) maintains 94 NS domains and organizes them into 46 nameserver groups. It leverages the separated nameserver groups to serve different user groups. Conversely, Cloudflare manages nearly 1k NS within a single nameserver group but implements an isolation strategy to constrain the operation ability of unauthorized users. A user-configured DNS RR can only be queried from the allocated nameservers if domain ownership validation (i.e., NS checking) fails. Both practices are considered secure in domain delegation validation. However, not all providers employ such secure practices. A case in point is NSONE, which synchronizes user-configured records across all nameservers

[4]Bluehost is a web hosting provider, and NSONE is a DNS hosting provider.

(a) SharedAuth-I (Top 5 groups)

(b) SharedAuth-II

Figure 11: Nameserver sharing relationships. Each node symbolizes an apex domain of an NS, with its degree indicating the count of NS apex domains sharing DNS infrastructure with it. A node cluster depicts an identified NS group.

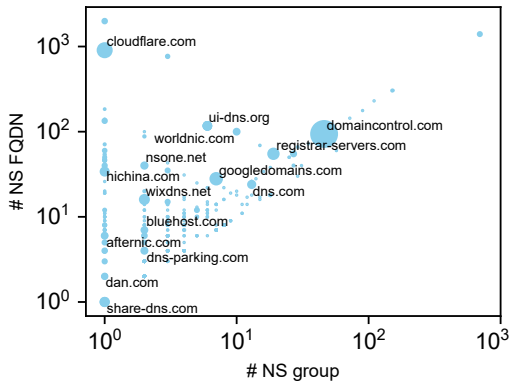


Figure 12: Distribution of each provider's NS FQDN count and SharedAuth group number. The providers are represented by circles whose sizes are proportionate to the number of delegated apex domains.

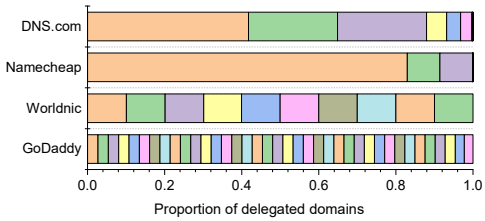

Figure 13: Examples of provider-specific nameserver preferences. The area of each bar segment reflects the proportion of domains served by each NS group.

in its SharedAuth pools regardless of whether the delegation validation is successful or not. This approach potentially creates vulnerabilities, as it allows adversaries an opportunity to inject malicious DNS records into the SharedAuth pools, thereby enabling the hijacking of victim domains.

Second, some service providers have preferences towards particular authoritative NS domains. The preference analysis involves quantifying the domain names managed by each NS group. Figure 13 displays the usage pattern examples of multiple NS groups across providers. While GoDaddy and Worldnic distribute user domains uniformly among their NS groups, providers like DNS.com and NameCheap show a noticeable bias toward the use of NS groups.

Third, despite rare exceptions, most NS domain names corresponding to multiple IPs indeed not only provide load balancing but also offer consistent results. Many providers assign multiple IPs to a single NS domain for load balancing, enhancing service quality. In our study, we collected 4,196 NSs with multiple IPs through multiple measurements at 3 locations and found that 4,055 (96.6%) NSs returned consistent results. For those yielding inconsistent results, our manual analysis attributed these discrepancies primarily to service quality issues or misconfigurations within the NS, often resulting in `TIMEOUT`, `REFUSED`, or `NXDOMAIN` responses.

5.3 Real-world Impact of XDAuth Threats

Overview of vulnerable providers and domain names. As shown in Table 1, our analysis identified 12 public hosting providers vulnerable to XDAuth attacks, all participating in shared NS groups with varying pool sizes, from 5 to 1,386 NS members. These vulnerable providers affect 1,881 authoritative nameservers (termed affected NSs below) of over 67 organizations that share DNS infrastructures with them, like McKesson. Among the affected NSs, 981 are ranked within

Table 1: Identified potentially vulnerable providers with shared nameservers.

Provider	Service Type	Threat	SharedAuth Category	# Shared NS		# Delegated Domain*	
				Total	Vulnerable	Total	Vulnerable
Digicert DNS [17]	DNS Hosting	T1, T2, T3	SharedAuth-I	1,199	850	797,782	50,546
Anon.C	DNS Hosting	T1, T3	SharedAuth-I&II	19	8	5,632,946	27,277
Amazon Route 53 [7]	DNS Hosting	T1, T4	SharedAuth-I	1,386	601	196,161	22,128
NSONE [43]	DNS Hosting	T1, T4	SharedAuth-I	66	45	362,302	12,211
Huaweicloud DNS [28]	DNS Hosting	T4	SharedAuth-II	35	8	330,933	6,962
DNSimple [19]	DNS Hosting	T1, T4	SharedAuth-I	45	26	185,971	3,194
Artglider [10]	Web Hosting	T1, T3	SharedAuth-I	776	248	25,954	1,660
1984.is [1]	DNS & Web Hosting	T1, T3, T4	SharedAuth-II	5	4	25,498	378
Hosting.de [27]	DNS & Web Hosting	T1, T3	SharedAuth-I	134	29	13,288	369
PointDNS [46]	DNS Hosting	T1, T4	SharedAuth-I	11	9	3,016	181
Exclusive Hosting [22]	Web Hosting	T1, T4	SharedAuth-I	185	45	5,447	165
Infinityfree [31]	Web Hosting	T1, T3	SharedAuth-I	71	8	10,053	53

*: The number of domain names delegated by shared NSs.

the Tranco[5] top 1M. Such vulnerable providers enable attackers to hijack domains delegated to the nameservers in these groups, like Canon, Porsche, and the BBC. Notably, DigiCert DNS and Amazon Route 53 emerge as the most critical providers, each potentially compromising the security of over 500 nameservers in their respective sharing pools.

It is evident that most vulnerable public hosting providers fall into the category of SharedAuth-I, referring to Table 1. This means the providers typically share DNS infrastructure by directing their NS domains to identical IP addresses, often managed by major hosting providers. Meanwhile, three providers are involved in SharedAuth-II. In such cases, even though NS domains and NS IPs differ, these systems likely rely on a shared backend DNS storage or cache system.

Additionally, to evaluate the influence caused by these providers, we extracted all apex domains delegated to the 1,881 affected nameservers from the TLD zone files and conducted testing as introduced in Section 4.4. Through this process, we pinpointed 125,124 domains vulnerable to XDAuth attacks. These vulnerable domains are hosted on the affected NSs associated with various types of entities, including web hosting services (e.g., Squarespace), domain registrars (e.g., Bigwww.com), and major organizations like Porsche, the World Bank, and the BBC.

Lessons from the vulnerable providers. First, most (10 of 12) of the vulnerable providers do not deploy any measures against domain name hijacking, allowing customers to claim any unauthorized domain names. Additionally, their NS allocation strategies are also vulnerable, enabling attackers to easily allocate the same NS set with victim domains. Second, certain providers (e.g., *Anon.C*) have implemented domain ownership verification, but they only check subdomains, neglecting apex domains. As a result, they fail to fail to prevent XDAuth. Third, some providers like Amazon Route 53 have made significant efforts to counter domain name hijacking [50]. They monitor all domain delegation pairs and do not allow any new zones of the domain to be created on those name servers. While this approach effectively mitigates previous domain takeover attacks, XDAuth's exploitation point lies in the shared DNS infrastructure rather than the conventional delegation relationship, which circumvents the delegation set inspection of Amazon Route 53.

Threat surfaces of XDAuth. The XDAuth threat spans a wide range of enterprises and organizations, leading to four distinct threat surfaces in cross-provider scenarios.

T1: Hijacking privately controlled corporate domains. Traditionally, hijacking domains controlled by a corporation or an organization is highly challenging without compromising the nameservers themselves. XDAuth, however, breaks down the boundaries of authoritative nameservers by exploiting SharedAuth pools. It allows for the injection of crafted records into shared DNS RR storage, paving the way for hijacking privately controlled domains.

T2: Hijacking domain names of legacy customers of hosting providers. Despite certain NS domains no longer being assigned to customers, XDAuth attackers can reactivate the resolution paths of these historical NS domains via new ones, making legacy customers' domains vulnerable to hijacking.

T3: Hijacking domain names delegated by domain registrars. Authoritative services provided by registrars are typically secure, as many do not offer public DNS hosting services. Although some provide it, they can directly use domain registration data for ownership validation. However, XDAuth targets vulnerabilities in DNS hosting providers sharing nameservers with registrars, allowing attackers to circumvent domain ownership validation and facilitate domain hijacking.

T4: Hijacking domains delegated to web hosting providers. This is the most typical scenario where two hosting providers adopt SharedAuth. Attackers can manipulate the storage of SharedAuth pools to activate hidden resolution paths, covertly hijacking customer domains from other web hosting providers.

[5]Tranco is a research-oriented top site ranking list that mainly consists of apex domains. https://tranco-list.eu/methodology

Table 2: Examples of indirectly affected businesses.

Provider[1]	AffectedBiz[2]	# Domain[3]	Business Field
NSONE	Squarespace	7,613	Web Hosting
	Com Laude	2,025	Domain Management
	BBC	137	News and Media
	McKesson[4]	80	Health
	Porsche	77	Vehicle
DigiCert DNS	Zacco Digital Trust	775	Cyber Security
	McKesson[4]	58	Health and Wellness
	Canon	37	Optics& Image
Anon.C	Bigwww.com	1,346	Registrar
Amazon Route 53	Ezoic	244	Digital Solutions
	Nike	66	Shopping
	Anon.E	57	Entertainment
DNSimple	Sectigo	184	Certificate Management
PointDNS	BrightFire	45	Digital Marketing

[1]: Examples of vulnerable providers.
[2]: Affected businesses or organizations.
[3]: Numbers of vulnerable domains.
[4]: Of McKesson's six NSs, four are shared with NSONE and the remaining two with DigicertDNS. We find all these NSs vulnerable.

Case Studies. We conducted a detailed analysis of the organizations associated with the affected NSs, highlighting examples from diverse industry fields in Table 2.

Case 1: Sectigo is the leading provider of automated certificate lifecycle management and digital certificates. It shared nameservers with DNSimple, putting 184 of its domains at risk of hijacking, which could affect the security of its customers' certificates.

Case 2: McKesson presents another notable example. It utilizes six authoritative nameservers, four of which are shared with NSONE and two with DigiCert DNS, likely as a redundancy measure for service continuity. However, both NSONE and DigiCert DNS's susceptibility to XDAuth attacks leaves 138 of McKesson's domains vulnerable to hijacking.

Case 3: Bigwww.com, functioning as both a domain registrar and DNS hosting provider, has established protective policies based on domain registration information to prevent domain takeovers. However, its shared DNS infrastructure with *Anon.C* opens a backdoor for XDAuth attackers to compromise its customer domains.

6 Discussion

6.1 Lessons Learned

First, securing the DNS infrastructure requires collaboration among various stakeholders, including registries, registrars, registrants, and DNS hosting platforms. With the development of the Internet, DNS is becoming more and more complex, with centralized infrastructure [40, 57], opaque public DNS resolvers with varying behaviours [48], and diverse deployment models [26], which presents both opportunities and challenges. The emergence of new services and features will enhance DNS's robustness and improve the user experience. However, it will also introduce potential attack surfaces. For example, MaginotDNS [34] exploits the resource record isolation vulnerabilities of the resolver in both forwarding and recursive modes to implement cache poisoning. Moreover, XDAuth reveals that cloud hosting providers fail to isolate data in customized DNS zones properly, enabling different NS to manipulate the same DNS RR database.

Second, emerging DNS hosting services are better to adhere to the best security practices of well-managed service providers. Successful examples include Godaddy and Cloudflare, which effectively thwart XDAuth attacks. GoDaddy employs a randomization strategy to prevent attackers from obtaining the same NS set as the victim's domain name, while Cloudflare isolates customers' domain names to prevent unauthorized claims. These practices prevent attackers from tampering with resource records stored in shared nameservers, thereby enhancing security.

6.2 Mitigation

In light of the potential trade-offs between availability and security, and following the analysis of well-managed providers, we provide a series of effective mitigation suggestions for hosting providers and domain owners:

Improve existing NS allocation strategy. NS allocation strategy is an effective policy for mitigating domain takeover threats on DNS hosting platforms. We suggest all providers refer to the secure practices adopted by well-managed providers like Godaddy and Cloudflare as discussed in Section 6.1.

Implementing discontinuation constraints upon customer service termination. A root cause of domain takeover is the failure of registrants to update the delegation information of their domain names after terminating services. While service providers cannot directly manage the NS records for customers' domain names, they can require customers to update NS records upon service termination and proceed with user operations only after confirming the modification.

Maintaining a global status of domain hosting. While Amazon Route 53 has implemented significant measures to thwart domain takeover, it remains susceptible to XDAuth. This vulnerability stems from oversights in managing shared nameservers, creating gaps in their DOV policies. Therefore, providers must maintain a comprehensive and up-to-date overview of global domain delegation statuses within shared nameserver pools. This approach is vital to prevent security breaches that might arise due to discrepancies in the hosting status across various service providers.

Employing domain registration information to perform domain ownership verification. A major challenge in verifying domain ownership is the difficulty in accessing information, such as incomplete WHOIS. The domain registration information held by registrars can serve as effective supplementary data. Thus, hosting service providers can use the registration information from registrars to verify the ownership of do-

mains, thereby alleviating XDAuth. *Anon.C* has adopted this suggestion and is in the process of deploying this solution.

Moreover, domain owners should also make efforts to mitigate the risk. All stale records should be promptly purged when they are no longer in use. This is particularly critical for large companies with global subsidiaries and hosting service vendors, as they may overlook DNS settings for the large volume of subdomains. Our disclosure brought this issue to *Anon.E*'s attention, prompting them to conduct an inspection of all their domain names. Additionally, well-configured DNSSEC ensures the authenticity of DNS RRs using digital signatures, which could effectively mitigate domain hijacking attacks, including XDAuth. DNSSEC records need to be actively generated and configured by the registrant, and not only in their nameservers but also in the parent zone (i.e., TLD).

6.3 Responsible disclosure

We responsibly disclosed to the affected service providers and corporations in compliance with vulnerability disclosure principles [24, 54]. Both *Anon.C* and Amazon Route 53 have acknowledged this vulnerability. *Anon.C* is currently implementing our proposed mitigation solution, while we are actively working with Amazon Route 53 to develop appropriate countermeasures. Also, NSONE has fixed the issue we reported. Furthermore, among the indirectly affected enterprises, *Anon.E* not only acknowledged the threat but also classified it as a CVE-level vulnerability, leading to the prompt fix of the hijackable domains. We noticed that the nameservers for the affected domains were transferred from Amazon Route 53 to CSC's services. In addition, McKesson has confirmed the issue and is working on a fix. We still await responses from other providers. Besides, all responded providers confirmed our testing did not affect their business.

6.4 Ethical considerations

Our experiments were conducted with strict adherence to ethical considerations. These were guided by the principles of the Menlo Report [32] and established best practices for network measurement [44]. Furthermore, our tests adhered to ethical vulnerability disclosure practices as outlined in [25], helping multiple entities mitigate potential threats.

First, we collected and utilized publicly accessible data that does not involve personal information, like TLD zone files, the Tranco domain ranking list, and data from search engines. We strictly followed the recommended practices for using public datasets as outlined in [5].

Second, our cross-resolution experiments required a large number of active queries to target authoritative servers. To mitigate this, we developed an efficient pruning algorithm that utilizes the characteristics of nameservers to reduce the query volume. Meanwhile, we fragmented the tasks across multiple vantage points and limited the query rate from each point to individual NS servers. These measures facilitate reducing the burden on the DNS ecosystem and avoiding excessive network load within a short timeframe.

Third, our cross-entity inspections need to validate the vulnerabilities of affected domain names. In this process, we strived to minimize the actual impact on the hosting providers and the affected organizations. To achieve this, we have designed two different test plans (*E1* and *E2*) based on the scenario, to minimize the potential impact on corporate domains. Moreover, we have also taken several measures to mitigate impact during tests: 1) We target inactive domains and release them immediately after testing, completing the entire process within 2 minutes to prevent client access during our tests. 2) We select a harmless and informational `TXT` as the verification record because multiple `TXT` records can coexist under one domain without overwriting each other, per DNS standards. This ensures our test record does not affect ongoing operations, even if the domain is actively used internally. Furthermore, to mitigate the potential negative cache impact of `NXDOMAIN` on the client, we set the negative cache's TTL to 1 second via SOA records, according to the requirements in RFC1034 [39]. 3) Post-testing, we delete our configured records immediately and verify that the domain has returned to the `REFUSED` status. And, we have checked query logs on hosting platforms and did not observe any requests from normal users during our test. In addition, we make efforts to contact all affected vendors, conduct responsible disclosures, and propose mitigation strategies to help them fix the threat. In discussions, they confirmed our testing did not affect their business. We will continue to engage with affected entities and the security community to promote remediation.

7 Conclusion

In this paper, we perform the first in-depth exploration of the security landscape of DNS hosting infrastructure. Our systematic analysis reveals flawed practices: the service provider's DNS infrastructures lack basic awareness of zone isolation. Based on this, we unveil XDAuth, a novel threat model that leverages shared nameserver infrastructures to breach authoritative service barriers, enabling covert out-delegation domain hijacking. Our findings show that 12 major hosting service providers, including Amazon Route 53, NSONE, and DigiCert DNS, employ inappropriate practices and are exploitable for XDAuth attacks. Through extensive measurements, we demonstrate that XDAuth poses a significant security threat, compromising 1,881 vulnerable nameservers and impacting 125,124 domain names across well-known organizations like Canon, and the BBC. Moreover, we responsibly disclose the issue to the affected providers and corporations. and offer feasible suggestions, and have received acknowledgments from 6 vendors, e.g., Amazon.

Acknowledgments

We sincerely thank all anonymous reviewers and our shepherd for their valuable comments on improving the paper. We also thank Christian Severt of Amazon Security for his support and discussion of our disclosure. A Hosting Service Provider Survey

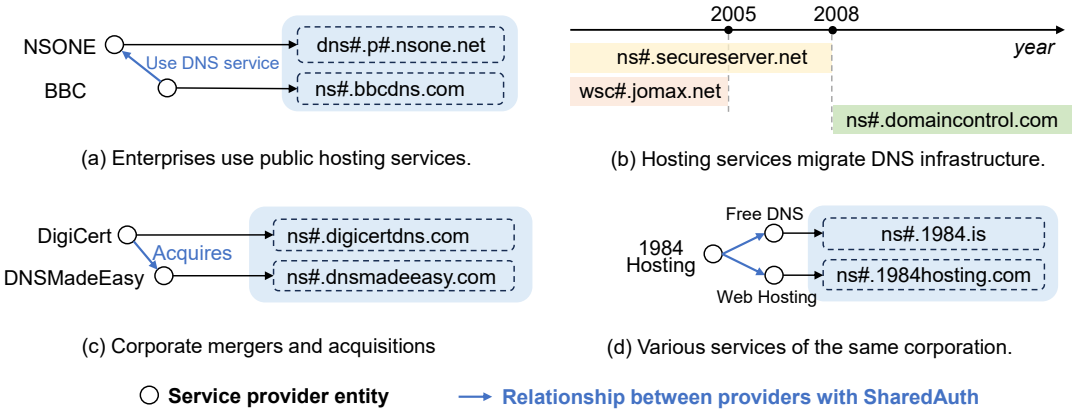
To provide foundational support for our analysis, we conducted a review of research, blogs, and hosting provider documentation spanning the last five years [6, 20, 30, 50, 60]. Following this, we meticulously collected a list of providers, which is presented in Table 3. This is so far the most comprehensive list showing the NS domain patterns of public hosting services, which is an important seed for this study.

B Share Nameservers Common Scenarios

We investigate the relationships between organizations that share DNS infrastructure, uncovering the underlying motives for such arrangements. Figure 14 shows four common scenarios where different entities tend to share nameservers.

C Nameserver owner identification algorithm

We display the pseudo-code (Algorithm 1) of the nameserver owner identification algorithm.



Algorithm 1 : Identifying nameserver's owner.

Input: NS domain (*ns_list*).
Output: Owner dictionary (*owner_dict*).

Abstract

While DNS is often exploited by reflective DoS attacks, it can also be weaponized as a powerful amplifier to overload itself, as evidenced by a stream of recently discovered application-layer amplification attacks. Given the importance of DNS, the question arises of what the fundamental traits are for such attacks. To answer this question, we perform a systematic investigation by establishing a taxonomy of amplification primitives intrinsic to DNS and a framework to analyze their composability. This approach leads to the discovery of a large family of compositional amplification (Camp) vulnerabilities, which can produce multiplicative effects with message amplification factors of hundreds to thousands. Our measurements with popular DNS implementations and open resolvers indicate the ubiquity and severity of Camp vulnerabilities and the serious threats they pose to the Internet's crucial naming infrastructure.

1 Introduction

As a public UDP service with an amplification effect, DNS has been frequently *abused* to launch reflective DoS attacks. Yet, as a foundational component of the Internet, DNS itself is also an inviting *target* for DoS attacks: a DNS outage can disrupt numerous online services. For instance, the infamous Mirai Dyn attack in 2016 rendered over one hundred thousand popular domains unavailable to tens of millions of users [22].

DNS-based reflection attacks leverage simple forms of *transport-layer* amplification: response messages are larger than request messages [38, 37], and an oversized response will trigger TCP fallback and hence a few extra messages [15]. Such generic amplification is also present in many other UDP-based protocols [34].

In contrast, emerging DoS attacks against DNS servers reveal more sophisticated forms of *application-layer* amplification: a single client request triggers a large number of resolver queries, as a result of allowable DNS features such as cascading referrals or query rewrites [5, 26, 29, 11]. Such attacks require the setup of DNS zones with specially crafted records on the target or auxiliary nameservers, which is easily achievable with today's popular and accessible DNS hosting services. Previous amplification vulnerabilities have been discovered mostly by the ad-hoc analysis on some particular aspect of DNS dynamics (see the discussion in Section 3). The sheer complexity of DNS protocols suggest the existence of many more such vulnerabilities yet to be unveiled.

The above motivates a systematic investigation of application-layer amplification vulnerabilities inherent to DNS. We start by establishing a taxonomy of *amplification primitives*, which prolong name resolution with excessive queries of distinct forms such as concurrent and chaining ns queries. This approach allows us to both characterize all existing vulnerabilities of this kind and uncover subtle new attack vectors.

Next, we thoroughly examine the *composability* of amplification primitives. This leads to the discovery of a large family of *compositional amplification* (Camp) vulnerabilities, where each derivative name of a primitive generates another primitive and so on. They can produce much higher *multiplicative* amplification effects than individual primitives. We exhaustively establish 16 valid two-dimensional (2D) compositions based on our taxonomy; they are *regular* in that all primitives in the second dimension are of the same type and size. The results from our composability analysis also enable the construction of exponentially many *irregular* and *multi-dimensional* compositions.

We demonstrate the perils of Camp with extensive measurement of three major DNS implementations (BIND, Unbound, and PowerDNS) and over 50 open resolvers. All of them are vulnerable to multiple Camp variants: 2D compositions can already achieve a message amplification factors (MAF) of several hundreds for many resolvers; the MAF of 3D compositions can ramp up to several thousands. We further illustrate the

high efficiency of distributed CAMP attacks by simulating them against our own authoritative nameservers. These results are highly concerning given the variety of CAMP, the prevalence of accessible DNS hosting services, and the existence of millions of exploitable open resolvers.

Mitigation. Mitigating CAMP attacks is non-trivial. Most compositions do not violate the standard DNS protocols specified in RFCs; in fact, some of them result from the protocol specifications' ambiguities, e.g., when query name minimization should be applied. Only one particular feature—assigning aliases to NS names—exploited by a few compositions is prohibited by the RFCs yet is still allowed by many practical implementations. Hence, to eliminate CAMP at the protocol level, a general consensus must be reached within the broad DNS community.

An essential mitigation mechanism is to restrict the resolver queries generated for the resolution of each client request. Such limits (e.g., `max-recursion-depth`) have been implemented by resolver software in response to previous amplification vulnerabilities. However, CAMP vulnerabilities stand out in that they can bypass individual limits and achieve an MAF equal to the multiplication of these limits. This necessitates the design of holistic query limiting algorithms that account for the subtle interactions between DNS features.

We propose and discuss a list of mitigation options in Section 6, ranging from protocol-level patches and configuration options that cap the MAFs of CAMP vulnerabilities, to system-wide rate limiting and anomaly detection that can counter distributed CAMP attacks.

Disclosure. We have reported our findings to the software vendors of the three DNS implementations used in our measurements. They have confirmed our results and are now working with us to implement and assess the mitigation options (more details in Section 6). We plan to submit a detailed vulnerability report to the DNS-OARC mailing list once our investigation with the three initial vendors is concluded.

In addition, we are working with a national cyber security centre to coordinate the responsible disclosure to the broader community. The process is planned in three phases: (1) informing the network operators of critical infrastructure and DNS service providers within our country of residency; (2) developing and executing a disclosure protocol to inform the centre's partner institutes of other jurisdictions; (3) disclosing the vulnerabilities to the general public through various channels (the center's and the university's websites, a dedicated project page, etc.), which is scheduled after the paper's publication. In the meantime, the centre will assist in the assignment of CVE and/or CWE numbers.

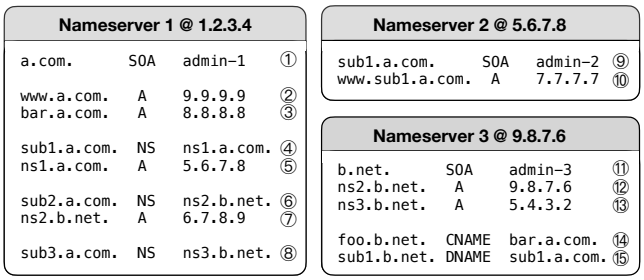

Figure 1: A DNS configuration for three zones containing the main types of RRs. Each zone is hosted by a separate nameserver. Below are examples for different response types. The notation $\langle \texttt{Q}, \text{T} \rangle \rightarrow \texttt{IP} : \langle \text{C}, (\text{n}) \rangle$ means that a query for name `Q` of type T to nameserver at address `IP` elicits a response with code C and an RR indexed by (n).

- $\langle \texttt{www.a.com.}, \text{A} \rangle \rightarrow \texttt{1.2.3.4} : \langle \text{NOERROR}, (2) \rangle$
- $\langle \texttt{qqq.a.com.}, \text{A} \rangle \rightarrow \texttt{1.2.3.4} : \langle \text{NXDOMAIN}, (1) \rangle$

- $\langle \texttt{www.sub2.a.com.}, \text{A} \rangle \rightarrow \texttt{5.6.7.8} : \langle \text{REFUSED}, - \rangle$
- $\langle \texttt{foo.b.net.}, \text{A} \rangle \rightarrow \texttt{9.8.7.6} : \langle \text{NOERROR}, (14) \rangle$
- $\langle \texttt{www.sub1.b.net.}, \text{A} \rangle \rightarrow \texttt{9.8.7.6} : \langle \text{NOERROR}, (15) \rangle$

2 DNS Preliminaries

DNS is a distributed database over a tree-structured namespace, where a name like `www.example.com.` consists of dot-delimited labels. The namespace is partitioned into administrative units (subtrees) called *zones*. Each zone can independently manage names within its authority and delegate parts of its authority to create subzones. By convention, the zones right below the root are called top-level domains (TLDs) such as `com` and `net`, which typically serve delegation-only data to create second-level domains (SLDs) like `example.com`.

A zone's data is organized as *Resource Records* (RRs) that are stored in a zone file. RRs map names to data of different types: network addresses (type A/AAAA for IPv4/IPv6), servers for zone delegation (type NS), other (canonical) names (type CNAME/DNAME), etc. Records of the same name and type but with different data are grouped as an RRset. Each zone has one Start of Authority (SOA) record that defines the zone's meta information.

An *authoritative nameserver* (hereafter, just nameserver) hosts zone files and responds to name lookup queries with matching RRsets. In practice, DNS clients do not directly send requests to nameservers but instead rely on a *recursive resolver* (hereafter, just resolver) that interacts with nameservers to find authoritative answers for clients. Caching RRs at resolvers significantly reduces the amount of queries sent to nameservers, especially those associated with the root and TLDs, and thus makes DNS scalable to serve the entire Internet.

The interaction between resolvers and nameservers is

Table 1: Summary of amplification primitives in each distinct form and variants of their construction.

Atomic Form	Amplification Primitive	Zone Setup			Reported first in
		Records	#Zone	#Server	
Fan-out	Concurrent referral	Glueless/Out-of-bailiwick NS RRset	1	1	[26, 5]
	Failover referral	Same as above, but the NS names own RRs	1	1	this work
Chaining	Referral chain	Chaining glueless/out-of-bailiwick NS RRs	1	1	[26]
			≥2	≥2	[29]
	Rewrite chain	Chaining CNAME/DNAME RRs	2	2	[11]
			≥1	1	[25]
Self-probing	QNAME minimization	One RR owned by a deep name	1	1	[8, 14]
	Dense delegation	One NS RR per label of a deep name	≥2	≥2	this work

the most intricate part of the name resolution process. Upon receiving a client request, if a resolver fails to find an answer directly from its cache, it will ask the most relevant nameserver it knows, and possibly many others, until it decides on a final response to the client. This process is often idealized in textbooks as an *iterative resolution*, where the resolver contacts nameservers on the delegation path of the query name (QNAME) in a top-down manner. However, the process is substantially more complex in reality due to the recursive nature of DNS: *the resolution of one name can lead to and depend on the resolution of other names.*

For each query a resolver sends to a nameserver, the response falls within one of the four possibilities below.

- **Definite answer.** This concludes the query either positively with a matching RRset, or negatively with an NXDOMAIN (non-existing domain) status code indicating that the QNAME (and any node below it in the namespace [9]) does not exist.
- **Referral.** This contains an NS RRset referring the resolver to other nameservers responsible for the QNAME. If the response contains no IP addresses for these servers or such data is deemed untrustworthy (explained in Section 3.1), the resolver must resolve their names as well.
- **Rewrite.** This means that the QNAME is an alias mapping to no meaningful data other than the canonical name in the returned CNAME/DNAME RR. The resolver should continue to resolve the name.
- **Failure.** An error code such as SERVFAIL or REFUSED indicates that the responding nameserver cannot process the query for some reason (technical issues, security policies, etc.). Error handling at the resolver varies across implementations, e.g., retrying another available nameserver.

A definite answer terminates the resolution of a query, whereas a referral, rewrite, or failure response can prolong the process by triggering new queries. Figure 1 give examples for all these cases.

3 Taxonomy of DNS Amplification

The hierarchical structure and recursive nature of DNS makes name resolution an inherently complicated process. We focus on analyzing application-layer DNS amplification vulnerabilities, where the resolution of a single name generates excessive queries. Since these queries can interleave with each other and also recursively trigger further queries, enumerating all possible ways of amplification presents an obvious challenge.

We tackle this by identifying distinct forms of amplification based on the relations between a QNAME (which we term *base name*) and the subsequent names (which we term *derivatives*) queried for its resolution. Depending on whether a base name and its derivatives belong to the same path in the namespace, and whether the derivatives can be independently queried, we can define three distinct forms that cover all possibilities: *self-probing*, *fan-out*, and *chaining*. We then enumerate DNS features that instantiate each form, establishing a taxonomy of *amplification primitives*, as summarized in Table 1 and elaborated in this section. The taxonomy serves as the basis for us to analyze how these primitives interact with each other (Section 4).

This paper does not consider transport-layer amplification (e.g., TCP fallback) and implementation bugs (e.g., [6, 2]) as well as temporal DoS attacks [4, 10]. They are orthogonal to, and can be potentially combined with, application-layer amplification vulnerabilities.

3.1 Fan-out

A fan-out effect occurs when a name's resolution triggers *parallelizable* queries for other names. That is, the triggered queries can be issued independently, and possibly at different times. This requires that the base name and the derivatives are not suffixes of each other.

Among all RR types, NS, CNAME, and DNAME are the only types that map a name to another name while influencing the DNS resolution process. By definition, each

name should have just one CNAME or DNAME RR, the existence of which prohibits any other RR of the same name. This restriction does not apply to NS: DNS requires each zone to be hosted by at least two nameservers for availability, and there are 13 *logical* root nameservers (each backed by an anycast constellation of servers). Therefore, fan-out is only possible with NS RRs.

Note that a referral response does not always lead to fan-out. An NS RR in a response can be accompanied by a *glue record*—an A/AAAA RR that maps the nameserver's name (NS name for short) to its address. If an NS name is under the same zone delegated by the corresponding NS RR (e.g., ④ in Figure 1), a glue record should be provided to avoid circular dependency; in this case, the NS name is regarded *in-bailiwick* (viz., within the answering zone's authority) and the associated glue is considered trustworthy [36]. For security reasons, a resolver should discard the glue record of an otherwise *out-of-bailiwick* NS name (e.g., ⑥ in Figure 1) and initiate separate resolution to obtain the nameserver's IP address. It is also possible that an NS RR comes as *glueless* without any glue record at all (e.g., ⑧ in Figure 1); a resolver should then separately resolve these NS name as well.

3.1.1 Concurrent Referral

Fan-out caused by a large glueless or out-of-bailiwick NS RRset was initially reported by Maury [26]. Later, Afek et al. [5] conducted a detailed analysis of this vulnerability, showing that for performance reasons resolvers attempt to proactively resolve all NS names in a referral response at once. They proposed a mitigation approach, MaxFetch(k), that limits the number of such concurrent NS queries to k for each client request. MaxFetch(k) has since been adopted by major resolver implementations.

3.1.2 Failover Referral

In addition to the above-mentioned concurrent version, fan-out can also happen sequentially. If a resolver fails to obtain the IP address of a seemingly resolvable nameserver (e.g., when the NS name owns a CNAME RR) or any useful answer from a resolved nameserver (e.g., a SERVFAIL response or a lame delegation [7]), it will try another nameserver. This natural failover mechanism (stated in the initial RFC1034 [27]) is overlooked in previous studies [26, 5]. It is activated after the initial concurrent queries for NS names and thus can bypass the limits enforced by MaxFetch(k). It turns out that resolver implementations are more generous to sequential failover queries than performance-oriented concurrent queries, making the former a more powerful amplifier.

3.2 Chaining

Chaining occurs when a name's resolution results in *recursive* queries for different names that are not suffixes of each other. These queries are generated in order. While fan-out expands a resolver's queries in breadth, chaining goes in depth. A chaining primitive should be constructed by RRs of a single type. A chain with more than one RR type is not considered as a primitive but rather a composite form of amplification.

3.2.1 Referral Chain

A referral chain consists of a sequence of glueless or out-of-bailiwick NS RRs. A resolver receives them one at a time and resolves the NS names sequentially. This is first exploited by the indefinite DNS (iDNS) attack [26], where a referral chain is constructed at a single zone. The chaining NS RRs can also reside in multiple zones hosted by different servers. A loop is formed if two names on a chain depend on each other. This is exploited by the TsuNAME attack [29], where a resolver keeps querying a set of nameservers hosting zones with cyclical delegations. However, most resolver implementations can detect such circular dependencies and terminate the resolution process [29]. Hereafter, we consider all chains (including referral and rewrite) to be loop-free.

3.2.2 Rewrite Chain

A rewrite chain consists of consecutive CNAME or DNAME RRs. These two RR types differ in that the former rewrites a name in its entirety, whereas the latter replaces a name's suffix (i.e., rewriting an entire zone). Since they are equivalent in terms of the construction of rewrite chains, hereafter we focus on CNAME only.

The Unchained attack [11] exploits a CNAME chain where names alternate between two zones hosted by separate nameservers. When matching a CNAME RR for a query, a nameserver will try to look up the rewritten name again in the zones it hosts and pack all related CNAME RRs into the response [27]. This allows a resolver to rewrite the names locally without sending extra queries. Splitting a rewrite chain across two servers necessitates the individual resolution of all names on the chain.

However, we observe that many resolver implementations actually discard all but the first RR on a rewrite chain carried in a response to prevent cache poisoning attacks. Therefore, it is possible to exploit a rewrite chain for amplification by employing just one nameserver that hosts all the CNAME RRs either in a single zone or multiple zones. This doubles the amplification effect that Unchained induces on a target nameserver.

3.3 Self-Probing

In contrast to fan-out and chaining, where different names are resolved, self-probing occurs when a resolver keeps sending queries for the *same* name or its suffixes. This is indeed a normal behavior during iterative resolution: for example, a resolver sends the same query for `www.a.com.` iteratively to the root, TLD, and SLD nameservers, and receives in-bailiwick referrals for `com.` and `a.com.`, and the final authoritative answer for `www.a.com.`, respectively. There are two ways to yield an amplification effect in the self-probing form.

3.3.1 Query Name Minimization

Conventionally, a resolver always sends the full QNAME of a client request when querying nameservers. This enables nameservers, especially those at the top of the DNS hierarchy, to collect massive amount of DNS traffic and track user activities. Query Name Minimization (QMIN) addresses this privacy concern by having a resolver ask nameservers with the minimal labels of a QNAME. For example, a QMIN-enabled resolver will send only `com` to the root server and `a.com.` to the TLD server, preventing them from learning more information than necessary.

However, QMIN introduces a new DoS risk: for a deep QNAME with many labels, a resolver may repeatedly ask the same nameserver with an increasing number of labels until the final RR is found, as illustrated in Figure 10a. While this vulnerability is generally recognized [8, 14, 39], and placing limits on the maximum number of QMIN iterations is mandated [8], we find that QMIN is a more subtle amplifier than previously assumed, as it can interact with the query rewrite and referral mechanisms.

3.3.2 Dense Delegation

A deep name can stimulate amplification even in the absence of QMIN. The idea is to set up zone delegation at each level of the name and trigger a prolonged iterative resolution process, as illustrated in Figure 10b. These zones should be hosted by different nameservers, because a server hosting multiple zones always uses the zone matching the longest suffix of a QNAME to find an answer, precluding the extra queries we expect. We refer to this primitive as dense delegation (DDLG) for the artificial and unusual delegation behavior.

It might appear that DDLG can be exploited to target a resolver only, since the query load is distributed to nameservers. Yet, we demonstrate that it can be combined with other primitives to concentrate queries towards a single nameserver as well (Section 4.2). Unlike a long referral chain that is sometimes regarded as abnormal, DDLG follows the legitimate iterative resolution mechanism without incurring recursion, and resolvers generally place no direct limits on it. This vulnerability is therefore more difficult to fix than others.

Table 2: Summary of regular multiplicative composability of 5 amplification primitives. F.O. is short for fan-out, R.C. for referral chain, W.C. for rewrite chain, Q.M. for query minimization, and D.D. for dense delegation. The primary primitive has x derivatives and each instance of the secondary primitive has y derivatives. The last three columns display the minimum number of nameservers required for setup and a single client request's amplification effect on a resolver and a nameserver. The rows are compressed to save space.

Prim.	Secd.	#Name Servers	#Queries from resolver	#Queries to focal
F.O.	D.D.	$1+y$	$1+x+xy$	$1+x$
	Others	1	$1+x+xy$	$1+x+xy$
R.C.	Q.M.	1	xy	xy
	D.D.	$1+y$	$1+x+xy$	$1+x$
	Others		**N/A**	
W.C.	F.O.	2	$2x+xy$	$x+xy$
	R.C.	2	$x+2xy$	$x+xy$
	W.C.		**N/A**	
	Q.M.	1	xy	xy
	D.D.	$1+y$	$1+x+xy$	$1+x$
Q.M.	Any		**N/A**	
D.D.	R.C.	$1+x$	$2xy$	$1+xy$
	D.D.	$1+\max(x,y)$	$2x+xy$	$1+x$
	Others	$1+x$	$1+x+xy$	$1+xy$

4 CAMP Attacks

Existing application-layer amplification attacks [5, 26, 29, 11] exploit *individual* amplification primitives covered by our taxonomy. However, the amplification potential of DNS goes far beyond what can be achieved by these primitives in isolation. In this section, we analyze the composability of amplification primitives and introduce a family of ***Compositional Amplification*** (CAMP) vulnerabilities, which combine multiple primitives to produce multiplicative amplification effects. We first examine all possible regular compositions of two primitives with concrete examples (Section 4.2), and then explain the extension to arbitrary compositions (Section 4.3). Finally, we discuss how an attacker can leverage these building blocks to launch real (D)DoS attacks on DNS servers (Section 4.4).

4.1 Adversary Model

We consider an attacker that attempts to exhaust a DNS server's communication or computational resources at disproportionate attack cost. The target can be a resolver or a nameserver, or both simultaneously, depending on the attack setting. While a resolver is necessarily an

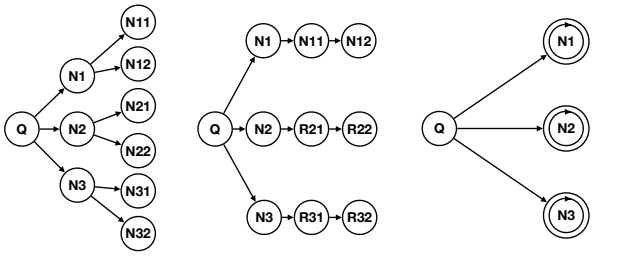

Figure 2: Example DNS zone configurations for compositions with the primary primitive being **fan-out**.

initiator and a potential victim for amplification, the excessive queries it generates can also be directed towards a victim nameserver. In line with prior studies [5, 11], we assume that the attacker can install zone files crafted for amplification on a *focal* nameserver, which is supposed to receive most queries and, if necessary, also on other auxiliary servers. The focal nameserver is not necessarily the target of an attack, and it can be provided by a DNS hosting service. The attacker should register the malicious zones' NS and glue records in the corresponding parent zones, e.g., through a domain registrar. The attacker is not required to access the involved nameservers in any other way.

4.2 Composability Analysis

The number of possible ways to arbitrarily compose amplification primitives may appear daunting at first sight. To start with, we narrow down the scope of our analysis to those *regular* compositions that produce a *multiplicative* effect. In a regular multiplicative composition of two primitives (denoted as **primary** × **secondary**), each derivative of the primary serves as the base of a separate instance of the secondary. Some compositions are easy to construct and comprehend (e.g., when the primary is fan-out), whereas others are less so and some are altogether impossible to construct. The resulting amplification effect also varies.

Table 2 summarizes the results of our composability analysis. We do not distinguish the two variants of fan-out because they have identical construction (glueless or out-of-bailiwick NS) and they can co-occur with an initial batch of concurrent queries followed by sequential queries for NS names. This leaves us 5 amplification primitives to analyze, and we identify 16 (out of 25) combinations that lead to meaningful and valid zone setups. All of them produce multiplicative amplification on a resolver and 12 of them on a nameserver.

(a) **Fan-out** × Fan-out (b) **Fan-out** × Chaining (c) **Fan-out** × Self-probing

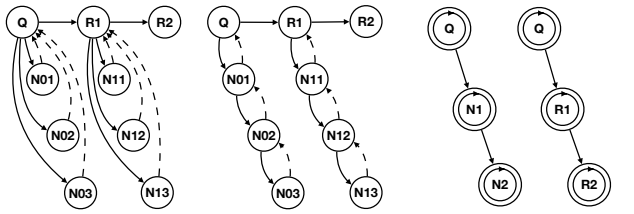
Figure 3: Illustration of compositions with the primary primitive being fan-out. Each arrow indicates an RR that maps one name to another. For (b), we mix the cases where the secondary chain is either referral or rewrite.

Our analysis proceeds in the following unified setting, which helps to illuminate the commonalities and nuances of different compositions. For space reasons, we provide examples for some of the compositions in this section and leave the others to Appendix A.

Analysis Setup. We analyze the amplification effect on a resolver and a focal nameserver triggered by a single client request. When a composition's construction needs auxiliary nameservers, the number of them should be kept to a minimum for cost efficiency and ease of management. The focal nameserver's IP is assumed to be `1.2.3.4` and the auxiliary nameservers be `5.6.7.8` or `x.x.x.x`.

We always configure the primary primitive under the SLD `a.com` and the secondary under `b.com`, except in some cases involving QMIN. For simplicity, all names in our example zone files are written ***in a shortened form relative to the TLD***, e.g., a fully qualified name `x.a.com.` is displayed as `x.a` without the trailing dot. An NS name starts with '`n`' and an alias (i.e., the owner of CNAME) with '`r`'. A set of names is denoted, for example, by `n[x]` or `n[xy]`, where `x,y` $\in \{1,2,...\}$. Unless otherwise specified, the client QNAME is always `w.q.a.com`.

We assume that the resolver already caches (glued) referrals for `a.com` and `b.com` so that it can directly



```

(b) Chaining (referral) as secondary

Figure 4: Example DNS zone configurations for compositions with the primary primitive being **chaining** (rewrite).

(a) **Chaining** × Fan-out (b) **Chaining** × Chaining (c) **Chaining** × Self-probing

Figure 5: Illustration of compositions with the primary primitive being chaining. A dashed arrow always starts from an NS name, indicating that the corresponding nameserver provides records for the name pointed by the arrow. We have four possible versions for (c): {rewrite chain, referral chain} × {QMIN, DDLG}.

reach their nameservers, but no record for other names under these zones is cached prior to the client request.

4.2.1 Fan-out as Primary

When used as the primary primitive, fan-out can be composed with any other primitive, as illustrated in Figure 3. Each derivative of the primary fan-out can elicit another fan-out or a chain, or be a deep name triggering self-probing. Figure 2 show example zone configurations for all these compositions except the secondary being DDLG. All of them require just one nameserver. To answer a client request, a resolver first issues one query for `w.q.a.com`, followed by queries for `n[x].a.com` and `n/r[xy].b.com`, or by QMIN queries for `l3.l2.l1.n[x].b.com`. All these queries are directed to the focal nameserver.

For **fan-out** × **fan-out**, the content of zone `b.com` is unimportant, but its delegation in zone `com` should be set properly to ensure that queries for the secondary primitive's derivatives `n[xy].b` arrive at the focal nameserver. Another subtlety is that some DNS implementations may signal in-bailiwick yet glueless NS RRs as misconfiguration [21] and reject the zone files. To avoid this issue, we can change `n[x].a` to `n[x].b` and `n[xy].b` to `n[xy].c`, without affecting the amplification effect.

The two versions of **fan-out** × **chaining** are similar, as shown side-by-side in Figure 2b. For the referral chain version, the aforementioned issue of missing glue may arise as well, but this can be resolved again by distributing the chaining NS names to different SLDs all hosted by the focal nameserver. For the rewrite chain version, we apply the construction based on a single zone (Section 3.2.2). In case a resolver does not implement strict response sanity checking, one can resort to an Unchained-style setup with an auxiliary nameserver [11].

Figure 2c gives an example zone configuration for **fan-out** × **self-probing** with QMIN being the secondary primitive. This composition is simpler to configure than the others, because a single record with a deep name suffices to induce multiple probing queries, and the type of such records does not matter as long as they exist.

The other version **fan-out** × **DDLG** requires extra servers to set up. It causes multiplicative amplification only on a resolver but not on a single nameserver because the queries are spread out.

4.2.2 Chaining as Primary

A referral chain is quite different from a rewrite chain when treated as the primary primitive in a composition.

Referral Version. Composing a referral chain with a secondary fan-out or chaining primitive is impossible, because this breaks the primary primitive's semantics and prevents the composition's regularity and multiplicative amplification. For example, imagine that the first derivative of the primary spawns multiple NS names, then all of them should be regarded as the derivatives of a fan-out instance, thus stopping the primary chain from growing further[1]. When the secondary is also a

[1]One may argue that one of the fan-out NS names can be used as

```
-The client query is l3.l2.l1.q.a.com
>zo a.com@1.2.3.4       |>zo b.com@1.2.3.4
q.a          NS  n01.b  |n01.b  A  0.0.0.0
q.a          NS  n02.b  |n02.b  A  0.0.0.0
q.a          NS  n03.b  |n03.b  A  0.0.0.0
>zo q.a.com@0.0.0.0     |
l1.q.a       NS  n11.b  |n11.b  A  1.1.1.1
l1.q.a       NS  n12.b  |n12.b  A  1.1.1.1
l1.q.a       NS  n13.b  |n13.b  A  1.1.1.1
>zo l1.q.a.com@1.1.1.1 |
l2.l1.q.a    NS  n21.b  |n21.b  A  2.2.2.2
l2.l1.q.a    NS  n22.b  |n21.b  A  2.2.2.2
l2.l1.q.a    NS  n23.b  |n21.b  A  2.2.2.2
```

Figure 6: Example for **self-probing** (DDLG) × fan-out.

referral chain, the two primitives would merge into a single chain[2]. When the secondary is a rewrite chain, the exclusiveness of CNAME RR will immediately terminate the primary referral chain at its first derivative.

Nevertheless, composing a primary referral chain with a self-probing primitive is permitted. The case of QMIN is straightforward and produces the expected multiplicative amplification on both resolver and nameserver. Similarly to **fan-out** × **DDLG**, **referral-chain** × **DDLG** distributes queries to multiple nameservers and so is applicable to targeting resolver only.

Rewrite Version. A rewrite chain as the primary primitive can be composed with each of the other four primitives, as illustrated in Figure 5. The central idea is to force a resolver to take a "detour" for each name while chasing the rewrite chain. But how would this be possible if the existence of a CNAME RR excludes any other RRs for the name?

We work around this restriction by employing a suffix (`r[x].a`) of each name on the primary rewrite chain, rather than the names themselves, to spawn NS names for a secondary primitive, as shown in Figure 4. Here we provide examples for fan-out and referral chain; the case for DDLG is similar, and the case for QMIN is trivial. Note that the base of a chaining primitive can already spawn a secondary primitive (indicated by index 0). The sequence of queries triggered by a client request will be: `w.q.a.com` → `n0[y].b.com` → `w.q.a.com` → `w.r1.a.com` → `n1[y].b.com` → `w.r1.a.com` → ...

There are a few important technicalities. First, we should host the primary rewrite chain on a different server (i.e., `5.6.7.8`) than the focal server, as otherwise the resolver will directly follow the chain without resolving the secondary NS names. This is required no matter how the construction varies (e.g., using multiple SLDs). Second, the nameserver(s) indicated by these NS names must be resolvable and provide the CNAME RRs to construct the rewrite chain. For the case of fan-out, providing the corresponding A records (all mapping to the same IP) is straightforward, and the resolver is always directed to the same server hosting CNAME RRs. The case of referral chain is trickier: the NS names are queried forward along the chain and they must be resolved in the reverse direction with extra queries. This requires the proper setup of all but the last NS names (i.e., `n[x][y-1].b.com`) in separate subzones.

4.2.3 Self-probing as Primary

QMIN cannot be used as the primary primitive of a composition because, unlike other primitives, it is not driven by a set of RRs crafted to guide the interactions between a resolver and nameservers, but rather by a single RR as a mere resolver-side mechanism. In contrast, DDLG can be composed with any primitives.

The derivatives of DDLG are a sequence of its base name's suffixes with increasing length. Conceptually, its compositions resemble those of a chaining primitive, as depicted in Figure 11. We give an example zone configuration for **DDLG** × **fan-out** in Figure 6, leaving examples for other cases and the discussion of subtleties to Appendix A. The client query now becomes a deep name, and the sequence of queries will be (assuming QMIN is enabled): `q.a.com` → `n0[y].b.com` → `l1.q.a.com` → `n1[y].b.com` → `l2.l1.q.a.com` ...

4.3 Arbitrary Composition

Our composability analysis enumerates all permissible and distinct ways to combine two amplification primitives in a regular form. The results extend naturally to the composition of arbitrary numbers of primitives. For example, in **fan-out** × **chaining**, making all names of the secondary primitive deep gives rise to a three-dimensional (3D) composition **fan-out** × **chaining** × **QMIN**; creating a chain from each derivative of the secondary in **chaining** × **fan-out** leads to **chaining** × **fan-out** × **chaining**.

Compositions can also be irregular, where a primitive's derivatives create different types of primitives: for example, a fan-out instance's first derivative initiates another fan-out instance, whereas the second initiates a rewrite chain and the third initiates a referral chain. This is illustrated in Figure 3 (b) and Figure 11 (b). Moreover, primitives in one dimension need not have a uniform size in terms of the number of derivatives. Their sizes can be

the primary chain's derivative to create another instance of fan-out, and so on. However, this will hinder a consistent definition of regular multiplicative composition.

[2]One may similarly argue that each derivative of the primary can spawn two NS names, one to create a secondary referral chain and the other to grow the primary chain. This will suffer from the same definitional dilemma as in the previous note.

adjusted according to the limits implemented by DNS servers. Allowing these irregularities substantially adds to the variety and flexibility of CAMP attacks.

Since regular compositions already achieve large amplification beyond the reach of any individual attack vector, we focus on them in the rest of this paper, leaving a full accounting of arbitrary composition for future work.

4.4 Launching Real Attacks

CAMP attacks build on the composition of amplification primitives. We define an instance of a composition as a group of RRs implementing it; each instance is activated by one triggering query. An attacker can start with a reconnaissance of the involved DNS servers for their vulnerabilities, then deploys the most effective composition instances, and finally sends coordinated queries to trigger the attack. Three types of targets are possible.

Focal Nameserver. At the center of amplification, a focal nameserver is a natural target of attacks. An attacker can employ an array of resolvers and coordinate them to process duplicate queries for composition instances installed at the focal nameserver. The resolvers can be those open ones on the order of millions [23], or the closed ones accessible to the attacker, e.g., through a botnet or Internet measurement probes [1]. An important factor for prolonged attacks is the bypassing of resolver caching. This can be achieved by deploying a large number of composition instances (which would increase the attacker's costs) for queries in rotation and/or setting small TTL values for attack-related RRs.

Arbitrary Nameserver. CAMP attacks can target an *arbitrary* nameserver, including the root and TLD servers, even if the attacker cannot install zone files on it. This is enabled by compositions where the primitives along the last dimension are fan-out. Specifically, we can change the derivatives of these fan-out instances to NS names in any zone hosted by the target nameserver. For example, changing `n[x][y].b.com` to `n[x][y].tld` if the target is a TLD server, or to `ns.n[x][y]` if the target is a root server. In some cases, such as **chaining** × **fan-out** or **self-probing** × **fan-out**, one of the NS names should remain under the attacker's control and resolve to a server that provides the necessary RR for the resolver to traverse along the primary primitive.

Resolver. When the target is a resolver, the attacker will need to deploy composition instances on multiple focal nameservers according to the servers' capacities, the expected attack intensity and duration, as well as the algorithm used to coordinate triggering queries.

Table 3: Default query limits implemented by popular open-source DNS resolvers to mitigate DoS risks.

Resolver Limits	BIND 9.18.4	Unbound 1.16.0	PowerDNS 4.7.3
Concurrent NS queries	5	3	1
Failover NS queries	-[1]	3	9
Total NS queries	-	6	10[2]
Referral chain length	7	4	15
Rewrite chain length	17	12	12
QMIN iterations	5	10	10
DDLG iterations	>20	>20	>20
Max queries per cli. req.	100	32	60[3]

1: No explicit limit according to our measurement.
2: Controlled by PowerDNS's `max-ns-address-qperq` parameter. The default value 10 decreases for every additional NS RR in a response to a minimum of 5.
3: Controlled by PowerDNS's `max-qperq` parameter and raised to 100 when QMIN is enabled.

5 Evaluation

We have validated CAMP vulnerabilities in both popular DNS software and public DNS services. The central metric in our measurement is the message amplification factor (MAF), which we define as the number of DNS queries *received*[3] by the *focal nameserver* during the resolution of one triggering client request. Other common metrics include the packet amplification factor (PAF) and the bandwidth amplification factor (BAF). Clearly, the MAF establishes a lower bound on amplification power[4]. Using MAF also aligns with our focus on analyzing application-layer vulnerabilities while abstracting away lower-layer details.

Ethical considerations. For measuring open resolvers (Section 5.2) and attack simulation (Section 5.3), we use our own domains and authoritative nameservers without affecting the public DNS infrastructure, except occasionally sending a few queries to root and TLD servers. Our servers run on cloud VMs. We have confirmed with the cloud provider that our experiments do not violate their user policy nor raise any security alert. The experiments generate small volumes of intermittent queries: even in the most intensive simulated attack, no more than 200 queries per second (QPS) on average are sent by each resolver within half an minute. The query load is negligible compared with their usual workloads (QPS in the millions or higher), and all attack-related RRs have a low TTL of 5 seconds. Therefore, our experiments have no impact on the public resolvers' normal operation.

[3]Some studies count both traffic sent and received by a server [5].
[4]For DNS amplification attacks, the PAF can be 5× larger than the MAF if TCP fallback is factored in [5], and the BAF can be even higher if, for example, DNSSEC is enabled.

Table 4: The MAF of CAMP compositions measured with resolver software. The composition instances are configured according to the default limits of the resolvers (Table 3), with several exceptions explained in the notes below. A shaded cell indicates that the composition fails to produce a multiplicative amplification effect.

Primary	F.O.				W.C.			R.C.	D.D.				F.O.	W.C.	D.D.
Secondary	F.O.	R.C.	W.C.	Q.M.	F.O.	R.C.	Q.M.	Q.M.	F.O.	R.C.	W.C.	Q.M.	W.C.	F.O.	W.C.
Tertiary	-	-	-	-	-	-	-	-	-	-	-	-	Q.M.	R.C.	Q.M.
Compo. Index	*a*	*b*	*c*	*d*	*e*	*f*	*g*	*h*	*i*	*j*	*k*	*l*	*m*	*n*	*o*
BIND	31	36	21	21	**119**	**136**	82	8	80	50	2	21	26	**731**	2
Unbound	12	17	73	61	28	60	**112**	43	30	67	**241**	**201**	**726**	23	**2400**
PowerDNS	57	57	56	91	24	31	99	98	21	30	53	90	97	11	97

- For BIND, we set the size of fan-out instances to 5 in attacks *a* and *b*, because it does not send failover queries for non-existing NS names; we increase the size to 20 in the other attacks *e*, *i* and *m* where failover NS queries are triggered.
- The deep names of QMIN instances contain 16 labels after the TLD, e.g., `15.14...1.a.com`. This ensures that all three resolvers, which implement different QMIN algorithms, reach their iteration limits. We disable their QMIN feature for compositions not involving it.
- None of the resolvers explicitly restricts the number of DDLG iterations, which seems to be restricted only by the global query limit. We choose a value of 20 for a balance between setup complexity and comparability with other primitives.
- We disable AAAA queries (IPv6 addresses) for NS names in all three resolvers to obtain a better picture of the multiplicative amplification effects. More queries will be generated if this feature is enabled.

5.1 Vulnerabilities in DNS Software

DNS resolvers play a central role in CAMP vulnerabilities because they drive the name resolution process, whereas nameservers answer queries passively. We examine three industry-standard resolver implementations: BIND in the recursive mode, Unbound, and PowerDNS recursor. For each of them, we choose a recent stable version that has been patched in response to the NXNS attack [5].

Methodology. We develop a Docker-based testbed to facilitate our evaluation and for the reproducibility of our results. It allows the flexible simulation of a realistic DNS infrastructure. All DNS servers and clients run in separate containers. Our architecture comprises: two nameservers for a customized root zone and TLD, plus the necessary number of nameservers for attacker-controlled zones, all running BIND in the authoritative mode; one resolver using one of the three implementations; and one client to generate triggering queries.

We focus on evaluating all 12 of the 16 regular 2D compositions that produce multiplicative amplification on the focal nameserver (i.e., those not employing DDLG as the secondary primitive), and 3 representative regular 3D compositions, each using different primitives.

Measurement Results. Our results are summarized in Table 4, *where each composition is assigned an index for brevity*. Overall, every composition results in multiplicative amplification for at least one resolver, with the measured MAF matching the expected value.[5] The strength of compositions varies across resolvers. While there is no clear winner, compositions involving the rewrite chain and QMIN tend to be the most powerful. Below we highlight our main observations from the evaluation, leaving further explanation to Appendix B.

O1: *CAMP can bypass individual query limits.* DNS resolvers have implemented various query limits (Table 3) to bound resource consumption and hence reduce the risk of DoS attacks. While effective for known attacks that exploit individual amplification primitives, these limits fail to address CAMP: a composition's MAF can far exceed individual limits. A global quote on resolver queries per client request would serve as a safety net to curb the overall effect caused by any application-layer amplification compositions. Yet a correct implementation is non-trivial: among the three resolvers, only PowerDNS gets this right (which is why it never reaches an MAF over 60, or 100 when QMIN is enabled), whereas both BIND and Unbound reset the corresponding counters after each query rewrite or referral.

O2: *CAMP can grow exponentially.* The results for 3D compositions demonstrate that the amplification power of CAMP can grow exponentially in the number of dimensions. In the case of Unbound, the tertiary primitives contribute a perfect multiplicative factor to the MAFs of compositions *m* and *o*. For a given resolver, it is possible to find the multi-dimensional, possibly irregular, composition that produce the highest MAF. This is especially alarming in the absence of a correctly implemented global query limiting mechanism.

O3: *RFC compliance is critical but complicated.* While it remains controversial among DNS implementations whether an NS name can own a CNAME/DNAME RR, it is explicitly stated in RFC 2181 [16, §10.3] that *"The domain name used as the value of an NS record, or part of the value of an MX record must not be an alias"*. BIND complies with this rule, protecting itself from

[5] Note that to calculate the expected MAF of a composition subject to a resolver query quota, we must account for queries sent to other nameservers in addition to the focal nameserver.

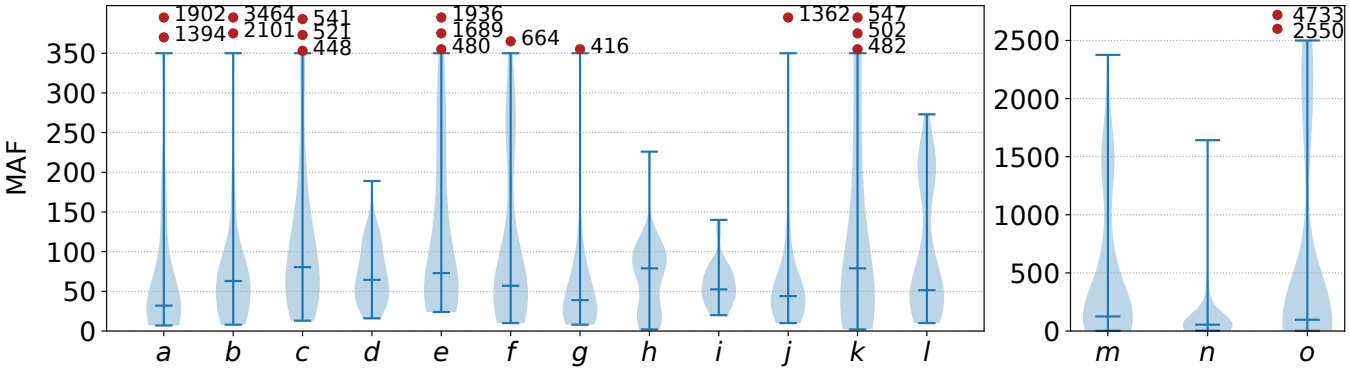

Figure 7: CAMP vulnerabilities measured on 60 public resolvers. Outliers with high MAFs are marked as red dots above the violin plots. The MAFs of most resolvers remain consistent across our measurements over a 10-month period, but some resolvers exhibit high variance from time to time (discussed in Section 5.2) and some seem to have applied security patches after our disclosure. The data reported above is collected between 2023-11-22 and 2023-11-29.

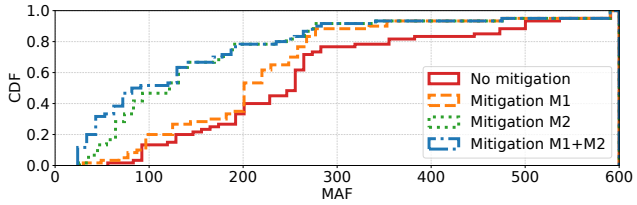

Figure 8: Distributions of the highest MAFs achieved by 2D compositions on 56 public resolvers. The solid red line represents our original measurement data. Other lines hypothesize the cases where all resolvers implement the mitigation options M1 and/or M2 (Table 5) and thereby become resistant to certain compositions.

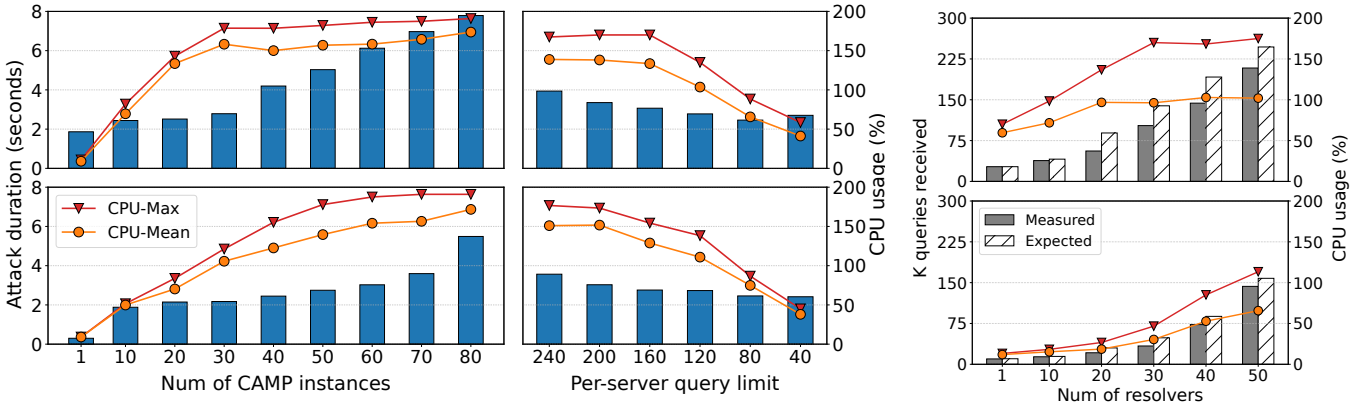
compositions c and k. In contrast, the more permissive implementation by Unbound and PowerDNS makes them more vulnerable. Nonetheless, RFCs are not always clear, which leaves room for interpretations that cause problems. One particularly relevant example is whether QMIN should be applied to resolver queries generated during the resolution of a client request [8]. All three resolver implementations perform QMIN for rewritten names (and two of them also for NS names) and therefore increase their attack surfaces. It is important to resolve such ambiguities in RFCs with a joint effort from Internet standardization bodies and DNS developer communities.

5.2 Vulnerabilities of Public Resolvers



Millions of public resolvers exist on the Internet [19]. Many of them can be abused or targeted by CAMP attacks. We extend our measurements from our local testbed to the real world, analyzing the susceptibility of 60 popular public resolvers (details in Appendix B).

Methodology. Unlike in our local setup, here we deploy attack-related RRs under our registered SLDs to our own public-facing nameservers running on cloud VMs. This allows public resolvers to communicate with the nameservers when receiving our triggering client requests. It is difficult to obtain the precise amplification-related query limits set by public resolvers. For ease of management, we use a set of default parameters for all compositions: 30 for fan-out, 26 for chaining, 16 for QMIN and 20 for DDLG. Some resolvers terminate resolution prematurely due to long referral or rewrite chains; in these cases, we reduce the chain length to a maximum value that allows the resolvers to continue. Nonetheless, our choice of parameters still produces underestimated MAF because premature termination may happen for other reasons and some resolvers indeed have higher query limits.

Our measurements are further complicated by several factors. Large public DNS resolver systems have complex internal architectures, e.g., multi-layer caching and load balancing [32]. They normally accept client requests at an ingress IP and employ multiple independent or collaborating egress resolvers to perform iterative resolution with authoritative nameservers. We have also observed shared egress resolvers used by different ingress resolvers and sporadic unsolicited queries to our nameservers. To reduce the noise in and the interference between measurements, we measure each pair of resolver and composition sequentially with a long cooldown period and estimate the MAF by counting at our nameservers the queries from all egress resolvers mapped to the ingress resolver.

Measurement Results. Figure 7 depicts the distribution of MAFs produced by each composition. Overall, all compositions are effective on multiple resolvers to varying extents, and 3D compositions can achieve higher MAFs than 2D compositions.

O4: *Some resolvers are exceptionally vulnerable.* We have observed multiple abnormal cases with exceptionally high MAFs, e.g., over 1000 for 2D compositions.

(a) Attacks using 10 closed resolvers. The two subplots on the left are for attacks with varying numbers of composition instances and the resolvers' per-server rate limiting disabled. The two subplots on the right are for attacks with 80 instances and varying `fetches-per-server` values set for the BIND resolvers. The attack's duration is shown in bars and the target server's (dual-core) CPU usage in lines.

(b) Attacks using varying numbers of open resolvers. The number of expected and actual queries received by the target server during an attack is shown in bars and the server's max and mean CPU usage in lines.

Figure 9: CAMP attack simulation results under different settings. The three upper subplots are for attacks targeting the focal nameserver. The three lower subplots are for attacks targeting an arbitrary nameserver. All attacks use composition e except that those reported in the upper subplot of (b) use c. Each upper subplot shares the x-axis with the corresponding lower subplot. All the four subplots in (a) share the same dual y-axes shown on the two sides.

There are several reasons behind this: (1) extra queries of type AAAA (and in some cases the obsolete type A6 [20]) for IPv6 addresses when resolving NS names; (2) TCP fallback—even after the DNS Flag Day 2020 where the maximum UDP response size for DNS is suggested to be 1232 bytes, many resolvers still stick to the original 512 bytes and switch to TCP when receiving large responses generated by some composition instances; (3) query retries due to timeout and SERFAIL responses, especially when the resolvers do not limit the number of failover queries for NS names. These findings further highlight the complexities involved in thoroughly analyzing DNS amplification vulnerabilities.

O5: *Diversity means high risks.* A resolver's risk to CAMP is determined by the composition with the highest MAF that it is vulnerable to. This cannot be seen from Figure 7, where the majority of compositions seem to produce an MAF below 100. We show a clearer picture in Figure 8, which depicts the resolvers' risk distribution with respect to the regular 2D compositions. Focusing on the solid red line, we can see that over 80% of the resolvers experience an MAF of over 100 and 60% over 200; the MAF will be higher if 3D and arbitrary compositions are factored in. These high risks result from the the variety of CAMP vulnerabilities. Moreover, the large variance in our measurement data reflects the diverse implementations and configurations of public resolvers. This diversity poses a practical challenge for countering the threat of CAMP at Internet scale.

5.3 Attack Simulation

In addition to individual compositions, we also evaluate the efficiency of real CAMP attacks by simulating them against our own public nameservers.

Methodology. We use small cloud VMs, each of which runs Ubuntu 22.04 with 2 dedicated Intel Xeon 8168 CPUs and 4GB of RAM, for the servers so that the dynamic change of their resource usage can be easily detected even under light workloads. The VMs have a network throughput limit of 2Gbps, and our DNS traffic is not shaped or filtered out by the cloud platform. We also tune the servers' networking buffers to ensure that no packet is dropped by the network interface or kernel throughout our experiments.

We consider two attack settings: the first employs 10 closed BIND resolvers (hosted by us on the same cloud platform as the nameservers) to understand the attack behavior in a controlled environment; the second employs up to 50 open resolvers to illustrate the real-world threat of CAMP. For the former case, we add an artificial delay of 30 ms to the nameservers' egress packets, simulating a typical network condition of authoritative DNS services [3]. For the latter, we use a fixed number of 50 composition instances for each attack.

We analyze two types of targets to demonstrate the versatility of CAMP: a focal nameserver (using composition c and e), and an arbitrary nameserver (using composition e; see Section 4.4). For the latter case, we assign 2/3 of the secondary fan-out primitives' NS names as

Table 5: Summary of mitigation mechanisms for CAMP attacks. In the 4th column, "Res" is short for resolver and "NS" for nameserver. In the last column, "B" is short for BIND, "U" for Unbound, and "P" for PowerDNS (and its associated load balancer dnsdist); a single letter without any symbol means the software has already implemented the mechanism before our disclosure to the vendor, a "!" symbol means the software's prior implementation is flawed in that it can be bypassed by CAMP, and a "*" symbol means the mechanism has been experimentally implemented or is under consideration by the vendor after our disclosure.

Category	Mitigation mechanism	Effective for CAMP	Change to	Adopted by
Protocol-wide patches	M1: Prohibit the rewrite of NS names	*c*, *k*	Res/NS	B, U*, P*
	M2: Restrict QMIN to original client queries	*d*, *g*, *h*, *l*	Res	B*, U*, P*
	M3: Enable QMIN only for the root and TLD	*d*, *g*, *h*, *l*	Res	B*, U*, P*
Holistic query limits	M4: Global quota on resolver queries per client request	All	Res	B!, U!, P*
	M5: Correlated limits on referral depth and width	*a*, *b*, *i*, *j*	Res	P!
	M6: Correlated limits on interacting referral and rewrite	*c*, *e*, *f*, *k*	Res	-
System-wide rate limiting	M7: Max outbound pending queries per nameserver/zone	All	Res	B, U, P*
	M8: Max inbound pending queries per source IP/AS	All	Res/NS	B, U, P
Anomaly detection	M9: Actively scan and remove suspicious zone files	All	NS	-
	M10: Actively monitor suspicious query pattern	All	Res/NS	P

non-existing to the zone hosted by the target server, while keeping 1/3 of the NS names resolvable and the corresponding nameserver reachable to ensure that the resolvers can chase the primary rewrite chains.

For each attack simulation, we use a single client to send a batch of concurrent triggering requests, one for each CAMP instance, to the involved resolvers, while monitoring the victim nameserver's performance metrics.

Simulation Results. DNS servers are compute-intensive, and we observe low memory consumption ($< 5\%$) and network I/O ($<$ 28K packets per second) in all the simulated attacks. Therefore, we choose the victim's CPU usage as the main indicator of attack efficiency, among other metrics like attack duration and query volume. The results are reported in Figure 9.

O6: *CAMP attacks can scale up and out.* As shown by the two subplots of Figure 9a on the left, with a growing number of composition instances, the attacks' intensity increases linearly until the victim reaches its computational capacity, and afterwards the victim maintains high CPU usage for an increasingly longer period of time. Comparing different targets, we can see that the attacks consume more resources on the focal nameserver than the arbitrary nameserver, which receives roughly 1/3 fewer queries according to our setup, as expected.

For the closed setting shown in Figure 9b, we can see similar attack scaling behaviors as the number of resolvers grows. We also find that the queries received by the victim during an attack are fewer than the expected amount estimated from the MAF of individual composition instances. This can be attributed to resolver-side mechanisms, e.g., the termination of client requests on timeout or rate limiting, since we do not observe any packet drops at our servers or in the cloud network.

Together, the simulation results demonstrate the vertical and horizontal scalability of CAMP attacks. We can estimate the client-side cost to overwhelm a large nameserver with 8 CPUs and 16 GB of RAM [13]. For example, assuming the victim is the arbitrary nameserver, the attacker's client only needs to sends around 20K queries every 25 seconds[6]. This is well within the capability of a personal computer.

O7: *Rate limiting helps to mitigate (parallel) attacks.* Resolvers often implement per-entity rate limiting mechanisms to mitigate DoS attacks in general. The entity can be a source IP, a server, a zone, etc. We evaluate how BIND's `fetches-per-server` feature (disabled by default) affects the attacks in the closed setting. It limits the number of in-transit queries a BIND resolver sends to each nameserver. The results are shown in the two subplots of Figure 9a on the right. As the limit drops, we observe a gradually reduced load on the victim server. This indicates the effectiveness of `fetches-per-server`. It can also alleviate *parallel attacks* that target or exploit overlapping nameservers, which is similar to our simulated attacks concurrently querying multiple composition instances installed on a single nameserver. One caveat, though, is that an attacker can still *scale out* an attack by employing more resolvers and/or nameservers.

6 Mitigation

Mitigating CAMP attacks requires a synergy of mechanisms at different levels, covering the protocol design, implementation, and configuration of DNS, as well as the

[6] 20K = 50 (instances) $*$ 100 (resolvers; 50$*$2 as per Figure 9b) $*$ 4 (hardware scaling factor based on our test server). The attack duration of 25 seconds (not shown in the plot) is long enough for most resolvers to clear cached attack RRs with low TTL values.

active monitoring of its runtime behavior. Any mechanism's implications on the system's functionality, performance, and security should be carefully assessed. Table 5 summarizes the mitigation options we have proposed to the relevant entities as part of our disclosure. Some of them have adopted several mechanisms and we are working together to evaluate their patched systems.

Protocol-level patches. Some CAMP vulnerabilities stem from the ambiguities of DNS RFCs. They can be patched if the protocol specifications are revised with precision and implemented correctly.

- **M1:** *Prohibit the rewrite of NS names*, as per RFC 2181 [16, §10.3]. This can be enforced by both nameservers and resolvers, e.g., BIND already signals CNAME's existence for NS names as illegal.
- **M2:** *Restrict QMIN to original client queries* received by resolvers and disable it for any resolver-generated queries, which does not defy the intent of protecting client query privacy.
- **M3:** *Enable QMIN only for the root and TLD*, which would retain the most privacy benefits while minimizing attack surfaces [18]

Holistic Query Limits. We have demonstrated that CAMP can bypass coarsely implemented query limits in unanticipated ways. This necessitates more prudent implementations of holistic and fine-grained query limiting algorithms that cover all corner cases.

- **M4:** *Enforce a global quota for resolver queries per client request* and never reset it for a given request.
- **M5:** *Implement correlated limits on referral depth and width*, e.g., reducing concurrent referral queries allowed for cascading fan-out. Limiting referral depth should consider both the recursive case (referral chain) and the iterative case (dense delegation).
- **M6:** *Implement correlated limits on interacting queries for referral and rewrite*, e.g., lowering the referral depth/width limit when chasing a rewrite chain, or setting varying rewrite depth limits when resolving concurrent NS names.

System-wide Rate Limiting. In addition to the above query limits that cap the MAF of composition instances, DNS servers should also implement rate limiting mechanisms to thrwart *distributed* CAMP attacks that exploit multiple clients and servers, as discussed in Section 5.3.

- **M7:** *Limit outbound queries to each zone and/or each downstream server.* BIND has implemented this with `fetches-per-server` and `fetches-per-zone`. Unbound has a similar option `ratelimit`. PowerDNS is considering adopting this feature.
- **M8:** *Limit inbound queries from each source IP address or AS.* This is a common countermeasure to DDoS attacks, also effective for distributed CAMP attacks especially when the victim is a nameserver.

Anomaly Detection. CAMP attacks exhibit abnormal zone setup and query patterns, rendering themselves detectable by DNS operators.

- **M9:** *Actively scan suspicious zone files* with RRs that can lead to large amplification. Nameservers should reject to load such zone files. This may require collaboration among different operators if an attacker disperses attack-related RRs across multiple zones and nameservers.
- **M10:** *Actively monitor suspicious query patterns* such as repetitive queries for chaining names, or excessive QMIN queries for deep names. This could be done within resolvers/nameservers or by separate monitoring systems such as middleboxes.

Effectiveness of Mitigation. We re-evaluate the risk of our 60 measured public resolvers as if they have implemented two simple option **M1** and **M2**. The results are depicted in Figure 8. **M1** alone reduces the risk for around 15% of the resolvers with MAFs over 200. **M2** is more effective, achieving substantial MAF reduction for about 40% of the resolvers. The two mechanisms together reduce the risk of half of the resolvers to an MAF lower than 100.

7 Related Work

Reflective DoS attacks that leverage public network services for amplification have posed long-standing threats to the Internet. Rossow analyzed and measured the reflective amplification vulnerabilities of popular UDP-based network protocols including DNS, which can generate large replies with EDNS0 extensions of a size up to 4096 bytes [34]. Researchers also studied such transport-layer DNS amplification risks enabled by DNSSEC [17, 38] and queries of type ANY [37].

Our work focuses on more sophisticated application-layer attacks targeting the DNS infrastructure itself. Prior studies explored individual attack vectors for this purpose [26, 5, 29, 11, 14], as discussed earlier in this paper. We generalize some of them in our taxonomy, and more importantly, systematically examine the composibility of amplification primitives. Researchers also start to inspect implementation-level DoS vulnerabilities in DNS software. The NRDelegation attack [6] drives up a resolver's CPU load using non-responsive nameservers. The TsuKing attacks make use of non-compliant handling of `RD` (recursion desired) flag in DNS headers to trigger recursive query loops among resolvers [40]. A promising area of future work is to extend our analytical framework for CAMP to capture implementation aspects,

such as computational resources and compliance checks, for more comprehensive analyses.

On the defensive side, Moura et al. [30] investigated how different DNS mechanisms, caching in particular, affect a server's resilience to DDoS attacks. One can draw inspirations from their findings when designing CAMP-resilient resolution protocols. To defend reflective DNS amplification attacks, Herzberg and Shulman [17] designed an authentication system that can filter requests with spoofed IP addresses and identify standard-compliant resolvers based on a challenge-response protocol. Rizvi et al. [33] developed a generic approach to mitigate DDoS attacks through traffic engineering and anycast routing, which is a common technique deployed in the DNS infrastructure especially by the root servers. Bushart and Rossow [12] propose an anomaly detection defense that can filter out the queries generated by an application-layer DNS amplification attack; this is in line with our observation that CAMP attacks can be spotted from abnormal query patterns.

Large-scale measurements of DDoS attacks that target and abuse DNS are crucial to understand the Internet's threat landscape. This is still a largely ongoing endeavor. For example, Sommese et al. [35] find from two longitudinal datasets that the authoritative nameservers for millions of domains were once under attack. Nawrocki et al. [31] report evidence of prevalent reflective DNS amplification attacks by peeking into Internet exchange points; they also observe that those attacks frequently rotate exploitable resolvers. Yazdani et al. [41] characterize the amplification potential of over 2.6M open resolvers, conjecturing that 20% of them contribute to 80% global DNS amplification power; yet their estimation does not consider subtle application-layer vulnerabilities. Moon et al. [28] propose a monitoring service that can continuously quantify the amplification risks of public servers according to malicious query patterns. Our preliminary measurement is the first step towards a comprehensive understanding of the scope and extent of CAMP threats faced by today's Internet.

8 Conclusion

We have developed a novel taxonomical approach to dissect the intricate name resolution process for studying amplification vulnerabilities. Our systematic analysis uncovers a family of fundamental CAMP vulnerabilities that can produce unprecedented amplification effects. We have confirmed their ubiquity and severity in mainstream DNS implementations and popular open resolvers. We also shed light on the effective mitigation of CAMP and the improvements to DNS standards. This work will hopefully set a milestone for improving the crucial Internet naming infrastructure's resilience to DoS attacks.

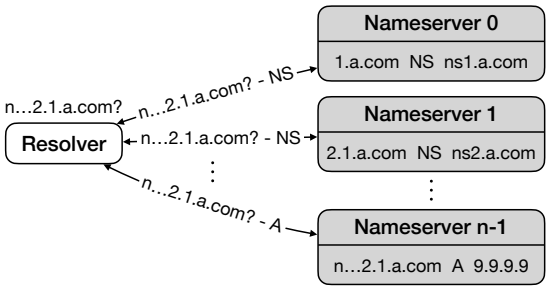
A Example Zone Configurations

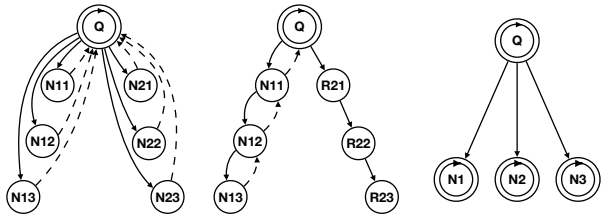


In this section, we give examples of more compositions of amplification primitives and explain subtleties therein.

Fan-out × DDLG: Each derivative of the primary fan-out is a deep name triggering a DDLG instance. The lowest-level zone for each DDLG instance can provide the IP address for the deep NS name (as shown in the example) or not; in either case, a resolver will treat the deep names as resolvable and therefore bypass the MaxFetch(k) limit with extra failover NS queries.

```
> zone a.com @ 1.2.3.4
q.a                 NS        l3.l2.l1.n1.b
q.a                 NS        l3.l2.l1.n2.b
q.a                 NS        l3.l2.l1.n3.b
> zone b.com @ 1.2.3.4
n1.b                NS        n1-l0.b
n1-l0.b             A         0.0.0.0
n2.b                NS        n2-l0.b
n2-l0.b             A         0.0.0.0
```

(a) QMIN. The resolver exposes only necessary labels of the client QNAME to the root and TLD nameservers for referrals (simplified for illustration). For the probing queries with more labels, the `a.com` nameserver returns NOERROR responses with SOA records, indicating the existence of empty non-terminals [24] and at least one RR for the deep QNAME.



(b) DDLG with a *QMIN-disabled* resolver. The root and TLD nameservers are omitted. The resolver's queries are responded with normal referrals, each by a separate nameserver hosting one zone on the long delegation chain, until the final answer.

Figure 10: Illustration of amplification by a deep name.

```
n3.b              NS       n3-10.b
n3-10.b           A        0.0.0.0
> zone n[x].b.com @ 0.0.0.0
l1.n[x].b         NS       n[x]-l1.b
n[x]-l1.b         A        1.1.1.1
> zone l1.n[x].b.com @ 1.1.1.1
l2.l1.n[x].b      NS       n[x]-l2.b
n[x]-l2.b         A        2.2.2.2
> zone l2.l1.n[x].b.com @ 2.2.2.2
l3.l2.l1.n[x].b A          5.6.7.8
```

Chaining × **DDLG**: This composition has two versions which are similar. Here the lowest-level zone of each DDLG instance is required to provide a proper NS or CNAME RR for the primary chain to advance.

```
> zone a.com @ 1.2.3.4
-v1: primary as referral chain
q.a               NS       l3.l2.l1.n1.a
n1.a              NS       n1-l0.a
n2.a              NS       n2-l0.a
n3.a              NS       n3-l0.a
-v2: primary as rewrite chain
q.a               CNAME    l3.l2.l1.r1.a
r1.a              NS       n1-l0.a
r2.a              NS       n2-l0.a
r3.a              NS       n3-l0.a
-common to both versions
n1-l0.a           A        0.0.0.0
```

(a) **Self-probing** × Fan-out (b) **Self-probing** × Chaining (c) **Self-probing** × Self-probing

Figure 11: Illustration of compositions with the primary primitive being self-probing. For (b), we mix the cases where the secondary chain is either referral or rewrite.

```
n2-l0.a           A        0.0.0.0
n3-l0.a           A        0.0.0.0
> zone n/r[x].a.com @ 0.0.0.0
l1.n/r[x].a       NS       n[x]-l1.a
n[x]-l1.a         A        1.1.1.1
> zone l1.n/r[x].a.com @ 1.1.1.1
l2.l1.n/r[x].a NS          n[x]-l2.a
n[x]-l2.a         A        2.2.2.2
> zone l2.l1.n/r[x].a.com @ 2.2.2.2
l3.l2.l1.n[x].a   NS   l3.l2.l1.n[x+1].a
l3.l2.l1.r[x].a   CNAME  l3.l2.l1.r[x+1].a
```

DDLG × **Chaining**: If the secondary primitive is the referral chain, all NS names on each of its instance must be resolved to allow a resolver to reach the corresponding nameservers and traverse along the primary primitive. This composition requires, in addition to the focal nameserver, x servers where x is the DDLG's size. In the example below, the zones `n[x]2.b.com` and `n[x]3.b.com` can be hosted by any of the nameservers for the DDLG zones, i.e., those at IP addresses `x.x.x.x`, instead of the extra nameserver at `5.6.7.8`. For the correct construction of **DDLG** × **rewrite-chain**, we should use the NS names pointed to by the primary's derivatives, rather than the derivatives themselves, as the bases for instances of the secondary primitive. Note that while RRs of the primary DDLG's derivatives (i.e., suffixes of its base) are hosted by separate servers, they will not trigger extra QMIN probing queries because there is no gap on the deep QNAME's delegation chain.

```
-client query: l3.l2.l1.q.a.com
-common to both versions
> zone a.com @ 1.2.3.4
q.a      NS       n01.b
> zone q.a.com @ 0.0.0.0
l1.q.a   NS       n11.b
> zone l1.q.a.com @ 1.1.1.1
l2.l1.q.a    NS   n21.b
> zone l2.l1.q.a.com @ 2.2.2.2
l3.l2.l1.q.a    A   9.9.9.9
-v1: secondary as referral chain

```

B More Details on Evaluation

B.1 Measurements on DNS Software

We explain some of our measurement results on popular resolver implementations summarize in Table 4.

Fan-out × **Fan-out**: The MAF for BIND matches exactly what is expected: 1 (query for the original QNAME) + 5 (queries for the primary NS names) + 5∗5 (queries for the secondary NS names). PowerDNS is also vulnerable, but the MAF is capped by its global query limit of 60, and the value 57 is obtained by excluding queries sent to higher-level zones. Unbound aborts the resolution after processing the first batch of 3 concurrent queries for the primary NS names, and for each of them, it sends 1–2 queries for the secondary NS names.

Rewrite Chain × **Fan-out**: BIND and Unbound are subject to multiplicative amplification but with non-deterministic behavior. After the initial concurrent version of fan-out, BIND sends varying numbers of queries for each subsequent derivative of the primary rewrite chain. This is also the case for Unbound. PowerDNS is somewhat resistant to this attack, resolving only 1 NS per derivative of the primary primitive, but it still produces an MAF of $2*12=24$. Note that BIND has a global limit per client request of 100, but it gets reset after a query rewrite operation.

Rewrite Chain × **Referral Chain**: All three implementations are vulnerable. For PowerDNS the measured MAF is lower than predicted because of its global limit and that many queries are sent to the server at `5.6.7.8`.

DDLG × **Rewrite Chain**: BIND terminates the entire resolution after receiving the first CNAME RR for the base name (`n01.b.com.`) of the first rewrite chain instance. This composition is especially detrimental to Unbound, producing the highest MAF (241) among all 2D compositions. PowerDNS is also vulnerable.

Table 6: List of open resolvers used in our measurements

Resolver	IP	Resolver	IP

GCore Free	95.85.95.85	xTom	77.88.8.8
Google DNS	8.8.8.8	114DNS	114.114.114.114

DDLG × **QMIN**: BIND disables QMIN for NS names and so is not vulnerable. This composition is highly effective on Unbound (201) and PowerDNS (90), which raises it global limit to 90.

Rewrite Chain × **Fan-out** × **Referral Chain**: Interestingly, this composition is effective on BIND with a high MAF over 700, as it is vulnerable to both **rewrite chain** × **fan-out** and **fan-out** × **referral chain**. PowerDNS's is not vulnerable, which can be explained by its resistance to **rewrite chain** × **fan-out**. Unbound here deviates from its behaviors in the related 2D compositions; it produces MAF values between 17 and 29 in a non-deterministic way. Since the result does not improve upon its performance in **rewrite chain** × **fan-out**, we consider this 3D composition ineffective for Unbound.

DDLG × **Rewrite Chain** × **QMIN**: BIND is immune to this attack as it prohibits the aliasing of NS names. PowerDNS is vulnerable up to its global query quota. Unbound is exceptionally vulnerable with a remarkable MAF of 2400 ($20*12*10$).

B.2 Measurements on Public Resolvers

The set of open resolvers used in our measurement study are selected from the union of several sources[7][8][9][10]. We narrow our set down to 60 resolvers that are geographically diverse and remain responsive throughout our measurements, as summarized in Table 6.

Moderating Illicit Online Image Promotion for Unsafe User Generated Content Games Using Large Vision-Language Models

Keyan Guo*, Ayush Utkarsh*, Wenbo Ding*, Isabelle Ondracek*,
Ziming Zhao◇, Guo Freeman†, Nishant Vishwamitra‡, Hongxin Hu*
*University at Buffalo, ◇Northeastern University
†Clemson University, ‡The University of Texas at San Antonio,

Abstract

Online user generated content games (UGCGs) are increasingly popular among children and adolescents for social interaction and more creative online entertainment. However, they pose a heightened risk of exposure to explicit content, raising growing concerns for the online safety of children and adolescents. Despite these concerns, few studies have addressed the issue of illicit image-based promotions of unsafe UGCGs on social media, which can inadvertently attract young users. This challenge arises from the difficulty of obtaining comprehensive training data for UGCG images and the unique nature of these images, which differ from traditional unsafe content. In this work, we take the first step towards studying the threat of illicit promotions of unsafe UGCGs. We collect a real-world dataset comprising 2,924 images that display diverse sexually explicit and violent content used to promote UGCGs by their game creators. Our in-depth studies reveal a new understanding of this problem and the urgent need for automatically flagging illicit UGCG promotions. We additionally create a cutting-edge system, UGCG-GUARD, designed to aid social media platforms in effectively identifying images used for illicit UGCG promotions. This system leverages recently introduced large vision-language models (VLMs) and employs a novel conditional prompting strategy for zero-shot domain adaptation, along with chain-of-thought (CoT) reasoning for contextual identification. UGCG-GUARD achieves outstanding results, with an accuracy rate of 94% in detecting these images used for the illicit promotion of such games in real-world scenarios.

Disclaimer. This manuscript contains discussions and visual representations of sexually explicit and violent content. Reader discretion is strongly advised.

1 Introduction

In recent years, online user generated content (UGC) has steadily shifted into the limelight, captivating a widespread audience. The sphere of gaming, in particular, has experienced a transformative impact [1]. Gaming platforms, such as Roblox, have established revenue-sharing models with these UGC creators [2]. This collaborative approach has attracted a multitude of UGC creators to build their UGC games (UGCGs) and, as a result, has attracted a large number of users, especially children and adolescents. Data from December 2022 illustrates that 60% of its user base is under 16 years old, with a substantial 45% comprising children who are under 13 years old [3]. To attract users, the creators advertise their UGCGs leveraging online social media platforms [4–8], such as X [9] (formerly Twitter), Reddit [10], and Discord [11]. In particular, X, as a platform that brings together a large number of UGC creators and gamers, is often utilized as the first choice [4]. However, the surge in user participation has also attracted individuals with malicious intentions, who have proliferated various harmful games with unsafe content, especially sexually explicit imagery and violence [2, 12–16]. These games present an unprecedented safety issue to underage users who, often, are ill-prepared to confront or manage such exposures [12, 17]. The exposure to explicit content and interactions violates not only ethical norms but also poses significant challenges to their psychological, emotional, and social development [2, 15, 18].

While moderation during UGCG play is a subject of discussion [19–22], alarmingly little effort has been made in moderating the *image-based illicit promotion of such UGCGs by malicious creators on social media platforms*, who are resorting to platforms like X to promote their games. As depicted in Figure 1, the creators share promotional unsafe images of UGCGs to draw a large number of young players to their harmful designs.

Currently, various existing tools, such as Google Cloud Vision API [23], Clarifai [24], and Amazon Rekognition [25], utilize artificial intelligence and machine learning (AI/ML) models for moderating harmful content [26]. However, there is a concern regarding the effectiveness of these tools in preventing the illicit promotion of unsafe UGCG images. While AI/ML-based systems, such as these detectors, have

(a) Sexually explicit UGCG (b) Violent UGCG

Figure 1: Illicit promotions of unsafe UGCGs on X.

demonstrated considerable efficacy in identifying traditional unsafe images (*i.e.*, real-world sexually explicit and violent images) [23–25, 27, 28], these systems exhibit diminished efficiency when tasked with detecting unsafe images that are used for illicit online promotions of UGCGs. There exist two key problems in flagging such images. *First*, a paramount problem stems from the requirement of extensive training data intrinsic to traditional machine learning models. These models are adept at identifying and classifying conventional unsafe content, such as sexually explicit and violence, through bolstering by large, annotated datasets. However, the acquisition of such large-scale data becomes a formidable task in the context of UGCGs, due to the ambiguous (*i.e.* undefined) nature of content within these virtual worlds, characterized by an eclectic mix of artificially rendered avatars and abstract geometrical representations. For example, in Figure 1 (a), the avatar is a mix of a female-like character with animal-like horns. *Second*, unlike traditional unsafe images, the UGCG images exhibit a substantial shift in the input domain. Traditional AI/ML-based systems are adept at detecting explicit content featuring real human forms. However, UGCGs introduce a complex landscape where there is a transition from real to artificial. The rendered avatars or personas in UGCGs embody a diverse array of forms and contexts, making their classification a complex endeavor. While such images are challenging for AI/ML, humans can easily perceive these images due to their contextual knowledge.

In this work, we take the first step towards studying the critical problem of image-based online illicit promotions of UGCGs. We first compile a real-world dataset of images collected from X. This dataset comprises a wide range of illicit online promotional images associated with UGCGs, shared by actual game creators. We collect these images based on keywords derived from a textual analysis of self-reported experiences shared by parents and children on Common Sense Media [29] about their experiences with UGCGs. We then conduct a study to explore the characteristics of these image-based illicit online promotions of UGCGs, discovering that the majority of these promotional images are screenshots taken from UGCGs. We further measure the performance of existing unsafe image detection systems against these illicit promotional images of UGCGs. The low success rate indicates that existing systems are severely limited in addressing the challenges presented by these images. Our findings underscore the urgent necessity for enhanced detection mechanisms for flagging image-based online illicit promotions of UGCGs on social media platforms.

Based on our findings, we design UGCG-GUARD [1], a novel system for flagging images used for the illicit promotion of unsafe UGCGs. UGCG-GUARD leverages recently introduced advancements of large vision-language models (VLMs) to detect these images, based on a novel conditional prompting strategy designed for zero-shot domain adaptation, which ensures that the model is attuned to the distinct and nuanced characteristics inherent in UGCG's image content, facilitating the flagging of these images without the need of a large dataset, and a chain-of-thought (CoT) reasoning mechanism [30] for contextual identification of the activities of the personas in these images, enabling UGCG-GUARD to discern and respond to the intricate patterns that define illicit promotional images of unsafe UGCGs. Our system achieves a state-of-the-art average accuracy of 94% in flagging such content.

The key contributions of this paper are as follows:

- **New dataset.** We compile a novel, comprehensive dataset consisting of 2,924 images used for unsafe UGCG promotions by the actual game creators on the social media platform X . These images were systematically gathered over the period from the beginning of 2020 to the end of 2022, serving as a valuable resource for analyzing the visual promotional strategies for UGCGs, and enhancing our understanding of how unsafe UGCGs are promoted on such platforms. Our dataset will be publicly available for verified researchers to facilitate future research in this area.

- **New understanding of unsafe UGCGs and their illicit promotions.** We conduct a study to understand the challenges presented by the illicit online image promotion of unsafe UGCGs. We find such promotions utilized inappropriate images, often screenshots taken from UGCGs, for their promotional purposes. Our measurement analysis further reveals the severe limitation of existing unsafe image detection systems in identifying unsafe UGCG images, underscoring the urgent need for new moderation approaches to counteract illicit UGCG image promotions.

- **New framework for the moderation of image-based illicit online promotion for unsafe UGCGs.** We introduce UGCG-GUARD, a state-of-the-art framework

[1] Our code and datasets are available at https://github.com/CactiLab/UGCG-Guard

to flag image-based illicit promotions of unsafe UGCGs. Rooted in a novel conditional prompting strategy and CoT reasoning approach, UGCG-GUARD effectively leverages large VLMs to achieve zero-shot adaption and contextual detection. UGCG-GUARD can efficiently distinguish content indicative of image-based illicit promotions of UGCGs, even without prior explicit training on similar content categories.

- **Extensive evaluation of UGCG-GUARD.** Our system's evaluation demonstrates its state-of-the-art average accuracy of 94%, surpassing existing baseline detectors of unsafe images by 23.7% to 77.7% in flagging image-based illicit UGCG promotions. Our experiment also shows that our prompting strategy is significantly efficient, outperforming generalized prompting with an improvement of 64.9%. In real-world scenarios, our framework successfully identifies and flags image-based illicit promotions of UGCGs, achieving an impressive average F1 score of 0.91.

2 Background and Related Work

2.1 Online UGCGs and Unsafe Content

The advent of the internet and social media spurred an interactive cultural evolution characterized by UGC posts online, including images, videos, text, and audio. UGC has significantly influenced gaming, promoting creativity, prolonging game lifespans, and fortifying communities [1]. UGCGs like "Minecraft" and "Roblox" epitomize this shift, transforming players into creators and expanding gameplay possibilities exponentially. Now, such UGCGs are wildly presented in today's game platforms for social interaction and gameplay. They allow players to create their own UGC and share it with others [1, 31, 32].

However, as the volume of UGCGs proliferates online, there is a corresponding surge in malicious content and activities within these games. Online communities in UGCGs are thriving spaces where participants interact through their avatars. While avatars can be vehicles for positive engagement, there is a dark side to this liberty. Some participants exploit this platform to introduce and engage in malicious activities, turning otherwise positive virtual interactions into avenues for undesirable behaviors such as fighting, having sex, and killing others. [14–16]. In addition, a recent study by Kou et al. [2] revealed another safety concern, the UGC creators misuse the creative latitude offered by platforms like Roblox to introduce harmful designs. Examples include games promoting Nazi roleplay and embedding gambling-like mechanisms within these user generated environments. The risks are manifold, from the direct introduction of inappropriate content to the more subtle integration of problematic incentive structures within the UGCGs, each posing significant ethical and safety concerns.

2.2 Content Moderation

Content moderation has been extensively studied as an effective modern mechanism to address issues of toxicity and harassment in online spaces. At a high level, content moderation can be broadly defined as *"the governance mechanisms that structure participation in a community to facilitate cooperation and prevent abuse"* [33], and can often be characterized as a series of trade-offs between actions, styles, philosophies, and values based on the context and facilitators of moderation [34]. Current moderation methods for UGCGs include filtering inappropriate or harmful words, filtering personal information, providing a reporting feature, and posting a public Code of Conduct the users of the games in question should obey [19, 21, 22]. Such content moderation strategies have been widely used in various online contexts but have also demonstrated several limitations. For example, TikTok users, who engage with a video-centric social media platform, have devised a strategy to circumvent the platform's algorithmic content moderation by deliberately misspelling prohibited words (e.g., using "seggs" instead of "sex") [35]. Cho et al. expand on this topic, discussing a wider array of text-based content moderation evasion tactics in their study [36]. These moderation strategies, however, are primarily text-based. Although there are effective methods for moderating textual content, there are no comprehensive solutions for moderating illicit image sharing for images used in UGCGs.

There exist AI/ML techniques aimed at identifying unsafe visual content, including inappropriate images and videos. Platzer et al. developed a machine learning approach utilizing Support Vector Machines (SVM) for recognizing pornographic images by analyzing distinct image features [37]. In another study, Yuan et al. explored the real-world issue of illicit online promotions involving pornographic images [38]. They introduced a novel deep learning approach that prioritizes regions in an image where sexual content is minimally obscured, aiming to overcome the challenges posed by adversarial sexually explicit images in the real world. Concerning video content, Tahir et al. highlighted the importance of detecting inappropriate videos within child-centric content-sharing platforms, such as YouTube Kids [39]. They collected a dataset of such videos and developed a multimodal model for detection purposes. Additionally, another study [40] provided a thorough analysis of inappropriate or disturbing videos aimed at toddlers, assembling a large-scale, labeled dataset for this purpose. The researchers trained a deep learning classifier, which yielded a promising detection rate. However, these techniques often rely on evaluating identified features, such as the extent of skin exposure in images and videos, or assessing the "humanness" of the subjects depicted [41]. Such criteria can be limiting and may not ef-

fectively address the diverse and complex nature of visual content in UGCGs. A significant gap persists in effectively moderating image content within UGCGs, as the existing AI/ML techniques are not tailored to discern the nuances of unsafe images specific to this domain [42]. Our study underscores this gap and emphasizes the imperative need for specialized moderation methods adept at identifying and mitigating the sharing of unsafe images in UGCGs, ensuring a safer and more inclusive gaming environment.

2.3 Large Vision-Language Models and Chain-of-thought Reasoning

The landscape of multimodal learning, especially in the domain of vision-language multimodal learning, has experienced significant advancements. Pioneering the contemporary discourse, models like CLIP [43] and BLIP [44] have marked noteworthy milestones. CLIP, for instance, has revolutionized the field by learning visual concepts from natural language descriptions, forging a symbiotic relationship between vision and language components to enhance performance across a multitude of tasks. BLIP further accentuates this integration, exemplifying robust performance and versatility in applications ranging from zero-shot to few-shot learning scenarios. As the discourse evolves, the emergence of large vision-language models heralds a new epoch in multimodal learning. These models, characterized by their incorporation of large language models (LLMs) to navigate vision-language tasks, are driving unprecedented progress. LLaVA [45], another significant development, underscores the synergy between visual and linguistic elements, optimizing performance in complex, dynamic environments. InstructBLIP [46], building upon the foundational principles of BLIP, integrates instructional learning paradigms to enhance model interpretability and task-specific adaptability. The GPT-4Vision [47] stands as a testament to the ongoing evolution, amalgamating extensive language modeling capacities with intricate visual comprehension, paving the way for a future where the confluence of vision and language is not just integrated but inherently synergistic. These cutting-edge large VLMs are characterized by their interpretability, adaptability, and enhanced contextual capability, offering many opportunities to tackle intricate and emerging challenges within the vision-language domain. In our study, we exploit the capabilities of large VLMs to address a specific issue: the illicit online promotion of unsafe images in UGCGs. These advanced models provide the necessary tools to identify and analyze subtle and complex patterns of unsafe content dissemination effectively.

Chain-of-thought (CoT) reasoning refers to the process where AI models, particularly LLMs, follow a sequence of logical steps to arrive at a conclusion or answer [30]. It involves connecting various information and ideas coherently and logically, akin to a human's natural thought process. This methodology enhances the model's ability to handle complex queries and problems, offering more contextually relevant and nuanced responses. The large VLMs with such enhanced reasoning capabilities herald a new phase in AI decision-making [48–50]. Although CoT has been instrumental in elucidating AI decisions [48, 51], its application and potential challenges in the specific realm of unsafe content moderation remain to be thoroughly explored and understood.

3 Threat Model

In our work, we examine the threat posed by adversaries who exploit social media platforms to promote unsafe UGCGs with inappropriate images, typically screenshots taken from UGCGs. We consider both adversaries and victims as users of these platforms and do not consider promotions outside the social media platforms. We do not attribute advanced capabilities to these adversaries nor assume the application of intricate adversarial tactics to evade content moderation. Our focus is on the straightforward yet effective strategies these actors employ to pervade digital platforms, exposing vulnerable online users to unsafe UGCGs.

In addition, we do not consider in-game content moderation of harmful content in our paper. Our system specifically targets identifying the illicit promotional images for unsafe UGCGs on social media platforms following a "soft moderation" strategy [52], *i.e.*, providing warnings to users about the potential harmfulness of the images, since some platforms may not consider such images illegal. X and Reddit allow users to flag inappropriate images as sensitive or "NSFW", which can prevent such content from appearing automatically in timelines, offering a form of user controlled moderation. Platforms such as X, Reddit, and Discord maintain their community guidelines and systems for reporting and eliminating inappropriate content. However, the enforcement of these guidelines can greatly differ across various community spaces, largely relying on the vigilance of community moderators or the effectiveness of automated detection tools. Despite these mechanisms, inconsistencies in enforcement create loopholes that enable the continued illicit image-based promotion of unsafe UGCGs, highlighting a significant safety challenge. The persistent threat of illicit UGCG promotions underscores a universal challenge: no social media platform should permit content that risks the safety of its users, particularly minors. Therefore, enhancing content moderation frameworks to address these gaps is crucial in our model, ensuring the digital environment remains safe and conducive to positive interactions.

Furthermore, we focus on illicit promotions of unsafe UGCGs based on images and do not consider the textual data in such posts, since images are the major components that drive promotions due to their visual appeal. We also posit that image-based promotions, by virtue of their visual appeal, pose a significant risk, particularly to children and adolescents.

4 Motivation and Observation

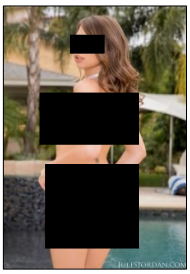
In this section, we present studies on understanding the nature of unsafe UGCGs in Roblox and their illicit promotions particularly among children, and the challenges in their detection. Our study begins with the analysis of real-world, self-reported stories related to unsafe UGCGs. Utilizing the identified keywords from our analysis, we then collect potential UGCG promotional images from social media platforms and engage human annotators to systematically annotate the images. We analyze the challenges of illicit online image promotions for unsafe UGCGs and assess the necessity for moderation techniques to flag illicit image promotions associated with unsafe UGCGs. This involves a comprehensive evaluation of the current tools designated for the detection of unsafe images online.

4.1 Data Collection and Annotation

Hashtag Identification. To find effective hashtags for collecting valid UGCG images, we first gathered online discussions with self-reported stories related to unsafe UGCGs from a public Internet resource, Common Sense Media [29]. This platform was chosen for two main reasons: it offers a comprehensive repository of real-world narratives related to UGCG, and it features insights specifically from children and parents, providing valuable perspectives on the effects of unsafe UGCG on younger groups. By October 2, 2023, we had compiled all Roblox-related discussions from this platform using an automated crawling technique, resulting in 7,081 stories collected. These stories span from July 9, 2009, to October 1, 2023. Then, a cleaning process ensued, during which we filtered out duplicated stories, those not written in English, and stories comprising fewer than five words to ensure the quality and relevance of the data. We employed KeyBERT [53] to automatically extract keywords from the collected stories. Then, we collected illicit promotional images of UGCGs by identifying hashtags associated with unsafe UGCGs. By analyzing self-reported stories, we first compiled keywords related to unsafe UGCGs. Utilizing these keywords, we constructed an initial hashtag list, including terms such as *#RobloxUGC*, *#RobloxCondo*, *#RobloxSex*, *#RobloxR34*, *#RobloxKiller*, and *#RobloxMurderMystery*. During the data collection phase, we systematically incorporated any new hashtag associated with a tweet containing one of the predetermined keywords into our evolving list. This list was continuously updated with emerging hashtags from new tweets until a saturation point was reached where no additional unique hashtags were discovered. The comprehensive list of these hashtags is detailed in Appendix A.

Image Collection. We used the Official X Streaming API[2] to collect public tweets during the period from January 1, 2020, to December 31, 2022 (*i.e.*, 2 years) based on the hashtags. More specifically, we used the tool's flag 'image' to make sure all the posts we collected were along with images. At the end of our data collection process, we have retrieved 38,182 image-based tweets and extracted 29,858 images immediately between January 2020 and December 2022.

Image Filtering and Annotation. We selected a random sample of 4,000 images to serve as the subjects of our study. Each image in the dataset was initially processed to enhance its clarity and quality. Inspired by the methodology outlined by Phan et al. [54], we employed a three-step filtering process to further refine our dataset. In the first step, we utilized the Python library called Pillow [55] to automatically eliminate images with either a width or height of fewer than 300 pixels. In the second step, we manually inspected the remaining images, filtering out those not associated with UGCGs. In the third step, we rigorously reviewed the images to ensure each was sufficiently clear to be easily perceived by humans. Finally, the images were independently annotated by three authors. We utilized Natural Language Processing (NLP) techniques, particularly the agglomerative hierarchical clustering (AHC) method [56], to categorize the stories into unsafe groups, resulting in the identification of four primary categories of unsafe UGCGs: "sexually explicit", "violent", "bullying", and "scam". By reviewing each group and their representative stories, we built our codebook for UGCG image annotation (see Appendix B). We further employed Fleiss' Kappa score [57], a statistical measure used to assess reliability among multiple annotators. The scores revealed a progressive improvement in inter-annotator agreement throughout the three coding rounds, beginning with a *substantial* agreement level of 74%, then increasing to an *almost perfect* agreement level of 92%, and finally reaching an *almost perfect* agreement level of 100%. Ultimately, this process resulted in the identification of 2,924 valid UGCG images, including 1,621 images classified as "sexually explicit", 202 as "violent", and 1,101 as "safe". However, we did not find any images that could be categorized as "bullying" or "scam".



4.2 Detection Challenges of Illicit Promotional Images of UGCGs

4.2.1 Nature of UGCG Promotional Images

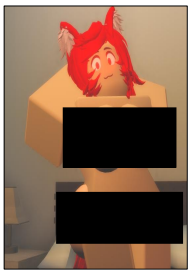
In the course of our data collection and annotation process, we noted a clear distinction in the nature of promotional images for UGCG advertisements compared to conventional game promotions, which typically use renditions crafted by professional entities. Specifically, we noted that the images for UGCG advertisements are predominantly generated by individual users who tend to utilize direct screenshots from the games to showcase their content, as exemplified in Figure 1.

To validate this observation and support our hypothesis regarding the nature of UGCG promotion, we conducted an analysis on a randomly selected subset of 500 images from our dataset. The findings were significant: 97.8% of

[2] https://developer.twitter.com/en/docs/twitter-api

Sexually-explicit-human

Sexually-explicit-anime



Sexually-explicit-UGCG

Figure 2: Samples of sexually explicit images. The Google Vision API's prediction for the image as *sexually-explicit-human*: "VERY_LIKELY" for "Adult" and "Racy"; for the image as *sexually-explicit-anime*: "VERY_LIKELY" for "Adult", "POSSIBLE" for "Racy"; for the image as *sexually-explicit-UGCG*: "UNLIKELY" for "Adult" and "Racy".

these images were indeed screenshots directly taken from user generated games. This prevalence underscores the subtlety with which these advertisements integrate into the platform, highlighting the need for enhanced moderation tools, which are essential to identify and mitigate the discreet yet pervasive spread of unsafe UGCG advertisements, safeguarding users from potentially unsafe content.

4.2.2 Evading State-of-the-Art Unsafe Image Detectors

Following our previous studies, We wanted to investigate the feasibility of using existing detectors for moderating the image-based illicit online promotion of UGCGs. To understand the effectiveness of existing unsafe image detectors, we conducted an experiment regarding state-of-the-art (SOTA), commercially available detectors by measuring their capability to detect promotional UGCG images from our dataset. In our work, we selected five SOTA detectors that are widely used and have the capability to detect unsafe images, which are Clarifai [24], Yahoo Open Not Safe For Work (NSFW) [28], Amazon Rekognition [25], Microsoft Azure [27], and Google Vision AI [23]. Due to the ubiquity and effectiveness of these detectors, they can be considered representative of the technology used to defend against unsafe content in existing online platforms. To study the capability of these detectors about new and traditional types of sexually explicit images, our experiments incorporated an existing dataset [58] that encompasses traditional sexually explicit content, both from real-world scenarios and animated sources. From this dataset, we randomly selected 1,000 images each from the categories labeled "porn" and "hentai", representing real-world (*i.e.*, sexually-explicit-human) and animated explicit content (*i.e.*, sexually-explicit-anime), respectively. Concurrently, another 1,000 images were randomly selected from our annotated dataset, all labeled as "sexually-explicit" (*i.e.*, sexually-explicit-UGCG). This selection served to evaluate the detectors' proficiency in identifying sexually explicit content in UGCGs, offering a comparative insight into their capability to detect traditional and emerging forms of explicit imagery. Figure 2 is an example demonstrating the different categories of images used in this study.

The responses from existing detectors exhibited a diversity in their output formats. Systems like Clarifai, Yahoo Open NSFW, and Amazon Rekognition provided probability scores in the range from 0 to 1 as outputs to quantify the likelihood of images being unsafe. In contrast, Microsoft Azure presented a binary true or false label to categorize such images. Google SafeSearch offered a more nuanced classification, with labels ranging from "UNKNOWN" to "VERY_UNLIKELY", "UNLIKELY", "POSSIBLE", "LIKELY", and "VERY_LIKELY", each indicating the varying degrees of probability for an image being deemed unsafe. Given this diversity in output formats, establishing a unified criteria for evaluation was crucial. Based on these varying methods of measuring whether or not an image is unsafe, we used the following thresholds to determine if an unsafe image is detected. For Clarifai, Amazon Rekognition, Azure, and Yahoo Open NSFW are logit values in the range $0-1$. The threshold value is set at 0.5 for unsafe images. For Google Vision AI, if the model output is "LIKELY" or "VERY_LIKELY", we assume that the model identifies unsafe images, which is a common criterion that has been discussed in previous work [59].

For the selected unsafe image detector, Google Vision AI, we provide different types of unsafe images as inputs and observe the detection results of the detector. Table 1 presents the results of this experiment. The results indicate that SOTA exhibit exemplary performance in detecting unsafe images depicting humans and anime characters, with all detectors achieving an average detection rate exceeding 90%. Notably, Google Vision AI demonstrates superior efficacy, achieving detection accuracies of 98% and 99% for human and anime sexually explicit images, respectively. Contrastingly, a pronounced decline in performance is observed when these models are tasked with identifying unsafe content within UGCG images. The detection efficacy of these sophisticated tools is markedly compromised in this context, with four of the tested models yielding detection rates below 20%. Google Vision

Image Type	State-of-the-Art Unsafe Image Detectors				
	Clarify	Yahoo Open NSFW	Amazon Rekog-nition	Micro-soft Azure	Google Vision AI
Sexually-explicit -human	88%	92%	98%	92%	98%
Sexually-explicit -anime	89%	81%	91%	90%	99%
Sexually-explicit -UGCG	13%	13%	17%	15%	67%

Table 1: Effectiveness of SOTA unsafe image detectors.

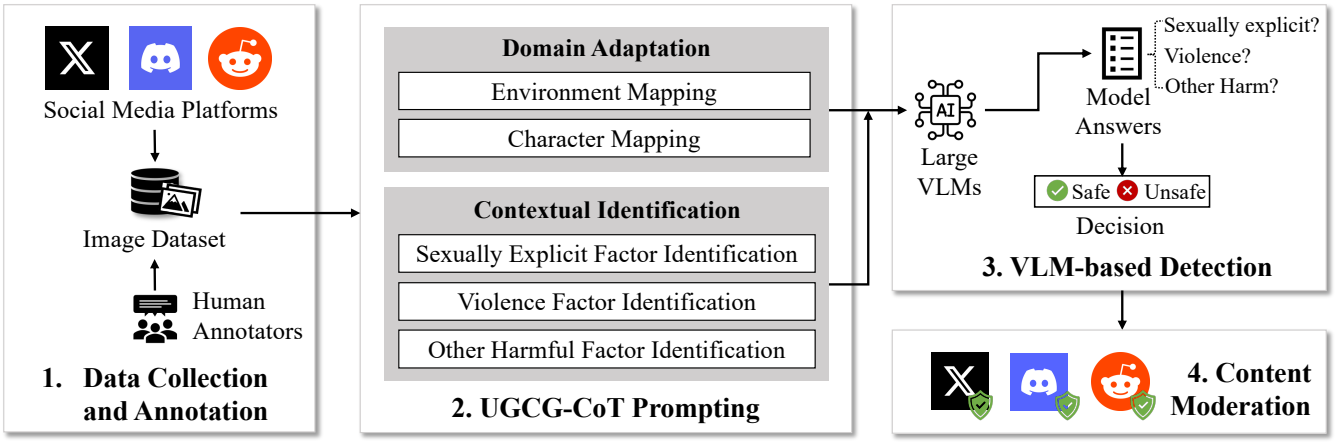


Figure 3: Overview of UGCG-GUARD.

AI, albeit the most effective among the evaluated models with a detection rate of 67%, falls short of the accuracy and reliability requisite for real-world content moderation applications. We believe that the superior performance of both human and anime images could be attributed to the similarity in the domain of these images, and also to the presence of training samples from both domains. Anime images, although animated, are semantically close to real human images, and are defined similarly to real humans. However, this is not the case for the UGCG images. As a result, this comparative analysis underscores the challenges in the detection of unsafe content within UGCGs: there is a marked domain shift in the case of UGCG images that renders existing systems severely limited.

5 UGCG-GUARD Design

5.1 Overview of UGCG-GUARD

The overview of our framework, UGCG-GUARD, is presented in Figure 3, which consists of four main components: (1) Data Collection and Annotation; (2) UGCG-COT Prompting; (3) VLM-based Detection; and (4) Content Moderation. The framework begins by compiling a dataset of illicit online promotional images for UGCGs, utilizing the methodology described in Section 4.1. UGCG-GUARD incorporates human annotators to verify and label images based on the activities identified from our study of unsafe UGCGs. Following this, we develop UGCG-COT prompts, a novel Chain-of-Thought (CoT) reasoning-based prompting strategy tailored to enable reasoning-based decision-making for the identification of images used for the illicit promotion of unsafe UGCGs, by addressing the challenges of domain shift and contextual reasoning posed by these images via conditional prompting and reasoning-based prompting. In the next stage, a large VLM is leveraged to run the prepared UGCG-COT prompts on a post with illicit promotional images, and the output from the VLM is parsed for answers to each of the UGCG-COT prompts. Finally, in our concluding stage, we use the parsed answer from the previous stage to determine whether the post contains illicit promotional images of unsafe UGCGs, and if yes, the post is flagged for moderation.

5.2 Our Approach

5.2.1 Crafting UGCG-COT Prompts

Navigating the intricacies of UGCGs requires our prompts to be adept at tackling the dual challenges of domain adaptation and contextual identification by leveraging large VLMs to make moderation decisions effectively. However, VLMs cannot be directly used for this purpose. In the following, we discuss how our novel CoT reasoning-based prompting approach, UGCG-COT, which is illustrated in Figure 4. This approach combines conditional prompting and reasoning-based prompting strategies and can effectively leverage VLMs to perform domain adaptation and contextual identification, respectively.

Conditional Prompting for Domain Adaptation. Domain adaption is a crucial methodology that facilitates AI/ML models in navigating and adapting to the transition between distinct domains, enhancing their performance and applicability across varied contexts [60, 61]. In this light, our domain-adaptation prompt is instrumental in aiding the model to delineate the nature of the provided images. We utilize conditional prompting for domain adaptation to instruct UGCG-GUARD to understand the specific characteristics of UGCG images in a zero-shot manner. More specifically, the purpose of conditioning in our approach is to refine the search space of VLMs, thereby enhancing the overall effectiveness of our approach. In our setup, we employed prompting as a method of conditioning, concentrating exclusively on images akin to those found in UGCGs. This strategy also aids in minimizing the influence of irrelevant training data on the model. This refinement is achieved through a two-step structure consisting

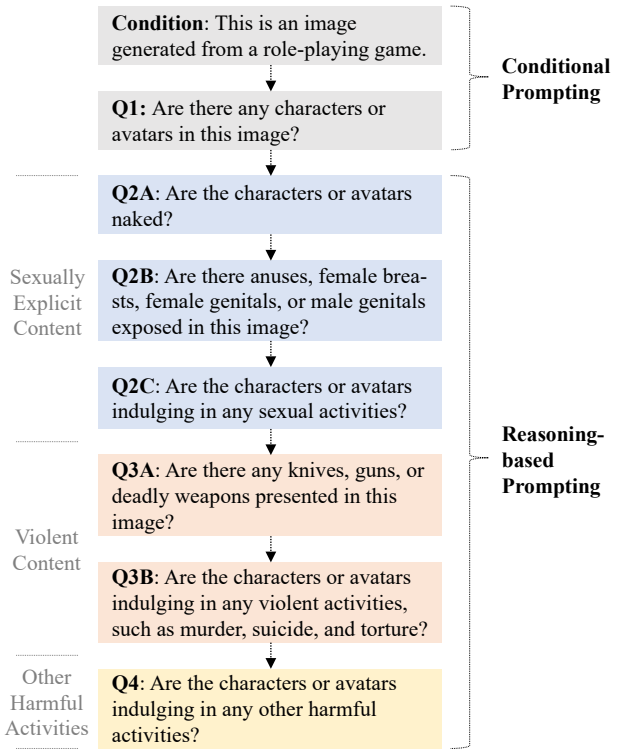

Figure 4: UGCG-CoT prompting.

of a condition and a guidance question. The condition articulated as *Condition*: *"This is an image generated from a role-playing game."* serves to anchor the model's understanding, clarifying that the image in question is a simulation, not a real-world photograph. This foundational insight is pivotal in ensuring the model's responses are contextually anchored. Complementing this, the guidance question Q_1: *"Are there any characters or avatars in this image?"* directs the model's attention to identify human-like figures within the UGCG images. This dual structure ensures that the model is not only informed of the simulated nature of the images but is also guided to focus on specific elements within them, facilitating a more refined and contextually appropriate analysis.

Reasoning-based Prompting for Contexual Identification. Having equipped large VLMs with the capability to interpret the distinct domain of UGCGs, we proceed to introduce reasoning-based prompts tailored to identify specific unsafe content categories, including sexually explicit material and violence. Such prompts enhance UGCG-GUARD ability to perform reasoning, consequently enabling the VLM to make contextual decisions [30] and ensuring that unsafe content can be identified and moderated. Our image filtering and annotation processes revealed a crucial observation: despite the pronounced domain shift characteristic of UGCG images, the attributes defining unsafe content remain analogous to those in traditional real-world images. Drawing inspiration from established methodologies in unsafe real-world image detection [54, 62–64], we meticulously crafted our contextual prompts. We pose the following question prompts to identify sexually explicit content: Q_{2A}: *"Are the characters or avatars naked?"*; Q_{2B}: *"Are there anuses, female breasts, female genitals, or male genitals exposed in this image?"*; Q_{2C}: *"Are the characters or avatars indulging in any sexual activities?"* To detect violent content, we incorporated these questions: Q_{3A}: *"Are there any knives, guns, or deadly weapons presented in this image?"*; Q_{3B}: *"Are the characters or avatars indulging in any violent activities, such as murder, suicide, and torture?"* We further exploit the analytical prowess of large VLMs with an additional question to uncover a broader spectrum of harmful activities: Q_4: *"Are the characters or avatars indulging in any other harmful activities?"* In the end, through our comprehensive Contextual Identification reasoning prompts, we equip large VLMs with the enhanced capability to efficiently identify and flag unsafe UGCG images, ensuring a balanced approach that is both domain-specific and context-sensitive.

5.2.2 Leveraging Large VLM for Processing UGCG-CoT Prompts

We leverage VLMs to process the UGCG images in conjunction with the UGCG-CoT prompts, with specific criteria to ensure optimal performance. The first requirement for running our prompts is that the selected VLM should be comprehensively trained on an extensive array of varied vision-language tasks. Training on both vision and language modalities allows VLMs to understand the commonalities among various input domains, thus giving them domain adaptation capabilities. Furthermore, the incorporation of powerful encoders ensures the precise extraction and processing of complex factors and features inherent in UGCG images. Our second requirement stipulates that the model must possess enhanced reasoning capabilities. This is paramount due to the intricate nature of UGCG images and the nuanced, potentially unsafe content embedded within them that needs contextual detection. The adoption of the chain-of-thought methodology [30] ensures advanced reasoning capacity. This approach has been empirically validated to significantly elevate the decision-making proficiency of large language models (LLMs) [30]. In this scenario, the role of LLMs becomes pivotal. They act as decision-making models that process vision and language, facilitating reasoning-based decision-making based on both textual and visual features. Moreover, LLMs, enriched by their extensive training datasets, are essential for embodying CoT reasoning, helping UGCG-GUARD leverage the extensive knowledge based on these models to make accurate decisions. Thus, the synergistic combination of large VLMs, intensively trained across a spectrum of tasks and endowed with amplified reasoning faculties, emerges as a suitable choice to run our prompts.

Our system leverages a VLM to operationalize our prompting strategy in the following way. Given im-

age input X_{vision} and supplemented by the UGCG-CoT prompts, characterized as the language input $X_{language} \in \{X_{language}^{condition}, X_{language}^{Q_1}, X_{language}^{Q_{2A}}, ...\}$, the output is computed as,

$$\hat{y} = \text{argmax } p(y|X_{vision}, X_{language}). \quad (1)$$

Using our UGCG-CoT prompts, we decompose the primary problem of detection of unsafe images used in the illicit promotion of unsafe UGCGs into a series of sub-problems. This enables a structured and sequential approach to decision-making, where the final output $\hat{y}$ is a culmination of insights derived from intermediate states. To be specific, the steps are as follows.

Step 1. We first condition the VLM to enable domain adaptation from the real-world context to the simulated gaming environment, enhancing its ability to interpret UGCG images. In this process, the model integrates and processes the UGCG image, denoted as X, in conjunction with a specified condition C. This integration tailors the model's attention features, represented as X_C, ensuring they are attuned to the nuances of the UGCG content within the image.

Step 2. We then condition the VLM to achieve domain adaptation from identifying real humans to identifying human-like figures within the UGCG image, depicted as follows:

$$A_1 = \text{argmax } p(a|X_C, Q_1), \quad (2)$$

where a is an intermediate answer that the VLM could output, such as *Yes*, *No*, *N/A*, etc. In this step, UGCG-GUARD identifies valid characters. If detected, the framework proceeds to perform a context check; otherwise, it allows the input image to pass through unchanged without further evaluation.

Step 3. Next, we prompt the VLM to check if sexually explicit content is presented in the input image.

$$\begin{aligned} A_{2a} &= \text{argmax } p(b|X_C, Q_{2A}), \\ A_{2b} &= \text{argmax } p(c|X_C, Q_{2B}), \\ A_{2c} &= \text{argmax } p(d|X_C, Q_{2C}), \end{aligned} \quad (3)$$

where $b, c, d, ...$ are intermediate answers as a in Equaiton 2.

Step 4. Then, we prompt the VLM to identify if violent content is presented in the input image.

$$\begin{aligned} A_{3a} &= \text{argmax } p(e|X_C, Q_{3A}), \\ A_{3b} &= \text{argmax } p(f|X_C, Q_{3B}). \end{aligned} \quad (4)$$

Step 5. In addition, we prompt the VLM to output whether other harmful activities are shown in the image.

$$A_4 = \text{argmax } p(g|X_C, Q_4). \quad (5)$$

Step 6. The final decision regarding the safety of a UGCG image is determined by aggregating all previous outputs from the VLM. If any of the contextual questions receive a positive answer *i.e.*, yes, the UGCG image is flagged as unsafe. This decision is represented as follows:

$$\begin{aligned} A_{\text{all}} &= \{A_{2a}, A_{2b}, A_{2c}, A_{3c}, A_4\}, \\ \hat{y} &= \begin{cases} \text{unsafe}, & \text{if } \exists a_i \in A_{\text{all}} : a_i = \text{yes}, \\ \text{safe}, & \text{otherwise.} \end{cases} \end{aligned} \quad (6)$$

5.2.3 Illicit Online Image Promotion Moderation

In this section, we outline the deployment of UGCG-GUARD for real-world social media platforms, as detailed in Algorithm 1. UGCG-GUARD employs the large VLM to evaluate promotional images of UGCGs systematically. Initially, it ascertains the presence of a valid character in the image. Subsequently, the framework assesses the content to identify sexually explicit or violent elements. Additionally, UGCG-GUARD scrutinizes the image for other potential safety concerns and annotates any identified issues. In the end, UGCG-GUARD aggregates the responses from the large VLM to determine the safety status of the promotional image. If an image is identified as "unsafe", UGCG-GUARD will flag the image and issue a warning stating why. Otherwise, UGCG-GUARD will approve the image for sharing on social media platforms. The comprehensive assessment ensures that images are flagged

Input: UGCG image X_{vision}, UGCG-CoT prompts $T = \{C, Q_{\text{dom}}, Q_{\text{sex}}, Q_{\text{violent}}, Q_{\text{harm}}, Q_{\text{dec}}\}$, Inference Function F, Large Vision Language Model (M);
Output: Safety prediction $\hat{y}$ with reason

```
                                        // Domain Adaptation
M_{X_C} ← M(X, C)
y_1 ← F_domain(M_{X_C}, Q_dom)
if y_1 = "no" then
    return y_1
end if
                                        // Contextual Identification
for q ∈ Q_sex ∪ Q_violent ∪ Q_harm do
    A_q ← F(M_{X_C}, q)
    if A_q = "yes" then
        continue
    end if
end for
                                        // Decision Making
if any A_q = "yes" then
    ŷ = 'unsafe'
    return ŷ,
      Flag the image and issue a warning with the reason.
end if
else
    ŷ = "safe"
    return ŷ, Approve the image for sharing.
end if
```

appropriately, enhancing the safety and quality of content on social media platforms.

6 Implementation and Evaluation

In this section, we first discuss the implementation of multiple components of our system, followed by experiments to evaluate our approaches to identify illicit promotional images of unsafe UGCGs from different perspectives. Our evaluation goals are summarized below.

- Understand the effectiveness of UGCG-GUARD by comparing it against existing baseline detectors. (§ 6.3)
- Analyzing the capability of UGCG-GUARD to address the challenge of the shift from traditional unsafe image to the UGCG input domain by comparing it with state-of-the-art object detection methods. (§ 6.4)
- Investigating the effectiveness of the conditioning process of UGCG-GUARD. (§ 6.5)
- Examining the effectiveness of the contextual identification process of UGCG-GUARD. (§ 6.6)
- Running UGCG-GUARD on "in-the-wild" samples from diverse social media platforms. (§ 6.7)
- Examining the limitations of traditional vision models for detecting unsafe UGCG images. (§ 6.8)

6.1 Implementation Details

In this section, we discuss the implementation specifics of UGCG-GUARD. We utilized the InstructBLIP model, *instructblip-vicuna-13b* [46], as our preferred large VLM for the large-scale execution and evaluation of UGCG-COT prompts. We deployed UGCG-GUARD with a High-Performance Computing (HPC) system equipped with two 40GB Nvidia A100 graphics cards. Most of our evaluation experiments were conducted using the labeled dataset described in Section 4.1, with an additional 322 illicit promotional UGCG images gathered from Reddit and Discord. This dataset formed as a test case that represented "in-the-wild" UGCG images, providing insights into the model's performance in real-world scenarios, as detailed in Section 6.7. In this experiment, we also built and evaluated UGCG-GUARD based on the GPT-4V(ision) model to demonstrate the generalizability of our framework. The other specific parameter settings, excluding those set to default values, are discussed in the evaluation.

6.2 Baselines

We evaluated UGCG-GUARD with several pertinent baselines to establish a comparative evaluation: (1) Google Vision AI, a SOTA commercial approach renowned for its efficacy; (2) A Convolutional Neural Network (CNN) model [65], trained with large-scale image data exceeding 60 gigabytes, comprises a diverse collection of real-world and animated NSFW images renowned for its benchmark performance [66]. In our experiment, we name it as "NSFW-CNN". (3) A general prompt for unsafe image detection, employing the same large VLM as UGCG-GUARD, to evaluate the impact of different prompt strategies on detection performance.

6.3 Comparison Against Baselines

In this experiment, we evaluated the efficacy of UGCG-GUARD in identifying image-based illicit promotion of unsafe UGCGs, comparing its performance against existing baseline detectors for unsafe images. We employed Google Vision AI [23] as a representative of cutting-edge commercial systems for unsafe image detection. Additionally, we considered the NSFW-CNN [66], a CNN model built upon MobileNetV2 architecture [67], which is fine-tuned on an extensive dataset of unsafe images to enhance its detection capabilities. Also, to understand the effectiveness of UGCG-COT, we contrasted its performance with the same large VLM model, InstructBLIP, which was probed using a general zero-shot prompting strategy, and our general prompt is crafted by aligning with the widely accepted definition of unsafe content [68], was phrased as follows: "Is this image unsafe? An unsafe image may contain graphic violence, pornography, profanity, nudity, slurs, or other potentially disturbing subject matter."

The results of our experiment are depicted in Table 2. The NSFW-CNN pre-trained model demonstrates the worst performance, as evidenced by its accuracy of 0.5 and F1 score of 0.47. This can be attributed to its high dependency on the dataset it was trained on. The images of UGCGs are very different compared to both real-world and animated visuals, presenting that the traditional pre-trained AI/ML models, such as the NSFW-CNN model, can not be sufficiently equipped to handle due to the training data limitations. Google Vision AI and InstructBLIP with a general prompt ("InstructBLIP-

Defenses	Accuracy	Precision	Recall	F1
Google Vision AI	0.68	0.79	0.68	0.65
NSFW-CNN	0.5	0.63	0.57	0.47
InstructBLIP -GEN	0.6	0.88	0.42	0.57
UGCG-GUARD	0.94	0.98	0.91	0.94

Table 2: Comparing UGCG-GUARD against the baselines.

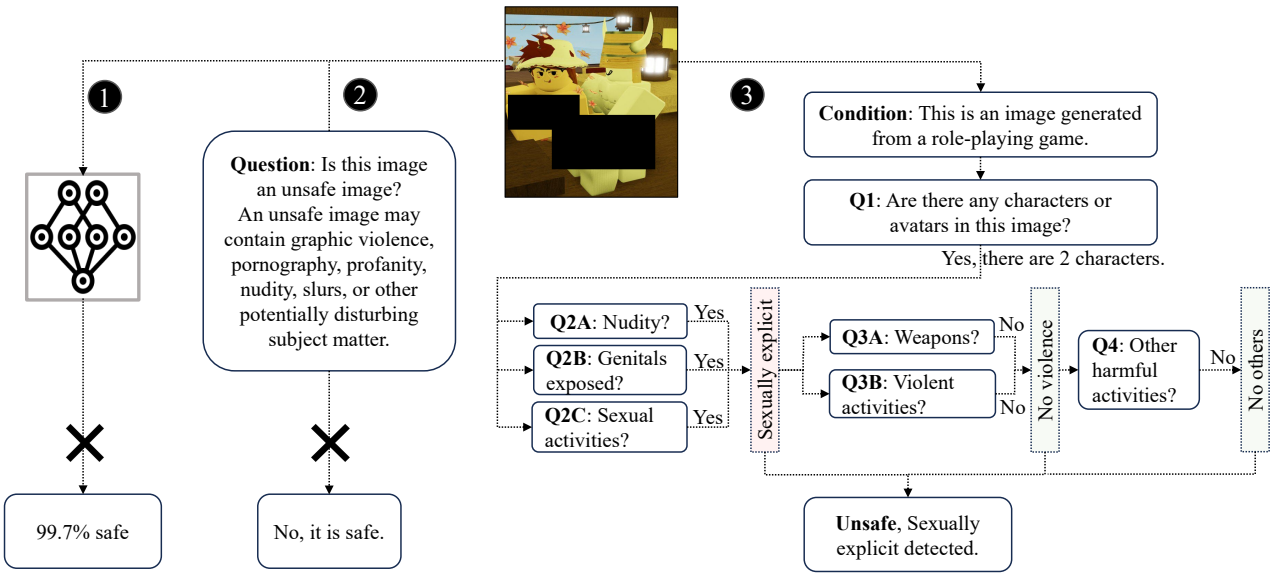

Figure 5: ❸ UGCG-GUARD for image-based illicit promotion of UGCG detection compared to ❶ traditional unsafe image detection models and ❷ large VLMs with general prompting strategy.

GEN") exhibit comparable results, with accuracy levels of 0.68 and 0.6, respectively. However, these systems are not suitable for practically flagging such content due to their limited efficacy. InstructBLIP-GEN excels in the precision score, indicating its strength in minimizing false positives. However, its recall is the lowest, pointing towards the limitation in identifying unsafe images of UGCGs. Google Vision AI has a more "balanced" performance, although it still achieves limited recall and F1 scores. UGCG-GUARD distinctly outperforms all the baselines, with an impressive accuracy of 0.94 and an F1 score of 0.94, indicating its effectiveness in flagging images-based illicit promotion of unsafe UGCGs. The results underscore the efficacy of employing chain-of-thought reasoning [30] in identifying unsafe UGCGs, as illustrated in the sample depicted in Figure 5. Unlike the general zero-shot prompting strategy that probes the large VLM once, UGCG-COT adopts a multi-step decision-making approach, integrating model conditioning and contextual questions. This method capitalizes on the large VLM's capabilities to enhance the detection of illicit promotional images of UGCGs through a structured reasoning process. It ensures that the final decision is not just an immediate output, but is derived from a comprehensive evaluation, resulting in increased precision and recall.

6.4 Capabilitiy of UGCG-GUARD in Domain Shift

In this experiment, our goal was to evaluate UGCG-GUARD's capability to interpret images of UGCGs, distinguishing them from the realm of traditional unsafe images. We focused on the response to question Q2 within UGCG-GUARD, detailed in Section 5.2.1. This approach allowed us to examine the adaptability of UGCG-GUARD in identifying the presence of characters or avatars amidst the domain shift to UGCG imagery. We assessed UGCG-GUARD's adaptability to this new domain by comparing it with four renowned object detection tools: Yolo [69], SSD [70], Faster RCNN [71], and Google Vision AI. These tools are capable of detecting objects that they're trained on and assign a confidence score to each prediction. In our study, we focused on the object "person" due to the nature of our task, in which unsafe images predominantly depict a persona. A threshold of 0.5 was established for the prediction scores to evaluate the performance of each model in identifying valid human-like figures in UGCG images. Three distinct datasets were employed to scrutinize the efficacy of each method. These include real-world and animated sexually explicit datasets, each containing 1,000 images, as detailed in Section 4.2.2, and an additional 1,000 sexually explicit images from our dataset. Each image in this custom dataset has been manually verified to contain human-like figures, ensuring consistency in our evaluation criteria.

Image Type	Yolo	SSD	Faster RCNN	Google Vision AI	UGCG-GUARD
Sexually-explicit-human	97.4%	98.8%	99.9%	89.6%	99.9%
Sexually-explicit-anime	97%	99%	99.9%	89.2%	100%
Sexually-explicit-UGCG	3.2%	18.2%	12.4%	12.8%	98.2%

Table 3: Comparing SOTA object detection tools.

Table 3 presents the results. Each technique demonstrates effectiveness in detecting real-world and anime people, with Faster RCNN and InstructBLIP achieving exemplary performance. However, their proficiency diminishes significantly when applied to UGCG sexually explicit images, with none of the object detection tools surpassing an 18.2% detection rate. In contrast, UGCG-GUARD is the only effective tool capable of identifying human-like figures in unsafe UGCG images, showing a remarkable 98.2% detection rate. The stark contrast in detection rates points out the significant shift in the input domain when transitioning from real-world and animated images to UGCGs, and the exceptional performance of UGCG-GUARD highlights the important role that large VLMs can play in adeptly navigating and overcoming this challenge, marking a notable advancement in adapting to and mitigating the complexities introduced by the diverse content in UGCGs.

6.5 Effectiveness of Conditioning Prompts

In this experiment, we investigated the impact of condition prompts in UGCG-COT, *i.e. Condition* and Q_1 as discussed in Section 5.2.1. To be specific, without the conditioning process, UGCG-GUARD probes the large VLM directly with contextual identification questions and derives conclusions based solely on their responses.

The results can be observed in Table 4. Without the conditional prompts, UGCG-GUARD exhibits notable performance, displaying an accuracy of 0.79 and an F1 score of 0.82, which significantly outperforms the baselines outlined in Table 2. The incorporation of conditioning, however, elevates UGCG-GUARD's performance exponentially. The precision escalates to an impressive 0.98, while recall advances to 0.91, denoting a substantial enhancement in identifying and capturing unsafe content of UGCGs. The results highlight the significance of the conditional prompts in narrowing the search space of large VLMs, enabling them to focus on knowledge pertinent to UGCG or similar images. This focus significantly boosts the overall efficacy of UGCG-GUARD in detecting unsafe content. This enhancement can also potentially be attributed to the combined vision and language training embedded in the large VLMs [43, 44, 72]. In contrast, visual models are solely trained on images. This dual training paradigm of large VLMs allows for a more comprehensive understanding and interpretation of content, leading to increased accuracy and efficiency in the detection of illicit UGCG images.

Methods	Accuracy	Precision	Recall	F1
UGCG-GUARD without conditioning	0.79	0.91	0.74	0.82
UGCG-GUARD with conditioning	0.94	0.98	0.91	0.94

Table 4: Comparison of UGCG-GUARD w/ and w/o the conditioning process.

Prompt Ablations		Detection Rate
Conditional Prompts +	only Q2A	86.5%
	only Q2B	56.6%
	only Q2C	42%
	only Q2A & Q2B	94.6%
	only Q2A & Q2C	93.3%
	only Q2B & Q2C	73.3%
	Q2A & Q2B & Q2C	98.2%

Table 5: Ablation study for reasoning-based prompts.

6.6 Effectiveness of Reasoning-based Prompts

In this experiment, we assessed the effectiveness of reasoning-based prompts for contextual identification. To illustrate this, we specifically focused on the application of these prompts in identifying sexually explicit content. Note that we ensured the consistency of our approach by maintaining conditional prompts for the domain adaptation process throughout all evaluations. We then applied specific reasoning-based prompts for identifying sexually explicit content, Q2A: "Are the characters or avatars naked?", Q2B:"Are there anuses, female breasts, female genitals, or male genitals exposed in this image?", and Q2C: "Are the characters or avatars indulging in any sexual activities?" to the same dataset of 1,000 sexually explicit UGCG images as mentioned in Section 4.2.2.

We further conducted an ablation study to evaluate the effectiveness of our reasoning-based prompting strategy. As shown in Table 5, we initially assessed the detection rates for each sexually explicit contextual identification prompt: Q2A, Q2B, and Q2C, with results of 86.5%, 56.6%, and 42%, respectively. These results indicate that while nudity is common in sexually explicit UGCG images, reliance on a single prompt for detection is inadequate. Subsequently, we evaluated the impact of removing each prompt individually. Removing Q2A decreased the detection rate from 98.2% to 73.3%. Eliminating Q2B made the detection rate drop to 93.3%, and upon removing Q2C, the rate decreased to 94.6%. The results demonstrate the remarkable effectiveness of UGCG-GUARD's reasoning-based prompts. Together, these prompts establish a comprehensive reasoning process, effectively guiding large VLMs toward accurate final decisions.

6.7 Running UGCG-GUARD on Unlabeled Samples "In-the-Wild"

We conducted an experiment on the *unlabeled* samples from two other social media platforms, Reddit and Discord, to simulate an "in-the-wild" running scenario that leverages our ap-

proach to control the real-world image-based illicit promotion of UGCGs. On Reddit, we employed the keywords associated with unsafe UGCGs, as identified in our preceding study detailed in Section 4.1, and manually collected a total of 112 images used for the illicit promotion of UGCGs. Of these, 33 were classified as safe, while 79 contained unsafe content. In the case of Discord, we obtained illicit promotional images of UGCGs utilizing a server listing platform [73]. This platform enabled our entry into a variety of Roblox game servers on Discord, leading to the discovery of 210 instances for image-based illicit promotions of UGCGs. Among these, 92 images were classified as unsafe, while the remaining 118 were safe. Subsequently, we evaluated UGCG-GUARD with these in-the-wild unsafe UGCG images and underwent an evaluative process, benchmarked against three pre-existing models: Google Vision AI [23], Clarifai [24], and NSFW-CNN [66]. The recent unveiling of GPT-4V(ision) [47, 74] has garnered significant attention, demonstrating exceptional performance in various studies [75, 76]. Our framework, UGCG-GUARD, with its adaptable architecture, can also be deployed based on different large VLMs such as GPT-4V. In this experiment, we assessed the generalizability of UGCG-GUARD by integrating it with both InstructBLIP and GPT-4V models.

Table 6 illustrates the results of the "in-the-wild" experiment. In this table, "R" stands for Reddit, "D" stands for Discord. Clarifai underperforms on both Reddit and Discord datasets, with F1 scores significantly lower than 0.5, indicating its limited capability in identifying unsafe UGCG images effectively. Compared to other baselines, NSFW-CNN achieved better performance with an average F1 score of 0.58. However, it still falls short of the feasibility required for practical applications. Despite Google Vision AI achieving comparatively decent results on both datasets with an average F1 score of 0.78, its low recall, especially for UGCG images from Reddit, suggests that this popular commercial detector is currently insufficient to meet the challenges posed by such illicit online image promotions. Both InstructBLIP-based UGCG-GUARD and GPT-4V-based UGCG-GUARD achieved significantly better results, outperforming other baselines. UGCG-GUARD integrated with InstructBLIP achieved an impressive average accuracy of 0.92 and an average F1 score of 0.93

Detectors	Accuracy		Precisioin		Recall		F1	
	R	D	R	D	R	D	R	D
Clarifai	0.44	0.73	1	1	0.22	0.27	0.36	0.43
NSFW-CNN	0.57	0.78	1	1	0.4	0.41	0.57	0.58
Google Vision AI	0.71	0.87	0.98	0.96	0.59	0.74	0.74	0.83
UGCG-GUARD (InstructBLIP)	0.91	0.93	0.96	0.88	0.92	0.98	0.94	0.92
UGCG-GUARD (GPT-4V)	0.88	0.9	1	0.97	0.83	0.79	0.91	0.88

Table 6: The "in-the-wild" experiment.

Figure 6: Samples of sexually explicit images used in the ablation study.

across the Reddit and Discord datasets, highlighting its exceptional ability to identify unsafe UGCG images. Similarly, UGCG-GUARD integrated with GPT-4V also showed strong results, with an average accuracy of 0.89 and an F1 score of 0.9, confirming its effective adaptability across different large VLMs. The overall performance, with an average F1 score of 0.91, validates the possibility of UGCG-GUARD for real-world deployment, and it also underscores the generalizability in detecting unsafe UGCG images within various resources.

6.8 Comparison Against Traditional Vision Models

In this experiment, we study the limitations of traditional, vision models for the detection of unsafe UGCG images. We fine-tune a ResNet-based CNN model [77] utilizing 80% of the samples from our annotated UGCG image dataset and the rest for testing. We conducted an ablation study, where we removed the sensitive regions of 20 unsafe UGCG, as depicted in Figure 6, and analyzed them with both the ResNet model and our system. These images should ideally not be considered sensitive since sensitive regions in these images have been removed. This enables us to discern if the ResNet model was effectively identifying unsafe UGCG images contextually, thereby ensuring its effectiveness in detecting such content reliably, or whether they are training on unrelated visual artifacts, like skin color patterns in sensitive images.

Initially, we tested the ResNet model on unaltered samples, achieving 0.9 accuracy and a 0.87 F1 score, competitive with UGCG-GUARD. Subsequently, we processed 20 modified images through our system, accurately identifying 18 as "safe" due to the removal of explicit content. However, the CNN model labeled all modified images as "unsafe". These outcomes underscore a critical observation: the traditional ResNet model, although adept in certain contexts, tends to overfit, becoming overly sensitive to specific visual cues that are not directly associated with unsafe content and is not practically suitable due to a high false positive rate. It highlights

an inherent limitation in its capacity to distinguish between genuine unsafe elements and incidental visual patterns. This revelation underscores the necessity for a more refined and nuanced architecture like UGCG-GUARD that is adept at detecting unsafe images in a contextual manner.

7 Discussion

Limitations. Our study has several limitations. First, our analysis is based on reviews obtained from Common Sense Media. Although this platform offers a rich array of insights from young users and parents, facilitating the identification of four distinct unsafe topics within UGCGs, it exclusively features English content. This linguistic limitation potentially narrows the scope of uncovered unsafe content in other languages and cultures. Broadening the research to incorporate additional review and community platforms, especially those in diverse languages, could yield a more nuanced and comprehensive understanding of the unsafe content prevalent in UGCGs. The evaluation of "in-the-wild" scenarios was constrained by a manually collected dataset, which has a limited number of data from Reddit and Discord. To enhance the generalizability of UGCG-GUARD, efforts will be enhanced towards amassing a broader dataset from various popular social media platforms. It will not only solidify the robustness of UGCG-GUARD but also ensure its efficacy and adaptability for real-world digital environments. Another limitation is that the focus of our study is currently confined to UGCGs within Roblox. Numerous other platforms exist, such as Minecraft [78], Terasology [79], and LEGO Worlds [80], which enable users to create their content and attract a significant population of children and adolescents. It is plausible that unsafe activities prevalent in Roblox might also be present in these platforms, and potentially manifest distinct characteristics that necessitate specific moderation strategies. Therefore, extending the analysis to include these platforms could provide a more holistic understanding of the safety challenges associated with UGCGs. Additionally, we observed that illicit promotions of unsafe UGCGs occasionally employ diverse modalities, including GIF images and short videos. We believe that once we collect enough data for these varied content formats, the incorporation and evaluation could fortify our analysis, offering a more comprehensive assessment of the multifaceted nature of the illicit promotion of unsafe UGCGs.

Ethical Considerations. In our work, we annotated the illicit promotional images of unsafe UGCGs by three of the authors, and no additional workers were recruited in the whole study. Our data collection task was approved by IRB. Every author participant in the process understands the unsafe content before our task. In our paper, we ensured the removal of mentions to user accounts so that no user information could be traced via public social media. In addition, we will take all the necessary steps, such as only sharing the data with verified researchers.

In-game Content Moderation Our present work is centered on identifying and moderating the image-based illicit promotion of unsafe UGCGs, a crucial endeavor given the associated risks posed to online users, particularly children [2]. However, we believe that the insights gleaned from our current research can shed light on the expansion of future work on in-game unsafe content moderation. By moderating both the game promotions and UGCGs themselves, we can minimize the dangers posed by the UGCGs as comprehensively as possible, thereby protecting users, especially young individuals, shielding them from exposure to unsafe content and activities.

8 Conclusion and Future Work

In this work, we have embarked upon an initial journey to understand and detect the threat of illicit promotion of unsafe UGCGs. We have conducted an insight study to understand the limitation of existing unsafe image detectors and present the urgent need for effective moderating mechanisms. With the studies, we proposed a novel framework UGCG-GUARD to practically address the problem of image-based illicit UGCG promotions. Our evaluation demonstrates that UGCG-GUARD can effectively capture the unsafe images used in the illicit promotion of unsafe UGCGs.

In the future, we plan to extend our framework to adapt it for moderating not only image-based illicit promotions but also in-game unsafe content. Furthermore, the evolving landscape of Virtual Reality (VR) presents both novel opportunities and challenges. We envision an extension of our work into the VR domain, adapting and enhancing our methodologies to address the special and complex safety challenges that arise in these immersive environments.

Abstract

With the recent proliferation of Large Language Models (LLMs), there has been an increasing demand for tools to detect machine-generated text. The effective detection of machine-generated text face two pertinent problems: First, they are severely limited in generalizing against real-world scenarios, where machine-generated text is produced by a variety of generators and spans diverse domains. Second, existing detection methodologies treat texts produced by LLMs through a restrictive binary classification lens, neglecting the nuanced diversity of artifacts generated by different LLMs, each of which exhibits distinctive stylistic and structural elements. In this work, we undertake a systematic study on the detection of machine-generated text in real-world scenarios. We first study the effectiveness of state-of-the-art approaches and find that they are severely limited against text produced by diverse generators and domains in the real world. Furthermore, t-SNE visualizations of the embeddings from a pretrained LLM's encoder show that they cannot reliably distinguish between human and machine-generated text. Based on our findings, we introduce a novel system, T5LLMCipher, for detecting machine-generated text using a pretrained T5 encoder combined with LLM embedding sub-clustering to address the text produced by diverse generators and domains in the real world. We evaluate our approach across 9 machine-generated text systems and 9 domains and find that our approach provides state-of-the-art generalization ability, with an average increase in F1 score on machine-generated text of 11.9% on unseen generators and domains compared to the top performing supervised learning approaches and correctly attributes the generator of text with an accuracy of 93.6%. We make the code for our proposed approach publicly available at https://github.com/SecureAIAutonomyLab/LLM-Cipher

1 Introduction

In the recent years, we have witnessed the explosive adoption of Large Language Models (LLMs), ushering in a new era of natural language processing. LLMs, such as ChatGPT [8], have demonstrated remarkable proficiency in generating human-like text, comprehending intricate nuances, and even performing tasks that traditionally required human intuition. Despite these successes, there has been increasing concern around these publicly available models being used in problematic applications such as to spread fake news [18]. In addition, there's evidence showcasing the ability to adapt and fine-tune LLMs for specific purposes quickly. Notably, Grover [63], which is based on the GPT-2 [49] architecture, was introduced just months after the release of GPT-2. In light of the advancements and capabilities of LLMs, there has been a burgeoning interest in discerning machine-generated text from human-generated text [23].

Although strides have been made in identifying machine-generated text in recent times [40], there has been little research in working towards methods that can effectively distinguish human and machine-generated text in real-world scenarios by malicious actors who have access to wide-ranging resources. Detecting machine-generated text in real-world scenarios faces two pertinent problems. *First*, given the escalating proliferation and sophistication of LLMs, adversaries can utilize a wide variety of LLMs through publicly available models [7] or even use one of the many publicly available APIs [1, 2, 9] to generate machine-generated text. In addition to utilizing a variety of models for text generation, adversaries can produce content in a wide range of domains [55], which presents a formidable challenge for current detection mechanisms. While existing detectors perform effectively on text generated from known generators or domains, they cannot generalize well on machine-generated text from diverse generators or domains [47]. *Second*, existing approaches for detecting machine-generated text consider these diverse generators as belonging to a single distribution. However, each text generator creates text that exhibits distinctive stylistic

and structural elements [29]. Considering the detection of machine-generated text as a binary problem oversimplifies the nuanced differences between generators and potentially reduces the effectiveness of detectors on unseen generators.

In this work, we take the first step towards developing a generalized strategy for detecting human vs. machine-generated text across diverse generators and domains. Given the challenge of texts produced by various generators across multiple domains, we carried out a study to detect machine-generated content in real-world settings, taking into account an array of generators and domains. We begin by evaluating the performance of current state-of-the-art methods [47]. Our findings suggest that these techniques face severe challenges in pinpointing text from diverse generators and across different domains with the top performing model showing an average F1 score of just 53.7% on this diverse data. Upon examining the distribution of embeddings from a pretrained LLM's encoder from a t-SNE visualization, we discover that there is potential in utilizing this embedding for differentiating between human and machine-generated texts.

Based on this observation, we propose to build a system designed to detect machine-generated text in real-world scenarios. We broadly address the following research questions: 1) Can we show how previous methods fail to generalize? 2) Can the encoders from LLMs be used to underpin an approach for generalized machine-generated text detection? 3) Are there fingerprints that can be detected to distinguish between multiple text generators? Guided by these research questions, we develop our system to detect machine-generated text. We present our system, T5LLMCipher, which uses a pretrained LLM encoder to extract the embeddings of diverse texts and improves generalization to in-the-wild machine-generated text by framing it as a multi-class classification problem. Investigating 9 machine text generators and 9 text domains, we find that our top-performing detector is able to correctly attribute the generator of a text with an accuracy of 93.6% and outperforms existing baselines by 19.6% for the task of detecting human vs machine-generated text on unseen domains and generators of machine-generated text, showing that these generators have specific fingerprints that can be detected. We further show in these experiments that multiclass classifiers may generalize better than binary classifiers for the binary classification task of detecting human vs machine-generated text in-the-wild. Then, we investigate classification architectures towards the analysis of the embeddings from the LLM encoders and show that classifiers built on these embeddings can be adversarially robust and provide state-of-the-art generalization to unseen generators and domains for machine-generated text detection.

Our work makes the following contributions:

- **New Findings.** We study the limitations of state-of-the-art methods in detecting machine-generated text created in real-world scenarios. Furthermore, we show that the embeddings from LLM encoders can be leveraged to robustly discern human-generated from machine-generated text. Our findings shed light on the severe limitation of existing methods on real-world machine generated text, and paves the way for developing methods that can detect machine-generated text in a generalized manner.

- **New Detection System.** We present a new machine-generated text detection system, T5LLMCipher, to robustly detect text as being machine generated using the embeddings from LLM encoders.

- **Comprehensive Evaluation.** We demonstrate that classifiers trained for the multi-class classification task of generator attribution show superior generalization and adversarial robustness to binary supervised classifiers in detecting in-the-wild machine-generated text.

2 Background

As the digital landscape evolves, ensuring security on social media platforms has become a paramount concern. One salient issue is the spread of false information. Platforms like X (formerly Twitter) [11] have attempted to address this by labeling misleading content. However, these interventions often lack uniformity, leaving considerable amounts of deceptive content unflagged [45]. Systems like LAMBRETTA have emerged as a response, offering automated solutions that outpace traditional methods by identifying and flagging erroneous information [45]. Beyond misinformation, a subtler but equally concerning issue is the proliferation of machine-generated profiles. LinkedIn, a prime example, is combating the rise of such fake profiles, as they pose risks ranging from privacy breaches to phishing attempts. Techniques like the Section and Subsection Tag Embedding (SSTE) have been developed to differentiate between legitimate and artificial profiles, even those generated by sophisticated language models [14]. The weaponization of social media, from manipulating public opinion to outright media warfare, only intensifies the need for robust security measures [21]. Amid these challenges, the detection of "toxic comments" also remains a focal point, with tools like the regression vector voting classifier (RVVC) aiming to combat online hostility [51]. As these various threats underscore, there's a pressing need for advanced detection mechanisms. Leading into this context, the challenge of discerning machine-generated text from human-authored content has emerged as a crucial problem, necessitating the development of robust detection methodologies.

In the realm of detecting machine-generated text, the literature has predominantly converged around three overarching strategies [23]. Many of the first approaches for detecting machine-generated text were feature-based approaches, which emphasize a myriad of characteristics, encompassing word frequency, a spectrum of statistical features, fluency markers,

and the consistency of linguistic attributes. More recently, there has been increasing focus on approaches to zero-shot methodologies, which intriguingly deploy the generative models themselves as tools to pinpoint machine-crafted content. Finally, there exists a set of techniques that engage in the fine-tuning of language models specifically for the detection of text generated by machines.

One of the subsets of statistical features leveraged in detecting machine-generated text revolves around term frequencies within text samples. Text authored by humans typically aligns with Zipf's Law, where the most frequent word in human-written text has roughly twice the frequency of the second most frequent word, and nearly three times that of the third most frequent word and so on [43]. Another feature-based method for detecting machine-generated text focuses on clarity and coherence. Earlier models like GPT-2 have shown that in longer outputs, there is a higher likelihood that inconsistencies, redundancy, or logical errors will emerge [53]. Some works build classifiers on bag-of-words features and TF-IDF [24] to analyze shorter text sequences. Other works such as Fröhling et al. [25] combine several features, including lack of syntactic and lexical diversity, repetitiveness, and extract linguistic features such as named entities and part-of-speech distributions to build a neural network classifier on this information. However, a notable limitation of these statistical and feature-based methods is their potential vulnerability to more advanced language models, which continually improve in generating human-like text patterns and linguistic diversity.

Zero-shot methods for detecting machine-generated text have garnered attention due to the lack of need to train models on large datasets. Works such as those by Gehrmann et al. [27] find that human-written texts exhibit a broader range of word choices, whereas machine-generated texts tend to be more constrained and predictable and calculate entropy on text sequences to help distinguish machine-generated text from human-generated text. Other works used simple log-probability thresholding, where LLM token probabilities are averaged and a threshold is determined [56]. Recent works like DetectGPT [40] take this idea further by introducing the observation that the curvature of a model's log probability function is typically more negative for machine-generated text compared to human-written text. Building on this insight, their algorithm leverages the hypothesis by approximating the log probability function's Hessian, and thresholding based off of the difference between perturbed samples and the input sample. However, these methods require access to the token probabilities of the models they are trying to detect.

Another class of methods is fine-tuning methods which utilize pretrained language models to identify machine-generated text. One detection method leverages energy-based models alongside a RoBERTa model [38], which were fine-tuned on datasets of machine-generated text [15]. More recent works including GPT-Sentinel also leverage a pretrained T5 model [50] and use a multi-layer-perceptron module to classify the hidden state vector of input, to directly encode the task as a sequence-to-sequence (seq-to-seq) problem [22]. Among this class of works, it is consistently demonstrated that the performance of fine-tuned models is heavily influenced by the specific models and datasets on which they are trained. There is a prevailing observation that these models struggle to generalize effectively when encountering generative models not present in their fine-tuning datasets. Additionally, for optimal performance, it is essential that these models are exposed to a diverse array of topics and writing styles during their training phase. Furthermore, the generation of these datasets may also prove to be expensive if attempting to include a greater and greater number of LLMs within the dataset to aid in generalization.

Overall, while these approaches have been shown to generalize well when applied to different LLMs, but have not necessarily shown good generalization *between* different LLMs and text domains. Given the growing number and complexity of LLMs, generalizable systems for detecting machine-generated text are of upmost importance.

3 Threat Model and Problem Scope

3.1 LLM Text Generation Objective

The core objective during the training of autoregressive language models is captured by the equation:

$$L(\theta) = -\log \prod_{i=1}^{n} f_\theta(x_i | x_1, \ldots, x_{i-1}) \tag{1}$$

This equation portrays the negative log-likelihood of a model with parameters θ, where the objective is to predict each token in a sequence based on its preceding tokens. Minimizing this likelihood value signifies that the model assigns higher probabilities to observed sequences, indicating a better fit to the training data.

However, as straightforward as this equation may appear, the ultimate behavior and artifacts of an LLM are influenced by several factors. The distribution and nature of the training data shape the model's behavior. For instance, an LLM trained on a broad, multi-domain dataset might demonstrate extensive generalization capabilities. In contrast, a model trained on niche data could display a more narrow understanding. Patterns present in the training data may manifest as artifacts in the machine-generated text. The model architecture further complicates how Equation 1 is learned. Choices surrounding the number of layers, attention mechanisms, and other hyperparameters can lead to differences in the artifacts present in the text outputs.

3.2 Threat Model

In the context of machine-generated text detection, we are introduced to two main parties at the heart of our investigation.

The first party is comprised of adversaries that produce or disseminate machine-generated text. These adversaries may leverage publicly available models, fine-tune existing models, use existing machine-text API, or even train their own LLM. One of the goals of the adversary is to evade detection of their use of machine-generated text. To evade detection, adversaries may use state-of-the-art LLMs to closely mimic the distribution of human texts or use adversarial attacks to perturb machine texts specifically to avoid detection by automated detectors. LLMs can craft texts that are increasingly indistinguishable from human-generated texts, presenting a complex challenge for detection systems. The second party is made of those invested in distinguishing between human and machine-generated text. A significant constraint faced by these stakeholders is their lack of prior knowledge about which specific LLM has been employed to produce any given text or the domains in which they may generate texts for. The primary objective for this party is to detect and flag content that is solely the product of machine generation.

Our study is anchored in scenarios where language models craft entire paragraphs, setting aside considerations of adversarial prompting [39, 64] or paraphrasing-based attacks [52] for future exploration. Additionally, we do not delve into detecting texts that were initially machine-generated but later edited by humans. Such texts, with their blend of human and machine nuances, introduce complexities in detection that lie outside of the scope of this work. Instead, our primary aim is centered on the pinpoint identification of text that is solely the product of machine generation.

4 Data

This work leverages diverse datasets collected by Wang et al. [61] in the M4 dataset to construct a robust detector for machine-generated text. We focus on the English corpora they released so that we can compare our approach against other in-the-wild machine-generated text datasets. We analyze five sources of human-generated data and five LLMs used to generate machine-generated text from the M4 dataset [61], for a total of 126,950 text samples. These LLMs are ChatGPT (gpt3.5-turbo) [6], davinci-003 [6], Cohere [3], Dolly-v2 [4], and BLOOMz [41]. Additional discussions on dataset assumptions and experiments that assess the quality of the machine-generated texts in the are detailed in Appendix A.2. This appendix presents results from an automatic evaluation using Universal Sentence Encoder [20], alongside human evaluations that assess the stylistic and semantic similarity between the human and machine-generated texts. The human text sources and the corresponding text generation strategies are described below, with further prompt details provided in Appendix A.1:

- **Wikipedia:** Comprises 3,000 articles from Wikipedia, each exceeding 1,000 characters. LLM's are given titles as prompts for generating new articles.

- **Reddit ELI5:** A collection of 3,000 preprocessed question and response pairs from subreddits r/explainlikeimfive, r/askscience, and r/AskHistorians. Questions are used as prompts for the LLM to generate an answer.

- **WikiHow:** Consists of 3,000 articles from WikiHow, each with a title, headline, and text. Articles are generated by LLMs using titles and headlines from the human data as prompts.

- **PeerRead Reviews:** The dataset includes title, abstract, and multiple human reviews of 586 papers from top-tier conferences in NLP and machine learning. Four different prompts to the LLM are used to create machine-generated peer reviews.

- **Arxiv Abstract:** This dataset includes 3,000 abstracts from Arxiv, each with a minimum of 1,000 characters. Abstracts are generated by LLMs using titles from the human data as prompts.

For our experiments on in-the-wild data, we use the in-the-wild data released by Pu et al. [47]. Each of these datasets of machine-generated text also contain an equal number of human-generated text from which the machine-generated text was spawned. The details of this data is presented below:

- **AI-Writer:** 1,000 real news articles were scraped from 20 popular news websites, sampled from the RealNews [63] dataset. Using the titles from these real articles, 1,000 synthetic articles were generated through the AI-Writer [1] service, which employs custom Transformer-based LMs.

- **ArticleForge:** 1,000 real news articles were collected, and using a set of keywords from these, 1,000 synthetic articles were generated through the ArticleForge [2] service, which utilized fine-tuned versions of GPT-2, BERT, and T5 for text generation.

- **Kafkai:** 1,000 real articles from 10 different categories were used as priming text to generate 1,000 synthetic articles through the Kafkai [9] service, which used fine-tuned models from OpenAI, including GPT-2.

- **RedditBot:** 887 real comments with a length greater than 192 tokens were randomly sampled from forum threads on Reddit, matched with 887 machine-generated comments generated by a GPT-3 powered bot under the username /u/thegentlemetre on /r/AskReddit.

5 Motivation

Numerous studies on machine-generated text detection employ a variety of domains and generators for testing purposes [13, 35]. Despite this diversity in evaluation, we demonstrate that many of the models developed and validated by these studies exhibit a failure to generalize effectively across domains and generators. These models, while perhaps adept at handling the specific types of machine-generated text present in their respective training environments, falter when applied to external datasets, underscoring a significant limitation in their practical utility and application.

We conduct a preliminary experiment to show that existing state-of-the-art methods for detecting machine-generated text fail to generalize to unseen data. To accomplish this, we test four of the models presented in the work of Pu et al. [47]: BERT-Defense, GLTR-BERT, GLTR-GPT2, and RoBERTa-Defense. GLTR-BERT and GLTR-GPT2 exploit the insight that synthetic text often contains tokens that are deemed highly probable by language models. GLTR extracts features based on the token probability distributions, such as the number of tokens in the Top-10, Top-100, and Top-1000 ranks. A logistic regression classifier then processes these extracted features. There are two GLTR variants: GLTR-BERT, which utilizes BERT as its backend LM, and GLTR-GPT2, which uses GPT2-XL. The training setup used WebText for real articles and GPT2-XL for synthetic ones, with a training set size of 4,000 articles per class. BERT-Defense is a binary classifier that builds upon the pre-trained BERT-Large LM by adding a classification layer. The defense is trained and tested using the WebText dataset for real articles and GPT2-Large for the synthetic ones, with a training set size of 10,000 articles for each class. RoBERTa-Defense is inspired by BERT-Defense but is built on the pre-trained RoBERTa with the addition of a classification layer. The RoBERTa-Defense model training setup is on the RealNews dataset for genuine articles and GROVER for synthetic ones, which comprises of 5,000 articles for each class.

We evaluate these models on a recently released dataset of machine-generated text [61], and show the F1 score of these detectors with respect to the machine-generated text. We test on the Arxiv, PeerRead, Reddit, Wikihow, and Wikipedia domains with the ChatGPT and Dolly generators. Further details about this dataset can be found in Section 4. The results of this experiment can be found in Table 1. These experiments reveal significant variations in the detection performance when state-of-the-art detectors are evaluated against unseen generators and domains. While the GLTR-BERT model shows good performance on the Reddit domain, this performance does not generalize well overall with an average F1 score of just 56.3. This inconsistency in performance is particularly detrimental in the context of security applications where detectors play a pivotal role in identifying and mitigating malicious activities. In scenarios where security is paramount, the ability of detectors to accurately identify machine-generated content from unknown generators and domains is vital.

Table 2: ΔR of existing detectors against black-box adversarial attacks. "+" indicates an improvement in performance, "-" indicates a deterioration in performance. "NA" values indicate that the baseline recall was 0.

To further show the vulnerability of existing methods, we evaluate the same detectors except for one against a recently introduced adversarial attack, called DFTFooler [47], where we generate adversarial samples designed to evade model detection. Following the evaluation strategy of DFTFooler, we calculate the percentage change in recall, ΔRecall (ΔR). We use this metric to evaluate model resilience to adversarial attacks because it quantifies the change in how well a model correctly identifies the machine-generated text under these attacks. A significant drop in recall indicates the model's vulnerability, as it fails to identify many adversarially altered instances correctly. The results presented in Table 2 underscore the vulnerabilities of current text detection methods against adversarial attacks. Examining the ΔR for both ChatGPT and Dolly generators, we observe a notable trend: GLTR-GPT2 consistently yielded a 100% drop in recall, highlighting its susceptibility to these attacks irrespective of the text domain. Furthermore, while the performance of detectors such as GLTR-BERT and RoBERTa-D varied based on the dataset, several instances showcased deterioration in performance, ranging from 70-90%. While the (ΔR) on BERT-D shows pos-

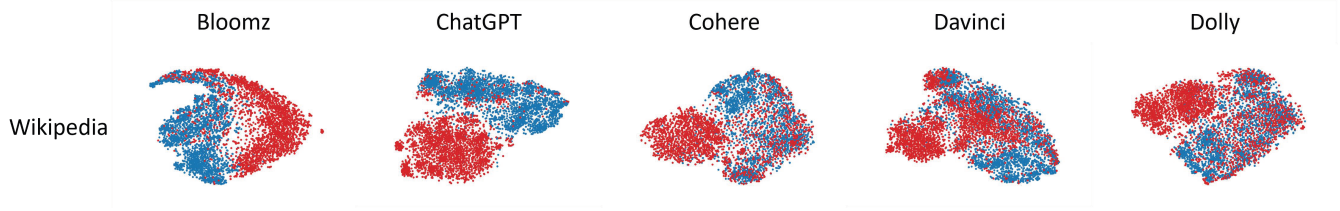

Figure 1: t-SNE visualization of T5 embeddings illustrating the distribution of Human (blue), and Machine (red) generated text. While there is some degree of separation, considerable overlap is still evident.

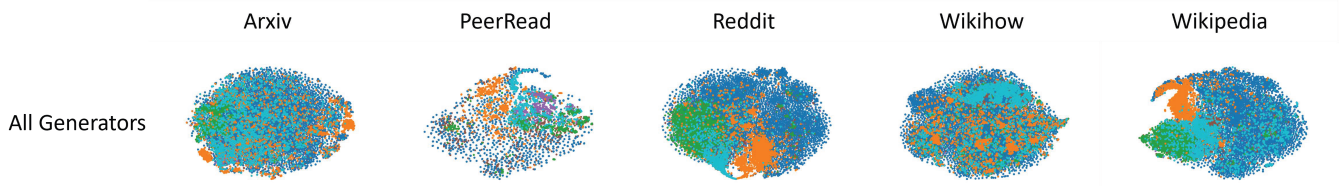

Figure 2: t-SNE visualization of T5 embeddings illustrating the distribution of Human (blue), Bloomz (orange), ChatGPT (green), Cohere (teal), Davinci (purple), and Dolly (brown) generated texts across different domains. It is even more difficult to distinguish the source generator in the multiclass setting.

itive values, meaning the adversarial attack actually increased the detection performance on adversarially perturbed samples, the baseline recall was already so low that the perturbations flipped the decisions on some of the originally incorrect predictions to being correct predictions. Such high drops in recall by the models accentuate the pressing need for enhancing the robustness of current detection methods, as even these advanced models demonstrate significant vulnerabilities in the face of adversarial attacks.

To underscore a potential method that could be used to robustly identify machine-generated text, we demonstrate that machine-generated text possesses unique characteristics or 'fingerprints' that can be identified and analyzed through the encoder of an LLM. For this experiment, we use text embeddings generated using the Google Flan-t5-xl implementation available on Huggingface [5]. This model is known for its effectiveness in capturing the semantic and syntactic nuances of text, making it a suitable choice for generating embeddings that can reveal the subtle differences between human and machine-generated content. Further details regarding the data utilized in this experiment are provided in Section 4. At the same time, insights into the specific parameters and configuration of the T5 model employed are documented in Section 7. We present the t-SNE of these embeddings to visualize a starting point for our proposed method of using LLM encoders to discern machine-generated text. t-SNE is a non-linear dimensionality reduction technique adept at embedding high-dimensional data for visualization in a two-dimensional space. It calculates the pairwise similarities between data points in the high-dimensional space and endeavors to find a low-dimensional representation that upholds these similarities [59]. Importantly, because t-SNE operates as an unsupervised algorithm, it doesn't rely on the true labels of the data. As a result, observing any degree of clustering or separation between classes in the t-SNE visualization is particularly encouraging.

In Figure 1, we present the t-SNE visualization of text embeddings derived from wikipedia text comprising both machine and human-generated text, as detailed in the study by Wang et al. [61]. The preliminary results from the t-SNE experiment are encouraging, showing some separation between human and machine-generated text in the reduced-dimension space created by t-SNE. While there is considerable overlap between the human and machine-generated texts, such initial findings warrant further exploration and analysis into these embeddings. Given that this embedding was never trained to discern human text from machine text, it shows potential to be developed into a robust classifier. The observed separation provides a foundation on which we can apply techniques like contrastive learning or deep neural networks to further refine the distinction between machine-generated and human-generated texts. In the subsequent Figure 2, we delve deeper, showcasing the t-SNE visualizations encompassing six distinct classes: human text and five different machine text generators. Here, the interplay of the classes paints a more complex picture. Figure 2 shows the increased complexity in distinguishing human-generated text from a diverse array of machine-generated sources, as compared to differentiating human text from a singular machine source. Given that there is some marginal difference in the distribution of the embeddings between the different generators even in this unsupervised visualization suggests that, with further refinement and training, the LLM embedding could be harnessed

to attribute the source generator of a specific text piece. This insight broadens the scope of our research, indicating that not only can we detect machine-generated content, but we might also be able to pinpoint its origin.

6 Approach

To effectively discern machine-generated from human-generated text, we leverage the power and sophistication of Large Language Model (LLM) encoders. These encoders, which have been proven adept at generating dense and semantically rich embeddings of textual data [62], serve as the foundation of our methodology. By feeding both human and machine-generated texts into such an encoder, we extract embeddings that inherently capture the unique characteristics and intricacies of each text type. These embeddings are then stored for further analysis. Atop these embeddings, we construct classifiers from Multilayer Perceptrons (MLPs) and K-Nearest Neighbors (KNN) to more advanced, contrastive learning-based KNN classifiers. We call this approach T5LLMCipher, based on the T5 [50] LLM encoder that we use in our implementation. In the ensuing sections, we describe LLM encoders, elucidate why they stand out as promising tools for machine-generated text detection, and provide a detailed exposition on the classifiers designed atop these embeddings. The overall proposed system architecture is shown in Figure 3.

6.1 LLM Text Encoder

Modern language models have shown impressive capabilities in various tasks, ranging from text generation to translation and summarization [58]. The strength of such models lies not just in their ability to generate coherent text, but also in their capacity to comprehend and encode the semantic essence of given input text into dense representations, known as embeddings [42]. An encoder in an LLM serves as a crucial component that transforms raw text input into these high-dimensional embeddings. Such embeddings capture intricate patterns, contextual relationships, and even abstract concepts from the text, making them a rich source of information. As depicted in Equation 2 the text encoder f transforms a text sample x into a representation e , which encapsulates the semantic essence of the input.

For our objective of building a system to distinguish machine-generated text, leveraging the power of these encoders offers a strategic advantage. As we aim to distinguish between human-generated and machine-generated content, it's imperative to obtain representations that capture the nuanced differences between these two types of content. Given the massive amount of data and diverse linguistic structures these LLMs are trained on, their encoders are likely to offer embeddings that can discern subtle differences in text structure and coherence [32]. Furthermore, using a frozen encoder from an established LLM provides a standardized way to obtain these embeddings without the need to train our own encoding mechanism. This not only reduces the computational burden but also ensures that we leverage state-of-the-art representations. For these reasons, in our approach, we employ the encoder from an LLM with an encoder-decoder architecture. The choice to avoid purely decoder-based LLMs is deliberate, as we aim to directly process and embed a given text sample without the need for generation.

Let $LLMEncoder(\cdot)$ denote a frozen LLM text encoder, which maps an input text sample x to an embedding space:

$$e = LLMEncoder(x) \tag{2}$$

6.2 Human vs. LLM Classifiers

Building on the rich embeddings provided by the LLM encoders, our methodology uses a range of classifiers, each designed to utilize the distinct characteristics of these embeddings. The following subsubsections outline the different types of Cipher models that we use to build off of these embeddings.

6.2.1 Multilayer Perceptron Classification

At the heart of our classification methodology lies the embeddings extracted from LLM encoders, dense representations with information necessary to differentiate between human and machine-generated texts. Multilayer Perceptrons (MLPs) [36], with their multiple layers of interconnected neurons, serve as our one of our tools to navigate and interpret these embeddings. While the embeddings capture the core distinctions between text types, the MLPs facilitate the transformation of this latent information into actionable classification decisions. They do this by modeling intricate relationships present in the embeddings and leveraging their inherent capacity to extract and amplify higher-level features, effectively bridging the gap between raw embeddings and the final classification outcome. The flexibility and adaptability of MLP architectures, coupled with their ability to generalize over complex datasets, position them as a natural choice for our initial classification endeavors on the embeddings.

6.2.2 K-Nearest Neighbors Classification

We also use the K-Nearest Neighbors (KNN) classifier to distinguish between human and machine-generated texts. At its core, the KNN algorithm attributes a classification label to an unseen sample based on the predominant label of its k closest neighbors. One of the innate strengths of the KNN algorithm is its resistance to overfitting, an issue that often plagues more complex classifiers. Models that are highly susceptible to overfitting excel on their training data but display a marked decline in performance on novel datasets [12]. Several advanced classifiers, despite their sophistication, are known to fall into this trap [17]. The non-parametric nature

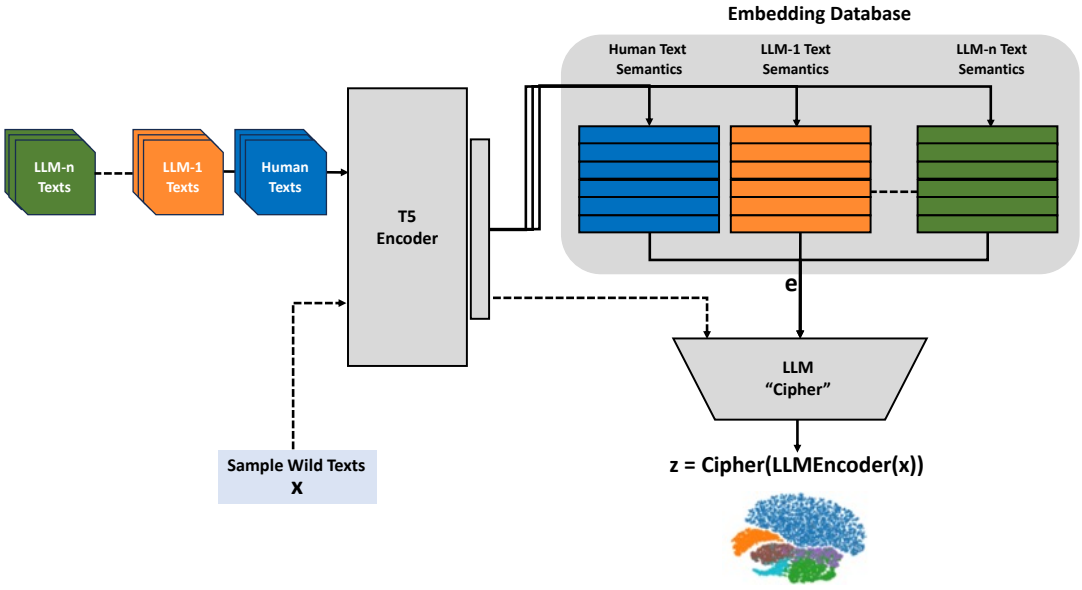

Figure 3: System Architecture of T5LLMCipher for distinguishing between human and machine-generated texts. The architecture consists of an LLM encoder, embedding databases to store the text embeddings extracted from the LLM encoder, and a classifier to map the text embedding to a classification decision.

of KNN circumvents this challenge by drawing on broader patterns and trends present in the data. We carefully choose the training data for our models to be paired in nature, where every human-generated text is coupled with a corresponding machine-generated text on the same topic. In the training datasets that are used for our models, each sample is a pair consisting of human-written text and the machine-generated text that was generated using this human-written text. This structure is particularly beneficial for KNN. When faced with paired texts that share thematic content but differ in their origins, KNN can sharply focus on the subtle distinctions between them. During inference, the classification decision should predominantly reflect the origin of the text rather than its content.

6.2.3 Contrastive K-Nearest Neighbors

We also employ a contrastive learning strategy, a technique rooted in the idea of understanding and distinguishing between similar and dissimilar data representations. The essence of contrastive learning is to pull together the representations of similar data while pushing apart representations of dissimilar data [48]. In our context, we leverage this methodology to explicitly accentuate the differences between human and machine embeddings. The rationale behind this is twofold: First, by emphasizing these differences, we can create a clearer distinction in the latent space between human and machine-generated content. Second, this distinct separation facilitates the KNN classifier's decision-making process, as it can more confidently assign labels based on proximity in this differentiated space. As a result, we aim to achieve enhanced classification accuracy and robustness against potential ambiguities between human and machine data points.

On top of the LLM encoder $LLMEncoder(\cdot)$, we add a series of fully connected layers, collectively represented as $g(\cdot)$, to process the embeddings further. Let $h = g(e)$ be the output after all these fully connected layers. The objective of these layers is to refine the embeddings such that they are more discriminative for our task.

Let the final layer's output of h be represented as z. This vector z serves as the refined embedding to be used for classification purposes.

Given a pair of samples (x_i, x_j), we first map them to their respective embeddings:

$$e_i = LLMEncoder(x_i) \tag{3}$$
$$e_j = LLMEncoder(x_j) \tag{4}$$

The Euclidean distance between two embeddings is given by:

$$D(e_i, e_j) = \|e_i - e_j\|_2 \tag{5}$$

We then construct a similarity matrix M where each element M_{ij} is given by:

$$M_{ij} = \begin{cases} 1 & \text{if both } x_i \text{ and } x_j \text{ are human-generated} \\ & \text{or both are machine-generated} \\ 0 & \text{if one of } x_i \text{ and } x_j \text{ is human-generated} \\ & \text{and the other is machine-generated} \end{cases} \tag{6}$$

The Triplet Margin Loss for a given anchor v_a, positive sample v_p, and negative sample v_n is defined as:

$$\mathcal{L}_{triplet}(v_a, v_p, v_n) = \max(0, D(v_a, v_p) - D(v_a, v_n) + m) \quad (7)$$

Where the m is the margin hyperparameter, and D is the function that computes the Euclidean distance between embeddings. The goal during training is to minimize this loss, ensuring that positive pairs are closer than negative pairs in the embedded space by at least a predefined margin.

With the embeddings z obtained, we employ a K-Nearest Neighbors (KNN) classifier to distinguish between human and machine-generated texts.

The Euclidean distance between these contrastively learned embeddings is used for the KNN classification:

$$D(z_i, z_j) = \|z_i - z_j\|_2 \quad (8)$$

Where z_i and z_j are the embeddings corresponding to text samples x_i and x_j, respectively.

In high-dimensional spaces, understanding the differences between embeddings can be approached from two primary perspectives: their orientation (direction) and their relative position (magnitude). Cosine similarity, and its derivative, cosine distance, focuses primarily on the angle between two vectors, effectively ignoring their magnitude. While this can be useful in scenarios where the magnitude (or the length) of the vectors is not informative or might introduce noise, it can miss nuances in situations where the magnitude contains discriminative information. On the other hand, Euclidean distance offers a more comprehensive measure as it accounts for both the orientation and magnitude of vectors in the high-dimensional space. By doing so, it captures the full spectrum of relationships between vectors, making it sensitive to more subtle variations and characteristics. Therefore, using Euclidean distance in our contrastive KNN model provides a more robust and encompassing evaluation of the distinctions between the text embeddings, enabling a more effective differentiation between human and machine-generated text.

7 System Implementation and Evaluation

7.1 Implementation

We utilized the Google Flan-T5-XL implementation available on Huggingface [5] to generate text embeddings. In our "in-the-wild" experiment detailed in Section 7.6, we also examined the impact of replacing the T5 text embedder by switching to RoBERTa-base [10]. T5 employs a SentencePiece tokenizer [34], which processes inputs as a continuous stream, obviating the need for prior tokenization. In contrast, RoBERTa leverages byte-level Byte-Pair Encoding (BPE) [54] for its tokenization. BPE, initially conceived to accommodate a vast range of vocabularies, focuses on sequentially merging the most frequent character pairs to create new tokens. Both T5 and RoBERTa implementations restrict their inputs to a maximum size of 512 tokens. To extract a text embedding from T5, we target the last hidden state in the encoder. In transformer models such as T5 [50], each layer successively captures increasingly abstract and high-level features. By the time data reaches the last hidden state, the model has assimilated a wealth of contextual nuances from both micro and macro perspectives, representing the entire text sequence. For RoBERTa, we obtain the embedding from the hidden state of the last layer's first token (CLS token). This particular hidden state is widely recognized for its ability to represent a given text and is thought to encapsulate the overarching semantic information of the input sequence [30, 57, 65]. The resulting T5 embedding yields a vector of size 2048, while the RoBERTa embedding produces a vector of size 768.

For our MLP, we utilize a fully connected feedforward network, consisting of six layers. The network architecture funnels down from an input size of 2048 to an output size of 6 for the 6-class multiclass classifier, an output size of 5 for the 5-class multiclass classifier, or an output size of 2 for the binary classifier. Each layer, except for the last, employs the ReLU activation function. For training, the model uses Cross Entropy Loss as its loss function, optimized using the Adam algorithm with a learning rate of 0.0001, all implemented using Pytorch [44]. All of the MLP models are trained and tested directly on the LLM embeddings without any additional processing. The datasets for the MLP models are partitioned into training, validation, and testing subsets. Specifically, 80% is allocated for training where the model is trained for 500 epochs, 10% serves as a validation set where the model demonstrating the highest validation accuracy is saved, and the remaining 10% is reserved for testing. We refer to the multiclass MLP classifiers as T5LLMCipher-MC and the binary MLP classifiers as T5LLMCipher-Bi.

For our KNN experiments, we implement it with the scikit-learn [46] library, using K = 5 with the Euclidean distance function. For the contrastive KNN We employed a straightforward MLP model comprising 150M parameters, using ReLU activations between layers. The output layer, of size 512, had no activation. The TripletMarginLoss was our chosen loss function. In our training (80%) and validation (10%) splits, each embedding served as an anchor once per epoch. Positives were randomly selected from the same class as the anchor, while negatives were from different classes. The model was trained for 100 epochs using the Adam optimizer [33] with a learning rate of 0.0001. We refer to the standard KNN trained on just the T5 embeddings as T5LLMCipher-KNN and the contrastive KNN as T5LLMCipher-C-KNN.

7.2 Evaluation

We conduct a series of comprehensive experiments designed to evaluate the performance and robustness of our proposed approach under various scenarios. Initially, an exper-

	Bloomz	ChatGPT	Cohere	Davinci	Dolly	Human
Bloomz	1238	0	3	8	15	8
ChatGPT	0	1068	55	110	13	1
Cohere	3	11	940	15	57	8
Davinci	1	109	19	1039	64	29
Dolly	19	14	91	49	978	74
Human	0	0	3	5	28	6620

Table 3: Confusion matrix for identifying the source generator using the T5LLMCipher-MC classifier

iment evaluates the potential to attribute text generations to known models. Next, a cross-domain experiment assesses the model's capability to generalize and adapt across different text domains. Following this, we perform a cross-generator experiment to investigate the model's effectiveness in distinguishing text originating from text generation models. An in-the-wild data experiment is also conducted to simulate real-world conditions where the data is from unknown generators and domains, testing the model's robustness and reliability in practical applications. To further probe the model's resilience, an adversarial robustness experiment is carried out, exposing the model to intentionally crafted adversarial inputs to explore our method's robustness. Lastly, we present a t-SNE visualization of our multiclass MLP classifier to show that it effectively separates human and machine texts on known data.

7.3 Text Generator Identification

We train a 6 class T5LLMCipher-MC classifier to distinguish between each generator, trained on M4 data across the Arxiv, PeerRead, Reddit, Wikihow, and Wikipedia domains.

Table 3 is a confusion matrix that details the number of times a given text source was classified as each possible source. The diagonal of the matrix represents true positives or instances where the classifier correctly identified the source. For example, the classifier correctly identified Bloomz-generated text 98.1% of the time. Human-generated text also seems to be distinctly characterized, as the classifier correctly attributed human texts to being human-generated 98.2% of the time.

Table 4 delves into the individual performance metrics of the classifier for each text generator. It lists precision, recall, F1-Score, and support for each class. This table shows that the classifier performs exceptionally well in identifying Human and Bloomz text, with F1 scores of 0.988 and 0.977, respectively. ChatGPT and Cohere texts are fairly distinguishable with F1-Scores above 0.870, whereas Davinci and Dolly have the lowest F1-Scores, suggesting these might be harder to distinguish or have characteristics that overlap with other classes. Additionally, we visualize the model's proficiency in differentiating between machine-generated and human-generated texts through the t-SNE presented in Figure 4. For this visualization, we extracted features from the layer before the classification layer, which has a vector size of 256. The domains showcased include Arxiv and Wikihow, spanning five distinct generators. In this figure, human and machine samples manifest as more defined clusters than the distribution observed in Figure 1. We further visualize the model's ability to attribute text to source generators in each domain in Figure 5. There we show the t-SNE visualization of 6 class classifier embeddings on each of the different generator's texts and see that each one forms a distinct cluster with minimal overlap. Compared to the original embedding space shown in Figure 2, we now see excellent separation between classes. Overall, these experiments show that the identification of the source generator of texts is feasible, and that different generators have unique identifiable characteristics, or "fingerprints," within their generated texts.

	Precision	Recall	F1-Score	Support
Bloomz	98.2	97.3	97.7	1272
ChatGPT	88.9	85.6	87.2	1247
Cohere	84.6	90.9	87.6	1034
Davinci	84.7	82.4	83.6	1261
Dolly	84.7	79.8	82.2	1225
Human	98.2	99.5	98.8	6656

Table 4: Results with respect to each class for identifying the source generator

7.4 Cross-Domain Experiment

In our cross-domain experiment, as illustrated in Table 5, we evaluated the capability of our classifiers to generalize in identifying machine-generated text from unseen domains. These classifiers were trained and tested using samples from the Human class and the five machine text generators: ChatGPT, davinci-003, Cohere, Dolly, and BLOOMz. The 6 class T5LLMCipher-MC classifier was trained to attribute text to the Human class and each of the five machine-text generators. For the testing of the 6 class T5LLMCipher-MC classifier in the cross-domain experiment, if the classifier detects a sample as a human sample, it is treated as a human sample, and if it is detected as any of the five machine generators, it is treated as a machine sample. All other classifiers were trained and tested on the binary classification task of distinguishing between

	Arxiv	PeerRead	Reddit	Wikihow	Wikipedia
T5LLMCipher-MC	73.3	86.0	85.6	70.9	72.7
T5LLMCipher-Bi	75.7	83.8	86.4	75.0	71.4
T5LLMCipher-C-KNN	75.4	87.0	90.0	76.4	74.2
T5LLMCipher-KNN	64.9	72.0	75.7	54.2	68.2

Table 5: Cross-domain experiment, showing the F1 score for the machine-generated text class where models are trained on four domains and tested on the domain it wasn't trained on. Each column shows the domain that is being tested on.

machine and human text.

In this experiment, the detectors were trained on four of the domains, and evaluated to detect machine-generated text in the domain that the detector wasn't trained on. The results on the 6-Class T5LLMCipher-MC classifier, T5LLMCipher-MC classifier, and the T5LLMCipher-C-KNN classifier demonstrated closely matched performance across multiple domains, suggesting a robustness in their adaptability. The generalization to unseen domains appears to vary between the test datasets, with Wikihow appearing to be the most difficult to generalize to. In this experiment, the T5LLMCipher-C-KNN classifier performed the best, with an average F1-score of 80.6 to unseen domains.

	Bloomz	ChatGPT	Cohere	Davinci	Dolly
T5LLMCipher-MC	76.0	96.3	92.6	84.4	69.8
T5LLMCipher-Bi	79.7	97.0	92.0	85.3	77.8
T5LLMCipher-C-KNN	78.4	99.4	92.5	85.8	78.1
T5LLMCipher-KNN	59.2	87.6	82.1	72.7	68.7

Table 6: Cross-generator experiment, showing the F1 score with respect to the machine-generated text class where models are trained on four generators and tested on the generator it wasn't trained on. Each column shows the generator that is being tested on.

7.5 Cross-Generator Experiment

In our cross-generator experiment, as illustrated in Table 6, we evaluated the capability of our classifiers to generalize in identifying machine-generated text from unseen generators. These classifiers were trained and tested using samples from all of the domains, which were Wikipedia, Reddit, WikiHow, PeerRead, and Arxiv. The 5 class T5LLMCipher-MC classifier was trained to attribute text to Human class and four of the machine generators and then tested on the one generator it was not trained on. For the testing of the 5 class T5LLMCipher-MC classifier in the cross-domain experiment, if the classifier detects a sample as a human sample, it is treated as a human sample, and if the machine sample that it wasn't trained on is detected as any of the four machine generators it was trained on, it is treated as a machine sample. All other classifiers were trained and tested on the binary classification task of distinguishing between machine and human text. In this experiment, Bloomz and Dolly appear to be the most difficult generators to generalize to, while ChatGPT looks to be the easiest to generalize to. Once again, in this experiment we find that the T5LLMCipher-C-KNN classifier narrowly beats out the other classifiers in generalizing to unseen generators, with an average F1 score of 86.8.

7.6 In-the-wild Experiment

To demonstrate our approach on in-the-wild data, we use the in-the-wild machine-generated text data released by Pu et al. [47]. Overall, three of these datasets consist of news article styled articles and one of the datasets consists of social media styled posts. The machine-generated text from this dataset were generated from API and while it is unknown what the exact model architecture was of these generations, the ArticleForge and Kafkai models were indicated to have used variants of GPT-2 models. Details of this dataset are discussed in Section 4. Given the available information, there is not known to be an overlap in domain or generators with the M4 dataset [61]. While both datasets contain data sourced from Reddit, the Reddit ELI5 data from M4 contains machine-generated text in the form of answers to questions, while the RedditBot data from Pu et al. [47] contains machine-generated text in the form of social media posts.

We train our models on the five generators across five domains from the M4 dataset. The 6 class T5LLMCipher-MC was trained to attribute text to Human class and each of the five machine-text generators. This model, which was trained to attribute texts to known generators, will instead be used for the binary task of attributing texts as machine-generated or human-generated. For the testing of the 6 class T5LLMCipher-MC classifier in the cross-domain experiment, if the classifier detects a sample as a human sample, it is treated as a human sample, and if it is detected as any of the five machine generators, it is treated as a machine sample. The rationale behind this testing strategy for our T5LLMCipher-MC is that these new samples from unseen LLMs will likely be far away from the human text cluster and may share some characteristics with one of many known generators that are already included in its training. All other classifiers were trained and tested on the binary classification task of distinguishing between machine and human text. Furthermore, to demonstrate the impact of the backbone LLM encoder, we also test a 6 class MLP classifier using RoBERTa instead of T5, which is indicated as RoBERTaLLMCipher-MC. We also compare against the four models discussed in Section 5 (BERT-D, GLTR-BERT, GLTR-GPT2, and RoBERTa-D) [47] by training these models on the same training dataset used to train our classifiers to provide an apples-to-apples comparison against existing supervised detection models. To compare against black-box detection methods, we examine the RADAR model [31], a framework

	AI Writer	Article Forge	Kafkai	Reddit Bot	Avg
T5LLMCipher-MC	62.3	84.4	61.8	84.6	**73.3**
T5LLMCipher-Bi	59.2	78.8	46.2	82.1	66.6
T5LLMCipher-C-KNN	57.2	83.2	49.2	82.9	68.1
T5LLMCipher-KNN	37.2	45.4	32.8	67.0	45.6
RoBERTaLLMCipher-MC	61.5	81.2	41.9	81.8	66.6
BERT-D	68.6	70.6	55.6	67.3	65.5
GLTR-BERT	49.2	83.8	29.0	73.8	59.0
GLTR-GPT2	29.6	83.1	29.2	83.5	56.4
RoBERTa-D	20.9	48.7	37.6	76.8	46.0
RADAR	50.2	61.6	60.2	18.0	48.0
Fast-DetectGPT	32.1	52.9	98.7	97.5	70.3

Table 7: Experiment comparing F1 score with respect to machine-generated text of existing state-of-the art approaches to our method on in-the-wild text.

designed for detecting machine-generated texts through adversarial learning. Central to RADAR are two key components: a paraphraser and a detector. The paraphraser, built on the T5-large model [50], is tasked with altering machine-generated text in an effort to bypass detection. Concurrently, the detector, leveraging the RoBERTa-large model [38], is trained to identify both the original AI texts and those that have been paraphrased. This adversarial training loop ensures that RADAR continuously evolves in its ability to discern AI-generated content. The training data for RADAR comprises a human text corpus, sourced from the OpenWebText dataset [28], and machine-generated text, which employs the Vicuna-7B model to create texts based on prefixes extracted from the human-text corpus. We further compare against Fast-DetectGPT [16], another black-box machine-text detection algorithm. This method quantifies the curvature of the conditional probability function, which is indicative of the likelihood of text being machine-generated based on the comparative evaluation of the probabilities of given and alternative token choices. The positive curvature at a point suggests a higher likelihood of the text being machine-generated, whereas a close-to-zero curvature indicates human authorship. GPT-Neo 2.7B [19] was used as the scorer model to obtain token probabilities.

We find that T5LLMCipher-MC provides the best results with an average F1 score of 73.3% across the four in-the-wild datasets. We also observe that our models have the toughest time generalizing to the Kafkai generations, and the easiest time detecting RedditBot generations. We also find that T5LLMCipher-MC with T5 as the LLM encoder outperforms RoBERTaLLMCipher-MC with RoBERTa as the LLM encoder. Some other notable results come from Fast-DetectGPT, where Kafkai and Reddit Bot generations are detected with very high F1 scores. This can be explained by the underlying scoring model used by Fast-DetectGPT, which is a GPT variant. Kafkai and Reddit Bot machine-texts use models from the GPT family. This corroborates with the results from the work of Bao et al. [16] where they show that their detection methodology generalizes well to other machine text generators from the same family. However, their method is shown to struggle in discerning human from machine-generated texts from different families of LLMs, as is shown from the poor detection performance on AI Writer and Article Forge texts.

7.7 Adversarial Robustness Experiment

To demonstrate our method's robustness to adversarial attacks, we evaluate our system against a recently introduced perturbation attack method for evading machine-generated text detection, DFTFooler [47]. DFTFooler carefully modifies machine-generated text to evade detection while attempting to preserve linguistic quality. This is achieved by pinpointing words in the text which are confidently predicted by a pre-trained LLM and substituting them with synonyms that are semantically similar yet less confidently predicted. The synonym selection process adheres to a meticulous protocol to uphold linguistic quality: First, potential synonyms are extracted based on cosine similarity between word embeddings, ensuring a semantic alignment with the original word. Subsequent steps involve part-of-speech checking, to maintain grammatical congruity, and semantic similarity checking to ensure the substituted word does not deviate semantically from the original text. The selected synonym is then one that is predicted with lower confidence by the language model, which alters the predictability of the word choices in the text. Notably, unlike other adversarial techniques, DFTFooler achieves this without necessitating any queries to the detection model, which makes it an attractive choice for potential adversaries who would want to attack a black-box detection model [26]. We use machine-generated perturbed texts using DFTFooler, setting the low probability threshold to 0.01, the synonym similarity threshold to 0.7, and allowing for 10 word perturbations. We show the results of this attack on the same datasets of in-the-wild data as in Section 7.6 on the T5LLMCipher-MC, T5LLMCipher-Bi, T5LLMCipher-C-KNN and T5LLMCipher-KNN classifiers, as well as test this attack on the other state-of-the art classifiers tested in Section 7.6. We randomly sample 200 texts from the human-generated texts and 200 texts from the machine-generated texts from each of the four datasets for a total of 1600 samples. We show the results of this experiment in Table 8, where we report the F1 score with respect to the machine-generated text class. These results show that the T5LLMCipher-MC classifier was the most adversarially robust model, with an F1 score of 67.2. This represents a reduction of just 6.1 points from the non-adversarially perturbed in-the-wild text from the experiment in Table 7.

8 Discussion and Future Work

Interestingly, we found that the T5LLMCipher-C-KNN outperformed the T5LLMCipher-KNN, T5LLMCipher-MC and the T5LLMCipher-Bi classifiers on the cross-domain and cross-generator experiments. The performance of the T5LLMCipher-C-KNN can be rationalized by the theoretical

	AI Writer	Article Forge	Kafkai	Reddit Bot	Avg
T5LLMCipher-MC	54.9	77.3	54.9	81.5	**67.2**
T5LLMCipher-Bi	62.4	66.9	22.8	50.0	50.5
T5LLMCipher-C-KNN	31.0	53.0	22.4	53.1	39.9
T5LLMCipher-KNN	19.8	23.7	37.3	37.3	29.5
BERT-D	54.6	55.2	52.1	58.8	55.2
GLTR-BERT	29.7	65.9	10.9	73.0	44.9
GLTR-GPT2	9.1	57.3	10.8	76.9	38.5
RoBERTa-D	13.0	36.6	29.1	82.6	40.3
RADAR	49.6	64.3	58.9	36.2	52.3
Fast-DetectGPT	29.1	54.0	54.0	97.7	58.7

Table 8: Experiment comparing F1 score with respect to machine-generated text of existing state-of-the art approaches to our method on adversarially perturbed in-the-wild text.

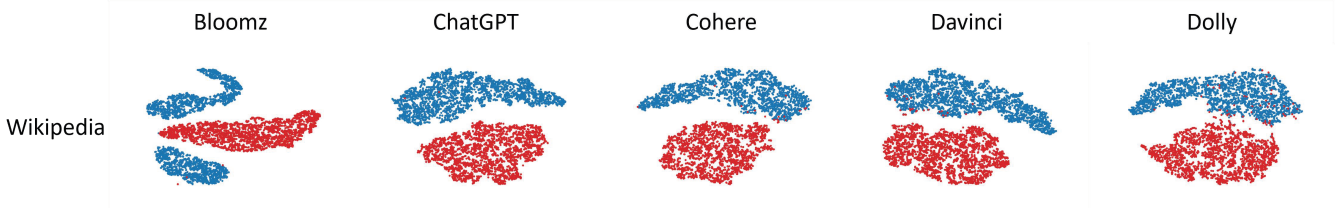

Figure 4: t-SNE visualization of T5LLMCipher-MC classifier embeddings illustrating the distribution of Human (blue), and Machine (red) generated text. There exists a clear separation between Human and Machine generated text.

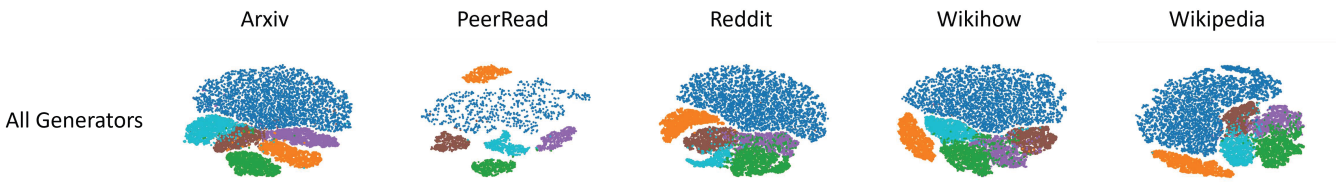

Figure 5: t-SNE visualization of T5LLMCipher-MC classifier embeddings illustrating the distribution of Human (blue), Bloomz (orange), ChatGPT (green), Cohere (teal), Davinci (purple), and Dolly (brown) generated texts across different domains. Our T5LLMCipher-MC classifier shows a strong ability to distinguish the source generator of text.

underpinning of its design, where the primary goal was to capture the inherent differences between human and machine-generated texts while being agnostic to their specific domains or the machine generators behind them. By leveraging a contrastive learning paradigm, the system was tailored to magnify the subtle nuances between these two categories. Contrastive learning inherently emphasizes on pulling apart representations of dissimilar pairs while bringing closer the representations of similar pairs. In the context of our application, this means that human-generated text embeddings are encouraged to be distinct from any machine-generated text, regardless of the particular machine generator or domain from which it originated. On the other hand, all human texts, irrespective of their domain, would be represented closely in the embedding space, and similarly for machine texts from various generators. When transitioning to cross-domain and cross-generator scenarios, this foundational design proved to be beneficial. Instead of being overly attuned to the specific characteristics of the training domain or generator, the T5LLMCipher-C-KNN was focused on the broader distinction between human and machine. Consequently, it was more resilient to shifts in domain or the introduction of texts from unfamiliar machine generators.

However, even though the T5LLMCipher-MC classifier fell short of the T5LLMCipher-C-KNN classifier by a small margin in both the cross-domain and cross-generator experiments, it provided the best detection performance in both the in-the-wild and adversarial robustness experiments. The in-the-wild experiment can be considered a joint case of a cross-generator and cross-domain experiment because the generator and domains are both unknown to the detectors, so it was initially surprising that the model that performed the best on the cross-generator and cross-domain experiment did not perform the best on the in-the-wild experiment. Even though the T5LLMCipher-MC classifier was broadly categorizing texts as human or machine during testing, the knowledge acquired from distinguishing among multiple machine generators added depth to its understanding. Hence, it was better equipped to generalize and accurately classify texts, even when the specifics of their origin were unknown or when the texts were adversarially perturbed. This finer-grained knowledge may have allowed the T5LLMCipher-MC classifier to outperform its binary counterparts in these particular settings. In simpler terms, each machine generator introduces unique elements into the content's semantics. When we group machine-generated texts separately by generator in the latent space, it becomes more straightforward to distinguish between human-generated and machine-generated texts. Additionally, this approach aids in generalizing to unseen generators, enhancing our ability to discern their origin using the sub-clustering of known machine-generated text artifacts rather than treating all machine-generators as a single cluster.

The results of the text generator attribution experiment in Table 4 and Table 3 show that it is possible to not only distinguish between human and machine-generated text, but it is also possible to attribute the text to a specific generator. Our framework successfully attributes authorship to specific generators included in the T5LLMCipher training data. However, for content produced by machine text generators not included in the initial training, while our system can recognize the content as not human-generated, it cannot pinpoint the exact generator. Detecting a novel generator necessitates retraining

of T5LLMCipher for accurate attribution. Fortunately, this process is computationally lightweight.

In this study, our primary focus was to emphasize the efficacy of LLM encoder embeddings in detecting machine-generated text, rather than on the complexity of the classifiers. Notably, our results show state-of-the-art generalization and robustness against adversarial attacks, despite the relatively simple nature of the MLP and KNN classifiers. This underscores the inherent quality and potential of the embeddings themselves towards the task of detecting machine-generated text. Given these promising outcomes with simple models, future research that explores more sophisticated architectures in tandem with the LLM encoder embeddings holds significant potential to push generalizability and robustness even further. Additionally, adversarial training strategies could potentially be utilized to improve adversarial robustness of classifiers built on top of these embeddings.

8.1 Ethical Considerations

The deployment of human versus machine text detection systems warrants important ethical considerations when deployed, particularly in light of the potential for false positives where genuine human-written texts are mistakenly identified as machine-generated. Such misclassifications carry significant ramifications, including but not limited to, the erosion of trust in automated systems, potential harm to individuals' reputations, and the broader societal impact of inadvertently censoring legitimate expressions in digital communications. In educational contexts, misattributed authorship due to AI-generated content can lead to significant consequences, as seen in an incident where a professor threatened to fail his entire class based on a machine-text detection tool [60]. This underscores the critical need for caution in relying on automated detectors for decision-making. Such tools are not foolproof and may lead to unjust outcomes, making it imperative to use them with caution. Machine-text detection tools have also been shown to be biased against non-native English writers [37], adding even more difficulty in achieving accurate and fair evaluations of texts. In this context, it is crucial to emphasize the limitations of relying solely on systems that assess textual authenticity based on input text alone. Therefore, it is important to recognize that automated machine-text detection systems should not be used for autonomous decision making without human supervision, especially in high-stakes scenarios.

9 Conclusion

The ever-growing prevalence of LLMs has sparked significant interest in developing reliable tools to detect machine-generated text. This necessity is accentuated by the realization that many existing detectors, although promising, stumble when faced with real-world complexities. Specifically, their capability to generalize over text from a multitude of generators and spanning various domains is called into question. Addressing this challenge has been central to our work, where we undertook a comprehensive exploration of machine-generated text detection across varying generators and domains. Our observations, primarily from the distribution patterns seen in t-SNE visualizations of embeddings from a pretrained LLM's encoder, signaled a promising direction. These patterns indicated the potential of these embeddings to differentiate between human-authored and machine-crafted texts. Acting on this observation, we proposed a novel system for the detection of machine-generated content, harnessing the encoder of a pretrained LLM. Our extensive evaluations, spanning nine machine-generated text systems and an equal number of domains, underscored the robustness of our approach where we show state-of-the-art generalization performance to detecting machine-generated text.

A Dataset Details

A.1 Prompts

The prompts given to the LLMs to create machine-generated text varied by domain. The PeerRead Reviews domain used four different prompts, to generate a set of peer reviews with different perspectives similar to a set of human generated peer reviews. Each prompt was provided to the LLM independently of the other prompts, and each prompt contains information from which to generate text similar to the human written text that the machine text is paired with. The information unique to each individual prompt is illustrated in [brackets] for illustrative purposes. Below are examples of prompts used for each domain.

- **Wikipedia:** Prompts included the title of the Wikipedia article. Example Prompt: Write a Wikipedia article with the title [title], the article should at least have 250 words.
- **Reddit ELI5:** Prompts included the question asked in the Reddit post. Example Prompt: Write a couple of paragraphs of at least 500 characters each to address the following question. [question].
- **WikiHow:** Prompts included the title and headline in the Wikihow article. Example Prompt: Write a WikiHow article content given a title and a headline. Use approximately 300 words. Title: [title] Headline: [headline].

Domain	Human Semantic Similarity ↑	Human Stylistic Similarity ↑	USE-Cosine Similarity ↑
Arxiv	5.52	5.66	0.67
Peerread	3.88	4.54	0.52
Reddit	4.53	4.28	0.65
Wikihow	5.70	4.94	0.68
Wikipedia	4.44	4.36	0.57

Table 9: The average semantic similarity and stylistic similarity score given by the human evaluations across 5 domains. "USE-Cosine Similarity" is the average cosine similarity of the pairs of human and machine texts after using the Universal Sentence Encoder (USE) to create vector representation of the texts, where a value of 0 means no semantic similarity and 1 means perfect semantic similarity.

- **PeerRead Reviews:** Prompts included the title and abstract of the research paper. Example Prompt: Write a peer review by first describing what problem or question this paper addresses, then strengths and weaknesses, for the paper [title], its main content is as below: [abstract].
- **Arxiv Abstract:** Write a long abstract of a scientific paper from arXiv.org. Use approximately 200-400 words. Title: [title]. Abstract:

A.2 Dataset Assumptions

Although it is not possible to assure with absolute certainty that each entry within the human-annotated datasets was solely produced by human, it is important to note that all data were compiled before the widespread availability of sophisticated and easily accessible language models capable of producing human-like text. The most recent collection of human-written texts in the dataset we use date back to early 2022, predating the introduction of ChatGPT or Gemini.

To ensure that the machine-generated text was reasonably similar to the human-generated texts that the machine-generated texts were based on, we use the Universal Sentence Encoder (USE) [20] to measure cosine similarity, and human evaluations of style and semantic similarity. USE is first utilized to create high-dimensional vector representations of the texts. Then we measured the cosine similarity between the human-machine text pairs. This method is used to measure the semantic similarity of the human and machine text as an automatic evaluator. Cosine similarity values of 1 indicate a perfect semantic similarity, and values of 0 indicate no semantic similarity. In the human evaluations of text similarity, a 7-point Likert Scale test is used to measure the participant's agreement or disagreement on a scale from 1 (strongly disagree) to 7 (strongly agree) with the statements of "The two text samples are similar in style?" and "The two text samples are similar in semantics". The authors were used to evaluate the similarity of 250 human-machine text-pairs, and their scores on these statements across these text-pairs were averaged. The 250 text-pairs were randomly sampled to include 10 text-pairs across each of the combinations of five domains and five generators in the M4 dataset described in Section 4. We report the average human evaluation scores across domains in Table 9. We also report the average cosine similarity across domains on the same samples used for human evaluations in Table 9. The average USE cosine similarity across all the evaluated samples is 0.62, which indicates that the level of semantic similarity is moderately high based on this metric. The median sentence length of the human generated and machine generated texts is 295 words and is 252 words, respectively. Given the lengths of the text samples and the expected decrease in similarity measures for longer texts generated by LLMs, the observed average similarity of 0.62 indicates a significant resemblance between the text pairs. This finding is further supported by human evaluation, as presented in Table 9.

As seen in Table 9, the average scores on stylistic and semantic similarity of the human and machine texts indicate good quality of the generated texts, with the Arxiv domain having the highest average human evaluation scores of 5.52 and 5.66 on semantic similarity and stylistic similarity, respectively. The level of similarity of texts between human and machine text pairs varied by domain, but were fairly consistent nonetheless. For instance, in PeerRead Reviews, there were bigger discrepancies between the human-generated and machine-generated samples than in other domains. One potential reason for this mismatch in semantics in the PeerRead Reviews dataset is that the machine generated peer reviews do not have access to the main body of the research papers and only consider the title and abstract of the paper, whereas the human reviewers have access to the full body of the paper in addition to the title and abstract. However, in general, the quality of the generated text seemed to be on par with the human text, even though the actual semantics did not always match on some of the datasets. We acknowledge that the evaluation of the human and machine texts in this experiment could be biased due to the author-led evaluations that might favor interpretations supporting the similarity of the texts. However, this limitation's impact on our overall system is likely minimal due to several factors. First, the USE cosine similarity measurement corroborates the author-led evaluations, providing automated confirmation of the similarity of the samples. Additionally, the model's strong performance on in-the-wild data as shown in Table 7 shows that the impact of this limitation on the validity of our model's results is minimal.

Prompt Stealing Attacks Against Text-to-Image Generation Models

Xinyue Shen Yiting Qu Michael Backes Yang Zhang

CISPA Helmholtz Center for Information Security

Abstract

Text-to-Image generation models have revolutionized the artwork design process and enabled anyone to create high-quality images by entering text descriptions called *prompts*. Creating a high-quality prompt that consists of a subject and several modifiers can be time-consuming and costly. In consequence, a trend of trading high-quality prompts on specialized marketplaces has emerged. In this paper, we perform the first study on understanding the threat of a novel attack, namely *prompt stealing attack*, which aims to steal prompts from generated images by text-to-image generation models. Successful prompt stealing attacks directly violate the intellectual property of prompt engineers and jeopardize the business model of prompt marketplaces. We first perform a systematic analysis on a dataset collected by ourselves and show that a successful prompt stealing attack should consider a prompt's subject as well as its modifiers. Based on this observation, we propose a simple yet effective prompt stealing attack, PromptStealer. It consists of two modules: a subject generator trained to infer the subject and a modifier detector for identifying the modifiers within the generated image. Experimental results demonstrate that PromptStealer is superior over three baseline methods, both quantitatively and qualitatively. We also make some initial attempts to defend PromptStealer. In general, our study uncovers a new attack vector within the ecosystem established by the popular text-to-image generation models. We hope our results can contribute to understanding and mitigating this emerging threat.[1]

1 Introduction

With the advent of Stable Diffusion [56], DALL·E 2 [53], and Midjourney [8], text-to-image generation models have revolutionized the artwork design process and sparked a surge of artwork creation in mainstream media. Rather than relying on professional artists, text-to-image generation models empower anyone to produce digital images, such as photorealistic images and commercial drawings, by entering text descriptions called *prompts*. According to [24, 34, 43], a high-quality prompt that leads to a high-quality image should consist of a *subject* and several *prompt modifiers*. The subject is a natural language description of the object or scenarios depicted in the image; the prompt modifiers are keywords or key phrases that are related to specific elements or styles of the image. Figure 1 shows an example of a typical prompt and the resulting generated image. In this example, "cozy enchanted treehouse in ancient forest" is the subject and the rest phrases, e.g., "diffuse lighting," "fantasy," etc., are prompt modifiers.

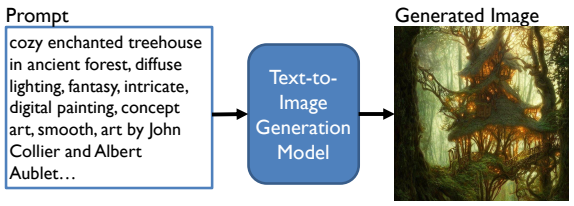

Figure 1: An image generated by Stable Diffusion and its corresponding prompt [56].

Although it seems that text-to-image generation models simplify the process of artwork design, crafting high-quality prompts is, in fact, complex and iterative. To create a desired and stable prompt, users need to constantly search for prompt modifiers and check the corresponding resulting images. Given the limited understanding of the impact of each prompt modifier, this process can be both time-consuming and costly. As a result, a new job type, namely *prompt engineer*, has emerged for people who specialize in producing high-quality prompts. Also, high-quality prompts become new and valuable commodities and are traded in specialized marketplaces, such as PromptBase [10], PromptSea [13], and Visualise AI [14]. The business model underlying these marketplaces is straightforward: customers browse sample images generated by text-to-image generation models. If they like a sample image, they can purchase the corresponding prompt. Then, customers can freely generate similar images

[1] Our code is available at https://github.com/verazuo/prompt-stealing-attack.

or modify the prompt's subject to generate other images in a similar style. Prompt marketplaces are gaining popularity. PromptBase has achieved 10K registered users until November 2022; approximately 45,000 prompts were sold by the top 50 prompt sellers (an estimated $186,525 in total) over 9 months; new prompt trading platforms, e.g., Prompti AI, Prompt Attack, etc, continue to emerge [9, 12, 66].

In such a context, a natural research question has emerged: given an image generated by a text-to-image generation model, whether an adversary is able to infer its corresponding prompt? We name this novel attack as *prompt stealing attack*. A successful prompt stealing attack directly violates the intellectual property of prompt engineers. Moreover, it poses a significant threat to the business model of prompt marketplaces. So far, few tools in the open-source community can be tailored for stealing prompts, such as applying an image captioning model or greedily searching for the modifier combinations with the highest similarity of the image [3, 31, 39]. However, it is still unclear whether and to what extent an adversary can effectively steal prompts from generated images. In this paper, we aim to fill the gap.

Our Contributions. We perform the first large-scale study on understanding the prompt stealing attacks against images generated by text-to-image generation models. We start by collecting a large-scale dataset from Lexica [5], a well-known image gallery with 5M+ prompts and generated images from text-to-image generation models. Overall, we collect 250,000 pairs of prompts and images. After preprocessing and de-duplication on prompts, we are left with 61,467 prompt-image pairs (see Section 3.1). We name the dataset as *Lexica-Dataset*. Our quantitative and qualitative analysis on Lexica-Dataset shows that both a prompt's subject and its modifiers are important factors for the generated image's quality (see Section 3.2). This implies a successful prompt stealing attack should consider both subjects and modifiers.

Based on the findings above, we propose a simple yet effective prompt stealing attack, *PromptStealer*. PromptStealer comprises two modules: a subject generator and a modifier detector. Given a target image, the subject generator infers the stolen prompt's subject and the modifier detector predicts modifiers of the stolen prompt simultaneously. Then, the subject and the prompt modifiers are concatenated as the final stolen prompt. Experimental results on Lexica-Dataset show that PromptStealer outperforms the three baseline methods across semantic, modifier, image, and pixel similarities. For instance, PromptStealer achieves 0.70, 0.43, 0.80, and 0.90 in these metrics, respectively, while the corresponding results for the better baseline CLIP Interrogator [3] are 0.52, 0.01, 0.77, and 0.89. We also qualitatively evaluate PromptStealer and find that the images generated by stolen prompts are similar to the target images. Our further experiments on real-world prompts traded in marketplaces demonstrate similar results. Moreover, we show that the performance of PromptStealer can be further boosted by involving the adversary in the loop or providing multiple target images.

Additionally, we make attempts to mitigate prompt stealing attacks by proposing *PromptShield*. This method adds an optimized perturbation to an image relying on the technique of adversarial examples such that the adversary cannot infer the image's prompt appropriately. Experimental results show that PromptShield works well (see Section 5); however, it requires strong assumptions for the defender, and its performance is reduced by the adaptive attack.

Implications. Our work, for the first time, reveals the threat of prompt stealing in the ecosystem created by the popular text-to-image generation models. We believe that our findings can serve as a valuable resource for stakeholders to navigate and mitigate this emerging threat. Moreover, we hope to raise awareness of academia to work on the safety and security issues of the advanced text-to-image generation models. We commit to sharing our dataset and code with the research community to facilitate the research in this field.

Ethics & Disclosure. According to the terms and conditions of Lexica [7], images on the website are available under the Creative Commons Noncommercial 4.0 Attribution International License. We strictly followed Lexica's Terms and Conditions, utilized only the official Lexica API for data retrieval, and disclosed our research to Lexica [6, 7]. We also responsibly disclosed our findings to prompt marketplaces such as PromptBase and PromptSea. PromptBase acknowledged our findings. They also launched a watermark editor for prompt engineers to defend against prompt stealing attacks. PromptSea explicitly discusses the risks of prompt stealing attacks in their white paper [50]. Our attack has also been recognized in Microsoft Vulnerability Severity Classification for AI Systems.[2]

2 Background

2.1 Text-to-Image Generation Models

Text-to-Image generation models aim to generate high-quality digital images with natural language descriptions, namely prompts. With the advancement of diffusion models, text-to-image generation has achieved a giant leap and gained significant attention [53, 56, 58]. Images generated by these models have been employed in various scenarios, such as children's books [48], magazine covers [22], and fashion imagery [1]. In this work, we focus on Stable Diffusion, the state-of-the-art and arguably the most popular text-to-image generation model. Besides, compared to other models like DALL·E 2 and Midjounry, Stable Diffusion is open-source and the community that promotes the usage of Stable Diffusion is very active. Since its release in March 2022, over 110K people have joined the Reddit community to share and discuss images generated by Stable Diffusion [54].

[2] https://www.microsoft.com/en-us/msrc/aibugbar.

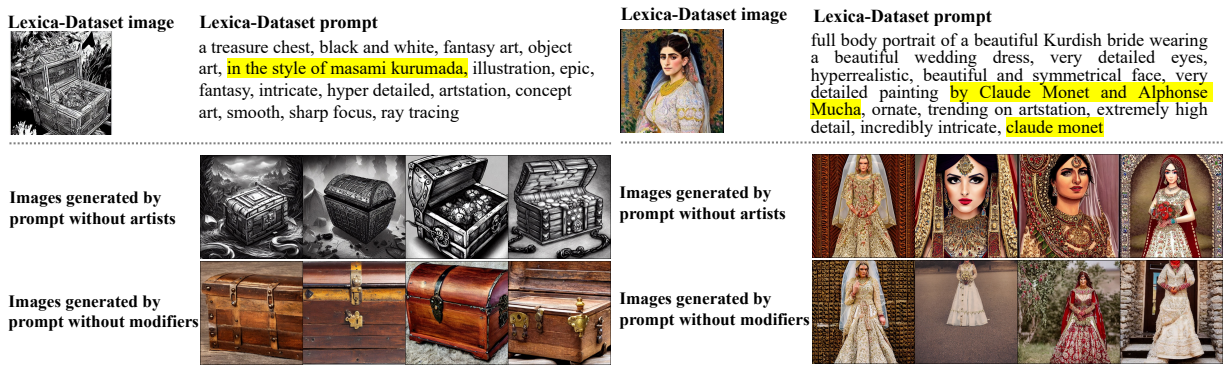

Figure 2: Two examples from Lexica-Dataset, and the corresponding generated images without artist modifiers and without any modifiers. The yellow highlight represents the artist modifiers. For the latter two cases, we generate four images with different random seeds to eliminate the potential biases.

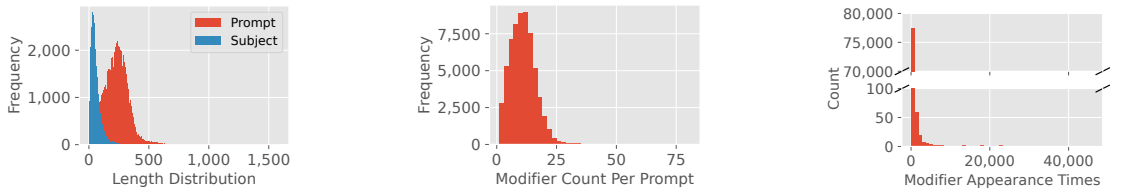
2.2 The Prompt Marketplace

While Text-to-Image generation models have gained popularity, producing high-quality images remains a laborious and costly manual process. A user needs to constantly search for prompt modifiers and check the corresponding resulting images. One example is the logo of OctoSQL, an open-source CLI project. The designers use DALL·E 2 to create the logo and spend around $30 interacting with the paid API [26]. As a result, prompt engineers, people who are skilled in producing high-quality prompts, start to sell their prompts in prompt marketplaces. In these marketplaces, a customer can explore sample images generated by different prompts; if they like a certain image, they can purchase the corresponding prompt through the marketplace.

Business Volume. To assess the potential impacts of prompt stealing attacks, we conducted a manual estimation of the business volume of a prompt marketplace, PromptBase. We chose PromptBase for two reasons: 1) PromptBase is the first and most widely recognized prompt marketplace, thus its business volume can represent the marketplaces to some extent; 2) PromptBase discloses the total sales of each prompt engineer. In our analysis, we calculate the sales volume of the top 50 prompt engineers over the past 9 months. We find that they collectively sold approximately 45,000 prompts, resulting in an estimated total revenue of $186,525.

Legal Perspectives of Prompt Trading. The terms of service and white papers of prompt marketplaces [49, 50] explicitly state that all prompts on their platforms are the intellectual property of the prompt engineers and cannot be obtained through purchase. Engaging in prompt stealing attacks would, therefore, violate intellectual property rights and jeopardize the business model of the prompt marketplace.



3 Preliminary Analysis

3.1 Data Collection

To the best of our knowledge, no large-scale prompt-image datasets are available at the time of our study. In order to assess prompt stealing attacks, we collect a dataset by ourselves via Lexica [5]. We opt for Lexica for two reasons. First, Lexica is a well-known image gallery of Stable Diffusion; it contains over 5M prompt-image pairs extracted from Stable Diffusion's discord server [21]. Lexica covers the art creations of many Stable Diffusion's active users, such as artists and prompt engineers. This allows us to better simulate the real-world attack scenario. Second, Lexica provides a query API [6] that given a specific prompt, returns the 50 most similar prompts and the corresponding images. Note that similar prompts are likely from the same user during their prompt engineering process. Therefore, the data from Lexica can closely reflect people's real-world usage of Stable Diffusion.

As Lexica only provides a query API and does not release its public dataset, we regard an open-source prompt dataset on Hugging Face[3] as a starting point for our data collection. This dataset contains 80K prompts crawled from Lexica, which are used to train a prompt generator. However, since this dataset does not contain any images and the image download link, we cannot directly use it. To address this, we randomly sample 5,000 prompts from the dataset and then query these prompts to Lexica's query API. As mentioned above, the API returns 50 results for each query, including images, prompts, grid, etc. In the end, we crawl 250,000 prompts and the corresponding generated images. We specifically exclude images generated by models other than Stable Diffusion, such as Aperture, a model designed to generate photorealistic images and can only be accessed on the Lexica website. We filter out the prompts and images that could not be parsed correctly. Also, images

belonging to the grid type (each of those images contains several generated images stitched together) are neglected as well. Finally, after the de-duplication of prompts, we get 61,467 prompt-image pairs. We name the dataset as *Lexica-Dataset*.

As mentioned before, each prompt consists of a subject and several prompt modifiers. Thus, we further decompose prompts in Lexica-Dataset into subjects and prompt modifiers. Concretely, we split each prompt by commas. The first part is regarded as the subject according to [34, 43], while the rest are treated as prompt modifiers. We standardize the format of some modifiers, e.g., "3 d" to "3d." We also remove the style-evocation words, including "in the style of," "inspired by," "trending on," etc. In the end, we obtain 77,616 prompt modifiers. Figure 2 depicts some samples from the dataset.

3.2 Data Analysis

Subjects and Prompt Modifiers. Figure 3a depicts the length distribution of subjects and prompts in Lexica-Dataset. On average, the length of a subject is 56 characters, while the length of a prompt is 237 characters. This means a subject takes only 23.63% of a prompt, and the rest is assembled with prompt modifiers. Figure 3b further depicts the distribution of modifier count per prompt. On average, each prompt contains 11 modifiers. This might suggest prompt modifiers play an essential role in the image generation process. To further investigate this, Figure 2 also shows some generated images without prompt modifiers. As we can see, modifiers indeed largely influence image quality in terms of style and details. Take the treasure chest as an example (see Figure 2a), if the modifiers are not considered, Stable Diffusion generates a plain treasure chest. Meanwhile, by considering various modifiers, the original image depicts a more stylized treasure chest with many fine-grained details. These results imply that a successful prompt stealing attack should not only consider the target prompt's subject but also put efforts into recovering the modifiers. In other words, using an image captioning model to get the caption (subject) of a target image is insufficient for prompt stealing. Experiment results in Section 4 further confirm this. On the other hand, we emphasize that the subject also plays an essential role in a prompt as it describes the main content of the image.

For the modifiers, we further show the distribution of their appearance times in Figure 3c. We can observe a Pareto distribution. Specifically, Lexica-Dataset contains 61,467 prompts and 77,616 modifiers. Among them, only 7,672 (9.88%) mod-

ifiers are used more than ten times, and 1,109 (1.43%) modifiers are used more than 100 times. From the adversary's perspective, this Pareto distribution eases the requirements for prompt stealing attacks, as a relatively small modifier set can already cover most modifiers used in prompts.

Modifiers in Category-Level. We further attribute prompt modifiers into different categories. The open-source prompt engineering tool CLIP Interrogator [3] defines five categories for modifiers, i.e., trending, artist, medium, movement, and flavor, and offers a relatively complete modifier list for each category. In our analysis, we adopt the same set of categories and assign all modifiers in Lexica-Dataset to them. Concretely, a modifier in Lexica-Dataset is considered as part of a category if it belongs to the corresponding modifier list from CLIP Interrogator. Table 1 shows the top 10 prompt modifiers with respect to their appearance times in each category of Lexica-Dataset. We find that users are less likely to use movement modifiers. The highest one is "fantasy art" with appearance times being only 1,567. This is probably because the usage of movement modifiers requires background knowledge of art. Conversely, the top three modifiers in the flavor category are all well-known image quality boosters [43], such as "highly detailed" and "8k." On average, 14.32%, 6.11%, 3.25%, 0.98%, and 75.33% of the modifiers in a prompt belong to the artist, trending, medium, movement, and flavor categories, respectively. Excluding the flavor category which contains various kinds of modifiers, the artist category occupies the largest proportion of prompts compared to the rest. This reveals that users are more likely to use artist modifiers to lead the generated images to certain visual styles. Figure 2 further shows some examples of generated images without artist modifiers. In Figure 2b, the artist modifiers "Claude Monet" and "Alphonse Mucha" indeed heavily influence the final outlook and fine-grained details of the original image, compared to the images without any artist modifiers. A similar observation can be made in the example depicted in Figure 2a.

Next, we investigate the semantic relations among modifiers of different categories. Diffusion-based text-to-image generation models like Stable Diffusion rely on CLIP [52] to obtain text embeddings of prompts. We thereby utilize CLIP's text encoder to obtain modifiers' embeddings and visualize them via a T-SNE [67] plot (see Figure 4). For each category, we consider the top 20 modifiers with respect to their appearance times. We find that the modifiers in the artist category are tightly grouped and distant from others. Meanwhile, the other four categories are relatively mixed. This again shows the importance of the artist modifiers in the image generation process. Meanwhile, it is expected that other categories are close to each other. For instance, movement modifiers are often accompanied by medium modifiers. This has also been uncovered in a previous qualitative study [34] and recommended by DALL·E 2 prompt book [46].

Takeaways. To summarize, we have established a prompt-image dataset Lexica-Dataset that can closely reflect people's

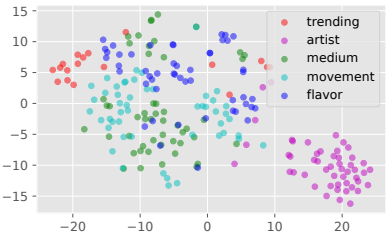

Figure 4: T-SNE visualization of modifier embeddings with respect to different categories.

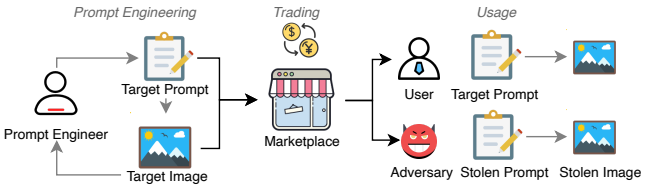

Figure 5: The scenario of prompt trading and stealing.

real-world usage of Stable Diffusion. Our data analysis reveals that besides its subject, a prompt's modifiers also play an essential role in determining its generated image's outlook. This suggests a successful prompt stealing attack should consider both the subject and modifiers of a prompt. Moreover, we attribute prompt modifiers into five different categories and discover that the artist modifiers heavily influence generated images' styles and details.

4 Prompt Stealing Attack

4.1 Threat Model

Scenario. Our attack is designed for the scenario shown in Figure 5. First, a prompt engineer performs an iterative exploring process to find an ideal prompt that can lead to a high-quality image using a text-to-image generation model. This prompt is referred to as the *target prompt*. Then, the prompt engineer can sell the prompt via marketplaces like PromptBase [10], by providing an example image generated by the target prompt, namely *target image*. If a regular user is interested in the style of the target image, the user can get the target prompt by trading with the prompt engineer through the marketplace. After getting the target prompt, one of the usage scenarios for the user is to modify the prompt's subject to generate other images with a similar style (see Section 2).

Conversely, an adversary aims to steal the target prompt from a target image. We refer to the prompt stolen by the adversary as *stolen prompt*. Moreover, the adversary can feed the stolen prompt to the text-to-image generation model again, and the generated image here is referred to as *stolen image*.

Adversary's Goal. Given a target image generated by a text-to-image generation model, the goal of the adversary is to steal the target prompt that leads to the target image. The

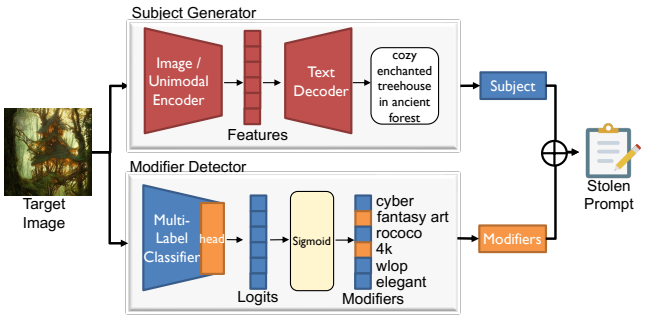

Figure 6: Overview of PromptStealer.

stolen prompt should ideally satisfy four quantitative goals.

- **Semantic Similarity.** The stolen prompt should share high semantic similarity with the target prompt, normally measured in the text embedding space. This is important because text-to-image generation models essentially condition on the text embeddings during the image generation. Here, the semantic similarity considers both subjects and prompt modifiers.
- **Modifier Similarity.** The stolen prompt should contain as many modifiers of the target prompt as possible. As the modifiers take an essential role in guaranteeing the quality of the generated image (see Section 3), higher modifier similarity results in better attack performance.
- **Image / Pixel Similarity.** By feeding the stolen prompt to the text-to-image generation model again, the adversary expects the model to generate a similar stolen image to the target image. Here, the similarity can be regarded as both image semantic and pixel-level similarity.

Besides, considering the usage of target prompt mentioned in Section 2, the stolen prompt should also lead to images depicting different subjects in style of the target image. Therefore, we also qualitatively assess PromptStealer from this angle.

Adversary's Capability. We assume the adversary's capabilities in a real-world setting. First, the adversary can collect public prompts and the corresponding images via online services like Lexica. Second, the adversary has black-box access to the target text-to-image generation model.

4.2 PromptStealer

In this work, we introduce PromptStealer, a simple yet effective prompt stealing attack. The design principle of PromptStealer is based on our observations in Section 3, i.e., a successful prompt stealing attack should focus on both the subject and modifiers of a target prompt. Specifically, PromptStealer consists of two modules: a subject generator and a modifier detector. Figure 6 shows the overview of PromptStealer.

Subject Generator. Given the target image, the subject generator aims to generate the subject of the stolen prompt. In this work, we adopt the image captioning framework for this purpose, which typically consists of an image/unimodal encoder and a text decoder [31, 68]. Concretely, the encoder first converts the target image to a fixed-length feature representation. This representation is then used in a text decoder to generate a caption/subject for the target image. Note, existing image captioning models are not directly suitable for subject generation for two main reasons. Firstly, they are trained on normalized data and are prone to use generic terms, such as referring to a specific celebrity as "a woman" or labeling a "terrier dog" simply as "a dog." In contrast, the subject of a high-quality prompt demands more specific and detailed information, such as race and landmarks. Secondly, image captioning models are trained to describe real-world pictures; however, the target images often showcase various art styles. To bridge this gap, we fine-tune the encoder as well as the decoder on the subjects and corresponding images in Lexica-Dataset. We evaluate two representative image captioning frameworks, i.e., BLIP and GIT, in our experiments (see Section 4.6).

Modifier Detector. Modifiers are keywords or key phrases related to specific elements or styles of the target image. A high-quality prompt typically includes numerous and varied modifiers that complexly interact with each other to dictate the style of the generated image. The goal of the modifier detector is thus to detect modifiers in a given target image. A similar task in the CV domain is object detection, which leverages a multi-label classifier to predict all objects in one given image simultaneously. Existing multi-label classifiers commonly consist of a backbone model and a multi-label classification head. The backbone model outputs an image representation, and the classification head transforms the representation into prediction logits. However, existing multi-label classifiers cannot be directly applied in the scenario of modifier detection. This is because they are primarily designed to output labels like "cat," "dog," and "airplanes," which are not modifiers such as artist names or painting styles. To adapt multi-label classifiers to our scenario, we reset the multi-label head layer of the multi-label classifier with Lexica-Dataset's modifier set and then fine-tune the whole model on the modifier sets and corresponding images in Lexica-Dataset. In addition, we apply a Sigmoid activation layer at the end of the multi-label classifiers to normalize the outputs to prediction posteriors. The labels/modifiers whose posteriors are higher than a predefined threshold are regarded as the stolen prompt's modifiers.

After applying the subject generator and the modifier detector to the target image, we concatenate the obtained subject and the prompt modifiers together as the final stolen prompt.

4.3 Experimental Settings

Text-to-Image Generation Model. We focus on Stable Diffusion as it is one of the most prevalent text-to-image generation models in the field. Besides, the open-source nature and the active community support (e.g., Lexica) of this model enable us to perform a large-scale evaluation. Most of our experi-

ments are directly performed on Lexica-Dataset. In certain cases, we also need to use Stable Diffusion to generate images for evaluation. To this end, we adopt the official Stable Diffusion v1.4 model.[4] For each image generation process, we sample 50 steps with default settings [69]. The size of the generated image is 512×512. We also consider other representative text-to-image generation models, like DALL·E 2 and Midjounery. However, since they are not open-source and only provide non-free APIs, collecting large-scale datasets from them is financially infeasible for us. As an alternative, we directly apply PromptStealer trained on Lexica-Dataset (based on Stable Diffusion) to them as a case study to test our approach's generalizability (see Section 4.8).

PromptStealer. PromptStealer consists of two modules: a subject generator and a modifier detector. For the subject generator, we evaluate two representative image captioning frameworks, i.e., BLIP [31] and GIT [68]. Concretely, we first adopt the BLIP and GIT model pre-trained on MS-COCO dataset and then follow their default settings to fine-tune them on the subjects and corresponding images of Lexica-Dataset. Regarding the modifier detector, we assess two multi-label frameworks, ML-Decoder [55] and Query2Label [33]. Note, we have in total of 77,616 prompt modifiers in Lexica-Dataset, which can all be treated as labels for the multi-label classifier. However, many modifiers only appear a few times (see Figure 3c). Therefore, in our main experiments, we only consider modifiers that appear more than 10 times (7,672 modifiers) as labels. We choose 0.6 as the threshold to decide whether a label/modifier is in the modifier set of the stolen prompt. The impacts of different label numbers and thresholds are investigated in Section 4.6. PromptStealer is trained on 80% of the samples in Lexica-Dataset, and the rest samples are used for testing.

Baseline Methods. We consider three baseline attack methods in our experiments. The first baseline is a pre-trained image captioning model. Given an image, the model produces a caption for the image, which is directly regarded as the stolen prompt. Here, we regard BLIP pre-trained on MS-COCO dataset as the first baseline. We further fine-tune the first baseline model on Lexica-Dataset as our second baseline. Besides, we also include an open-source prompt engineering tool, CLIP Interrogator [3] in our evaluation. This method iteratively calculates the similarity between the combinations of modifiers and the target image. Once the similarity stops rising, it regards the current combination as the stolen prompt. Before comparison, we evaluate the performance of CLIP Interrogator with two modifier sets, i.e., the same modifier set as PromptStealer (7,637 modifiers) and the complete modifier set of Lexica-Dataset (77,616 modifiers). As shown in our technique report [62], CLIP Interrogator with larger prompt modifiers demonstrates slightly better performance, therefore we utilize CLIP Interrogator with the complete modifier set as the third baseline method.

[4] https://huggingface.co/CompVis/stable-diffusion-v1-4.

Evaluation Metric. As discussed in Section 4.1, the adversary has four quantitative goals: semantic similarity, modifier similarity, image similarity, and pixel similarity. Thus, we adopt four quantitative metrics for these goals, respectively.

- **Semantic Similarity.** The semantic similarity is the cosine similarity between the embeddings of the target prompt and the stolen prompt. We use CLIP's text encoder to get the embeddings.
- **Modifier Similarity.** The modifier similarity is the Jaccard similarity between the modifiers of the target prompt and those of the stolen prompt.
- **Image Similarity.** The image similarity is the cosine similarity between the embeddings of the target and stolen images, which is a widely adopted metric to measure similarity between images, both at the semantic level and the visual/pixel level [60]. Following previous works [15, 60], we rely on CLIP's image encoder to obtain an image's embedding. For each stolen prompt, we generate four stolen images from Stable Diffusion (by varying the random seed) to eliminate the potential biases. We then calculate the similarity between each stolen image and the target image and, in the end, average the results.
- **Pixel Similarity.** The pixel similarity is a traditional metric to quantify the pixel differences between the target image and the stolen, which are commonly calculated by the complement of the mean squared error (MSE) [70].

We acknowledge that any metric has limitations. To perform a comprehensive assessment, we also provide qualitative evaluations to assess the similarity perceived by the end-users.

- **Human-Rated Similarity.** The human-rated similarity refers to the perceived similarity between target and stolen images by end-users. Specifically, for each target image and its corresponding stolen images, two labelers are assigned to label it using a 5-level Like-scaler, ranging from "not similar at all" to "very similar." The detailed criteria for each level is stated in Table 11 in Appendix. We randomly sample 10 target images in our test set and report the mean value.

4.4 Quantitative Evaluation

Table 2 shows the performance of PromptStealer together with the three baselines. We first observe that the image captioning model itself is not sufficient to achieve a successful prompt stealing attack. Even fine-tuned on the Lexica-Dataset, it only achieves 0.45, 0.14, 0.74, and 0.89 in semantic, modifier, image and pixel similarities. To compare, PromptStealer

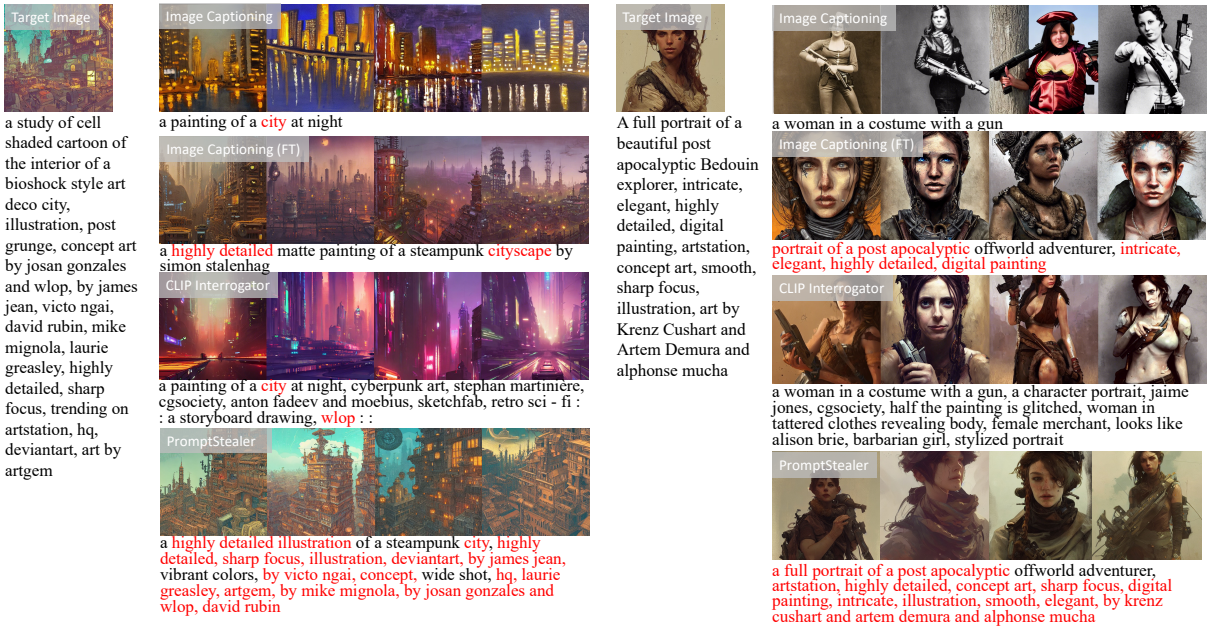

Figure 7: Two attack examples of PromptStealer and the three baselines. The text below each image is the target/stolen prompt.

achieves 0.70, 0.43, 0.80, and 0.90 in these metrics, respectively, while the corresponding results for the better baseline CLIP Interrogator are 0.52, 0.01, 0.77, and 0.89. We also notice that the modifier similarity of PromptStealer is not as high as other metrics. This is primarily because the modifier similarity is based on exact word matching, which is typically not high in the NLP domain [25]. For example, modifiers like "digital art" and "digital painting" are not considered a match despite their high semantic similarity. To address this, we offer semantic similarity as an additional metric. We further observe that the pixel similarity is not very distinguishable in this scenario. For instance, PromptStealer performs slightly better than CLIP Interrogator (0.90 vs. 0.89 in pixel similarity). This might be due to the pixel similarity metric itself. Since it is sensitive to changes in pixel values, it does not necessarily consider the human perception of similarity. We have evaluated other pixel-level metrics such as SSIM [70] and pHash [63]. The performance is similar. Therefore, we introduce human-rated similarity in the qualitative evaluation.

4.5 Qualitative Evaluation

Table 2 shows the human-rated similarity of PromptStealer and three baselines. The Cronbach's Alpha among the labelers is 0.90 on average, demonstrating good inter-reliability. We observe that PromptStealer gets far better human-rated similarity compared with other methods. For instance, the human-rated similarity for ImgCap, ImgCap (FT), Clip Interrogator, and PromptStealer are 1.65, 3.20, 2.95, and 4.45.

Figure 7 further shows two attack examples of PromptStealer and the baselines. Here, for each stolen prompt, we let Stable Diffusion generate four images with different random seeds to eliminate the potential biases. In both cases, we can see that the stolen images by PromptStealer are more

Table 2: The performance of PromptStealer and the three baselines on Lexica-Dataset. ImgCap refers to the image captioning method; ImgCap (FT) represents the image captioning method fine-tuned on Lexica-Dataset. Human refers to human-rated similarity.

Method	Semantic	Modifier	Image	Pixel	Human
ImgCap	0.19	0.00	0.65	0.89	1.65
ImgCap (FT)	0.45	0.14	0.74	0.89	3.20
CLIP Interrogator	0.52	0.01	0.77	0.89	2.95
PromptStealer	**0.70**	**0.43**	**0.80**	**0.90**	**4.45**

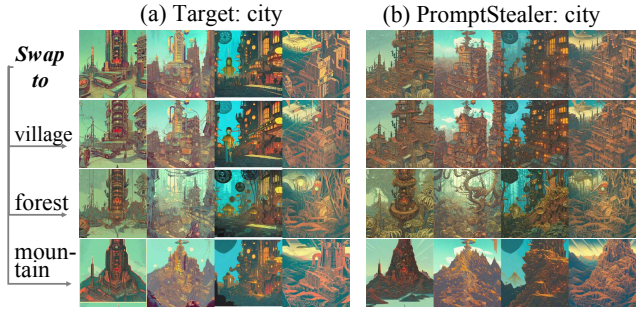

Figure 8: Transferability results of the example in Figure 7a.

Figure 9: Transferability results of the example in Figure 7b.

similar to the target images compared to the baselines. Take Figure 7b as an example, the stolen images by the image captioning method are the least similar to the target image. Concretely, the first, second, and fourth stolen images by image captioning are in vintage style, while the third image has some modern features with respect to color and clothing fabric. However, none of the images share a similar style to the target image. With modifiers introduced, the qualities of the stolen images generated by CLIP Interrogator improved a lot. All four images show the same vintage yellow tint as the target image. However, the wrong modifiers steer the stolen images in the wrong direction, thus reducing the efficacy of CLIP Interrogator. For example, the modifier "looks like alison brie," which is not part of the target prompt, directs the results toward the celebrity Alison Brie (see the first, second, and fourth images). To compare, we find that PromptStealer is able to recover a large proportion of the modifiers of the target prompt. The large coverage of modifiers thus promises coherence between the target and stolen images.

As mentioned before, an important usage of the prompt traded through the marketplace is that the user can modify its subject to generate other images with a similar style. We refer to this usage as transferability. Ideally, the stolen prompt should have high transferability as well. To validate the transferability of the stolen prompts, we continue using two examples in Figure 7, and compare the generated images when the subject in the prompt is replaced with new ones. For example, we replace "city" in the subject of the stolen prompt with new ones such as "village," "forest," and "mountain." We also provide the generated images using the target prompts, which are replaced with the same new subjects. Figure 8 and Figure 9 showcase the transferability results. We find that with the stolen prompts, the adversary can generate images that adapt well to other subjects while maintaining similar features to those generated using target prompts, indicating that the stolen prompts by PromptStealer have high transferability.

Table 3: Performances of subject generators. (FT) denotes that the model is fine-tuned on the subjects and corresponding images of Lexica-Dataset.

	Semantic	Modifier	Image	Pixel	Human
GIT	0.62	**0.43**	0.72	0.89	3.20
GIT (FT)	0.68	**0.43**	0.79	**0.90**	4.25
BLIP	0.66	**0.43**	0.79	**0.90**	3.55
BLIP (FT)	**0.70**	**0.43**	**0.80**	**0.90**	**4.45**

Table 4: Performances of different modifier detectors.

	Semantic	Modifier	Image	Pixel	Human
Query2Label	0.63	0.34	0.75	0.89	4.00
ML-Decoder	**0.70**	**0.43**	**0.80**	**0.90**	**4.45**

4.6 Ablation Study

We further evaluate whether PromptStealer is still effective with 1) different subject generators; 2) different modifier detectors; 3) label number; and 4) posterior threshold.

Subject Generator. Table 3 shows the performance of different subject generators. Regarding the model architectures, we find that BLIP performs slightly better than GIT in the prompt stealing scenario. Besides, it is clear to observe an increase for both of the two models across all metrics after fine-tuning on Lexica-Dataset. For instance, BLIP obtains an increase of 0.90 in human-rated similarity after fine-tuning and exhibits the best performance among all other models. Therefore, we utilize the fine-tuned BLIP as our subject generator in the following experiments.

Modifier Detector. We consider two modifier detector architectures, i.e., ML-Decoder and Query2Label, in our experiments. As illustrated in Table 4, we observe that ML-Decoder achieves better performance than Query2Label, as evidenced by the higher scores across all evaluation metrics. This can be attributed to the group-decoding scheme of ML-Decoder. Different from Query2Label which assigns a query per class, ML-Decoder uses a fixed number of queries and interpolates to reach the final number of classes using a group fully-connected block.

Label Number. In the main experimental setting, we only consider modifiers appearing more than 10 times in Lexica-Dataset as the labels (7,672) for the multi-label classifier. We are interested in whether changing the label number affects the attack performance. To this end, we consider two other variants, i.e., modifiers appear more than 50 times and 100 times which lead to 1,966 labels and 1,109 labels, respectively. Figure 17a in the Appendix shows the results. We find that for semantic, modifier, image, and pixel similarities, PromptStealer with 1,109 labels and 1,966 labels have slightly weaker performance than PromptStealer with 7,672 labels. For instance, the semantic similarities for 1,109, 1,966, and 7,672 labels are 0.67, 0.68, and 0.70, respectively. This is

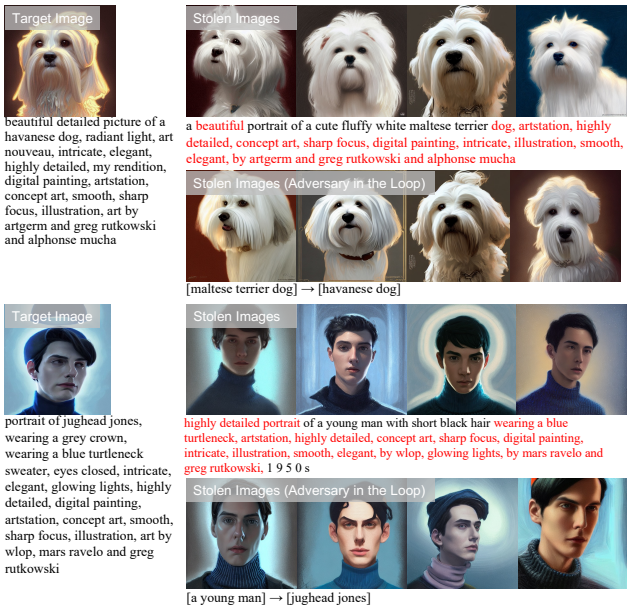

Figure 10: Two examples of improving PromptStealer by manually modifying subjects, i.e., adversary in the loop. The red color marks the correctly predicted modifiers.

reasonable as a relatively small modifier set can already cover most modifiers in target prompts, as shown in Figure 3c.

Threshold. Figure 17b in the Appendix shows the results regarding the impact of the posterior threshold for the multi-label classifier. We find that PromptStealer obtains the highest modifier, image, and pixel similarity when the threshold is set to 0.6. For semantic similarity, the highest result (0.71) is achieved when the threshold is 0.3, which is very close to the semantic similarity (0.70) when the threshold is 0.6. In conclusion, 0.6 is a suitable threshold for the multi-label classifier of PromptStealer.

4.7 Adversary in the Loop

We acknowledge that PromptStealer is not perfect. Figure 10 shows some failed cases of PromptStealer. We find that the main reason for these failed cases to happen is that PromptStealer cannot accurately capture the key subjects from the target images, such as celebrities and animals. However, the adversary can easily improve this by manually modifying the stolen prompt with their knowledge, e.g., replacing "a young man" with "jughead jones," or modifying the misidentified "maltese terrier dog" to "havanese dog." Examples in Figure 10 show the effects of involving the adversary in the loop. As we can see, the attack results improve significantly. Besides involving an adversary in the loop, more advanced machine learning models can be used to solve the issue as well, like adding a subject detector when generating subjects. We leave this as future work.

Table 5: The performance of PromptStealer and baseline methods on DiffusionDB.

Method	Semantic	Modifier	Image	Pixel	Human
ImgCap	0.28	0.00	0.69	0.88	1.65
ImgCap (FT)	0.50	0.22	0.79	0.88	3.25
CLIP Interrogator	0.51	0.01	0.79	0.88	2.15
PromptStealer	**0.64**	**0.30**	**0.82**	**0.89**	**3.95**

Table 6: The performance of PromptStealer and baseline methods on real-world traded prompts.

Method	Semantic	Modifier	Image	Pixel	Human
ImgCap	0.44	0.00	0.80	**0.89**	2.85
ImgCap (FT)	0.55	0.08	**0.83**	0.88	3.35
CLIP Interrogator	0.56	0.00	0.80	0.88	3.40
PromptStealer	**0.63**	**0.22**	**0.83**	**0.89**	**4.05**

4.8 Open-World Evaluation

Other Datasets. So far, all the testing samples for PromptStealer are from Lexica-Dataset. To simulate more realistic attack scenarios, we evaluate whether PromptStealer can be generalized to target images from out-of-distribution datasets.

DiffusionDB. DiffusionDB [4] is a recent open-source prompt-image dataset and we randomly sample 1k prompts and corresponding images for evaluation. We find PromptStealer outperforms the three baselines both quantitatively and qualitatively. As illustrated in Table 5, PromptStealer achieves 0.64, 0.30, 0.82, and 0.89 on semantic, modifier, image, and pixel similarity, respectively. Regarding qualitative performance, PromptStealer also obtains the highest human-rated similarity with a score of 3.95. See our technical report [62] for the qualitative attack examples.

Real-world Traded Prompts. Additionally, we apply PromptStealer to 10 randomly selected/purchased real-world prompts traded on two prompt marketplaces, PromptBase [10] and PromptDB [11]. Table 6 shows that PromptStealer consistently outperforms baseline methods both quantitatively and qualitatively. As Figure 11 shows, PromptStealer successfully identifies the main subject and modifiers in the target prompts. For instance, for the first target image, PromptStealer can successfully infer "lighthouse" and "a stormy sea" in the subject and the modifiers "highly detailed" and "pixar." Moreover, the stolen images exhibit a strong resemblance to the target image, indicating the capability of PromptStealer in open images.

Other Text-to-Image Generation Models. Midjourney and DALL·E 2 are also mainstream text-to-image generation models. However, as mentioned before, the two models are still not open-source, so we could not conduct large-scale quantitative experiments on them. Instead, we perform a case study and hope it could shed light on the generalizability of PromptStealer on these unseen models. Concretely, we first use two target prompts from Lexica-Dataset to generate two target

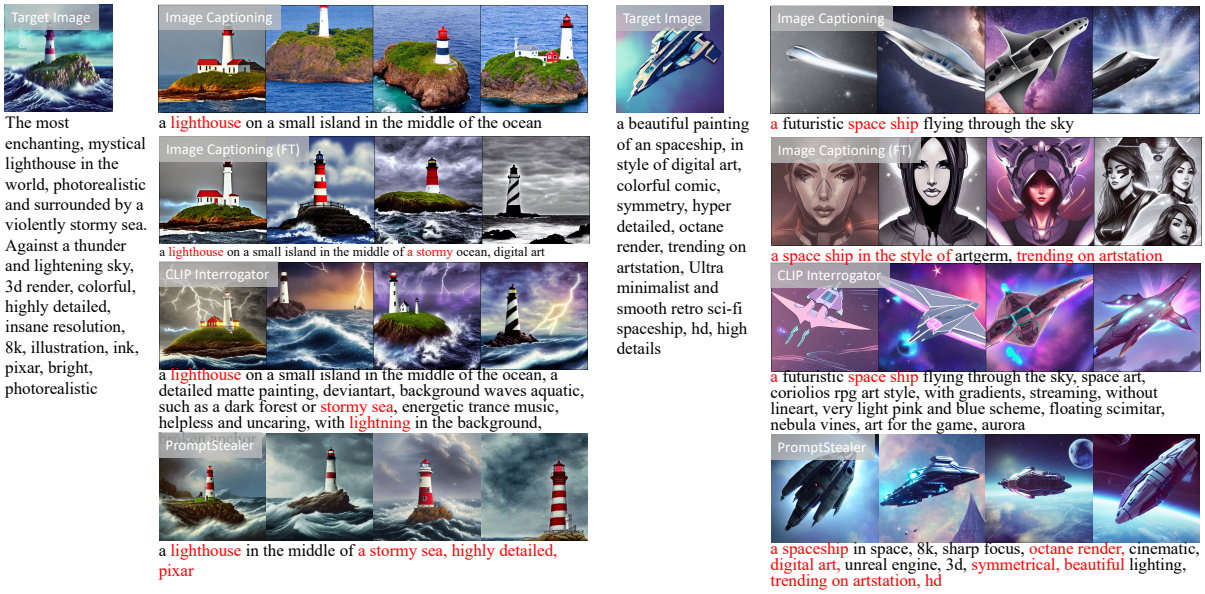

Figure 11: Two attack examples of PromptStealer and the three baselines on real-world traded prompts. The first one is from PromptDB, and the latter one is from PromptBase. The red color marks the correctly predicted modifiers.

Table 7: Performances across Stable Diffusion versions.

Version	Semantic	Modifier	Image	Pixel	Human
v1.4	**0.63**	0.43	0.79	0.90	**4.5**
v1.5	**0.63**	**0.45**	0.79	**0.91**	4.3
v2.0	0.53	0.32	**0.82**	0.88	4.25

images from Midjourney and DALL·E 2. We then directly apply the trained PromptStealer to steal the prompts from the two target images and use the corresponding text-to-image generation models again to get the stolen images. The results are displayed in Figure 12 and Figure 13.

We find that even though PromptStealer has never seen images generated from Midjourney and DALL·E 2 before, it still manages to catch certain key prompt modifiers, such as "octane render" and "artstation." This indicates that PromptStealer still works on these unseen text-to-image generation models to a certain extent. We also notice that PromptStealer does not perform as well as it does on Stable Diffusion. For example, it cannot accurately deduce the artist modifiers. This could be caused by the different architectures and weights of these text-to-image generation models. One possible solution is to train PromptStealer on multiple datasets related to different models like Midjourney and DALL·E 2. However, as no dataset is available by the time we perform this study, we leave this as future work.

Newer Versions of Stable Diffusion. With the advancement of Stable Diffusion, it is also interesting to observe whether PromptStealer works on different versions of Stable Diffusion.

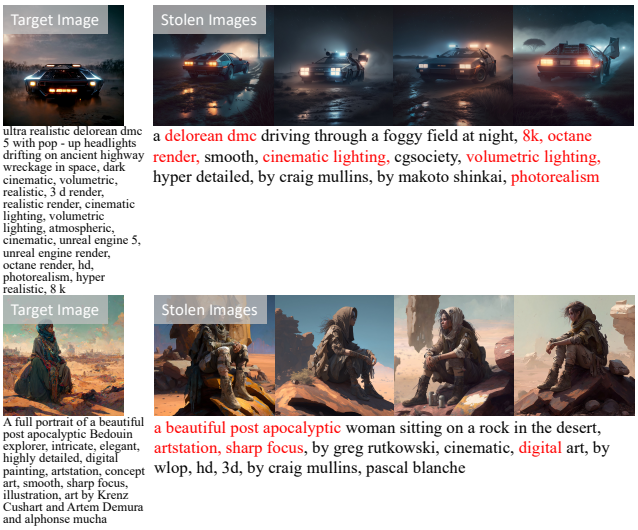

Figure 12: Two attack examples of PromptStealer in open-world evaluation (other model Midjourney). The target and stolen images are generated by Midjourney. The red color marks the correctly predicted modifiers.

Note that the data we collected contains no model version information. Therefore, given a target prompt, we utilize a certain version of Stable Diffusion to generate the target image and then apply PromptStealer to steal its prompts. We test three versions of Stable Diffusion: v1.4, v1.5, and v2.0. Table 7 shows the results. Overall, PromptStealer performs

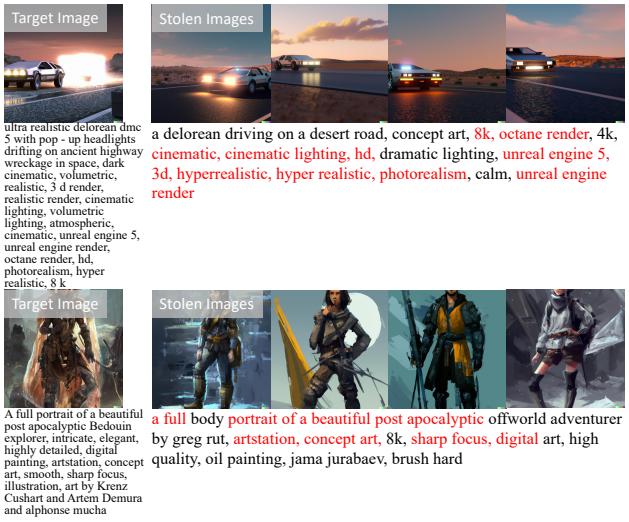

Figure 13: Two attack examples of PromptStealer in open-world evaluation (other model DALL·E 2). The target and stolen images are generated by DALL·E 2. The red color marks the correctly predicted modifiers.

similarly on v1.4 and v1.5 but slightly worse on v2.0. This may be because v2.0 came out after our data collection, so its samples are not included in the training set. We also display attack examples in our technical report [62].

4.9 Performance on Multiple Target Images

In some cases, the adversary is able to obtain multiple target images generated by one target prompt. Therefore, we also explore the potential of PromptStealer when multiple target images are provided. In this scenario, the adversary first gets a set of the stolen prompts (including the subject and modifiers) via PromptStealer and then applies different strategies to get the best prompts. We examine three strategies: 1) random: randomly choose one from all stolen prompts; 2) best: choose the stolen prompt achieving the best performance; 3) union: greedy-search the best caption and union all modifiers predicted from these target images. The results can be found in Table 8. We find that providing multiple target images indeed increases the attack performance, and the union strategy performs the best. We also provide qualitative examples in our technical report [62].

4.10 ChatGPT in Prompt Stealing Attacks

ChatGPT (GPT-4), as an advanced vision-language model, can also be prompted to infer the target prompt given a target image. Therefore, we evaluate its performance by leveraging a prevalent prompt generator in the GPT store [2]. Its semantic, modifier, image, pixel, and human-rated similarities are 0.35, 0.00, 0.72, 0.91, and 3.2, suggesting PromptStealer still outperforms ChatGPT. In Figure 14, we present two attack examples between PromptStealer and ChatGPT. A key

Table 8: Performances of different strategies when facing multiple target images. "Single" is the performance of a single target image.

	Semantic	Modifier	Image	Pixel	Human
Single	0.70	0.43	0.80	0.90	4.45
Random	0.70	0.43	0.80	0.90	4.25
Best	0.72	0.42	**0.83**	0.90	4.50
Union	**0.77**	**0.44**	**0.83**	**0.91**	**4.65**

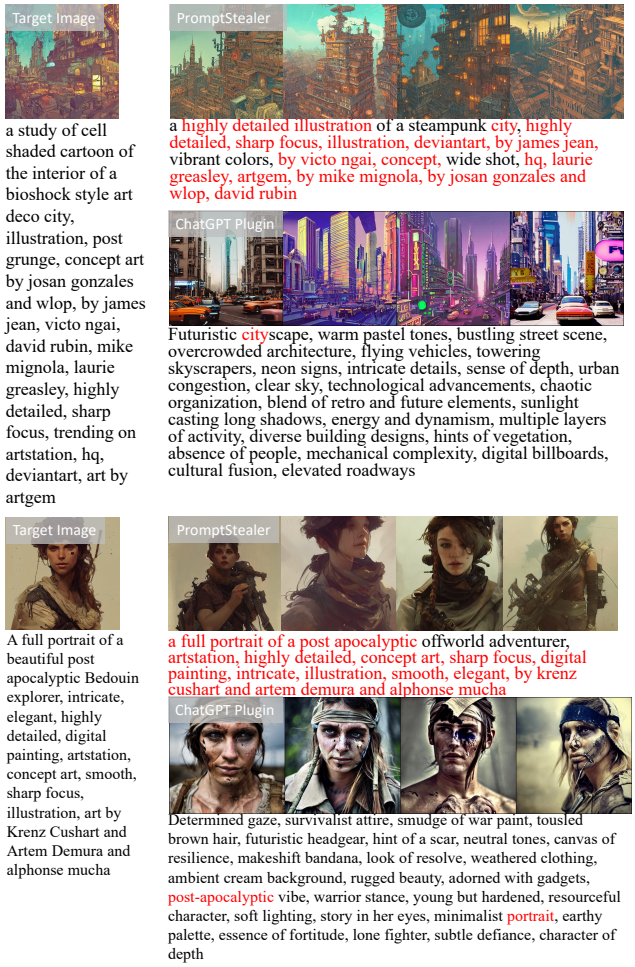

Figure 14: Two attack examples of PromptStealer and ChatGPT Plugins. The red color marks the correctly predicted modifiers.

observation is that PromptStealer outperforms ChatGPT in recognizing the art style of the target image. For instance, in the first example, while ChatGPT accurately recognizes the subject as a city, it incorrectly identifies the target art style - from "cartoon, Josan Gonzales, Wlop" to "Futuristic, warm pastel tones." This misinterpretation significantly hampers the quality of the output.

Table 9: The performance of PromptShield against PromptStealer. The second row refers to modifier categories.

	Semantic	Modifier	Image	Pixel	Human
Unshielded	0.70	0.43	0.80	0.90	4.45
Shielded	0.62	0.74	0.71	0.88	1.85
	Artist	**Medium**	**Flavor**	**Movement**	**Trending**
Unshielded	0.49	0.44	0.43	0.03	0.42
Shielded	0.06	0.53	0.79	0.06	0.48

5 Defense

After demonstrating the efficacy of PromptStealer, we further propose a defense method, namely *PromptShield*.

5.1 PromptShield

The adversary relies on machine learning models to realize PromptStealer. To mitigate the attack, one natural solution is to use adversarial examples to reduce the performance of PromptStealer's machine learning models. Specifically, we aim to add an optimized perturbation to a target image to obtain a *shielded image* such that PromptStealer cannot infer the stolen prompt from the shielded image effectively. PromptShield has two goals, i.e., effectiveness and utility. High effectiveness indicates the performance of PromptStealer drops significantly on shielded images; high utility implies perturbations on the shielded images are imperceptible to humans.

PromptStealer consists of two machine learning models: a subject generator and a modifier detector. Technically, PromptShield can generate shielded images against either of the models or both. Here, we focus on the modifier detector instead of the subject detector. The reason is that if PromptShield creates a shielded image to mislead the subject detector, then PromptStealer will obtain a subject misaligned with the shielded image. By manually checking, the adversary can easily fix the error in the subject, as we show in Section 4.7, which reduces the effectiveness of PromptShield. Meanwhile, if the shielded image is against the modifier detector, then PromptStealer will infer a stolen prompt with wrong or missing modifiers. As each prompt has multiple modifiers and the total number of modifiers is large, it is not easy for the adversary to spot which modifiers are missing or wrong.

To generate a shielded image against the modifier detector, PromptShield can choose any or all of the 7,672 labels/modifiers. Here, we choose the modifiers in the artist category. The reasons are twofold. First, as shown in Section 3.2, artist modifiers play important roles in driving the generated images to specific styles. Second, focusing on artist modifiers also directly protects artists' intellectual properties.

The concrete process of PromptShield is as follows. For the modifier set of a target prompt, we first remove all its artist modifiers to obtain a shielded modifier set. Then, we optimize a perturbation for the target image such that the final shielded image is classified towards the shielded modifier set. In other words, we do not mislead the modifier detector to classify the shielded image to a different set of artist modifiers. Instead, we generate the perturbation that can ideally remove the artist-related information from the target image. For optimization, we adopt I-FGSM [28]. We set the iterative step to 100 and ϵ to 0.2. We also evaluate the performance of another representative method, namely C&W [18]. The performance is reported in Section A.1 in Appendix. As the design principle of PromptShield is general, we further apply it to the optimization-based baseline attack CLIP Interrogator. The results are listed in our technical report [62]. Note that we assume the defender has white-box access to the modifier detector of PromptStealer. We acknowledge that this is a strong assumption and the main weakness of our defense.

5.2 Experimental Settings

We follow the same experimental settings in Section 4.3 for the text-to-image generation model and the attack model.
Evaluation Metric. We design our evaluation metrics based on the two goals of the defender: effectiveness and utility.

- **Effectiveness.** We adopt the same quantitative metrics, i.e., semantic, modifier, image, and pixel similarity, from Section 4.3 as the effectiveness metrics.
- **Utility.** For utility, we measure the mean squared error (MSE) between the target image and the shielded image. Lower MSE implies higher utility.

Besides, we also provide human-rated similarity as qualitative evaluation.

5.3 Quantitative Evaluation

Table 9 shows the effectiveness of PromptShield. We observe that the artist modifiers exhibit the greatest reduction in similarity (from 0.49 to 0.06) while the overall modifier similarity increases. This is expected, as the shielded image contains less information related to artist modifiers, the attack model has a higher capacity to predict other modifiers more accurately. On the other hand, we find that both semantic and image similarities decrease. Concretely, the semantic similarity decreases from 0.70 to 0.62, and the image similarity decreases from 0.80 to 0.71. Considering the previous worse baseline (the image captioning method) only gets a 0.65 image similarity, we conclude that PromptShield achieves strong performance in defending against PromptStealer.

Regarding utility, we find PromptShield performs well in producing concealed perturbation. The average MSE between the target and shielded images is 0.0007 which implies that the added perturbation is imperceptible to humans.

We observe comparable results when C&W is adopted as the optimization method for PromptShield (see Section A.1 in Appendix). In addition, PromptShield also achieves promising results on CLIP Interrogator (see our technical report [62]).

5.4 Qualitative Evaluation

Figure 15 further shows two defense examples of PromptShield against PromptStealer. In both cases, we can see that the stolen images originating from the shielded images are less similar to the target images. Take the first target image in Figure 15 as an example. The artist modifiers in the target prompt is "james gilleard," "atey ghailan," "makoto shinkai," and "goro fujita." We find that for the unshielded target image, the artist modifier can be successfully stolen by PromptStealer. However, after applying PromptShield, the attack model cannot predict the artist modifier from the shielded image. Moreover, even though the stolen prompt based on the shielded image contains some correct modifiers such as "lush vegetation," the stolen images are quite different from the target image without the artist modifier. This has been further confirmed in our human study. As shown in Table 9, the human-rated similarity decreases from 4.45 to 1.85. Besides, by comparing the target and shielded images, we find they are quite similar, demonstrating the utility of PromptShield.

5.5 Limitations

As mentioned before, PromptShield is effective but it requires a strong assumption for the defender, i.e., white-box access to the attack model. We have also experimented with the transfer defense. Concretely, we apply PromptShield on CLIP Interrogator and use the generated perturbation to defend PromptStealer; however, the experimental results are not promising. In addition, our evaluation shows that the defense performance can be reduced by the adaptive attack, which trains the modifier detector with shielded images and ground-truth modifiers (see our technical report [62]). We emphasize that our goal is to assess whether the defense under a strong assumption is effective, and we hope our results can provide guidance for developing more advanced defenses in the future.

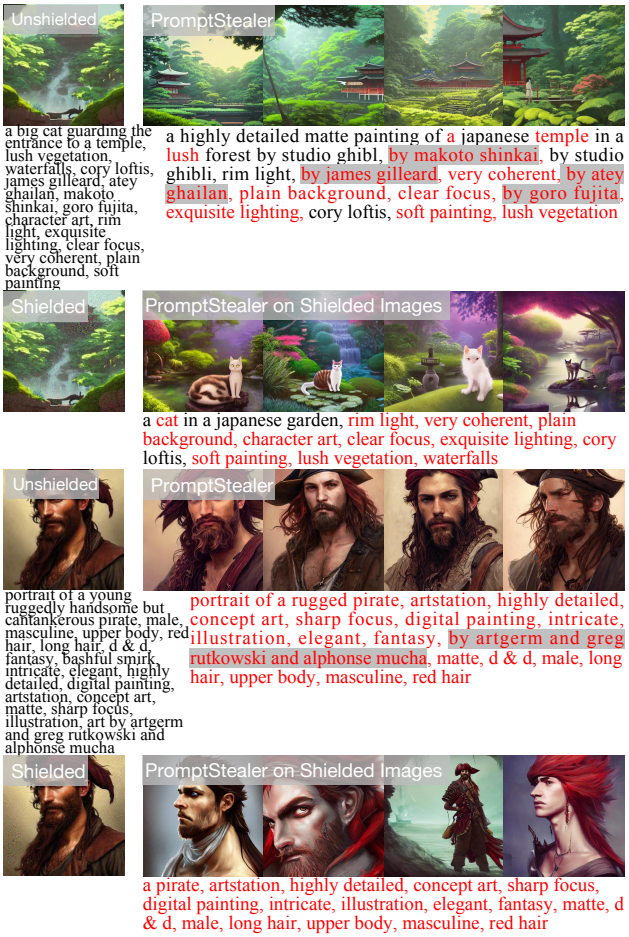

Figure 15: Two defense examples of PromptShield against PromptStealer on the artist modifiers. The red color marks the correctly predicted modifiers. We highlight in grey the target artist modifiers stolen by PromptStealer.

6 Related Work

Prompt Engineering. Prompt engineering in text-to-image generation models aims to improve the quality of generated images by developing prompt design guidelines [34, 43, 47]. Liu and Chilton [34] qualitatively investigate what prompt components and model parameters can produce high-quality images and provide seven suggestions for prompt design. They emphasize that using proper modifiers, rather than rephrasing the prompt with the same modifier set, is a key factor in image generation quality. Oppenlaender [43] presents a taxonomy of prompt modifiers based on an ethnographic study and highlights the significance of correctly using prompt modifiers. Pavlichenko and Ustalov [47] study a human-in-the-loop approach to find the most useful combination of prompt modifiers with a genetic algorithm. Overall, these works suggest that modifiers, especially proper modifiers, are crucial in generating high-quality images. In addition to our data analysis in Section 3.2, these previous works also inspire the design of PromptStealer.

Image-to-Text Synthesis. There are also studies focusing on image-to-text synthesis, such as image captioning tasks [3, 31, 39]. Li et al. adopt the multimodal mixture of encoder-decoder architecture and an additional filter to remove the noisy captions during the caption generation process [31]. Wang et al. design GIT, which simplifies the image captioning architecture to an image encoder and a text decoder. Besides, CLIP Interrogator, a tool in the open-source community also put efforts into searching prompts to match a given image [3]. CLIP Interrogator relies on CLIP to iteratively calculate the similarity between modifiers and the target image. It is inefficient due to its iterative design and many manually defined hyperparameters. Intuitively, the above-mentioned works can all be tailored to steal prompts. However, our experimental results reveal these methods fail to reverse prompts satisfactorily. Instead, we propose a simple yet effective prompt

stealing attack.

Security Issues of Machine Learning Models. The security issues of machine learning models have been increasingly discussed for years. Researchers have identified various types of attacks such as adversarial examples [18, 19, 30, 44, 45], membership inference [16, 20, 32, 40, 59, 64, 65], backdoor [23, 27, 35, 36, 57, 61, 72], etc. Most of these works focus on classification models. The security vulnerabilities of text-to-image generation models have received little attention. To the best of our knowledge, only limited works discuss the possible attack vector or misuse of the text-to-image generation models [17, 29, 51, 60, 71]. However, none of them investigates the emerging threat of stealing prompts from the images. We hope our study can provide insights into this novel attack and inspire more research in this field.

7 Discussion

Legal Debates / Copyright Laws Concerning Prompts. The legal environment for AI-generated content (AIGC) is quickly changing, with various legal authorities worldwide working to adapt copyright laws for the digital era. In 2023, the US Copyright Office opened a public comment period from August to October to address complex issues related to AI and copyright [41]. Currently, copyright ownership in AIGC remains ambiguous due to unclear data collection regulation, the need for equitable benefit distribution, inconsistent global legal views on AI copyright, and challenges in tracing all original works used in AI training [38]. Compared to the complex copyright landscape of generated images, user-curated prompts involve significant human efforts and thereby align more closely with traditional copyright concepts that copyright laws protect works created and fixed by humans [37, 42]. Prompt marketplaces like PromptBase and PromptSea also explicitly state that the prompts on their platforms are owned by the individuals who created them [49, 50]. Therefore, prompt stealing attacks infringe on intellectual property rights.

Societal Impacts. This work has three important implications for the AIGC participants, prompt engineers, and marketplace owners. First, our work demonstrates the feasibility of prompt stealing attacks. Given the image showcased in the prompt marketplace, an adversary is capable of inferring the selling prompt without payment quickly. The extremely short attack time makes the threat severity of prompt stealing attacks more than just stealing a certain prompt, but represents a new data breach channel to prompt marketplaces. For example, an adversary can perform prompt stealing attacks to quickly steal thousands of prompts on marketplaces and sell them on underground forums or a competitive marketplace. This data breach incident causes substantial financial losses to the victim marketplaces and jeopardizes their business models, which has also been seriously discussed in PromptSea's white paper [50]. Second, we bring insights on how to mitigate prompt stealing attacks, i.e., by introducing unperceived perturbations on the showcased images. We argue that there is an urgency to propose effective and flexible defenses against prompt stealing attacks. The proposed defense method PromptShield can serve as a foundational baseline for this direction. Third, we contribute by collecting Lexica-Dataset, a dataset with 61,467 prompt-image pairs and categorized modifiers. This dataset can be used not only in training the attack model but also to provide insights to prompt engineers such as helping them to understand the impact of a certain modifier or the joint effects among modifier combinations. As the first systematic study of prompt stealing attacks, we believe that our findings can serve as a valuable resource for the research community and stakeholders to navigate and mitigate this emerging threat.

Limitations & Future Work. Our work has limitations. First, we mainly evaluate the attack on Stable Diffusion and perform case studies on other text-to-image models such as Midjourney and DALL·E 2. Though PromptStealer infers certain keywords under this open-world setting, it is essential to quantitatively evaluate whether other text-to-image models are under the threat of prompt stealing attacks. Considering Midjourney and DALL·E 2 are close-sourced, we leave this as future work. Second, our research focuses on prompts for text-to-image generation models. But as prompts for large language models are appearing on marketplaces, it would be interesting to investigate if prompt stealing attacks also apply to them.

8 Conclusion

In this paper, we conduct the first investigation on prompt stealing attacks against text-to-image generation models. A successful prompt stealing attack directly violates the intellectual property of prompt engineers and threatens the business model of prompt marketplaces. In detail, we first collect a dataset Lexica-Dataset and perform a large-scale measurement on it to show that a successful prompt stealing attack should consider a target prompt's subject as well as its modifiers. We then propose a simple yet effective prompt stealing attack, PromptStealer. Experimental results show that PromptStealer outperforms the three baseline methods both quantitatively and qualitatively. We also make attempts to defend against PromptStealer. In general, our study shed light on the threats existing in the ecosystem created by the popular text-to-image generation models.

A Appendix

A.1 PromptShield With C&W

C&W is another representative method for generating adversarial examples. Different from I-FGSM, C&W utilizes two losses to control the attack effectiveness and utility. In our experiments, we set the iterative step to 100, the learning rate to 0.05, and the loss trade-off hyperparameter to 0.001. Table 10 reports the effectiveness of PromptShield (C&W). We observe that semantic, modifier, and image similarities decrease from 0.70, 0.43, and 0.80 to 0.58, 0.21, and 0.74, respectively. Similar to the results shown in Table 9, the artist modifiers drop the greatest in similarity (from 0.49 to 0.13). Regarding utility, we find C&W also produces invisible perturbation. The average MSE between the target and shielded images is 0.08. Figure 16 shows one defense example of PromptShield (C&W) against PromptStealer.

Table 10: The performance of PromptShield (C&W) against PromptStealer. The second row refers to modifier categories.

	Semantic	**Modifier**	**Image**	**Pixel**	**Human**
Unshielded	0.70	0.43	0.80	0.90	4.45
Shielded	0.58	0.21	0.74	0.88	2.50
	Artist	**Medium**	**Flavor**	**Movement**	**Trending**
Unshielded	0.49	0.44	0.43	0.03	0.42
Shielded	0.13	0.19	0.17	0.01	0.42

Table 11: The criteria for scoring human-rated similarity.

Level	**Description**
1 Not similar at all	The objects depicted are different, and the style is different.
2 Slightly similar	The objects depicted share some common elements or themes, but there are notable differences in both content and style.
3 Moderately similar	The objects depicted are similar in content or subject matter, but the styles are quite different.
4 Quite similar	The object depicted are similar in content or subject matter, but there are some differences in details, such as background color or minor elements.
5 Very similar	The objects depicted are almost identical in content, style, and details; they strongly resemble each other.

Quantifying Privacy Risks of Prompts in Visual Prompt Learning

Abstract

Large-scale pre-trained models are increasingly adapted to downstream tasks through a new paradigm called prompt learning. In contrast to fine-tuning, prompt learning does not update the pre-trained model's parameters. Instead, it only learns an input perturbation, namely prompt, to be added to the downstream task data for predictions. Given the fast development of prompt learning, a well-generalized prompt inevitably becomes a valuable asset as significant effort and proprietary data are used to create it. This naturally raises the question of whether a prompt may leak the proprietary information of its training data. In this paper, we perform the first comprehensive privacy assessment of prompts learned by visual prompt learning through the lens of property inference and membership inference attacks. Our empirical evaluation shows that the prompts are vulnerable to both attacks. We also demonstrate that the adversary can mount a successful property inference attack with limited cost. Moreover, we show that membership inference attacks against prompts can be successful with relaxed adversarial assumptions. We further make some initial investigations on the defenses and observe that our method can mitigate the membership inference attacks with a decent utility-defense trade-off but fails to defend against property inference attacks. We hope our results can shed light on the privacy risks of the popular prompt learning paradigm. To facilitate the research in this direction, we will share our code and models with the community.[1]

1 Introduction

Recent research has provided ample evidence that increasing the size of machine learning (ML) models, i.e., the number of parameters, is a pivotal factor in enhancing their overall performance [6, 11, 40]. One of the commonly employed strategies for adapting such large-scale pre-trained ML models to downstream tasks is fine-tuning [59], which updates model parameters for specific downstream tasks via back-propagation. Fine-tuning, however, suffers from two main drawbacks. First, it leads to high computational costs because all model parameters need to be updated. In addition, it is storage inefficient since a separate copy of the fine-tuned model needs to be stored for each downstream task.

In order to address these limitations, researchers have proposed prompt learning as an alternative to fine-tuning [4, 5, 20, 25, 26, 30, 31, 41, 56]. Prompt learning involves learning an input perturbation, referred to as a *prompt*, that enables shifting downstream task data to the original data distribution. The pre-trained model generates a task-specific output based on this prompt. It is important to note that, during prompt learning, the pre-trained model remains frozen, leading to a significant decrease in the number of learned parameters compared to fine-tuning (see Section 2). In recent years, prompt learning has been extensively validated and shown to be effective in the domains of computer vision (CV) [4, 5, 20, 31, 56] and natural language processing (NLP) [25, 26, 30, 41]. It is expected that prompt as a service (PaaS) will gain popularity.[2] In this scenario, a user can request a prompt for a downstream task from the PaaS provider without the need for arduous fine-tuning. The user then combines their data with the prompt and inputs them into the pre-trained model to obtain the predictions, as depicted in Figure 1. In this way, the user can run the pre-trained model and keep their data on-premise, while the PaaS provider can reuse a single pre-trained model to support multiple downstream tasks. These benefits differentiate PaaS from machine learning as a service (MLaaS) [42]. As a result, a well-generalized prompt becomes a valuable asset for PaaS providers, as they invest significant efforts and use proprietary data to develop it.

Previous research has demonstrated that ML models are vulnerable to various privacy attacks, such as property inference attacks [14, 55] and membership inference attacks [28, 44, 46], which can disclose sensitive information about the training data used to create the models. Such data leakage can

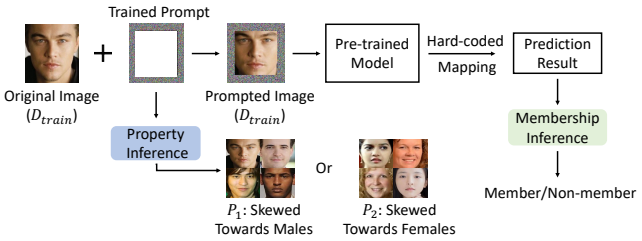

Figure 1: Overview of prompt usage and inference attacks. The prompt is a pixel patch. The prompted image is an original image with an added prompt. Property inference infers sensitive properties of the target prompt's training dataset that the PaaS provider does not intend to disclose. Membership inference infers whether a given sample was in the target prompt's training dataset.

severely damage the provider's privacy as well as intellectual property. However, to the best of our knowledge, previous research about such privacy risks has focused on ML models at the model level and has not yet been explored on prompts at the input level. As the number of learned parameters is significantly reduced in prompt learning, it is natural to assume that this paradigm would compress the proprietary information of its training data, leading to less effective privacy attacks (see Section 2.2). This motivates us to investigate whether a prompt also leaks the proprietary information of its training data that the PaaS provider does not intend to disclose, especially when such prompts are generated from images containing sensitive private information.

Contributions. In this paper, we conduct the first privacy risk assessment of prompts learned by prompt learning. We focus on prompt learning for image classification tasks [4], which represents one of the most promising directions in computer vision research [4,5,8,20,22,31,49,51,56]. Our primary objective is to determine *to what extent a visual prompt possesses the potential to disclose confidential information.* Specifically, we perform property inference and membership inference, two dominant privacy attacks against ML models [7,14,36,46], where the former aims to deduce sensitive properties of the dataset used to train the target prompt, and the latter determines if a given data sample is part of the target prompt's training dataset. We adopt the existing attack methodologies for property inference [3,14] and membership inference (neural network-based attacks [44,46], metric-based attacks [47], and gradient-based attacks [24,38]). Note that our goal is not to develop new property inference attacks or membership inference attacks against prompts. Instead, we aim to use existing methods with well-established threat models to systematically assess the privacy risks of prompt learning. The overview of our study is depicted in Figure 1.

The empirical evaluation shows prompts are susceptible to property inference attacks across multiple datasets and pre-trained models. For example, we can achieve at least 81% accuracy in inferring different target properties from prompts learned for CelebA [34]. Moreover, when inferring the training dataset size of the prompt, we can achieve 100% test accuracy in all cases. We also conduct a cost analysis to show that the adversary can either train the shadow prompts for fewer epochs or use fewer shadow prompts to minimize their cost while maintaining decent attack performance.

Our study also provides empirical evidence that membership inference poses a practical threat to prompts. The experimental results demonstrate that existing attack methodologies are effective across a range of datasets and pre-trained models. In particular, the metric-based attack with modified prediction entropy is the most effective one, e.g., achieving 93% membership inference accuracy on the AFAD dataset [39]. The gradient-based attacks follow closely behind and outperform the neural network-based (NN-based) attacks. We further investigate factors that may affect membership inference from both the victim's and the adversary's perspectives. Specifically, from the victim's side, we conduct a detailed analysis of the relationship between the overfitting levels of prompts and attack success [50]. The results indicate that the attack success is positively correlated with the overfitting level. Moreover, excessive training epochs and inadequate training data increase overfitting levels, exacerbating the privacy threat posed by membership inference attacks. From an adversarial perspective, we demonstrate that the adversary can relax the assumption that the shadow dataset has the same distribution as the target prompt's training dataset. This finding further exemplifies the membership privacy risks of prompts learned by prompt learning.

We also conduct preliminary investigations into mitigating privacy risks associated with prompt learning. In particular, we explore the effectiveness of adding Gaussian noise to prompts, as proposed in prior research [18,54,57]. Our experiments demonstrate that there exists a decent utility-defense trade-off when mitigating both naive and adaptive membership inference attacks. However, when defending against property inference attacks, we need higher Gaussian noise to reduce the attack performance, leading to unacceptable utility deterioration. Our findings indicate that the statistical information of the training dataset in the target prompts is harder to hide than individual information, i.e., membership. Our results highlight the need for further research into more effective defense mechanisms for mitigating property inference attacks in prompt learning.

Impact. This study presents an exploration of the privacy risks associated with prompt learning, an emerging machine-learning paradigm. Our investigation represents the first of its kind in this area. Our findings indicate that prompts learned through prompt learning are susceptible to privacy breaches. We hope our study will increase the awareness of the stakeholders when deploying prompt learning in real-world applications. Moreover, to facilitate research in the field, we will share our code and models.

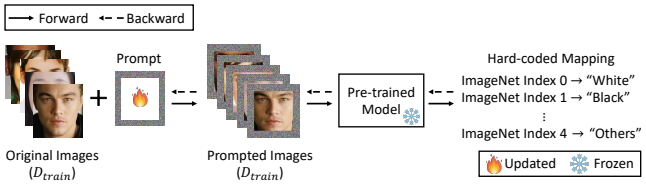

Figure 2: Overview of visual prompt learning (VPL). We learn an input prompt via back-propagation [4] at the input transformation stage. We apply hard-coded mapping [13] to map the pre-trained model's outputs into the target labels at the output transformation stage.

2 Preliminaries

2.1 Prompt Learning

Overview. Prompt learning is a new machine-learning paradigm introduced to address the limitations of fine-tuning [4, 5, 20, 25, 26, 30, 31, 41, 56]. It aims at learning a task-specific prompt that can be added to the input data while keeping the pre-trained model's parameters frozen. With this new paradigm, the service provider can share the same pre-trained model across various downstream tasks with different prompts in a space- and computation-efficient manner. In this paper, we focus on prompt learning in computer vision, i.e., *visual prompt learning (VPL)* [4]. It is generally composed of two stages: input transformation and output transformation.

Input Transformation. As shown in Figure 2, the goal of input transformation is to learn an input prompt δ in the pixel space, *i.e., in the form of a single image*, via back-propagation. Given a dataset $\mathcal{D} = (\mathcal{X}, \mathcal{Y})$, a pre-trained model $\mathcal{M}$ parameterized by ω, and a prompt δ parameterized by θ, the prompt generation process $q(\mathcal{D}, \mathcal{M})$ uses Equation 1 to maximize the likelihood of $\mathcal{Y}$:

$$\max_{\theta} P_{\theta;\omega}(\mathcal{Y}|\mathcal{X} + \delta_\theta), \tag{1}$$

where the prompt parameters θ are learned via back-propagation and the model parameters ω are frozen. Note that the prompt can be any visual template chosen by the users, e.g., padding [4]. At inference time, the learned prompt δ is added to each test image x to specify the task.

Output Transformation. Usually, the pre-trained model has a different number of classes from the downstream tasks. To accomplish the downstream task, the prompt owner supplies a label mapping scheme τ to map the model's outputs into the target labels. As shown in Figure 2, a commonly used scheme is hard-coded mapping [13]. It consists of mapping the first n pre-trained model class indices to the downstream class indices, where n is the number of classes in the downstream task. The unassigned pre-trained classes are left out for the loss computation. We rely on hard-coded mapping due to its simplicity and proven effectiveness [4].

2.2 Prompt Learning vs. Fine-Tuning

Training Time. The fine-tuning paradigm updates all parameters of the pre-trained model via back-propagation. However, as shown in Figure 2, VPL learns a visual prompt, *i.e., in the form of a single image*, on the training dataset $\mathcal{D}_{train} = (\mathcal{X}, \mathcal{Y})$. During the back-propagation, the pre-trained model is frozen, and only the parameters of the visual prompt are updated. In this way, prompt learning dramatically lowers the bar for users adapting large-scale vision models for real-world applications. Prompt learning saves significant training resources and storage space, especially when a pre-trained model serves multiple downstream tasks. For example, the Vision Transformer (ViT-B) [23] we use in later experiments has 86,567,656 parameters, and the visual prompt, i.e., a padding template with a prompt size of 30, has 69,840 parameters. For each downstream task, the fine-tuning paradigm updates the entire model (86,567,656 parameters), whereas, in prompt learning, a single prompt, i.e., a single image with only 69,840 parameters, is updated. The number of parameters updated by prompt learning is only 0.08% of those of fine-tuning, so it is natural to assume that prompt learning would heavily compress the training dataset information, leading to less effective privacy attacks. However, we show that the prompts are still susceptible to two privacy attacks in later experiments.

Inference Time. As shown in Figure 1, both the trained prompt and pre-trained models are involved in the inference process. Given a test image x, the user gets the prompted image, i.e., adding the trained prompt δ to x, and then feeds the prompted image into the pre-trained model $\mathcal{M}$ to get the prediction result. In the fine-tuning approach, the user directly feeds the given test image x into the fine-tuned model to get the prediction result.

2.3 Application Scenario

Taking a medical researcher as an example, they aim to classify CT images for COVID-19 diagnosis. Instead of hiring a computer vision expert to fine-tune a model, the researcher can request a prompt from a PaaS provider. They can either opt for a publicly available pre-trained model or allow the PaaS provider to select a suitable one for them. The provider uses their proprietary data, e.g., CT images with explicit consent, to learn a customized prompt and return it to them. At inference time, the researcher simply combines their testing data with the prompt and feeds them to the pre-trained model to get the predictions. In this way, users minimize their effort in developing a well-generalized prompt and keep their data on-premise, while the PaaS provider can reuse a single pre-trained model to support multiple downstream tasks. Meanwhile, the user can adapt to different tasks, e.g., clinical decision support, by trivially switching to different prompts. These benefits differentiate PaaS from machine learning as a service (MLaaS) [42].

3 Property Inference Attacks

We first measure the privacy risks of prompt learning through the lens of property inference attacks. Our objective here is not to devise novel attacks for prompts but rather to leverage well-established threat models and existing techniques to gauge the privacy implications of prompts.

3.1 Threat Model

Attack Scenario. The PaaS provider is a resourceful entity that uses a pre-trained model $\mathcal{M}$ and their private dataset $\mathcal{D}_{target}$ to create well-generalized prompts Δ for downstream tasks. The adversary can be any legitimate user of this PaaS provider and can obtain a prompt δ for a target downstream task together with the white-box access to $\mathcal{M}$. Note that a pre-defined label mapping τ is also provided by the PaaS provider (see Section 2.1). The adversary runs the target downstream task locally and does not interact with the PaaS provider.

Adversary's Goal. Given a target prompt δ_{target}, the goal of the adversary is to infer confidential macro-level properties of the training dataset $\mathcal{D}_{target}$, which the PaaS provider does not intend to share. Taking a prompt δ_{target} for facial recognition as an example, the adversary may intend to infer the confidential properties of the private dataset $\mathcal{D}_{target}$, such as the proportion of males and the proportion of youth. The adversary considers such confidential properties as targets, causing real-world harm to the PasS provider, e.g., reputation damages, if the adversary can infer that certain classes of people, such as minorities, are underrepresented in the training data [14]. For simplicity, we focus on binary properties, such as if the proportion of males in the training dataset is 30% or 70%, in most of our experiments, following previous work [14]. We later show that our attack can be generalized to properties with multiple choices (see Section 3.4).

Adversary's Knowledge and Capability. We assume that the adversary has white-box access to the pre-trained model $\mathcal{M}$ and the label mapping τ. Note that the white-box access in the paper is more restricted than conventional white-box access, as the latter can retrieve all information about the model, such as model parameters and intermediate outputs. In this paper, the adversary only needs to know the architecture and version of the pre-trained model from the PaaS provider, and such knowledge is often disclosed by the PaaS provider for marketing purposes. We also assume that the adversary has a shadow dataset $\mathcal{D}_{shadow}$ of similar distribution as $\mathcal{D}_{target}$. For instance, in our evaluation (see Section 3.3), we select both $\mathcal{D}_{shadow}$ and $\mathcal{D}_{target}$ from the same dataset CelebA [34]. These two subsets are disjoint and may have different statistical properties, such as gender/race/age ratios. We emphasize that previous property inference attacks also make the same assumption [14, 55].

3.2 Measurement Methodology

Shadow Prompt Generation. Given a shadow dataset $\mathcal{D}_{shadow}$ and associated data properties $\mathcal{P} = \{p^1, ..., p^k\}$, the adversary uses Equation 2 to generate the shadow prompts:

$$\Delta_{shadow} = \{q(s_{\mathcal{P}}(\mathcal{D}_{shadow}, \Phi_i, N_i), \mathcal{M})\}_{i=1}^{m}, \quad (2)$$

where $s_{\mathcal{P}}$ denotes a sampling function that samples N_i data points from $\mathcal{D}_{shadow}$ without replacement and the distribution of sampled data with properties $\mathcal{P}$ satisfying the conditions Φ_i. Note that, $\Phi_i = \{\phi_i^1, \phi_i^2, ..., \phi_i^k\}$, ϕ_i^k is the actual value of p^k in round i, m denotes the number of shadow prompts, and N_i denotes the size of the sampled dataset from $\mathcal{D}_{shadow}$ in round i. In previous work [14, 36, 55], apart from the targeted property, say p^1 (and associated ϕ^1), they tend to use a fixed set of other conditions, i.e., $\{\phi^2, ..., \phi^k\}$, and N. For example, the target property is the proportion of males. They tend to keep the training data size the same when training all target prompts and shadow prompts in their evaluation. However, the training data size of target prompts and shadow prompts is likely to be different in a realistic scenario. If the target prompt is trained on 500 samples with 70% males, but shadow prompts are trained on 2000 samples with 70% males. Such discrepancies in training dataset sizes, e.g., 500 and 2000, may influence the attack performance. In contrast to those approaches, we consider a *mixed setting* by design. As we can see in Equation 2, in every round i, we generate a prompt δ_i from a subset sampled by $s_{\mathcal{P}}(\mathcal{D}_{shadow}, \Phi_i, N_i)$ with properties $\mathcal{P}$ satisfying different Φ_i. For instance, given $\mathcal{P} = \{youth, male\}$, $\Phi = \{70\%, 70\%\}$, and $N = 2000$, $s_{\mathcal{P}}(\mathcal{D}, \Phi, N)$ samples 2000 data points from $\mathcal{D}$ to train the prompt. Among them, 980 data points are *young males*, 420 data points are *young females*, 420 data points are *old males*, and 180 data points are *old females*. As such, our approach can guarantee a more realistic shadow prompt generation and fairer evaluation.

Attack Model Training. After obtaining the shadow prompts Δ_{shadow}, we can build the attack model for each property p^k:

$$\mathcal{A} : \Delta_{shadow} \rightarrow y^k. \quad (3)$$

We train the attack model $\mathcal{A}$ by optimizing the following loss function:

$$\mathcal{L}[\mathcal{A}(\Delta_{shadow}), y^k], \quad (4)$$

where $\mathcal{L}$ is a cross-entropy loss function in this paper. Concretely, the attack model takes $\delta_i \in \Delta_{shadow}$ as input. To incorporate the input size of the attack model, we use zero value to pad it to an image of size 224×224, with RGB channels. This means the attack model is an image classifier. The adversary then treats the corresponding condition value ϕ_i^k of the target property p^k as the class labels y_i^k. To infer the target property p^k of $\mathcal{D}_{target}$, the adversary queries the attack model $\mathcal{A}$ with δ_{target} and obtains the corresponding prediction result, i.e., the exact condition value of p^k.

Table 1: Experimental settings of the property inference attacks with the corresponding attack performance.

Inference Task	Dataset	Downstream Task	Target Property	Inference Labels	Test Accuracy RN18	BiT-M	ViT-B
T_1	CIFAR10	Image Classification	Size (T_1^{size})	{500, 2000}	100.00	100.00	100.00
T_2	CelebA	Multi-Atrribute Classification	Size (T_2^{size})	{500, 2000}	100.00	100.00	100.00
			Proportion of Males (T_2^{male})	{30%, 70%}	99.75	99.25	93.00
			Proportion of Youth (T_2^{youth})	{30%, 70%}	93.00	90.75	81.00
T_3	UTKFace	Race Classification	Size (T_3^{size})	{500, 2000}	100.00	100.00	100.00
			Proportion of Males (T_3^{male})	{30%, 70%}	80.50	80.50	82.00
			Proportion of Youth (T_3^{youth})	{30%, 70%}	81.75	87.50	84.00

			Proportion of Males (T_4^{male})	{30%, 70%}	80.75	78.00	72.25

3.3 Measurement Settings

Datasets and Downstream Tasks. We use four datasets in our study, including CIFAR10 [1], CelebA [34], UTKFace [52], and AFAD [39]. These datasets contain sensitive properties (the proportion of males, the proportion of youth, etc.) and are widely used to evaluate the performance of property inference attacks [14, 55]. The introduction of these datasets and corresponding downstream tasks are as follows.

- **CIFAR10** is a benchmark dataset for image classification that contains 60K images in 10 classes. In this paper, the downstream task is a 10-class image classification.
- **CelebA** is a large-scale facial attribute dataset containing more than 200K facial images with 40 binary attributes. We pick three attributes, including *MouthSlightlyOpen*, *Attractive*, and *WearingLipstick*, and use their combinations to create an 8-class attribute classification as the downstream task.
- **UTKFace** has about 23K facial images. Each image has three attributes: *gender*, *race*, and *age*. We consider race classification, i.e., White, Black, Asian, Indian, and Others, as the downstream task.
- **AFAD** is short for Asian Face Age Dataset. It contains more than 160K facial images, each with *age* and *gender* attributes. In this paper, we consider age classification as the downstream task. Specifically, we divide the values of *age* attribute into five bins: $15 \leq age < 20$, $20 \leq age < 25$, $25 \leq age < 30$, $30 \leq age < 35$, and $35 \leq age < 40$, leading to a 5-class image classification.

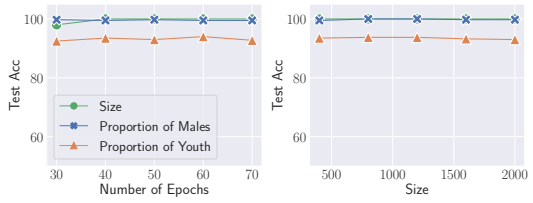
Property Inference Task Configurations. For each task, we split the dataset into three disjoint subsets $\mathcal{D}_{target}$, $\mathcal{D}_{shadow}$, and $\mathcal{D}_{validation}$ in the ratio of $0.475 : 0.475 : 0.05$. $\mathcal{D}_{target}$ and $\mathcal{D}_{shadow}$ are used to develop the target prompt set Δ_{target} and shadow prompt set Δ_{shadow}, respectively. We evaluate the utility of all prompts on $\mathcal{D}_{validation}$. We train 2000 shadow prompts to construct the attack training dataset and 400 target prompts to build the attack testing dataset in our experiments. Our property inference targets include training dataset size, proportion of males, and proportion of youth. Note that recent research demonstrates that the size of the training dataset significantly affects the performance of the model, necessitating substantial efforts to identify the optimal values [35, 58]. Consequently, we also view the training dataset size as confidential information and as one of our inference objectives. We outline the details of all inference tasks below and summarize them in Table 1.

- **Inference Task on CIFAR10 (T_1).** For CIFAR10, we only consider the size of the prompt training dataset N as the property inference target (T_1^{size}). We focus on two training data sizes, i.e., $y^1 \in \{500, 2000\}$, and run the sampling function (see Equation 2) 1000 times on $\mathcal{D}_{shadow}$ to generate 1000 shadow prompts for each training data size. Meanwhile, we generate 200 target prompts in the same manner for each training data size.
- **Inference Task on CelebA (T_2).** For CelebA, we consider the size of the prompt training dataset (T_2^{size}), the proportion of males (T_2^{male}), and the proportion of youth (T_2^{youth}) of the data samples used to train the target prompts as the property inference targets. T_2^{male} is based on the *male* attribute, and T_2^{youth} is based on the *young* attribute. Both attributes are binary. The inference labels of each property are: $y^1 \in \{500, 2000\}$, $y^2 \in \{30\%, 70\%\}$, and $y^3 \in \{30\%, 70\%\}$. Recall that we consider a mixed data sample strategy. Given these three properties, we end up with eight sampling functions in total. We run each sampling function 250 times on $\mathcal{D}_{shadow}$ and 50 times on $\mathcal{D}_{target}$ to generate the shadow prompt set Δ_{shadow} and target prompt set Δ_{target}, respectively.
- **Inference Task on UTKFace (T_3).** For UTKFace, we also consider the size of the prompt training dataset (T_3^{size}), the proportion of males (T_3^{male}), and the proportion of youth (T_3^{youth}) as the property inference targets. Note that T_3^{male} is based on the *gender* attribute, and T_3^{youth} is based on the *age* attribute. Specifically, we use the median of *age* values from all images, i.e., 30, as the threshold. We then label samples with $0 \leq age \leq 30$ as Young and $30 \leq age \leq 116$ as Old. The inference labels

of each property are the same as those of CelebA. Thus, we follow the same sampling settings as those of T_2 to generate the shadow and target prompts.

- **Inference Task on AFAD (T_4).** For AFAD, we consider the size of the prompt training dataset (T_4^{size}) and the proportion of males (T_4^{male}) as the property inference targets. T_4^{male} is based on the *gender* attribute. The inference labels of each property are: $y^1 \in \{500, 2000\}$ and $y^2 \in \{30\%, 70\%\}$. We use four sampling functions to generate the shadow and target prompts. We run each sampling function 500 times on $\mathcal{D}_{shadow}$ and 100 times on $\mathcal{D}_{target}$ to generate the shadow prompt set Δ_{shadow} and target prompt set Δ_{target}, respectively.

Metric. As the attack training/testing dataset is balanced in terms of class distribution, we use test accuracy as the main metric to evaluate the prompt utility and the property inference attacks.



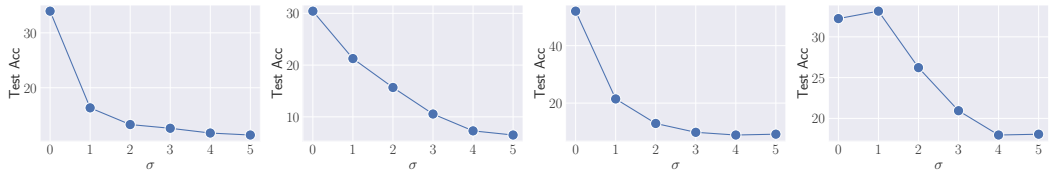
Pre-trained Models. We select three representative vision models in our experiments, including ResNet-18 (RN18) [15], Big Transfer (BiT-M) [23], and Vision Transformer (ViT-B) [12]. More details can be found in Appendix A.

Prompts. We follow the default training settings [4] to train prompts on the above vision models. Specifically, we choose the padding template with a prompt size of 30. The number of parameters for each prompt is calculated as $2 \times C \times p \times (H + W - 2p)$, where p, C, H, and W are prompt size, image channels, height, and width, respectively. All images are resized to 224 $\times$ 224 to match the input of the pre-trained models. The number of parameters for each prompt is 69,840. We leverage the same hard-coded mapping method [4] to map the first n indices of the pre-trained model's outputs to the target labels, where n is the number of target classes. We adopt cross-entropy as the loss function and SGD as the optimizer with a learning rate of 40 and the cosine scheduler. In our property inference attacks, we train all prompts for 50 epochs for efficiency.

Attack Models. We leverage the pre-trained RN18 [15] as the backbone of the attack model $\mathcal{A}$. We fit a linear classifier on top of the pre-trained RN18 to infer the property labels. We employ cross-entropy as the loss function and Adam as the optimizer with a learning rate of 1e-5. The attack model is trained on the shadow prompt set Δ_{shadow} for 100 epochs.

3.4 Measurement Results

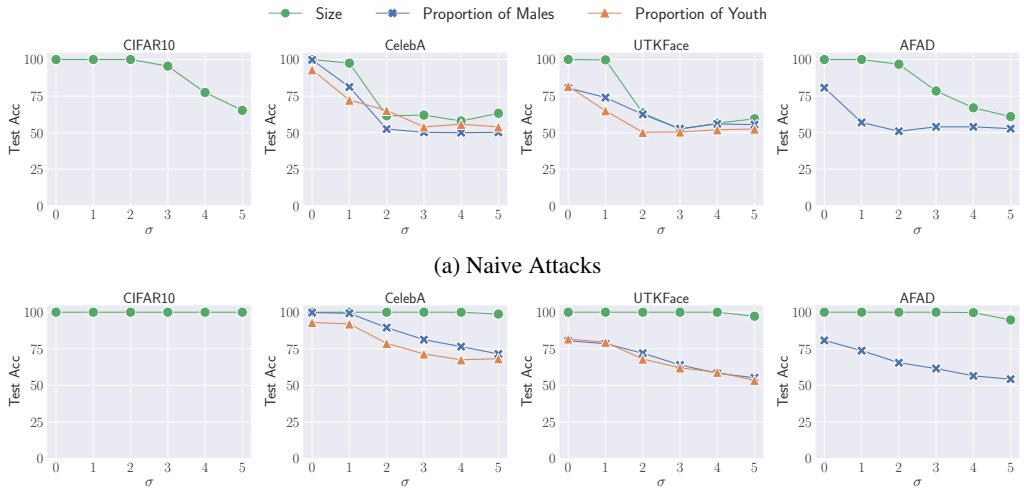
Property Inference Privacy Risks. We report the main results on four datasets and three pre-trained models in Table 1. In general, we observe that proposed attacks achieve good performance across different pre-trained models and datasets. For example, on CelebA and RN18, we achieve at least 93.00% accuracy in inferring target properties. Furthermore, we achieve maximum performance (100.00%) on all datasets, considering the size of the prompt training dataset as the target property.



(a) Epoch Effect (b) Size Effect

Figure 3: Attack performance of the proposed property inference attacks on CelebA with (a) different numbers of epochs for training shadow prompts and (b) different sizes of the attack training dataset, using RN18 as the pre-trained model.

Additionally, we observe that the pre-trained model has a moderate influence on the attack performance. Specifically, when inferring the proportion of youth on UTKFace (T_3^{youth} in Table 1), the test accuracy is 81.75% on RN18, 87.50% on BiT-M, and 84.00% on ViT-B. Although the test accuracy varies across pre-trained models and datasets, the proposed attacks are generally effective, indicating prompts are indeed vulnerable to property inference attacks.



Extension to Multi-Class Property Inference. In the above experiments, we treat property inference as a binary classification task. Here, we extend it to multi-class classification and explore if the adversary can infer finer granularity information from the prompts. To this end, we adjust the condition values of the proportion of males in CelebA to {10%, 30%, 50%, 70%, 90%} and use RN18 as the pre-trained model. Note that the condition values of the training dataset size and the proportion of youth remain the same. In turn, we have 20 sampling functions in total. We keep the sizes of Δ_{shadow} and Δ_{target} unchanged and run each sampling function 100 times on $\mathcal{D}_{shadow}$ and 20 times on $\mathcal{D}_{target}$ to generate the shadow prompt set Δ_{shadow} and target prompt set Δ_{target}, respectively. We further adjust the condition values of the training dataset size in CIFAR10 to {500, 1000, 1500, 1750, 1800, 2000} and use RN18 as the pre-trained model to explore the performance of the property inference attack when the range of options for the dataset size is closer together. To this end, we have 6 sampling functions in total and run each sampling function 400 times on $\mathcal{D}_{shadow}$ and 80 times on $\mathcal{D}_{target}$ to generate the shadow prompt set Δ_{shadow} and target prompt set Δ_{target}, respectively. The test accuracy for the proportion of males is 90.25%, while for training dataset size is 95.40%, demonstrating that property inference attacks can successfully infer finer granularity information from prompts.

Takeaways. We show that the property inference attacks achieve remarkable performance on diverse datasets and pre-trained models. Moreover, the proposed attacks can be extended to multi-class classification, providing evidence that the adversary can infer fine granularity property information from prompts.

The x-axis denotes the magnitude of Gaussian noise, from 0 to 5, where 0 means the proposed defense mechanism is not implemented. The y-axis represents the attack performance with respect to the test accuracy.

3.5 Factors Affecting Property Inference

We conduct an empirical analysis to investigate the factors that may influence the performance and cost of property inference attacks on prompts.

Number of Epochs. Previously, we train both shadow prompts and target prompts for 50 epochs. However, it is likely that the adversary has no knowledge about the number of epochs for target prompts. Next, we investigate whether the number of epochs in the training process of shadow prompts must match that of the target prompts in order to maintain a strong attack performance. Concretely, we vary the number of epochs for shadow prompts from 30 to 70 while fixing the number of epochs for target prompts to 50. The minimum number of epochs is 30 because the prompt starts to outperform the pre-trained model solely on the downstream task at this point. We show the attack performance on CelebA in Figure 3a. In general, the proposed attacks work similarly well when the number of epochs for target and shadow prompts do not match. The results also show that the proposed attacks can achieve comparable performance even with fewer epochs, e.g., 30 epochs, to train shadow prompts. In addition, increasing the number of epochs for shadow prompts does not improve the attack performance. For example, the test accuracy for inferring the proportion of youth is between 92.50% and 94.00% depending on the number of epochs. This implies that the proposed attacks are robust to variations in the number of epochs for training shadow prompts, making them more practical and efficient.

Attack Training Dataset Size. So far, we have assumed the adversary can rely on an attack training dataset containing 2000 shadow prompts. However, creating such a dataset costs considerable computational resources. Hence, we investigate the influence of the attack training dataset size on the attack performance. Specifically, we randomly sample balanced subsets from the original attack training dataset on CelebA with different sizes {400, 800, 1200, 1600, 2000}. The size of the attack testing dataset remains the same as for the previous experiments, i.e., 400 target prompts. As shown in Figure 3b, the size of the training dataset only has negligible influence on the

attack performance, indicating that a relatively small number of training samples, e.g., 400 shadow prompts, are sufficient to launch the property inference attacks against prompts. This finding implies that the cost of the proposed attack can be further reduced.

Takeaways. We demonstrate that the proposed attacks can be performed with cost-efficiency by training the shadow prompts with fewer epochs or a smaller number of shadow prompts. We further show that to achieve a good attack performance, the adversary must have a shadow dataset of similar distribution as the target dataset and must have access to the same pre-trained model. The results are displayed in Appendix B.

3.6 Defense

Gaussian Noise as Defense. We propose a defense mechanism [18, 54, 57]. Specifically, the PaaS provider adds Gaussian noise $\mathcal{N}(0,\sigma^2 I)$ to the released prompts, resulting in noised target prompts $\Delta'_{target} = \{\delta_i + \varepsilon_i \mid \forall \delta_i \in \Delta_{target}, \varepsilon_i \sim \mathcal{N}(0,\sigma^2 I)\}$. The magnitude of the noise is controlled by the value of σ, with larger values corresponding to higher noise. We examine the effectiveness of the proposed defense with $\sigma \in \{1,2,3,4,5\}$. We first report the target performance, i.e., prompt utility, on all datasets in Figure 4. The evaluation metric is the average test accuracy of all target prompts in the attack testing dataset on specific downstream tasks. In general, we observe that the target performance decreases on all datasets by a large margin with the increase of σ. For example, the prompt utility decreases from 33.95% to 10.55%, which is even lower than random guess (12.50%), meaning the prompt is no longer usable. We present the attack performance in Figure 5a. We can observe that the effectiveness of the proposed attack significantly declines with the increase of σ. The test accuracy on CelebA and UTKFace drops to almost random guess when $\sigma \geq 2$. The attacks on CIFAR10 are more robust to the defense, but the performance still starts decreasing when $\sigma = 3$.

Adaptive Attacks. We further consider an adaptive adversary [21] who is aware of the defense mechanism, i.e., that Gaussian noise has been added to the target prompts. They can construct their attack training dataset with noised shadow prompts. Similarly, we set $\sigma \in \{1,2,3,4,5\}$ for both shadow and target prompts. We report the performance of adaptive attacks on all datasets in Figure 5b. The results show that the attack performance declines less and more slowly. For example, the attack performance barely decreases when $\sigma = 1$ on all datasets. In addition, when considering the size of the prompt training dataset as the target property, the attack performance only has negligible degradation with the growth of Gaussian noise. For example, the attack performance has almost no drop even with $\sigma = 5$ on all datasets.

Takeaways. These findings indicate that adding Gaussian noise as a defense mechanism can ostensibly decrease the attack performance. But the defender suffers from unacceptable prompt utility degradation. Moreover, this defense can be bypassed by the adaptive attack. We leave it as future work to investigate more effective defenses. We later show that the proposed defense can achieve a decent utility-defense trade-off by using a smaller σ, e.g., $\sigma = 0.6$, indicating that the statistical information of the training dataset in the target prompts is harder to hide than individual information, i.e., membership (see Section 4.7).

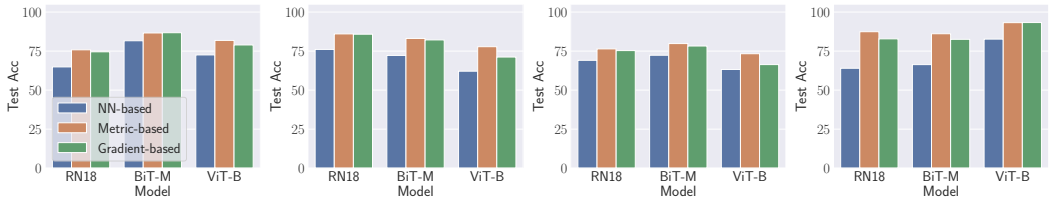
4 Membership Inference Attacks

In this section, we leverage the membership inference attacks to quantify the privacy risks of prompts.

4.1 Threat Model

Adversary's Goal. In membership inference, the goal of the adversary is to infer whether a given data sample x is in the training dataset of the target prompt δ_{target}.

Adversary's Knowledge and Capability. Similar to the property inference attack, the adversary can query the PaaS service to get δ_{target} and has white-box access to the pre-trained model $\mathcal{M}$. The adversary has a shadow dataset $\mathcal{D}_{shadow}$ that is from the same distribution as $\mathcal{D}_{target}$ to train the shadow prompt δ_{shadow}. We later demonstrate that the adversary can operate in a data-free manner, i.e., leveraging $\mathcal{D}_{shadow}$ that comes from a different distribution than $\mathcal{D}_{target}$.



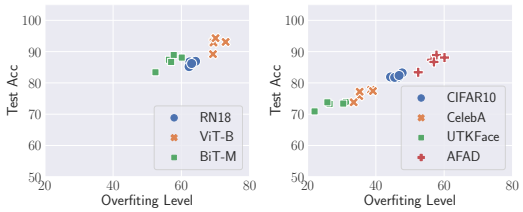
4.2 Measurement Methodology

Attack Setup. The adversary first divides the shadow dataset into two disjoint subsets: $\mathcal{D}^{train}_{shadow}$, referred to as the member split, and $\mathcal{D}^{test}_{shadow}$, referred to as the non-member split. The member split is then utilized for training the shadow prompt δ_{shadow}, which mimics the behavior of δ_{target}.

Attack Descriptions. We adopt three types of membership inference attacks, i.e., neural network-based (NN-based) attacks [44], metric-based attacks [47], and gradient-based attacks [24, 38]. We outline their technical details below.

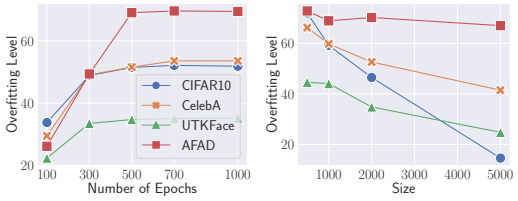
NN-based Attacks [44]. The adversary constructs the attack training dataset on $\mathcal{D}_{shadow}$. Specifically, they combine each sample in $\mathcal{D}_{shadow}$ with the shadow prompt trained on $\mathcal{D}^{train}_{shadow}$ and query the corresponding pre-trained model to get the top-5 posteriors as attack input features. Then, for each sample in the member split, the adversary labels the corresponding top-5 posteriors as "member." For samples that belong to the non-member split, their top-5 posteriors are labeled as "non-member." At inference time, the adversary queries the pre-trained model with the given data sample x and δ_{target} to obtain the top-5 posteriors and feeds them to the attack model to obtain its membership prediction.

Metric-based Attacks [47]. Song and Mittal propose metric-based attacks using four metrics, i.e., prediction correctness



(a) CIFAR10 (b) CelebA (c) UTKFace (d) AFAD

Figure 6: Attack performance of three membership inference attacks on four datasets.



(metric-corr), prediction confidence (metric-conf), prediction entropy (metric-ent), and modified prediction entropy (metric-ment). Unlike NN-based attacks where a neural network is trained to make membership predictions, metric-based attacks first calculate class-wise thresholds over δ_{shadow}. Then, at inference time, the adversary calculates the metric values and compares them with the pre-calculated thresholds to determine the membership status for given data samples. It is worth noting that in scenarios where the adversary possesses data from a different distribution than the target dataset, we calculate an overall threshold for all classes. This is because certain classes present in the target dataset may not be represented in the shadow dataset, so class-specific thresholds would not be applicable.

Gradient-based Attacks [38]. Nasr et al. propose gradient-based attacks on the basis of the NN-based attacks by incorporating augmented input information. Specifically, the adversary has white-box access to the pre-trained model and target prompt with its intermediate computations, e.g., gradients. They combine each sample x with the prompt and input resulting data into the pre-trained model to obtain top-5 posteriors, the loss incurred during the forward pass, the gradient of the prompt during the backward pass, and an indicator that denotes the correctness of the prediction. These obtained data are treated as the attack input for the attack model.

(a) Pre-trained Models (b) Datasets

(a) Epoch Effect (b) Size Effect

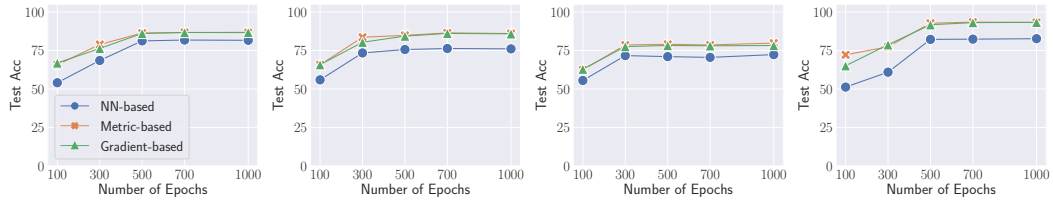

Figure 8: Overfitting levels of target prompts with (a) different numbers of epochs and (b) different sizes of the training dataset, using ViT-B as the pre-trained model.

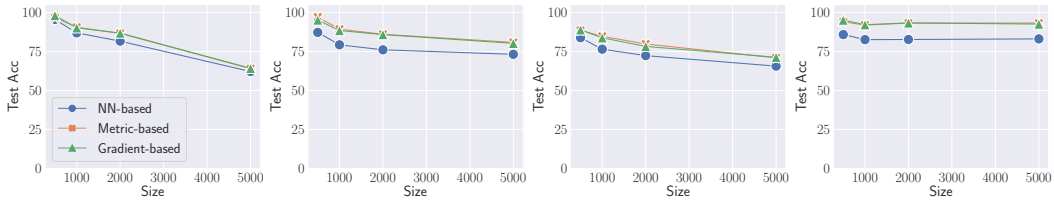
4.3 Measurement Settings

Datasets and Downstream Tasks. We reuse CIFAR10, CelebA, UTKFace, and AFAD to evaluate membership inference attacks. The downstream tasks for all datasets are the same as those for property inference attacks (see Section 3.3). We randomly sample 8000 data samples for each dataset in the main experiments and then evenly split each dataset into four disjoint sets, i.e., $\mathcal{D}^{train}_{target}$, $\mathcal{D}^{test}_{target}$, $\mathcal{D}^{train}_{shadow}$, and $\mathcal{D}^{test}_{shadow}$. $\mathcal{D}^{train}_{target}$ is used to develop the target prompt δ_{target}, and $\mathcal{D}^{test}_{target}$ is the evaluation set. $\mathcal{D}^{train}_{shadow}$ and $\mathcal{D}^{test}_{shadow}$ are used to build the attack model as discussed in Section 4.2.



Attack Configurations. All experimental settings of the pre-trained models and target prompts are the same as those for property inference attacks except for the number of epochs. We follow the default setting to train all prompts for 1000 epochs. For attacks that leverage neural networks as the attack model, we employ the cross-entropy loss function and optimize it using Adam optimizer. We conduct a grid search on {1e-2, 1e-3, 1e-4, 1e-5} to determine the optimal learning rate for each attack, and all attack models are trained for 100 epochs. For the NN-based attacks, we use a 2-layer MLP as the attack model and set the size of the hidden layer to 32. For the gradient-based attacks, we utilize an attack model composed of four sub-networks, each corresponding to one attack information (gradient, top-5 posteriors, loss, and indicator), and the outputs of these sub-networks are concatenated to form the final input of a 2-layer MLP.

Metric. Following the convention [17, 46], we use test accuracy as the main metric to evaluate the attack performance.

4.4 Measurement Results

Membership Inference Privacy Risks. We report the performance of three membership inference attacks in Figure 6. We conduct three separate runs of each attack experiment and report the average values as the final results. We observe that metric-based attacks achieve the best performance in most cases, e.g., 93.20% membership inference attack accuracy on AFAD. Unless otherwise specified, we use metric-ment attacks as the representative of the metric-based attacks, as they consistently achieve the best performance across all datasets (see Appendix C). The gradient-based attacks also exhibit strong performance, with results that are closely comparable to those of the metric-based attacks. Song and Mittal [47] also report that the metric-based attacks can outperform NN-based attacks and have similar performance as gradient-based attacks. NN-based attacks perform worse than gradient-based attacks. This is expected since the adversary leverages less information from the target prompt.

Analysis. Figure 6 shows that the performance of three attacks varies on different pre-trained models and different datasets. We hypothesize that the different overfitting levels may affect the attack performance. Following previous work [17, 43], we calculate the difference between train accuracy and test accuracy to measure the overfitting level of a given target prompt. We train five target prompts with different random seeds for each experimental setting. The relationship between overfitting levels and attack performance is illustrated in Figure 7. We observe that different pre-trained models and different datasets have different overfitting levels. Meanwhile, our results demonstrate that overfitting does have a significant effect on membership inference attacks. The overall trend is that the higher the overfitting level, the better the attack performance. To quantify this correlation, we calculate the Pearson correlation scores between the overfitting level and attack performance. The result is 0.89. Our finding is in line with previous analyses [33, 45].

Takeaways. We show that prompts can leak sensitive membership information of their training dataset. Similar to previous analyses, overfitting is strongly correlated with the membership inference performance.

4.5 Factors Affecting Membership Inference From the Victim's Side

In this section, we measure the factors that may affect the membership inference privacy risks from the perspective of the victim. As shown in Figure 8, the number of epochs used to train the target prompt and its training dataset size ($\mathcal{D}_{target}^{train}$) are closely related to the overfitting level of the target prompt. A larger number of epochs results in larger overfitting levels. On the contrary, a larger training dataset size results in reduced overfitting levels. Therefore, we explore how these two factors affect the attack performance.

Number of Epochs. We set the number of epochs for the target prompt to {200, 400, 600, 800, 1000} and use the same number of epochs for the shadow prompt in each experiment. The results are shown in Figure 9. We observe that, in general, more epochs lead to better attack performance, hence greater membership inference privacy risks. The attack performance becomes steady after 500 epochs, while the overfitting level also becomes stable simultaneously in Figure 8a.

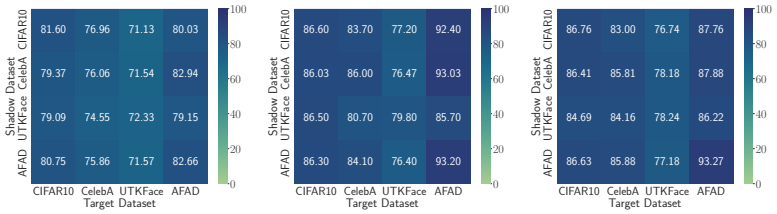
Prompt Training Dataset Size. We investigate the effect of the training dataset size on the attack performance by varying

the size from 500 to 5000. To control the variables, we always fix the other three sets ($\mathcal{D}^{test}_{target}$, $\mathcal{D}^{train}_{shadow}$, and $\mathcal{D}^{test}_{shadow}$) to the same size as $\mathcal{D}^{train}_{target}$. As illustrated in Figure 10, the attack performance decreases as the dataset size grows. The general trend of the attack performance is also consistent with the findings in Figure 8b. That is, more training data reduces the overfitting level in most cases, leading to a decrease in the attack performance. There is a significant drop in the overfitting level on CIFAR10 when increasing the size of $\mathcal{D}^{train}_{target}$ from 2000 to 5000. Therefore, the test accuracy of metric-based attacks drops from 86.60% to 64.00%.

Takeaways. We perform an analysis of the relation between overfitting levels and attack performance. Our results show that more epochs and fewer training data can aggravate overfitting and pose a more severe threat to membership privacy.

4.6 Factors Affecting Membership Inference From the Adversary's Side

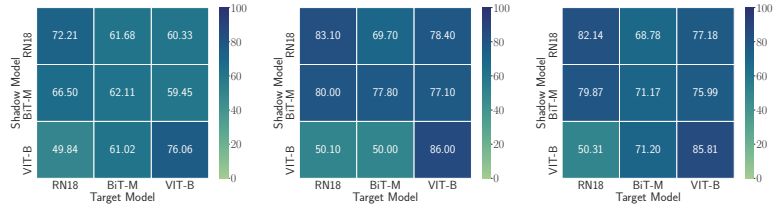
We evaluate the factors that may affect the membership inference privacy risks from the perspective of the adversary. In previous experiments, we made two assumptions: 1) the adversary has a dataset $\mathcal{D}_{shadow}$ that comes from the same distribution as $\mathcal{D}_{target}$, and 2) the PaaS provider offers users the target prompt with white-box access to the pre-trained model. Here, we evaluate if these two assumptions are needed to mount a successful membership inference attack.



Dataset Assumption. We relax the same distribution assumption by leveraging a shadow dataset that comes from a different distribution than $\mathcal{D}_{target}$ to train the shadow prompt; the results with three attack methodologies are shown in Figure 11. In the diagonal of the heatmaps, we show the results of the adversary having access to $\mathcal{D}_{shadow}$ that comes from the same distribution as $\mathcal{D}_{target}$. We observe that the performance of NN-based, metric-based, and gradient-based attacks is slightly reduced but remains effective. For instance, as shown in Figure 11b, using any one of the four datasets as the shadow dataset to launch the metric-based attack can achieve a test accuracy of around 86.00%, when the target dataset is CIFAR10. Interestingly, CIFAR10 contains images of 10 classes such as cars and trucks, but the other three datasets only include facial images. This supports the findings of Salem et al. [44] and Li et al. [27], which also report the effectiveness of membership inference using shadow datasets from different domains.

Moreover, we present the average test accuracy and the average drop in accuracy of three attacks on different pre-trained models in Appendix D. The results show that the metric-based and gradient-based attacks achieve the best attack performance on average, while the NN-based and gradient-based attacks, in general, are more robust than metric-based attacks. Hence, we conclude that the gradient-based attacks exhibit superior performance in terms of both utility and robustness after relaxing the dataset assumption. However, it should be noted that the gradient-based attacks come at the cost of high computational resources and a significant amount of information needed. Overall, our findings suggest that we can relax the assumption of the same-distribution shadow dataset, implying greater membership inference privacy risks of prompts.

Pre-trained Model Assumption. In the previous evaluation, we assume the adversary has white-box access to the pre-trained model. However, the PaaS provider may only allow users to submit prompted images and receive corresponding results, thus limiting access to the pre-trained model. The adversary has to develop their pre-trained models, which may be different from the pre-trained models used to train the target prompts (abbreviated as the target model). We, therefore, measure the impact of the discrepancy in architecture between the pre-trained model used to train the shadow prompts (abbreviated as shadow model) and the target model on the attack performance. The results of three attacks are shown in Figure 12.



In the diagonal of the heatmaps, we show the results of the adversary having white-box access to the same pre-trained model used to train the target prompt. We observe that, in some cases, the attack performance decreases noticeably but remains effective. For example, when the pre-trained model of the target prompt is ViT-B on CelebA, the performance of metric-based attacks drops from 86.00% to 78.40% (77.10%) when using RN18 (BiT-M) as the pre-trained model for the shadow prompt. However, in certain cases, all three attacks fail completely, i.e., they become random guesses. For instance, when the adversary uses ViT-B to attack the target prompt trained on RN18, these three methodologies become random guesses. We also present the average test accuracy and the average drop in accuracy of three attacks on different datasets in Appendix D. The gradient-based and metric-based attacks achieve the best attack performance, and the gradient-based attacks are more robust than the metric-based attacks. However, the average drop in accuracy of all attacks after relaxing the pre-trained model assumption, in general, is larger than that of relaxing the dataset assumption.

Discussion. We have shown that all methodologies only have slight performance degradation after relaxing the dataset assumption. Meanwhile, after relaxing the pre-trained model assumption, these attack methodologies are effective in some cases but fail to maintain high robustness, i.e., they fail in other cases. Previous work [27, 44] on membership inference against traditional ML classifiers has shown that having shadow models with different architectures than the target models does not have a strong impact on the attack performance. However, we do not observe the same in VPL. One possible explanation is that a prompt is specific to the machine learning model it is trained on. In other words, prompts from different models share less similarity, which makes the membership inference knowledge hard to transfer among them. As illustrated in Figure 13, we find that metric-corr attacks have no performance deterioration after relaxing these assumptions, as they do not rely on the shadow technique. Thus, the

(a) NN-based (b) Metric-based (c) Gradient-based

Figure 11: Attack performance of three attacks after relaxing the dataset assumption, using ViT-B as the pre-trained model.

(a) NN-based (b) Metric-based (c) Gradient-based

Figure 12: Attack performance of three attacks after relaxing the pre-trained model assumption on CelebA.

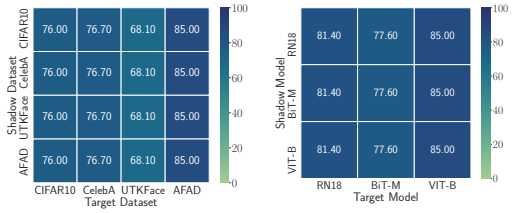


Figure 13: Attack performance of metric-corr attacks after relaxing (a) dataset assumption using ViT-B as the pre-trained model and (b) pre-trained model assumption on AFAD.

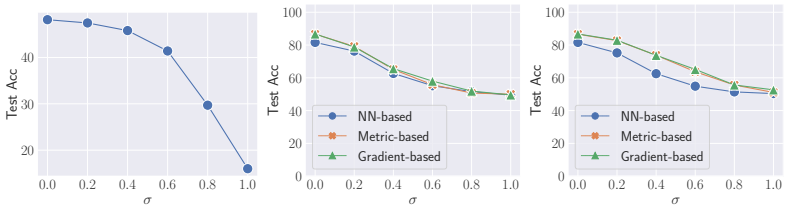

adversary can leverage the metric-corr attacks when relaxing the data assumption and the pre-trained model assumption.

Takeaways. Our results show that the adversary can be data-free, as the attack performance only has a slight deterioration and remains effective. The results also indicate that the adversary has some dependency on the knowledge of pre-trained models to steal private information, as not all attack methodologies can be successfully launched after relaxing the pre-trained model assumption. However, we show that the adversary can still leverage the metric-corr attacks to obtain decent attack performance with high robustness, as they do not rely on the shadow technique.

4.7 Defense

Gaussian Noise as Defense. We have demonstrated that the prompts are also vulnerable to membership inference attacks. Meanwhile, in the above experiments, we observe that the performance of membership inference is heavily related to the overfitting level of the target prompt. Potentially, a defender can decrease the threat to membership privacy by reducing the overfitting level. As shown in Figure 9 and Figure 10, leveraging fewer epochs and more data to train the target prompt can decrease the attack performance to some extent. However, using these methods comes at the cost of either the utility of the target prompt or the resource to collect and process data. We also apply the widely adopted Differential Privacy-Stochastic Gradient Descent (DP-SGD) [2], which involves adding noise to clipped gradients, as a defense mechanism. However, the experimental results show that it is hard to maintain the prompt utility even with a larger privacy budget, e.g., $\varepsilon = 20$. We hypothesize that DP-SGD may work on large datasets, but not on the data for prompt learning since it is relatively small. Hence, we investigate if the defense mechanism used in Section 3.6, i.e., adding Gaussian noise to the prompts, can reduce the risks of membership leakage. We set $\sigma \in \{0.2, 0.4, 0.6, 0.8, 1.0\}$. We first report the target performance on CIFAR10 in Figure 14a. The evaluation metric is the test accuracy of the target prompt. We observe that the target performance, i.e., prompt utility, only decreases heavily when $\sigma \geq 0.6$. For example, the prompt utility remains above 41.40% when $\sigma \leq 0.6$ and then decreases heavily from 41.40% to 29.70% on CIFAR10 when increasing σ from 0.6 to 0.8. We then present the attack performance where the adversary is unaware of the defense mechanism in Figure 14b. We can observe that all attacks are close to random guesses when $\sigma \geq 0.6$, showing that there is a practical utility-defense trade-off when $\sigma = 0.6$.

Adaptive Attacks. We further consider an adaptive adversary [21] who is aware of the defense mechanism. Hence,

(a) Prompt Utility (b) Naive Attacks (c) Adaptive Attacks

Figure 14: Prompt utility and attack performance using the proposed defense on CIFAR10.

the adversary can craft their attack training datasets using the shadow prompt with Gaussian noise. We set $\sigma \in \{0.2, 0.4, 0.6, 0.8, 1.0\}$ for both shadow and target prompts. We report the performance of adaptive attacks on CIFAR10 in Figure 14c. The results show that the attack performance is still close to random guess when $\sigma \geq 0.6$.

Takeaways. When defending against membership inference attacks, the proposed defense mechanism can achieve a decent utility-defense trade-off when setting $\sigma = 0.6$. A similar conclusion can be drawn from the other three datasets.

5 Related Work

Property Inference Attacks. Property inference [3, 7, 14, 36, 53, 55] aims to extract sensitive global properties of the training data distribution from an ML model that the model owner does not want to share. It is an important privacy attack against ML models, as it can violate prompt owner's privacy, i.e., proprietary information about the dataset, and enable attackers to perform tailored attacks, e.g., enhancing membership inference attacks [55]. The main approach for launching these attacks is building a meta-classifier on a large number of shadow models [3]. Existing work focuses on deep neural networks, including fully connected neural networks [14], generative adversarial networks (GANs) [55], and graph neural networks (GNNs) [53].

Membership Inference Attacks. Membership inference [24, 28, 29, 38, 44, 46, 47] is another important type of privacy attack against ML models, where the adversary aims to infer whether the given data sample was involved in a target model's training dataset. Shokri et al. [46] propose the first membership inference attack which depends on training multiple shadow models for developing their attack models. Salem et al. [44] then relax assumptions proposed by Shokri et al. [46]. Yeom et al. [50] attribute the vulnerability of membership inference to the overfitting of ML models. Song and Mittal [47] propose metric-based attacks that rely on pre-calculated thresholds over shadow models to determine the membership status. Nasr et al. [38] perform a thorough investigation of membership privacy in both black-box and white-box settings for both centralized and federated learning scenarios. More recently, Liu et al. [32] leverage the loss trajectory to further enhance the attack performance. Most recent work focuses on deep neural networks, including GNNs [16, 48], multi-modal models [19], and multi-exit networks [27].

Previous work has demonstrated that the fine-tuning paradigm is vulnerable to these privacy attacks [10, 37]. The privacy risk in the fine-tuning paradigm resides at the model level, as the privacy information is leaked through fine-tuned models. This differs from the privacy risk associated with the prompt learning paradigm, where the risk lies at the input level, as the prompt exists in the pixel space.

6 Limitation and Future Work

Efficacy of VPL. VPL is an emerging ML paradigm. Although its current performance cannot rival that of a fine-tuned model, an increasing number of studies are attempting to enhance its performance through various approaches, e.g., label mapping [9] and better data homogeneity [20]. Since we are the first to explore the vulnerabilities of the visual prompt, we have focused on the widely recognized VPL paradigm and followed their default training settings [4]. We anticipate that as VPL with enhanced performance are introduced in the future, it will be straightforward for us to extend our measurement, and thus we recognize this as a promising avenue for future research.

Defense. In the evaluation, we show that adding Gaussian noise to the prompt can mitigate the membership inference attacks with a decent utility-defense trade-off but fails to defend against property inference attacks. DP-SGD fails to preserve the original prompt utility. Since the privacy risk in the prompt learning paradigm is at the input level, devising diverse defense mechanisms for it is more challenging compared to addressing the privacy risk at the model level. We leave it as a future work to explore effective defenses against property inference attacks.

NLP Prompt Learning. Another interesting future work is to apply the two proposed privacy attacks along with their motivation to prompt learning in the NLP domain [25, 26], as the NLP prompt is essentially a (soft) token that can be added to the text input, operating at the input level.

7 Conclusion

In this paper, we conduct the first privacy assessment of prompts learned by VPL through the lens of property inference attacks and membership inference attacks. Our empirical evaluation shows that prompts are vulnerable to both of these attacks. Moreover, we have discovered that an adversary can successfully mount the property inference attacks by training only a few shadow prompts. They can also relax the dataset assumption to achieve effective membership inference attacks. We further make some initial investigations on possible defenses. Experiments show that our method, i.e., adding Gaussian noise to prompts, can mitigate the membership inference attacks with a decent utility-defense trade-off but fails to defend against property inference attacks. We hope our results can raise the awareness of the stakeholders when deploying prompt learning in real-world applications. Moreover, we will share our code and models to facilitate research in this field.

Appendix

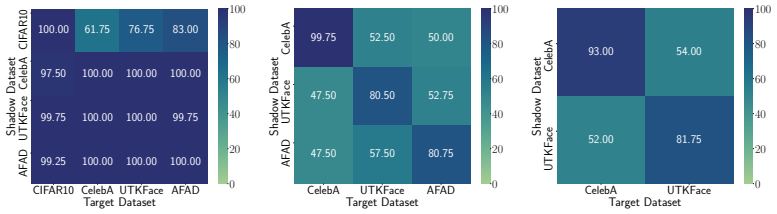
A Details of Pre-trained Models

Table 2 shows details about the architectures and pre-trained datasets of the pre-trained models used in the paper.

Table 2: Overview of the pre-trained models.

Model	Architecture	Pre-trained Dataset	# Parameters
RN18	ResNet-18	1.2M ImageNet-1k	11,173,962
BiT-M	ResNet-50	14M ImageNet-21k	23,520,842
ViT-B	ViT-B/16	14M ImageNet-21k	86,567,656

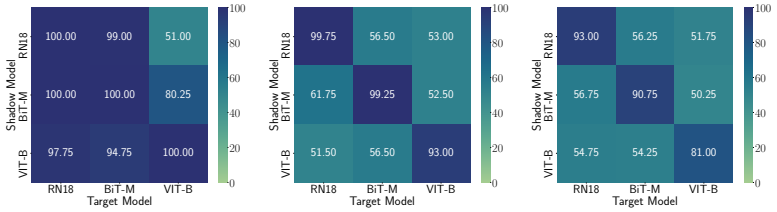
B Relax Assumptions of Property Inference Attacks



We first relax the assumption that the adversary has a shadow dataset of similar distribution as the target dataset, i.e., the dataset assumption. As shown in Figure 15, we observe that the performance of the property inference attack is close to a random guess, considering the proportion of males and youth as the target properties. When inferring the prompt training dataset size, the property inference attacks maintain high accuracy in most cases. However, the attack performance decreases significantly when leveraging CIFAR10 as the shadow dataset. We reason this is because the CIFAR10 datasets contain objections such as cars and birds, whereas other datasets only contain facial images. We then relax the assumption that the pre-trained model used to train the shadow prompts and target prompts are the same, i.e., the pre-trained model assumption. As illustrated in Figure 16, we notice that the attack performance has a significant degradation when inferring the proportion of males and youth. When inferring the prompt training dataset size, the property inference attacks are effective in some cases. However, they are not robust, as they become random guesses in certain cases. For example, when the target prompt is trained on ViT-B and the shadow prompt is trained on RN18, the property inference attacks fail. Thus, we conclude that it is necessary to leverage a shadow dataset of similar distribution as the target dataset and the same pre-trained model to train the shadow prompt.

C Performance of Metric-based Attacks With Different Metrics

As shown in Figure 17, metric-conf and metric-ment attacks achieve the best performance in all cases. The reason why they work better than the other two metrics is that they take both prediction correctness and confidence into account, while the other two metrics only consider prediction correctness.



D Average Test Accuracy and Drop in Accuracy

We present the average test accuracy and drop in accuracy of three attacks on different pre-trained models in Figure 18. We calculate these values based on the heatmap in Figure 11. Specifically, for each heatmap, we take the average of all values as the average test accuracy for each attack methodology on a pre-trained model. We calculate the difference between each cell value and the diagonal value in the corresponding column and take the average as the average drop in accuracy. Basically, a lower drop accuracy value means a more robust attack when relaxing the dataset assumption. As illustrated in Figure 18a, metric-based and gradient-based attacks achieve the best attack performance on average. Meanwhile, as shown in Figure 18b, we observe that the average drop in accuracy is smaller than 5.00% in most cases. The NN-based and gradient-based attacks, in general, are more robust than metric-based attacks. We also present the average test accuracy and drop in accuracy of three attacks on different datasets in Figure 19. The gradient-based and metric-based attacks achieve the best attack performance, and the gradient-based attacks are more robust than the metric-based attacks.

Pandawan: Quantifying Progress in Linux-based Firmware Rehosting

Ioannis Angelakopoulos, Gianluca Stringhini, and Manuel Egele
Boston University
{jaggel, gian, megele}@bu.edu

Abstract

The Internet of Things (IoT) is frequently the epicenter of cyberattacks due to its weak security. Prior works introduce various techniques for analyzing the firmware of IoT devices for bugs and vulnerabilities, especially through firmware re-hosting. However, comparing the emulation outcomes of different re-hosting approaches can be very challenging. In this paper, we present `Firmware Initialization Completion Detection` (`FICD`), a technique that enables the comparison of full-system re-hosting approaches across their re-hosting capabilities. In addition, prior works lack an important capability; they do not focus on both the user and privileged aspect of IoT firmware as a unit. Since prior work is not capable of *holistically* analyzing (both the user and privileged level) IoT firmware, we develop `Pandawan`, a framework that enables the holistic re-hosting and analysis of IoT firmware at scale. We use `FICD` to illustrate `Pandawan`'s re-hosting improvements over the state-of-the-art, such as Firmadyne, FirmAE, and FirmSolo on a dataset of 1,520 firmware images. Our experiments show that `Pandawan` outperforms these systems, by executing up to 6% more user level programs and 21% more user code basic blocks, on average, than these systems. Furthermore, `Pandawan` loads 9% more IoT kernel modules and executes 26% more kernel module basic blocks on average than FirmSolo. We also use `Pandawan` to holistically analyze the firmware images by inspecting the interactions (through system calls) of user level code with kernel module code. `Pandawan` transforms the system call information into seeds for the TriforceAFL kernel fuzzer to analyze the kernel modules within the firmware images. The TriforceAFL experiment on 479 firmware images with seeds, discovered 16 bugs on 12 binary kernel modules, 6 of which are previously unknown bugs. The bugs affect 8 closed and 4 open source kernel modules.

1 Introduction

The Internet of Things (IoT) has gained immense popularity in the past decade. Billions of embedded devices and gadgets, such as WiFi routers, IP cameras, and smart wearables fill up tech store shelves and find their way into customers' homes and businesses [26]. Despite its growth, the IoT is infamous for its weak security. This is evident from impactful cybersecurity attacks assisted by the IoT such as the Mirai [2], Trickbot [33], and Meris [47] botnet attacks, which rattled the Internet infrastructure's foundations. Attackers exploited the poor security posture of the IoT vendors' devices, primarily the use of weak passwords, hardcoded backdoors, and legacy (outdated) software to compromise millions of devices and gadgets [36]. Even though these security incidents raised awareness about the security of the IoT, device vendors still prioritize profit over protecting their products against malicious actors [24]. Thus, it is imperative to improve the security of these devices and gadgets to protect them against cyber threats in the future. Fortunately, the research community has already directed its focus on exposing bugs and vulnerabilities in the firmware that runs on these IoT devices.

A subset of prior works in this research area conduct their analysis directly on firmware running on physical IoT devices. They either rely on a mobile or Web application [8, 19, 49] to communicate with the IoT firmware or execute the firmware within an emulated environment while forwarding memory accesses to the actual device [12, 30, 50]. Other works that eschew physical devices can be categorized into static and dynamic analysis approaches. Both static analysis [13, 20] and dynamic analysis such as firmware re-hosting [7, 28, 48] are popular approaches that have lately dominated the IoT firmware analysis landscape.

When considering Linux-based firmware, full-system re-hosting (or emulation) techniques are the most popular. Static analysis techniques generally suffer from a multitude of false positives or false negatives [20]. Even though re-hosting techniques revolutionized IoT firmware analysis, by extending bug and vulnerability testing towards increasingly sophisticated firmware, the field is characterized by the absence of two important aspects.

First, the community lacks a mechanism to objectively compare the capabilities of different re-hosting systems beyond crude metrics (e.g., number of bugs found within 24

hours). However, to assess the re-hosting progress we need to answer the following question:

> ***Q:*** *How can we quantify the forward progress of IoT firmware analysis approaches in full-system re-hosting?*

Prior full-system Linux-based re-hosting works showcase their progress and improvements over their predecessors by relying on ad-hoc and coarse-grained metrics (e.g., number of bugs or vulnerabilities found or networking connectivity achieved [28, 48]). However, each re-hosting system adopts a different design directly affecting the firmware execution flow and the emulation performance (e.g., emulating both user and kernel level code *vs*. emulating user level code only), thus introducing disparity in the firmware emulation outcome. The existing metrics are too generic to capture these discrepancies and quantify the contribution of each system in the IoT re-hosting landscape. Thus, to answer *Q* we first require metrics (e.g., programs executed, code coverage, kernel modules loaded, etc.) that better reflect the systems' re-hosting capabilities. Importantly, such finer-grained metrics imply a new challenge: At which point during the emulation should we measure them to ensure an objective comparison between re-hosting approaches? Clearly, relying on elapsed wall-clock emulation time as the indicator for taking a measurement is not sufficient, as emulation speed is directly impacted by a re-hosting system's design. Fundamentally, to enable objective comparisons, we require a conceptual reference point (with respect to system progress rather than wall-clock time) that can be identified in any re-hosting system. Once this reference point is reached, we can take the measurement (i.e., collect the metrics) and perform the comparison. We discuss below how it is possible to identify such a reference point to mark the completion of the firmware initialization logic.

The second missing capability of full-system Linux-based re-hosting is that current state-of-the-art systems target only one aspect of IoT firmware; either its user level [7,28,46,48,55] or its privileged (kernel) level aspect [1, 38, 55]. In real world devices, though, both the user and privileged aspect of the IoT firmware run cooperatively. To effectively analyze IoT firmware code it is therefore important to follow a more *holistic* approach that includes both aspects of the IoT firmware in the re-hosting and analysis process.

On the surface it seems that FirmSolo [1] is readily capable of holistic re-hosting since it builds kernels that can re-host a variety of binary IoT kernel modules and also support IoT user level code re-hosting due to the stable Linux system call ABI. However by design, FirmSolo's kernels are specifically tailored to kernel *module* re-hosting. As a result, these kernels might lack functionality (in the form of kernel symbols – functions and data structures) required by user level firmware code to execute successfully. Figure 2 in Section 3.2 describes such an example as the capability to access a `Memory Technology Device` (MTD) peripheral through a character device, via the `mtd_[open,read,write]` functions. Since these functions are not required nor accessed by kernel modules, the aforementioned functionality will be omitted from FirmSolo's kernels. Then, if a user level program requires these functions to execute successfully, it will fail. To mitigate these scenarios it is crucial to identify and supplement FirmSolo's kernels with kernel functionality not used by the firmware's kernel modules, but required by user level firmware code to execute.

To address the aforementioned shortcomings, in this paper, we present `Firmware Initialization Completion Detection` (`FICD`), a technique that detects the reference point at which the firmware's initialization phase is complete during emulation. `FICD` makes it possible to quantify the forward progress in firmware re-hosting, by enabling the meaningful comparison of different full-system re-hosting approaches on metrics such as the number of user programs executed, user and kernel code coverage, or number of kernel modules loaded, up to that point. The reference point represents a concept common to all full-system re-hosting approaches despite their differences; the end of the firmware initialization phase. Since the firmware operation is usually predetermined (e.g., network routing), IoT devices are primarily configured during startup by the firmware's configuration and bootup scripts. Every full-system re-hosting approach will inevitably execute these scripts and thus undergo the firmware initialization phase. Thus, the reference point detected by `FICD` can be used to meaningfully compare these systems along a metric that can showcase their contribution to re-hosting (e.g., code coverage).

In addition, to fill the void in holistic full-system firmware re-hosting we introduce `Pandawan`, a re-hosting framework that builds atop of (Py)PANDA [14, 17] and FirmSolo's firmware re-hosting capabilities to provide Operating System (OS) level introspection and dynamic analysis of both user and privileged (i.e., kernel module) firmware code. To achieve holistic firmware re-hosting and analysis, `Pandawan` features the `Kernel Augmentation` (`KA`) technique. `KA` first isolates the kernel functionality typically included by vendors in their IoT firmware kernels (in the form of kernel symbols). Then, it builds `Pandawan`'s "augmented" kernels which contain this functionality to enable the successful re-hosting of firmware user level code and kernel modules alike.

To showcase the improvements of `Pandawan` over the state-of-the-art, we rely on `FICD` to compare `Pandawan`, Firmadyne, FirmAE and FirmSolo. For our experiments we use a dataset consisting of 1,520 firmware images. Our investigation shows that `Pandawan` outperforms Firmadyne, FirmAE, and FirmSolo, by executing up to 6% more user level programs and 21% more user code basic blocks, on average, than these systems. In addition, `Pandawan` loads 9% more IoT kernel modules and executes 26% more kernel module basic blocks on average than FirmSolo.

To demonstrate `Pandawan`'s utility in firmware analysis, we use it to fuzz the kernel modules within the firmware images. Fuzzing the entire system call interface would not be efficient, since the majority of system calls (depending on the

arguments they are given) would target the core kernel code instead of kernel module code. Thus, Pandawan targets only the subset of system calls that result in the execution of code in IoT kernel modules. To this end, Pandawan's holistic analysis approach fundamentally enables the tracing of system calls invoked by user level programs which lead to kernel module code execution. In turn, the traces expose entry points from user level to kernel (module) level code. Pandawan uses the entry point information to generate system call chains in a format (seeds) compatible with the TriforceAFL [34] kernel fuzzer to fuzz the kernel modules within the firmware images. Pandawan collects traces for 479 firmware images. After transforming these traces into seeds and providing them to TriforceAFL, the fuzzer triggers 16 bugs on 8 closed and 4 open source kernel modules. Twelve of the bugs found are previously known and six are previously unknown bugs.

In summary we make the following contributions:

- We introduce Firmware Initialization Completion Detection, a technique that enables the meaningful comparison of full-system re-hosting approaches despite their discrepancies and quantify their progress in the firmware re-hosting domain.
- We propose the Kernel Augmentation technique which configures and builds kernels that contain functionality usually included by IoT vendors in their privileged firmware code, so that these kernels are conducive to holistic firmware re-hosting and analysis.
- We present Pandawan, the prototype implementation of Kernel Augmentation. Pandawan constitutes an OS level introspection and dynamic analysis framework that enables holistic (user and privileged level) re-hosting and analysis of IoT firmware.
- To quantify Pandawan's improvements over the state-of-the-art we use FICD to compare it with Firmadyne, FirmAE and FirmSolo re-hosting frameworks. Furthermore, we use Pandawan's holistic analysis capabilities to analyze the firmware images in our dataset. The information collected is then used by the TriforceAFL kernel fuzzer to analyze the kernel modules within the firmware images.

To further foster the research in this area, we will make Pandawan's source code publicly available[1].

2 Background

Before discussing the design of Pandawan, we first provide background information about full-system firmware re-hosting and the systems we will reference throughout the paper; PyPANDA, Firmadyne, FirmAE and FirmSolo.

2.1 Full-system Firmware Re-hosting

Full-system firmware re-hosting (or emulation) [18] is a technique used to run a binary firmware image without the need for the IoT hardware it was designed for. Particularly, the firmware (image) code is executed within an emulated environment (e.g., QEMU [4]), where hardware accesses are handled by the emulator. Full-system firmware re-hosting has become popular mainly due to two major benefits; 1) allowing the emulation of IoT firmware at scale, and 2) exposing firmware code to dynamic analysis (e.g., fuzzing) and operating system level introspection. However, full-system firmware re-hosting can be challenging. A recurring issue in the IoT infrastructure is the *lack of standarization* [15]. Particularly, the absence of common specifications and protocols leads to the production of billions of devices with diverse and proprietary hardware (e.g., NVRAM and Wireless NICs). Hence, IoT firmware and specifically its kernel component is dependent on each particular IoT device's System on Chip (SoC) and hardware peripherals.

Unfortunately, state-of-the-art emulators such as QEMU only support a fraction of the hardware peripherals used by IoT and embedded devices [18] and thus are unable to emulate the IoT firmware kernels. As a result, current full-system re-hosting approaches either target only user level IoT firmware code [7, 28, 48] or the IoT kernel modules [1, 38], by substituting the original firmware kernel with a custom kernel compatible with the emulators.

2.2 (Py)PANDA

One of the core foundations of Pandawan is PyPANDA [14], a Python frontend to PANDA [17], an Operating System (OS) level introspection framework built on top of QEMU. Besides emulating IoT related architectures (e.g., ARM and MIPS), (Py)PANDA also enables users to control the guest code execution and inspect the guest's internal state (e.g., memory). The OS level guest introspection is possible through a set of PANDA's existing C/C++ plugins and through PyPANDA's Python plugin interface. These plugins unlock unique capabilities not available in the upstream version of QEMU, such as system call and basic block tracing, and guest OS function hooking. Pandawan builds upon PyPANDA's Python interface to introduce new custom plugins and enable holistic analysis and introspection of IoT firmware.

2.3 Firmadyne & FirmAE

Firmadyne [7] and FirmAE [28] are among the state-of-the-art when it comes to full-system firmware re-hosting and dynamic analysis approaches. Specifically, they are designed to emulate the user level code of IoT firmware images and subject it to various bug and vulnerability analyses, such as testing against exploits from the Metasploit framework [39] or fuzzing. By design, both systems replace the original firmware kernels, which are incompatible with QEMU, with custom pre-built kernels that can be booted under QEMU. Since both the original IoT kernels and the pre-built kernels are based on Linux, they share the same stable system call interface required by user level firmware code to run.

Unfortunately, by relying on custom pre-built kernels,

[1] https://github.com/BUseclab/Pandawan

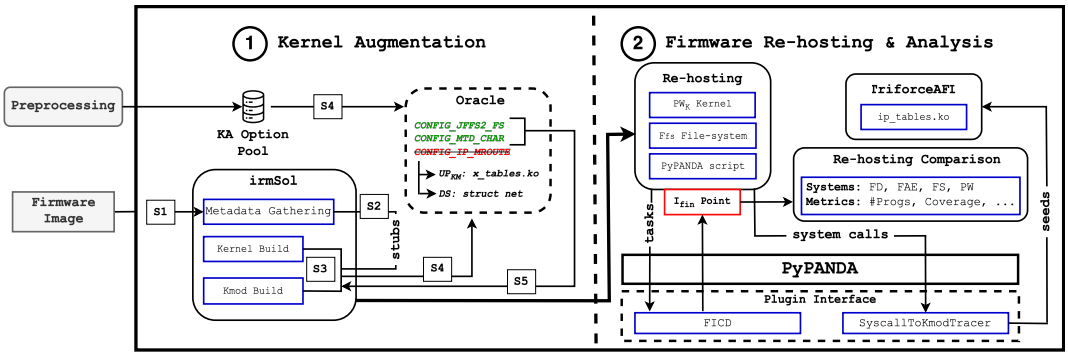

Figure 1: System overview of Pandawan: The figure features the two components of Pandawan. The first component, Kernel Augmentation is a 5-step process that produces Pandawan's PW_k kernels. The second component, Firmware Re-hosting & Analysis uses a PyPANDA script to emulate the PW_k kernel and the F_{fs} file-system under PyPANDA. It also uses PyPANDA's plugins to holistically analyze the target firmware.

Firmadyne and FirmAE only support user level firmware code. The Linux kernel modules contained within the IoT firmware file-systems cannot be loaded by the pre-built kernels. These kernels do not meet the requirements of Linux's module loading process, such as exporting kernel symbols (i.e., functions and data structures) required by the kernel modules to load into the kernel. As a result, the analysis of privileged IoT firmware code is out of scope for both Firmadyne and FirmAE.

2.4 FirmSolo

FirmSolo [1] is the first framework that facilitates dynamic analysis of Linux-based IoT kernel modules at scale. Unlike Firmadyne and FirmAE, FirmSolo targets the privileged level aspect of IoT firmware. Specifically, it automatically configures and builds kernels that can load the kernel modules contained in the file-systems of IoT firmware images. Existing dynamic analysis systems (e.g., kernel fuzzers) can leverage FirmSolo as the foundation to analyze the IoT firmware kernel modules for bugs and vulnerabilities. While FirmSolo is also capable of re-hosting user level firmware code through its compatibility with Firmadyne, it was not designed for that purpose. In particular, the kernels produced by FirmSolo are configured exclusively based on the metadata extracted from the IoT kernel modules and the original firmware kernels if they are available. Figure 2a shows why this configuration process is not always effective.

3 Overview

In this section we detail the FICD technique and the system overview of Pandawan. The goal of FICD is to detect the (reference) point in emulation where the firmware's initialization is complete. Since this point is conceptually common across re-hosting systems, it is possible to compare these systems along various metrics (e.g., user and kernel code coverage).

In Section 4.1 we discuss in detail how to apply FICD on different full-system re-hosting approaches and compare them based on their emulation capabilities.

To fill the void in holistic firmware re-hosting we present Pandawan, a framework capable of holistic (both user and privileged) re-hosting and analysis of IoT firmware code. As illustrated in Figure 1, Pandawan constitutes a two-component framework: ① The Kernel Augmentation (KA) component supplements FirmSolo's kernels (FS_k) with kernel functionality frequently included by vendors in their IoT firmware kernels (IoT_k) and used by user level firmware code. We refer to this functionality as user-code-required functionality. The outcome of component ① are Pandawan's "augmented" kernels (PW_k), which support both user level and kernel module code (i.e., holistic) re-hosting. ② The Firmware Re-hosting & Analysis component is responsible for the holistic re-hosting of the firmware code while emulating the PW_k kernels under PyPANDA. This component also employs PyPANDA's plugins to conduct a series of OS introspection and holistic analyses (e.g., tracing system calls that lead to kernel module code execution) during the firmware emulation run. Then, the results of the analyses can be transformed into seeds to fuzz the firmware kernel modules with a kernel fuzzer (e.g., TriforceAFL).

Throughout the rest of the paper we use the notations *user* code to refer to user level firmware code and *kernel* code to refer to privileged/kernel level code. The privileged level component can be further classified into the core kernel and kernel module code. We also reference the terms *program*, *process*, and *task*. Intuitively, a program corresponds to an executable in the firmware's file-system. We define a process as the running instantiation of a program during emulation. Finally, we refer to a task as the concatenized argv vector, representing (as a string) a program (name) along with its arguments.

3.1 Firmware Initialization Completion Detection

As mentioned previously, quantifying the progress of full-system re-hosting approaches is challenging, due to their unique implementation features that impact the emulation of a firmware image (F_{image}) for each re-hosting framework. For

```
[ncc_runtimecfg.c: 539 initRunTimeCfg()] ::: Total 4470 nodes, each node 24 bytes.
[ncc_runtimecfg.c: 540 initRunTimeCfg()] ::: Total 107280 byte for all nodes.
[ncc_runtimecfg.c: 207 loadCfg()] ::: Start loadCfg
[ncc_lz77.c: 509 flash2rootfs()] ::: BUG ON!!
[ncc_lz77.c: 538 flash2rootfs()] ::: Load Fail(/var/tmp/cfg.txt)
[ncc_runtimecfg.c: 213 loadCfg()] ::: flash2rootfs() fail!! restore to default!!
[ncc_lz77.c: 621 rootfs2flash()] ::: BUG ON!!
[ncc_runtimecfg.c: 215 loadCfg()] ::: Del TAG default file!!
[ncc_lz77.c: 509 flash2rootfs()] ::: BUG ON!!
...
```

(a) Example firmware image serial log when re-hosting with FirmSolo.

```
undefined4 loadCfg(void)
{
  bool bVar1;
  char *__stream;
...
  while( true ) {
    (*pcVar7)(__stream);
LAB_004a73cc:
    iVar3 = \
    flash2rootfs("/tmp/cfg.txt");
    if (iVar3 != 0) break;
    bVar1 = true;
    pFVar4 = \
     fopen64("/dev/console","a");
    if (pFVar4 != (FILE *)0x0) {
      uVar2 = getpid();
...
      fclose(pFVar4);
    }
...
  }
```

(b) Ghidra snippet of `ncc`'s `loadCfg` function

```
undefined4 rootfs2flash(undefined4
     param_1)
{
  bool bVar1;
  FILE *pFVar2;
...
  if (pFVar2 == (FILE *)0x0) {...}
  else {
...
    pFVar2 = \
    fopen64("/dev/mtdblock4","wb");
    if (pFVar2 != (FILE *)0x0) {
...
      return 1;
    }
...
  }
  fputs("BUG ON!!\n",pFVar2);
  fclose(pFVar2);
  return 0;
}
```

(c) Ghidra snippet of `ncc`'s `rootfs2flash` function

Figure 2: An example of a firmware re-hosting with FirmSolo. The firmware targets the `D-Link DIR-826L` Wi-Fi router. The figure provides the serial log output of the firmware under test as well as the Ghidra snippets of the `loadCfg` and `rootfs2flash` functions called by the `ncc` user program during the firmware's initialization.

example, the combination of both *user* and *kernel* code being re-hosted may result in different emulation speeds and thus in a different amount of overall code executed at the same point in time compared to only *user* code emulation. Thus, simply using ad hoc comparative methods such as the wall-clock time as the common denominator to assess the progress of re-hosting systems does not produce objective results. Instead, `FICD` aims to detect the point (I_{fin}) during the emulation of F_{image} where its initialization phase has finished. At I_{fin}, full-system re-hosting approaches can be compared using different metrics, such as the number of executed user level programs, *user* and *kernel* code coverage, or number of kernel modules loaded, which we call `emulation-based` metrics. In Section 5.5 we use these `emulation-based` metrics to compare the emulation progress of `Pandawan`, Firmadyne, FirmAE and FirmSolo. However, these metrics can of course be supplemented with additional ones depending on the analysis' requirements (see Section 6). We note that I_{fin} is not fixed (in time) for any two re-hosting systems, especially if their emulation speed varies.

The rationale behind `FICD` is that all the firmware activity up to the I_{fin} point is automated via the configuration and startup scripts within F_{image}'s file-system. Beyond I_{fin}, there is none to little automated activity occurring, since IoT firmware primarily invokes new functionality (i.e., tasks), such as setting new firewall rules or recording a video, based on its interactions with external actors (i.e., human interaction [27]). We consider detecting events that lead to new activity after I_{fin} as a problem orthogonal to this research and we leave it as future work.

Since the activity after the firmware initialization phase is limited, I_{fin} can be considered as any point during the emulation of F_{image} after it has stopped executing new tasks. Specifically, `FICD` defines a grace period (or *time frame*) tf during which the emulation of F_{image} can stay alive while F_{image} does not execute any new tasks (to see how we choose tf refer to Section 5.5). If during the emulation of F_{image}, time greater than tf elapses without executing a new task, `FICD` marks that point as I_{fin}. Here, metrics can be collected and compared. Even though I_{fin} might not be fixed (timewise) between different full-system re-hosting approaches that emulate F_{image}, it will always represent F_{image}'s end of initialization phase (regardless of the re-hosting framework).

3.2 Holistic Re-hosting & Analysis

As discussed previously, there is currently no prior work that supports holistic firmware re-hosting and analysis. At first glance, FirmSolo (see Section 2.4) seems to be readily capable of supporting holistic firmware re-hosting and analysis by emulating both firmware *user* and *kernel* (i.e., kernel module) code. On the contrary though, our investigations reveal that FirmSolo's FS_k kernels lack important `user-code-required` functionality required by *user* code to execute.

Specifically, the absence of the `user-code-required` functionality in the FS_k kernels might result in firmware *user* code to either prematurely terminate its execution or exhibit unwanted behavior, such as getting stuck in an infinite loop. We provide a motivating example of such a case for `D-Link DIR-826L` Wi-Fi router firmware in Figure 2a. The example illustrates the serial console output of F_{image}'s emulation run, where the capability to access a `Memory Technology Device` (MTD) through a character device is missing from the FS_k kernel. As a result, the `ncc` program which handles the configuration of the IoT device and uses character devices

to interact with the MTD peripheral, gets stuck in an infinite loop when executed in FirmSolo (lines 7-9 in Figure 2a). Specifically, `ncc` executes the `loadCfg` function which in turn calls the `rootfs2flash` function. We provide the Ghidra decompilation snippets for these functions in Figures 2b and 2c. The `loadCfg` function calls `flash2rootfs` within an infinite loop (lines 6-21 in Figure 2b) and exits the loop only when `flash2rootfs` returns a non zero value (line 11 in Figure 2b). The return value of `flash2rootfs` depends on the successful opening of the `/dev/mtdblock4` character device (lines 9-14 in Figure 2c). The ability to access a MTD peripheral through a character device is included in the kernel via the `CONFIG_MTD_CHAR` configuration option. As none of the firmware kernel modules use any functionality guarded by `CONFIG_MTD_CHAR`, FirmSolo did not enable this configuration option in its FS_k kernel. In Section 3.2.2, we explain how `Kernel Augmentation` adds `user-code-required` functionality (e.g., `CONFIG_MTD_CHAR`) required by user level firmware programs to execute successfully, into `Pandawan`'s kernels. Next, we detail `Pandawan`'s components.

3.2.1 Preprocessing

Based on our observations (see Section 5.3) vendors use similar configuration parameters (options) to configure their IoT firmware kernels (IoT_k). In particular, it is common for privileged firmware code of different IoT devices to share the same capabilities, such as supporting MTD peripherals or networking subsystems (i.e., `netfilter`), which are accessed by *user* code. Thus, by knowing the configuration of the IoT_k kernels of firmware images we also acquire the `user-code-required` functionality required by *user* code to execute. This `user-code-required` functionality is crucial for firmware images without a `KALLSYMS` entry. The `KALLSYMS` entry is a table containing information about the kernel symbols exported by the kernel (and thus about its configuration). The entry is optionally embedded in the kernel binary if the kernel is compiled with the `CONFIG_KALLSYMS` configuration option. We consider the configuration of the IoT_k kernels of firmware images without a `KALLSYMS` entry partially known since the only source about these images' kernel configuration originates from their kernel modules. Thus, to account for the missing kernel configuration (and in turn `user-code-required` functionality) from these firmware images, `Pandawan` collects popular configuration options from the IoT_k kernels of firmware images with a `KALLSYMS` entry. Then, `Pandawan` enables these options in its PW_k kernels for the firmware images without a `KALLSYMS` entry, to provide the `user-code-required` functionality needed by *user* code to execute.

3.2.2 Kernel Augmentation

Component ① is responsible for supplementing the FS_k kernel of F_{image} with `user-code-required` functionality generally used by *user* code. The product of component ① is the PW_k kernel for F_{image}, which is conducive to holistic firmware code emulation and analysis.

To produce the PW_k kernel for F_{image}, `Pandawan` follows these five steps: [S1]: Extract the file-system of F_{image} and gather metadata information, such as the `KALLSYMS` entry from the IoT_k kernel (if both the kernel and entry exist in F_{image}). [S2]: Furthermore, to aid the loading process of additional kernel modules, supplement PW_k kernels (their code) with "stubs" of symbols that are not present in the upstream kernel source code, but required by F_{image}'s kernel modules. [S3]: Build the upstream counterparts (UP_{kos}) of open-source kernel modules within F_{image}'s file-system. The UP_{kos} modules are compiled with debugging information available (i.e., `DWARF`). We note here that [S3] and [S4] will only executed for firmware images that do not have an available `KALLSYMS` entry. We consider the kernel configuration of firmware images with a `KALLSYMS` entry to be "fully" known. Particularly, the entry reveals information about the specific symbols needed by both the *user* and *kernel* code in these images. In these cases, the respective configuration options for these symbols (also used in the IoT_k kernels) will be added (by default) in [S5] in the PW_k kernels. [S4]: Invoke the *Oracle* process with the UP_{kos} modules and either the MIPS or ARM configuration option pool (depending on F_{image}'s architecture). The *Oracle* is a filtering process which checks and removes configuration options from the MIPS or ARM pools that affect the layout of kernel data structures used by the UP_{kos} modules (produced in [S2]). [S5]: Finally, feed the "safe" configuration options that remain from [S4] to its kernel configuration and build process to produce the PW_k kernels.

3.2.3 Firmware Re-hosting & Analysis

In component ②, `Pandawan` relies on the custom file-system creation and network configuration logic of FirmAE [28] to produce a dedicated PyPANDA script for F_{image} (see Section 4.2.3). We note here that the custom file-system also supports `Pandawan`'s (and FirmSolo's) kernel module loading logic. Next, `Pandawan` uses the modified file-system, the PW_k kernel and the PyPANDA script to emulate F_{image} under PyPANDA and conduct a series of analyses on the target firmware using PyPANDA's plugins. Examples of the analyses implemented are the collection of coverage about the *user* code executed during the firmware emulation, such as the executed program names and their executed QEMU Translation Block (TB) addresses, and the tracing of system calls (i.e., ID and arguments) invoked by *user* code during the emulation.

Furthermore, through its holistic re-hosting, `Pandawan` captures the interactions between the *user* code and *kernel* code. This introspection provides information about the inner workings of both the user and privileged code of F_{image}, which can then be used by dynamic analysis systems to thoroughly analyze F_{image}. Since prior works only focus on one aspect of the firmware; either the user or the privileged level, they lack

insights about how both these firmware aspects actually work together. Thus, these approaches have to resort to heuristics or impose limitations during their firmware analysis. For example, FirmSolo does not have the ability to extract information about system calls that interact with the kernel modules. It is limited only to fuzzing these modules through their `IOCTL` interface.

On the contrary, `Pandawan` does not suffer from these limitations. Instead, `Pandawan` makes use of its OS introspection capabilities to trace the system calls of processes that lead to the execution of code in kernel modules. These traces expose entry points (i.e., through the system calls and their arguments) from user space to kernel space. `Pandawan` relies on these entry points to detect kernel modules in F_{image} that communicate with *user* code through a *socket* or a *file descriptor* such as `iptables.ko` and `gpio.ko`, respectively. Next, `Pandawan` uses this information to create seeds for a modified version of the TriforceAFL kernel fuzzer that supports fuzzing MIPS and ARM IoT kernel modules, to analyze the kernel modules in F_{image}.

4 Implementation

In this Section, we discuss the implementation details behind `FICD` and `Pandawan`.

4.1 Firmware Initialization Completion Detection

`FICD` seeks to identify the reference point I_{fin} in the emulation of a firmware image where the firmware completed its initialization phase. To this end, `FICD` considers that a firmware image reached I_{fin} if no previously unseen (i.e., unique) tasks are launched within tf seconds. We refer to tf as the *time frame* parameter. To assess whether a task is unique, `FICD` uses the *Levenshtein*[2] edit distance (`ed`) to check the similarity of a task executed at a given point in time with all the tasks that have been executed prior to that point. We define a task (t) as previously unseen if it has a similarity below a certain threshold h (see Section 5.5) with all the previously executed tasks. That is, t is previously unseen iff $\forall_{t_i} ed(t,t_i) < h$ where t_i refers to all tasks started before t. The use of `ed` rather than strict equality is crucial to mitigate cases where nearly identical tasks (e.g., `/bin/iptables -t` **`filter`** `-F` and `/bin/iptables -t` **`nat`** `-F`) impact the discovery of the I_{fin} point. Our implementation of `FICD` uses a thread that runs alongside the main emulation and evaluates the above expression every five seconds. Once tf expired without a previously unseen task being launched, `FICD` declares I_{fin} reached and signals that measurements can be taken.

4.2 Holistic Re-hosting & Analysis

Next we provide the implementation details behind `Pandawan`. Since `Pandawan` uses FirmSolo as its foundation to configure and build its PW_k kernels, `Pandawan` reuses FirmSolo's reverse engineering and hybrid kernel configuration and build process.

[2] https://www.cuelogic.com/blog/the-levenshtein-algorithm

4.2.1 Preprocessing

Before proceeding to the execution of `Pandawan`'s components we first execute the *Preprocessing* step. In this step we pre-compute the `user-code-required` functionality that needs to be included in the PW_k kernels in component ① to support the successful re-hosting of *user* code. Specifically, we extract the `KALLSYMS` kernel symbols (where available) from all the available IoT_k kernels in our dataset (950 kernels). Then, we group the symbols into two sets S_{MIPS} and S_{ARM} matching the IoT_k kernel architecture respectively. Next, we use FirmSolo's `symbol-to-configuration-option` mapping mechanism to map each symbol s in S_{MIPS} and S_{ARM} to the corresponding configuration option that guards s's implementation in the kernel source code. This yields two pools (sets) of configuration options, one for MIPS (O_{MIPS}) and one for ARM (O_{ARM}). These pools represent the `user-code-required` functionality that is added to the PW_k kernels in component ①.

4.2.2 Kernel Augmentation

In component ①, `Pandawan` consumes a binary firmware image F_{image} as input and invokes the `Kernel Augmentation` (`KA`) technique. The goal of `KA` is to produce the PW_k kernels that are conducive to holistic firmware code emulation and analysis. The `KA` phase consists of five steps:

Step S1 In this step, `Pandawan` executes its metadata gathering process for F_{image}. This process extracts the file-system of F_{image}, metadata information such as IoT_k's `KALLSYMS` symbol entry (if both IoT_k and the entry are available) and also maps these symbols to their corresponding configuration options in the kernel source code.

Step S2 To improve its kernel module re-hosting capabilities, `Pandawan` implements the technique used by EASIER [38] for loading out-of-tree kernel modules. Specifically, `Pandawan` supplements the PW_k kernels with "stubs" of kernel symbols (not present in the upstream kernel source code) required by F_{image}'s kernel modules. `Pandawan` detects these symbols in step S1. The symbol stubs simply return a `NULL` value and make the corresponding symbol available to the kernel modules through the kernel's `EXPORT_SYMBOL` macro. Without these symbol stubs the kernel modules would immediately fail to load during the kernel module loading process. Next, if F_{image} contains a `KALLSYMS` entry, `Pandawan` immediately skips to step S5.

Step S3 `Pandawan` executes its kernel build process to build and acquire the upstream versions (UP_{kos}) of open-source kernel modules within F_{image} (since `Pandawan`, like FirmSolo, uses the upstream version of the IoT_k kernel). The UP_{kos} kernel modules are compiled with debugging information enabled (DWARF), required in step S4.

Step S4 In this step, `Pandawan` invokes the *Oracle* process whose goal is to provide the necessary `user-code-required` functionality to each PW_k kernel. First though, *Oracle* makes

sure to filter out any option $o \in O_{MIPS}$ (or O_{ARM}) that affects the layout of kernel data structures used by the kernel modules within F_{image}. If the PW_k kernel and F_{image}'s kernel modules do not agree about the layout of their common data structures, then misaligned data structure member accesses and in turn kernel module crashes might occur during emulation.

To this end, *Oracle* uses the DWARF information from the UP_{kos} kernel modules compiled in S3 and extracts the data structures used by F_{image}'s kernel modules. The intuition behind this process is that both the UP_{kos} modules and their open-source counterparts within F_{image} (if they are unmodified) make use of the same data structures since they share the same source code. Afterwards, *Oracle* parses the upstream kernel modules' source code and detects all the configuration options (O_{ups}) that modify the layout of the data structures (*DS*) used by these modules (also used by their counterpart modules in F_{image}). These options are considered "unsafe" since, if they were included in `Pandawan`'s kernel build process, they would misalign the layout of these data structures. Next, *Oracle* proceeds to filter out any configuration options from $O_{MIPS/ARM}$ that belong to the set O_{ups}. We consider the remaining configuration options ($O_{safe} = O_{MIPS/ARM} - O_{UP}$) as "safe" options that can be included in `Pandawan`'s kernel build process to supplement its kernels with the `user-code-required` functionality. We note that *Oracle* cannot detect the data structures exclusively used by the proprietary kernel modules in F_{image} since these modules do not have a counterpart in UP_{kos}. However, these modules can indirectly benefit from the *Oracle* process if they use any data structures in *DS*, since *Oracle* prevents these data structures from becoming misaligned.

Step S5 Finally, `Pandawan` includes the O_{safe} options in its kernel build process. Next `Pandawan` produces the PW_k kernels which are conducive to both *user* and *kernel* (in the form of binary kernel modules) code re-hosting. For images that contain `KALLSYMS` in their kernels, *Oracle* is redundant as `Pandawan` simply obtains all the necessary configuration options corresponding to the symbols in `KALLSYMS` during S1.

4.2.3 Firmware Re-hosting & Analysis

The goal of component ② of `Pandawan` is to initiate an emulation run using a modified version of F_{image}'s file-system (F_{fs}), the PW_k kernel and a dedicated PyPANDA script and analyze F_{image} using PyPANDA's plugins. Component ② is a two-pronged process; 1) `Pandawan` creates the F_{fs} file-system and PyPANDA script for F_{image}, and 2) it holistically emulates and analyzes F_{image}'s code with PyPANDA and TriforceAFL.

File-system and PyPANDA script creation. At first, `Pandawan` uses the custom file-system and network configuration process of FirmAE to create the F_{fs} file-system and set the network connectivity of F_{image}. Specifically, the custom file-system creation process proceeds as follows. Similar to FirmAE and FirmSolo, `Pandawan` uses `binwalk`[3] to extract F_{image}'s file-system, but ensures that it supports `Pandawan`'s kernel module loading logic. The F_{fs} file-system also contains a custom serial console binary, which `Pandawan` uses to issue commands to the emulated firmware (e.g., run TriforceAFL's fuzzing harness). Since the original startup scripts within the F_{fs} file-system are responsible for loading any of the kernel modules, `Pandawan` has to ensure that these scripts do not load the kernel modules that crashed during the hybrid kernel build process in S5. `Pandawan` applies any kernel module substitutions in-place, meaning that if a kernel module c that crashed during S5 has a substitution s (i.e., a counterpart in UP_{kos}), then c is replaced by s within F_{fs}, else c is deleted from F_{fs} altogether. Thus, when a startup script attempts to load c during emulation, it will either load s instead or no module at all.

To infer the networking configuration of F_{image}, `Pandawan` initiates an emulation run with the F_{fs} file-system, the PW_k kernel and QEMU. During emulation, `Pandawan` gathers information about the networking interfaces (e.g., bridge mode) and IP configuration of F_{image}. Finally, `Pandawan` embeds F_{image}'s network configuration within a PyPANDA script, used to emulate and analyze F_{image} with PyPANDA and its plugins.

`Pandawan` also addresses kernel module crashes that occur during its re-hosting experiments (see Section 5.3). In these cases, `Pandawan` first uses FirmSolo's data structure layout recovery mechanism to address the errors. If the crashes persist then `Pandawan`, during the creation of F_{fs}, substitutes the crashing modules with their counterparts in UP_{kos} (if they exist) else it removes the crashing modules from F_{fs} entirely.

Holistic Re-hosting & Analysis. Next, `Pandawan` initiates a firmware emulation run using the PW_k kernel, the F_{fs} file-system and PyPANDA. During emulation, `Pandawan` enables the OS introspection (Py)PANDA plugins `osi_linux` (enabled by default), `coverage`, and `syscalls_logger` to analyze F_{image}. Primarily, the information collected are the executed program names, their executed QEMU Translation Blocks (TBs), and the system calls (ID and arguments) that were invoked by *user* code during the emulation. We note here that we modified PyPANDA's `coverage` plugin, in its *summary* mode, to not only provide information about the programs and the number of unique TBs executed, but also the addresses of the TBs along with their origin (e.g., the program itself or the symlink target if the program is a link). `Pandawan` also introduces two additional custom plugins; the `FICD` and the `SyscallToKmodTracer`.

As the name suggests the former plugin implements the `FICD` technique in `Pandawan`, while the goal of the `SyscallToKmodTracer` is to showcase `Pandawan`'s utility in holistic firmware analysis. Specifically, `SyscallToKmodTracer` traces system calls invoked by *user* code that lead to the execution of code in kernel modules. These traces expose entry points from user level to kernel level,

[3] https://github.com/ReFirmLabs/binwalk

which Pandawan transforms into seeds for the TriforceAFL kernel fuzzer to analyze the binary kernel modules. Essentially, Pandawan leverages the hooking infrastructure of PyPANDA to hook all system calls. Upon entering a system call, the corresponding hook triggers and Pandawan stores information about the execution context at the time (i.e., the current process name, its pid and creation time) and correlates the running system call (ID) with that context. Keeping track of the different execution contexts and their running system calls is mandatory, since the kernel can alternate between different contexts via *context switches*. Pandawan uses this information to detect the context in which the kernel module code is executed in and also the system call that led to the execution of that kernel module code.

To detect when kernel module code is executed, Pandawan also places a hook on memory regions occupied by kernel modules depending on the underlying architecture of F_{image} (e.g., 0xc0000000 - 0xc2000000 for MIPS). Specifically, if a system call leads to code residing in these regions then the aforementioned hook will trigger. Within the hook, Pandawan checks the current execution context and iterates all the previously traced execution contexts (captured by the system call hooks) until it finds a match. When it does, Pandawan correlates the current kernel module code address (i.e., the start of the TB currently executed) with the current execution context and the (running) system call associated with that context. The aforementioned system call is considered the one that led to the kernel module code execution.

Seed Creation. However, to create useful seeds for the TriforceAFL fuzzer, Pandawan also requires information about the arguments (i.e., values) of the system calls that lead to the execution of kernel module code. Another PyPANDA plugin, the syscalls_logger, is responsible for collecting the arguments of all the system calls executed during the emulation. Pandawan combines the data collected by the syscalls_logger and SyscallToKmodTracer plugins to create seeds and fuzz the firmware kernel modules. Seed generation for fuzzers is not a new research topic. Prior works [3, 9, 37, 42, 53] leverage either system call traces, concolic execution or static analysis to extract information about the program execution and use it to create seeds for popular fuzzers such as syzkaller [23] or AFL/AFL++ [21, 51]. Our approach is similar to [37] in the sense that it relies on system call traces to create seeds for the TriforceAFL kernel fuzzer. However, we target only kernel modules that are accessed by system calls either through a socket or a file descriptor since TriforceAFL's fuzzing agent [35] is inherently compatible with these types of system calls.

As we show in Section 5, the majority of TriforceAFL compatible system calls (*sc*) that lead to kernel module code execution are networking (e.g., sys_setsockopt) or file-based system calls (e.g., sys_write). Thus, to create valid seeds for the fuzzer, Pandawan first has to detect which sys_socket and sys_open system call creates the file descriptor accessed by each *sc*, respectively. To gain this information, Pandawan leverages the first argument of a *sc* which corresponds to the file descriptor number fd. Then for each *sc*, Pandawan parses the information of syscalls_logger and detects the sys_socket or sys_open system call that was invoked by the same process as *sc* and returned a value equal to fd. System calls that operate on the same fd are grouped together in the same seed.

Fuzzing. To start fuzzing the kernel modules in F_{image}, Pandawan runs the PW_k kernel along with the F_{fs} file-system and the seeds found previously under TriforceAFL. The I_{fin} point for F_{image} plays a critical role also in this scenario. In particular, Pandawan spawns a thread that runs alongside the TriforceAFL process and waits until F_{image} reaches its I_{fin} point, since all the target kernel modules would be loaded by that point. Then, the thread connects through a UNIX socket to the custom serial console within the F_{fs} file-system and initiates the fuzzing harness to begin the kernel module fuzzing. We note here that Pandawan limits the range of system calls that the fuzzing harness can execute to the twelve system calls illustrated in Table 6 in Appendix C. The rationale behind this limitation is to only execute system calls compatible with TriforceAFL's fuzzing agent.

5 Evaluation

In this Section, we first evaluate Pandawan's effectiveness on holistic IoT firmware re-hosting and analysis and then FICD's capability to meaningfully compare full-system re-hosting approaches. Specifically, we answer the following three research questions:

RQ1 Is Pandawan capable of holistically re-hosting firmware code (§ 5.3)?

RQ2 How effective is Pandawan on enabling holistic firmware analysis (§ 5.4)?

RQ3 How efficient is FICD when it comes to quantifying the forward progress in full-system IoT firmware re-hosting (§ 5.5)?

First, we describe our dataset and our experimental setup, then we detail the experiments we use to evaluate Pandawan and finally discuss the comparative experiments with FICD.

5.1 Dataset

For our evaluation, we use the dataset of FirmSolo and a subset of firmware images used in Greenhouse [46]. The Greenhouse dataset was shared with us upon request to the authors. We use the FirmSolo dataset since it is supported by FirmSolo, Firmadyne, and FirmAE. We do not use the entire Greenhouse dataset (consisting of 7,347 firmware images) since the majority of the images use the same kernel version as the images in the FirmSolo dataset. Instead, we pick at random 50 images from the 97 images that use a kernel version between 4.4.198 (latest version used by FirmSolo) and 4.9.206 (the latest kernel

version used by the ARM/MIPS 32bit images in Greenhouse). Our dataset consists of 1,520 firmware images containing a total of 61,319 binary kernel modules. The firmware images in the dataset target the MIPS (984 images) and the ARM (536 images) platforms. Finally, the firmware images span a total of 95 unique Linux kernel versions, ranging from version `2.6.18` to version `4.9.206`.

5.2 Experimental Setup

We run all our experiments Intel Xeon machines using 2 cores with minimum of 16GB of RAM. All of our re-hosting experiments consist of three runs and the results correspond to the averages across these runs.

5.3 Holistic Re-hosting

In this section we evaluate the ① `Kernel Augmentation` and ② Firmware Re-hosting & Analysis components of `Pandawan` to answer RQ1.

Preprocessing. We execute this step only once in our experiments, to generate the configuration option pools O_{MIPS} and O_{ARM}, which constitute the `user-code-required` functionality that is added in the PW_k kernels in component ①. We include these configuration option pools as part of `Pandawan`'s repository. During this step, we extract 754 options in the O_{MIPS} and 726 options in the O_{ARM} pools, respectively. We opt to only keep the most popular options in both sets. In Figures 3a and 3b in Appendix A, we provide the Cumulative Distribution Function (CDF) of the configuration options in O_{MIPS} and O_{ARM} pools, respectively, over the images that have `KALLSYMS` available. To find the most popular options in each pool we use the Kneedle algorithm [40] to deduce the "knee" points in both figures (marked with the red lines). We filter out the options that reside beneath these knee points. Specifically, the knee point in Figure 3a is 30 (images), 418 (options), while the knee point in Figure 3b is 85 (images), 513 (options). In the end, 336 (754 - 418) and 213 (726 - 513) options remain in the O_{MIPS} and O_{ARM} pools, respectively.

Kernel Augmentation. Regarding the unresolved symbols required by kernel modules to load into the PW_k kernels, `Pandawan` successfully adds the stubs for all these 4,254 unique symbols into the PW_k kernels' source code. Next, we evaluate the *Oracle* only on the subset of 570 (38%) firmware images that do not contain a `KALLSYMS` entry, since the *Oracle* only affects the PW_k kernels produced for these images. After S4, 200 configuration options (out of O_{MIPS} and O_{ARM}) on average remain as the "safe" options that can be included in S5 to produce the PW_k kernels for the images without a `KALLSYMS` entry. Regarding the 950 firmware images that contain a `KALLSYMS` entry, there are no additional options included in S5, thus the PW_k kernels are identical to the FS_k kernels produced (by default) by FirmSolo.

Network configuration. Since `Pandawan` leverages FirmAE's network configuration logic, every PyPANDA script by default sets at least a networking interface in PANDA for each firmware image. Unfortunately, we notice that the PyPANDA/-PANDA emulation hangs for the ARM images in our dataset that target the `Versatile` and `Realview` platforms (498/536 images) when the networking interfaces are enabled. The remaining 38 images target the "dummy" `virt` QEMU platform and are unaffected. Since FirmAE's pre-built ARM kernel targets the `virt` platform, FirmAE does not suffer from the same issue. Thus, we disable these interfaces for the affected images to successfully re-host them with `Pandawan`. We have notified the PyPANDA/PANDA developers about this issue.

Re-Hosting Success. Component ② of `Pandawan` is responsible for initiating an emulation run, using the F_{fs} file-system and the PW_k kernels while concurrently enabling PyPANDA's OS level introspection and analysis plugins. `Pandawan` successfully re-hosts 1,389 (91%) of all the images in our dataset. We define as successfully re-hosted all the cases where the emulation successfully executed `init` without panicking or freezing. Unfortunately, `Pandawan` cannot re-host the remaining 123 firmware images since for 38 images there is no working `init` script available in the file-system, `init` immediately crashes for 12 images or important libraries are missing in the file-system for 11 images. Additionally, 29 images use a kernel with `MIPS Thread Context`, a feature that improves parallelism in MIPS systems, but not supported by QEMU. Furthermore, 2 images use a very old kernel version (`2.6.18`), resulting in the emulation freezing while the kernel boots up. We also notice 13 cases where the kernel cannot not mount the file-system because the latter is corrupted and 8 cases where the kernel hangs while mounting the file-system. Finally, PyPANDA crashed for 18 images during emulation, while triggering a bug in its `osi_linux` plugin (used by default by PANDA). We have notified the (Py)PANDA developers about the issue. Since these failures are not specific to `Pandawan`'s implementation, we do not consider them as a limitation of our work.

Serial Console Connectivity. As discussed in Section 4.2.3, to run the fuzzing harness within a target firmware image, `Pandawan` has to first connect through a `UNIX` socket to a custom serial console within the image's file-system. To discover the number of firmware images that are accessible through their serial console, we conduct an experiment where we emulate each firmware image with `Pandawan` and attempt to connect to its serial console through a `UNIX` socket after 30 seconds of emulation time and run a dummy command (e.g., `/bin/ls`). A successful connection with a serial console means that we get the output of the dummy command in the serial log output of the firmware image. We are able connect to the serial console of 1,200 (86%) out of the 1,389 firmware images that `Pandawan` successfully re-hosts. We "break down" the reasons behind the console connectivity issues for the 189 failed cases in Table 5 in Appendix B.

Kernel Module Re-hosting. During the firmware emulation runs in component ②, `Pandawan` loads 14,413 (24%) kernel modules out of the 61,319 IoT kernel modules in our dataset. As illustrated in [1], the configuration and bootup scripts

Plugins	I_{fin} Avg. (sec)	Overhead (%)
All	496	22
No `syscall_logger`	496	22
No `coverage`	460	13
No `SyscallToKmodTracer`	440	8
Only `coverage`	462	14
Only `SyscallToKmodTracer`	456	12
Only `syscall_logger`	413	2
Only `FICD`	407	0
Frameworks		
FirmSolo	476	17
Firmadyne	441	9
FirmAE	477	17

Table 1: `Pandawan`'s plugin performance ablation study. The experiment includes every plugin combination used by `Pandawan`. The second column provides the average I_{fin} points marked by `FICD` for every plugin combination. The third column provides the performance overhead incurred by each plugin combination. The table also includes the average I_{fin} measured for FirmSolo, Firmadyne and FirmAE on the same dataset with all the plugins enabled.

dictate which kernel modules will be loaded into the kernel during the firmware initialization, which is merely a fraction of all the kernel modules in the images' file-systems. Finally, `Pandawan` executes 336 kernel module TBs on average.

In cases where kernel module crashes occur during emulation, `Pandawan` uses its custom crash solving method (see Section 4.2.3) to address the issue. In total, `Pandawan` addreses 249 kernel module errors.

User Code Re-hosting. When considering its *user* code re-hosting capabilities, `Pandawan` executes 30 user level programs and 15,671 unique QEMU TBs on average. The startup scripts within the firmware images dictate which programs are executed during bootup. We make sure to substitute symlinks with their actual targets in our results so that the TBs executed get attributed to their actual origin. For example, if the firmware executes `/bin/ls` which is a symlink to `/bin/busybox`, we only include and count the TBs executed towards the `busybox` executable in our results. Note that each TB is attributed only once (counted one time only) to their origin. For instance, a TB that belongs to a shared library and executed by multiple programs will only be counted once towards the shared library it belongs to. In Section 5.5, we discuss how these results compare against Firmadyne, FirmAE and FirmSolo.

Kernel Augmentation Ablation Study. To demonstrate the contribution of `KA` in firmware re-hosting, we also conduct an ablation study where we measure the effectiveness of the two key features of `KA`: 1) The addition of the `user-code-required` functionality by the `Oracle` and 2) the addition of the kernel symbol stubs (required by kernel modules to load into the kernel). For this experiment we use a smaller dataset of 150 firmware images (100 images without `KALLSYMS` and 50 images with `KALLSYMS`). We bias our selection towards images without `KALLSYMS` since `KA` benefits these images the most. We present the results of this study in Table 3 in the third group column. Based on our results the contribution of `KA` is apparent when taking into account all

Module	Type	Vendor	Kernel	Paths	Path var (std)	Bugs
MIPS						
arp_tables	O	AT&T	2.6.31	121	43 (7)	2
led	P	Linksys	2.6.31	26	39 (6)	1

					Total	16

Table 2: Statistics about the fuzzing experiments with TriforceAFL. The `O` and `P` in column two represent kernel modules that are *open-source* and *proprietary*, respectively. Column six provides the variance and standard deviation for the paths found by the fuzzer over the ten runs.

of our metrics. Specifically, `Pandawan` with `KA` executes 6% more user level programs and executes 11% more TBs than `Pandawan` without `KA` (i.e., FirmSolo), while also loading 3% more kernel modules and executing 17% more kernel module TBs. Finally, our experiments show that the addition of only the `user-code-required` functionality by the `Oracle` is more beneficial than simply adding the kernel symbol stubs, since the majority of the metrics are the closest to `Pandawan` with `KA`. Specifically, `Pandawan` with only the `Oracle` enabled manages to surpass `Pandawan` with `KA` in kernel module loading by 1%. Upon further inspection, two images whose the kernel modules crashed and deleted from the F_{fs} file-system (see Section 4.2.3) during the emulation with `Pandawan` with `KA`, skew the results in favor of `Pandawan` with only the `Oracle` enabled.

Plugin Overhead. To measure the performance overhead of each PyPANDA plugin, we pinpoint the I_{fin} points using every possible combination of the plugins enabled in `Pandawan`'s analysis (i.e., `syscalls_logger`, `coverage` and `SyscallToKmodTracer`) excluding `FICD` which is responsible for determining the I_{fin} points and thus is always enabled. For this study we use again a smaller dataset of 150 images (95 with `KALLSYMS` and 55 without `KALLSYMS`) that better represents the distribution of the images in our dataset. We provide the results in Table 1. When all the plugins are enabled we notice a 22% slowdown compared to enabling only `FICD`. This is expected since each plugin contributes an additional level of analysis which impacts the overall emulation speed. Specifically in our case, the most computational heavy plugins are `coverage` and `SyscallToKmodTracer` since they constantly track the execution of QEMU TBs during the emulation, incurring a slowdown of 14% and 12%, when enabled individually and a slowdown of 22% when both are enabled.

5.4 Holistic Analysis

To demonstrate `Pandawan`'s contribution to holistic firmware analysis and answer RQ2, we evaluate how the information collected by the `SyscallToKmodTracer` plugin is used to further analyze the binary kernel modules with TriforceAFL.

Dataset	All Images (/w cov) (1328)				No KALLSYMS (/w cov) (456)				KA Ablation Dataset (/w cov) (135)			
Framework	FD	FAE	FS	P	FD	FAE	FS	P	No KA	KA w/o oracle	KA w/o stubs	KA
Avg. Progs	**30**	**31**	**31**	31	**35**	**36**	**34**	36	**32**	**32**	33	34
Avg. TBs	**15,483**	**16,767**	**15,523**	16,360	**15,715**	16,552	**13,835**	16,740	**15,099**	**14,961**	**16,611**	16,790

Table 3: Comparison results between the Pandawan (P), Firmadyne (FD), FirmAE (FAE) and FirmSolo (FS) re-hosting frameworks. The table depicts the average number of user programs and QEMU TBs executed, the number of kernel modules loaded and kernel module TBs executed, for each system respectively. The green cells represent the best results for each metric. The bold values represent the cases with statistical significance, where p-value $p < 0.05$ (using the Wilcoxon signed-rank test).

Seed Generation. The `SyscallToKmodTracer` plugin monitors the interactions between the *user* and *kernel* code during the firmware emulation run in component ②. `Pandawan` processes the information collected by the `SyscallToKmodTracer` plugin (i.e., system calls that lead to kernel module code execution) and generates seeds that are used by TriforceAFL, as explained in Section 4.2.3.

During our experiments, the plugin identified 927 out of the 1,389 successfully re-hosted firmware images that load at least a kernel module. In addition, within these images, 353 processes invoke 6,954 system calls on average that lead to kernel module code being executed. The remaining 462 firmware images did not successfully load kernel modules.

Unlike FirmSolo which targets only the IOCTL system call, `Pandawan` can trace and generate seeds for all types of system calls that interact with kernel modules. However, we opt to create seeds only for cases involving popular system calls that interact with kernel modules through a file descriptor created either by a `sys_socket` or `sys_open` system call, due to their compatibility with TriforceAFL's fuzzing agent. We also provide details about the system calls we did not fuzz in Table 7 in Appendix C. In the end, `Pandawan` creates seeds for 479 images whose *user* code invokes system calls (see Table 6 in Appendix C) which lead to the execution of kernel module code. Out of these images, 466 (97%) have serial console connectivity, thus can be fuzzed by TriforceAFL.

Kernel Module Fuzzing. After the seed creation, `Pandawan` uses TriforceAFL to fuzz the IoT modules within the firmware images. We run all experiments ten times for 12 hours.

While `Pandawan` creates seeds for 479 firmware images, we chose to fuzz only the kernel modules in a subset of 20 randomly selected firmware images (with serial console connectivity to invoke the fuzzing harness) due to computational resource constraints. We provide the information about our fuzzing campaigns in Table 2. The table provides the average number of paths found by TriforceAFL, the path variance and standard deviation over the ten runs and the number of bugs we confirmed, for each image. Based on the path variance and standard deviation measured (see column six in Table 2), the coverage found in all the fuzzing campaigns is consistent (the variances and standard deviations are insignificant).

Specifically, TriforceAFL triggers 16 bugs in 12 kernel modules (8 proprietary and 4 open-source – see Table 2). The bugs fall into the stack corruption (6), arbitrary memory reads and writes (7), and large virtual memory allocation (3) categories. Three of these bugs (`gpio` (1) and `ipv6_spi` (2)) were also detected by FirmSolo. In addition, the seven bugs triggered for the open source kernel modules (`arp_tables` (2), `ip6_tables` (2), `ip_tables` (2), and `x_tables` (1)) are related to known bugs (`CVE-2016-4998` and `CVE-2016-3135`), which is why we did not report these bugs to the Linux kernel developers. Finally, the six remaining bugs on the proprietary kernel modules `led` (1) `ipt_STAT` (2), `gpio_module` (1), `statistics` (2) are previously unknown bugs. We have disclosed these bugs to the respective vendors, and two vendors acknowledged our findings; `TP-Link` and `DLink`.

5.5 Comparative Results

The previous evaluation based on the coarse-grained "number-of-bugs-found" metric shows that `Pandawan` finds more diverse bugs than FirmSolo. Even when it comes to bug finding speed, `Pandawan` is four times faster on average than FirmSolo (see Table 8 in Appendix E). However, `FICD` helps to assess re-hosting process on a finer granularity than just bugs found. Thus, in this Section, we evaluate `FICD`'s utility in comparing full-system re-hosting approaches based on the `emulation-based` metrics. Specifically, we compare the `Pandawan` , FirmAE, Firmadyne and FirmSolo re-hosting frameworks to answer RQ3.

As mentioned previously, the `FICD` technique requires two parameters; 1) the task similarity threshold h for the *Levenshtein* edit distance (`ed`) which `Pandawan` uses to identify previously unseen tasks, and 2) the time frame tf which indicates how long can the emulation continue without the firmware executing a previously unseen task. For our experiments, we set the threshold h equal to 0.5 (for all re-hosting frameworks) and tf equal to 300 seconds for `Pandawan` and FirmSolo and 220 seconds for FirmAE and Firmadyne, respectively. To obtain these values we initiate a ten minute experimental run with FirmAE and `Pandawan` for all the images in the dataset, without the `FICD` plugin enabled. We set the h and tf of Firmadyne and FirmSolo the same as FirmAE's and `Pandawan`'s due to the re-hosting similarities shared between the frameworks (i.e., Firmadyne with FirmAE and FirmSolo with `Pandawan`). To calculate the threshold h, we first sort all tasks based on their creation time. Then, for each task in the sorted list we use `ed` to calculate its similarity against all the tasks with an earlier creation time, as a ratio between 0 and 1. According to

Figures 4a and 4b in Appendix D, almost 90% of the tasks have a similarity less than 0.5 with any other task created earlier, for both FirmAE and Pandawan, thus we choose $h = 0.5$. Then, to get the time frame tf, we measure the average $\bar{t}$ and standard deviation (σ) of the time that passes between the execution of previously unseen tasks. Based on the ten minute experiment runs, FirmAE's $\bar{t} = 52sec$ and $\sigma = 81sec$, while Pandawan's $\bar{t} = 69sec$ and $\sigma = 115sec$. To ensure statistical relevance we choose a time frame $tf > \bar{t} + 2\sigma$, thus we set $tf = 220sec$ as our optimal time frame for FirmAE and Firmadyne and $tf = 300sec$ for Pandawan and FirmSolo, respectively.

Re-hosting Fidelity Comparison. To showcase Pandawan's progress on holistic firmware re-hosting, we use theFICD technique to compare it with the Firmadyne, FirmAE, and FirmSolo re-hosting frameworks, based on the number of executed user level programs (non symlinks), the QEMU TBs executed in these programs, the number of kernel modules loaded, and the kernel module TBs executed during emulation. To make our comparison fair among all compared re-hosting frameworks we only include images where we collected coverage in all three emulation runs with a maximum total emulation time of $45min$ for all frameworks. Thus, we compare Pandawan , Firmadyne, FirmAE, and FirmSolo on 1,328 out of the 1,520 images in our dataset. We note here that throughout all our experiments FICD was successful in detecting the I_{fin} point for each framework and each image and terminating the emulation way before the $45min$ global timeout (see Table 1).

Pandawan executes up to 3% more user level programs on average than Firmadyne, FirmAE and FirmSolo (see column group 1 in Table 3). Similarly, Pandawan outperforms both Firmadyne and FirmSolo on the average number of TBs executed by up to 5%. However, FirmAE executes 3% more TBs on average than Pandawan. The predominant reasons behind this outcome are twofold; 1) the emulation speed of Pandawan is slower than FirmAE's due to the SyscallToKmodTracer affecting only Pandawan (and FirmSolo) which loads and analyzes the IoT kernel modules, and 2) KA impacts negatively the re-hosting progress. Since FirmAE and Firmadyne focus solely on user level re-hosting and do not load any firmware kernel modules, the plugin's module TB tracing functionality is ineffective for these frameworks. As illustrated in Table 1 both Firmadyne and FirmAE are 13% and 4% faster than Pandawan on average. In addition, for 36 out of the 1,328 images used in the comparison experiments, the PW_k kernels produce a crash (i.e., Oops), while the FS_k kernels do not suffer from the same issue. The addition of the user-code-required functionality and the kernel symbol "stubs" by KA hinders the re-hosting progress of the images in these cases. This small regression can be attributed to the heuristic nature of KA.

When it comes to the kernel module loading we compare only Pandawan and FirmSolo, since neither Firmadyne nor FirmAE load IoT kernel modules. Specifically, Pandawan loads 6% more kernel modules and executes 5% more kernel module TB's on average than FirmSolo. To be fair towards FirmSolo we addressed the crashes during its emulation runs using Pandawan's crash solving methods (see Section 4.2.3). In this case, we address 225 crashes in total.

Data	Avg. TBs			
Framework	FD	FAE	FS	P
httpd	1,784	1,886	1,803	1,790
uhttpd	268	279	249	252
mini_httpd	751	782	743	744
lighttpd	2,281	2,448	2,267	2,270
goahead	194	198	188	185
httpd	699	637	596	595

Table 4: Coverage information of popular IoT webservers.

Since Pandawan only includes the user-code-required functionality in images without a KALLSYMS entry (see Section 3.2.2), the improvements of Pandawan over FirmSolo can be better observed on these images (see column group 2 in Table 3). In particular, Pandawan executes 6% more user programs and 21% more TBs on average than FirmSolo. Pandawan also outperforms FirmSolo on the number of kernel modules loaded and kernel module TB's executed by 9% and 26% on average, respectively. Both the user-code-required functionality and the symbol "stubs" added by Pandawan in the PW_k kernels for these images, greatly benefit the progress of holistic (*user* and *kernel* code) re-hosting as well as the loading of additional kernel modules.

We also test the statistical significance of our results using the Wilcoxon signed-rank test [45]. Specifically, for each metric we compare Pandawan's data with Firmadyne's, FirmAE's and FirmSolo's data (28 comparisons). We exclude the kernel module related metrics (loaded and TBs executed) for Firmadyne and FAE since they do not load the IoT kernel modules. We note that the majority of our measurements (24/28) are statistically significant with a p-value $p < 0.05$ (see Table 1).

Webserver Re-hosting. To further showcase the efficiency of Pandawan in *user* code re-hosting, we conduct a study about the re-hosting of webservers used by firmware images. We provide the results in Table 4. Specifically, we collect coverage information for 6 popular webservers used in IoT [28]. Our findings show that FirmAE and Firmadyne which are the state-of-the-art in *user* code re-hosting marginally outperform Pandawan in re-hosting webservers by executing up to 8% more QEMU TBs across all the servers in our study. Given the fact that Pandawan aims to holistically re-host and analyze Linux-based IoT firmware, Pandawan's slight deficiency in webserver re-hosting is an acceptable tradeoff. We leave the qualitative analysis of the differences in webserver re-hosting between the compared frameworks as future work.

6 Discussion

In this Section we discuss future applications of FICD and Pandawan. With the introduction of FICD, developers can efficiently improve upon the existing works by comparing their implementations with the state-of-the-art. Furthermore, Pandawan could be leveraged to develop future frameworks whose re-hosting capabilities closely approximate physical IoT devices. For instance, the re-hosting techniques imple-

mented in Honware [48] could be integrated into Pandawan to further improve its holistic re-hosting capabilities. In addition, the FICD and setup of Pandawan (i.e., using PyPANDA for firmware emulation) are generic and OS agnostic. Thus, any firmware that can be emulated by QEMU and uses a concept of process/task (e.g., FreeRTOS [22]) can be adapted to leverage FICD. Next, we explore the categories of metrics that could be used to quantify re-hosting progress and lastly specify certain limitations of both FICD and Pandawan.

Alternate Metrics. In general, we can distinguish the metrics that quantify the emulation progress in two categories; system- and process-oriented metrics. Our existing metrics; number of programs executed and number of kernel modules loaded fall into the system-oriented metrics, since they showcase emulation progress from a higher (system) level of abstraction. Other metrics in this category could be the number of networking interfaces successfully initialized and/or the successful firewall configuration (e.g., the number of successfully applied rules).

The average number of QEMU TBs traced belong in the process-oriented (lower-level) metrics, since (Py)PANDA correlates each TB executed to a running program or kernel module. Another metric that could fit in this category is the number and identity of successful and unsuccessful system calls executed by each process. In summary, the metrics used in this paper work well and other metrics can be easily integrated.

Regarding techniques to assess a successful firmware initialization, generally there is no reliable indicator to establish the end of a firmware's initialization phase. However, 33 of our images print a specific message about the end of bootup and timewise this message coincides with I_{fin}- tf, thus I_{fin} accurately corresponds to these images' end of initialization phase.

Limitations. As far as FICD's limitations are concerned, the time frame tf is directly dependent on which (Py)PANDA plugins are enabled during a firmware emulation run. When many computationally heavy plugins are enabled, the emulation speed will decrease, thus tf requires an adjustment. In our re-hosting experiments we use three (Py)PANDA plugins (coverage, syscalls_logger, and SyscallToKmodTracer) along with the FICD plugin, which results in the optimal $tf = 220sec$ and $tf = 300sec$ for FirmAE and Pandawan, respectively. Furthermore, Pandawan, like other re-hosting frameworks, faces specific limitations. Since the *Oracle* targets only the data structures used by open-source kernel modules with a counterpart in UP_{kos}, it does not guarantee that the layout of data structures used by proprietary kernel modules will be unaffected. The options produced in S4 can potentially misalign the layout of data structures used by proprietary kernel modules causing the modules to crash during emulation. Furthermore, as shown in Section 5.3 only a fraction of the total modules in the F_{fs} file-systems are loaded during emulation by the firmwares' bootup scripts. Consequently, the SyscallToKmodTracer plugin only collects system call information for a subset of user level programs that interact with the loaded kernel modules during emulation. The kernel modules that are not loaded and user level programs that are not executed during the emulation do not contribute to the holistic firmware analysis.

7 Related Work

Benchmarking. These studies are important for establishing reliable metrics for evaluating the contributions of works and also setting the standards for future directions in a research area. Both [29, 31] introduce metrics to evaluate the performance and effectiveness (i.e., bug finding) of fuzzing tools as well as guidelines that should be followed by future fuzzing applications. AIR [52] proposes a metric to quantify the protection offered by Control Flow Integrity techniques on binary executables. Similar to these works, FICD uses specific metrics (i.e., the number of user level, user and kernel module code coverage and number of kernel modules loaded) to evaluate different approaches in the full-system re-hosting domain.

IoT Firmware Analysis. There are plenty of academic works focusing on firmware analysis. On the one hand, static analysis and symbolic execution [16, 25, 43, 44] are two of the most prominent techniques for firmware analysis. While some works rely solely on static analysis [13, 20] to analyze IoT firmware, it is mostly used to aid symbolic executors [5, 6, 10] to explore firmware code more efficiently.

On the other hand, dynamic analysis has also gained a lot of popularity in the IoT firmware analysis landscape in the past few years. Firmadyne [7] and FirmAE [28] are two examples of frameworks which use firmware re-hosting at their core to emulate IoT firmware and subject it to various dynamic analyses, such as vulnerability and bug testing. Similarly, Honware [48] relies on re-hosting techniques to deploy emulated IoT firmware as honeypots on the Internet to observe and study real world network attacks. FirmGuide [32] is a re-hosting framework that semi-automatically creates QEMU peripheral models to successfully re-host the Linux IoT kernels of open-source firmware images (e.g., OpenWRT). However, both the need for human intervention and source code availability renders FirmGuide unable to re-host proprietary firmware, unlike Pandawan. Finally, FirmSolo [1] is a framework that re-hosts and enables the dynamic analysis of IoT firmware binary kernel modules.

In contrast to Pandawan, which holistically re-hosts and analyzes IoT firmware, most of the works above focus exclusively on either the user or the kernel level aspect of IoT firmware.

Hardware-In-The-Loop. Frameworks in this category combine both a physical IoT device and re-hosting to dynamically analyze binary IoT firmware. Specifically, AVATAR [50] leverages the debugging interface (i.e., JTAG) of IoT devices and the QEMU emulator (driven by a symbolic execution engine) to forward I/O operations to the physical device while the firmware code is executed within the emulator. Similarly, SURROGATES [30] and Inception [12] follow a similar logic. While effective at analyzing IoT firmware, these systems are intrinsically limited in terms of scalability due to their

dependence on the IoT hardware.

Firmware Fuzzing. Both Greenhouse [46] and EQUAFL [55] rely on user mode QEMU to emulate user level firmware applications and analyze these applications through fuzzing. EASIER [38] is a framework that loads binary kernel modules on pre-configured Android kernels within an emulated environment and analyzes these modules with AFL [51]. FirmAFL [54] combines a hybrid firmware re-hosting technique (user and full system mode) with fuzzing to analyze user level firmware code. Fuzzware [41] is a system that relies on dynamic symbolic execution (DSE) to infer hardware created values (provided to the firmware through MMIO) which are used to drive a fuzzer while analyzing the embedded firmware code. On a similar fashion, Halucinator [11] uses Hardware Abstraction Layers (HALs) to model hardware peripherals along with a fuzzer to dynamically analyze embedded firmware.

Unlike Pandawan, these systems are unable able or only suitable of analyzing specific categories of firmware kernel modules. Pandawan can load and analyze a variety of binary Linux IoT kernel modules, due to its holistic analysis capabilities.

8 Conclusion

In this work, we present `FICD`, a technique that enables the objective comparison of full-system re-hosting approaches on their emulation capabilities. Also, we introduce `Pandawan`, a framework that enables holistic re-hosting and analysis of Linux-based IoT firmware. `Pandawan`, implements the `Kernel Augmentation` technique which produces kernels conducive to holistic re-hosting and analysis. We use `Pandawan` to holistically analyze IoT firmware and provide the information produced to the TriforceAFL fuzzer to analyze the firmware's kernel modules. Finally, we rely on `FICD` to showcase `Pandawan`'s progress in firmware re-hosting by comparing it with the Firmadyne FirmAE, and FirmSolo re-hosting frameworks.

A User-Code-Required Functionality

In Figures 3a and 3b we showcase the popularity of the configuration options in the O_{MIPS} and O_{ARM} pools, respectively.

(a) CDF of the configuration option usage in O_{MIPS}.

(b) CDF of the configuration option usage in O_{ARM}.

Figure 3: CDFs of the configuration option popularity/usage in O_{MIPS} and O_{ARM}, respectively. We use the Kneedle algorithm to detect the "knee" points in both figures. The options used by the number of images below the "knee" points are filtered out.

B Console Connectivity Issues

Table 5 provides the breakdown of the reasons and the number of cases behind Pandawan's console connectivity issues

Issue	# of Images
Console is unresponsive	82
The console binary crashes	59
The kernel panics	45
Firmware reboots	3
Total	**189**

Table 5: Console connectivity issues during the Pandawan emulation experiments. Column one illustrates the reasons behind the console connectivity issues.

C System Calls Traced Statistics

In Table 6 we present the twelve system calls that lead to kernel module code execution and are explicitly fuzzed by Pandawan (using TriforceAFL). We opt to fuzz only these system calls due to their inherent compatibility with TriforceAFL's fuzzing agent (harness), TriforceLinuxSyscallFuzzer [35]. Even though the fuzzing agent is capable of invoking any system call, it primarily supports socket or file-descriptor based system calls (see Table 6).

Table 7 illustrates the top ten traced system calls, which lead to kernel module code execution, but not fuzzed during our fuzzing experiments. We opt out from fuzzing these system calls for two reasons. First these system calls do not operate on a file descriptor or socket (i.e., the most compatible system calls with TriforceAFL's fuzzing agent). Second, invoking these system calls does not lead to kernel module code being executed until certain conditions are met. For example, sys_select is used to monitor file descriptors until they are ready for I/O, which the fuzzer is not sophisticated enough to generate. Also fuzzing this specific system call would not produce any interesting results (i.e., crashes). The same premise is true for the rest of the system calls we did not fuzz.

System Call	# of Invocations
sys_setsockopt	1,769,439
sys_ioctl	671,531
sys_getsockopt	648,336
sys_sendto	424,880
sys_close	123,338
sys_read	43,126
sys_open	42,847
sys_write	32,187
sys_send	10,564
sys_fcntl	4,611
sys_socket	3,584
sys_connect	1,115

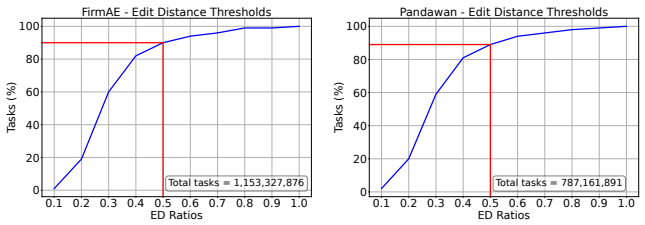

Table 6: The most popular system calls used in Pandawan's fuzzing experiments.

System Call	# of Invocations
sys_recvmsg	301,866
sys_select	293,624
sys_nanosleep_time32	291,664
sys_nanosleep	211,628
sys_gettimeofday	85,761
sys_brk	49,077
sys_fork	23,625
sys_execve	19,625
sys_rt_sigprocmask	14,718
sys_wait4	13,704

Table 7: The top 10 traced system calls that are not "compatible" with TriforceAFL.

D Edit Distance Threshold Experiments

Figures 4a and 4b depict the results of the ten minute edit distance threshold experiments for FirmAE and Pandawan.

(a) FirmAE edit distance threshold experiment.

(b) Pandawan edit distance threshold experiment.

Figure 4: Edit distance threshold experiments for FirmAE and Pandawan. For both frameworks, we measure the similarity between a task and all the tasks created at an earlier point in time using the *Levenshtein* edit distance algorithm.

E FirmSolo Bug Finding Speed

Table 8 depicts the bug finding speed measurements for Pandawan and FirmSolo. For Pandawan's experiments we use the images where TriforceAFL triggered at least a bug in one of their kernel modules. For FirmSolo' experiments, we choose images that load the same kernel modules that FirmSolo originally found bugs in (except rt_rdm.ko which did not load in any of our images). We run the experiments 10 times for 12 hours and the results are the averages over these runs. The measured Time-To-Crash (TTC) variances and standard deviations for both Pandawan and FirmSolo (see columns three and six in Table 8) indicate that TriforceAFL is inconsistent regarding the time it requires to arrive to the first crash/bug.

Pandawan			FirmSolo		
Module	**TTC (sec)**	**TTC var (std)**	**Module**	**TTC (sec)**	**TTC var (std)**
MIPS					
ipv6_spi	1,644	14e+5 (1e+3)	ipv6_spi	16,262	126e+6 (11e+3)
gpio	751	114e+3 (337)	gpio	51	678 (26)
arp_tables	1,488	24e+4 (490)	acos_nat	70	570 (24)
led	n/a	n/a	art	n/a	n/a
ipt_STAT	3,856	25e+6 (5e+3)	art-wasp	151	39e+2 (62)
x_tables	880	200e+3 (448)	edinvram2	25	379 (20)
statistics	152	5,071 (71)			
ip6_tables	811	536e+3 (732)			
ip_tables	1,811	72e+3 (270)			
gpio_module	124	3 (2)			
ARM					
ipt_STAT	2,776	18e+5 (1.4e+3)	gpio	189	91e+3 (302)
statistics	169	6,878 (83)	IDP	28,919	74e+6 (86e+2)
			smcdrv	7	1 (1)
			u_filter	1,029	440e+3 (663)
Avg.	**1,315**			**5,189**	

Table 8: Pandawan's and FirmSolo's bug finding speed measurements. TTC in column two and four stands for Time-To-Crash (i.e, the time it takes the fuzzer to reach the first crash). Columns three and six provide the measured variance and standard deviation for TTC. Regarding the led.ko kernel module, in line four, TriforceAFL registers the bug as a *hang* and not a *crash*, hence there is no TTC in this case. The art.ko kernel module in line two crashed while being loaded into FirmSolo's kernels and thus the measurement is invalid.

DEEPTYPE: Refining Indirect Call Targets with Strong Multi-layer Type Analysis

Tianrou Xia

Dinghao Wu
Pennsylvania State University

Abstract

Indirect calls, while facilitating dynamic execution characteristics in C and C++ programs, impose challenges on precise construction of the control-flow graphs (CFG). This hinders effective program analyses for bug detection (e.g., fuzzing) and program protection (e.g., control-flow integrity). Solutions using data-tracking and type-based analysis are proposed for identifying indirect call targets, but are either time-consuming or imprecise for obtaining the analysis results. Multi-layer type analysis (MLTA), as the state-of-the-art approach, upgrades type-based analysis by leveraging multi-layer type hierarchy, but their solution to dealing with the information flow between multi-layer types introduces false positives. In this paper, we propose strong multi-layer type analysis (SMLTA) and implement the prototype, DEEPTYPE, to further refine indirect call targets. It adopts a robust solution to record and retrieve type information, avoiding information loss and enhancing accuracy. We evaluate DEEPTYPE on Linux kernel, 5 web servers, and 14 user applications. Compared to TypeDive, the prototype of MLTA, DEEPTYPE is able to narrow down the scope of indirect call targets by 43.11% on average across most benchmarks and reduce runtime overhead by 5.45% to 72.95%, which demonstrates the effectiveness, efficiency and applicability of SMLTA.

1 Introduction

Indirect call, used commonly to determine the functions to be called at runtime, is a fundamental feature of C/C++ for achieving dynamic program characteristics. Production software (e.g., nginx) and operating systems (e.g., Linux) intensively utilize indirect calls to dynamically adapt program behaviors according to runtime environments and demands, through loading and linking the desired shared libraries.

Precise identification of indirect call targets is of paramount importance, as the control-flow transitions between indirect calls and their respective targets play an essential role in the construction of a global control-flow graph (CFG), which is extensively adopted in various security-related fields. Static analysis tools rely on CFG for bug detection and program hardening [17, 20, 22, 25, 43, 61–63, 66, 68], program partitioning and privilege separation [5, 8, 18, 26, 28, 42], pruning redundant paths in symbolic execution [4, 7, 10, 50, 58], and guiding directed fuzzing for specific objectives [3, 9, 32, 36, 38, 39, 47]. Additionally, control-flow Integrity (CFI) defenses [1, 6, 14, 34, 35, 49, 65, 67] have been proposed to mitigate control-flow hijacking attacks. However, the strength of CFI depends on the precision of CFG. Imprecise CFG construction results in advanced attacks that bypass CFI [19, 29, 41, 44, 45, 60].

The key challenge in construction of an accurate CFG is identifying the targets of indirect calls. Modern compilers like GCC and Clang cannot determine these targets without additional analysis and instrumentation. Conservative approaches [65, 67] consider all functions or those with address taken as potential targets for each indirect call, producing a considerable number of false positive edges within CFG, which impair the functionality of the applications built upon CFG and impose unnecessary cost. Data tracking analysis [14, 23, 46, 48, 68] tracks value flow, which pursues accuracy at the cost of high performance overhead while the accuracy depends on the precision of the taint analysis and points-to analysis techniques they employ. Type-based analysis [34, 49, 52] checks function signatures to identify functions whose types match with an indirect call. While this approach is efficient, it is susceptible to false positive targets if many functions share the same type as the actual target.

Multi-layer type analysis (MLTA) [27] was proposed for the purpose of improving the accuracy of type-based analysis. Given the fact that function pointers can be members of composite data structures, the type of a function pointer along with the composite types holding it compose a multi-layer type. For example, if function pointer `ptr` with type *void (int)** is a member of object `a` with type *struct.A*, the variable `a.ptr` has multi-layer type *void (int)** | *struct.A*. A function *f* also has this multi-layer type if it is assigned to `a.ptr`. MLTA matches multi-layer types of functions and indirect calls to refine indirect call targets.

However, multi-layer types introduce challenges in type matching because address-taken functions may be propagated between different multi-layer types through information flow, making it hard to collect all targets for an indirect call (see §2.2). MLTA bypasses the challenges by splitting a multi-layer type into several two-layer types, and adopts each layer's type as the basic unit for information storage and type matching (see §2.4), which avoids missing targets while producing false positive targets. It relinquishes the type information between spitted layers and weakens the restrictions provided by multi-layer types, thereby negatively affecting accuracy.

This paper proposes an advanced approach, Strong Multi-Layer Type Analysis (SMLTA), to mitigate the false positive targets produced by MLTA. It adheres to the strong restriction that identifies only those functions as targets whose entire multi-layer types match with the indirect calls. SMLTA addresses the challenges in multi-layer type matching by resolving the relationships between multi-layer types based on the directions of information flow, and utilizes an adapted breadth-first search (BFS) algorithm [56] to discover all multi-layer types engaged in the propagation of target functions. It also employs a conservative strategy to deal with ambiguous type information due to information flow.

We implemented SMLTA within a prototype, DEEPTYPE,[1] which contains two working phases: 1) information collection and 2) target identification. In the first phase, DEEPTYPE establishes and maintains the mappings between multi-layer types and their associated functions (§4.1). The collected multi-layer types are organized in a hierarchical manner for the purpose of quick retrieval (§4.2). It also preserves the relationships between multi-layer types as indicated by the directions of information flow, facilitating the tracing of multi-layer types engaged in function propagation (§4.3). In the second phase, DEEPTYPE determines the multi-layer type of each indirect call and discovers all other multi-layer types engaged in target propagation (§5.1). Then, it verifies whether the engaged multi-layer types match with the indirect call to precisely identify associated functions as targets (§5.2). Additionally, DEEPTYPE handles diverse instructions and code patterns in real-world programs to reduce the inaccuracy caused by corner cases.

We evaluated DEEPTYPE on Linux kernel, 5 server programs, and 14 user-level applications. We compared it with TypeDive (i.e., the prototype of MLTA), as MLTA is the-state-of-the-art approach in type-based analysis. The results indicate that DEEPTYPE outperforms TypeDive in the precision of indirect call target identification, reducing the average number of indirect call targets by 43.11% on average across most benchmarks. In terms of performance, DEEPTYPE decreases the runtime overhead by 5.45% to 72.95% and achieves lower memory consumption in all evaluated benchmarks. Additionally, a case study on a real-world CVE shows that SMLTA is more powerful than MLTA in reducing attack surface and preventing exploits.

In summary, this paper makes the following contributions.

- Propose a novel approach called strong multi-layer type analysis (SMLTA) that employs strong restrictions provided by multi-layer types to refine indirect call targets.
- Develop a prototype, DEEPTYPE, which overcomes challenges in multi-layer type matching and utilizes SMLTA to precisely and efficiently identify indirect call targets.
- Evaluate DEEPTYPE with 20 benchmarks and compare it with TypeDive, exhibiting its capability in further refining indirect call targets and reducing both runtime overhead and memory consumption. Additionally, we demonstrate that SMLTA offers a higher level of security.

2 Motivation

This section clarifies the challenges in indirect call target identification using multi-layer types, describes how MLTA and SMLTA address these challenges, and highlights the accuracy improvement achieved by SMLTA through an example.

2.1 Motivating Example

Listing 1 shows a code snippet with buffer overflow vulnerability. The `strcpy` at line 25 can overwrite the memory location adjacent to `buf` if the length of `msg` is larger than `MAX_LEN`. The adjacent memory location belongs to `w_op`, which is afterwards assigned to `u->uw` at line 26. So, the function pointer `u->uw->low_priv` can point to an address manipulated by the attacker after buffer overflow occurs. At line 29, this function pointer is used to make an indirect call, resulting in arbitrary execution if a lenient CFG is deployed on this program. To prevent such control-flow hijacking attack and other unexpected bugs caused by imprecise CFG, precisely identifying indirect call targets is crucially required.

2.2 Challenges

The use of multi-layer types presents challenges in matching indirect calls with all potential targets, particularly when functions are propagated across multi-layer types due to information flow. We categorize the challenges into three classes consistent to three forms of information flow.

First, type assignment and casting operations can transform one multi-layer type into another, resulting in information flow from the original to the transformed type, as well as affecting members of composite types. For example, the type assignment operation (line 26) indicates information flow from `w_op` to `u->uw`, as well as `w_op->low_priv` to `u->uw->low_priv`. In this context, the function `write_to_shared_mem` with multi-layer type *void (char*)** | *struct.Write* (line 7), should be propagated to *void (char*)** | *struct.Write* | *struct.User*. Because information flow affects

[1] DEEPTYPE is available at https://github.com/s3team/DeepType.git.

```
1  typedef void (*fp)(char*);
2  struct Write {fp low_priv; fp high_priv;};
3  struct User {struct Write *uw; ...};
4  struct Kernel {struct Write *kw; ...};
5
6  void func_init(struct Write *w_op, struct Kernel *k) {
7      w_op->low_priv = &write_to_shared_mem;
8      w_op->high_priv = &write_to_protected_mem;
9      k->kw->low_priv = &write_to_protected_mem;
10     k->kw->high_priv = &write_to_kernel_mem;
11 }
12
13 void user_priv_write(fp icall_ptr, char *buf) {
14     ...
15     (*icall_ptr)(buf);
16 }
17
18 void write_to_mem (char *msg) {
19     struct Kernel *k;
20     struct User *u;
21     struct Write *w_op;
22     char buf[MAX_LEN];
23     func_init(w_op, k);
24     strcpy(buf, msg);   // buffer overflow
25     u->uw = w_op;
26     ...
27     if (user_mode()) {
28         if (low_priv()) (*u->uw->low_priv)(buf);
29         else user_priv_write(u->uw->high_priv, buf);
30     }
31 }
```

Listing 1: A program vulnerable to control-flow hijacking attack through indirect call. The `strcpy` at line 25 has buffer overflow vulnerability, which allows attackers to rewrite the function pointer `u->uw->low_priv` and redirect control-flow through the indirect call at line 29.

individual layers as well as overall multi-layer types, it is challenging to track various multi-layer types involved in function propagation and identify all potential targets.

Second, a function pointer performing as an actual parameter can sometimes discard outer layers during parameter passing, leading to discrepancies of type information at different positions. For instance, the actual parameter `u->uw->high_priv` (line 30) has multi-layer types *void (char*)** | *struct.Write* and *void (char*)** | *struct.Write* | *struct.User*, while the corresponding formal parameter `icall_ptr` (line 13) has type *void (char*)**. The obscured outer layers can result in mismatch of multi-layer types, making it challenging to identify all potential targets for an indirect call that uses a formal parameter.

Third, some mechanisms, such as virtual tables [57] used by compilers, can introduce information flow between composite types (e.g., struct.Write) and general pointer types (e.g., char*). These general pointer types can hinder function propagation since they do not have associated functions, resulting in missing potential targets.

2.3 Traditional Type-Based Analysis

Traditional type-based analysis examines the signatures of address-taken functions and the types of indirect calls. If these types match, the function is identified as a potential target. This approach is not impacted by the challenges described in Section 2.2 because it solely relies on the types of function pointers, ignoring composite data structures holding them.

Type	Index	Functions

void (char)**	-	`write_to_shared_mem(7)`
		`write_to_protected_mem(8,9)`
		`write_to_kernel_mem(10)`

struct.Write	0	`write_to_shared_mem(7)` `write_to_protected_mem(9)`
	1	`write_to_protected_mem(8)` `write_to_kernel_mem(10)`
struct.User	0	-
	...	-
struct.Kernel	0	`write_to_protected_mem (9)` `write_to_kernel_mem(10)`
	...	-

Table 1: Mappings between types and functions in MLTA for Listing 1. MLTA splits multi-layer types into two-layer types and maintains mappings between these types and associated functions. The two-layer types are presented by a composite type along with an index, which indicates the member type at a specific position. For example, *struct.Write* with index 0 represents the two-layer type *void (char*)** | *struct.Write*. The numbers in parenthesis indicate the line numbers where the functions are confined to the types.

In Listing 1, the indirect call at line 29 has type *void (char*)**, which matches with functions `*shared*`,[2] `*protected*`, and `*kernel*`. As a result, all of them are identified as targets though only `*shared*` is the real target. Similarly, the indirect call at line 15 also has the three targets while only function `*protected*` is the real target.

2.4 MLTA

MLTA utilizes the extra type information extracted from composite data structures and supports field-sensitivity considering that a composite data structure may have multiple members holding different functions. If one function is assigned to a pointer, MLTA records the mappings between the multi-layer type and the function, which is called "type-func confinement". It splits multi-layer types and uses each layer type along with an index as key, as Table 1 shows. Similarly, the original and transformed types in type assignment and casting operations are logged in a split manner as well.

In Listing 1, the indirect call at line 29 has multi-layer type *void (char*)** | *struct.Write* | *struct.User*. MLTA identifies potential targets by collecting associated functions for each layer and calculating the intersection to find common functions. For the first layer *void (char*)** and the second layer *struct.Write* with index 0, both have no original type. Thus, MLTA retrieves the associated functions from Table 1, resulting in set {`*shared*`, `*protected*`, `*kernel*`} for the first layer and set {`*shared*`, `*protected*`} for the second layer. The third layer *struct.User* with index 0 has an original type *struct.Write* (line 26), thus MLTA gathers the associated functions for both types, generating a set {`*shared*`,

[2] In example descriptions, we use simplified function names for readability. For instance, we use `*A*` to represent `write_to_A_mem`.

Type	Functions
void (char)* | s.Write#0*	`write_to_shared_mem(7)`
void (char)* | s.Write#1*	`write_to_protected_mem(8)`
void (char)* | s.Write#0 | s.Kernel#0*	`write_to_protected_mem(9)`
void (char)* | s.Write#1 | s.Kernel#0*	`write_to_kernel_mem(10)`

Table 2: Mappings between types and functions in SMLTA for Listing 1 program. SMLTA treats each multi-layer type as a whole and uses the entire multi-layer type as a basic unit in storage-purposed data structures. In this table, the structs are abbreviated as "s". The index of each member in a composite type is denoted as "#N" where N is a number. For instance, *s.Write#0* represents *struct.Write* with index 0.

`*protected*`, `*kernel*`}. Finally, it computes the intersection of these three sets. The common functions in resulting set {`*shared*`, `*protected*`} are identified as targets. The indirect call at line 15 with type *void (char*)** has no original type. So, MLTA directly generates the target set {`*shared*`, `*protected*`, `*kernel*`}, according to Table 1. In contrast with tradition type-based analysis, MLTA narrows down the target set for the indirect call at line 29, but there is still a visible gap between MLTA result and ground truth.

In MLTA, the first challenge is addressed by splitting multi-layer types. The complex information flow between them is simplified to straightforward flow between individual types, which is easier to track. The second challenge is addressed by conservatively confining a function to each layer of its multi-layer type, ensuring no missing target even if the outer layers are discarded. To overcome the third challenge, MLTA marks all general pointer types and composite types that interact with them as "escaping types". It skips the layers with escaping types when calculating intersection, which removes the impact of general pointer types.

2.5 SMLTA

SMLTA employs entire multi-layer types as keys for information storage, as Table 2 shows, to circumvent the false positive targets caused by splitting multi-layer types. The relationships between multi-layer types are recorded in the same way. We call multi-layer type *T2* a "*friend type*" relative to multi-layer type *T1* if information flows from *T2* to *T1* (i.e., a function may be propagated from *T2* to *T1*). To identify targets for an indirect call, SMLTA exhaustively searches for its friend types and gathers all associated functions as targets.

In Listing 1, the indirect call at line 29 has multi-layer type *void (char*)* | struct.Write#0 | struct.User#0* where "*#0*" indicates the index. SMLTA exhaustively discovers all friend types that may have information flowing to this multi-layer type, only *void (char*)* | struct.Write#0* in this example, and then gathers associated functions of these multi-layer types. The resulting set {`*shared*`} contains the identified target, which is exactly the real target. The indirect call at line 15 has type *void (char*)**. Because the function pointer `icall_ptr` is a parameter, SMLTA adds a "*fuzzy type*" as its outer layer, which matches with any type. Thus, this indirect call can match with all address-taken functions whose first layer is *void (char*)**, resulting in the target set {`*shared*`, `*protected*`, `*kernel*`} without missing potential targets.

In SMLTA, the first challenge is addressed by maintaining the relationships between multi-layer types and the exhaustive search of all friend types engaged in function propagation. The second challenge is addressed by fuzzy type, which conservatively admits that all types could possibly match with the discarded outer layer types, ensuring no missing targets. The third challenge is also solved by conducting an exhaustive search of friend types. This search treats general pointer types as bridges between composite types, unblocking function propagation stuck on general pointer types.

3 Overview

The prototype of SMLTA is called DEEPTYPE, which contains two phases, as is shown in Figure 1.

Given bitcode file(s) as input, phase 1 analyzes initialization instructions and type propagation instructions to collect information. An initialization instruction assigns a function to a function pointer. We say, it "confines" the function to the corresponding multi-layer type. The mappings between the entire multi-layer types and associated functions are stored in *Type-Func Map*. For quick access and retrieval purpose, DEEPTYPE archives these multi-layer types in *Type Lookup Maps* in a hierarchical manner using multi-layer mappings. Type propagation instructions include type assignment and casting instructions that possibly propagate functions from one multi-layer type to another through information flow. DEEPTYPE records the mappings between destination and source multi-layer types of information flow in *Type-Type Map* using entire multi-layer types as keys and values. The sources are "friend types" relative to destinations.

In phase 2, DEEPTYPE analyzes each indirect call instruction to figure out its multi-layer type. If the function pointer is a formal parameter, fuzzy type is added to represent potentially discarded outer layers. Then, DEEPTYPE exhaustively searches for friend types from *Type-Type Map*, retrieves multi-layer types that match with the indirect call or its friend types from *Type Lookup Maps*, and obtains associated functions from *Type-Func Map*. The union of all associated functions are potential targets for the indirect call. Finally, DEEPTYPE outputs a list of indirect calls in the analyzed program along with their locations and respective targets.

4 Phase 1: Information Collection

This section presents how SMLTA collects information from initialization and type propagation instructions, and how it organizes multi-layer types hierarchically.

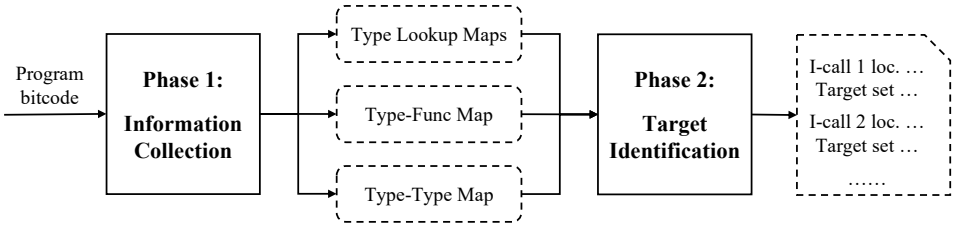

Figure 1: Workflow of DEEPTYPE. DEEPTYPE contains two working phases. In phase 1, it collects and records type information in three data structures. In phase 2, it refers to the recorded type information to discover friend types, gather associated functions, and identify targets.

4.1 Type-Function Confinements

A function could be considered as a potential target of an indirect call only if it is utilized to initialize local and/or global variables. We confine the function to the multi-layer type of the initialized function pointer by establishing a mapping between them in *Type-Func Map*. It is straightforward to determine the multi-layer types of local variables, by extracting the types layer by layer as they are loaded. However, the multi-layer types of formal parameters and nested global variables may not be fully ascertainable using the same method.

The multi-layer type of a formal parameter is uncertain because it may have extra outer layers that are lost during parameter passing. To complete its multi-layer, we introduce *fuzzy type*, as defined in Definition 1, to cover for missing layers. The fuzzy type can be matched with any type. For instance, *void (int)* | fuzzy type* matches with any multi-layer type whose first layer is *void (int)**, including *void (int)**, *void (int)* | struct.A#0*, and *void (int)* | struct.A#0 | struct.X#0*, etc. Similarly, when an index is uncertain,[3] we employ *fuzzy index* to conservatively match with any index.

Definition 1 ***Fuzzy type*** *marks the type of an uncertain layer. The existence of this layer is uncertain, and the type of this layer is uncertain. In type verification, a fuzzy type can match with any type, even if the corresponding layer does not exist.*

A nested global variable is one that initializes members of other variables, thus may have extra layers involved in other initialization instructions. Its multi-layer type is uncertain when analyzing the instruction initializing it. To gather complete type information, we track all variables that hold this global variable iteratively. For instance, Listing 2 shows a nested global variable `x86_64_elf32_vec` (line 8) with type *struct.bfd_target*, which initializes a member of another global variable `_bfd_target_vector` (line 13). Thus, the function pointer`bfd_read_ar_hdr_fn` (line 4), as a member of the global variable, should be confined to both *void (bfd*)* | struct.bfd_target#53* and *void (bfd*)* | struct.bfd_target#53 | vector.bfd_target#237*, ensuring that a potential target could be identified through both multi-layer types.

```
1  typedef struct bfd_target
2  {
3      ...
4      void* (*_bfd_read_ar_hdr_fn) (bfd *);
5      ...
6  } bfd_target;
7
8  extern const bfd_target x86_64_elf32_vec;
9      ...
10 static const bfd_target * const _bfd_target_vector[] =
11 {
12     ...
13     &x86_64_elf32_vec,  // nested global variable
14     ...
15 };
```

Listing 2: Nested global variable. `x86_64_elf32_vec` is a nested global variable because it serves as a member in another global variable `_bfd_target_vecor`. This example is from targets.c from binutils-2.35.

4.2 Multi-layer Type Organization

For efficient access and retrieval, we organize the collected multi-layer types hierarchically using multi-layer mappings and store them in *Type Lookup Maps*. We prepare N maps for a program, in which the multi-layer types have up to N+1 layers. More details are illustrated in Appendix A.

To archive a multi-layer type T, the first n layers of T is used as a key in the n-th map (where $1 \leq n \leq N$), and the n-th layer of T is stored as the corresponding value. If T consists of M layers, where M is less than N, only the first M maps are utilized for storage. Figure 2 shows an outline of *Type Lookup Maps* and exemplifies the utilization of this data structure via two multi-layer types: ① *void (int)* | struct.A | struct.X* and ② *void (int)* | struct.B | struct.Y | struct.P*.[4]

The First Map stores the mapping between the common first-layer type *void (int)** and respective second-layer types *struct.A*, for ①, and *struct.B*, for ②. *The Second Map* stores mappings between first-two-layer types and corresponding third-layer types, among which the first entry is for ① and the second entry is for ②. *The Third Map* works in a similar way to store the rest part of ②. If a multi-layer type contains more than four layers, we will establish more maps based the number of layers, to record the rest parts.

[3] In LLVM IR, index is typically derived from GetElementPtrInst when the corresponding operand is a constant. However, index may be non-constant operand such as a phi instruction, indicating an uncertain index until runtime.

[4] The indexes are omitted to simplify the example and emphasize the key point, which is how to hierarchically archive multi-layer types.

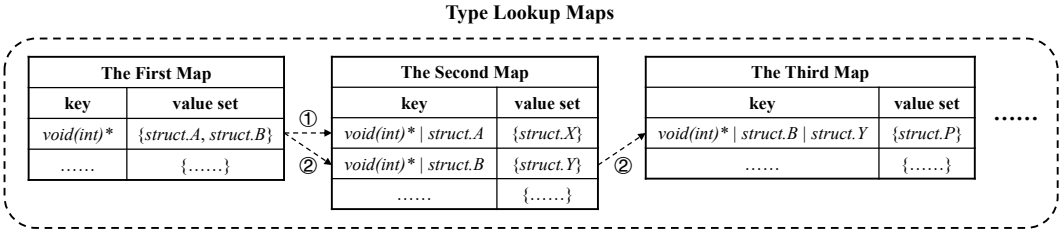

Figure 2: Outline of Type Lookup Maps with two example types stored. Type Lookup Maps use multi-layer mappings to archive multi-layer types. The First Map records the first-layer types and corresponding second-layer types; The Second Map records the first-two-layer types and corresponding third-layer types; So on so forth. ① *void (int)* | struct.A | struct.X* and ② *void (int)* | struct.B | struct.Y | struct.P* are archived as examples.

```
1  struct section_add {...; asection *section;};
2
3  asection *bfd_get_section_by_name (bfd *abfd, const
       char *name);
4
5  copy_object (bfd *ibfd, bfd *obfd, const
       bfd_arch_info_type *input_arch)
6  {
7      ...
8      struct section_add *pupdate;
9      ...
10     pupdate->section = bfd_get_section_by_name (ibfd,
        pupdate->name);
11     ...
12 }
```

Listing 3: Type assignment. A variable with multi-layer type *asection* is assigned to another variable with multi-layer type *asection|struct.section_add#5* in line 10. This example is from objcopy.c in binutils-2.35.

4.3 Type Relationship Resolving

A function can be propagated from one multi-layer type to another via type propagation instructions. To collect all involved multi-layer types, we analyze type assignment and casting instructions and introduce *friend type*, as defined in Definition 2, to describe their relationships.

Definition 2 *A is a **friend type** relative to B if either of the following holds:*

1. *There exists information flow from A to B.*
2. *There exists information flow from A to C, and C to B.*

Due to the information flow, the associated functions of A are propagated to B. We say, A "shares" functions with B.

The second condition manifests that one multi-layer type is a friend type relative to another if there exists a chain of information flow following the first condition. This chain can be as long as the entire program. We record the mapping between one multi-layer type and its *direct friend types*, satisfying the first condition, in *Type-Type Map*. The *indirect friend types*, satisfying the second condition, can be inferred by the recorded relationships.

A type assignment instruction assigns the value of one variable to another. They have different multi-layer types, but share the same first-layer type. Such instructions create a one-way relationship: the source type of information flow is a friend type relative to the destination type. For example, Listing 3 shows a type assignment operation (line 10) where the

```
1  static struct bfd_hash_entry *
2  string_hash_newfunc (struct bfd_hash_entry *entry,
       struct bfd_hash_table *table, const char *string)
3  {
4      struct string_hash_entry *ret = (struct
        string_hash_entry *) entry;
5      ...
6      return (struct bfd_hash_entry *) ret;
7  }
```

Listing 4: Type casting. *struct.bfd_hash_entry* is casted to *struct.string_hash_entry* in line 4. *struct.string_hash_entry* is casted to *struct.bfd_hash_entry* in line 6. This example is from ecofflink.c in binutils-2.35.

return value of function `bfd_get_section_by_name` is assigned to `pupdate->section`, resulting in information flow from the source type *asection* to the destination type *asection | struct.section_add#5*, which allows *asection* to share its associated functions with *asection | struct.section_add#5*.

A type casting instruction transforms one multi-layer type into another, with the first layers of each being distinct. In Listing 4, the original type of `entry` is *struct.bfd_hash_entry** (line 2). It is transformed to *struct.string_hash_entry* at line 4. The type casting at line 6 transforms *struct.string_hash_entry** to *struct.bfd_hash_entry**. Considering the flow-insensitivity feature of our static analysis, [5] it is uncertain whether a type casting instruction executes before or after an indirect call, making it uncertain whether the multi-layer type of the indirect call is transformed from another multi-layer type. To address this ambiguity, we conservatively establish a bidirectional relationship between the source and destination types, allowing them to share associated functions with each other so that indirect calls do not miss any potential target.

5 Phase 2: Target Identification

This section presents how SMLTA identifies indirect call targets utilizing the type information stored in *Type-Func Map*, *Type-Type Map* and *Type Lookup Maps*.

5.1 Friend Type Discovery

For each indirect call, SMLTA examines whether the function pointer is a formal parameter to decide if fuzzy type should be

[5] SMLTA is flow-insensitive for efficiency. Tracking the execution sequence of instructions is beyond our scope.

Before-Part	Fragment	After-Part
	A	$\|B\|C$
$A\|$	B	$\|C$
$A\|B\|$	C	
	$A\|B$	$\|C$
$A\|$	$B\|C$	
	$A\|B\|C$	

Table 3: A table recording the fragments of multi-layer type *A|B|C*. A multi-layer type $A|B|C$ with 3 layers has 6 possible fragments, including single-layer fragments, two-layer fragments, and three-layer fragments.

added to complete its multi-layer type. Once the multi-layer type of an indirect call is ascertained, we discover all of its friend types to ensure that the associated functions shared by the friend types will be identified as potential targets. Given that a multi-layer type can be partially transformed from another type, we extract all possible *fragments*, as defined in Definition 3, to support the exhaustive search of friend types relative to the entire multi-layer type of the indirect call.

Definition 3 *A **fragment** of multi-layer type T is one or multiple continuous layers in T.*

A multi-layer type with N layers has $\frac{(1+N)\times N}{2}$ possible fragments, as exemplified in Table 3. The `Fragment` column lists all possible fragments while the layers before and after each fragment are respectively listed in `Before-Part` and `After-Part` columns. We can substitute each fragment with its friend types and concatenate these types with corresponding Before-Part and After-Part to generate friend types relative to the entire multi-layer type, thereby transforming the task of searching for friend types relative to the multi-layer type into discovering friend types for individual fragments.

For each fragment, the search of direct friend types is straightforward, which is achieved by querying *Type-Type Map*. However, the exhaustive search of indirect friend types can be challenging because these types may be buried in long, cyclic chains of information flow. To address this issue, SMLTA employs an exhaustive search algorithm adapted from Breadth-First Search, which monitors the state of discovered friend types to bypass cycles in chains. This algorithm is detailed in Algorithm 1, where Frag represents a fragment and $\mathsf{Frag_{ft}}$ represents its friend types.

We prepare three sets, $S_{checked}$, $S_{checking}$, and $S_{unchecked}$, to manage friend types in different states and prevent cyclic search. A friend type currently being used to query the *Type-Type Map* is held in $S_{checking}$ and is moved to $S_{checked}$ post-query. $S_{unchecked}$ holds newly discovered friend types for the next round of search. Initially, the current Frag is placed into $S_{checking}$. In each search iteration, we look for friend types for elements in $S_{checking}$ by querying *Type-Type Map* and place newly discovered friend types to $S_{unchecked}$. After each iteration, update the three sets for the following round of search. Repeat this process until $S_{checking}$ is empty and S_{cheked} is no more updated, indicating that all $\mathsf{Frag_{ft}}$ have been discovered.

Algorithm 1 Exhaustive search of $\mathsf{Frag_{ft}}$

Require: *Type-Type-Map*, Frag
Ensure: All $\mathsf{Frag_{ft}}$ are placed in $S_{checked}$
1: $S_{checked} \leftarrow \{\}$
2: $S_{checking} \leftarrow \{Frag\}$
3: $S_{unchecked} \leftarrow \{\}$
4: $S_{checked}\_origSize \leftarrow 0$
5: $S_{checked}\_newSize \leftarrow 0$
6: **while** $S_{checking}$ is not empty **do**
7: **for** e in $S_{checking}$ **do**
8: $S_{unchecked} = SetMerge(S_{unchecked}, Type\text{-}Type\text{-}Map[e])$
9: $S_{checked}\_origSize = S_{checked}.size()$
10: $S_{checked} = SetMerge(S_{checked}, S_{checking})$
11: $S_{checked}\_newSize = S_{checked}.size()$
12: $S_{checking}.empty()$
13: $S_{checking} = S_{unchecked}$
14: $S_{unchecked}.empty()$
15: **if** $S_{checked}\_origSize == S_{checked}\_newSize$ **then return** $S_{checked}$

Given friend types of each fragment, we generate the friend types relative to the entire multi-layer type of an indirect call by concatenation operations, and gather them in a set S along with the multi-layer type itself for type verification.

5.2 Type Verification

The elements in S, are not exactly the multi-layer types that confine target functions of this indirect call due to three kinds of mismatches: 1) Some friend types generated through fragments do not exist among the recorded multi-layer types; 2) Some elements in S, containing fuzzy type and index, apparently differ from but actually match with the recorded multi-layer types; 3) Some recorded multi-layer types, containing fuzzy type and index, apparently differ from but actually match with the elements in S. Hence, we query *Type Lookup Maps* for type verification and collecting *verified types*, which is defined in Definition 4.

Definition 4 *A **verified type** is a multi-layer type that is recorded in Type-Func Map and Type Lookup Maps, and matches with an element in S.*

To perform type verification, we check each element in S to find verified types in *Type Lookup Maps*. Given a multi-layer type T in S, first of all, we pass the first-layer type of T to *The First Map* to achieve a scope of second-layer types. Then, check whether the elements in this scope match with the second-layer type of T. Concatenate the first-layer type with every matched second-layer type to generate a set of first-two-layer types. Lookup *The Second Map* to achieve a scope of third-layer types and find those who match with the third-layer type of T. Following this working pattern to check the remaining layers until all verified types are retrieved from *Type Lookup Maps*. Finally, query *Type-Func Map* with verified types to find associated functions. The union of such functions are identified as potential targets of the indirect call.

```
store <2 x i64> %12, <2 x i64>* bitcast (i32 ()**
    getelementptr inbounds (%struct.Sqlite3Config, %
    struct.Sqlite3Config* @sqlite3Config, i64 0, i32
    13, i32 0) to <2 x i64>*), align 8, !dbg !56905, !
    tbaa !11590
```

Listing 5: A composite instruction. The `store` instruction in sqlite is composite, incorporating an embedded `bitcast` instruction, which in turn is composite and contains an embedded `getelementptr` instruction.

6 Implementation

DEEPTYPE is built on LLVM 15.0 in 2.8k lines of C++ code. It supports C and C++ programs, providing particular advantages for programs that frequently employ composite data structures. This section delineates the enhancements in accuracy and performance from implementation perspective.

6.1 Special Handlings

In addition to the novel approach SMLTA, DEEPTYPE enhances accuracy from implementation aspect by addressing diverse instructions and rare code patterns. We identified four typical corners cases and applied special handlings to each, aiming to mitigate inaccuracy resulting from the imprecise processing of these corner cases.

6.1.1 Composite instructions

A composite instruction encapsulates one or more embedded instructions as operands. When analyzing composite instructions, DEEPTYPE cannot acquire complete type information due to the obscured types within the embedded instructions. Listing 5 demonstrates a composite instruction. It is a `store` instruction that encapsulates a `bitcast` as its second operand, which itself is also a composite instruction embedding a `getelementptr` instruction as its first operand.

To gather complete type information, we employ ordered trees to represent hierarchical structure of composite instructions and their embedded instructions, and conduct a systematic analysis of instructions within ordered trees from the lowest to the highest levels, ensuring that the types hidden in embedded instructions can be utilized to generate complete multi-layer types when analyzing their parent instructions. For example, we construct a three-level tree to represent the instructions in Listing 5. The `store` instruction occupies the root node in level 0, the `bitcast` instruction is situated in the second child node at level 1, and the `getelementptr` instruction resides in the first child node of the `bitcast` at level 2, as Figure 3 depicts. The `getelementptr` instruction returns a three-layer type *i32()* | *struct.sqlite3_mutex_methods#0* | *struct.Sqlite3Config#13*, which serves as the source type for the *bitcast*. So, we record it and the destination type *void (int)** | *struct.A* as friend types each other in *Type-Type Map*. This relationship contributes to accuracy, but it could be missed without the special handling to composite instructions.

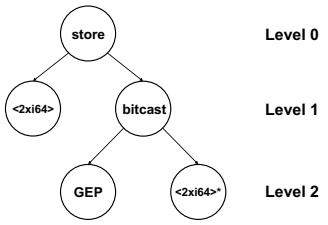

Figure 3: Ordered tree of the instructions in Listing 5. The root node represents the composite instruction `store`. Its child nodes at level 1 denote the instruction's operands. The second operand is another composite instruction `bitcast`. The child nodes at level 2 correspond to the operands of `bitcast`, among which the first one is a `getelementptr` instruction.

6.1.2 Anonymous structures

In LLVM bitcode, structs are sometimes anonymous when the specific names are not necessary or when they help to optimize the internal representation. This anonymity helps reduce IR size, but can lead to type mismatches, resulting in imprecise target identification.

We address this by assigning a unique identifier to each anonymous struct based on the sequence of member types. [6] This identifier assists in linking anonymous structs to named equivalents elsewhere in the bitcode, thus mitigating inaccuracy caused by mismatches of anonymous structs. If no named equivalent is found, they are named as *struct.anon*, which conservatively matches with any struct, preventing missing targets resulted from anonymous structs.

6.1.3 Dead functions

The iterative updating and patching of applications often results in the presence of dead functions, which are declared but not invoked, thus will not be executed during runtime. The analysis of instructions within these dead functions generates redundant type information, leading to false positive targets and unnecessary performance overhead. To enhance both accuracy and efficiency, our analysis omits dead functions.

6.1.4 Empty Type

In LLVM IR, the notation "{}" is employed to denote an anonymous struct type when the specific details of the data structure are unnecessary and subsequently omitted. We name it as "empty type." Contrary to the anonymous structs discussed in Section 6.1.2, which merely lack names, the empty type is anonymous and contains no fields. However, what it represents can often be inferred from `bitcast` and other corresponding instructions in proximity. We categorize the code patterns involving empty types into two distinct classes, addressing each class with tailored solutions. Otherwise, the presence of empty type can impact the precision of our analysis as itself does not match with any struct.

[6] As of October 2023, the latest version of TypeDive uses similar method to identify anonymous structs. However, it ignores those anonymous structs whose names never appear in the bitcode, which may lead to missing targets.

When the empty type serves as the destination type in a `bitcast`, we observed that any subsequent utilization of the empty type in IR corresponds to the usage of the source type in source code. Accordingly, we record the source type as a friend type relative to the empty type, mitigating missing targets that may result from type mismatch. Conversely, when the empty type is the source type in a `bitcast`, we observed that its outer layer types in IR are the outer layer types of the destination type in source code. Thus, we record the empty type's outer layer types as those of the destination type's, ensuring that complete multi-layer types are gathered for type matching and target identification.

6.2 Caches

To diminish the performance overhead, we deploy two caches aiming at reducing runtime cost without affecting accuracy. The first one is used to store the verified types of a multi-layer type so that the exhaustive search algorithm and type verification process only run once for each multi-layer type. The second one is used to store identified targets of an indirect call so that another indirect call with the same multi-layer type can be quickly resolved by accessing the cache.

7 Evaluation

We evaluate the effectiveness of DEEPTYPE in Section 7.1 and overhead in Section 7.2, comparing it with TypeDive (commit acb8f4c) since MLTA is the-state-of-the-art approach in type-based analysis. Additionally, we evaluate the contribution of SMLTA in accuracy in Section 7.3 and present its security impact through a case study in Section 7.4.

Our evaluation is conducted on linux kernel, 5 web servers and 14 user applications. The GNU Binutils-2.35 is a collection of binary tools. We selected 13 among 15 programs as the discarded ones barely use indirect calls.[7] SQLite-3.45.1 is a database engine which contains numerous multi-layer types. 5 server programs are nginx, httpd, openVPN, proftpd and sshd. We use Linux-5.1 as the benchmark to show the scalability of DEEPTYPE.

Experiments are conducted on Ubuntu 20.04 with 8-core Intel Core i9-9880H CPU @ 2.30GHz and 16GB DDR4 RAM. The benchmarks are compiled by WLLVM [54] with LLVM-15. We use -g -O0 [8] flags to ensure that the generated bitcode contains debug information and type information, and that the instructions DEEPTYPE analyzes are not optimized out. Another flag -Xclang -no-opaque-pointers is used to disable opaque pointers so that pointers' types are sustained.

[7]The program sysinfo does not contain any indirect call; The program elfedit only has 53 indirect calls without complex multi-layer types, showing exactly the same result for TypeDive and DEEPTYPE.

[8]This optimization level compiles the fastest and generates the most debuggable IR code, with which we can determine whether a function pointer is a local variable or formal parameter.

To compare with TypeDive, we execute both tools on LLVM-15 and apply dead function elimination on them to make sure the benchmark bitcode analyzed by DEEPTYPE and TypeDive are exactly the same. In the experiments, we deploy 7-layer mappings in *Type Lookup Maps*, which are sufficient to archive the multi-layer types in our benchmarks. Appendix A shows how to determine the number of mappings.

7.1 Effectiveness of DEEPTYPE

The effectiveness of DEEPTYPE is demonstrated by its ability to narrow down the scope of indirect call targets. We use Average Number of Targets (ANT) as metric to quantitatively measure effectiveness, which is defined as:

$$ANT = \frac{Num(T)}{Num(IC)},$$

where $Num(T)$ represents the total number of identified targets, $Num(IC)$ represents the total number of indirect calls that have targets. While the metric in TypeDive paper [27] is also average number, it only takes into account the indirect calls whose multi-layer types have at least two layers. Their metric neglects the fact that single-layer types can also benefit from MLTA, and that some indirect calls have no target identified because they are not initialized or because DEEPTYPE and TypeDive miss targets due to inevitable obstacles in implementation, as elaborated in Section 8.1. Therefore, we define ANT to precisely evaluate the effectiveness. To clarify *false positive (FP)* and *false negative (FN)* subsequently used in this paper, we define them in Definition 5.

Definition 5 *Given an indirect call, a **false positive (FP)** is a function erroneously included in the target set contrary to the ground truth. A **false negative (FN)** is a function erroneously excluded from the target set contrary to the ground truth.*

Table 4 presents the ANT for the benchmarks tested by DEEPTYPE and TypeDive, and the reduction rate in ANT achieved by DEEPTYPE compated to TypeDive. Given that the binutils programs share numerous library functions, leading to analogous ANT value, we only list their average ANT. The details are available in Appendix B. The data in Table 4 indicates that DEEPTYPE reduces the ANT by 43.11% on average across most benchmarks, including binutils, httpd and linux. However, DEEPTYPE does not manage to decrease the ANT for nginx, openvpn and proftpd.

The reduction in ANT can be attributed to SMLTA and special handlings in DEEPTYPE. SMLTA follows the strong restriction that checks the entire multi-layer type of an indirect call to identify targets that match with it. In contrast, TypeDive employs MLTA which separately resolves each layer of a multi-layer type and calculates intersection to determine the target set, potentially leading to FPs. The special handlings in DEEPTYPE are tailored to address corner cases where type

Program	DEEPTYPE	TypeDive	Reduction Rate
binutils	2.47	10.98	77.50%
sqlite	6.24	8.32	25.00%
nginx	6.38	5.60	-13.93%
httpd	6.23	12.27	49.23%
openvpn	2.35	1.62	-45.06%
proftpd	3.10	2.96	-4.73%
sshd	5.43	5.57	2.51%
linux	9.74	25.17	61.30%

Table 4: Average number of inidrect call targets. This table shows the average number of indirect call targets, and the reduction rate produced by DEEPTYPE over TypeDive. binutils shows the average of the 13 programs in binutils, the detailed data of each is elaborated in Appendix B.

information may be obscured, which enable DEEPTYPE to extract more accurate type information, thereby reducing FPs.

To validate the reasons for ANT reduction, we conducted a manual analysis on `objcopy`, as it contains substantial yet manageable number of indirect calls. By manually examining the indirect calls for which DEEPTYPE collects fewer targets than TypeDive, we confirmed the contributions of SMLTA and special handlings, and additionally unveiled another factor contributing to the reduction of ANT.

Field-sensitivity deployed in DEEPTYPE enables the differentiation of distinct members within in a composite data structure, even if they share the same type, which further refines indirect call targets. Despite the assertion of field-sensitivity in TypeDive paper, our manual analysis discovered FPs due to its field-insensitive. For instance, in a simplified scenario, a function is confined to *i64(i8*)* | struct.bfd_target#13*, whereas an indirect call has multi-layer type *i64(i8*)* | struct.bfd_target#23*, without any type propagation involved. TypeDive identifies this function as a target because its first and second layers respectively match *i64(i8*)** and *struct.bfd_target*. By contrast, field-sensitive DEEPTYPE mitigates such FPs. Thus, field-sensitivity is another reason for ANT reduction.

Table 4 also shows that DEEPTYPE does not consistently reduce ANT, particularly in the cases of nginx and openvpn. There are two reasons for the increasing ANT. First, the adoption of fuzzy type leads to the conservative inclusion of all potentially matching types. It decreases FNs meanwhile inevitably brings in FPs, consequently raising the ANT value. Second, the special handlings enable DEEPTYPE to extract more precise type information, diminishing both FPs and FNs. In situations where the reduction in FNs surpasses that in FPs within a program, the ANT value increases. Given that the rising ANT is attributed to the reduction in FNs, it is deduced that DEEPTYPE is theoretically and practically effective in refining indirect call targets.

Figure 4 shows the distribution of indirect calls with different number of targets in linux kernel. We choose linux kernel because it is a complicated program that can demonstrate the distribution patterns as comprehensive as possible. In the experiment, although a number of indirect calls have no target according to either DEEPTYPE or TypeDive or both, we observe that DEEPTYPE is capable of finding more valid targets for more indirect calls, thus DEEPTYPE and DeepType-Cumu have more indirect calls than TypeDive and TypeDive-Cumu in most intervals. The main difference between DEEPTYPE and TypeDive falls in intervals [2,4) and [4,8), the number of targets represented by these two intervals is much smaller than the average number of indirect call targets reported by TypeDive. As the number of indirect call targets increases, the difference between DEEPTYPE and TypeDive gradually decreases and becomes trivial except for interval [64,128), where DEEPTYPE has more indirect calls, and interval [128,256), where TypeDive has more indirect calls.

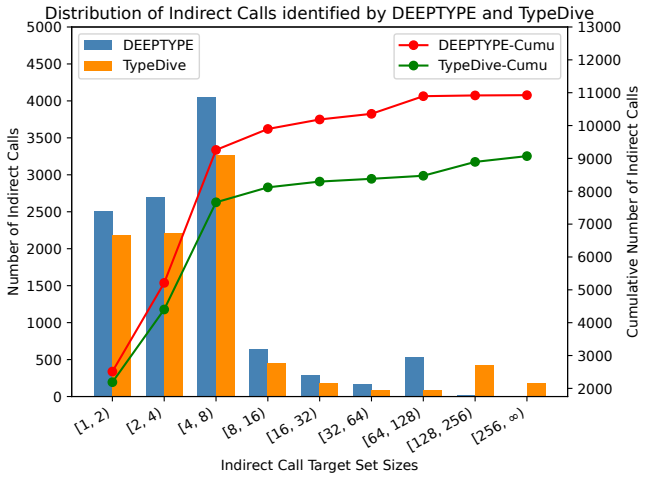

Figure 4: Distribution of indirect calls with different sizes of target sets in linux. The y-axis on the left shows number of indirect calls. The y-axis on the right shows cumulative number of indirect calls. The x-axis shows indirect call target sets' sizes ranging from 1 to infinite divided into 9 intervals. DEEPTYPE and TypeDive respectively represents the number of indirect calls reported by DEEPTYPE and TypeDive. DeepType-Cumu and TypeDive-Cumu respectively represents the cumulative number of indirect calls reported by two tools.

This trend indicates that the ratio of indirect calls with small target sets is lower in DEEPTYPE. We define *small* by different values of threshold in Table 5. A target set is considered as small when its size is less than the threshold. We observe that when the threshold is 2 or 4, DEEPTYPE has lower ratio of indirect calls with small target sets. However, this does not imply that TypeDive outperforms DEEPTYPE for these indirect calls. At lower thresholds (i.e., 2 or 4), a single FP or FN can significantly impact whether an indirect call is categorized as with a small or large target set. Conversely, at higher thresholds, the influence of false reports on categorizing diminishes. Therefore, the general trend is more indicative. In most cases, DEEPTYPE demonstrates a higher ratio of indirect calls with small target sets, underscoring its effectiveness in refining indirect call targets.

Additionally, we compiled the benchmarks on various optimization levels to assess the effectiveness of DEEPTYPE across these levels. The data presented in Table 6 indicates that DEEPTYPE reports higher ANT when the benchmarks

Threshold	DEEPTYPE	TypeDive
2	23.0%	24.1%
4	47.7%	48.5%
8	84.7%	84.5%
16	90.6%	89.5%
32	93.2%	91.5%
64	94.8%	92.4%
128	99.7%	93.4%
256	99.9%	98.1%

Table 5: Ratio of indirect calls with *small* target sets. The definition of *small* depends on the threshold. If the indirect call's target set size is smaller than the threshold value, this indirect call is considered as with *small* target sets. The last two columns respectively show the ratios of indirect calls with *small* target sets in DEEPTYPE and TypeDive.

Program	O0	O1	O2	O3
binutils	2.47	3.20	3.20	3.13
sqlite	6.24	6.46	6.48	6.56
nginx	6.38	8.00	8.02	7.99
httpd	6.23	6.23	6.23	6.23
openvpn	2.35	2.80	2.45	2.45
proftpd	3.10	3.10	3.10	3.10
sshd	5.43	5.43	5.43	5.43
linux	9.74	9.74	9.74	9.74

Table 6: The effectiveness of DEEPTYPE on different optimization levels. This table shows the ANT reported by DEEPTYPE when analyzing benchmarks respectively compiled with optimization level O0, O1, O2 and O3.

are compiled with more aggressive optimization settings for the majority of the programs examined. The increasing ANT can be attributed to the fact that higher optimization levels tend to optmize away certain instructions that DEEPTYPE relies upon for analysis, leading to incomplete type information being gathered. Consequently, DEEPTYPE produces an increased number of FPs and FNs. When there is a predominance of FPs over FNs, the ANT increases.

The stability of ANT values across different optimization levels for programs such as http, proftpd, sshd, and linux can be explained by two factors. First, the FPs and FNs caused by the optimized-out instructions achieve a balance, neutralizing the impact on ANT. Second, the minimal number of FPs and FNs does not significantly alter the ANT metric.

Despite the reduced efficacy of DEEPTYPE on higher optimization levels compared to the O0 level, it nevertheless outperforms TypeDive in those benchmarks where DEEPTYPE with O0 optimization surpasses TypeDive. This observation demonstrates that while there is a marginal decrease in effectiveness with higher optimization levels, DEEPTYPE retains its comparative advantage over TypeDive.

7.2 Performance

DEEPTYPE employs caches to obviate redundant analysis and improve performance. To evaluate the runtime overhead comprehensively, we disabled the caches in DEEPTYPE, resulting in a variant denoted as DT-nocache. We executed DEEPTYPE, DT-nocache, and TypeDive on each benchmark for three times to obtain average execution time, which yields more reliable statistics as it helps mitigate the impact of hardware conditions and operating system states through averaging.

Figure 5 presents the execution time for each benchmark. DEEPTYPE significantly outperforms TypeDive, showing a reduction in overhead ranging from 5.45% to 72.95%, with an average reduction of 37.02%. DT-nocache also demonstrates reduced overhead compared to TypeDive, despite TypeDive is equipped with caches.

To deduce the primary source of runtime overhead and reveal the reason for DEEPTYPE's efficiency, we separately measured the execution time of information collection and target identification phases, considering the shared general workflow of all tools. The experiments were conducted on linux benchmark, which manifests noticeable differences among three tools. According to Figure 6, the percentages of runtime overhead incurred during target identification exhibit a progressive increase among DEEPTYPE, DT-nocache, and TyepDive, standing at 20.6%, 44.2%, and 65.0%, respectively. Thus, the lower overhead of DEEPTYPE should owe to the target identification phase, wherein DEEPTYPE straightforwardly deals with the entire multi-layer type of each indirect call. In contrast, TypeDive addresses each two-layer type within the multi-layer type and calculates intersections, incurring additional runtime overhead. The fact that DEEPTYPE refines indirect call targets also indicates that TypeDive consumes extra computational resources on FPs.

An additional observation reveals that the distinction in runtime overhead is evident in binutils, sqlite and linux, whereas it is negligible in the five server programs. The reason for this distinction is the higher prevalence of multi-layer types with more layers in binutils, sqlite and linux as illustrated in Figure 7. The efficiency advantage of DEEPTYPE over TypeDive is primarily attributed to DEEPTYPE's one-time resolution on the entire multi-layer type, in contrast to the laborious resolution in TypeDive for each two-layer type. It is noteworthy that a multi-layer type may consist of multiple two-layer types. Consequently, the benchmarks containing a greater number of multi-layer types with more layers amplify the runtime overhead discrepancy between DEEPTYPE and TypeDive.

Typically, memory overhead is not a main concern in static analysis, as tools that offer efficient performance without compromising precision are often favored. We still measure the memory overhead of DEEPTYPE using Massif tool in Valgrind [31] tool suite with `-pages-as-heap=yes` option enabled, to measure all the memory used, and compare it with TypeDive for a thorough performance assessment.

Figure 8 shows the memory overhead of DEEPTYPE and TypeDive. Regarding user applications and server programs in the benchmarks, both tools exhibit memory overhead below 150 MB. However, in the context of the Linux kernel, both DEEPTYPE and TypeDive demonstrate higher memory overheads ranging from 4.2 GB to 4.3 GB. This discrepancy is attributed to the larger size of kernel program, which involves

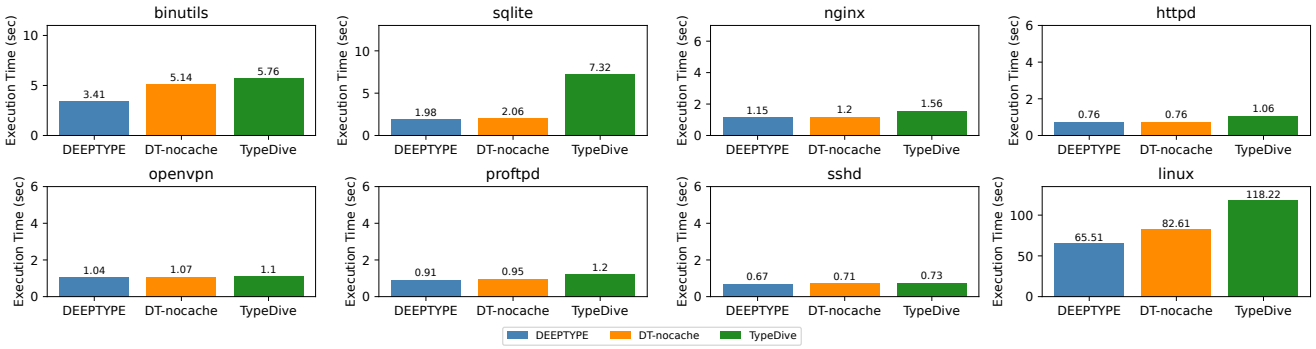

Figure 5: Execution time of DEEPTYPE, DT-nocache and TypeDive. DT-nocache represents DEEPTYPE without caches deployed. For each benchmark, we plot a bar chart to depict the execution times of DEEPTYPE, DT-nocache, and TypeDive, and the y-axis scale of which is adjusted to encompass the full data range without excessive magnification, allowing for clear differentiation in execution times. Specifically, the binutils chart illustrates the average execution times across all assessed binutils programs.

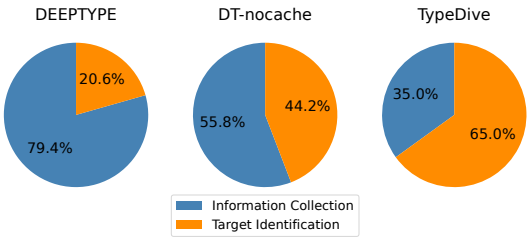

Figure 6: Runtime overhead distribution of DEEPTYPE, DT-nocache and TypeDive. DEEPTYPE and TypeDive follow the same general workflow that contains two phases: 1) collect information and record it in data structures, 2) analyze indirect call sites and recorded information to identify targets.

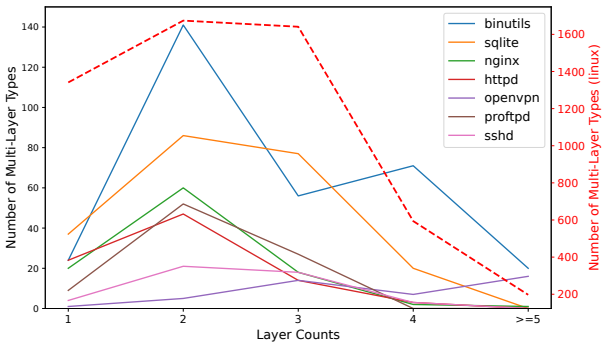

Figure 7: Number of multi-layer types with different layer counts. The y-axis on the right shows the number of multi-layer types in linux while the y-axis on the left shows the number of multi-layer types in other benchmakrs.

more multi-layer types. As a result, both tools record a greater volume of type information, leading to increased sizes of data structures and consequently consuming more memory spaces.

DEEPTYPE shows lower memory overhead than TypeDive, while the subtle difference between two tools remains consistent across all benchmarks. This consistency is attributed to the comparable memory space occupied by the data structures in two tools. Although DEEPTYPE records entire multi-layer types, which have larger sizes than two-layer types, it allocates fewer entries in maps for storage. The difference is due to the additional memory space utilized in TypeDive for recording escaping types, which is designed to overcome the third challenge, as elaborated in Section 2. In contrast, DEEPTYPE adopts the exhaustive search algorithm which does not consume so much memory space as escaping types.

7.3 Contribution of SMLTA in Accuracy

As described in Section 7.1, DEEPTYPE is capable to narrow down the scope of indirect call targets. This capability owes to SMLTA and special handlings to corner cases. To further investigate the impact of SMLTA on effectiveness, we disabled the special handlings in DEEPTYPE, resulting in a variant denoted as DT-noSH. Different ANT values of DEEPTYPE and DT-noSH exhibit the impact of special handlings, thus revealing the contribution of SMLTA.

Table 7 presents the ANT reported by DEEPTYPE and DT-noSH. The ANT of DT-noSH is close to that of DEEPTYPE, indicating that disabling the special handlings has minimal impact on the effectiveness of DEEPTYPE, which reveals the primary role of SMLTA in accuracy improvement. The rationale behind the statistics is that the special handlings are specifically implemented to address corner cases. Without them, DEEPTYPE generates slightly more FPs and FNs. Given the definition of ANT, minor fluctuations in the total number of indirect call targets do not significantly alter ANT value when the volume of indirect calls is relatively high. Nonetheless, these special handlings remain crucial, as they play a vital role in mitigating the FPs and FNs that are orthogonal to SMLTA.

Recall that there are four special handlings. First, the systematic analysis of composite instructions facilitates the generation of complete multi-layer types. Among all the benchmarks, nginx and linux exhibit the most significant improvement owing to this special handling, given their relatively higher prevalence of composite instructions. Second, linking anonymous structs with named equivalents enables DEEPTYPE to accurately recognize and match multi-layer types. We observe that openvpn and linux obtain the most ben-

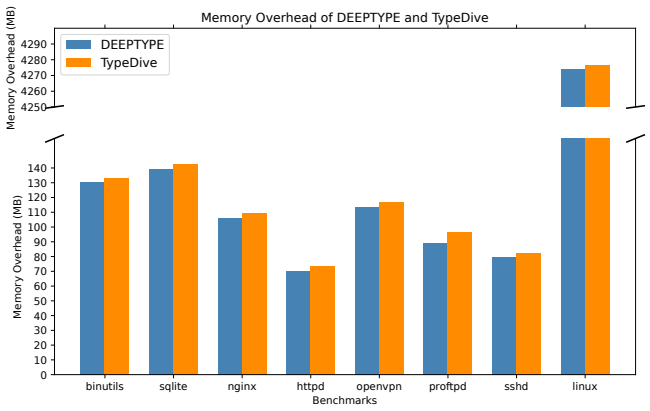

Figure 8: Memory overhead of DEEPTYPE and TypeDive. The scales from 150 to 4250 on y-axis are cut out because there is a gap between the memory overheads of linux and other benchmarks. DEEPTYPE always has lower memory overhead than TypeDive while the difference between two tools is consistently subtle.

Program	DEEPTYPE	DT-noSH	DT-weak
binutils	2.47	2.48	2.70
sqlite	6.24	6.33	6.97
nginx	6.38	8.62	12.99
httpd	6.23	6.23	7.66
openvpn	2.35	2.39	2.35
proftpd	3.10	3.13	4.22
sshd	5.43	5.42	5.43
linux	9.74	9.72	13.09

Table 7: ANT values of DEEPTYPE, DT-noSH and DT-weak. DT-noSH exhibits the contribution of SMLTA. DT-weak shows the impact of storing entire multi-layer types in *Type-Func Map*.

efit from this special handling compared to other benchmarks. Third, DEEPTYPE eliminates dead functions to discard redundant information, thereby mitigating FPs. All benchmarks, except for httpd and openvpn, benefit from this special handling. Last, DEEPTYPE handles empty types accordance to specific code patterns. Due to the infrequent occurrence of the empty type, its impact on ANT is negligible.

Although the comparison between DEEPTYPE and DT-noSH reveals the significant contribution of SMLTA to effectiveness, we also implemented a weak version of DEEPTYPE, denoted as DT-weak, which stores two-layer types in *Type-Func Map*, to help examine the impact of recording entire multi-layer types. As depicted in Table 7, DT-weak demonstrates a higher ANT than DEEPTYPE across most benchmarks, indicating that recording entire multi-layer types, rather than two-layer types, effectively refines indirect call targets. The difference between two tools is particularly evident on nginx and linux, which contain relatively more complex multi-layer types than other benchmarks. Note that, DT-weak still benefits from SMLTA because only the method of recording multi-layer types in *Type-Func Map* has been modified, while other SMLTA designs, such as multi-layer mappings, continue to play a role in filtering out FPs.

```
1  void track_set_index (...) {
2      ...
3      track->index[i] = ind;
4  }
5

7      TrackerExtractInfo *info;
8      ...
9      tracker_extract_info_unref(info);
10     ...
11 }
12
13 gboolean g_option_context_parse (...) {
14     ...
15     if (!(* group->pre_parse_func) (context, group,
                                       group->user_data, error))
16     ...
17 }
```

Listing 6: CVE-2023-43642 vulnerable code. Line 3 is vulnerable to out-of-bounds access. An exploit for this vulnerablity can overwrite a function pointer in glib to gain code execution.

7.4 Case Study

While SMLTA is a fundamental tool applicable across various security-related fields (e.g., static bug detection, symbolic execution, fuzzing, and etc.), we demonstrate its security impact through the example of CFI enforcement.

CVE-2023-43641 [11] is an out-of-bounds access that enables arbitrary write in libcue. As detailed in Listing 6 at line 3, both the value of index `i` and `ind` can be controlled by attacker. By setting the index `i` negative, an attacker can achieve arbitrary write through preparing the value of `ind`. The exploit [2] utilized this vulnerability to corrupt a function pointer in glib (cross-referenced by libcue) to achieve arbitrary code execution. To be specific, the exploit overwrites the heap object `info` (line 7), which is allocated in a function invoked by `track_set_index` (line 1). This overwrite enables the corruption of function pointer `pre_parse_func` (line 15) in glib, and the corrupted function pointer is subsequently used to call the `initable_init` function, which behaves similarly to the `system` function, enabling arbitrary code execution.

Similar to many typical CVE exploits, this exploit assumes Control Flow Integrity (CFI) is not deployed. The function pointer `pre_parse_func` has a type mismatch with the target function `initable_init`, making the exploit preventable by both MLTA and SMLTA. However, this does not imply that the vulnerability can be completely mitigated by either MLTA or SMLTA, as attackers may still conduct exploits by corrupting alternative function pointers.

We further examined glib and revealed 5 function pointers that can bypass MLTA, see Table 8. MLTA fails to prevent the exploits that corrupting these function pointers because it identifies the function `initable_init` as a valid target for these function pointers, though it is a FP in fact. This FP can be attributed to MLTA's approach of splitting multi-layer types, which confines the function `initable_init` respectively to *gboolean (Ginitable*, GCancellable*, GError**)**

Function Pointers	MLTA	SMLTA
callback	✗	✓
callback*	✗	✓
traverse_func	✗	✓
func	✗	✓
predicate	✗	✓

Table 8: The capability of MLTA and SMLTA in preventing exploits. The listed function pointers, located in glib, can be corrupted through the vulnerability. MLTA fails to prevent the exploits through the 5 function pointers while SMLTA can prevent these exploits. To differentiate two function pointers named "callback" in separate functions, one is denoted as "callback*".

and *struct._GInitableIface* with index 1, weakening the restriction of multi-layer type matching.

For example, `traverse_func` in Table 8 has type *gboolean (gpointer*, gpointer*, gpointer*)**, which matches with *gboolean (Ginitable*, GCancellable*, GError**)** due to information flow in glib. Thus, MLTA identifies `initable_init` as a potential target, enabling attackers to rewrite the function pointer with the address of `initable_init` and achieving arbitrary code execution.

In contrary, SMLTA is able to prevent these exploits because it strictly confines `initable_init` to its entire multi-layer type *gboolean (Ginitable*, GCancellable*, GError**)* | *struct._GInitableIface#1*, which does not match with any function pointer in Table 8. Consequently, SMLTA effectively reduces the attack surface of control-flow hijacking attacks utilizing this vulnerablity. By limiting the attacker's ability to corrupt function pointers, SMLTA offers a higher level of security compared to MLTA in CFI implementation.

8 Discussion

8.1 Soundness

This section discusses the soundness of SMLTA. In theory, SMLTA belongs to type-based analysis, the soundness of which has already been proved [30, 33, 37, 53, 59]. In general, the static analysis in DEEPTYPE is flow-insensitive, indicating that it does not track the sequences of instructions or data-flow between basic blocks, but purely collects type information, which does not yield any FN.

Specifically, SMLTA contains 4 novel designs, none of which produces FNs. First, fuzzy type and fuzzy index stand for uncertain layers and indexes. They match with any type and index to ensure that no potential targets can be missed. Second, multi-layer mappings are used to archive the collected multi-layer types without any omission. It does not produce any FN because all recorded multi-layer types can be retrieved through querying the mappings. Third, the relationships among multi-layer types involved in an information flow chain is conservatively recorded. Any potential information flow between two multi-layer types is considered when identifying targets. Finally, the exhaustive search algorithm discovers all friend types that can share associated functions with the multi-layer type of the indirect call, ensuring all potential targets being identified.

8.2 Limitations

The implementation of DEEPTYPE does not robustly address all corner cases in real-world programs. Besides the ones addressed in Section 6, some corner cases are out of our scope. For example, LLVM IR only contains type information but omits instantiated values of the members in global variables with composite type. If a function pointer as a member of a global variable is initialized at the global scope, the function assigned to it is apparent in source code but does not appear in the corresponding IR, thus does not appear in bitcode.[9] Given this fact, DEEPTYPE is unable to record the mappings between multi-layer types and functions for such initialization instructions, resulting in missing targets for involved indirect calls. Take binutils programs as another example, some indirect call targets are functions in the GNU linker, `LD`, while we use Clang to compile the programs which uses `LLD` as linker.

Albeit the accuracy improvement contributed by SMLTA and special handlings, DEEPTYPE still exhibits deficiencies in terms of accuracy. For small programs that contain few complicated multi-layer types, DEEPTYPE is limited in reducing FPs compared to TypeDive meanwhile possibly yielding extra FPs instead due to the conservative design and implementation choices for soundness purpose. In addition, if several function pointers have the same multi-layer type but points to different functions, SMLTA produces FPs in this scenario.

In evaluation aspect, there is no standard scale available to calculate the statistics such as FP rate, FN rate and accuracy, due to the absence of ground truth. Although "pseudo ground truth" [24] is a feasible solution, it highly depends on the precision of dynamic analysis adopted. If the dynamic analysis result is not proved to be extremely close to the ground truth, the numerical data of soundness and precision relative to the pseudo ground truth is not convincing subsequently. We use ANT as metric to reflect the accuracy improvement. But it is convincing only in the context that both SMLTA and MLTA pertain to type-based analysis and the novel designs in DEEPTYPE does not produce FNs.

8.3 Future Work

SMLTA generates FPs when multiple functions share the same multi-layer type with an indirect call. This is a limitation intrinsic to type-based analysis that relies solely on type verification. To enhance accuracy, we intend to integrate data-flow analysis with SMLTA, assessing both value and multi-layer type to further constrain potential targets, thereby reducing the FPs inherent to SMLTA. To maintain a balance between accuracy and performance, this data-flow analysis will be designed to be lightweight, focusing on intra-procedural analysis.

[9] Bitcode is a binary encoding of LLVM IR.

Motivated by the absence of a standard and reliable metric for comparing various approaches, we also plan to develop a benchmark that includes a comprehensive ground truth. This ground truth will encompass, but is not limited to, indirect call targets, alias pointers, and value sets. This will enable a wide range of basic tools used in both static and dynamic analysis to evaluate their effectiveness, identify the fundamental reasons for any inaccuracies, and enhance their design and implementation accordingly.

9 Related Work

Conservative solutions. Zhang et al. propose a protection mechanism called CCFIR [65] which implements a policy pertaining to indirect control transfers. It prohibits any indirect calls/jumps to locations other than those included in a white-list, which is derived from the relocation tables of ASLR [55] that provides absolute addresses of valid functions. Similarly, Zhang and Sekar [67] conservatively count all valid functions as targets given the assumption that source code is not available. These solutions are exceedingly conservative and may produce numerous false positives targets.

Type-based analysis. In cases where the source code of a program is available, types of function pointers are utilized to deduce potential targets. Each indirect call is restricted to being directed towards only the functions with the same type. Tice et al. present VTV and IFCC that provide forward-edge CFI protection respectively for GCC and LLVM [49]. VTV conducts a validation process to ensure the correctness of the vtable pointer used for a virtual call by confirming the vtable pointer to be used for the indirect call points either to the vtable for the static type of the object, or to a vtable for one of its descendant classes. IFCC forces a function pointer into the right function-pointer set in jump tables to mitigate CFI violations and each function-pointer set has a specific function type signature. Niu and Tan present MCFI [34] where an indirect call is allowed to call any address-taken function whose type is structurally equivalent to the function pointer's type. Victor et al. propose TypeArmor [52] to reduce the number of targets for indirect calls where function type and argument number is checked to identify valid targets. MLTA [27] utilizes multi-layer type, which includes function type signature and type of composite data structures, to significantly refine indirect call targets. The majority of the prior work on resolving C++ virtual functions depend on class hierarchy analysis combined with object type information [15, 21, 40, 49, 64]. These approaches employ an expanded single-layer type to identify targets, but our approach can further improve the accuracy by utilizing types of multiple involved data structures.

Data tracking Analysis. Ge et al. utilize taint analysis in their fine-grained CFI to identify targets for kernel software [14]. They begin with a function and taint all function pointers that are initialized with the function or the tainted function pointers. If a function pointer is in a structure, they taint the field for all memory objects of that structure's type. This policy enables fine-grained CFI to leverage the information of directly related data structure instead of only considering the function pointer itself, but it is still less precise than SMLTA which uses type information of all involved data structures to restrict targets. Kim et al. use block-based pointer analysis (BPA) [23] to identify indirect call targets, which generates memory blocks for heaps, stack frames, and global data sections following specific rules and perform pointer analysis in each memory block to infer points-to relationships. They also upgrade BPA by offset-sensitivity in BinPointer [24], which tracks the offset in each memory block for more fine-grained pointer analysis. Compared with strong MLTA, such approach is deficient in handling type casting, which will cause missing targets. Another limitation is that it does not support C++. CFGAccurate [46] interleaves four techniques including forced execution, backward slicing, symbolic execution and value set analysis to construct CFG, which is precise at the expense of high performance overhead.

Dynamic Analysis. Many other solutions [12, 13, 16, 35, 51] use dynamic analysis which relies on runtime information to identify indirect call targets. These solutions address a distinct problem area, which is the assurance of the validity of a runtime target. Conversely, our work statically deduces the range of potential targets for each indirect call.

10 Conclusion

In this paper, we have introduced strong multi-layer type analysis (SMLTA), a novel approach in refining indirect call targets, that thoroughly utilizes type information provided by multi-layer types. It treats the entire multi-layer type as a basic unit for information storage and type verification to improve accuracy. SMLTA resolves relationships between multi-layer types, exhaustively discovers friend types for indirect calls, and employs fuzzy type to overcome the challenges in indirect call target identification using multi-layer types. Additionally, multi-layer mappings are deployed to hierarchically archive multi-layer types for quick access. We implemented SMLTA in DEEPTYPE, which is equipped with special handlings to address diverse code patterns and corner cases. DEEPTYPE is scalable to large applications with superior effectiveness as well as performance. The experiment results showed that DEEPTYPE narrows down the scope of indirect call targets by 43.11% on average across most benchmarks, reduces runtime overhead by 37.02% on average and consumes less memory compared to TypeDive. A case study in CVE exploit demonstrated that SMLTA is more powerful than MLTA in reducing attack surface and preventing exploits. However, the intrinsic limitation of type-based analysis can still produce false positive targets. We leave it as future work to further improve accuracy through lightweight data-flow analysis.

Appendix

A Multi-Layer Mappings

To efficiently organize and access the collected multi-layer types, we use multi-layer mappings to hierarchically archive them as described in Section 4.2. The question is *how many mappings are sufficient in Type Lookup Maps?* The number should neither be too large to guarantee the performance of DEEPTYPE nor too small to hold the multi-layer types. So, we decide the number of mappings conforming to the multi-layer types in benchmarks.

Table 9 shows the number of multi-layer types with different layer counts. Across all benchmarks, the multi-layer types in them contain at most 8 layers, which means 7-layer mappings are sufficient to record these multi-layer types. Thus, we adopt 7-layer mappings in our implementation. If multi-layer types with more than 8 layers are common in other programs, more mappings can be deployed in DEEPTYPE to supply extra precision in practice.

Programs	Total	<=8 layers	> 8 Layers
binutils	311*	311*	0
sqlite	220	220	0
nginx	101	101	0
httpd	88	88	0
openvpn	43	43	0
proftpd	88	88	0
sshd	46	46	0
linux	5,447	5,447	0

Table 9: Number of multi-layer types with different layer counts. 311* indicates the average of binutils programs.

B Binutils Test results

Binutils programs consist of similar indirect calls as they utilize shared library function, thus displaying similar results. For someone who is interested in, we provide detailed data for each individual program in Table 10.

Program	DEEPTYPE	DT-weak	TypeDive
addr2line	2.38	2.62	8.60
ar	2.45	2.69	12.73
bfdtest1	2.38	2.62	12.89
bfdtest2	2.38	2.63	12.89
cxxfilt	2.37	2.62	8.64
nm-new	2.48	2.72	13.01
objcopy	2.63	2.87	13.08
objdump	2.95	3.19	11.26
ranlib	2.45	2.69	12.73
readelf	2.29	2.29	2.30
size	2.39	2.64	12.95
strings	2.37	2.62	8.64
strip-new	2.63	2.87	13.08

Table 10: Average number of targets for each program in binutils.

Improving Indirect-Call Analysis in LLVM with Type and Data-Flow Co-Analysis

Abstract

Indirect function calls are widely used in building system software like OS kernels for their high flexibility and performance. Statically resolving indirect-call targets has been known to be a hard problem, which is a fundamental requirement for various program analysis and protection tasks. The state-of-the-art techniques, which use type analysis, are still imprecise. In this paper, we present a new approach, `TFA`, that precisely identifies indirect-call targets. The intuition behind `TFA` is that type-based analysis and data-flow analysis are inherently complementary in resolving indirect-call targets. `TFA` incorporates a co-analysis system that makes the best use of both type information and data-flow information. The co-analysis keeps refining the global call graph iteratively, allowing us to achieve an optimal indirect call analysis. We have implemented `TFA` in LLVM and evaluated it against five famous large-scale programs. The experimental results show that `TFA` eliminates additional 24% to 59% of indirect-call targets compared with the state-of-the-art approaches, without introducing new false negatives. With the precise indirect-call analysis, we further developed a strengthened fine-grained forward-edge control-flow integrity scheme and applied it to the Linux kernel. We have also used the refined indirect-call analysis results in bug detection, where we found 8 deep bugs in the Linux kernel. As a generic technique, the precise indirect-call analysis of `TFA` can also benefit other applications such as compiler optimization and software debloating.

1 Introduction

One of the powerful features of advanced programming languages like C/C++ is the *function pointer*, which allows developers to dynamically invoke different functions depending on the runtime context. Function pointers are widely used in modern software such as OS kernels to implement flexible and efficient functionalities. The invocation site of a function pointer is called an *indirect-call* (*icall* for short in this paper). However, the dynamic nature of icall makes it challenging to determine its possible targets. This challenge hinders the construction of a precise Control-Flow Graph (CFG), which is essential for many significant program analysis and protection tasks (e.g., bug detection, program optimization, and control-flow integrity).

Researchers have been actively proposing techniques to identify icall targets. There are two main categories of techniques for this problem. The first category is dynamic techniques, which record the icall targets at runtime and update the control flow graph accordingly [7, 23, 27, 51, 53]. However, it has limitations in terms of soundness and performance, as it depends on the code coverage and the runtime support. Therefore, we focus on the second category: static techniques, which compute the possible icall targets without executing the program. Some static techniques rely on whole program pointer analysis to identify icall targets [20, 24, 47, 54], but this approach faces challenges in balancing efficiency, soundness, and effectiveness [29, 42]. In particular, precise interprocedural pointer analysis is often infeasible for analyzing large programs such as OS kernels (e.g., Andersen [21]). Moreover, the pointer analysis itself presupposes a global control flow graph, which implies knowing the icall targets beforehand.

As a result, most existing practical solutions rely on type analysis for identifying icall targets [40, 50, 58, 60, 63, 64]. Specifically, they consider all *address-taken functions* (i.e., functions whose addresses have been referenced) that have the same function type as the icall as possible targets. This is known as *type matching* or *signature matching*. This approach is common in CFI schemes [10, 48, 50] and static program analysis [28, 60, 63]. However, it suffers from high false positives, as many unrelated functions can also match the function type of the icall, especially for simple types (e.g., `void (*)(int)`). To address this limitation, *two-layer type matching* [37, 43, 68] is proposed based on the observation that most icalls in large programs are stored and used in com-

Qinming He and Shouling Ji are the co-corresponding authors.

posite types like structures. By using the outer-layer struct type information as an additional filter, it can eliminate many invalid icall targets. `TypeDive` [42] extends this idea and proposes *multi-layer type matching* (*MLTA*), where it tracks the outer-layer struct types recursively (i.e., one struct type is stored into another struct type) to obtain richer type information for icall analysis.

The state-of-the-art method, MLTA, has achieved great success in precisely identifying icall targets, and has been adopted in many static analysis tasks [22, 32, 39, 62, 69]. However, it still suffers from several problems. (1) It is ineffective for programs that rarely use composite types. For instance, we found that only 25% of icalls in the OpenSSL library involve composite types, and thus most icalls in OpenSSL cannot benefit from MLTA. (2) Even for large programs that extensively use composite types, the impact of icalls that cannot benefit from MLTA (i.e., icalls that do not involve composite types) is highly significant. Our experimental results indicate that the minority (23%) icalls that do not involve composite types account for the majority of icall targets (77%) in the Linux kernel.

One fundamental problem of existing approaches is that they do not fully utilize type and data-flow information. In this paper, we present a new approach, `TFA` (Type and Flow co-Analysis), for precise and sound indirect-call resolution. The basic idea of `TFA` is to leverage the complementary advantages of type analysis and data-flow analysis to resolve indirect-call targets optimally. Specifically, for icalls with rich type information, type analysis (e.g., MLTA) could provide us an initial CFG, which enables the inter-procedural data-flow analysis. For icalls with limited or general type information (i.e., MLTA is ineffective), data-flow analysis kicks in to help eliminate unrelated targets. Given an initial CFG generated by MLTA, `TFA` iteratively improves it through type and data-flow co-analysis until convergence is reached. The refined CFG will make the subsequent analysis round more precise and more manageable because it narrows the scope of inter-procedural analysis.

While the intuition of `TFA` is straightforward, implementing `TFA` needs to overcome two challenges. (1) The type information used for icall analysis is not always accurate. Many type-based icall analysis methods [37, 42, 43] are implemented based on LLVM [13], a popular static analysis framework. However, we discovered a series of LLVM composite types that lack essential information (§2.2). We call them *broken types* in this paper. Broken types affect the precision and soundness of type-based analysis and introduce both false positives and false negatives. (2) Directly performing inter-procedural data-flow analysis to track the data-flow relations between icalls and their targets is costly, especially for large programs like OS kernels. Furthermore, `TFA` needs to repeat the analysis iteratively, which poses a challenge to the efficiency of `TFA`.

To address the first challenge, we propose a type recovery technique that leverages the source code information to identify and reconstruct the missing or broken types. Our technique could enhance not only our icall analysis, but also general type-based analysis in LLVM. To address the second challenge, we present a two-dimensional data-flow analysis method customized for icall analysis. It captures both the data-flow dependencies between icalls and their targets, and the type information that is hidden behind complex data-flows. The rich type information obtained by our data-flow analysis significantly improves the existing type analysis methods.

We have implemented `TFA` based on LLVM and evaluated `TFA` with five representative C/C++ programs: the *Linux kernel*, the *FreeBSD kernel*, the *OpenSSL library*, the *OpenCV library*, and the *MongoDB database*. `TFA` could analyze the complex Linux kernel in less than two hours. The experimental results show that `TFA` further eliminates 24% to 59% icall targets compared to the state-of-the-art multi-layer type analysis method. The evaluation also indicates that the type recovery method is effective in improving the soundness of type analysis. The data-flow analysis of `TFA` does not introduce any additional false negatives. We demonstrate the practical benefits of `TFA` in two applications: CFI and bug detection. We have implemented a prototype of a forward-edge CFI scheme leveraging `TFA` for the Linux kernel, where each icall's valid target set is computed according to its unique semantic. We also use `TFA` to detect bugs related to the misuse of device release call-back functions in the Linux kernel. We confirm 6 double-free bugs and 2 memory leak bugs that are hidden behind indirect-calls and would be missed by existing static bug detection tools. In summary, we make the following contributions:

- **A new approach for icall target analysis.** We propose a new approach, `TFA`, to precisely identify icall targets. `TFA` integrates the type analysis and data-flow analysis in such a way that they complement each other to compute icall targets optimally. The approach is designed to be practical for large programs, both kernel and user levels. We will open source `TFA` to facilitate further researches.

- **New techniques.** We propose multiple techniques to address challenges in implementing `TFA`. We propose a type recovery technique to fix the broken types in LLVM. We also design a customized two-dimensional data-flow analysis for icall target resolving, which not only precisely finds icall targets for cases where type analysis fails, but also identifies richer type information.

- **Extensive evaluation and feasible applications.** We extensively evaluate `TFA`'s efficiency, effectiveness, and soundness on five large-scale programs. Compared with the state-of-the-art methods, `TFA` further eliminates 24% to 59% icall targets without introducing more false negatives. The evaluation results confirm that `TFA`'s icall analysis is precise, scalable, and sound. We then implement a strengthened

```
1  typedef void (*f_ptr)(int a, int b);
2  struct S {f_ptr field1; f_ptr field2};
3
4  void address_taken_func1(int a, int b){...}
5  void address_taken_func2(int a, int b){...}
6  void address_taken_func3(int a, int b){...}
7  void address_taken_func4(int a, int b){...}
8
9  struct S s1 = {.field1 = address_taken_func1,
10                .field2 = address_taken_func2};
11 struct S s2 = {.field1 = address_taken_func3,
12                .field2 = address_taken_func4};
13
14 void main() {
15     ...
16     s1.field1(100, 200); // address_taken_func1 is called here
17     ...
18 }
```

forward-edge CFI scheme based on our precise icall analysis results and apply it to the complex Linux kernel. We also apply TFA in bug detection and found 8 new bugs in the Linux kernel.

2 Background and Motivation

2.1 Type-Based Indirect-Call Analysis

We present an example of an icall in Figure 1 to compare different type analysis methods. This icall occurs at line 16 and has a function type defined at line 1. A one-layer type matching method would consider any address-taken function with the same function type as the icall as a possible target. Thus, it would include all four functions defined from line 4 to line 7 as valid targets. A two-layer type matching method would also examine if an address-taken function is assigned to a field of a structure, which is a common pattern in large software such as OS kernels. In this example, the icall is retrieved from the first field (`.field1`) of struct `S`. Only `address_taken_func1()` and `address_taken_func3()` are used to initialize this field. Therefore, two-layer type matching identifies these two functions as valid targets of the icall, which eliminates 50% of false positives compared to one-layer type matching.

2.2 Problems with the Type Analysis in LLVM

LLVM is one of the most widely used static analysis frameworks, which is essential for implementing various type-based icall analysis techniques. However, LLVM suffers from two issues that compromise the soundness of type analysis. In this paper, we call these issues *broken types*.

2.2.1 Unreliable Type Equality Checking

One essential requirement of the aforementioned type-based analysis is to determine the equality of different types, especially for struct types. However, even such a fundamental

```
1  /* source code */
2  struct A {
3      int i;
4      int (*f)(int, struct A*);
5      int (*g)(char, struct A*);
6  };
7
8  /*Expected LLVM IR of struct A */
9  %struct.A = type {i32, i32 (i32, %struct.A*), i32 (i8, %struct.A*)}
10
11 /*Actual LLVM IR of struct A */
12 %struct.A = type {i32, {}*, i32 (i8, %struct.A*)}
```

Figure 2: Example of omitting function pointer fields.

```
1  /* source code */
2  struct dvb_usb_adapter_properties adapter[2];
3
4  /*Expected LLVM type of variable adapter */
5  [2 x %struct.dvb_usb_adapter_properties]
6
7  /*Actual LLVM type of variable adapter */
8  <{{i8, i8, i32 (%struct.dvb_usb_adapter*, i32)*,
9  i32 (%struct.dvb_usb_adapter*, i32, i16, i32)*, {i8, i8, i8,
10 {%struct.anon.163, [8 x i8]}}}, %struct.dvb_usb_adapter_properties}>
```

Figure 3: Example of type unfolding.

task is hard to accomplish in LLVM intermediate representations (IRs). The default type-pointer comparison is only applicable for types within the same LLVM module. Some previous works [42, 43] rely on the hashed type strings to perform cross-module type comparison, which is effective for primitive types (e.g., integers). However, this approach is unsound in comparing struct types due to the following anomalies in LLVM type representations:

- **Omitting function pointer fields.** In some cases, the function pointer field of a structure will be replaced as an empty pointer (`{}*`) rather than its point-to type, as shown in Figure 2. This issue has been reported and discussed in several different technical forums [2–5], but it still persists in LLVM 15. Some developers suggest this is a known bug in Clang [1, 2].

- **Missing struct names.** A common programming practice is to initialize a global variable at the point of its declaration (e.g., line 9 and line 11 in Figure 1). In our analysis on the Linux kernel, we found that 17.8% of global struct variables are declared without specifying their struct type names in LLVM IRs. This poses a challenge for the two-layer type matching algorithm, as we cannot determine that `address_taken_func1()` is used to initialize a field of struct `S` in Figure 1, which occurs for 13.5% of outer-layer struct types in the Linux kernel.

- **Type unfolding.** One challenge in analyzing the content of a struct's fields is that they may be partially unfolded, as shown in Figure 3. Sometimes, an `i64` type could be split into two `i32` types. Based on our manual analysis, this scenario is likely to occur when a structure has a union field.

These type representations make type comparisons based on type strings unreliable. LLVM provides a built-in type comparison method [9], which recursively verifies every struct field of the two struct types. LLVM linker also employs another type comparison method based on isomorphism checking [8]. Denisov et al. proposed a tree-automata-based type comparison method for LLVM [6]. However, none of these methods can guarantee the soundness of type comparison.

2.2.2 Type Information Omission in Optimized Code

One of the key tasks in type-based analysis is to determine the type information of different layers (i.e., identify which field of a structure a variable belongs to). In LLVM IRs, this is done by using the `getelementptr` instructions, which are used to access struct fields. For instance, given a GEP instruction like *%ptr = getelementptr inbounds %struct.S* %0, i64 0, i32 5*, we can infer that the pointer `%ptr` originates from the fifth field of struct S.

Previous works on icall analysis have focused on programs compiled with no optimization (O0) [42, 43], and the impact of code optimization on type analysis has not been well studied. We discovered that many GEP instructions in optimized code (e.g., O2 optimization level), which is often preferred by static analysis techniques for its advantages on data-flow analysis [52, 60, 69], would lose crucial type information. For example, the GEP instruction above would be transformed into *%ptr = getelementptr inbounds i8, i8* %0, i64 28* after optimization. The struct pointer type is replaced by a primitive pointer type `i8*`. The field index is replaced by a byte offset based on the primitive pointer. In this scenario, existing methods are unable to retrieve the nested struct types or fields.

2.2.3 Causes of Broken Types

We argue that the above abnormal cases should not be regarded as mere bugs, since they do not cause any observable runtime errors in our experiments. The optimization that eliminates type information in §2.2.2 is justified, as it simplifies the address calculation and improves the runtime performance. Previous work also shows that types in LLVM IRs are not always consistent with the source code (i.e., cases in §2.2.1) for the sake of *optimal machine code generation* [36]. However, this poses a challenge for researchers who want to perform type-based analysis on LLVM IRs. Therefore, instead of modifying LLVM's type system directly, we propose a program analysis oriented type recovery approach to address the issues caused by broken types.

2.3 Type Recovery and Co-Analysis

As discussed in §2.2, broken types can exhibit various patterns, but they all share a common problem: the lack of type information. To address this challenge, we present a novel type recovery technique (§4.1) that can infer the missing type information for broken types, enabling more sound and precise type-based analyses (e.g., icall analysis).

The icall in Figure 1 has only one possible target: `address_taken_func1()`, which cannot be determined by type analysis alone. However, if we can leverage additional data-flow analysis to identify that the icall only involves variable `s1`, we can reduce the set of potential targets to `address_taken_func1()` and `address_taken_func2()`. By combining the results of two-layer type matching and data-flow analysis, we can achieve the exact ground-truth result in this example. This observation inspires us to design and implement `TFA`.

3 Overview

The goal of `TFA` is to resolve icall targets soundly and precisely. The key idea of `TFA` is to combine multi-layer type analysis and data-flow analysis in an iterative manner to refine the control-flow graph (CFG) progressively. The overview of `TFA` is shown in Figure 4, which consists of two analysis phases.

In the first phase, `TFA` takes the LLVM IR files as inputs and performs type recovery on them. `TFA` scans all struct variables and GEP instructions of the program in the LLVM IRs to detect and fix broken types. Specifically, `TFA` leverages the source code information and recovers the missing type information layer by layer. Based on the recovered type information, `TFA` then conducts multi-layer type analysis to generate an initial CFG of the program, which enables inter-procedural data-flow analysis in the next phase. `TFA` also records the detailed analysis results of each icall in this phase to guide the subsequent data-flow analysis.

In the second phase, `TFA` refines the icall targets iteratively using a *two-dimensional data-flow analysis*. This analysis establishes the data-flow relationships between the icalls and their possible targets, and also extracts layered type information from inter-procedural context. These two analysis flows enhance the icall analysis directly and indirectly, respectively.

The icall target analysis produces a refined CFG in each round, and stops when the CFGs of two consecutive rounds are sufficiently similar. The final CFG is then stored in a database to facilitate further static analysis.

4 System Design

In this section, we first introduce our type recovery approach, which aims to improve existing type analysis. Next, we present the customized alias analysis method we used. Finally, we introduce the two-dimensional data-flow analysis of `TFA`, which cooperates with the type analysis on refining icall targets.

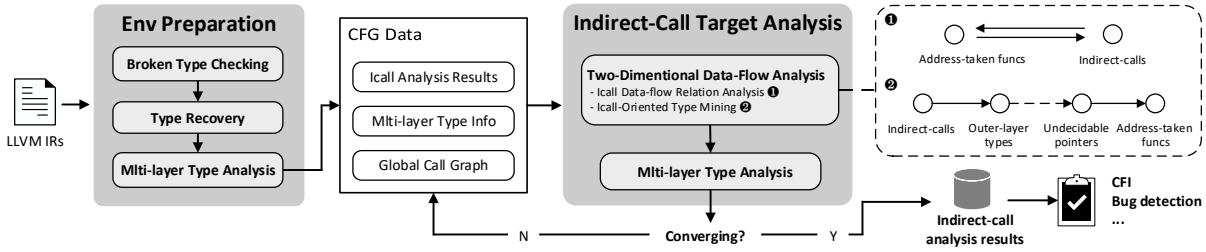

Figure 4: The overview of TFA. It has a preparation phase and an iterative icall analysis phase. It takes the LLVM IRs as inputs and outputs the icall analysis results to a local database.

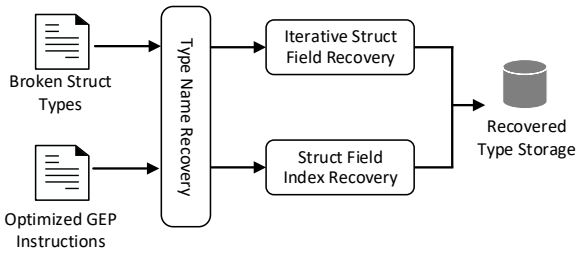

Figure 5: The overview of type recovery.

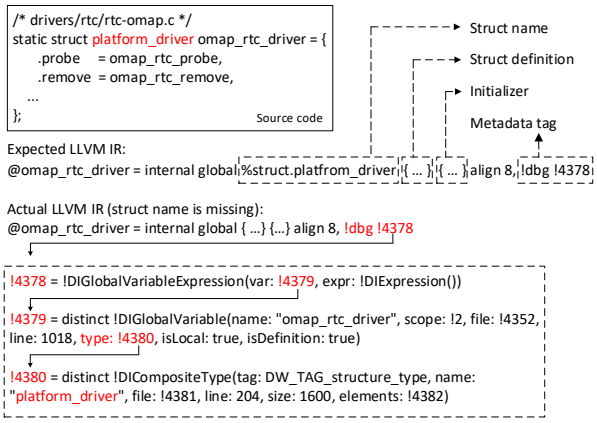

Figure 6: The workflow of type name recovery.

4.1 Type Recovery

Type recovery aims to recover the missing struct type information to support precise and sound type analysis. The overview of type recovery is shown in Figure 5. It takes two types of inputs that have incomplete or distorted type information: (1) the broken struct types (i.e., cases in §2.2.1), and (2) the optimized LLVM GEP instructions (i.e., cases in §2.2.2). For the broken struct types, TFA will reconstruct the erased struct type names and fields. For the optimized GEP instructions, TFA will infer the struct types and field indices from the optimized types (i.e., `i8*`) and byte offsets.

For both types of inputs, the first step of type recovery is to recover the corresponding struct type names. For the broken struct types, we then recursively examine and restore their possible broken field types. For the optimized GEP instructions, we additionally recover the field indices that the instructions originally accessed. TFA maintains a global map to store the recovered types for facilitating subsequent type-based static analysis in LLVM.

4.1.1 Type Name Recovery

We present a case study from the Linux kernel to demonstrate the process of type name recovery, as shown in Figure 6. This case involves a global variable `omap_rtc_driver` with a struct type named `platform_driver`. Ideally, its representation in LLVM IR should include three essential elements: struct name, struct definition, and initializer. However, its struct name is absent. We examined the entire Linux kernel and discovered 64,457 global struct variables (17.8%) that lacked their struct type names in the definition.

Our approach is to leverage the source code information (stored in the LLVM metadata nodes) to recover the missing struct name. For instance, in Figure 6, by tracking the metadata layer by layer (`!4378`→`!4379`→`!4380`), we can identify the type name of `omap_rtc_driver` and construct a complete struct type in LLVM IRs.

For an optimized LLVM GEP instruction, we first obtain the pointer operand of this instruction (e.g., `i8* %0` in the example of §2.2.2). We then inspect the use-chain of this value to locate the `llvm.dbg.value` instruction, which records the corresponding source code information. Finally, we extract the metadata node from this instruction and recover the type name of this value (`Struct.S` in the example of §2.2.2) using the same process as in Figure 6.

4.1.2 Iterative Struct Field Recovery

Struct types that contain fields of other struct types are frequently used in programming. One challenge of the type recovery is that the broken struct types could propagate through nested struct fields, and we need to recover all possible broken

field types accurately. For instance, if the name of a struct type is missing, its nested struct fields are also likely to have missing names. Usually, the incorrect types are mixed with correct types, which complicates the recovery process.

To address this problem, we propose the following recovery methods for a given broken struct type. We first recover the missing name with the workflow in §4.1.1. We then search the type definition list of the current module and find the intact struct definition (i.e., *identified struct type*) of the broken type based on the recovered name. Finally, we iteratively match all fields of the broken and intact struct types to recover all potential broken field types. In the matching procedural, we apply three additional strategies to ensure soundness: (1) We recursively unfold all composite types into primitive types to enable sound and effective type comparison. (2) We split all integer types into multiple `i8` types according to their bit-width. (3) We conservatively allow void pointer type to cast to any function pointer type.

4.1.3 Struct Field Index Recovery

For an optimized GEP instruction, we need to additionally recover the exact struct field index that the GEP instruction intends to access. Since we have recovered the original struct type names, we can use the LLVM API [1] to obtain the field index by computing the byte offset. However, this approach is not always reliable. We manually examined the corresponding LLVM IRs and discovered that the code optimization pipline could merge multiple GEP instructions. For instance, given a C code snippet `s = a->b->c`, LLVM would normally generate two GEP instructions to get the address of variable `s`: one GEP for computing the address of `b` from `a`, and another for computing the address of `c` from `b`. However, these two GEP instructions could be combined into one during the code optimization, which sums up the two address offsets and loses the information of struct `b`. Consequently, existing methods fail to analyze the struct accessing behaviors correctly.

To address this problem, we propose an algorithm to identify the types and indices for the merged fields, as illustrated in Algorithm 1. The basic idea of our algorithm is to recursively compute the address offset layer by layer until it matches the given offset. In particular, when we encounter a struct field (line 5), we find the nearest field index according to the current offset (line 6) and compute the delta between this field's offset and the given offset (line 7-8). If the delta is non-zero, then the GEP must access a subfield of the current struct field, and we use the delta as the new offset to locate the subfield. When we encounter a struct array field (line 12-14), we simply descend into the element struct type and use the remainder of the given offset and the element type size to locate the subfield (line 15-17).

[1] LLVM API getElementContainingOffset(): given a valid byte offset into the struct type, it returns the struct index that contains it.

Algorithm 1: Get layered types and indices

Input: BST: Base struct type of the GEP instruction;
$offset$: Byte offset in the GEP instruction
Output: $STList$: The recovered struct type list;
$indexList$: The index list of the fields in $STList$

```
1  cur_offset ← 0;
2  CST ← BST;
3  index ← 0;
4  while offset > 0 do
5      if CST is Struct Type then
6          index ← CST.GETINDEXFROMOFFSET(offset);
7          cur_offset ← CST.GETELEMENTOFFSET(index);
8          offset ← offset − cur_offset;
9          STList.PUSH_BACK(CST);
10         indexList.PUSH_BACK(index);
11         CST ← CST.GETELEMENTTYPE(index);
12     else if CST is Array Type then
13         eleTy ← GETELEMENTTYPE(CST);
14         if eleTy is Struct Type then
15             type_size ← GETTYPESIZE(eleTy);
16             CST ← eleTy;
17             offset ← offset mod type_size;
18         end
19     else
20         return NULL, NULL;
21 end
22 return STList, indexList;
```

4.2 Alias Analysis

To perform data-flow analysis of TFA, we need to track alias relationships among program variables. We adopt a data structure called *alias graph* [35, 38] to store these relationships. The alias analysis method is inter-procedural, flow- and field-sensitive, and it achieves a good trade-off between efficiency and precision for large-scale programs. In this paper, we enhance the soundness of the alias analysis for icall analysis scenario by making the following modifications:

Flow-insensitivity. Flow-sensitivity is a property of alias analysis that takes control-flow information into account. For our analysis, we require both forward and backward data-flow exploring, which makes the flow-sensitivity irrelevant. Therefore, we use a flow-insensitive approach that simplifies the computation and improves the soundness of our analysis.

Field-insensitivity. Field-sensitivity is the ability to distinguish different fields of the same composite object. We do not support field-sensitivity in alias analysis for two reasons: (1) Our analysis result is the intersection of data-flow analysis and multi-layer type analysis, which already provides field-sensitivity. (2) The Linux kernel has a mechanism, called `container_of`, to obtain the starting address of a struct value from its field value. This mechanism introduces soundness issue [41] because it prevents us from getting the correct outer-layer struct type (which is missing) or the correct index

of the current field (which is negative).

Supporting May-Alias Query. Current design of the alias graph based alias analysis mainly supports must-alias query [35], which will introduce soundness issues in icall analysis. Therefore, we re-design the graph updating algorithms to support may-alias query.

We have reimplemented the alias analysis according to the above requirements. Our analysis is integrated with a data-flow analysis framework that performs alias and data-flow analysis simultaneously. Whenever a new instruction is processed by the data-flow analysis, the alias analysis updates the global alias graph accordingly. We provide more details about the alias graph structure and the graph updating algorithm in §A.1 in the Appendix.

4.3 Two-Dimensional Data-Flow Analysis

Previous work has tried to utilize data-flow analysis or point-to analysis to resolve icall targets [30, 49, 55, 61]. These techniques attempt to establish the data-flow or alias relationships between icalls and address-taken functions directly. However, for large-scale programs (e.g., OS kernels), these relationships can be very complex and intricate, which leads to inefficiency, imprecision, and unsoundness of existing data-flow based analysis methods [29, 42].

Our key observation is that existing multi-layer type analysis can effectively reduce the false positives of icall analysis by exploiting the rich layered struct type information, but such information is often obscured by complex data-flows. Therefore, improving icall analysis does not necessarily require a complete data-flow analysis between icalls and their targets, but a lightweight type information mining. Based on this insight, we present a two-dimensional data-flow analysis to improve icall analysis. Specifically, it aims to analyze not only the direct data-flow relationships between icalls and their targets, but also icall-related layered struct type information across inter-procedural contexts.

4.3.1 Icall Data-Flow Relation Analysis

Bidirectional Data-Flow Analysis. To obtain rich data-flow information, `TFA` analyzes the data-flows of icall traces inter-procedurally from two directions, i.e., *bidirectional data-flow analysis*. (1) A backward data-flow analysis that starts from an icall and identifies the possible address-taken functions that can be its targets. After completing the backward analysis, `TFA` calculates the intersection of the alias set of the icall and the result of multi-layer type analysis to obtain the final icall targets. (2) A forward data-flow analysis that starts from an address-taken function and determines which icalls can have it as one of their targets. For icalls that are not in the alias set of the address-taken function, `TFA` can safely exclude the address-taken function from their target sets.

Fall Back Strategies. Occasionally, data-flow analysis may confront cases that compromise analysis soundness and result in false negatives. To cope with this problem, we have introduced several early termination conditions designed to preserve soundness while balancing effectiveness and efficiency. The data-flow analysis halts and the results are conservatively reverted to type analysis upon triggering any of the specified conditions:

- **The number of the aliased value reaches the threshold.** `TFA` allows users to specify a maximum number (500 by default) of values that are aliased with the input value (e.g., an icall pointer). `TFA` terminates the data-flow analysis when the number of aliased values reaches the limit and falls back to type analysis.
- **The input value is aliased with assembly code.** Assembly code is currently out of the scope of our analysis. Therefore, when the input value is aliased with assembly calls, `TFA` terminates the data-flow analysis and falls back to type analysis. In addition, `TFA` also stops the data-flow analysis when the subgraph includes global variables named `llvm.compiler.used` (`llvm.used` in LLVM 14 and earlier versions). Usually, this could happen when the program initializes and updates global variables through assembly code (e.g., Linux static calls).
- **The input value is aliased with arithmetic operated values.** A pointer value may be modified by arithmetic operations in practice. Static analysis of its alias set is still an open challenge, and the soundness of the results is hard to guarantee. Therefore, `TFA` terminates the data-flow exploration in this case and falls back to type analysis.

4.3.2 Icall-Oriented Type Mining

The state-of-the-art multi-layer type analysis achieves more precise icall analysis by utilizing richer layered struct type information. However, in large programs (e.g., OS kernels), the storage relationships between structural types and icalls could be complex (e.g., involves inter-procedural data-flows). As a result, existing methods fail to resolve these cases, which limits the effectiveness of MLTA. `TFA` aims to resolve this problem through data-flow based type mining. However, type mining can be costly and impractical for programs with a large number of structural types. To address this problem, we present *icall-oriented type mining*, a technique that focuses on tracking and extracting type information that is relevant to indirect call analysis from two perspectives.

Type Mining for Icalls. We found that many indirect function calls with nested type information are not handled correctly in multi-layer type analysis. A common case in the Linux kernel is illustrated in Figure 7. Multi-layer type analysis assumes that the indirect call at line 4 lacks any enclosing struct type information and resorts to one-layer type analysis.

```
1  /* sound/core/pcm_lib.c */
2  static int interleaved_copy(..., pcm_transfer_f transfer) {
3      ...
4      return transfer(...); //No outer-layer type in MLTA
5  }
6
7  snd_pcm_sframes_t __snd_pcm_lib_xfer(...) {
8      ...
9      pcm_copy_f writer;
10     pcm_transfer_f transfer;
11     ...
12     writer = interleaved_copy; //An icall of interleaved_copy
13     ...
14     transfer = substream->ops->copy_kernel;
15     ...
16     err = writer(..., transfer);
17 }
```

Figure 7: Example of hidden layered type.

However, there is a caller of `interleaved_copy()` at line 16, which passes a function pointer `transfer` as an argument. The origin of `transfer` reveals that it does have an enclosing type `substream->ops->copy_kernel` at line 16.

To make these icalls benefit from multi-layer type analysis, we perform a backward data-flow analysis starting from them and track their origins. `TFA` conducts an inter-procedural analysis to determine if an icall is derived from a struct field, which indicates aliasing with a struct field. Unlike the previous data-flow analysis, this phase terminates early when an aliased value with nested type information (i.e., GEP instructions in LLVM IRs) is encountered during data-flow propagation.

Type Mining for Undecidable Targets. Multi-layer type analysis requires recording the confined targets for a struct type. However, this could be infeasible when a struct field has an undecidable target (i.e., *type-escaping* [42]). Figure 8 illustrates a typical case in the Linux kernel. A function pointer is assigned to the `detach` field of the struct pointer `ap` at line 7, which has the type `struct drm_aperture`. Since the function pointer originates from the argument (`detach` at line 3), its potential identities cannot be determined by type analysis alone. Multi-layer type analysis maintains a global map to record the fields of structs that encounter type-escaping (e.g., `drm_aperture->detach` in this case). When an indirect call has an escaped outer-layer type (e.g., the indirect call at line 16), multi-layer type analysis will fall back to one-layer type matching conservatively to ensure soundness.

`TFA` addresses this problem through backward data-flow tracking. In this example, we choose the function pointer whose source is undecidable (i.e., `detach` at line 3) as the starting point of data-flow analysis. `TFA` precisely identifies the origin of the input pointer (`drm_aperture_detach_firmware()` at line 22). This allows us to eliminate the escaped layered types (`drm_aperture->detach`) from the global escaping map. As a result, more icalls could benefit from MLTA.

Mutual Enhancement. Our type mining approach for indirect calls has a remarkable feature: its two analysis components can mutually enhance each other in the iterative data-flow analysis process. The type mining for indirect calls enables more indirect calls to benefit from the multi-level type analysis, but it also generates more undecidable targets. The type mining for undecidable targets effectively addresses this issue. This forms a positive feedback loop that improves the precision of indirect call resolution.

```
1  /* drivers/gpu/drm/drm_aperture.c */
2  static int devm_aperture_acquire(struct drm_device *dev, ...
3              void (*detach)(struct drm_device *)) {
4      ...
5      struct drm_aperture *ap;
6      ...
7      ap->detach = detach; //An undetermined pointer is stored
8  }
9
10 static void drm_aperture_detach_drivers(resource_size_t base,
11             resource_size_t size) {
12     ...
13     struct drm_aperture *ap = container_of(...);
14     struct drm_device *dev = ap->dev;
15     ...
16     ap->detach(dev); //Indirect call site
17     ..
18 }
19
20 int devm_aperture_acquire_from_firmware(...) {
21     ...
22     return devm_aperture_acquire(...,
23         drm_aperture_detach_firmware);
24 }
```

Figure 8: Example of type-escaping because of undecidable targets.

5 TFA Implementation

We have implemented `TFA` on LLVM of version 15-init as several analysis passes, which contains 12k lines of C++ code (including 1.7k LoC of the implementation [2] of `TypeDive` [42] for multi-layer type analysis). It accepts unlinked LLVM bitcode files as inputs, and outputs the analysis results into a local MYSQL database.

5.1 LLVM Bitcode Generation

We use an independent LLVM pass for bitcode generation, which uses LLVM API `WriteBitcodeToFile()` to dump bitcode files. We modify the Makefiles of our target programs to load this pass. We add `-g` flag into the CFLAGS of Makefiles to retain debug information for type recovery and icall information storage. Additionally, we have observed instances where the same struct type is compiled as a *packed struct* in certain modules and as a normal struct elsewhere, resulting in disparate struct layouts that affect the type recovery in `TFA`. To resolve this inconsistency, we employ the Clang compilation option `-mms-bitfields` to ensure uniform struct layouts across different modules.

[2] https://github.com/umnsec/mlta

5.2 Type Comparison

In TFA, we use struct type names to compare different struct types. For struct types with the same name in different modules, we include the struct's definition file as part of the struct name. The missed type names would be recovered through type recovery. However, developers could define struct or union types without names in C/C++. LLVM will automatically generate type names for them (e.g., `%union.anon.157`, `%struct.anon.8`). The type recovery of TFA conservatively regards them as invalid because different LLVM modules could generate different names for the same nameless struct field. This affects the type analysis when a function pointer is stored in a nameless field. In such cases, we fall back to one-layer type matching, which means that any icall that has the same function type as the function pointer can potentially target it. Fortunately, this limitation only affects 270 (0.4%) address-taken functions in the Linux kernel.

5.3 Multi-Layer Type Analysis

We adopt the implementation of existing state-of-the-art multi-layer type analysis as a part of TFA with necessary modifications. Specifically, we use the implementation [3] of TypeDive [42] with the following modifications: (1) We set the outer-layer number as two, so TypeDive executes two-layer type matching for icall analysis. Considering that we need to iteratively execute multi-layer type analysis, two-layer type matching is the most cost-effective type analysis for us. (2) We rewrite its type recording system to apply our type recovery approach.

5.4 Kernel Macro Optimization

The Linux kernel macro `EXPORT_SYMBOL` is frequently utilized to make functions from one kernel module available in other modules. Theoretically, it should not affect the analysis of icalls. However, the function pointer associated with this macro emits an LLVM IR pattern identical to that of assembly code, encompassing `llvm.used` for data-flow propagation and potentially causing premature termination of the analysis. To mitigate this issue, we meticulously examine the source code of each address-taken function by checking the corresponding LLVM metadata. Should a function be engaged with `EXPORT_SYMBOL`, TFA continues the data-flow propagation without interruption.

5.5 Supporting C++

In C++ programs, virtual function calls constitute a significant proportion of icalls. According to our manual analysis, such icalls are often devoid of sufficient outer layer type information. Furthermore, the analysis of data-flows associated with these icalls tends to be resource-intensive. Consequently, existing approaches for type or data-flow analysis tend to be ineffective for such icalls. To address this challenge, we employ the strategy outlined in TypeDive [42]. Specifically, we analyze the constructors of all C++ classes to catalog their virtual function tables (VTables). Upon the invocation of a virtual function call, we first identify the class issuing the call and subsequently pinpoint the precise callee function by referencing the corresponding VTable.

[3] https://github.com/umnsec/mlta

5.6 Convergence Checking

Previous works [30, 42, 68] evaluate the effectiveness of icall analysis based on the number of icall targets. In this paper, we adopt the same metric to compare the effectiveness of different analysis rounds of TFA. We consider the analysis to have reached convergence and terminate the analysis when the difference of icall targets between adjacent analysis rounds is less than 10,000.

6 Evaluation

We aim to answer the following research questions (RQs) in our evaluation.

- **RQ1:**Compared to existing methods, how effective and efficient is TFA in refining icall targets?
- **RQ2:** Could TFA guarantee the soundness after introducing data-flow analysis?
- **RQ3:** How do broken types affect icall analysis? Moreover, how effective is the type recovery in addressing this challenge?
- **RQ4:** Does TFA benefit real-world applications?

6.1 Experimental Setup

We evaluate TFA on top of a Linux server (Ubuntu 20.04.1) with 126GB RAM and an Intel Xeon Silver 4316 CPU at 2.30GHz (80 cores). We choose five widely used programs as the analysis targets: the Linux kernel (v5.18), the FreeBSD kernel (v12.4), the OpenSSL library (v3.0.6), the OpenCV library (v4.9.0), and MongoDB (v8.0.0). Additionally, for the Linux kernel, we built it with two different configurations: the `allyesconfig` to evaluate the scalability of TFA, and the `localmodeconfig` to emulate the most common kernel usage scenario.

6.2 Performance on Eliminating Icall Targets

TFA aims to eliminate false positives for icall analysis and provide a more fine-grained icall target result. Similar to existing

icall analysis works [30, 42, 68], we use the average icall target number to evaluate the performance of TFA on eliminating icall targets. We leverage the OpenMP library [15] to enable multi-core parallel acceleration for TFA, with a concurrency of 32 threads in our evaluation. Even for the Linux kernel, which comprises nearly 28 million lines of code, TFA could complete the entire icall analysis in two hours. This result is promising, given the complexity of the analysis task.

6.2.1 Performance Comparison with Existing Tools

Comparison with Type Analysis. We present the comparison of three icall target analysis methods in Table 1: signature (the most commonly used method), MLTA (the state-of-the-art method), and TFA. MLTA effectively reduces false positives compared with the signature matching method. In MLTA's paper [42], only icalls that have multi-layer type information are included in the evaluation. Therefore, it reports a higher precision. In comparison, our evaluation includes all icalls. The results indicate that TFA could further eliminate 24% to 59% of icall targets compared with state-of-the-art type-based MLTA method.

For C++ programs, multi-layer type analysis is suboptimal in eliminating redundant icall targets. The virtual function analysis method presented in §5.5 demonstrates superior performance. Even when both virtual function analysis and MLTA are applied, our system, TFA, succeeds in eliminating 44% to 56% of icall targets in C++ programs, thereby confirming its effectiveness.

Comparison with Program Modularization. We further compare TFA with TyPM [41], a program modularization based icall analysis approach. The basic idea of TyPM is to refine icall analysis by performing type matching locally within modules that have type dependencies, rather than globally as in existing techniques. We evaluate TyPM on the Linux kernel compiled with the `localmodeconfig` and measure its effectiveness in reducing icall targets. TyPM further eliminates 19.8% of icall targets compared with the results of MLTA. On comparison, TFA eliminates additional 55.4% of icall targets compared with MLTA for the same program, demonstrating the benefits of type and data-flow co-analysis of TFA.

Comparison with Abstract Interpretation. Abstract interpretation is a technique that projects a program's behavior into an abstract domain, systematically over-approximating the possible states of the program, and by extension, the potential targets of icalls. We investigated two representative tools: Frama-C [18] and Ikos [25]. Frama-C actually necessitates developers to explicitly annotate potential icall targets via specialized comments, which implies that precise and automated icall analysis remains unaddressed by this tool. Furthermore, an attempt to apply Ikos to the Linux kernel did not culminate within 12 hours, and a significant portion of the analysis was marred by substantial runtime errors arising from unsupported LLVM types, affecting approximately 40% of the modules. These observations indicate that for extensive codebases, abstract interpretation-based methods for icall analysis may lack scalability. TFA, in contrast, aims to provide a more feasible solution.

Comparison with Other Co-Analysis Method. KELP [26] shares a similar observation with TFA: a multitude of function pointers in icall analysis are straightforward and could be resolved through affordable data-flow analysis. KELP conducts localized pointer analysis for such functions and integrates this analysis with MLTA. As the source code of KELP was unavailable at the time of this paper's writing, and its icall analysis metrics appear to differ from those used by TFA, a high-level comparison is provided here for clarity and completeness. The primary distinctions in design between KELP and TFA are twofold: (1) KELP makes data-flow analysis as a separate preliminary stage prior to MLTA, whereas TFA integrates data-flow analysis and type analysis into a unified co-analysis framework, allowing for mutual enhancement. (2) KELP is designed for a single execution with an emphasis on efficiency, whereas TFA employs an iterative analysis to achieve greater accuracy.

6.2.2 Performance of Analysis Rounds and Phases

In this subsection, we conduct an in-depth evaluation of the performance across different analysis rounds within our two-dimensional data-flow analysis, as well as its distinct phases. Due to page constraints, we have selected the Linux kernel (kernel space C program), OpenSSL (user space C program), and MongoDB (user space C++ program) as representative targets for evaluation.

Analysis Rounds. Table 2 shows the numbers of the total icall targets that remain after each analysis round of TFA. The two-dimensional data-flow analysis utilizes the results of MLTA as its initial inputs. For MongoDB, the initial results incorporate virtual function analysis subsequent to MLTA. We found that the first analysis round eliminates the most icall targets. The convergence speed of our analysis depends on the size and complexity of the target software. Smaller software could reach convergence faster than larger software. However, even for OS kernel-level software, our analysis converges within three rounds. This demonstrates the effectiveness and efficiency of TFA for resolving indirect calls in real-world software.

Analysis Phases. We studied the impact of each analysis phase in our two-dimensional data-flow analysis, as presented in Table 3. The bidirectional data-flow analysis has the most significant effects on eliminating the number of icall targets for all the three programs. The two components of icall-oriented type mining also contribute substantially to the precision of our analysis.

Table 1: Icall target analysis results. Avg. indicates the average icall target number. Sig, MLTA, and MLTA+VH indicate the signature matching, multi-layer type analysis, and multi-layer type analysis + virtual function analysis, respectively.

System	Language	Bitcode Files	Total Icalls	Avg. (Sig)	Avg. (MLTA)	Avg. (MLTA+VH)	Avg. (TFA)	Analysis Rounds	Analysis Time
OpenSSL	C	1,309	2,200	32.3	27.5	27.5	20.9 (24%↓)	2	34s
Linux-loc	C	2,978	9,527	52.5	18.6	18.6	8.3 (55%↓)	2	4m 8s
FreeBSD	C	3,826	20,901	38.1	20.2	20.2	11.6 (43%↓)	3	19m 4s
MongoDB	C++	4,406	23,885	34.8	30.0	11.7	6.6 (44%↓)	2	1h 57m
OpenCV	C++	1,583	33,602	44.5	44.5	32.6	14.2 (56%↓)	2	42m 2s
Linux-all	C	21,438	73,163	161.7	44.9	44.9	18.6 (59%↓)	3	1h 59m

Table 2: Results of different analysis rounds of TFA. Each number in the table indicates the number of total icall targets after the current round of co-analysis analysis.

Systems	Init	Round1	Round2	Round3
Linux-all	3,288,024	1,465,868	1,360,894	1,358,831
OpenSSL	60,417	46,224	46,038	-
MongoDB	279,272	158,971	158,177	-

Table 3: Results of different analysis phases of two-dimensional data-flow analysis. The BDA in the table indicates the bidirectional data-flow analysis. The TM-I and TM-UT indicate type mining for icalls and undecidable targets, respectively. Each number in the table indicates the reduced number of total icall targets brought by corresponding analysis phases.

Systems	BDA	TM-I	TM-UT
Linux-all	1,157,344	362,363	409,486
OpenSSL	7,204	1,501	5,674
MongoDB	94,968	8,633	17,494

6.3 False Negative Analysis

One important concern for TFA is to ensure the soundness of the data-flow analysis results. In this subsection, we present the false negative analysis of TFA and the method we used to collect icall traces as the ground-truth for evaluation. We selected the Linux kernel and OpenSSL library as the evaluation targets in this section.

6.3.1 Trace Collection

We collect icall traces through LLVM instrumentation for the Linux kernel. Specifically, we compile the kernel with Clang and insert a hook function that records the icall information before each icall site. This function logs the source location and the callee name of each icall to the system log. We implement the function in the kernel source code and make it globally visible. It utilizes the kernel API `sprint_symbol()` to retrieve the callee names from their addresses. We also filter out any duplicate traces before logging them to simplify the subsequent trace analysis. To obtain a sufficient number of icall traces, we run the Linux Test Project [12] on the Linux kernel. We finally collect 6,929 unique traces. Our instrumentation is implemented as an LLVM pass with 230 lines of C++ code.

The tracing strategy of OpenSSL is similar to the OS kernels, where we also instrument the program to collect traces. To obtain the name of the callee function from the symbol table, we initially attempted to use the Linux API `dladdr()`, but this API often failed and returned empty results. Hence, we leveraged the *LLVM prefix data* to identify callees. In particular, we assigned a fixed-size function name as the prefix data for every address-taken function, which could be accessed with a fixed offset from the function's entry point. We compiled the hook function as a static library and linked it to OpenSSL by modifying its Makefile. We stored the icall traces in a local MYSQL database. We used the *openssl speed* [16] benchmark to collect icall traces and obtained 851 unique traces in total.

6.3.2 Results for False Negative Analysis.

We apply two criteria to select the icall traces that are valid for our analysis. First, we discard traces that do not have valid callee names, which indicates that the symbols are not resolved correctly. Second, we exclude traces that have mismatched icall or callee locations with the source code, which implies that the binary code is not consistent with the source code. After applying these filters, we obtain 6,452 unique and valid icall traces from the Linux kernel and 683 traces from the OpenSSL library.

FN Results of the Linux Kernel. TFA only misses two callees in our analysis, which come from two icalls in function `__apply_relocate_add()`. Specifically, these two icalls miss the same callee: `__memcpy()`. The reason for the two false negatives is that our *type analysis* phase fails to identify the callee. We examine the whole kernel code and discover that the address of `__memcpy()` is never assigned to any pointer (i.e., it is not an address-taken function). There are only a few direct calls to this function. Therefore, `__memcpy()` is

not considered as a possible icall target by our type analysis, even when we use signature matching. We also investigate the icall target sets produced by TFA, and we notice a wrapper function of `__memcpy()`: `memcpy()`. We suspect that some compiler optimizations replace `memcpy()` with `__memcpy()` and cause this false negative.

FN Results of the OpenSSL Library. We identified 58 false negatives in OpenSSL in total. We investigate these cases and find all of them are missing since *type analysis* (signature matching). In particular, the OpenSSL tends to define icalls with general parameter types (e.g., `void *`). However, the actual parameters could cast to other types (e.g., `MD5_CTX *`). This is a common challenge for many existing icall analysis works [30, 42, 58], and leads to false negatives even for signature matching. One feasible solution for this problem is conservatively equating void pointers with any other pointer types. We applied this approach to TFA and reevaluated its performance on the OpenSSL library. The average number of icall targets for both signature matching and MLTA increased significantly (63.6%↑ and 60.2%↑). However, the impact on TFA was relatively small (12.1%↑). Moreover, this approach eliminated all false negatives for TFA.

> ***Finding 1:*** The data-flow analysis of TFA does not introduce more false negatives than existing type-based analysis methods. TFA performs better when we adopt more conservative type analysis methods.

6.4 Effectiveness of Type Recovery

To better understand how broken types impact type-based analysis, in this subsection, we use the traces collected from the Linux kernel to check the effectiveness of our type recovery.

6.4.1 Broken Struct Type Recovery

To evaluate the impact of broken struct types in §2.2.1, we build a Linux kernel with O0 optimization and turn off the type recovery feature in TFA. We then reexamine the icall analysis outcomes. The number of false negatives for the Linux kernel rises to 879 (13.6%). Figure 9 illustrates a typical false negative case in the Linux kernel, where the callee `con_write_room()` is omitted for the icall at line 4. The omitted callee is assigned to the `write_room` field of struct type `tty_operations` at line 13. Ideally, when the icall is generated from the same field of the same struct type (i.e., the `ops->write_room` at line 4), the callee should have been detected as a possible target. However, the representations of the struct type `tty_operations` are inconsistent in the two LLVM bitcode files, where one of them represents two function pointers' types as `{}*`. Consequently, type analysis considers them as distinct struct types, which results in false negatives. By

```
1  /* drivers/tty/tty_ioctl.c */
2  unsigned int tty_write_room(struct tty_struct *tty){
3      if (tty->ops->write_room)
4          return tty->ops->write_room(tty);
5      return 2048
6  }
7
8  /* drivers/tty/vt/vt.c */
9  static unsigned int con_write_room(struct tty_struct *tty){...}
10
11 static const struct tty_operations con_ops = {
12     ...
13     .write_room = con_write_room,
14     ...
15 };
16
17 // struct tty_operations in tty_ioctl.bc
18 %struct tty_ioctl_operations = type {... {}*, {}*, ...}
19
20 // struct tty_operations in vt.bc
21 %struct tty_ioctl_operations = type {... i32 (%struct.tty_struct*)*,
22 i32 (%struct.tty_struct*)*, ...}
```

Figure 9: False negative example of MLTA in the Linux kernel.

applying type recovery, we can eliminate all false negatives caused by broken struct types.

6.4.2 Optimized GEP Instruction Recovery

To evaluate the impact of optimized GEP instructions, we build a Linux kernel with O2 optimization and disable the GEP instruction recovery in TFA. We repeat the icall analysis results and observe that the number of false negatives rises to 80. The main sources of false negatives are imprecise storage analysis of address-taken functions and nested struct fields, which require accurate identification of nested struct types and field indices from GEP instructions. By applying type recovery, we successfully eliminate 77 false negatives. There is one additional false negative compared to the previous experiment due to a GEP instruction that performs an implicit type casting. Since this scenario is rare, we leave it as future work.

> ***Finding 2:*** The broken types significantly influence the soundness of type analysis. The type recovery in TFA effectively prevents false negatives introduced by broken types.

6.5 Application I: Fine-Grained CFI

We implemented a forward-edge CFI scheme that leverages our fine-grained icall analysis results, which is built based on the KCFI sanitizer [10, 11]. It prevents control-flow hijacking attacks by disallowing changes to the pre-defined CFG. Currently, our CFI scheme is implemented on LLVM IRs in Clang compiler to support various backends. We load the valid target sets from the database during compilation and encode them as read-only data. We utilize LLVM prefix data to determine which function will be called before we emit the icall. We insert a verification function before each icall to check if the callee belongs to the corresponding target set.

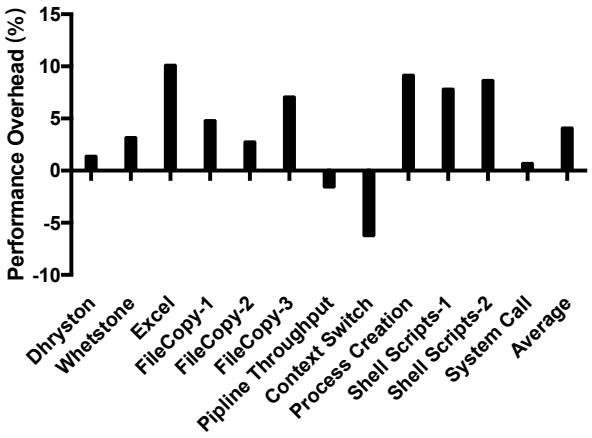

Figure 10: Overheads of the CFI scheme.

If an invalid function is invoked, the CFI scheme redirects the control flow to a user-defined error-handling function for further debugging. Our scheme is compatible with any forward-edge CFI scheme that allows specifying a target set for each independent icall (e.g., Clang CFI [58]).

We measured the performance of our forward-edge CFI scheme on a Ubuntu virtual machine with 4 CPUs (Intel Core i7-8770 CPU, 3.20Ghz). We used the UnixBench 5.1.2 [17] as the benchmark, which offers a diverse range of workloads and is widely used in CFI evaluation [30, 37]. Compared with the original system without CFI protection, the average system performance decreased only by 4.1% on average. The detailed overheads of each task are shown in Figure 10. The evaluation result confirms that our fine-grained CFI scheme is feasible in practice. Notably, we observed negative overheads, a phenomenon also reported in other CFI research [30]. This improvement may be attributed to the CFI instrumentation altering the code layout, resulting in enhanced code alignment or more efficient utilization of the instruction cache, thereby accelerating context switches. The overhead of the CFI could be further optimized through architecture-specific (e.g., x86) implementation, which is mainly an engineering effort. We leave this part as further work.

6.6 Application II: Bug Detection

One of the potential applications of icall analysis is static bug detection, which requires a precise CFG for inter-procedural analysis. We leverage our fine-grained icall analysis to analyze the Linux kernel, focusing on a specific type of icalls: the release call-back functions in devices. These functions are responsible for resource cleanup when a device is no longer in use. They are controlled by reference counting and assigned by the device allocators. However, the device allocators may also have their own error handling code for resource cleanup, which could conflict with the release call-back functions. This scenario involves three challenging mechanisms for static analysis: indirect-call, reference counting, and error handling. Existing methods typically overlook this scenario and only address one of these mechanisms [33, 34, 43, 46, 56, 57, 65].

TFA Assisted Trace Analysis. To understand the triggering mechanism of the release callback, we perform a trace analysis in the first step. We use the icall analysis results generated by TFA and trace backward from a callback function. The trace consists of six function calls originating from `put_device()`, among which three are indirect calls. TFA accurately determines that the three indirect calls have only one caller each. With TFA's assistance, a non-expert researcher can complete this task in 15 minutes. If we use type analysis instead of TFA's co-analysis for icall target identification, there would be 64 possible callers of the release callback, and we would have to manually examine all these callers and their transitive callers.

Bug Detection. From the trace analysis, we identify that the release callback is invoked by `put_device()` after the device reference count reaches zero. In this step, we use TFA to detect two types of bugs in the release callbacks: (1) redundant cleanup, which may lead to use-after-free or double-free vulnerabilities, and (2) missing resource release, which may cause memory leaks. We compared the release callback code with the error handling code after `put_device()` in the device allocators to detect these bugs. Out of 243 release callbacks generated by co-analysis, TFA reported nine bugs. We manually verified them and found eight real bugs, including six double-free bugs and two memory-leak bugs, as shown in Table 4. Three of them have been fixed by other developers in the latest kernel. We submitted patches for the remaining bugs and four of them have been applied. If we use type analysis instead of co-analysis, we would have 671 potential release callbacks, and 63.8% of them would be false positives, which would make the bug detection ineffective.

Table 4: List of bugs detected in the Linux kernel. The S, A, and F in the Status column indicate submitted, applied, and fixed by other developers in the latest version, respetively.

Bug function	Impact	Status
zfcp_port_enqueue	Double-free	A
ptp_ocp_device_init	Double-free	A
ocxl_file_register_afu	Double-free	F
rpmsg_virtio_add_ctrl_dev	Double-free	F
rpmsg_probe	Double-free	F
stm_register_device	Double-free	S
css_alloc_subchannel	Memleak	A
i3c_master_register_new_i3c_devs	Memleak	A

7 Discussion

Assembly Code Analysis. At present, TFA does not have the capability to analyze assembly code. When encountering assembly code, we adopt a conservative approach and terminate

the data-flow analysis, falling back to type analysis. Prior works [30, 37] rely on manual analysis to resolve indirect calls and jumps in assembly code. We manually checked some failure cases due to assembly calls in the Linux kernel and found many of them are introduced by a new feature called *Linux static call*. We plan to design a dedicated analysis pass for this feature in our future work.

Type Analysis in LLVM. In addition to the broken types discussed in §2.2, prevalent type analysis methods, such as signature matching, also falter due to type casting. For instance, unexpected type casting can engender substantial false negatives in the analysis of icalls within the OpenSSL library. To address this problem, Ge et al. used taint analysis to infer icall targets [30]. IFCC [58] used two more conservative approaches to construct icall target set: *Single* (which collects all functions into a single set) and *Arity* (which infers icall targets according to the number of arguments). FINE-CFI [37] presented some IR-based methods to address this problem, but they were ineffective for eliminating the false negatives in our analysis. As a result, LLVM 16 introduces an *opaque pointer type* to replace all pointer types containing their point-to types, due to various issues with the latter [14]. Furthermore, typed pointers have been deprecated in LLVM 17+, as the LLVM community discourages the reliance on LLVM's internal type system for conducting type-based analyses. Nevertheless, the latest LLVM releases have introduced 'tbaa' metadata [19], designed to represent the type system of higher-level languages and aid in type analysis. This metadata has been employed in the implementation of type-based alias analysis. We posit that this feature holds considerable promise as a solution, and we propose the examination of this new capability as an avenue for future work.

8 Related Work

Indirect-Call Analysis for CFI Schemes. CFI schemes usually give priority to the soundness of icall analysis. Many existing CFI schemes adopt Single or Arity to construct icall targets [58, 59, 66, 67]. These methods do not rely on type information and can be applied to binary executables. A more precise approach is to use the types of function pointers to match icall targets [10, 48, 50], but this approach suffers from soundness degradation due to primitive type casting. Recently, some CFI schemes have leveraged the idea of MLTA to further refine icall targets [30, 37]. However, they do not address the problem of broken types, which can affect the security of CFI. In this paper, we systematically study the causes and impacts of this problem and propose a type recovery system to solve it.

Indirect-Call Analysis for Bug Detection. Icall analysis is essential for static bug detection, which relies on a global CFG to perform inter-procedural analysis. A common challenge for this task is the high false positive rate caused by inaccurate icall analysis. Therefore, some tools opt to ignore icalls altogether [33, 38, 45]. Many static bug detection tools adopt one-layer type matching to resolve icalls (e.g., Deadline [63], LRSan [60], and K-MELD [28]). When multi-layer type analysis was introduced, it was quickly applied to bug detection [22, 32, 39, 52, 62]. Recently, *directed fuzzing* also demands precise icall analysis to calculate the cross-function distance [44]. We believe `TFA` could benefit both existing and future static or dynamic analysis.

Type and Data-Flow Co-Analysis. Ghavamnia et al. proposed two filtering schemes to refine the results of Andersen's points-to analysis and obtain more accurate icall targets [31]. These schemes exactly perform one-layer type matching, which do not exploit the rich layered type information for optimization. FINE-CFI [37] introduced the concept of *struct location vector* to enable two-layer type analysis. However, when an icall originates from a function argument, FINE-CFI falls back to one-layer type matching. The data-flow analysis approach of `TFA` could effectively resolve this problem. Ge et al. applied taint analysis from address-taken functions for icall analysis [30]. When a function pointer is assigned to a struct's field, all memory objects of this struct's field are tainted, which is similar to two-layer type matching. This method relies on two strict assumptions on function pointer operations to support its taint analysis. When a violation occurs, users have to interrupt the analysis and manually resolve it. `TFA` does not make any assumptions or require frequent manual intervention. `TFA` also improves the icall analysis through mining the hidden layered types, which is missed by existing methods.

9 Conclusion

In this paper, we present `TFA`, which performs type and data-flow co-analysis to optimally resolve indirect-call targets. We also propose several techniques to enhance the scalability, soundness, and precision of `TFA`. We evaluate `TFA` on five famous C/C++ programs, and show that `TFA` could further eliminate 24% to 59% of indirect-call targets compared with the state-of-the-art approaches. We also apply `TFA` to improve the security of forward-edge CFI and the ability of static bug detection. As a generic technique, we believe that the precise indirect-call analysis of `TFA` can benefit various security research domains.

A Appendix

A.1 Customized Alias Analysis

A.1.1 Alias Representation

Figure 11 shows an example of alias graph, in which we define four variables: `a`, `b`, `c`, and `d`. The alias graph of this code snippet consists of three nodes. Each node represents an *alias set*, whose member pointers are aliased with each other. An edge in the alias graph represents a pointer dereference operation. In this paper, the single alias graph is always linear, as shown in the example. Multiple subgraphs constitute the global alias graph that represents the alias relationships for a program.

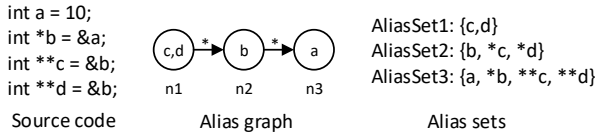

Figure 11: Alias graph and alias set.

A.1.2 Graph Building and Updating

The alias analysis mainly focuses on three types of alias relationships: `Move` (i.e., $v_1 = v_2$), `Load` (i.e., $v_1 = *v_2$), and `Store` (i.e., $*v_2 = v_1$). Figure 12 shows the graph updating process while handing these alias relationships.

Handle Move. The `Handle_Move()` accepts three parameters: the two values v_1 and v_2 with move relationship ($v_1 = v_2$), and the global alias graph `G`. The algorithm first gets the two nodes which v_1 and v_2 belong to respectively, namely n_1 and n_2 (line 1 and line 2). If v_1 or v_2 does not belong to any node in `G`, `GetNode()` will create a new node for it and add it into `G`. It then merges these two nodes into one that contains all values of the original two nodes (line 3). If n_1 or n_2 has a predecessor or successor node, `MergeNode()` will recursively execute node merging for the two alias graphs that contain

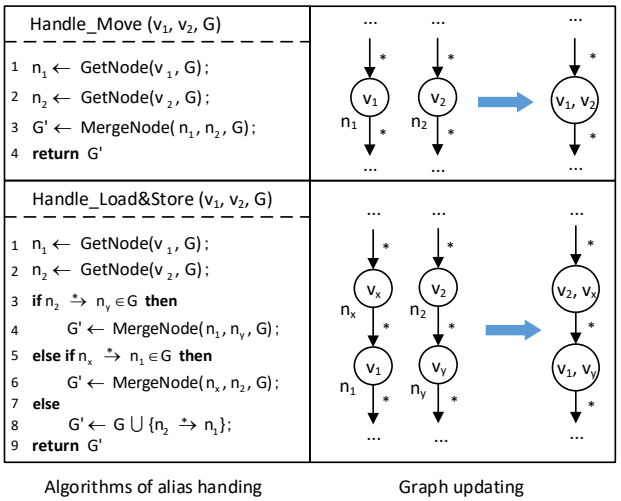

Figure 12: Alias graph building.

n_1 and n_2. The global alias graph will be updated to `G'` after `Handle_Move()`.

Handle Load & Store. The logic for handling `Load` ($v_1 = *v_2$) and `Store` ($*v_2 = v_1$) is the same, where the algorithm also takes two values (v_1 and v_2) and a global alias graph `G` as inputs. It then gets the two nodes that v_1 and v_2 belong to (i.e., n_1 and n_2) and checks whether there exists an edge that starts from n_2 and ends at another node (e.g., n_y) in `G` (line 3). If so, the algorithm will execute a recursive node merging the same way as handling `Move` for n_1 and n_y (line 4). If not, the algorithm then checks whether there exists an edge ending at n_1 and starting from another node (e.g., n_x) in `G` (line 5). If the edge exists, the algorithm recursively merges n_x and n_2 (line 6). If none of the above-mentioned cases happen, we only need to add a new edge starting from n_2 and ending at n_1 into `G` (line 8).

ChainReactor: Automated Privilege Escalation Chain Discovery via AI Planning

Abstract

Current academic vulnerability research predominantly focuses on identifying individual bugs and exploits in programs and systems. However, this goes against the growing trend of modern, advanced attacks that rely on a sequence of steps (i.e., a chain of exploits) to achieve their goals, often incorporating individually benign actions. This paper introduces a novel approach to the automated discovery of such exploitation chains using AI planning. In particular, we aim to discover privilege escalation chains, some of the most critical and pervasive security threats, which involve exploiting vulnerabilities to gain unauthorized access and control over systems. We implement our approach as a tool, ChainReactor, that models the problem as a sequence of actions to achieve privilege escalation from the initial access to a target system. ChainReactor extracts information about available executables, system configurations, and known vulnerabilities on the target and encodes this data into a Planning Domain Definition Language (PDDL) problem. Using a modern planner, ChainReactor can generate chains incorporating vulnerabilities and benign actions. We evaluated ChainReactor on 3 synthetic vulnerable VMs, 504 real-world Amazon EC2 and 177 Digital Ocean instances, demonstrating its capacity to rediscover known privilege escalation exploits and identify new chains previously unreported. Specifically, the evaluation showed that ChainReactor successfully rediscovered the exploit chains in the Capture the Flag (CTF) machines and identified zero-day chains on 16 Amazon EC2 and 4 Digital Ocean VMs.

1 Introduction

Current vulnerability research focuses on identifying individual security bugs in the ever-evolving cybersecurity landscape. Several state-of-the-art techniques are employed in this endeavor. Fuzzing [17, 37], for instance, involves providing inputs to a program to detect various vulnerabilities. It is an automated process that can quickly cover a large code base and discover flaws that might be overlooked during manual testing. Symbolic execution [4] is another vulnerability detection technique that systematically explores feasible paths of a program by treating inputs as symbolic values instead of concrete ones. This method effectively uncovers edge-case vulnerabilities by considering heavily guarded execution paths, thus identifying non-trivial conditions that could lead to a security breach. Static analysis [8], both for source code and binaries, is also widely used in vulnerability detection. This approach examines code without executing it to find problematic coding patterns, insecure coding practices, and other potential sources of vulnerabilities.

While some vulnerabilities, such as those in the Linux kernel, can offer an attacker complete control over a system, others are less severe. The presence of a vulnerability does not necessarily translate into a severe threat, as the implementation of anti-exploitation techniques might counterbalance its potential impact. These techniques, such as Control Flow Integrity (CFI) [6] or Address Space Layout Randomization (ASLR) [66], restrict how an attacker can exploit a discovered bug, thus limiting potential damage. Therefore, in modern exploitation scenarios, a single vulnerability may not be sufficient to achieve the attacker's objectives. Security competitions and research efforts targeting real-world software, like Pwn2Own [30] and Google Project Zero [22], highlight the need to develop multi-step exploits.

These steps form a chain where each link, though not necessarily exploiting a critical vulnerability, contributes to the system's eventual corruption. Consequently, the significance of each vulnerability is assessed not merely by the additional attacker capabilities it provides but by its role within the exploitation chain. This includes the number of additional exploits it enables and its contribution to moving the attacker closer to the final step in the desired chain. Furthermore, within the context of an exploitation chain, some benign actions may be necessary for the attacker to get closer to reaching their exploitation goals.

A simple example of the chaining of two vulnerabilities was demonstrated at the Pwn2Own Vancouver event in 2023 [73]. In this case, the attack used an uninitialized variable bug

(CVE-2023-20870 [47]) and a stack-based buffer overflow (CVE-2023-20869 [46]) in VMware Workstation to escalate from a guest OS and execute code in the underlying hypervisor. The first vulnerability involved the misuse of an uninitialized variable within VMware's virtual Bluetooth USB device, leading to an information leak. The second exploit took advantage of a stack-based overflow in the Service Discovery Protocol (SDP) – a feature of the same virtual Bluetooth USB device. Combined, these vulnerabilities allowed the execution of arbitrary code from the guest OS in the context of the hypervisor. This instance illustrates the concept of exploit chains, where multiple vulnerabilities are exploited in a sequence to achieve an attacker's goal, underscoring the need for our approach to automated exploit chain identification.

Currently, the identification of exploitation chains is mostly a manual process. However, the complexity of modern operating systems and execution environments might hide subtle interactions among their components, making it a daunting task for an expert to discern the most suitable path among the myriad possibilities.

To address this issue, we present a systematic approach to automated exploitation chain identification in this paper. Our approach is a classical AI planning problem, encoding the system's initial state (pre-attack) and the goal state (specifying the attacker's objectives). To extract chains, we automate gathering information about the capabilities available to the attacker on the target system. These capabilities represent the possible actions an attacker can perform on the system, from executing specific commands (e.g., downloading content, reading or writing files, and linking specific libraries) to manipulating system configurations or exploiting vulnerable binaries (e.g., binaries with assigned Common Vulnerabilities and Exposures (CVE) numbers [41]). In addition to identifying the presence of standard system binaries (e.g., `cp`), we employ GTFOBins [54], a database that associates specific system binaries with their potential roles in post-exploitation activities (e.g., downloading content). We automatically identify other aspects of system interactions, such as manipulating incorrect permissions in file configurations and system services, which could further expand the attacker's capabilities.

After obtaining the capabilities, we encode them into the initial state of the planning problem as facts. This is done by defining a specific predicate for each capability type and instantiating it. Then, for our planning problem, we select as the goal state the attacker's ability, starting from an unprivileged shell, to gain complete control of the system (i.e., obtaining a root shell) or obtain a shell as another user with higher privileges. ChainReactor does not focus on any particular kind of privilege escalation chain, as the specific instantiation is decided by the planner, which combines the actions based on the facts provided initially, or derived by applying other actions. For instance, if the system has misconfigured permissions, they might be used in the exploit chain, but the planner is not forced to use them.

In this paper, we make the following contributions:

- We introduce the first automated approach for exploit chain discovery based on AI planning.
- We develop a novel method for automated extraction of system programs and configurations, translating them into a format that AI planners can reason with.
- We evaluate ChainReactor on a benchmark of 3 known VMs with privilege escalation bugs and then proceed to test it on 504 Amazon EC2 and 177 Digital Ocean instances as real-world scenarios, identifying 16 and 4 zero-day chains as plans, respectively.
- Lastly, we demonstrate how we can transform the planner's outputs into operational exploitation sequences, obtaining working exploits for all chains that ChainReactor discovered.

2 Background

2.1 Privilege Escalation

Privilege escalation involves exploiting a bug, design flaw, or configuration oversight in an operating system or software application to gain elevated access to resources that are typically protected from (unavailable to) an unprivileged application or user. This can occur in two forms: horizontal privilege escalation, where a user gains the privileges of another user, and vertical privilege escalation, where a user with lower privileges can obtain higher privileges, usually those of a system administrator, also referred to as `root`.

2.2 Planning

Planning Domain Definition Language (PDDL), an expressive language that describes planning domains and problems has become a standard input for AI planners – solvers that generate sequences of actions to transition from an initial state to a goal state [18].

The strength of these AI planners lies in their ability to efficiently search an ample space of possible states and actions to find an optimal (or, at least, satisfactory) plan. PDDL's structure is split into domain and problem files, ensuring a clear distinction between universal problem space aspects and individual problem instance specifics. In the context of our research, this design facilitates the modeling of Unix systems (e.g., user permissions, file hierarchy) and the encoding of attacker goals as problem files, highlighting the potential of AI planners as tools for security analysis.

The *domain file*, serving as a blueprint of the problem space, describes the types of entities or objects in the domain, categorizing them into different classes. These objects, ranging from tangible entities such as robots or tools to abstract concepts such as tasks or states, are instances of specific types

defined within the domain file. In our domain, the entities include system users, groups, different types of files - including executables and directories - and file system permissions. Complementing the objects in the domain file are predicates, representing properties or relationships between the objects. Predicates, essentially Boolean functions, return true or false, depending on the state of the objects they refer to. For instance, a predicate could be `(user_group ?user ?group)`, which is true if the user `?user` is part of the group `?group`, i.e., there is an instantiation with concrete objects replacing `?user` and `?group` parameters that make the predicate true. The domain file further defines the actions or operators that can be performed within the domain. Each action is described in terms of its parameters, preconditions, and effects. Preconditions, often expressed in terms of predicates, specify the conditions for executing the action. At the same time, the effects describe how the action modifies the truth values of certain predicates. Considering an action whose goal is to write to a file, a precondition could be `(executable_can_write_to_file ?executable ?file)`, which needs to be true for an executable `?executable` to be able to write to a file `?file`.

In contrast, the *problem file* specifies a particular problem instance within the defined domain. It provides a concrete definition of the initial state of the domain, describing which predicates are true and false at the beginning of the planning process. The problem file also defines the objects and goal state, usually expressed as a conjunction of predicates, specifying the conditions that must be met to solve the problem.

Together, the domain and problem files form a comprehensive and flexible framework for defining problems in PDDL. The domain file provides the general structure and rules of the problem space, while the problem file offers the specific details of the problem instance.

3 Motivation & Threat Model

An exploitation chain is necessary when achieving an attacker's goal requires multiple steps. This often occurs when the initial access to a system is limited, necessitating a series of actions to compromise the system. In this process, the attacker leverages a combination of specific vulnerabilities and generic system capabilities. These generic system capabilities - such as file access permissions - are integral building blocks for system interaction. Unlike vulnerabilities, which introduce additional or unexpected capabilities, these system capabilities are consistently present and fundamental to the system's operation. These inherent capabilities can provide an attacker with other avenues for exploitation, making them a crucial component of the exploitation chain where every step is designed to escalate privileges or gain additional access, building on the foothold established by the previous step.

3.1 Motivating Example

We present the scenario outlined in Figure 1 to highlight the necessity of chaining vulnerabilities for effective privilege escalation. This scenario is inspired by findings in our experimental evaluation, which revealed multiple Linux systems with CVE-affected binaries and misconfigurations.

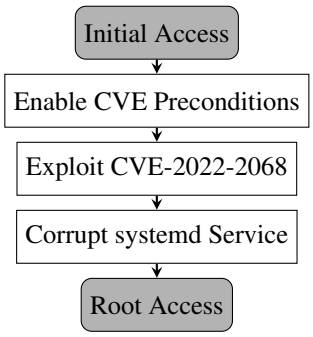

Figure 1: Exploitation steps for the motivating example.

The system in our scenario comprises three users: *Alice*, *openssl*, and *root*. Initially, the attacker controls *Alice*'s account, a basic user account without any special privileges. The goal of the attacker is to obtain root access. In our scenario, the attacker first targets CVE-2022-2068 [44]. This OpenSSL vulnerability arises from the application's failure to properly sanitize shell meta-characters in the file names of certificates being hashed. Under normal circumstances, these files are not directly accessible to non-privileged users, but through a misconfiguration, an attacker might inject malicious content into these file names. After exploiting the OpenSSL vulnerability, the attacker leverages their newly-gained privileges to tamper with a system service file, enabling them to execute code as *root*. The following discussion describes the steps needed to exploit the system in more detail:

1. **Enabling CVE Preconditions** The first finding is a misconfiguration of the directory `/etc/certs/`, inadvertently set to allow write permissions for non-privileged users. Non-privileged users, such as the account controlled by the attacker (*Alice*), should be unable to write or modify files in this directory. This misconfiguration is important because CVE-2022-2068 requires the attacker to feed maliciously crafted file names to OpenSSL. A non-privileged user typically cannot perform this action, due to restricted access to the relevant directories where OpenSSL processes certificate files. By identifying and exploiting this misconfiguration, the attacker can place maliciously crafted files within `/etc/certs/`, creating the necessary precondition for successfully exploiting CVE-2022-2068.

2. **Exploiting CVE-2022-2068** Using the ability to write to the `/etc/certs/` directory, the attacker moves

to exploiting CVE-2022-2068. To this end, they place maliciously-crafted certificate file names in the `/etc/certs/` directory and then trigger the `c_rehash` script, which is executed by the *openssl* user. This script, failing to sanitize shell meta-characters in the file names properly, executes the attacker's code with the privileges of the *openssl* user.

3. **Corrupting a systemd Service** For the third step, the attacker uncovers another misconfiguration: Specifically, the *openssl* user has permission to modify systemd service files. This misconfiguration arises from the fact that systemd service files are incorrectly associated with an administrative group with write permissions to these files, and the *openssl* user is a part of that group. This is not a standard configuration but a possible setup where an admin group is used to manage a variety of system services. The attacker uses this misconfiguration (and the fact that they can run code as the *openssl* user) to inject a malicious modification into the systemd service file. Since the service file runs with *root* privileges when the system or the service is restarted, the modified service file executes code or commands inserted by the attacker. This effectively allows the attacker to escalate their privileges to *root*, granting them complete control over the system.

The exploitation chain highlighted in this scenario leverages a combination of three distinct security issues: the presence of misconfigured directory permissions, the exploitation of a known vulnerability (CVE), and finally, the manipulation of a systemd service for the final escalation to *root*.

Problem Size. The current approach to finding privilege escalation chains requires the manual composition of each step. Some of these steps can be identified by tools such as linPEAS [56] that perform system analysis and report potential vulnerabilities. However, the end-to-end analysis must navigate a vast search space to discover privilege escalation chains automatically. For the exploitation chain we discuss in this section, the analysis must explore millions of possible states, even on basic Linux installations. This complexity is beyond simple brute-force exploration, but different optimized search algorithms can address it. However, any search strategy will require a flexible and extensible mechanism to encode a problem and must support diverse exploitation primitives and attacker goals. We find that PDDL (discussed in Section 2) is a powerful encoding mechanism that enables us to express problems generically. Moreover, it allows us to directly leverage state-of-the-art search algorithms integral to AI planners.

3.2 Threat Model

ChainReactor operates on the premise that the attacker aims to elevate their initial shell access. Methods for securing initial access vary, ranging from exploiting remote vulnerabilities for service-user access to using stolen credentials for user login.

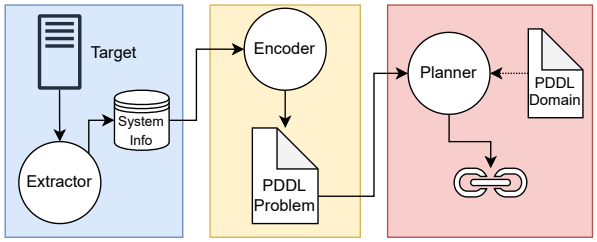

Figure 2: ChainReactor architectural overview.

The attacker's initial capabilities are limited to using the executables present on the system. However, they can retrieve external tools to aid in the exploitation process if they find a way, with no specific constraints on these tools. The attacker does not know about the system architecture or the software running on the machine. However, they can gather this information using the tools available on the system.

Our research primarily focuses on Unix systems, specifically those fully-fledged and equipped with init systems. This current focus is not a fundamental limitation of ChainReactor but rather a design choice to obtain more intricate chains, as init systems (such as [19]) facilitate the automatic execution of routine scripts and executables. Due to this emphasis on init systems, our threat model does not encompass containerized environments.

Moreover, we assume that the attacker initially does not have access to any of the other users' passwords, which rules out the straightforward approach of using privileged commands through the system's built-in permission elevation mechanisms, e.g., using SUDO to assume the identity of another user or log in as that user. However, attackers can exploit known vulnerabilities, e.g., CVEs, to incrementally increase their capabilities.

Furthermore, this work aims to discover privilege escalation chains. It is not limited to any particular kind of privilege escalation chain, as its type (and the involved steps) are decided by automated analysis that combines the actions the attacker can perform on the target system. For example, if there are misconfigured permissions within the system, the planner decides whether to leverage them in the exploit chain.

4 Approach

ChainReactor is built from three main components: the *extractor*, the *encoder*, and the *domain*. The extractor identifies potential vulnerabilities and generic capabilities within the target system. The encoder then converts these capabilities and vulnerabilities into facts formatted in the Planning Domain Definition Language (PDDL). As described in Section 2, the PDDL *domain* outlines the possible actions that the system

can perform, and PDDL *problem* defines the initial state of the system and the goal state to be achieved. ChainReactor then uses an AI planner to solve the problem, the sequence of actions that brings the system from the initial state to the goal state. This sequence is a *plan* corresponding to an exploitation chain. A visual representation of this system can be found in Figure 2. The following sections delve into the specifics of each component.

4.1 Extractor

The extractor is run on the target system under the unprivileged account that the attacker controls according to our threat model discussed in Subsection 3.2. Operating as an unprivileged user, the extractor examines the target system. The tasks performed by the extractor can be categorized into two groups: (1) enumeration of generic capabilities and (2) extraction of vulnerabilities.

Generic Capabilities. To obtain a chain, we require not only knowledge about a system's vulnerabilities but also generic information about it. As part of generic capabilities extraction, our system performs the following tasks:

- *Retrieving System Users and Groups*: Identifies all users and groups on the target system, providing an initial understanding of potential users and groups that an attacker could exploit.
- *Retrieving System Executables*: Identifies all executable programs on the system, including both binary ELF executables and scripts (e.g., shell, Python, and Perl scripts).
- *Retrieving Linked System Libraries*: Identifies all libraries automatically loaded by the system executables extracted in the process. This is done to find libraries with incorrect permissions that could be later corrupted.
- *Retrieving Writable Files and Directories*: Scans for files and directories to which the unprivileged user has write access, emphasizing those not owned by this user, as they may facilitate exploitation.
- *Retrieving SUID / SGID Files*: Identifies all executables for which the SetUID or SetGID bit is set. When executed, such programs run with the permissions of the file owner or group and could be exploited for privilege escalation.
- *Retrieving RC files*: Identifies all bash `.rc` files automatically sourced by shells upon login. If writable, these files can execute arbitrary code as other users.
- *Collecting File Ownership and Permissions*: For every file identified on the system, including executables, scripts, and libraries, the extractor collects information regarding file ownership and permissions. This metadata is crucial for understanding potential security vulnerabilities and access control across the system.
- *Retrieving Background Processes*: Extracts which process is executed by which user. If the process has a vulnerability, this information determines the affected user.

Vulnerabilities. Together with generic capabilities, the extractor also checks for known software vulnerabilities, providing the attacker with additional capabilities on the target system. In particular, the vulnerability extraction includes:

- *Retrieving misconfigured systemd services and cronjobs*: This step identifies all `systemd` [19] services and `cronjobs` [38] running on the system. Misconfigured or vulnerable services and jobs could be exploited to manipulate the system's operations, e.g., to execute a malicious script. Misconfigurations are primarily identified by inspecting configuration file permissions.
- *Mapping Executables to Capabilities Using GTFOBins*: In this step, we leverage GTFOBins [54], a curated database that links specific system binaries to potential post-exploitation tasks. By cross-referencing the executables present on the system with the GTFOBins database, we can identify the potential capabilities that each binary could be used for, such as reading or writing files or downloading content.
- *Retrieving Fine-Grained Version Information of Binaries*: This phase first identifies the CVEs associated with the binaries by utilizing the cve-bin-tool [12]. Subsequently, we access fine-grained data regarding the version and patch status of each program installed using Ubuntu's CVE API [75]. This approach allows us to ascertain whether a system's version has been patched in an Ubuntu image. Armed with this precise information, we can efficiently identify vulnerable programs (CVEs) on Linux Ubuntu distributions.

4.2 Encoder

The encoder is responsible for translating the raw data gathered by the extractor into PDDL format, specifically into PDDL *problems* discussed in Subsection 2.2. These and the domain files constitute the input for the AI planner.

The data received by the encoder holds a comprehensive collection of information about the target system, i.e., generic capabilities and vulnerabilities described in Subsection 4.1. Acting as a translator, the encoder converts this collection into corresponding PDDL objects and predicates.

4.2.1 Encoding Generic Capabilities

The encoder parses the generic capabilities provided by the extractor and maps them to one or more facts. These facts

could include the capability of reading or writing a file (e.g., `(cap_write_file usr_bin_busybox)`, Figure 3, Line 4), downloading or uploading a file, executing a shell command, present system executables (e.g., `(system_executable usr_bin_busybox)`, Figure 3, Line 11) and more. Facts reflect properties of the current system state, such as users, groups, files, file permissions, executables periodically called by users, daemon files, and cross-references between executables and libraries.

4.2.2 Encoding CVEs

We adopt a two-step strategy to enhance ChainReactor by integrating information from the Common Vulnerabilities and Exposures (CVE) database.

First, we manually added support for GTFObin(aries) and 11 CVEs to ChainReactor. The effort involved in adding a new vulnerability or CVE is twofold. First, we need to define the effects of exploiting a CVE on the system state and the attacker's capabilities. Then, we need to translate these effects into predicates (discussed in Subsection 2.2) that the planner understands. If the effects of exploiting a CVE introduce new capabilities that are not currently covered by the domain, we need to introduce new predicates. This process is manual and requires an understanding of the CVE and the domain. Still, it allows us to gradually build up a library of CVEs and associated predicates over time.

Let's consider CVE-2022-1271 [43] that we added to ChainReactor as an example. This CVE enables GZIP to write files arbitrarily. The encoder maps this CVE to a predicate, `CAP_CVE_write_any_file`, which signifies this capability within the PDDL problem. This mapping informs the planner that if this particular CVE is exploited, then GZIP can be used to write any file to which the user executing GZIP has permission. This effectively extends the writing capabilities of the executable, which may not have been possible without the exploitation of the CVE.

While performing a manual study of CVEs commonly found on recent Linux distributions, we noticed that these vulnerabilities fall into a (small) number of categories that provide similar capabilities to attackers when exploited. For example, exploiting a CVE might allow the attacker to execute arbitrary code as the vulnerable application's user. As another example, the attacker might be able to overwrite files for which they do not have permissions.

Therefore, in the second step, we develop an automated system that can label a given CVE based on the capabilities this vulnerability provides to an attacker (assuming they can successfully exploit it). This approach enables us to encode (in PDDL) the effects of exploiting any CVE for which we can determine a label. This significantly streamlines the process of modeling and incorporating CVEs into our tool.

To facilitate this labeling, we have developed a classifier using GPT-4 Turbo [50]. For a given CVE number, our system first recovers the full CVE description from the National Vulnerability Database (NVD) [42]. Subsequently, the description is included in a prompt that is sent to GPT-4 (via OpenAI APIs [49]). This prompt is written such that it asks GPT-4 to assume the role of a security engineer and assign a label to the CVE description. To ensure consistency between different vulnerabilities, we have defined several different labels (categories), and the prompt includes these labels. The prompt also includes information on what to do in case it is not possible to perform any assignment.

```
1  (define (problem micronix-problem-root)
2      (:objects etc_systemd_system_calyptia_service
           - file usr_bin_busybox - executable
           ubuntu_u - user ubuntu_g - group root_u -
           user root_g - group)
3      (:init
4       (cap_write_file usr_bin_busybox)
5       (controlled_user ubuntu_u)
6       (daemon_file
            etc_systemd_system_calyptia_service)
7       (default_file_permission
            etc_systemd_system_calyptia_service
            FS_READ)
8       (executable_systematically_called_by
            opt_calyptia-core_bin_core-start_sh
            root_u)
9       (file_owner
            etc_systemd_system_calyptia_service
            ubuntu_u ubuntu_g)
10      (file_owner usr_bin_busybox root_u root_g)
11      (system_executable usr_bin_busybox)
12      (user_group root_u root_g)
13      (user_group ubuntu_u ubuntu_g)
14      (user_is_admin root_u)
15      ; more facts...
16     )
17     (:goal (controlled_user root_u)))
```

Figure 3: Simplified example of a PDDL problem file generated by the Encoder component of ChainReactor.

4.2.3 Encoding Example

We use a simplified problem description presented in Figure 3 to exemplify the workings of the encoder. The problem file, automatically generated first by running the Extractor and then the Encoder, consists of three parts: `objects` – constants used in the predicates (Line 2), `init` – initial state description (Lines 3-15), and `goal` – goal state description (Line 17).

Problem objects. The objects defined within the domain represent the entities involved in the problem space, such as the files, users, and executables on the system. Their attributes and relationships dictate the possible actions and the state transitions within the problem scenario.

Initial State. In the initial state description, the encoder puts all the identified objects into facts, i.e., each fact is a predicate instantiation as discussed in Subsection 2.2. To accomplish

this, we equip the encoder with an extendable capability-predicate database. Currently, our database consists of 45 predicates, allowing us to describe information about the system as facts, as we exemplify in the following paragraphs.

A fact with predicate `cap_write_file` (Line 4) is introduced if the extractor finds an executable capable of writing files. In our example, `/usr/bin/busybox` was used to instantiate the predicate and also introduced as an object of type `executable` (Line 2). Together, they express that there is a binary in the system capable of writing files. The same executable (`busybox`) is also a system executable, which is expressed by the predicate `system_executable` (Line 11).

Our system also manages executables periodically invoked by a system's service, indicated by the predicate `executable_systematically_called_by`. In our example, the name of the executable is `/opt/calyptia-core/bin/start.sh`, executed with the privileges of the user `root_u` (Line 8).

We also model the file system, generating the corresponding facts for file ownership and permissions, among others. For instance, the executable discussed above (`/usr/bin/busybox`) is owned by the user and group `root_u:root_g` (Line 10). To map the association between a user and a group, the encoder generates the predicate `user_group` (Line 12). In addition to ownership, we also capture the facts about the permissions, e.g., for a daemon configuration file (Line 6); on this specific system, we generate the fact that the file is read-only (Line 7).

According to our threat model introduced in Subsection 3.2, the system under analysis has an (unprivileged) user controlled by the attacker. In our example, this user is called `ubuntu_u`, which is captured by a fact with the predicate `controlled_user` (Line 5). We also extract the fact that the admin of the system is the user `root_u` (Line 14).

Goal State. The goal state for the PDDL problems generated by the encoder is currently predefined. Specifically, the attacker aims to become the root user, represented by the fact `controlled_user root_u` (Line 17). However, in principle, our system supports other goals, such as data exfiltration.

4.3 Domain & Plan

In Subsection 4.2, we discussed how the encoder produces facts instantiating predicates with objects to obtain a PDDL problem description. As discussed in Subsection 2.2, AI planning also requires another component, namely, domain specification. The PDDL domain is manually developed and includes the predicates' definitions. These predicates are defined in the PDDL domain description. Figure 4 contains examples of such predicate definitions, namely, predicates `cap_write_file` (Line 2) and `system_executable` (Line 3). Predicate specification tells us that instantiation for both predicates requires one element of type `executable`, and this is how they are used by the encoder (Figure 3, Line 4 and Line 11, respectively).

Next, the domain encompasses the description of the planner's possible actions to bring the target system from the initial state in the problem description to the goal state. As described in Subsection 2.2, each action contains typed *parameters*, which can be used in both the predicates and the effects, *preconditions* describing the conditions that needed to be satisfied to apply the action, and *effects* describing the outcome of the application of an action. We formulated the actions to correspond with the specific commands or sequences of commands executed during the development of the multi-stage exploit.

We depict example actions in Figure 4. The first action `write_data_to_file` (Lines 6-16) allows the planner to write to a file (specified by the parameter `?f`) as a step in the attack sequence. To execute the action, there must be an executable `?e` in the target system that can write to files (Line 10), and it should be spawned as process `?p` (Line 11) by a user `?u` with the rights allowing them to write to the file `?f` (Line 12). In addition, the file `?f` that we write to must be different from the executable `?e` used to write to a file. If the planner finds in the `init` state or can derive – by replacing the parameters with the objects – the facts in the preconditions, the action can be executed as a part of the plan. Executing this action leads to the introduction of the effects. In particular, the process `?p` that writes to a file will no longer be active (Line 14), and file `?f` can be moved to location `?l` of choice with data `?d`. It is important to note that the planner chooses the location and the data. Hence, if there is a precondition that can be satisfied if file `?f` is present at location `?l` with data `?d`, the planner can use action `write_data_to_file` to obtain it.

Figure 4 also contains another example action, namely, `spawn_injected_shell_from_corrupted_daemon` (Lines 17-23). It has two preconditions: there should be a daemon `?f` present on the target (Line 20), and the contents of this daemon should contain the attacker-introduced shellcode (Line 21). As the extractor establishes the daemon's presence, the first precondition must be part of the initial state specification. But the second precondition can be derived, for instance, by the previous action `write_data_to_file` application. If both preconditions are satisfied, the effect would be for the attacker to control any user `?u` (Line 23). Thus, this action can be the last step in achieving privilege escalation.

Here, we just highlighted a couple of actions. Our domain specification contains 30 more actions, providing the planner with additional steps that it can use to achieve privilege escalation, e.g., manipulating sensitive files or exploiting the CVEs. This comprehensive approach ensures our system can leverage known vulnerabilities while discovering new exploit combinations. The process of establishing the domain requires a one-time effort. Once accomplished, it can be iteratively utilized to tackle a variety of problem instances, with

```
(:predicates
    (CAP_write_file ?e - executable)
    (system_executable ?e - executable)
    ; ... more predicates
)
(:action write_data_to_file
    :parameters (?p - process ?e - executable ?f -
         file ?d - data ?l - local ?u - user ?g -
        group)
    :precondition (and
      (not (= ?e ?f))
      (CAP_write_file ?e)
      (process_executable ?p ?u ?e)
      (user_can_write_file ?u ?g ?f))
    :effect (and
      (not (process_executable ?p ?u ?e))
      (file_present_at_location ?f ?l)
      (file_contents ?f ?d)))
(:action
    spawn_injected_shell_from_corrupted_daemon
    :parameters (?u - user ?f - file)
    :precondition (and
      (daemon_file ?f)
      (file_contents ?f SHELL))
    :effect (and
      (controlled_user ?u)))
```

Figure 4: Examples of PDDL predicates and actions in the domain description used by ChainReactor.

arbitrary attack objectives expressed through the designated predicates. Furthermore, the extensibility of the domain is facilitated, accommodating the inclusion of additional predicates to address previously unsupported capabilities or actions representing novel steps in the attack sequence.

The combined specifications of the domain and problem (detailed in Subsection 4.2) constitute a valid input for a planner. Once a plan is obtained, it guides the construction of the multi-stage attack. Given that the actions are meticulously aligned with specific commands or sequences, it is plausible to establish a one-to-one correspondence between the plan and the actual attack sequence.

5 Implementation

In this section, we discuss the implementation of ChainReactor, providing some implementation details about the extractor and planner components.

Extractor. The extractor serves as the initial data collection point and is responsible for gleaning necessary information about the system stat, it is fully automated. We developed the extractor in PYTHON. It collects required data through SSH or reverse-shell communication with instances and the execution of a series of commands. We considered leveraging tools like LinPEAS [56] in our Extractor component. We ultimately decided to implement our version, as it provided additional configuration and vulnerability data and was tailored to our exact use case. A crucial function of the extractor is the identification of Common Vulnerabilities and Exposures (CVEs) discussed in Subsubsection 4.2.2. After extracting the CVEs from a target, we associate these CVEs with a class, obtaining a domain that links a CVE class with its effects.

Planner. The critical observation is that the Extractor component (as well as existing vulnerability checkers) only provide basic facts about the system. ChainReactor adds the crucial step where we can reason about combinations of these basic facts to achieve generic multi-stage exploit chains. This is not possible with current tools. To implement this combination step, ChainReactor incorporates an off-the-shelf AI planner that resolves the generated PDDL problem. The planner generates a sequence of actions progressing from the initial to the goal state, thereby constructing an exploitation chain. However, it's crucial to note that the planner does not enumerate all possible plans. Instead, it employs a satisficing strategy, determining the conditions that must be met or the information that must be obtained to reach a satisfactory decision. Once a solution is identified, the planner then focuses on optimizing the cost of that specific solution rather than seeking alternative solutions. If no solution is found, the system is informed accordingly, and the scenario is marked as such.

We utilized Powerlifted, a lifted PDDL planner [14] to enable effective reasoning and planning. Lifted planners operate using abstract representations with objects and potential states, dynamically grounding details during the search process as needed. They work directly on the abstract domain model without fully grounding specific instances and scenarios. This approach eliminates the need for an expensive pre-processing phase and prevents excessive memory usage, which is particularly beneficial when dealing with large state spaces.

The multitude of objects in our domain results from our automatic system information extraction. This leads to a vast state space, making the grounding process extremely expensive and causing an exponential blow-up even before the solving starts. Therefore, while grounded planners might offer faster search times under certain conditions, a lifted planner is necessary to scale to our automatically generated problems and manage the complexity of our domain.

6 Evaluation

The evaluation of ChainReactor was conducted in a two-stage process to ensure its effectiveness and applicability. The first stage involved testing synthetic environments, specifically vulnerable Capture-The-Flag (CTF) Virtual Machines (VMs) published for educational purposes. The second stage aimed at a real-world scenario, evaluating the performance of our system on Amazon Web Services EC2 (AWS) and Digital Ocean (DO) instances.

Our experiments were performed on an Ubuntu 22.04 LTS

Figure 5: Plan generated for the CTF VM.

server running on an Intel Xeon CPU E5-2690 3.00GHz with 256GB of RAM. Notably, the PDDL solving process is single-threaded and not CPU-intensive but memory-intensive. The significant RAM capacity allowed batches of 8-9 problem instances to be solved simultaneously [71], and the number of concurrent solver processes was tuned to saturate the available memory for maximum efficiency. The evaluation used a 30-minute overall limit for each planning task.

6.1 CTF VMs

In the first stage, we tested ChainReactor on 3 CTF VMs from a curated list designed explicitly for privilege escalation [72]. These VMs, inherently vulnerable, served as a controlled environment to assess ChainReactor's ability to identify and exploit vulnerabilities. We started with a hands-on approach of manually identifying privilege escalation paths by following published walkthroughs and conducting independent investigations; the walkthroughs served as both a guide and a baseline to measure ChainReactor's ability to detect and exploit vulnerabilities.

This process allowed us to understand the various privilege escalation methodologies commonly used by attackers and identify privilege escalation chains in these controlled settings, demonstrating ChainReactor's ability to detect vulnerabilities and formulate effective escalation paths accurately. Misconfigured SetUID binaries and writeable scripts periodically called by other users were among the most common attack vectors identified in these VMs.

The plan in Figure 5 outlines a sequence of actions that result in a privilege escalation on the CTF VM "Escalate My Privileges" [76]. We consider two users in this scenario: the unprivileged `apache` user, which we control, and the `root` user.

The exploitation chain begins with Line 1 and Line 2, where the planner identifies that the `apache` user, a member of the `apache` group, possesses execution rights for `vim` and a script located at `opt/my_backup.sh`. In Line 3, the planner establishes that the `apache` user has write permissions on `opt/my_backup.sh`. Next, in Line 4, the planner launches a `vim` process under the `apache` user. In Line 5, the planner leverages the write permissions of `apache` on `opt/my_backup.sh` to inject shellcode into the script. Finally, in Line 6, the corrupted `opt/my_backup.sh` script is automatically invoked as part of a cronjob, leading to the execution of the injected shellcode.

The security bug in this scenario is that the backup script, `opt/my_backup.sh`, is both writable and executable by the unprivileged `apache` user. Yet, it is scheduled to run under administrative privileges. This vulnerability is what allows the escalation of privileges to occur.

6.2 AWS EC2 and Digital Ocean Instances

In the second stage of the evaluation, ChainReactor analyzed cloud-hosted instances to understand how our tool performs under conditions representative of typical real-world use cases. We tested 504 Amazon Web Service EC2 (AWS) and 177 Digital Ocean (DO) droplet instances of available Linux images.

Setup. Both official and customized marketplace images were included to provide diversity in software configurations. We retrieved image lists from Amazon's and Digital Ocean's APIs (`describe_images` and `doctl compute image list`). We used the entire Digital Ocean list and a random subset of the AWS images for our testing. Importantly, it should be noted that no modifications were made to these instances after spawning. The instance sizes were `t2.micro` on AWS and `s-4vcpu-8gb` on Digital Ocean. Additionally, port 22 was exposed.

We established SSH access using the default unprivileged user for each instance to simulate the attacker's initial foothold. It is crucial to highlight that in this scenario, we assumed the default user does not have `sudo (ALL:ALL)` permissions and that the user and root passwords are unknown.

Exploring the State Space. To automatically find sequences of actions that lead to privilege escalation, ChainReactor needs to examine many possibilities, both in terms of the different objects involved and the states it must consider. This complexity is shown in Figure 6 for the number of objects and in Figure 7 for the number of states. On average, our system encounters 2,008 objects for AWS images (with a maximum of 16,574) and 897 objects for DO images (with a maximum of 8,374). Regarding the states to be explored, the average numbers are 8 million (with a maximum of 141 million) for AWS and 924 thousand (with a maximum of 85 million) for DO. This level of complexity surpasses that of brute-force exploration.

Generating Facts and Solving Problems. As we explain

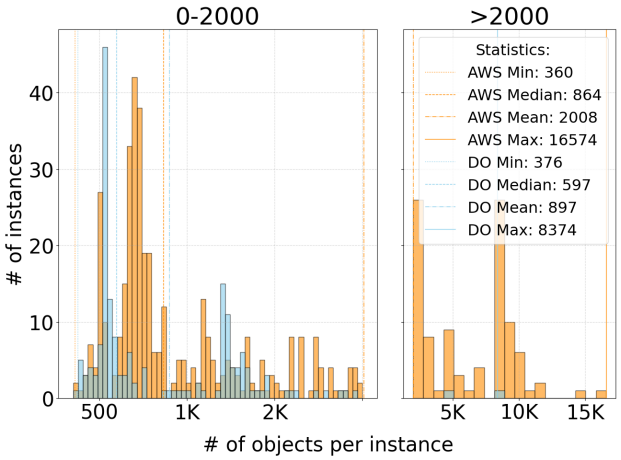

Figure 6: Objects distribution in the generated problems: AWS is orange, and Digital Ocean is blue.

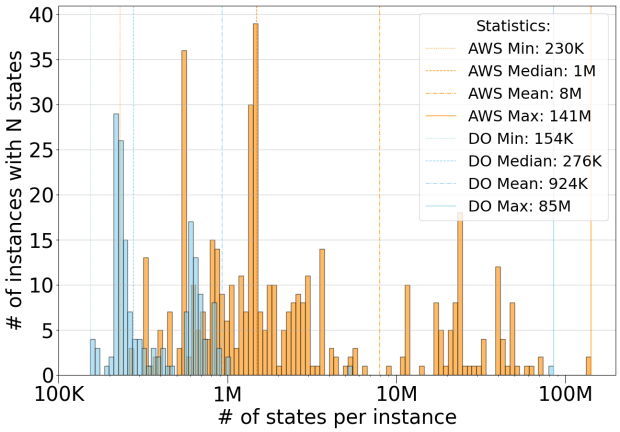

Figure 7: States distribution in the search space: AWS is orange, and Digital Ocean is blue.

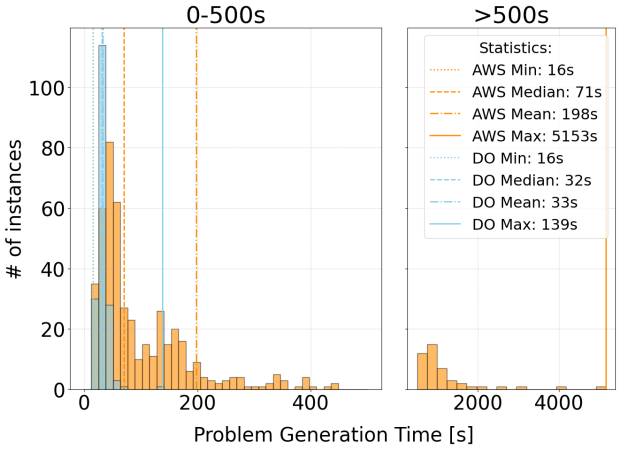

Figure 8: Distribution of time to generate the PDDL problem file: AWS is orange, and Digital Ocean is blue.

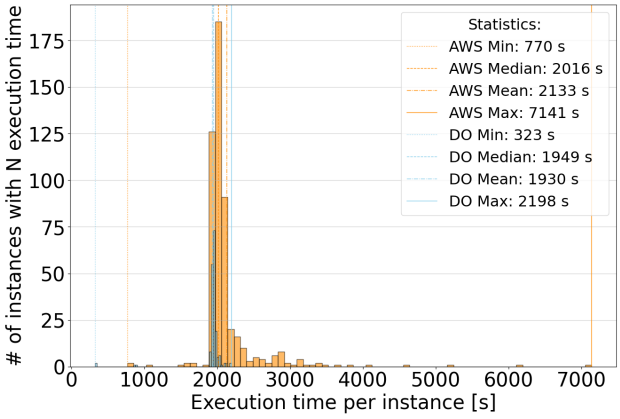

Figure 9: Total analysis time (problem generation + solving) distribution: AWS is orange, and Digital Ocean is blue.

in Section 4, the process with ChainReactor begins with the automated generation of facts about the system being analyzed. This is to set up a problem in the PDDL format. To do this, ChainReactor encompasses the extractor (Subsection 4.1) and the encoder (Subsection 4.2). In Figure 8, we illustrate the time required to create a problem file for each instance. Specifically, creating a problem file with ChainReactor takes, on average, 3 min (max. 86 min) for AWS environments and 33 sec on average (max. 2 min) for DO environments.

Once the PDDL problem is ready, ChainReactor moves on to the planning phase. We show the total time taken, including problem file creation and the planning process, in Figure 9. The average time for processing all EC2 instances, regardless of whether a solution is found, is around 36 min (max. 2h). For DO instances, the average total time for all cases is around 32 min (max. 37 min).

Identified Vulnerabilities. Our evaluation identified several previously unknown privilege escalation chains, specifically 16 targeting AWS and 4 aimed at DO images. Figure 10 displays the duration required to create each chain, arranged from the quickest (5 minutes) to the slowest (half an hour).

We manually reproduced all identified chains. The common thread across these vulnerable instances was the presence of misconfigured permissions. The vulnerabilities we discovered revolved around two main exploitable scenarios. The first involved corrupting a systemd service unit file [19]. It is a configuration file that specifies which executables are to be invoked by systemd, under which user context they will run, and the scheduling of their execution. An attacker with write access to a service unit file can launch a malicious script instead of the intended service. The same can be achieved via the attacker's modifications of a cron-invocable script [38]. The misconfiguration allowed for modifying the daemon file, which, when subsequently executed with root privileges, could

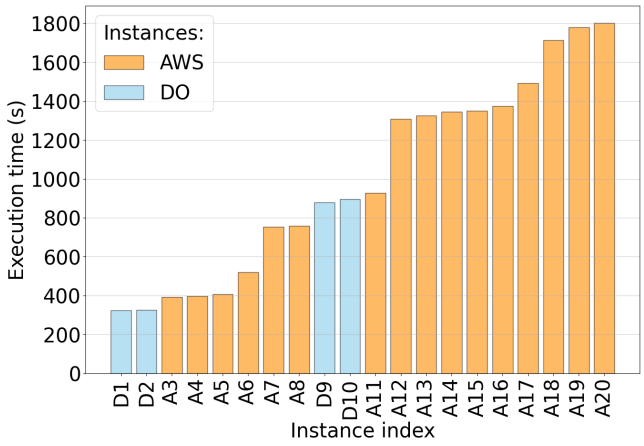

Figure 10: Execution time distribution for exploited instances: AWS is orange, and Digital Ocean is blue.

lead to potentially harmful actions. The second scenario involved the corruption of scripts directly invoked by `root`. Here, too, the misconfiguration of permissions allowed for modifying these scripts, creating a similar risk.

Our two case studies provide a deeper dive into these scenarios, illustrating the risks and potential impacts of these vulnerabilities.

Case study 1. The plan in Figure 11 represents a series of actions that lead to privilege escalation on an EC2 instance. It is important to note that this plan is valid and can be used to exploit the reference instance.

We have two users in this scenario: the unprivileged `ubuntu` user, which we control, and the `root` user.

The chain starts with Line 1, where the planner identifies that the `ubuntu` user, a member of the `netdev` group, has execution rights for `busybox`. This binary combines many common Unix utilities into a single executable. Subsequently, in Line 2, the planner determines that the `ubuntu` user also has write access to the `systemd` service file `calyptia`. In the third step (Line 3), the planner initiates a `busybox` process under `ubuntu` credentials. The fourth step (Line 4) leverages the write access to the `calyptia` service file by injecting shellcode into the `calyptia` service file. Finally, in Line 5, the corrupted `calyptia` service is invoked, leading to the execution of the injected shellcode. Since this `systemd` service runs with `root` privileges, this results in the spawning of a shell as `root`, effectively achieving privilege escalation.

In the presented example, ChainReactor opts for `busybox` to facilitate the exploitation in the outlined steps. However, in other identified chains, we observed the use of different binaries such as `nohup`, `wget`, and `xxd` to achieve similar outcomes.

Case study 2. The plan in Figure 12 represents a series of actions that lead to privilege escalation on another EC2 instance. As in the previous case, this plan is valid and can be used to exploit the reference instance.

We have two users in this scenario: the unprivileged `ec2-user` user, which we control, and the `root` user.

The exploitation chain begins with Line 1 and Line 2, where the planner identifies that the `ec2-user` user, a member of the `docker` group, has execution rights for `vim` and a script located at `opt/aws_dlami/bin/apply_instance_tag_service.sh`. Next, in Line 3, the planner identifies that the `ec2-user` user has write permissions for `opt/aws_dlami/bin/apply_instance_tag_service.sh` script. The planner then launches a `vim` process under the `ec2-user`, denoted by Line 4. In Line 5, the planner leverages the write permissions of `ec2-user` on the script to inject shellcode into this file. Finally, in Line 6, the corrupted `opt/aws_dlami/bin/apply_instance_tag_service.sh` script is assumed to be automatically invoked as part of a routine process, leading to the execution of the injected shellcode. Since the script is executed with `root` privileges, this results in spawning a shell with administrative privileges.

Similarly to the first case study, ChainReactor opted for `vim` while using other binaries to reach the same goal in other chains.

6.3 Expanding ChainReactor with Ubuntu Linux Vulnerability Information

As discussed in Subsection 4.1, our Extractor component has the ability to extract fine-grained vulnerability information for Ubuntu Linux. To demonstrate the effectiveness of incorporating this additional information into ChainReactor, we analyzed all 930 Ubuntu-based Amazon EC2 instances.

We first ran our Extractor component on these instances and identified 264 CVEs. Then, we utilized our GPT-based classifier (Subsubsection 4.2.2), which divided the CVEs into 12 groups. We manually validated that all CVEs within each group indeed introduced the same capabilities, and hence, were labeled correctly. Then, we focused on the largest cluster, containing 120 CVEs, and integrated the corresponding actions into ChainReactor. This process took 6 hours, a significant speedup compared to the initial manual approach, where we needed around the same time to add support for a single CVE.

Upon integrating the 120 new CVEs into ChainReactor, we executed our tool across all Ubuntu-based Amazon EC2 instances. This process unveiled a privilege escalation chain leveraging this action in 20 instances. Specifically, we noted the presence of CVE-2023-45044 [45] in all derived escalation strategies, a vulnerability impacting the Common UNIX Printing System (CUPS) operating as a daemon. Subsequent manual verification confirmed the exploitability of CUPS, thus validating all identified privilege escalation chains in these instances.

7 Discussion & Limitations

The following sections delve into a detailed discussion of our research findings. We also acknowledge the constraints of our current approach and identify potential avenues for future enhancements. This balanced examination allows us to better understand our tool's capabilities while setting the stage for further research in automated exploitation chain discovery via AI planning.

7.1 Discussion

A key strength of the ChainReactor system is its ability to model and simulate the behavior of threat actors already present on a target system. This contributes to the field, as many current security measures focus primarily on preventing initial system breaches. Our research addresses a gap in our understanding of advanced persistent threat (APT) actors by shifting the focus to post-breach activities. However, it is essential to clarify that the specific entry points for these threat actors are out of the scope of this paper. Future work could integrate our approach with intrusion detection systems to provide a more comprehensive end-to-end security analysis.

The results from our evaluation suggest that ChainReactor can identify previously unreported chains in addition to rediscovering known privilege escalation exploits. This ability to discover new chains is particularly noteworthy, as it indicates that ChainReactor can adapt to evolving threats and provide valuable insights into potential future attacks.

Responsible Disclosure. Upon identifying exploitation chains, we prioritized the responsible disclosure of these vulnerabilities to the relevant parties, specifically Amazon AWS Security Team [65] and Digital Ocean [48], to mitigate potential security risks. With AWS, our immediate actions led to removing two images from their offerings based on the vulnerabilities we reported.

Throughout this process, we follow the ethical disclosure guidelines, ensuring that no details of live exploits are published or disclosed publicly until they have been addressed adequately by the involved parties. Thus, this work does not contain any information that allows for identifying vulnerable instances.

7.2 Limitations and Future Work

Despite the promising results, there are several limitations to our current approach and areas for future improvement.

First, ChainReactor currently targets privilege escalation but is adaptable to various attacker goals formulated within the PDDL framework. Our suite of test problems extends beyond escalation, covering goals like file exfiltration — utilizing binaries with download/upload functions to transfer files in/out of the compromised system.

Second, the current version of ChainReactor supports a limited set of actions. While the actions supported are sufficient to generate meaningful exploitation chains, expanding the range of actions could lead to the discovery of more complex and subtle exploitation chains.

Third, while ChainReactor can generate exploitation chains, it currently does not produce executable exploit code that can be run directly on the target system. This means that while ChainReactor can identify chains, it cannot automatically validate them by executing them. This is an area for future development, as automatic validation would provide further evidence of the validity of the identified chains.

Fourth, this paper does not cover the initial infiltration phase. ChainReactor's framework could potentially be expanded to include it as a preliminary step.

Last, there are several specific areas of system functionality that ChainReactor does not currently support, including Linux capabilities, network mounts, and path environment variable

injection. These are all potential avenues for exploitation and should be considered in future iterations of ChainReactor.

In conclusion, while ChainReactor represents a significant step forward in automated exploit discovery, work remains. The limitations identified above provide a roadmap for future research and development, with the ultimate goal of creating a fully automated system capable of identifying and validating a wide range of exploitation chains.

8 Related Work

Network Attacks. Various approaches have been proposed to investigate network attacks utilizing Artificial Intelligence (AI). Cohen [11] was among the pioneers in this field, studying attacks as simulations in a cause-effect model. This simulation approach has been further leveraged for evaluating penetration testing practices through planning [3, 27, 68], reinforcement learning [20, 78, 80], Bayesian networks [60], and a blend of Boolean logic and machine learning [28].

Network attacks have also been examined through various modeling techniques. Graph-based models (attack graphs) have been particularly popular, as evidenced by several studies [29, 33, 34, 40, 51, 53, 67]. Other modeling approaches include Petri-net-based models [58, 79], formal logical models [36], and game-theoretic models [1].

AI Planning for Network Attacks. The application of AI planning in the domain of network attack simulation and modeling has proven to be beneficial [3, 27, 39, 68]. Choi et al. [9] applied this concept to smart grid attack response.

"Classical" Single-Step Vulnerability Discovery. This category encompasses a wide variety of techniques. Fuzzing, a method of testing where large amounts of data are inputted into a system, has been examined in several studies [17, 37]. Symbolic execution, a means of analyzing a program to determine what inputs cause each part of it to execute, has also been leveraged [4]. Hybrid fuzzing, which combines fuzzing and symbolic execution, has been explored in depth [7, 55, 69]. Other techniques include bounded model checking, a method for checking properties of programs [5], static analysis, the analysis of computer software performed without executing programs [8], and formal verification, the act of proving or disproving the correctness of programs concerning a certain formal specification or property [25].

Privilege Escalation. Investigations into privilege escalation have spanned across numerous domains, commencing with the early exploration of UNIX's design and security model [23, 63]. Since then, the model has faced a myriad of privilege escalation threats [57, 59], including hardware-targeted attacks [74]. Among the prevalent techniques, the abuse of SetUID permissions has been particularly noteworthy [31, 32], as well as the exploitation of race conditions [16]. In the hardware context, the focus has been on zero-overhead malicious modifications or fabrication attacks [74]. Meanwhile, studies in the browser environment have shed light on privilege escalation attacks via extensions [35]. Trusted Execution Environments (TEEs), despite their promise of enhanced security, have shown vulnerabilities to Horizontal Privilege Escalation (HPE) [70]. The Android platform has also been extensively analyzed for potential privilege escalation threats [2, 15, 61]. Cross-technology performance features have been exploited in the wireless sector for inter-chip privilege escalation [10]. In the cloud environment, potential privilege escalation attack scenarios and misconfiguration vulnerabilities have been identified within Kubernetes and Microsoft's Azure Active Directory [24, 52]. Lastly, investigations into UEFI firmware have utilized protocol-centric static analysis to uncover privilege escalation vulnerabilities in SMM [77].

Grounded and Lifted Planners. To improve the performance of the solving process, planners use preprocessing steps. Among these, a crucial step is grounding. Grounding transforms the problem from the abstract, logic-based PDDL representation to a more concrete, propositional form [13, 21, 26]. Despite their potential efficiency in specific domains, grounded planners are known to be memory-intensive [64]. This is due to the grounding process, which potentially leads to an exponential explosion proportional to the number of predicates, actions, and objects.

Unlike grounded planners, lifted planners operate directly on the abstract, logic-based representation of the problem [14, 62], i.e., they do not perform grounding. While this approach might be less efficient in some scenarios, it provides a significant advantage for larger problems where the resources required for grounding are prohibitive. For our research, dealing with large-scale problems, the immediate search capabilities of lifted planners, despite their potential inefficiency, make them a viable and necessary alternative to grounded planners.

9 Conclusion

This paper presents ChainReactor, an automated system for discovering exploitation chains to achieve privilege escalation on Unix systems. ChainReactor models the problem as an AI planning task, extracting capabilities from the target system, encoding them into a planning problem, and leveraging modern planners to derive exploitation chains.

The evaluation on CTF VMs and real-world Amazon EC2 and Digital Ocean instances demonstrated ChainReactor's ability to rediscover known privilege escalation exploits and identify novel chains. On CTF VMs, it found chains matching or extending published walkthroughs. When evaluated on hundreds of EC2 and Digital Ocean images, it discovered previously unreported exploitable privilege escalation paths.

Overall, ChainReactor offers a practical application of AI planning for security, automating a process to uncover chained exploits.

VeriSimplePIR

Verifiability in SimplePIR at No Online Cost for Honest Servers

Leo de Castro

Keewoo Lee
Seoul National University

Abstract

We present VeriSimplePIR, a verifiable version of the state-of-the-art semi-honest SimplePIR protocol. VeriSimplePIR is a stateful verifiable PIR scheme guaranteeing that all queries are consistent with a fixed, well-formed database. It is the first efficient verifiable PIR scheme to not rely on an honest digest to ensure security; any digest, even one produced by a malicious server, is sufficient to commit to some database. This is due to our *extractable* verification procedure, which can extract the entire database from the consistency proof checked against each response.

Furthermore, VeriSimplePIR ensures this strong security guarantee without compromising the performance of SimplePIR. The online communication overhead is roughly 1.1-1.5× SimplePIR, and the online computation time on the server is essentially the *same*. We achieve this low overhead via a novel one-time *preprocessing* protocol that generates a *reusable* proof that can verify any number of subsequent query-response pairs as long as no malicious behavior is detected. As soon as the verification procedure rejects a response from the server, the offline phase must be rerun to compute a new proof. VeriSimplePIR represents an approach to maliciously secure cryptography that is highly optimized for honest parties while maintaining security even in the presence of malicious adversaries.

1 Introduction

Private information retrieval (PIR) [CKGS98] addresses the question of how users can fetch a record from a database without leaking their access patterns to the machine hosting the database. PIR schemes have found numerous uses in privacy-preserving applications, such as certificate transparency [LG15], metadata-hiding messaging [AS16, ACLS18], password-breach alerting [TPY+19, LPA+19, PIB+22], private contact discovery [KRS+19], and many others.

Despite the ubiquity of PIR, essentially all constructions, including all practical constructions, do not address the fundamental issue of *verifiability*. In other words, practical PIR schemes crucially assume that the host server behaves at least *semi-honestly*, which is to say that it correctly executes the protocol with some fixed database. However, in the real world, a malicious server can deviate arbitrarily from the prescribed protocol with potentially disastrous consequences. One class of attacks involves equivocating on the database used to respond to each client. Such attacks allow a malicious server to alter all entries of the database for a particular client, effectively choosing the client's output. Malicious servers can even compromise the client's query privacy by performing a *selective-failure attack* [KO97, KS06, HKE13], where the server mauls specific entries of the database in an attempt to learn the client's query.

At a higher level, the deployment of any semi-honest PIR scheme will be plagued by the strong assumptions required for security. The reality of many distributed systems is that "honest" behavior cannot always be guaranteed even without true malicious actors. Deviations from the honest protocol could be caused by software bugs, network delays, faulty hardware, or any number of emergent failures that occur when computing at scale. Any system with security that is contingent on such failures *never* occurring will be hard to justify in sensitive applications. Nevertheless, true malicious behavior remains exceedingly rare, and a major optimization challenge is how to achieve security against malicious adversaries without sacrificing the performance of the best semi-honest protocols. In this work, we address the challenge of verifiable, single-server PIR by asking the following question:

How can a client ensure that a server is using a fixed, well-formed database to respond to all PIR queries while maintaining the efficiency of semi-honest PIR?

1.1 Prior Work

Semi-honest PIR. The starting point for this work is the semi-honest PIR protocol of Henzinger et al. [HHCG+23], referred to as SimplePIR. This protocol represents the state-of-the-art

in semi-honest PIR, where queries can be answered as fast as the database can be read from memory. SimplePIR is a stateful PIR protocol, where the server sends an initial, one-time *digest* of the database to each client. The clients then use this digest to improve the efficiency of all subsequent queries. This work will follow the same approach, having each client engage in a one-time protocol with the server, and the output of this protocol is used to process and verify queries in the online phase.

Verifiable PIR. The verifiable PIR primitive was first introduced in the multi-server setting by Zhang and Safavi-Naini [ZSN14] and in the single-server setting by Wang, Zhao, and Huang [WZ18, ZWH21]. In these works, the client issues a challenge with each query to ensure that the server correctly computed the response. These challenges resemble plaintext checksums, essentially requiring that the server evaluate the PIR computation on several random queries in addition to the real query. Unlike our work, these verifiable PIR schemes do not have a database commitment, so they do not defend against attacks where a malicious server changes the database in between queries.

The work of Ben-David, Kalia, and Paneth [BDKP22] extends the notion of verifiable PIR by verifying more complex predicates over the database in addition to the PIR query. While this work also does not have a database commitment, both this work and our work achieve *extractability* of the database used to respond to the PIR query. Our work can be viewed as an intermediate protocol between the original security notion of verifying that the server is using some well-formed database and this stronger notion given by Ben-David, Kalia, and Paneth. Our protocol only verifies the consistency of the PIR queries (rather than more complex predicates), but it does achieve the strong security property of database extractability. In addition, we leverage the stateful properties of our protocol to prove that all responses are consistent with a *single* database, which is a stronger requirement than all prior works. In other words, once the one-time protocol is complete, the only responses that will pass verification must all be consistent with a fixed, well-formed database.

Authenticated PIR. A very recent work of Colombo, Nikitin, Corrigan-Gibbs, Wu, and Ford [CNCG+23] constructs a slightly weaker primitive called *authenticated* PIR (APIR). The single-server protocols in this work are also based on the SimplePIR protocol [HHCG+23]. In particular, these protocols are also stateful, where the server sends an initial, one-time digest of the database to each client. While both authenticated PIR and our verifiable PIR protocol use an initial database digest, authenticated PIR differs from the notion of verifiable PIR in that it assumes the initial digest sent by the server is well-formed. This assumption is crucial in their security proof. The authentication method for the APIR queries closely resembles a plaintext MAC. This introduces significant overhead since each plaintext bit is mapped to roughly λ (security parameter) bits in the encoding, and the defense against selective-failure attacks requires error-correcting codes implemented on top of the PIR query. In a somewhat unintuitive result, our work achieves far superior performance over the APIR protocols by relying on *stronger* security. As we discuss below, only responses that are *exactly* correct will pass verification with a probability greater than $2^{-\lambda}$. This allows us to retain the efficient database packing schemes from SimplePIR while also removing the honest digest assumption. We discuss in section 6 how this assumption can be reintroduced as a performance optimization.

1.2 Our Contributions

We construct and implement VeriSimplePIR, the first efficient, verifiable PIR scheme, achieving industrial-strength security without compromising state-of-the-art performance.

Morally, the security property we achieve is the strongest one could hope for in any (nontrivial) PIR scheme. The initial database digest is accompanied by a noninteractive proof-of-knowledge of some fixed database, and then every response is verified against this proof to ensure that it is consistent with the committed database. This forces all responses with respect to a given digest to be consistent with the database that is fixed before the client performs the first query. In addition, this initial proof allows us to remove the assumption that the digest is well-formed, since this is directly verified by the client at the start of the protocol.

This verifiability comes at almost no performance overhead as long as the server remains honest. This is due to our novel *preprocessing* protocol that the client runs once with the server when it downloads the initial database digest. The result of this preprocessing protocol is a single noninteractive proof that allows the client to verify an *arbitrary* number of query-response pairs. The soundness of the verification is maintained as long as the server does not attempt to learn information about the private randomness held by the client that is used for verification. Here, we leverage the very strict property of this proof system, where only the response ciphertext that is *exactly* correct will pass verification. Therefore, the server cannot deviate from the honest protocol and pass verification with a non-negligible probability. If the server is running the honest protocol, then there is no leakage from the client's verification accepting (our verification algorithm has perfect completeness), so the client can safely *reuse* the preprocessed proof for any number of queries. In other words, as long as the server remains honest, there is essentially *no overhead* from adding verification to the SimplePIR protocol.

In particular, the concrete communication overhead for the online phase is between 13% and 50% over SimplePIR, depending on database sizes and whether or not the honest-digest assumption is in place. The computation overhead for VeriSimplePIR is at most 40% if the honest digest assumption is not in place. More details are given in section 6.

Roadmap. We define a verifiable PIR scheme with a preprocessed proof in section 3, then define our new VLHE scheme in section 4. The VeriSimplePIR construction is given in section 5 as it follows immediately from the VLHE construction. We present the full implementation and compare it to the semi-honest SimplePIR in section 6. To demonstrate practicality, in section 7 we discuss applying VeriSimplePIR to an important industry application: secure password checking.

2 Preliminaries

Notation. For $m \in \mathbb{N}$, define $[m] := \{1, \ldots, m\}$. For $i \in [m]$, let $\mathbf{b}_i \in \mathbb{Z}_q^m$ be the vector of all zeros with 1 in the i^{th} position. For $\mathbf{M} \in \mathbb{Z}_q^{n \times m}$, let $\mathbf{M}[i]$ denote the i^{th} row of $\mathbf{M}$ and let $\mathbf{m}_j$ denote the j^{th} column of $\mathbf{M}$. Similarly, for a vector $\mathbf{m} \in \mathbb{Z}_q^n$, let $\mathbf{m}[i]$ denote the i^{th} element of $\mathbf{m}$. For a finite set $\mathcal{S}$, let $x \xleftarrow{\$} \mathcal{S}$ denote sampling an element x uniformly at random from $\mathcal{S}$.

2.1 Short Integer Solution Problem

We review the Short Integer Solution (SIS) problem [Ajt96] on which the verifiability of our scheme is based.

Definition 2.1 (Short Integer Solution Problem)**.** *The statement of short integer solution problem $\mathsf{SIS}_{n,m,q,\beta}$ is the following: Given a random matrix $\mathbf{A} \leftarrow \mathbb{Z}_q^{n \times m}$, find a vector $\mathbf{x} \in \mathbb{Z}^m$ such that $\mathbf{Ax} = \mathbf{0} \pmod q$ and $0 < ||\mathbf{x}||_\infty \leq \beta$.*

Note that we use ℓ_∞-norm in the definition instead of ℓ_2-norm.

For the concrete hardness of $\mathsf{SIS}_{n,m,q,\beta}$, we follow [Lyu12] and use the analysis of [GN08, MR09] to choose parameters. Based on experiments of [GN08], Micciancio-Regev [MR09] analyzed that the shortest solution to $\mathbf{Ax} = \mathbf{0} \pmod q$ one can obtain by lattice reduction algorithms is of length (up to ℓ_2-norm) roughly $\min(q, 2^{2\sqrt{n \log q \log \delta}})$. Here δ is the root Hermite factor which depends on the output quality of the lattice reduction algorithm being used. We set parameters to satisfy the following condition to ensure the concrete hardness of $\mathsf{SIS}_{n,m,q,\beta}$ (up to ℓ_∞-norm).

$$\beta\sqrt{m} < \min\left(q, 2^{2\sqrt{n \log q \log \delta}}\right) \tag{1}$$

In this paper, we set $\delta = 1.005$ when choosing parameters. We note that the current best lattice reduction algorithms achieve around $\delta = 1.01$ and [CN11] conjectured that $\delta = 1.005$ is *totally out of reach* with thorough experiments.

2.2 Extractable SIS Commitments

We review a statistically extractable SIS-based commitment scheme. The scheme is described in fig. 1. It is essentially the amortized zero-knowledge proof of knowledge from [BBC+18] but adapted to our setting where zero-knowledge is not needed.

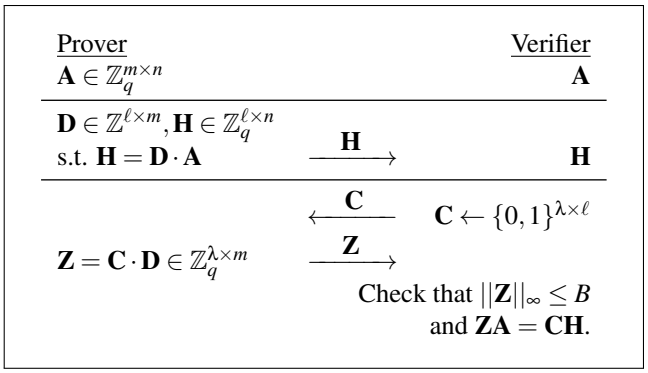

Figure 1: Extractable SIS-based Commitments [BBC+18]. The prover provides a commitment $\mathbf{H}$ to the verifier of some short matrix $\mathbf{D}$. The prover then provides $\mathbf{Z}$ in response to a challenge $\mathbf{C}$. $\mathbf{Z}$ is a proof of knowledge of some $\mathbf{D}'$ such that $||\mathbf{D}'||_\infty \leq 2B$ and $\mathbf{D}'\mathbf{A} = \mathbf{H}$.

Lemma 2.1 (Completeness)**.** *Let $\mathcal{P}$ be an honest prover (in fig. 1) who follows the protocol with respect to some $\mathbf{D}$ such that $||\mathbf{D}||_\infty \leq B'$ with $\ell \cdot B' \leq B$. Then, $\mathcal{P}$ always passes the verification.*

Proof. $||\mathbf{Z}||_\infty \leq \ell \cdot ||\mathbf{D}||_\infty \leq B$ and $\mathbf{ZA} = \mathbf{CDA} = \mathbf{CH}$. □

Lemma 2.2 (Extractability [BBC+18, Lemma 3])**.** *Let $\mathcal{P}$ be a prover (in fig. 1) who succeeds with probability $\varepsilon > 2^{-\lambda+2}$ over his random tape and the challenge choice $\mathbf{C} \leftarrow \{0,1\}^{\lambda \times \ell}$. Then, there exists a knowledge extractor $\mathcal{E}$ which makes $O(\ell \log \ell / \varepsilon)$ calls to $\mathcal{P}$ to extract a witness $\mathbf{D} \in \mathbb{Z}^{\ell \times m}$ such that $\mathbf{DA} = \mathbf{H}$ and $||\mathbf{D}||_\infty \leq 2B$ with overwhelming probability.*

We note that this extractability does not rely on the hardness of SIS; a matrix $\mathbf{D}$ such that $\mathbf{DA} = \mathbf{H}$ can be extracted from any prover that completes the protocol in fig. 1 with non-negligible probability. The hardness of SIS is used to guarantee the *computational uniqueness* of this matrix $\mathbf{D}$ (lemma 2.3). We refer the reader to [BBC+18, Lemma 3] for the full proof of lemma 2.2. Instead, we give a brief description of an extractor, since it will be relevant to the following lemmas.

Extractor for the SIS Commitment. We focus on extracting the i-th row of some $\mathbf{D}$ such that $\mathbf{D}[i] \cdot \mathbf{A} = \mathbf{H}[i]$ and $||\mathbf{D}||_\infty \leq 2B$. The idea of the extractor is to obtain valid responses $\mathbf{Z}$ and $\mathbf{Z}'$ to two challenges $\mathbf{C}$ and $\mathbf{C}'$ such that $\forall j \neq i$, $\mathbf{c}_j = \mathbf{c}'_j$ and $\mathbf{c}_i \neq \mathbf{c}'_i$. Since the responses are valid, we have the sum of the following outer products:

$$\mathbf{ZA} = \mathbf{CH} = \sum_{j=1}^{\ell} \mathbf{c}_j \cdot \mathbf{H}[j] \quad \text{and} \quad \mathbf{Z}'\mathbf{A} = \mathbf{C}'\mathbf{H} = \sum_{j=1}^{\ell} \mathbf{c}'_j \cdot \mathbf{H}[j].$$

Taking the difference gives $(\mathbf{Z} - \mathbf{Z}')\mathbf{A} = \sum_{j=1}^{\ell} (\mathbf{c}_j - \mathbf{c}'_j) \cdot \mathbf{H}[j] = (\mathbf{c}_i - \mathbf{c}'_i) \cdot \mathbf{H}[i]$. Consider an index $k \in [\lambda]$ such that

$\mathbf{c}_i[k] \neq \mathbf{c}'_i[k]$ and assume that $\mathbf{c}_i[k] - \mathbf{c}'_i[k] = 1$ without loss of generality. Then, if we consider the k-th row in the previous equality, we have $(\mathbf{Z}[k] - \mathbf{Z}'[k])\mathbf{A} = \mathbf{H}[i]$. Since $\mathbf{Z}$ and $\mathbf{Z}'$ passed verification, $||\mathbf{Z}[k] - \mathbf{Z}'[k]||_\infty \leq 2B$ holds. Thus, we can output $(\mathbf{Z}[k] - \mathbf{Z}'[k])$ as the i-th row of $\mathbf{D}$.

Binding Commitments from SIS Hardness. The hardness of SIS combined with the statistical extractability makes the protocol in fig. 1 a computationally binding commitment.

Lemma 2.3 (SIS Commitment Binding)**.** *Let $\mathcal{P}$ be a computationally bounded prover in fig. 1. Consider the extractor $\mathcal{E}$ guaranteed by lemma 2.2 running on $\mathcal{P}$. Either (i) the extractor $\mathcal{E}$ outputs a unique matrix $\mathbf{D}$ with all but negligible probability, or (ii) the prover $\mathcal{P}$ can be used to solve $\mathsf{SIS}_{n,m,q,\beta}$ for $\beta = 4B$.*

Proof. Suppose condition (i) does not hold. Then, we can run $\mathcal{E}$ polynomially many times to obtain two matrices $\mathbf{D} \neq \mathbf{D}'$ such that $||\mathbf{D}||_\infty, ||\mathbf{D}'||_\infty \leq 2B$ and $\mathbf{H} = \mathbf{D}\mathbf{A} = \mathbf{D}'\mathbf{A}$ by lemma 2.2. This gives a solution for $\mathsf{SIS}_{n,m,q,\beta}$ for $\beta = 4B$ of the form $(\mathbf{D} - \mathbf{D}')\mathbf{A} = 0$, since $\mathbf{D} - \mathbf{D}' \neq 0$. □

Let B' be the honest bound on the matrix $\mathbf{D}$; $B' \geq ||\mathbf{D}||_\infty$. Then, the correctness bound on $||\mathbf{Z}||_\infty$ is $B \geq \ell \cdot B'$. The extractability of the commitment scheme in fig. 1 guarantees that we can extract an SIS solution of size at most $4B$ (by taking the difference of extracted databases with size at least $2B$), which means that we need SIS to be hard for $4B$ in order to ensure computational binding. Setting $\beta = 4B = 4\ell B'$, we require that $4\ell B'\sqrt{m} \leq \min\left(q, 2^{2\sqrt{n \log q \log \delta}}\right)$.

A Useful Statistical Lemma. We prove a lemma on the probability of a vector being in the nullspace of $\mathbf{C} \xleftarrow{\$} \{0,1\}^{\lambda \times \ell}$.

Lemma 2.4 (Guessing an Element in the Nullspace)**.** *Let $\ell, \lambda \in \mathbb{N}$ and $p \geq 2$. For all $\mathbf{x} \in \mathbb{Z}_p^\ell$ such that $\mathbf{x} \neq \mathbf{0}$, the following holds:*

$$\Pr_{\mathbf{C} \xleftarrow{\$} \{0,1\}^{\lambda \times \ell}} [\, \mathbf{C} \cdot \mathbf{x} = \mathbf{0} \,] \leq 2^{-\lambda}.$$

Proof. Since $\mathbf{x} \neq \mathbf{0}$, there exists some $i \in [\ell]$ such that $\mathbf{x}[i] \neq 0$. Consider two vectors $\mathbf{c}_0, \mathbf{c}_1 \in \{0,1\}^\ell$ which are identical except the i-th bits: $\mathbf{c}_0[i] = 0$ and $\mathbf{c}_1[i] = 1$. Then, $\langle \mathbf{c}_0, \mathbf{x} \rangle$ and $\langle \mathbf{c}_1, \mathbf{x} \rangle$ cannot be simultaneously zero, since $\langle \mathbf{c}_1, \mathbf{x} \rangle - \langle \mathbf{c}_0, \mathbf{x} \rangle = \mathbf{x}[i] \neq 0$. Thus, $\Pr[\, \langle \mathbf{c}, \mathbf{x} \rangle = 0 \,] \leq 1/2$ holds, where the probability is over $\mathbf{c} \xleftarrow{\$} \{0,1\}^\ell$. Since λ rows of $\mathbf{C}$ are sampled independently from $\{0,1\}^\ell$, the lemma follows. □

Fiat-Shamir Transform. Below, we will use that fact that fig. 1 is a public-coin proof of knowledge with negligible soundness error, which allows us to apply the Fiat-Shamir transform [FS87] to generically make this protocol non-interactive in the random oracle model [PS96]. Concretely, the prover generates the challenge $\mathbf{C} \leftarrow \mathsf{Hash}(\mathbf{A}, \mathbf{H})$ and then computes the response $\mathbf{Z} \leftarrow \mathbf{C}\mathbf{D}$, where the hash function Hash is modeled as a random oracle.

2.3 Learning with Errors

The security of our PIR scheme is based on the decisional Learning with Errors (LWE) problem [Reg09]. Consider a uniformly random matrix $\mathbf{A} \in \mathbb{Z}_q^{m \times n}$, a short *error* vector $\mathbf{e} \leftarrow \chi^m$ such that $\mathbf{e} \in \mathbb{Z}_q^m$, and uniformly random vectors $\mathbf{s} \in \mathbb{Z}_q^n$. Note that χ is an *error* distribution over $\mathbb{Z}_q$, typically a zero-centered discrete Gaussian modulo q. The LWE problem is to distinguish the distribution of $(\mathbf{A}, \mathbf{A}\mathbf{s} + \mathbf{e})$ from the distribution of $(\mathbf{A}, \mathbf{r})$, where $\mathbf{r}$ is uniformly sampled in $\mathbb{Z}_q^m$. More formally, we say that the (n, q, χ)-LWE problem with m samples is (T, ε)-hard if no adversary running in time T can distinguish these distributions with probability better than ε.

Linearly Homomorphic Encryption. We briefly define the linearly homomorphic encryption (LHE) scheme from LWE given by Regev [Reg09]. We use the same "hoisted" variant as in Henzinger et al. [HHCG+23], where the matrix $\mathbf{A}$ is reused across multiple ciphertexts but the secret $\mathbf{s}$ is sampled independently for each ciphertext, allowing us to preprocess data dependent on the matrix $\mathbf{A}$.

The plaintext space of the LHE scheme is vectors over $\mathbb{Z}_p$. Let $\mu \in \mathbb{Z}_p^m$ be a plaintext. To encrypt μ, sample a uniform matrix $\mathbf{A} \in \mathbb{Z}_q^{m \times n}$, a uniform secret key $\mathbf{s} \leftarrow \mathbb{Z}_q^n$, and an error vector $\mathbf{e} \leftarrow \chi^m$. The ciphertext is $(\mathbf{A}, \mathbf{A}\mathbf{s} + \Delta\mu + \mathbf{e}) \in \mathbb{Z}_q^{m \times (n+1)}$, where $\Delta := \lfloor q/p \rfloor$. To decrypt a ciphertext $(\mathbf{A}, \mathbf{u}) \in \mathbb{Z}_q^{m \times (n+1)}$, compute $\mathbf{A}\mathbf{s}$ and output $\lfloor (\mathbf{u} - \mathbf{A}\mathbf{s})/\Delta \rfloor \in \mathbb{Z}_p^m$. The correctness of this decryption holds as long as $\Delta/2 > ||\mathbf{e}||_\infty$.

To see why this scheme is linearly homomorphic, consider a linear transformation $\mathbf{D} \in \mathbb{Z}^{\ell \times m}$. We can homomorphically compute $\mathbf{D}$ over an encryption of a vector μ. Consider the ciphertext $\mathsf{ct} = (\mathbf{A}, \mathbf{A}\mathbf{s} + \Delta\mu + \mathbf{e})$. Observe that the product $\mathbf{D} \cdot \mathsf{ct} = (\mathbf{D}\mathbf{A}, \mathbf{D}\mathbf{A}\mathbf{s} + \Delta\mathbf{D}\mu + \mathbf{D}\mathbf{e}) \in \mathbb{Z}_q^{\ell \times (n+1)}$ is a well-formed encryption of $\mathbf{D}\mu$. Decryption correctness holds as long as $\Delta/2 > ||\mathbf{D}\mathbf{e}||_\infty$.

LHE Correctness. We now discuss the constraints on the LWE parameters to ensure correct decryption with good probability after a homomorphic linear transformation. We follow the analysis of Henzinger et al. (see e.g. [HHCG+23, Theorem C.1]). We will make use of the following helpful lemma. Here, D_s denotes the discrete Gaussian distribution over $\mathbb{Z}$ with variance $s^2/2\pi$.

Lemma 2.5 ([LP11, Lemma 2.2], [Ban95, Lemma 2.4])**.** *For any real $s > 0$ and $T > 0$, and any $\mathbf{x} \in \mathbb{R}^n$, we have*

$$\Pr_{\mathbf{e} \leftarrow D_s^m} \left[|\langle \mathbf{x}, \mathbf{e} \rangle| \geq T \cdot s ||\mathbf{x}||_2 \right] < 2\exp(-\pi \cdot T^2).$$

For some $\mathbf{D} \in \mathbb{Z}^{\ell \times m}$, consider the decryption of the ciphertext $(\mathbf{A}, \mathbf{A}\mathbf{s} + \Delta\mu + \mathbf{D}\mathbf{e}) \in \mathbb{Z}_q^{m \times (n+1)}$, where $\mathbf{e}$ is a fresh sample from D_s^m. As noted above, we need $\Delta/2 > ||\mathbf{D}\mathbf{e}||_\infty$ to decryption correctly. Regarding $||\mathbf{D}\mathbf{e}||_\infty$, we apply lemma 2.5 to each row of $\mathbf{D}$. Note that we can bound the ℓ_2 norm of any row of $\mathbf{D}$ by $\sqrt{m} \cdot ||\mathbf{D}||_\infty$. Then, setting $T = \Delta/(s\sqrt{m} \cdot ||\mathbf{D}||_\infty)$,

we have that $\Pr[||\mathbf{De}||_\infty \geq \Delta/2] < \delta$, where

$$\delta = 2\exp\left(-\pi\left(\frac{\Delta}{s\sqrt{m}\cdot||\mathbf{D}||_\infty}\right)^2\right).$$

Equivalently, we have decryption failure probability of at most δ if

$$\Delta \geq s\sqrt{m}\cdot||\mathbf{D}||_\infty\cdot\sqrt{\frac{\ln(2/\delta)}{\pi}} = \sigma\cdot||\mathbf{D}||_\infty\sqrt{2m\ln(2/\delta)}.$$

Here, σ denotes the standard deviation of D_s, i.e. $\sigma^2 = s^2/2\pi$. In summary, this gives us a lower bound on q as

$$q \geq p\cdot\sigma\cdot||\mathbf{D}||_\infty\sqrt{2m\ln(2/\delta)}. \tag{2}$$

This saves us roughly a $\sqrt{m}$ factor over the naïve worst-case analysis.

2.4 Semi-honest PIR

We begin by giving the API for PIR with a preprocessed database. These core algorithms will be identical to those used in the preprocessed verifiable PIR below. The database elements are treated as elements of $\mathbb{Z}_t$, where t is some integer modulus. The parameters for this primitive are a modulus t, a database length N, and a security parameter λ. The algorithms are described below, and the usage of the API is given in fig. 2

- $\mathsf{pp} \leftarrow \mathsf{Setup}(1^\lambda, 1^N, t)$
  Outputs public parameters pp.
- $\mathsf{d} \leftarrow \mathsf{Digest}(\mathsf{pp}, \mathbf{D} \in \mathbb{Z}_t^N)$
  Takes in a database $\mathbf{D}$ of size N of elements of $\mathbb{Z}_t$ and outputs a *short* digest d (i.e. $|\mathsf{d}| \ll |\mathbf{D}|$).
- $\mathsf{q}, \mathsf{st} \leftarrow \mathsf{Query}(\mathsf{pp}, i \in [N])$
  Takes in an index $i \in [N]$ and produces a query q with a query state st.
- $\mathsf{a} \leftarrow \mathsf{Answer}(\mathsf{pp}, \mathbf{D}, \mathsf{q})$
  Takes in a database $\mathbf{D}$ and a query q and produces an answer a.
- $\mathsf{r} \leftarrow \mathsf{Recover}(\mathsf{pp}, \mathsf{st}, \mathsf{a}, \mathsf{d})$
  Takes in a query state st generated from an index $i \in [N]$, an answer a, and a digest d of $\mathbf{D}$. Outputs a database element r. If inputs are honestly generated, the output r should be $\mathbf{D}[i]$. This is formalized below (definition 2.2).

We now define basic correctness and security requirments for the semi-honest PIR primitive.

Definition 2.2 (Correctness)**.** *We say that a PIR scheme has* correctness error δ *if, for security parameter λ, for all databases $\mathbf{D} \in \mathbb{Z}_t^N$ and for all indices $i \in [N]$,*

$$\Pr\left[\begin{array}{r|l} \mathsf{Recover}(\mathsf{st},\mathsf{a},\mathsf{d}) & \mathsf{pp} \leftarrow \mathsf{Setup}(1^\lambda, 1^N, t) \\ = \mathbf{D}[i] & \mathsf{d} \leftarrow \mathsf{Digest}(\mathbf{D}) \\ & \mathsf{q}, \mathsf{st} \leftarrow \mathsf{Query}(i) \\ & \mathsf{a} \leftarrow \mathsf{Answer}(\mathbf{D}, \mathsf{q}) \end{array}\right] \geq 1 - \delta.$$

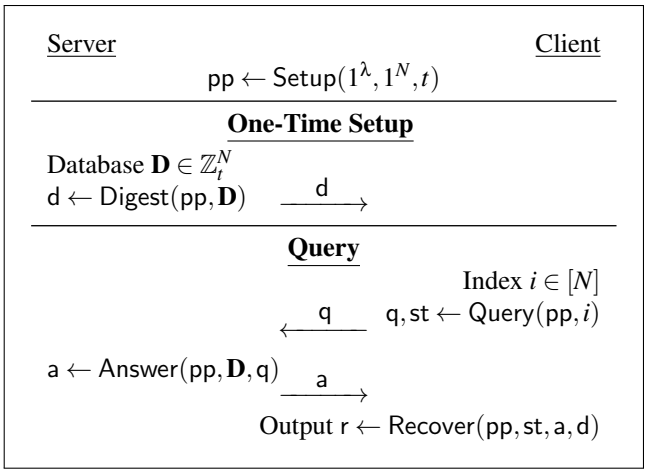

Figure 2: Usage of the Semi-honest PIR API.

The public parameters pp are implicit inputs in all algorithms following Setup.

Definition 2.3 (Query Hiding)**.** *We say that a PIR scheme is (T, ε)-*Query Hiding *if, for all adversaries $\mathcal{A}$ running in time at most T, on database size N and for all $i, j \in [N]$,*

$$\Big|\Pr[\mathcal{A}(\mathsf{pp},\mathsf{q}) = 1 : (\mathsf{q},\mathsf{st}) \leftarrow \mathsf{Query}(\mathsf{pp}, i)] - \Pr[\mathcal{A}(\mathsf{pp},\mathsf{q}) = 1 : (\mathsf{q},\mathsf{st}) \leftarrow \mathsf{Query}(\mathsf{pp}, j)]\Big| \leq \varepsilon$$

Remark 2.1 (Selective Failures & Query Hiding)**.** *We note that definition 2.3 is insufficient when considering malicious adversaries, since selective failure attacks could compromise query hiding even when the query message alone reveals nothing about the client's desired index.*

2.4.1 SimplePIR

We give the semi-honest PIR protocol, denoted SimplePIR, from [HHCG+23] below. The API usage is given in fig. 2. Parsing the public parameters pp as $\mathbf{A}$ and the digest d as $\mathbf{H}$ is implicit. Note that the database here is represented as a matrix $\mathbf{D} \in \mathbb{Z}_p^{\ell\times m}$. We omit the details of encoding vectors in $\mathbb{Z}_t^N$ to matrices over $\mathbb{Z}_p$.

- $\mathsf{pp} \leftarrow \mathsf{Setup}(1^\lambda, 1^N, t)$
  Output a uniform $\mathbf{A} \in \mathbb{Z}_q^{m\times n}$ as pp.
- $\mathsf{d} \leftarrow \mathsf{Digest}(\mathsf{pp}, \mathbf{D})$
  Compute $\mathbf{H} \leftarrow \mathbf{DA} \in \mathbb{Z}_q^{\ell\times n}$. Output $\mathsf{d} \leftarrow \mathbf{H}$.
- $\mathsf{q}, \mathsf{st} \leftarrow \mathsf{Query}(\mathsf{pp}, i \in [N])$
  Write i as $(i_r, i_c) \in [\ell] \times [m]$. Sample a uniform secret $\mathbf{s} \leftarrow \mathbb{Z}_q^n$ and an error vector $\mathbf{e} \leftarrow \chi^m$. Compute $\mathbf{u} \leftarrow \mathbf{As} + \mathbf{e} + \lfloor q/p \rfloor \mathbf{b}_{i_c}$. Output $(\mathsf{q}, \mathsf{st}) \leftarrow (\mathbf{u}, (\mathbf{s}, i))$.
- $\mathsf{a} \leftarrow \mathsf{Answer}(\mathsf{pp}, \mathbf{D}, \mathsf{q})$
  Parse q as $\mathbf{u} \in \mathbb{Z}_q^m$. Output $\mathbf{v} \leftarrow \mathbf{Du}$ as a.

- $\mathsf{r} \leftarrow \mathsf{Recover}(\mathsf{pp}, \mathsf{st}, \mathsf{a}, \mathsf{d})$
  Parse $(\mathbf{s}, i) \leftarrow \mathsf{st}$ and $\mathbf{v} \leftarrow \mathsf{a}$. Write i as $(i_\mathrm{r}, i_\mathrm{c}) \in [\ell] \times [m]$. Compute $\hat{\mathsf{r}} \leftarrow \mathbf{v}[i_\mathrm{r}] - \langle \mathbf{H}[i_\mathrm{r}], \mathbf{s} \rangle \in \mathbb{Z}_q$. Output $\mathsf{r} \leftarrow \lfloor p \cdot \hat{\mathsf{r}}/q \rceil \in \mathbb{Z}_p$.

The constraints on the LWE parameters to ensure correctness of the protocol are given in eq. (2) in section 2.3.

3 Verifiable PIR Definitions

In this section, we define the algorithms that comprise the preprocessed verifiable PIR primitive as well as the correctness and security definitions that this primitive must satisfy.

As in the semi-honest definition, the database elements are treated as elements of $\mathbb{Z}_t$, where t is some integer modulus. The parameters for this primitive are a modulus t, a database length N, and a security parameter λ. The API consists of the following algorithms in addition to the algorithms in the semi-honest PIR API (see section 2.4). The usage of this API is described in fig. 3.

- $\mathsf{Accept}/\mathsf{Reject} \leftarrow \mathsf{DigVer}(\mathsf{pp}, \mathsf{d})$
  Takes in the public parameters and a digest and outputs Accept if the digest is well-formed with respect to some database. Outputs Reject otherwise.

- $\mathsf{q}_\pi, \mathsf{st}_\pi \leftarrow \mathsf{PrQry}(\mathsf{pp})$
  This is the proof query algorithm, where the client generates a request used by the server to precompute the proof for the query phase. The output is a proof query q_π and a proof query state st_π.

- $\mathsf{a}_\pi \leftarrow \mathsf{PrAns}(\mathsf{pp}, \mathbf{D}, \mathsf{d}, \mathsf{q}_\pi)$
  This is the proof answer algorithm that is run by the server to respond to a proof query. The output is returned to the client.

- $\pi/\perp \leftarrow \mathsf{PrRec}(\mathsf{pp}, \mathsf{d}, \mathsf{q}_\pi, \mathsf{st}_\pi, \mathsf{a}_\pi)$
  This is the final algorithm in the proof preprocessing phase, which is run by the client to verify the response from the server and output the proof. If the response does not verify, the algorithm outputs $\perp$. Otherwise, it outputs the proof π.

- $\mathsf{Accept}/\mathsf{Reject} \leftarrow \mathsf{Verify}(\mathsf{pp}, \mathsf{d}, \mathsf{q}, \mathsf{a}, \pi)$
  Takes in the digest d, a query q, an answer a, and a proof π. Outputs Accept if the answer a was correctly computed over the query q and the digest d.

At a high level, the goal of this API is to allow the client to query the server for a *single* proof that is then *reused* across many PIR queries. This proof can be safely reused as long as the verification does not fail. As soon as the verification fails, the client must rerun the proof preprocessing phase in order to maintain the integrity of the verification.

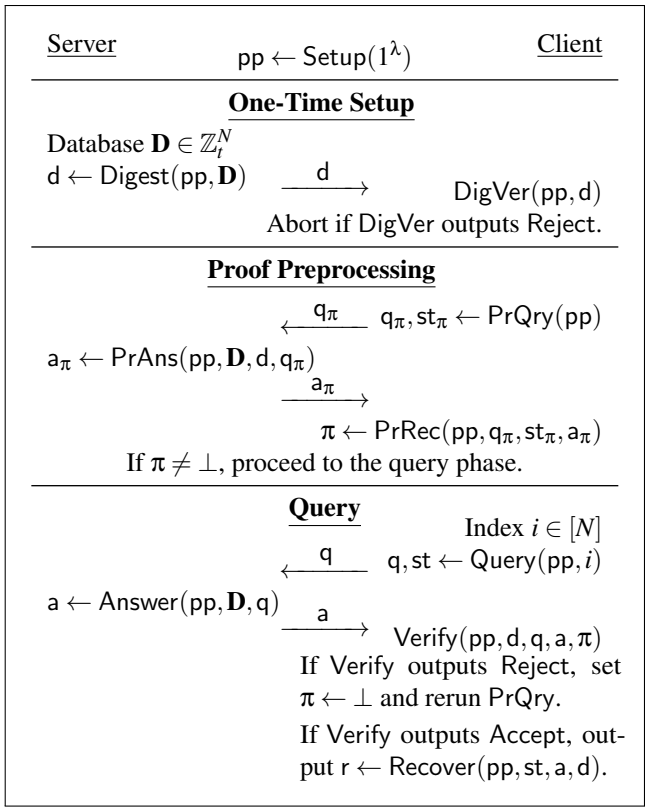

Figure 3: Usage of the Preprocessed Verifiable PIR API.

Security Definitions. We give an intuition for the security definitions of the vPIR primitive here. The full definitions are in appendix A.

- **Completeness.** Our verification procedures will have perfect completeness; messages produced by honest servers will always verify. This is in addition to the standard PIR correctness given in definition 2.2.

- **Digest Binding.** We require that the digest be a computationally binding commitment to the database $\mathbf{D}$. This will allow us to define honest behavior with respect to this fixed database as long as the initial DigVer check passes.

- **Soundness.** The soundness requirement for the verification procedure is very strict. Not only must the returned answer a give the correct output upon running Recover, but a must be the *unique* value defined by the query q and the fixed database $\mathbf{D}$. This uniqueness requirement is extended to the proof π. The only value π that will pass verification in the preprocessing phase is the exact value defined by pp, q_π, st_π, and the fixed database $\mathbf{D}$.

Reusable Proofs from Strict Soundness. The strict soundness requirements achieved by this primitive immediately imply that it is safe to reuse the proof. If the only answers that

the server can return are exactly the honest values, then there is no leakage on the proof from client passing verification, since due to the perfect completeness the honest messages will always pass verification. Furthermore, since the proof π does not depend on the query or answer, the safety of using this proof once extends to reusing this proof many times, since the server has no additional information about π once a query phase is complete.

4 Verifiable Linearly Homomorphic Encryption

In this section, we construct our verifiable linearly homomorphic encryption scheme, denoted VLHE. This scheme begins with the Regev LHE described in section 2.3. In this scheme, a ciphertext that encrypts a vector $\mu \in \mathbb{Z}_p^m$ has the structure

$$(\mathbf{A}, \mathbf{As} + \lfloor q/p \rfloor \mu + \mathbf{e}) = (\mathbf{A}, \mathbf{u}) \in \mathbb{Z}_q^{m \times n} \times \mathbb{Z}_q^m.$$

This scheme supports the homomorphic evaluation of linear functions $\mathbf{D} \in \mathbb{Z}^{\ell \times m}$ that map $\mathbb{Z}_p^m$ to $\mathbb{Z}_p^\ell$. Note that we allow $\mathbf{D}$ to define linear maps between larger rings, e.g., $\mathbb{Z}_q^m \to \mathbb{Z}_q^\ell$ for $q > p$. The ciphertext that encrypts the output of the function $\mathbf{D}$ has the form

$$(\mathbf{DA}, \mathbf{DAs} + \lfloor q/p \rfloor \mathbf{D}\mu + \mathbf{De}) = (\mathbf{H}, \mathbf{v}) \in \mathbb{Z}_q^{\ell \times n} \times \mathbb{Z}_q^\ell,$$

where we defined $\mathbf{v} := \mathbf{Du} \in \mathbb{Z}_q^\ell$ and $\mathbf{H} := \mathbf{DA} \in \mathbb{Z}_q^{\ell \times n}$. At a high level, we use the fact that the matrix $\mathbf{H}$ is an extractable commitment to the matrix $\mathbf{D}$. Furthermore, we can use the extractable proof described in section 2.2 to efficiently prove knowledge of the function $\mathbf{D}$. Overall, the basic equation that we will use throughout this section is

$$\mathbf{D} \begin{bmatrix} \mathbf{A} & \mathbf{u} \end{bmatrix} = \begin{bmatrix} \mathbf{H} & \mathbf{v} \end{bmatrix}, \tag{3}$$

which also has the form of an extractable SIS commitment described in section 2.2.

4.1 Verifiable LHE Construction

We now give the API for the (secret-key) VLHE primitive along with the construction based on the Regev LHE scheme [Reg09].

Construction 4.1 (Verifiable Linearly Homomorphic Encryption)**.** *The scheme is parametrized by a computational security parameter n, a statistical security parameter λ, a plaintext modulus p, a ciphertext modulus q, and an error distribution χ. The final parameter is a hash function* Hash *that is modeled as a random oracle. This hash function is used to apply the Fiat-Shamir transform [FS87] to the public-coin proof described in section 2.2 on the commitment defined in eq. (3).*

- $\mathsf{pp} \leftarrow \mathsf{VLHE.Setup}(1^n, 1^m, q)$
  Samples a uniformly random matrix $\mathbf{A} \leftarrow \mathbb{Z}_q^{m \times n}$ and outputs $\mathsf{pp} \leftarrow \mathbf{A}$ as the public parameters.

- $\mathbf{H}, \mathbf{Z} \leftarrow \mathsf{VLHE.Commit}(\mathbf{A}, \mathbf{D} \in \mathbb{Z}_p^{\ell \times m})$
  Takes in a linear function $\mathbf{D}$ and computes $\mathbf{H} \leftarrow \mathbf{DA} \in \mathbb{Z}_q^{\ell \times n}$ as the commitment to $\mathbf{D}$. Compute $\mathbf{C} \in \{0,1\}^{\lambda \times \ell}$ as $\mathbf{C} = \mathsf{Hash}(\mathbf{A}, \mathbf{H})$ and set $\mathbf{Z} \leftarrow \mathbf{C} \cdot \mathbf{D}$. Output $\mathbf{H}, \mathbf{Z}$.

- $\mathsf{Accept}/\mathsf{Reject} \leftarrow \mathsf{VLHE.VerCom}(\mathbf{A}, \mathbf{H}, \mathbf{Z})$
  This verifies the initial commitment to the linear function. Check $||\mathbf{Z}||_\infty \leq \ell \cdot p$ and output Reject *if this check fails. Compute $\mathbf{C} \leftarrow \mathsf{Hash}(\mathbf{A}, \mathbf{H})$ exactly as in* Commit*. Check that $\mathbf{ZA} = \mathbf{CH}$. Output* Reject *if this check fails and* Accept *if this check passes.*

- $(\mathbf{u}, \mathbf{s}) \leftarrow \mathsf{VLHE.Encrypt}(\mathbf{A}, \mu \in \mathbb{Z}_p^m)$
  Sample a uniform secret $\mathbf{s} \leftarrow \mathbb{Z}_q^n$ and an error vector $\mathbf{e} \leftarrow \chi^m$. For $\Delta := \lfloor q/p \rfloor$, compute the ciphertext $\mathbf{u} := \mathbf{As} + \Delta\mu + \mathbf{e} \in \mathbb{Z}_q^m$. Note that this is identical to the Regev LHE encryption. Output $(\mathbf{u}, \mathbf{s})$.

- $\mathbf{v} \leftarrow \mathsf{VLHE.Eval}(\mathbf{D}, \mathbf{u})$
  This is homomorphic evaluation; output $\mathbf{v} \leftarrow \mathbf{Du}$.

- $\nu \leftarrow \mathsf{VLHE.Decrypt}(\mathbf{H} \in \mathbb{Z}_q^{\ell \times n}, \mathbf{s} \in \mathbb{Z}_q^n, \mathbf{v} \in \mathbb{Z}_q^\ell)$
  We define this operation for the outputs of homomorphic evaluation. This operation is identical to Regev decryption, where the output is $\nu \leftarrow \lfloor (\mathbf{v} - \mathbf{H} \cdot \mathbf{s})/\Delta \rfloor \in \mathbb{Z}_p^\ell$.

- $\mathbf{Z} \leftarrow \mathsf{VLHE.Prove}(\mathbf{A}, \mathbf{H}, \mathbf{u}, \mathbf{v}, \mathbf{D})$
  Compute $\mathbf{C} \in \{0,1\}^{\lambda \times \ell}$ as $\mathbf{C} \leftarrow \mathsf{Hash}(\mathbf{A}, \mathbf{H}, \mathbf{u}, \mathbf{v})$. Output $\mathbf{Z} \leftarrow \mathbf{CD}$.

- $\mathsf{Accept}/\mathsf{Reject} \leftarrow \mathsf{VLHE.Verify}(\mathbf{A}, \mathbf{H}, \mathbf{u}, \mathbf{v}, \mathbf{Z})$
  Check $||\mathbf{Z}||_\infty \leq \ell \cdot p$. Output Reject *if this check fails. Compute $\mathbf{C} \leftarrow \mathsf{Hash}(\mathbf{A}, \mathbf{H}, \mathbf{u}, \mathbf{v})$ exactly as in* Prove*. Check that $\mathbf{Z} \begin{bmatrix} \mathbf{A} & \mathbf{u} \end{bmatrix} = \mathbf{C} \begin{bmatrix} \mathbf{H} & \mathbf{v} \end{bmatrix}$. Output* Reject *if this check fails and* Accept *if this check passes.*

Observe that Verify performs the exact checks that correspond to verifying an opening of the commitment defined in eq. (3).

4.1.1 Verifiable LHE Correctness & Security

We first prove the security of the verification, then show how to obtain correctness for all (even malicious) functions that pass verification.

Security. Semantic security follows directly from the security of the Regev encryption scheme and the hardness of LWE. Below, we give the constraint parameters that guarantees correct decryption as long as VLHE verification passes.

We can now focus on the security of the proof verification. We obtain a very strong security guarantee, which is that only *one* ciphertext (the correct ciphertext) will pass verification. We focus our security proofs on the interactive variant of the verification given in fig. 5, and the security of construction 4.1 follows by applying the Fiat-Shamir heuristic [FS87].

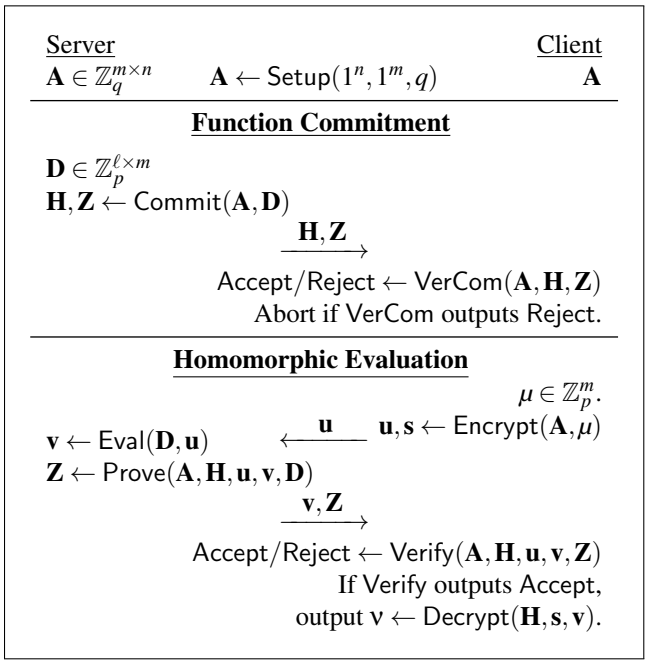

Figure 4: Usage of the VLHE API in construction 4.1.

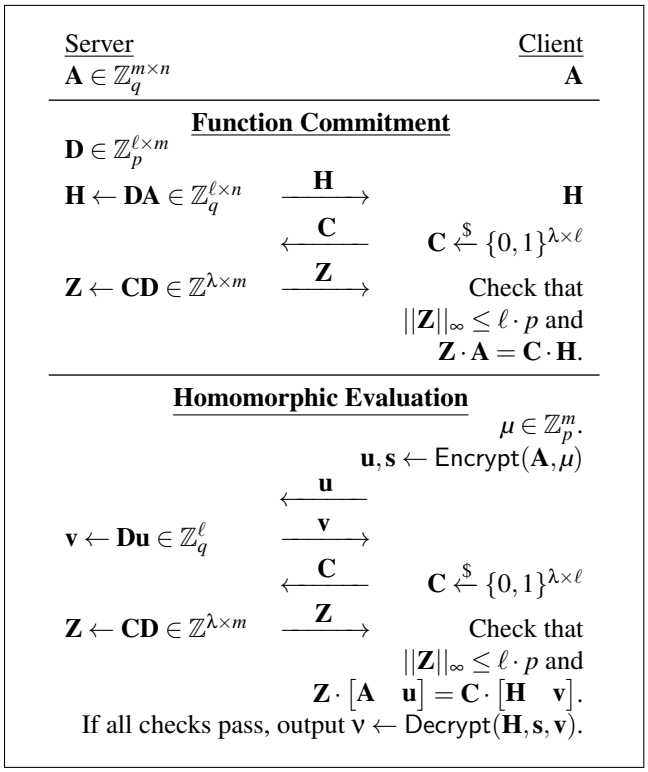

Figure 5: Variant of the VLHE construction in that uses interactive commitment openings. Construction 4.1 can be derived by applying the Fiat-Shamir heuristic to this protocol.

Lemma 4.1 (Verification Uniqueness)**.** *Let $\mathcal{P}$ be a computationally bounded server (prover) in fig. 5, and let $\mathbf{H}$ be the matrix sent by $\mathcal{P}$ in the function commitment phase. Consider the extractor $\mathcal{E}$ from lemma 2.2 running on $\mathcal{P}$ in the function commitment phase. Let $\mathbf{D} \in \mathbb{Z}^{\ell \times m}$ be the unique matrix that can be extracted from $\mathcal{E}$, under hardness assumption of $\mathsf{SIS}_{n,m,q,\beta}$ for $\beta = 4\ell p$ (lemma 2.3). Consider a ciphertext $\mathbf{u}$ as in fig. 5 and a response $\tilde{\mathbf{v}}$. Assuming the hardness of $\mathsf{SIS}_{n,m,q,\beta}$ for $\beta = 4\ell p$, $\tilde{\mathbf{v}} = \mathbf{Du}$ must hold.*

Proof. Assume for contradiction that the response ciphertext $\tilde{\mathbf{v}} \neq \mathbf{Du}$, but the server is able to produce some $\widetilde{\mathbf{Z}}$ such that $||\widetilde{\mathbf{Z}}||_\infty \leq \ell p$ and $\widetilde{\mathbf{Z}} \cdot \begin{bmatrix} \mathbf{A} & \mathbf{u} \end{bmatrix} = \mathbf{C} \cdot \begin{bmatrix} \mathbf{H} & \tilde{\mathbf{v}} \end{bmatrix}$. We can invoke lemma 2.2 on the commitment defined by $\begin{bmatrix} \mathbf{A} & \mathbf{u} \end{bmatrix}$ and $\begin{bmatrix} \mathbf{H} & \tilde{\mathbf{v}} \end{bmatrix}$ to extract some database $\mathbf{D}'$ such that $||\mathbf{D}'||_\infty \leq 2\ell p$ and $\mathbf{D}' \begin{bmatrix} \mathbf{A} & \mathbf{u} \end{bmatrix} = \begin{bmatrix} \mathbf{H} & \tilde{\mathbf{v}} \end{bmatrix}$. If $\mathbf{D}' \neq \mathbf{D}$, then we have $(\mathbf{D}' - \mathbf{D})\mathbf{A} = \mathbf{0}$, where $\mathbf{D}' - \mathbf{D} \neq \mathbf{0}$. This is an SIS solution for $\mathbf{A}$ of magnitude $||\mathbf{D}' - \mathbf{D}||_\infty \leq 4\ell p$. This contradicts the hardness of $\mathsf{SIS}_{n,m,q,\beta}$ for $\beta = 4\ell p$, so we must have $\mathbf{D}' = \mathbf{D}$. Therefore, $\tilde{\mathbf{v}} = \mathbf{Du}$. □

Correctness. In the original Regev scheme, correctness was only guaranteed for a function $\mathbf{D} \in \mathbb{Z}_p^{\ell \times m}$. The correctness requirement for this scheme must account for the slack between the honest entry-size p and the bound guaranteed by extractability, which is $||\mathbf{D}||_\infty \leq 2\ell p$ (recall lemma 2.2). By slightly increasing the ciphertext modulus, we can account for any matrix $\mathbf{D} \in \mathbb{Z}_{2\ell p}^{\ell \times m}$, which allows us to guarantee that if verification passes then decryption will only fail with negligible probability. We can use this bound in eq. (2) to obtain the following correctness requirement for the VLHE scheme:

$$q \geq \sigma \cdot 2\ell p^2 \sqrt{2m \ln(2/\delta)}. \tag{4}$$

4.1.2 Batch Verification of Output Ciphertexts

We briefly note that the proofs in construction 4.1 can efficiently verify a batch of input-output pairs. More formally, we batch-verify t input-output ciphertext pairs $(\mathbf{u}_i, \mathbf{v}_i) \in \mathbb{Z}_q^m \times \mathbb{Z}_q^\ell$ by first defining the matrices

$$\mathbf{U} := \begin{bmatrix} \mathbf{u}_1 & \cdots & \mathbf{u}_t \end{bmatrix} \in \mathbb{Z}_q^{m \times t}$$
$$\mathbf{V} := \begin{bmatrix} \mathbf{v}_1 & \cdots & \mathbf{v}_t \end{bmatrix} \in \mathbb{Z}_q^{\ell \times t}.$$

We then observe that the server's computation across all t pairs can be viewed as an SIS commitment $\mathbf{D} \cdot \begin{bmatrix} \mathbf{A} & \mathbf{U} \end{bmatrix} = \begin{bmatrix} \mathbf{H} & \mathbf{V} \end{bmatrix}$ which can be verified using the relation

$$\mathbf{Z} \cdot \begin{bmatrix} \mathbf{A} & \mathbf{U} \end{bmatrix} = \mathbf{C} \cdot \begin{bmatrix} \mathbf{H} & \mathbf{V} \end{bmatrix}. \tag{5}$$

Observe that the matrix $\mathbf{Z}$ in eq. (5) is identical to the $\mathbf{Z}$ matrix in eq. (3). In addition, the $\mathbf{C}$ matrices in both equations are also the identically distributed, which results in identical norm bound on the $\mathbf{Z}$ matrices. In fact, the only piece of the BatchProve and BatchVerify algorithms that grow with t is the computation of the hash function Hash on the t tuples and, of course, the matrix multiplication itself, which now

has $n+t$ columns rather than $n+1$ columns. The algorithms are give formally below.

- $\mathbf{Z} \leftarrow \mathsf{VLHE.BatchProve}(\mathbf{A},\mathbf{H},\mathbf{U},\mathbf{V},\mathbf{D})$
  Compute $\mathbf{C} \leftarrow \mathsf{Hash}(\mathbf{A},\mathbf{H},\mathbf{U},\mathbf{V})$ where $\mathbf{C} \in \{0,1\}^{\lambda \times \ell}$. Compute $\mathbf{Z} \leftarrow \mathbf{CD} \in \mathbb{Z}^{\lambda \times m}$ and output $\mathbf{Z}$.

- $\mathsf{Accept/Reject} \leftarrow \mathsf{VLHE.BatchVerify}(\mathbf{A},\mathbf{H},\mathbf{U},\mathbf{V},\mathbf{Z})$
  Compute $\mathbf{C} \leftarrow \mathsf{Hash}(\mathbf{A},\mathbf{H},\mathbf{U},\mathbf{V})$ exactly as in BatchProve. Check that $||\mathbf{Z}||_\infty \leq \ell \cdot p$ and that $\mathbf{Z} \cdot \begin{bmatrix}\mathbf{A} & \mathbf{U}\end{bmatrix} = \mathbf{C} \cdot \begin{bmatrix}\mathbf{H} & \mathbf{V}\end{bmatrix}$. If all the checks pass, output Accept. Otherwise, output Reject.

The security of these functions follows an identical argument to the proof of lemma 4.1.

4.2 Reusable VLHE Proof

We present a useful protocol to compute a *reusable* VLHE proof. When a fixed linear function is applied to many encrypted vectors, this reusable proof a prevents repeatedly computing and sending a fresh $\mathbf{Z}$ for every response ciphertext. Looking ahead, our final VeriSimplePIR protocol leverages this proof preprocessing protocol to allow verifiability at no online cost in SimplePIR.

Our proof preprocessing protocol combines two observations. The first is that the proof $\mathbf{Z} = \mathbf{CD}$ does not directly depend on any other aspect of the protocol beyond the matrix $\mathbf{D}$. This allows us to precompute this proof before the input ciphertext is given. A caveat here is that the proof $\mathbf{Z}$ must be computed while keeping the client's challenge $\mathbf{C}$ secret from the server. Otherwise, the server might use its knowledge of the challenge for malicious actions in homomorphic evaluation. Meanwhile, if the proof is computed while keeping the challenge secret, we can even reuse the preprocessed proof across several queries as long as C is not leaked.

The second observation is that the proof $\mathbf{Z} = \mathbf{CD}$ is, in fact, computed as a *linear* function evaluation defined by $\mathbf{D}$. That is, we can use construction 4.1 on the matrix $\mathbf{D}^T$ where the ciphertexts encrypt the rows of the challenge $\mathbf{C}$. This allows the server to *verifiably* compute $\mathbf{D}^T\mathbf{C}^T = \mathbf{Z}^T$ for the client while not knowing the challenge $\mathbf{C}$.

The full proof preprocessing protocol, along with the corresponding verifiable homomorphic evaluation, is given in fig. 6. In the construction, two commitments, $\mathbf{H}_1$ and $\mathbf{H}_2$, are used. The first commitment $\mathbf{H}_1$ plays the same role as the commitment $\mathbf{H}$ in the original VLHE construction (section 4.1, fig. 5). The second commitment $\mathbf{H}_2$ is introduced to commit to $\mathbf{D}^T$. This commitment is used when checking whether the server has run the proof preprocessing phase honestly. This complication occurs since the direction of the $\mathbf{D}$ multiplication differs when preprocessing proofs and homomorphically evaluating answers. We also replace Verify with a simpler PreVerify, which verifies with preprocessed proof rather than fresh proofs.

- $\mathsf{Accept/Reject} \leftarrow \mathsf{VLHE.PreVerify}(\mathbf{u},\mathbf{v},\mathbf{C},\mathbf{Z})$
  Check that $\mathbf{Zu} = \mathbf{Cv}$. If the check passes, output Accept. Otherwise, output Reject.

Correctness. In order to accommodate the encryption of a row of $\mathbf{Z}$, we will need an Encrypt algorithm with the plaintext space $\mathbb{Z}_{p\ell}$ and the evaluation of the linear function $\mathbf{D}^T \in \mathbb{Z}_p^{m \times \ell}$. Let $\mathsf{Encrypt}_{p\ell}$ denote this algorithm and let $\mathsf{Decrypt}_{p\ell}$ denote the corresponding decryption algorithm. We have an updated correctness requirement from eq. (4):

$$q \geq \sigma \cdot 2\ell^2 p^2 \sqrt{2\ell \ln(2/\delta)}. \tag{6}$$

to account for this increase in the plaintext modulus increasing from p to ℓp in the preprocessing encryptions and the length ℓ of the rows of $\mathbf{D}^T$. Note that the encryptions in the homomorphic evaluation phase still use p as the plaintext modulus.

The correctness of the proof preprocessing protocol follows directly from the correctness of the homomorphic computation of $\mathbf{Z} = \mathbf{CD} = (\mathbf{D}^T\mathbf{C}^T)^T$. Observe that the homomorphic computation produces ciphertexts that encrypt each row of $\mathbf{Z}$. These rows are computed as $\mathbf{Z}[i] = \left(\mathbf{D}^T \cdot (\mathbf{C}[i])^T\right)^T$ for the sampled $\mathbf{C}$, where $\mathbf{C}[i]$ is the i^{th} row of $\mathbf{C}$.

Security. We give an intuition for the security of this preprocessed protocol. The full security proofs are given in appendix B.

The security of the proof processing protocol in fig. 6 follows from the security of our VLHE scheme (construction 4.1). In particular, the server does not learn any information on the challenge $\mathbf{C}$ during the protocol since the semantic security of the encryption hides $\mathbf{C}$. For soundness, we argue that $\mathbf{Z} = \mathbf{CD}$ must hold if the checks pass (in particular, if the check $\mathbf{ZA}_1 = \mathbf{CH}_1$ passes). At a high level, this follows from the soundness of our VLHE (lemma 4.1) together with lemma 2.4: By lemma 4.1, the server has committed to some fixed linear function $\mathbf{D}'$ with $\mathbf{H}_2$, and it is guaranteed that $\mathbf{Z} = \mathbf{C}(\mathbf{D}')^T$. Therefore, we have $\mathbf{ZA}_1 = \mathbf{C}(\mathbf{D}')^T\mathbf{A}_1 = \mathbf{CH}_1$, so $\mathbf{C}\left((\mathbf{D}')^T\mathbf{A}_1 - \mathbf{H}_1\right) = 0$ holds. By lemma 2.4, this occurs with negligible probability if $(\mathbf{D}')^T\mathbf{A}_1 - \mathbf{H}_1 \neq 0$, so we have that $(\mathbf{D}')^T\mathbf{A}_1 = \mathbf{H}_1$ with overwhelming probability. Then, by SIS hardness, we must have that $(\mathbf{D}')^T = \mathbf{D}$ and thus $\mathbf{Z} = \mathbf{CD}$.

The security of the simplified homomorphic evaluation phase in fig. 6 is straightforward from the security of our VLHE scheme (construction 4.1). The only difference is that we can skip a fraction of the checks as it is already done in the proof preprocessing phase. We note that, however, when verification fails, leakage on $\mathbf{C}$ may occur. Then, the client must discard $\mathbf{C}$ and the corresponding $\mathbf{Z}$ and rerun the proof preprocessing phase.

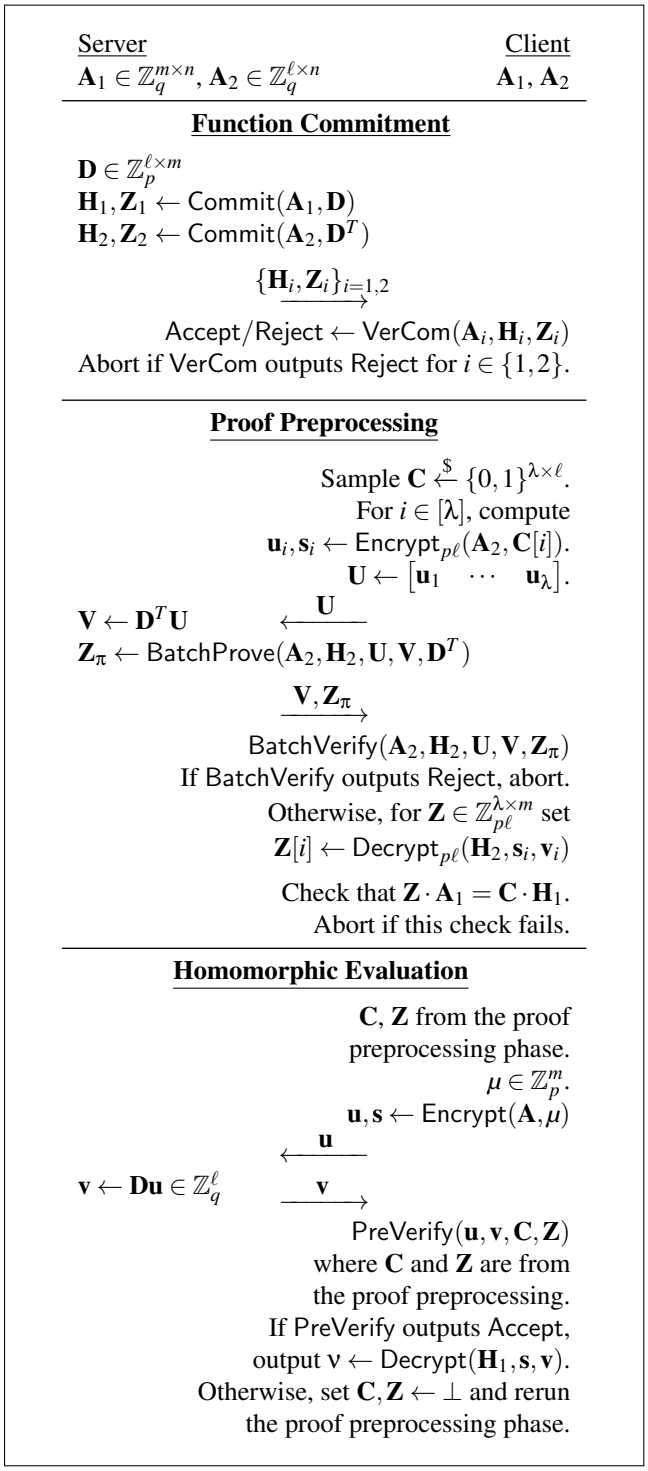

Figure 6: Protocol for computing reusable VLHE proofs. The proof is safe to reuse in many homomorphic evaluations as long as verification PreVerify passes. Once verification fails, a new proof must be computed.

5 Verifiable SimplePIR Construction

In this section, we present our full VeriSimplePIR protocol. The protocol follows directly from the VLHE construction from section 4. Recall from section 2.4.1 that we can view a database as a matrix $\mathbf{D} \in \mathbb{Z}_p^{\ell \times m}$ and queries as one-hot vectors $\mathbf{b}_i$. The response to this query is $\mathbf{d}_i = \mathbf{D} \cdot \mathbf{b}_i$, the i^{th} column of $\mathbf{D}$. The scheme is instantiated using the preprocessed VLHE scheme described in fig. 6. Observe the parallel structure of the preprocessed VLHE construction in fig. 6 and the preprocessed verifiable PIR API in fig. 3. We give the construction in construction 5.1. Note that the algorithms Query, Answer, and Recover are identical to the SimplePIR definitions in section 2.4.1.

Construction 5.1 (Preprocessed Verifiable PIR)**.** *The input parameters to this scheme are a computational security parameter n, a statistical security parameter λ, a plaintext modulus t, and a database size N. Let $p, \ell, m \in \mathbb{N}$ be such that a database in $\mathbb{Z}_t^N$ can be packed into an element of $\mathbb{Z}_p^{\ell \times m}$. For q that satisfies eq. (6), assume the hardness of $\mathsf{SIS}_{n,m,q,\beta_1}$ for $\beta_1 = 4\ell p$ and $\mathsf{SIS}_{n,\ell,q,\beta_2}$ for $\beta_2 = 4mp$. Furthermore, assume the hardness of (n,ℓ,q)-LWE and (n,m,q)-LWE.*

Let VLHE *denote construction 4.1 instantiated with plaintext modulus p and ciphertext modulus q.*

- $\mathsf{pp} \leftarrow \mathsf{Setup}(1^\lambda, 1^N, t)$
  Output
  $$\mathbf{A}_1 \leftarrow \mathsf{VLHE.Setup}(1^n, 1^m, q)$$
  $$\mathbf{A}_2 \leftarrow \mathsf{VLHE.Setup}(1^n, 1^\ell, q)$$
  as pp.

- $\mathsf{d} \leftarrow \mathsf{Digest}(\mathsf{pp}, \mathbf{D})$
  Compute
  $$\mathbf{H}_1, \mathbf{Z}_1 \leftarrow \mathsf{VLHE.Commit}(\mathbf{A}_1, \mathbf{D})$$
  $$\mathbf{H}_2, \mathbf{Z}_2 \leftarrow \mathsf{VLHE.Commit}(\mathbf{A}_2, \mathbf{D}^T).$$
  Output $\mathsf{d} \leftarrow (\mathbf{H}_1, \mathbf{Z}_1, \mathbf{H}_2, \mathbf{Z}_2)$.

- $\mathsf{Accept/Reject} \leftarrow \mathsf{DigVer}(\mathsf{pp}, d)$
  Run $\mathsf{VLHE.VerCom}(\mathbf{A}_i, \mathbf{H}_i, \mathbf{Z}_i)$ *for* $i \in \{1,2\}$. *Output* Reject *if either* VerCom *iterations outputs* Reject. *Otherwise, output* Accept.

- $\mathsf{q}_\pi, \mathsf{st}_\pi \leftarrow \mathsf{PrQry}(\mathsf{pp})$
  Sample $\mathbf{C} \xleftarrow{\$} \{0,1\}^{\lambda \times \ell}$. *For* $i \in [\lambda]$, *compute* $\mathbf{u}_i, \mathbf{s}_i \leftarrow \mathsf{VLHE.Encrypt}_{p\ell}(\mathbf{A}_2, \mathbf{C}[i])$. *Set* $\mathbf{U} \leftarrow \begin{bmatrix} \mathbf{u}_1 & \cdots & \mathbf{u}_\lambda \end{bmatrix}$. *Output* $\mathsf{q}_\pi \leftarrow \mathbf{U}$ *and* $\mathsf{st}_\pi \leftarrow (\mathbf{C}, \{\mathbf{s}_i\}_{i \in \lambda})$.

- $\mathsf{a}_\pi \leftarrow \mathsf{PrAns}(\mathsf{pp}, \mathbf{D}, \mathsf{d}, \mathsf{q}_\pi)$
  Set $\mathbf{V} \leftarrow \mathbf{D}^T\mathbf{U}$ *and compute*
  $$\mathbf{Z}_\pi \leftarrow \mathsf{VLHE.BatchProve}(\mathbf{A}_2, \mathbf{H}_2, \mathbf{U}, \mathbf{V}, \mathbf{D}^T).$$
  Output $\mathsf{a}_\pi \leftarrow \mathbf{V}, \mathbf{Z}_\pi$.

- $\pi/\perp \leftarrow \mathsf{PrRec}(\mathsf{pp}, \mathsf{d}, \mathsf{q}_\pi, \mathsf{st}_\pi, \mathsf{a}_\pi)$
  Run $\mathsf{VLHE.BatchVerify}(\mathbf{A}_2, \mathbf{H}_2, \mathbf{U}, \mathbf{V}, \mathbf{Z}_\pi)$ *and output* $\perp$ *if* BatchVerify *outputs* Reject. *Otherwise, for* $\mathbf{Z} \in \mathbb{Z}_{p\ell}^{\lambda \times m}$ *set* $\mathbf{Z}[i] \leftarrow \mathsf{VLHE.Decrypt}_{p\ell}(\mathbf{H}_2, \mathbf{s}_i, \mathbf{v}_i)$. *Check that* $\mathbf{Z} \cdot \mathbf{A}_1 = \mathbf{C} \cdot \mathbf{H}_1$. *If this check fails, output* $\perp$. *Otherwise, output* $\pi \leftarrow \mathbf{Z}$.

- $\mathsf{q}, \mathsf{st} \leftarrow \mathsf{Query}(\mathsf{pp}, i \in [N])$
  Write i *as* $(i_r, i_c) \in [\ell] \times [m]$. *Compute*
  $$\mathbf{u}, \mathbf{s} \leftarrow \mathsf{VLHE.Encrypt}(\mathbf{A}_1, \mathbf{b}_{i_c}).$$
  Output $(\mathsf{q}, \mathsf{st}) \leftarrow (\mathbf{u}, (\mathbf{s}, i))$.

- $\mathsf{a} \leftarrow \mathsf{Answer}(\mathsf{pp}, \mathbf{D}, q)$
  Output $\mathbf{v} \leftarrow \mathbf{D}\mathbf{u}$ *as* a.

- $\mathsf{r} \leftarrow \mathsf{Recover}(\mathsf{pp}, \mathsf{st}, \mathsf{a}, \mathsf{d})$
  Write i *as* $(i_r, i_c) \in [\ell] \times [m]$. *Compute*
  $$\nu \leftarrow \mathsf{VLHE.Decrypt}(\mathbf{H}_1, \mathbf{s}, \mathbf{v})$$
  for $\nu \in \mathbb{Z}_p^\ell$. *Output* $r \leftarrow \nu[i_r]$.

- $\mathsf{Accept}/\mathsf{Reject} \leftarrow \mathsf{Verify}(\mathsf{pp}, \mathsf{d}, \mathsf{q}, \mathsf{a}, \pi)$
  Output the result of $\mathsf{VLHE.PreVerify}(\mathbf{A}_1, \mathbf{H}_1, \mathbf{u}, \mathbf{v}, \mathbf{C}, \mathbf{Z})$.

The security of this scheme follows immediately from the security of the preprocessed VLHE scheme presented in section 4. The full proofs are given in appendix C.

6 Implementation & Performance Analysis

In this section, we present our implementation of the preprocessed VeriSimplePIR protocol[1]. We give performance benchmarks and compare against the semi-honest SimplePIR protocol.

Simple Optimizations. We enumerate some simple optimizations that we incorporate into our implementation. These optimizations are designed to maximize the performance for the honest server, who will essentially never have to run the proof preprocessing more than once for each client.

1. **Optimizing Client Storage.** The client does not need to store the second database commitment $\mathbf{H}_2$ once the preprocessing phase is complete. As soon as the client holds valid $\mathbf{C}$ and $\mathbf{Z}$ matrices, it discards all other messages from the commitment and preprocessing phases. The persistent client storage for the online phase is only the matrices $\mathbf{H}_1$, $\mathbf{C}$, and $\mathbf{Z}$. We include the download of $\mathbf{H}_2$ and the corresponding $\mathbf{Z}_2$ in the communication of the proof preprocessing as an initial message before the encrypted $\mathbf{C}$ is sent to the server.

2. **Minimizing Ciphertext Overhead.** Observe that the correctness constraint on the VLHE ciphertext modulus for the preprocessing operations (given in eq. (6)) is more strict than the constraint on this modulus in the online phase (given in eq. (4)). Observe that if a modulus q that satisfies the online constraint in eq. (4) then $q' \geq \kappa \cdot q \geq \sqrt{\ell^3/m}$ will satisfy the preprocessing constraint in eq. (6). We set the online modulus q to be a machine word size (either 2^{32} or 2^{64}), then run the preprocessing over the larger modulus $q' \geq \kappa \cdot q$. This introduces only a slight overhead to the preprocessing phase, since if κ is odd then q and κ are coprime. Therefore, $\mathbb{Z}_{q'} = \mathbb{Z}_q \otimes \mathbb{Z}_\kappa$, so almost no multiprecision arithmetic is required to implement the VLHE operations over $\mathbb{Z}_{q'}$. This allows us to maximize the usage of the machine-word modulus in the online phase.

3. **Optional Assumption of Honest Digest.** Recall that the VLHE correctness must account for a database $\mathbf{D}$ that is as large as the extractability bound of $||\mathbf{D}||_\infty \leq 2\ell p$, which is larger than the honest database bound of $||\mathbf{D}||_\infty \leq p$. Since the database digest is the same across all clients, additional checks on this digest could be implemented fairly easily. In particular, if the digest is signed by a sufficient number of trusted parties, a client can be confident that the digest was generated with a database $\mathbf{D}$ such that $||\mathbf{D}||_\infty \leq p$. Note that the SIS assumption still fixes this database (since $p \leq 2\ell p$) so even if the server is corrupted at a later time the database must still be this fixed, honest value. This allows us to further relax the correctness requirement on the VLHE ciphertext modulus q (see eq. (2)).

Below, we will benchmark optimal parameters with and without the assumption of an honest digest.

Experimental Setup. Our implementation is in C/C++. All computational benchmarks presented here were run on a single thread of a machine running Ubuntu 20 with an Intel i7 chip operating at 2.5 GHz with 32 GB of RAM. The VeriSimplePIR code was compiled with version 10 of the `clang++` compiler using the `-O3` option. All SimplePIR benchmarks were taken with the VeriSimplePIR library using optimal parameters. Both VeriSimplePIR and SimplePIR parameters were chosen to minimize online communication. In particular, all SimplePIR benchmarks throughout this work use $\log(q) = 32$, $\log(n) = 10$, and $\log(p)$ chosen to minimize online communication. We also give benchmarks of the SimplePIR protocol with a 64-bit modulus, which is optimized for online computation on a 64-bit machine. For all of these benchmarks, database entries are one bit ($d = 1$). Note that due to the tight database packing scheme, the database entry size has essentially no effect on the parameters[2]. Only changing the overall database size (i.e. $N \cdot d$) will change

[1] https://github.com/leodec/VeriSimplePIR

[2] The only exception to this is when the database entry size is greater than a $\sqrt{N}$ fraction of the database, but this is much larger than entries in essentially all practical applications.

the parameters of both SimplePIR and VeriSimplePIR. All benchmarks are presented in terms of the total database size.

Benchmarks: Online Phase. In fig. 7, we present the online performance of preprocessed VeriSimplePIR and compare to the online performance of SimplePIR. This comparison shows that verifiability can be achieved with very low overhead. In particular, VeriSimplePIR without the honest digest assumption has a 12% to 40% slowdown in the compute time and a 40% to 50% increase in the total communication. When the honest assumption is introduced, the communication overhead of VeriSimplePIR drops to 13% to 20%, and the online computation actually *outperforms* the original semi-honest SimplePIR protocol. Note that this is because parameters are optimized to minimize communication rather than computation. The minimal communication parameters from SimplePIR use $\log(q) = 32$, while the minimal parameters for VeriSimplePIR use $\log(q) = 64$. This means that the VeriSimplePIR protocol is able to pack more database bits into each machine word, which results in an improved throughput on a 64-bit machine. Growing the SimplePIR modulus to 64 bits would more than double the size of the database digest, as we will see below.

Benchmarks: Offline Phase. In fig. 8, we present the one-time offline communication required to both download the initial database commitment and preprocess a proof. The VeriSimplePIR bars in fig. 8 are split into two parts. The bottom part of the bar represents the data that must be stored locally on the client's machine throughout the protocol (including the online phase). This data is dominated ($> 95\%$) by the size of the digest $\mathbf{H}_1$, although it also contains the $\mathbf{C}$ and $\mathbf{Z}$ matrices that are output from the proof preprocessing phase. The top part of the bar represents the communication in the proof preprocessing phase that is *not* stored once the proof preprocessing phase is finished. Again, this data is almost entirely ($> 95\%$) the matrix $\mathbf{H}_2$, the commitment to $\mathbf{D}^T$.

Due to space constraints, we briefly summarize the offline computation benchmarks. On a single-core, the offline computation with a dishonest digest is roughly 100 seconds for a 4 GB database is roughly 200 seconds and for an 8 GB database. The computation is almost entirely on the server and scales linearly with the database. As we mentioned above, a full system would take advantage of the parallel nature of the server's computation and the optimizations admitted by the machine-words modulus.

6.1 Comparing APIR with VLHE PIR

We now compare the performance of our *non-preprocessed* PIR protocol to the authenticated PIR protocols (called APIR and APIR+) of Colombo et al. [CNCG+23]. The performance of the APIR protocol is essentially unaffected by malicious behavior, while our preprocessed protocol would require rerunning the proof precomputation after each verification failure. In order to account for a setting where the server is frequently malicious, we compare against a simplified variant of our protocol that simply applies the (non-preprocessed) verifiable linearly homomorphic encryption scheme defined in fig. 4 to the PIR computation. We call this variant VLHE PIR, and this version requires no per-client offline computation; the client simply downloads the database commitment and expects the server to send a fresh proof with each PIR response. To account for the larger dependence on the row length in the proof $\mathbf{Z}$, we rebalance the database dimensions to get a roughly $\sqrt{\lambda}$ communication overhead over SimplePIR. Note that all benchmarks in this section consider VLHE PIR *without* the honest hint assumption.

While all benchmarks in the previous section considered single-bit database entries, it is important to consider the database entry size when benchmarking the APIR protocols. While SimplePIR and VLHE PIR scale only with the size of the database, APIR and APIR+ crucially rely on 1-bit entries for security, handling larger entries via repetition.

Due to space constraints, we briefly summarize the online performance comparison, where VLHE PIR outperforms APIR and APIR+ in both communication and computation for all database sizes and all entry widths. When the database entries are a single bit, the total runtime of APIR+ is roughly $5\times$ greater than the runtime of VLHE PIR, and the runtime of APIR is about $25\times$ greater than VLHE PIR. When compared the the APIR protocol, VLHE PIR sees a near 40% reduction in the online communication. The comparison to APIR+ is even better, where the VLHE PIR online communication is 7-12$\times$ smaller.

The only metric for which either protocol outperforms VHLE PIR is the offline communication, with the APIR+ offline communication at about $4.5\times$ smaller than VLHE PIR when the database entries are a single bit. However, as displayed in fig. 9, the performance of APIR+ quickly decays as the database entries grow. For example, with a 64 GiB database with 32-bit entries, VLHE PIR outperforms both protocols on all metrics. By the time the database entry bitwidth reaches 1024, the offline communication of APIR+ is roughly $7\times$ the offline communication of VLHE PIR.

7 Application: Password Leak Detection

In this section, we discuss an application of VeriSimplePIR: secure password leak detection. The goal of this application is to allow clients to query a database of leaked passwords from sources such as "Have I Been Pwnd?"[3] without revealing the queried password they are requesting to the server. The need for privacy in this application is clear, since honest clients would essentially always be interested in their own passwords. Revealing the query to the server would reveal the client's credentials.

[3] https://haveibeenpwned.com/Passwords

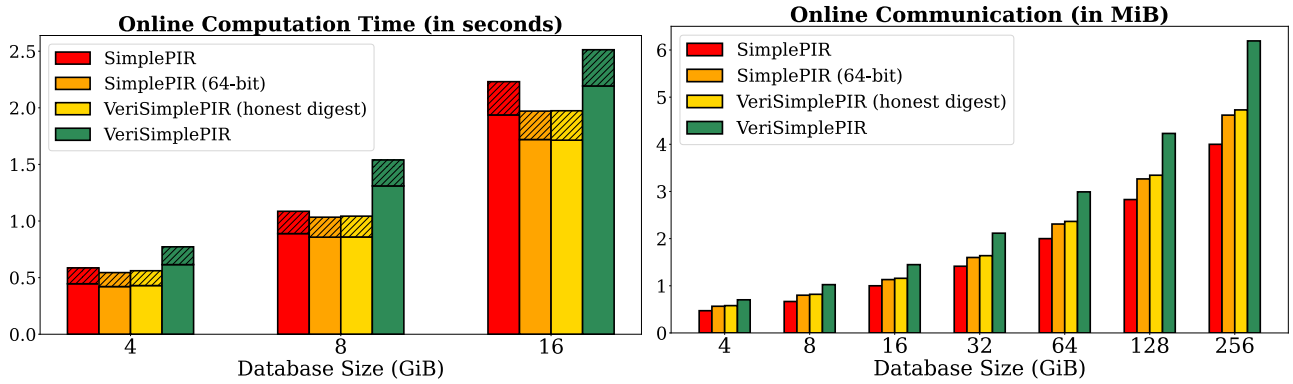

Figure 7: Online performance of SimplePIR and preprocessed VeriSimplePIR for databases of various sizes. The left figure is the per-query online computation, and the right figure is the per-query online communication. The hatched portion of the computation graph represents work on the client side (Query, Verify, and Recover). In the communication benchmarks, the upload and download sizes are equal.

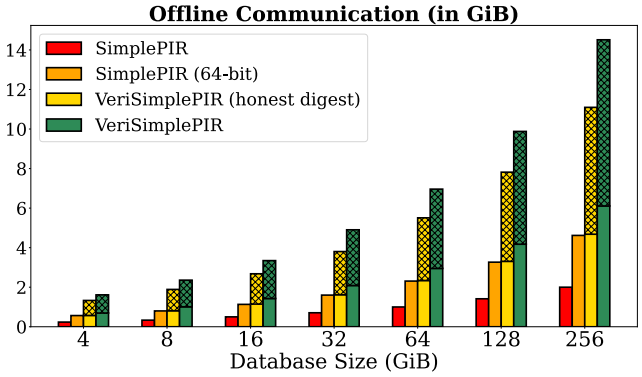

Figure 8: Offline communication of SimplePIR and preprocessed VeriSimplePIR for databases of various sizes. The hatched portions in the VeriSimplePIR columns represent the communication that is *not stored* once the precomputation is finished. The unhatched portion represents the data that the client must store locally throughout the protocol (including the online phase).

This application is based on the Blyss private password checker[4]. In the Blyss implementation, the database consists of around 400 million SHA1 hashes (20 bytes each) of passwords that have appeared in data breaches. These passwords are stored in a hash table about 8 GB in size. The hash function is public, so a client can map their hashed password to a candidate database index. The Blyss implementation uses either Spiral [MW22] or DoublePIR [HHCG+23], both of which are semi-honest implementations. Despite the significantly weaker security guarantees, VeriSimplePIR is highly competitive with the online performance of both schemes. DoublePIR is worse in both online communication and online computation, and Spiral has around 25× slower online computation [MW22, Table 2] than VeriSimplePIR. The only overhead from VeriSimplePIR is the roughly 800 MB of data that each client must locally store throughout the online phase. This is perhaps too large for mobile devices, but it is certainly feasible for a laptop or desktop computer. Furthermore, it is likely that queries requiring a higher level of security would come from desktop or laptop computers, such as the master password for a password manager. In such cases, clients would require the strong guarantees of verifiable PIR and would likely have the local storage to keep the digest.

If clients make infrequent queries, they could avoid storing the full digest and instead only store a hash of the digest. Redownloading the digest from the server would maintain verifiability by checking against the stored hash. Note that the client must store the preprocessed proof or offload this data only in encrypted form. We leave a full implementation of this system as well as exploration of other applications (such as the PGP server proposed in the work of Colombo et al. [CNCG+23]) for future work.

8 Related Work

The first PIR scheme was presented by Kushilevitz and Ostrovsky [KO97]. This work was also the first to identify that a malicious server could dynamically maul database to try to learn the client's query in what became known as a selective failure attack.

Stateless verifiable PIR. Recent work [BDKP22] introduced another notion of verifiable PIR in which the client can verify arbitrary local properties of the database used for the response. This verifiability notion differs from our work in that it is *stateless*, which is to say there is no initial commitment to a database. The stateless notion of verifiability is defined *per* query and thus does not defend against attacks that modify the database across the queries. In contrast, our verifiability is defined for a database that is fixed throughout the lifetime of the scheme (or at least the digest). We also note that this stateless construction is based on recent developments in the batch argument for NP, placing it outside the realm of

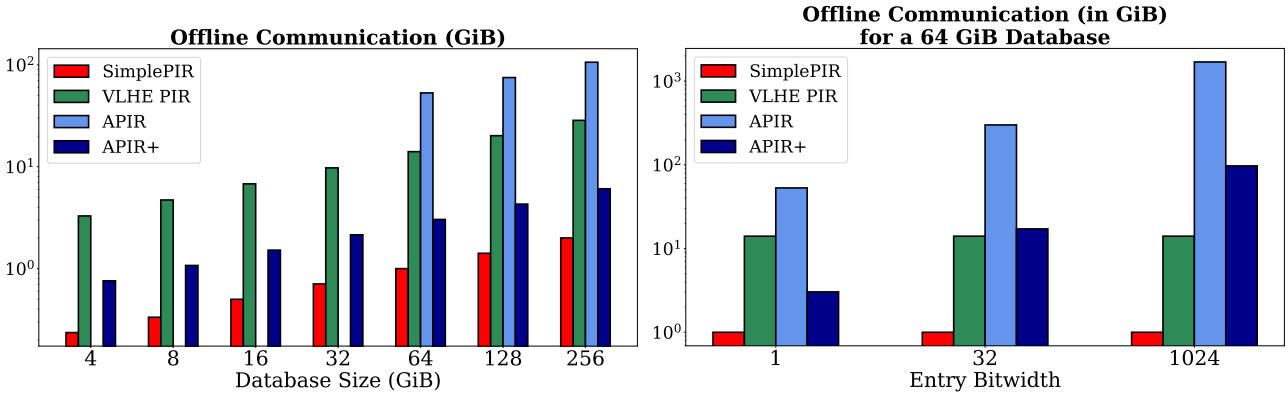

Figure 9: Offline communication comparison of VLHE PIR with APIR and APIR+. The left plot is for 1-bit database entries. APIR benchmarks below 45 GB are ommitted since the download is larger than the database size.

practicality.

Several other prior works [WZ18, ZWH21] have considered verifiable PIR in the single-server setting. However, the security guarantees achieved in these works are much weaker than in ours. In particular, they only guarantee that the PIR response was generated with respect to some well-formed database, but there is no commitment to fix this database across multiple queries.

Semi-honest PIR. In addition to SimplePIR, a number of recent works have improved both the theoretical and practical performance of semi-honest PIR. This includes FrodoPIR [DPC23], which is essentially the same protocol as SimplePIR. There have been several recent works exploring the exciting direction of PIR with *sublinear* online complexity [CGK20, CGHK22, LMW23, ZPSZ23]. It remains an interesting open question how to add malicious security to these schemes.

Acknowledgments

We would like to thank Vinod Vaikuntanathan for insightful conversations and Alexandra Henzinger for helpful discussions, especially regarding the implementation.

A Verifiable PIR Detailed Definitions

In this section, we give detailed definitions for preprocessed verifiable PIR correctness and security.

Completeness Definition. In addition to the correctness requirement for the PIR output (definition 2.2), we require that messages produced by honest servers pass verification in both the preprocessing and the online phase. We formalize this requirement as the following.

Definition A.1 (Verification Completeness)**.** *We say a vPIR scheme is* complete *if the following holds for all security parameter* λ*, database* $\mathbf{D} \in \mathbb{Z}_t^N$*, and index* $i \in [N]$*. (The public parameter* pp *is an implicit input for all algorithms other than* Setup*.)*

$$\Pr\left[\begin{array}{c|r} \pi \neq \perp \\ \& \\ \mathsf{Verify}(\mathsf{d},\pi,\mathsf{q},\mathsf{a}) \\ = \mathsf{Accept} \end{array} \middle| \begin{array}{r} \mathsf{pp} \leftarrow \mathsf{Setup}(1^\lambda, 1^N, t) \\ \mathsf{d} \leftarrow \mathsf{Digest}(\mathbf{D}) \\ \mathsf{q}_\pi, \mathsf{st}_\pi \leftarrow \mathsf{PrQry}(\mathsf{d}) \\ \mathsf{a}_\pi \leftarrow \mathsf{PrAns}(\mathbf{D}, \mathsf{q}_\pi) \\ \pi \leftarrow \mathsf{PrRec}(\mathsf{d}, \mathsf{q}_\pi, \mathsf{st}_\pi, \mathsf{a}_\pi) \\ \mathsf{q}, \mathsf{st} \leftarrow \mathsf{Query}(i) \\ \mathsf{a} \leftarrow \mathsf{Answer}(\mathbf{D}, \mathsf{q}) \end{array}\right] = 1.$$

Security Definitions. The following are security requirements for vPIR. At a high level, we require any malicious behavior of a server in vPIR should lead to an abort. Additionally, we need a stronger notion of privacy than the query-hiding of semi-honest PIR (definition 2.3) to defend against malicious attacks such as selective failures.

Definition A.2 (Digest Binding)**.** *For a security parameter* λ*, let* $\mathcal{S}$ *be a computationally bounded server. Let* pp *be an honestly-generated public parameter. We say a vPIR scheme is* digest binding *if the following holds:*

1. *It is infeasible for* $\mathcal{S}$ *to produce two databases* $\mathbf{D}$ *and* $\mathbf{D}'$ *such that* $\mathsf{Digest}(\mathsf{pp}, \mathbf{D}) = \mathsf{Digest}(\mathsf{pp}, \mathbf{D}')$.

2. *Suppose $\mathcal{S}$ can output a_π such that* $\mathsf{PrRec}(\mathsf{pp},\mathsf{d},\mathsf{q}_\pi,\mathsf{st}_\pi,\mathsf{a}_\pi) \neq \perp$ *for* $\mathsf{q}_\pi,\mathsf{st}_\pi \leftarrow \mathsf{PrQry}(\mathsf{d})$ *with non-negligible probability, where the probability is over the randomness of* PrQry *and* $\mathcal{S}$*. Then, there exists an efficient extractor $\mathcal{E}$ that extracts some database $\mathbf{D}$ such that* $\mathsf{Digest}(\mathsf{pp},\mathbf{D}) = \mathsf{d}$ *by rewinding $\mathcal{S}$, with probability at least* $1-2^{-\lambda}$.

Definition A.3 (Verification Soundness)**.** *For a security parameter λ, let $\mathcal{S}$ be a computationally bounded server. For an honestly-generated public parameter* pp*, let* $\mathsf{d} \leftarrow \mathsf{Digest}(\mathsf{pp},\mathbf{D})$ *for some $\mathbf{D}$. Furthermore, let $\pi \neq \perp$ be the auxiliary information computed in the preprocessing phase described in fig. 3. Let* a *be a response computed by $\mathcal{S}$ for a query* q*. We say a vPIR scheme satisfies* verification soundness *if the following holds with probability at least* $1-2^{-\lambda}$*:*

$$\mathsf{Verify}(\mathsf{pp},\mathsf{d},\pi,\mathsf{q},\mathsf{a}) = \mathsf{Accept} \implies \mathsf{a} = \mathsf{Answer}(\mathbf{D},\mathsf{q}).$$

Definition A.4 (Query Hiding Against a Malicious Server)**.** *For a security parameter λ, let* pp *be an honestly-generated public parameter. We say a vPIR scheme that satisfies* verification completeness *(definition A.1),* digest binding *(definition A.2), and* verification soundness *(definition A.3), is also* query hiding against a malicious server *if the following holds.*

For every computationally bounded adversary $\mathcal{A}$ let $\mathsf{d},\mathsf{st}_\mathcal{A} \leftarrow \mathcal{A}(\mathsf{pp})$ *be the digest produced by $\mathcal{A}$ such that* $\mathsf{Accept} \leftarrow \mathsf{DigVer}(\mathsf{pp},\mathsf{d})$*. Let $\mathbf{D}$ be the database the adversary used to produce* d*; the existence and uniqueness of $\mathbf{D}$ is guaranteed by definition A.2. For every index sequence $\vec{i} = \{i_1,\ldots,i_L\} \in [N]^L$, define the distribution*

$$REAL_{\mathcal{A},\vec{i}} := \left\{ \begin{array}{c} \mathsf{q}_\pi,\mathsf{st}_\pi \leftarrow \mathsf{PrQry}(\mathsf{pp},\mathsf{d}) \\ \mathsf{a}_\pi,\mathsf{st}_\mathcal{A} \leftarrow \mathcal{A}(\mathsf{st}_\mathcal{A},\mathsf{q}_\pi) \\ \pi \leftarrow \mathsf{PrRec}(\mathsf{pp},\mathsf{d},\mathsf{q}_\pi,\mathsf{st}_\pi,\mathsf{a}_\pi) \\ \beta \leftarrow \mathcal{A}(\mathsf{st}_\mathcal{A}) \quad \mathit{if}\ \ \pi = \perp \\ \mathit{While}\ \ \pi \neq \perp \\ \beta : \left\{ \begin{array}{c} \mathsf{q},\mathsf{st} \leftarrow \mathsf{Query}(\mathsf{pp},i_k) \\ \mathsf{a},\mathsf{st}_\mathcal{A} \leftarrow \mathcal{A}(\mathsf{st}_\mathcal{A},\mathsf{q}) \\ \mathsf{b} \leftarrow \mathsf{Verify}(\mathsf{pp},\mathsf{d},\pi,\mathsf{q},\mathsf{a}) \\ \mathsf{st}_\mathcal{A} \leftarrow \mathcal{A}(\mathsf{st}_\mathcal{A},\mathsf{b}) \\ \mathit{If}\ \ \mathsf{b} = \mathsf{Reject},\ \ \mathit{set}\ \ \pi \leftarrow \perp \\ \mathit{Otherwise} \\ r \leftarrow \mathsf{Recover}(\mathsf{pp},\mathsf{st},\mathsf{a},\mathsf{d}) \\ \mathsf{b}' \leftarrow 1[r = \mathbf{D}[i_k]] \\ \mathsf{st}_\mathcal{A} \leftarrow \mathcal{A}(\mathsf{st}_\mathcal{A},\mathsf{b}') \end{array} \right\}_{k=1}^{L} \\ \beta \leftarrow \mathcal{A}(\mathsf{st}_\mathcal{A}), \end{array} \right\}$$

where the L iterations are run sequentially. Similarly, for a computationally bounded simulator $\mathcal{X}$, define the distribution

$$IDEAL_{\mathcal{A},\mathcal{X}} := \left\{ \begin{array}{c} \mathsf{q}_\pi,\mathsf{st}_\pi \leftarrow \mathsf{PrQry}(\mathsf{pp},\mathsf{d}) \\ \mathsf{a}_\pi,\mathsf{st}_\mathcal{A} \leftarrow \mathcal{A}(\mathsf{st}_\mathcal{A},\mathsf{q}_\pi) \\ \pi,\mathsf{st}_\mathcal{X} \leftarrow \mathcal{X}(\mathsf{pp},\mathsf{d},\mathsf{q}_\pi,\mathsf{st}_\pi,\mathsf{a}_\pi) \\ \beta \leftarrow \mathcal{A}(\mathsf{st}_\mathcal{A}) \quad \mathit{if}\ \ \pi = \perp \\ \mathit{While}\ \ \pi \neq \perp \\ \beta : \left\{ \begin{array}{c} \mathsf{q},\mathsf{st}_\mathcal{X} \leftarrow \mathcal{X}(\mathsf{pp},\mathsf{st}_\mathcal{A}) \\ \mathsf{a},\mathsf{st}_\mathcal{A} \leftarrow \mathcal{A}(\mathsf{st}_\mathcal{A},\mathsf{q}) \\ \mathsf{b},\mathsf{b}' \leftarrow \mathcal{X}(\mathsf{pp},\mathsf{d},\pi,\mathsf{q},\mathsf{a},\mathsf{st}_\mathcal{A}) \\ \mathsf{st}_\mathcal{A} \leftarrow \mathcal{A}(\mathsf{st}_\mathcal{A},\mathsf{b}_k) \\ \mathit{If}\ \ \mathsf{b} = \mathsf{Reject},\ \ \mathit{set}\ \ \pi \leftarrow \perp \\ \mathit{Otherwise} \\ \mathsf{st}_\mathcal{A} \leftarrow \mathcal{A}(\mathsf{st}_\mathcal{A},\mathsf{b}') \end{array} \right\}_{k=1}^{L} \\ \beta \leftarrow \mathcal{A}(\mathsf{st}_\mathcal{A}), \end{array} \right\}$$

where the L iterations are run sequentially as in REAL. We say that a vPIR scheme is query hiding against a malicious server *if the following holds:*

$$|\Pr[REAL_{\mathcal{A},\vec{i}} = 1] - \Pr[IDEAL_{\mathcal{A},\mathcal{X}} = 1]| \leq \mathsf{negl}(\lambda).$$

B Security Proofs for Reusable VLHE

Here, we give the security proofs for the VLHE scheme with preprocessed proofs presented in section 4.2.

Lemma B.1 (Semi-honest Preprocessed Protocol)**.** *Let $\mathcal{S}$ be a computationally bounded server that correctly runs the protocol described in fig. 6. Let $b_F \in \{0,1\}$ indicate if the client aborts on the function commitment phase and let $b_P \in \{0,1\}$ indicate if the client aborts on the proof preprocessing phase. Let $\mathbf{U}$ be the client's message in the proof preprocessing phase, as in fig. 6. The view of $\mathcal{S}$ at the end of the preprocessing phase is $(b_F,\mathbf{U},b_P)$.*

For q that satisfies eq. (6), assume the hardness of (n,ℓ,q)-LWE. The view of $\mathcal{S}$ is computationally indistinguishable from $(0,\mathbf{R},0)$, where $\mathbf{R}$ is a uniformly random element of $\mathbb{Z}_q^{\ell\times\lambda}$.

Proof. This follows directly from the semantic security of the Regev encryption scheme and the perfect completeness of the verification algorithms VerCom and BatchVerify. □

Lemma B.2 (Correct Encryption of $\mathbf{Z}$)**.** *Let $\mathcal{S}$ be a computationally bounded adversary acting as the server in the protocol described in fig. 6. Define the view of $\mathcal{S}$ at the end of the proof preprocessing phase $(b_F,\mathbf{U},b_P)$ as in lemma B.1. Let q, ℓ, p, and m satisfy eq. (6). Assume the hardness of $\mathsf{SIS}_{n,m,q,\beta_1}$ for $\beta_1 = 4\ell p$ and $\mathsf{SIS}_{n,\ell,q,\beta_2}$ for $\beta_2 = 4mp$. As in lemma B.1, assume the hardness of (n,ℓ,q)-LWE.*

Consider the commitment defined by $(\mathbf{A}_1,\mathbf{H}_1)$ and the extractor $\mathcal{E}$ guaranteed by lemma 2.2 running on $\mathcal{S}$ in the function commitment phase. Let $\mathbf{D} \in \mathbb{Z}^{\ell\times m}$ be the unique matrix that can be extracted from $\mathcal{E}$ on the commitment $(\mathbf{A}_1,\mathbf{H}_1)$ (i.e. $\mathbf{H}_1 = \mathbf{D}\mathbf{A}_1$), under hardness assumption of $\mathsf{SIS}_{n,m,q,\beta_1}$

(lemma 2.3). Define $\mathbf{D}' \in \mathbb{Z}^{m \times \ell}$ *similarly on the commitment* $(\mathbf{A}_2, \mathbf{H}_2)$ *(i.e.* $\mathbf{H}_2 = \mathbf{D}'\mathbf{A}_2$*), under hardness assumption of* $\mathsf{SIS}_{n,m,q,\beta_2}$.

If a client running the prescribed protocol completes the proof preprocessing without aborting, then with probability at least $1 - 2^{-\lambda}$ *the* $\mathbf{Z}$ *value held by the client equals* $\mathbf{CD}$ *for the client-sampled* $\mathbf{C}$*. Furthermore, the view of* $\mathcal{S}$ *is indistinguishable from the semi-honest view in lemma B.1 of with probability at least* $1 - 2^{-\lambda}$.

Proof. To see that the client's $\mathbf{Z}$ value will equal $\mathbf{CD}$, observe that since the ciphertext modulus q satisfies eq. (6), applying the linear function $\mathbf{D}' \in \mathbf{Z}^{m \times \ell}$ to the ciphertexts comprising the columns of $\mathbf{U}$ will result in correctly decrypting ciphertexts $\mathbf{V}$. Since BatchVerify accepts, then by lemma 4.1 and the hardness of $\mathsf{SIS}_{n,\ell,q,\beta_2}$ for $\beta_2 = 4mp$ it must be that $\mathbf{V} = \mathbf{D}'\mathbf{U}$. Therefore, by the correctness of the VLHE scheme, it must be that the plaintext encrypted in the columns of $\mathbf{V}$ is $\mathbf{Z}^T = \mathbf{D}'\mathbf{C}^T$.

Meanwhile, the check $\mathbf{Z} \cdot \mathbf{A}_1 = \mathbf{C} \cdot \mathbf{H}_1 = \mathbf{C}(\mathbf{D}')^T\mathbf{A}_1$ passes, and thus we have $\mathbf{C}((\mathbf{D}')^T\mathbf{A}_1 - \mathbf{H}_1) = 0$. Since $\mathbf{A}_1$, $\mathbf{H}_1$, and $\mathbf{D}'$ are all fixed before $\mathbf{C}$ is sampled, then lemma 2.4 implies that $(\mathbf{D}')^T\mathbf{A}_1 - \mathbf{H}_1 = \mathbf{0}$ with probability at least $1 - 2^{-\lambda}$. We now have that $(\mathbf{D}')^T = \mathbf{D}$ by the hardness of $\mathsf{SIS}_{n,m,q,\beta_1}$ for $\beta_1 = 4\ell p$, which implies $\mathbf{Z} = \mathbf{CD}$.

The claim regarding the view of $\mathcal{S}$ follows from lemma 4.1. The correct ciphertext $\mathbf{V}$ is defined by the linear function committed with $(\mathbf{A}_2, \mathbf{H}_2)$. Since anything other than the correct ciphertext $\mathbf{V}$ will be rejected by BatchVerify with probability at least $1 - 2^{-\lambda}$, then the server must return the correct ciphertext with at least this probability. Since the ciphertext $\mathbf{V}$ is correct, then there is no leakage from verification and decryption proceeding as in the prescribed protocol. The remainder of the lemma follows from the semantic security of the Regev encryption scheme, which makes $\mathbf{U}$ computationally indistinguishable from a random element in $\mathbb{Z}_q^{m \times \lambda}$. □

Lemma B.3 (Soundness of Preprocessed Verification)**.** *Let* $\mathcal{S}$ *be a computationally bounded adversary acting as the server in the protocol described in fig. 6. Define the view of* $\mathcal{S}$ *at the end of the proof preprocessing phase* $(b_F, \mathbf{U}, b_P)$ *as in lemma B.1. Let* q, ℓ, p, *and* m *satisfy eq. (6). Assume the hardness of* $\mathsf{SIS}_{n,m,q,\beta_1}$ *for* $\beta_1 = 4\ell p$ *and* $\mathsf{SIS}_{n,\ell,q,\beta_2}$ *for* $\beta_2 = 4mp$*. As in lemma B.1, assume the hardness of* (n, ℓ, q)*-LWE.*

Consider the commitment defined by $(\mathbf{A}_1, \mathbf{H}_1)$ *and the extractor* $\mathcal{E}$ *guaranteed by lemma 2.2 running on* $\mathcal{S}$ *in the function commitment phase. Let* $\mathbf{D} \in \mathbb{Z}^{\ell \times m}$ *be the unique matrix that can be extracted from* $\mathcal{E}$ *on the commitment* $(\mathbf{A}_1, \mathbf{H}_1)$ *(i.e.* $\mathbf{H}_1 = \mathbf{D}\mathbf{A}_1$*), under hardness assumption of* $\mathsf{SIS}_{n,m,q,\beta_1}$ *(lemma 2.3).*

If the client has completed the proof preprocessing phase without aborting, then $\mathsf{Accept} \leftarrow \mathsf{PreVerify}(\mathbf{u}, \mathbf{v}, \mathbf{C}, \mathbf{Z})$ *implies that* $\mathbf{v} = \mathbf{Du}$ *with probability at least* $1 - 2^{-\lambda}$*. Furthermore, this guarantee is maintained across any number of homomorphic evaluation protocols as long as* PreVerify *does not output* Reject.

Proof. The security of a single instance of the homomorphic evaluation phase follows directly from lemma B.2, since the server has no information about the challenge $\mathbf{C}$ used to verify the response. The uniqueness of the ciphertext $\mathbf{v}$ then follows from lemma 4.1.

The second claim follows from the simulatability of the client accepting the correct transcript. Strong uniqueness of the response ciphertext $\mathbf{v}$ guarantees that the only way the server will pass verification with probability better than $2^{-\lambda}$ is if $\mathbf{v} = \mathbf{Du}$. If the server returns the correct ciphertext, then clearly there is no additional information about $\mathbf{C}$ that is learned, since the fact that the client accepts this transcript follows directly from the perfect completeness of the PreVerify algorithm. Therefore, with probability at least $1 - 2^{-\lambda}$, no information about $\mathbf{C}$ is leaked if PreVerify outputs Accept. This means that the challenge $\mathbf{C}$ and the corresponding $\mathbf{Z}$ can be safely reused as long as PreVerify outputs Accept. □

C VeriSimplePIR Security Proofs

We give the security proofs of the VeriSimplePIR construction in section 5.

Lemma C.1 (VeriSimplePIR Completeness)**.** *Construction 5.1 satisfies definition A.1.*

Proof. This proof follows directly from the perfect completeness of the VLHE verification in section 4. In particular, the bound on $\mathbf{Z}$ will never be exceeded as long as the database $\mathbf{D}$ is within the honest bound $||\mathbf{D}||_\infty \leq p$. The perfect completeness of the check $\mathbf{ZA} = \mathbf{CH}$ follows immediately from the honest values of $\mathbf{H}$ and $\mathbf{Z}$. □

Lemma C.2 (VeriSimplePIR Digest Binding)**.** *Construction 5.1 satisfies definition A.2.*

Proof. This follows directly from the SIS hardness assumptions given in construction 5.1. This SIS assumption immediately implies computational binding for the digest from lemma 2.3. □

Lemma C.3 (VeriSimplePIR Verification Soundness)**.** *Construction 5.1 satisfies definition A.3.*

Proof. This follows directly from lemma B.3. □

Lemma C.4 (VeriSimplePIR Query Hiding)**.** *Construction 5.1 satisfies definition A.4.*

Proof. This follows from lemma B.3 along with the correctness of the VLHE parameters. Lemma B.3 guarantees that the only ciphertexts that pass verification with probability better than $2^{-\lambda}$ are the honest ciphertexts. Decryption of the honest ciphertext will yield the correct result with probability at least $1 - 2^{-\lambda}$ by lemma 2.5. Therefore, the second bit b' in the distributions in definition A.4 are also simulatable. □

Batch PIR and Labeled PSI with Oblivious Ciphertext Compression

Alexander Bienstock[*] *Sarvar Patel*[†] *Joon Young Seo*[‡] *Kevin Yeo*[§]

Abstract

In this paper, we study two problems: oblivious compression and decompression of ciphertexts. In oblivious compression, a server holds a set of ciphertexts with a subset of encryptions of zeroes whose positions are only known to the client. The goal is for the server to effectively compress the ciphertexts obliviously, while preserving the non-zero plaintexts and without learning the plaintext values. For oblivious decompression, the client, instead, succinctly encodes a sequence of plaintexts such that the server may decode encryptions of all plaintexts value, but the zeroes may be replaced with arbitrary values. We present solutions to both problems that construct lossless compressions only 5% more than the optimal minimum using only additive homomorphism. The crux of both algorithms involve embedding ciphertexts as random linear systems that are efficiently solvable.

Using our compression schemes, we obtain state-of-the-art schemes for batch private information retrieval (PIR) where a client wishes to privately retrieve multiple entries from a server-held database in one query. We show that our compression schemes may be used to reduce communication by up to 30% for batch PIR in both the single- and two-server settings.

Additionally, we study labeled private set intersection (PSI) in the unbalanced setting where one party's set is significantly smaller than the other party's set and each entry has associated data. By utilizing our novel compression algorithm, we present a protocol with 65-88% reduction in communication with comparable computation compared to prior works.

1 Introduction

Protecting user privacy is becoming a core problem in today's society with the continuing growth of cloud-based applications. There are many important cloud services that provide databases of essential information that need to be retrieved by users. In many cases, it is necessary to hide the queried database entry to preserve the user's privacy. This privacy requirement has appeared in many cloud services provided by large organizations including certificate transparency [3], contact discovery [10], device enrollment [7], password leak check [5, 6] and URL blocklists [8].

Private information retrieval (PIR) [24] is an important cryptographic protocol that enables an user to retrieve entries from a public database without revealing the identity of queried entries. PIR has been studied in both the single- and multi-server settings. The main difference is that multi-server PIR requires stronger assumptions of non-colluding servers. In our work, we will study both types of PIR protocols.

For many use cases, it is required that users retrieve a batch of multiple entries from the same public database. Some examples include anonymously retrieving encrypted recent messages from a communication system [15], privately fetching relevant advertisements according to user interests [38,54] and checking validity of multiple certificates [42, 49].

To solve this problem, prior works have studied the notion of batch PIR where the user retrieves a set of t entries in a single query. The naive approach of executing t single-query PIR has the high computational overhead of $O(tn)$ as state-of-the-art single-query PIR schemes still require $O(n)$ server computation linear in the database size. Instead, current batch PIR solutions drastically decrease computation at the cost of increased communication. Angel *et al.* [14] presented a solution that reduce computation to $3n$ that required performing $1.5t$ independent PIR queries on smaller databases. Unfortunately, the number of requests and responses are 50% larger than the naive approach of t single-query PIR executions.

To reduce communication, prior works packed multiple multiple single-query PIR requests into a single ciphertext [13, 14] as well as encoding multiple PIR responses for small database entries into a single ciphertext using vectorization techniques [52]. However, this still requires explicitly encoding $0.5t$ "dummy" requests and responses. Furthermore, response techniques only apply for small entries where ci-

Ours: Single-Server	$O(1)$	$\lceil (1+\varepsilon)/r\rceil$x	1.5x
Ours: Single-Server	$O(1)$	$\lceil 1.5/r\rceil$x	$\lceil (1+\varepsilon)/d\rceil$x
Ours: Two-Server*	$O(1)$	1.5x	$(1+\varepsilon)$x

Figure 2: Keyword batch PIR comparisons for retrieving ℓ entries from n-entry database. Request and response overhead is compared to baseline of performing ℓ independent single-query PIR executions. We use r and d to denote the number of requests and plaintext database entries that can fit into a single ciphertext. Asterisks(*) denote two-server PIR protocols.

phertexts can pack multiple entries. In this work, we present compression techniques to avoid encoding non-essential values that are applicable regardless of the database entry size.

While PIR considers the setting of public database, the same problem also occurs for retrieving mutliple entries from private databases with sensitive data where users should not receive information irrelevant to them. This problem has been studied as labeled private set intersection (PSI) or batch symmetric PIR. We will use labeled PSI throughout the rest of our work. Examples use cases with a private database include discovering any contacts using a service [44] and checking all credentials of a user against a database of leaked credentials [13]. In our work, we will also study ways to reduce communication for labeled PSI using ciphertext compression.

1.1 Our Contributions

We identify two compression problems and present efficient schemes for both problems relying only on additive homomorphism of the underlying encryption scheme. This leads to improved batch PIR and labeled PSI constructions (when the encryption scheme used for these constructions is indeed somewhat homomorphic, as required in prior state-of-the-art work).

Oblivious Ciphertext Compression. We study the problem of *oblivious ciphertext compression* where a compressor is given n ciphertexts of which $t < n$ are non-zero. The compressor is unaware of the identity of the t non-zero ciphertexts. The decompressor has the private key for decryption and knows the location of the t non-zero ciphertexts. The goal is to enable the compressor to construct a succinct encoding that may be correctly decoded by the decompressor.

We present LSObvCompress with encodings of $(1+\varepsilon)t$ ciphertexts (where ε is a configurable parameter) while requiring only homomorphic addition of ciphertexts. In practice, we achieve ε to be as small as 0.05. Note, this is only 5% larger than the optimal compression rate that would consist of only t ciphertexts. Furthermore, oblivious compression requires only $O(n\lambda)$ homomorphic additions and decompression requires only $O(t\lambda)$ plaintext additions such that decompression is successful except with probability $2^{-\lambda}$. Our protocol, LSObvCompress, utilizes novel techniques to compress ciphertexts by encoding them as random linear systems that are efficiently solvable.

LSObvCompress significantly outperforms any prior compression schemes applicable to our setting. In particular, all prior schemes with efficient encoding and decoding produce encodings with $O(t\lambda)$ ciphertexts that is significantly larger than LSObvCompress in practice. Only one previous solution produced encodings with $O(t)$ ciphertexts [31], but the decoding is prohibitively expensive requiring computation of $O(t\sqrt{n})$ discrete logarithms. See Figure 1 for more comparisons. To be fair, we note that prior works study a more challenging version of this problem (see Section 2.1).

Oblivious Ciphertext Decompression. *Oblivious ciphertext decompression* switches the roles of compressor and decompressor. The compressor is given n plaintexts $\mathbf{p} = [p_1,\ldots,p_n]^T$, a subset $I \subset [n]$ of $t < n$ indices and a private encryption key. The goal is to produce a succinct encrypted compression of $\mathbf{p}$. The decompressor must be able to correctly retrieve the ciphertext vector $\tilde{\mathbf{c}} = [\tilde{c}_1,\ldots,\tilde{c}_n]^T$ such that $\tilde{c}_i$ must be an encryption of p_i for all $i \in I$. There are no requirements for any $i \notin I$. The decompressor must decompress obliviously without knowledge of the indices, $I \subset [n]$.

We present LSObvDecompress with nearly identical efficiency as LSObvCompress, with encodings of size $(1+\varepsilon)t$ ciphertexts. In practice, we get ε to be as small as 0.05 that is only 5% larger than optimal.

For decoding failure probability at most $2^{-\lambda}$, compression requires $O(t\lambda)$ plaintext additions while decompression requires $O(n\lambda)$ homomorphic additions. To our knowledge, no prior works are applicable to this specific problem.

Batch PIR. We apply our compression techniques to obtain state-of-the-art batch PIR schemes with reduced communication in both the single- and two-server settings. Our techniques work for both small and large entry databases. See Figure 2 for detailed comparisons with prior works.

The cuckoo hashing framework of Angel *et al.* [14] transforms any single-query PIR into a batch PIR protocol. To retrieve ℓ entries, the batch PIR performs 1.5ℓ single-query PIR executions. Recent work by Mughees and Ren [52] used vectorization techniques to pack multiple small entries into a single ciphertext. If d database entries fit into a ciphertext, vectorized batch PIR returns $\lceil 1.5\ell/d \rceil$ ciphertexts. However, this only works for small entries where $d \geq 2$.

In our work, we first present a batch PIR that can reduce response size regardless of database entry sizes. In the cuckoo hashing framework, at most ℓ PIR responses will be encryptions of relevant values while the remaining 0.5ℓ will be encryptions of zero. Using LSObvCompress, we reduce the response size from 1.5ℓ to 1.05ℓ PIR responses. To our knowledge, this is the first response reduction for batch PIR with large database entries. We also show that our techniques are compatible with the vectorization techniques of Mughees and Ren [52]. If d entries fit into a ciphertext, our techniques reduce the response size from $\lceil 1.5\ell/d \rceil$ ciphertexts to $\lceil 1.05\ell/d \rceil$ ciphertexts.

Similar ideas may also be used to reduce the request communication as well. Again, the client only cares about ℓ PIR requests and the remaining 0.5ℓ may be ignored. We leverage LSObvDecompress to reduce the total request size by only compressing values of the ℓ important requests and, essentially, ignoring the other 0.5ℓ requests. Combined with packing techniques [14] where r single-server PIR requests may fit into a ciphertext, we reduce request sizes from $\lceil 1.5/r \rceil$ to $\lceil 1.05/r \rceil$ ciphertexts. We stil apply apply vectorization [52] to obtained $\lceil 1.5/d \rceil$ response ciphertexts.

Finally, we show similar response reduction may also be obtained in two-server batch PIR protocols by applying LSObvCompress to prior constructions [19].

Labeled PSI. Next, we show that LSObvCompress and LSObvDecompress may also be used to construct improved schemes for labeled PSI. In particular, one can combine our above batch PIR construction, leveraging LSObvCompress and LSObvDecompress, with any oblivious PRF (OPRF) to obtain a labeled PSI protocol. Our labeled PSI schemes provides a 65-88% reduction in communication with comparable computation over prior solutions [21, 25].

2 Preliminaries

Linear Algebra. We denote $\mathbf{v}$ as column vectors and $\mathbf{v}^T$ as row vectors. We denote the i-th entry of $\mathbf{v}$ by $\mathbf{v}_i$. For two vectors n-length vectors $\mathbf{v}$ and $\mathbf{u}$, we denote the dot product operator as $\mathbf{v} \cdot \mathbf{u} = \sum_{i=1}^{n} \mathbf{v_i} \cdot \mathbf{u_i}$. We define a $n \times m$ matrix using its column vectors as $\mathbf{M} = [\mathbf{v}_1, \ldots, \mathbf{v}_m]$ where the i-th column vector is $\mathbf{v}_i$ of length n. We may also define a matrix using its row vectors as $\mathbf{M} = [\mathbf{v}_1^T, \ldots, \mathbf{v}_n^T]$ where $\mathbf{v}_i^T$ is the i-th row vector of length m. We denote the matrix-vector product $\mathbf{M} \cdot \mathbf{u} = [\mathbf{v}_1 \cdot \mathbf{u}, \ldots, \mathbf{v}_n \cdot \mathbf{u}]$ where $\mathbf{u}$ is a m-length vector. We solve the linear system associated with $n \times m$ matrix $\mathbf{M}$ and n-length vector $\mathbf{u}$ by computing m-length vector $\mathbf{v}$ such that $\mathbf{M} \cdot \mathbf{v} = \mathbf{u}$.

For a vector $\mathbf{v}$ of length n and subset $I = \{i_1, \ldots, i_k\} \subseteq [n]$, we denote by $\mathbf{v}_I = [\mathbf{v}_{i_1}, \ldots, \mathbf{v}_{i_k}]$ containing the entries of $\mathbf{v}$ with indices in I. For $n \times m$ matrix $\mathbf{M} = [\mathbf{v}_1^T, \ldots, \mathbf{v}_n^T]$ and subset $I = \{i_1, \ldots, i_k\} \subseteq [n]$, we denote the sub-matrix consisting of row vectors with indices in I as $\mathbf{M}_{\mathsf{r}(I)} = [\mathbf{v}_{i_1}^T, \ldots, \mathbf{v}_{i_k}^T]$. Similarly, for a $n \times m$ matrix $\mathbf{M} = [\mathbf{v}_1, \ldots, \mathbf{v}_m]$ and subset $I = \{i_1, \ldots, i_k\} \subseteq [m]$, we denote the sub-matrix consisting of column vectors with indices in I as $\mathbf{M}_{\mathsf{c}(I)} = [\mathbf{v}_{i_1}, \ldots, \mathbf{v}_{i_k}]$.

Homomorphic Encryption. Throughout our work, we will define ciphertexts using $\tilde{c}$. A vector of ciphertexts will be defined as $\tilde{\mathbf{c}} = [\tilde{c}_1, \ldots, \tilde{c}_n]$.

In our work, we will mainly consider lattice-based somewhat homomorphic encryption (SHE) where parameters are chosen to support a limited number of homomorphic operations, as used in prior state-of-the-art constructions of batch PIR and labeled PSI [21,22,25,51,53]. Our compression protocols only use additive hommorphism of these schemes, where noise grows additively. We refer to the full version for more details on SHE and recent PIR schemes using SHE [51, 53].

2.1 Oblivious Ciphertext Compression

We define the notion of an *oblivious ciphertext compression* scheme. For this primitive, we only assume additive homomorphism (ciphertext-ciphertext addition). The problem consists of two parties: a compressor and a decompressor. The compressor is given n ciphertexts, $\tilde{\mathbf{c}} = [\tilde{c}_1, ..., \tilde{c}_n]$, to be compressed. Both the compressor and the decompressor know the number of non-zero plaintext entries t. In addition, the decompressor has the private decryption key and the indices of the t non-zero entries, $I \subset [n]$. If $i \in I$, then $\tilde{c}_i$ is an encryption of a non-zero entry. The compressor's job is to produce a succinct encoding of the input ciphertexts with knowledge of only t. The encoding is consumed by the decompressor to recover the original t non-zero plaintext entries. We formally define oblivious ciphertext compression below.

Definition 1 (Oblivious Ciphertext Compression)**.** *Let* $\mathbf{p} = [p_1, ..., p_n] \in \mathbb{F}^n$ *be a vector of n plaintexts with at most t non-zero entries. Let* $\mathcal{E} = (\mathsf{Gen}, \mathsf{Enc}, \mathsf{Eval}, \mathsf{Dec})$ *be an additive homomorphic encryption scheme, and let* $\tilde{\mathbf{c}} = [\tilde{c}_1, ..., \tilde{c}_n]$ *where* $\tilde{c}_i = \mathcal{E}.\mathsf{Enc}(\mathbf{pk}_{\mathcal{E}}, p_i)$ *for each* $i \in [n]$*. An oblivious ciphertext compression scheme consists of a pair of algorithms (*$\mathsf{ObvCompress}, \mathsf{Decompress}$*) satisfying:*

- $\hat{\mathbf{c}} \leftarrow \mathsf{ObvCompress}(\mathbf{pk}_{\mathcal{E}}, \tilde{\mathbf{c}}, t; R)$*: Oblivious compression takes in a public key* $\mathbf{pk}_{\mathcal{E}}$*, n ciphertexts* $\tilde{\mathbf{c}} = [\tilde{c}_1, ..., \tilde{c}_n]$*, the number of non-zero plaintext entries t, and randomness R. It outputs compressed ciphertexts* $\hat{\mathbf{c}}$*.*

- $\mathbf{p} \leftarrow \mathsf{Decompress}(\mathbf{sk}_{\mathcal{E}}, \hat{\mathbf{c}}, I; R)$*: Decompression takes in a secret key* $\mathbf{sk}_{\mathcal{E}}$*, compressed ciphertexts* $\hat{\mathbf{c}}$*, the non-zero*

plaintext entry indices $I \subset [n]$ ($|I| \leq t$) of p, and randomness R. It outputs the non-zero plaintext values $\{i, p_i\}_{i \in I}$.

Let $\gamma = \gamma(\lambda)$ be the bit length of all n ciphertexts produced by the homomorphic encryption scheme $\mathcal{E}$. An oblivious ciphertext compression is δ-compressing if the bit length of $\hat{\mathbf{c}}$ is at most $\delta \cdot \gamma \cdot |\tilde{\mathbf{c}}|$. The failure probability is at most ε if, for each plaintext vector $\mathbf{p} = [p_1, ..., p_n]$ and associated ciphertexts $\tilde{\mathbf{c}} = [\tilde{c}_1, \ldots, \tilde{c}_n]$ with at most t non-zero values,

$$\Pr[\mathsf{Decompress}(\mathbf{sk}_{\mathcal{E}}, \hat{\mathbf{c}}, I) \neq \{i, p_i\}_{i \in I}] \leq \varepsilon$$

where $\hat{\mathbf{c}} \leftarrow \mathsf{ObvCompress}(\mathbf{pk}_{\mathcal{E}}, \tilde{\mathbf{c}}, t)$.

Comparison with Prior Work. Liu and Tromer [48] implicitly studied oblivious ciphertext compression, without explicitly defining the primitive. Fleischhacker *et al.* [31] considered another variant closer to our compression problem that was also implicitly studied in [48]. where the decompressor is not given the identity of the non-zero plaintext indices, $I \subset [n]$. Therefore, this is a harder setting than our compression problem. It is not surprising that the resulting compression rates or decoding efficiency are significantly worse than our constructions (see Figure 1). To our knowledge, our specific variant of compression has not been explicitly studied previously.

2.2 Oblivious Ciphertext Decompression

Next, we define *oblivious ciphertext decompression* that switches the compressor and decompressor roles. The compressor is given the plaintext vector, $\mathbf{p} = [p_1, \ldots, p_n]$ and a subset of t indices, $I \subset [n]$ with $|I| = t$ to produce a succinct encoding $\hat{\mathbf{c}}$. The decompressor is given $\hat{\mathbf{c}}$ and must produce the ciphertext vector $\tilde{\mathbf{c}} = [\tilde{c}_1, \ldots, \tilde{c}_n]^T$ such that each $\tilde{c}_i$ is an encryption of p_i for all $i \in I$. No correctness is required for $i \notin I$. In other words, $\tilde{c}_i$ needs to be an encryption of p_i only when $i \in I$. However, the decompressor must obliviously decode without any knowledge of the relevant indices, I. In fact, the compressed ciphertexts $\hat{\mathbf{c}}$ must not reveal any information about neither the underlying plaintext values $\mathbf{p} = [p_1, \ldots, p_n]^T$ nor the relevant indices I. To our knowledge, no prior works have studied this setting.

Definition 2 (Oblivious Ciphertext Decompression)**.** *Let $p = [p_1, ..., p_n]^T \in \mathbb{F}^n$ be a vector of n plaintexts and $I \subset [n]$ be a subset of $t < n$ indices. Let $\mathcal{E} = (\mathsf{Gen}, \mathsf{Enc}, \mathsf{Eval}, \mathsf{Dec})$ be an additive homomorphic encryption scheme. A oblivious ciphertext decompression scheme consists of a pair of algorithms ($\mathsf{Compress}, \mathsf{ObvDecompress}$), where:*

- $\hat{\mathbf{c}} \leftarrow \mathsf{Compress}(\mathbf{sk}_{\mathcal{E}}, p, I; R)$*: The compression algorithm takes in a secret homomorphic encryption key $\mathbf{sk}_{\mathcal{E}}$, a vector of n plaintexts $p = [p_1, ..., p_n]^T$, a subset of t indices $I \subset [n]$ and randomness R. Then, it outputs the compressed ciphertexts $\hat{\mathbf{c}}$.*
- $\mathbf{p} \leftarrow \mathsf{ObvDecompress}(\mathbf{pk}_{\mathcal{E}}, \hat{\mathbf{c}}, n; R)$*: The decompression algorithm takes in a public homomorphic encryption key $\mathbf{pk}_{\mathcal{E}}$, compressed ciphertexts $\hat{\mathbf{c}}$, the number of total plaintexts n, and randomness R. Then, it outputs the ciphertext vector $\tilde{c} = [\tilde{c}_1, \ldots, \tilde{c}_n]^T$.*

Let $\gamma = \gamma(\lambda)$ be the bit length of all n ciphertexts produced by the homomorphic encryption scheme $\mathcal{E}$. A oblivious ciphertext decompression is δ-compressing if the bit length of $\hat{\mathbf{c}}$ is at most $\delta \cdot \gamma \cdot |\tilde{c}|$. The failure probability is at most ε if, for each plaintext vector $p = [p_1, ..., p_n]^T$ and subset $I \subset [n]$ of size t, the following holds:

$$\Pr[\exists i \in I \mid \mathsf{Dec}(\mathbf{sk}_{\mathcal{E}}, \tilde{c}_i) \neq p_i] \leq \varepsilon$$

where $\hat{\mathbf{c}} \leftarrow \mathsf{ObvCompress}(\mathbf{sk}_{\mathcal{E}}, p, I)$ and $[\tilde{c}_1, \ldots, \tilde{c}_n]^T \leftarrow \mathsf{Decompress}(\mathbf{pk}_{\mathcal{E}}, \hat{\mathbf{c}})$. We note that there are no correctness requirements for ciphertexts $\tilde{c}_i$ such that $i \notin I$.

The scheme is computationally oblivious if, for all pairs of plaintext vectors $p = [p_1, \ldots, p_n]^T$ and $p' = [p'_1, \ldots, p'_n]^T$ and pairs of index sets $I, I' \subset [n]$ of size t, a computationally adversary cannot distinguish between the following:

- $\hat{\mathbf{c}} \leftarrow \mathsf{Compress}(\mathbf{sk}_{\mathcal{E}}, p, I)$
- $\hat{\mathbf{c}}' \leftarrow \mathsf{Compress}(\mathbf{sk}_{\mathcal{E}}, p', I')$.

2.3 Batch PIR and Labeled PSI

Batch (Keyword) PIR. In batch keyword PIR, the client holds a batch of ℓ keys, $\{q_1, \ldots, q_\ell\}$, and the server holds a public database $D \in (\mathcal{K} \times \mathcal{V})^n$ of n key-value pairs with n distinct keys, $\{(k_1, v_1), \ldots, (k_n, v_n)\}$. The client wishes to retrieve the database entries $\{D[q_1], \ldots, D[q_\ell]\}$ from the server. For any $q \in \mathcal{K}$, $D[q]$ denotes the value associated with key q. If $q = k_i$, then $D[q] = v_i$. Otherwise, $D[q] = \perp$. The following two properties must hold:

- *Correctness*: If the protocol is executed correctly, the client recovers $\{D[q_1], \ldots, D[q_\ell]\}$ as desired.
- *Query Privacy*: The server learns no information about the batch query, $\{q_1, \ldots, q_\ell\}$.

One can obtain the definition of single-query PIR if the batch query contains only a single index, $\ell = 1$. Furthermore, one can obtain non-keyword PIR if we restrict the database's key universe to be $\mathcal{K} = [n]$. Throughout our work, we will consider keyword PIR unless otherwise specified.

(Unbalanced) Labeled PSI. In labeled PSI, the receiver and sender hold sets X and Y respectively. The sender also holds a database of associated labels $\{L_y \mid y \in Y\}$. The goal is for the receiver to receive labels that appear in the intersection, $\{(z, L_z) \mid z \in X \cap Y\}$. The following properties must hold:

- *Correctness*: If the protocol is executed correctly, the receiver recovers $\{(z, L_z) \mid z \in X \cap Y\}$ as desired.

- *Receiver (Query) Privacy*: The sender learns no information about the receivers's set X beyond its size $|X|$.
- *Sender (Database) Privacy*: The receiver learns no information about the sender's set Y except for the desired output and its size $|Y|$.

In the unbalanced setting, the receiver's set X is typically much smaller than the sender's set Y, $|X| \ll |Y|$. Note, labeled PSI is similar to batch keyword PIR with the main difference being the additional sender (database) privacy guarantee.

3 Oblivious Ciphertext Compression

In this section, we present our oblivious ciphertext compression scheme, LSObvCompress, based on linear systems. We start with a simpler scheme before presenting our main construction.

3.1 First Attempt: Balls-into-Bins

In this section, we start with a construction which leverages the balls-into-bins random process. Given m bins and n balls, each of the n balls are thrown into one of the m bins uniformly at random. In the context of ciphertext compression, bins correspond to compressed ciphertexts and balls correspond to input non-zero ciphertexts. Throwing a ball into a bin corresponds to homomorphically adding an input ciphertext to one of the compressed ciphertexts. Decompression works by re-simuluating the ball throws for non-zero ciphertexts and decrypting the values at relevant bins. The main observation is that adding a zero-encrypting ciphertext can be thought of as "skipping" the ball throw, as its addition doesn't change the value of the underlying plaintext. Conceptually, the algorithm fails if any of the bins contains more than one ball. We describe the algorithm below.

We suppose that both parties share a hash function H. Upon receiving the input ciphertexts $\tilde{\mathbf{c}} = [\tilde{c}_1, \ldots, \tilde{c}_n]^T$ and the number of non-zero plaintext entries t, the compression algorithm first initializes a vector of $m \geq t$ zero ciphertexts $\hat{\mathbf{c}} = [\hat{c}_1, ..., \hat{c}_m]^T$, where $\hat{c}_i = \mathcal{E}.\mathsf{Enc}(\mathbf{pk}_{\mathcal{E}}, 0)$. Then, for each input ciphertext $\tilde{c}_i$, the algorithm executes the following two operations. First, compute index $j = H(i) \in [m]$ where H is a random function with range $[m]$. Next, homomorphically add $\tilde{c}_i$ to $\hat{c}_j$, that is, $\hat{c}_j = \mathcal{E}.\mathsf{Eval}(\mathbf{pk}_{\mathcal{E}}, +, [\tilde{c}_i, \hat{c}_j])$. Finally, the algorithm outputs the resulting vector $\hat{\mathbf{c}}$.

The decompression algorithm receives the compression $\hat{\mathbf{c}} = [\hat{c}_1, \ldots, \hat{c}_m]^T$ and non-zero plaintext entry indices I. For every non-zero ciphertext index $i \in I$, the algorithm computes $j = H(i)$ and sets $p_i = \mathcal{E}.\mathsf{Dec}(\mathbf{sk}_{\mathcal{E}}, \hat{c}_j)$. Finally, the algorithm outputs all non-zero plaintext values, $\{i, p_i\}_{i \in I}$.

Note this algorithm can recover the original plaintext vector as long as the hash outputs $H(i)$ are all distinct for every $i \in I$. However, the probability of collision is high unless $m = \Omega(t^2)$ (due to the birthday problem) that is a quadratic blowup with respect to t. Ideally, we would like m to be not much larger than t to obtain an efficient compression rate.

Reformulating as a Linear System. We generalize the aforementioned scheme as constructing and solving a system of linear equations. More specifically, the compression algorithm is responsible for constructing a linear system that the decompression algorithm attempts to solve to recover the original plaintext vector. While this viewpoint seems rather unnecessarily complex, it will serve as an important basis to our main construction. We outline the reformulated algorithm below.

For each $i \in [n]$, the compression algorithm constructs a column vector $\mathbf{v}_i \in \mathbb{F}^m$ where only the $H(i)$-th element is set to 1 and the rest are set to 0. Let $\mathbf{M} = [\mathbf{v}_1, ..., \mathbf{v}_n] \in \mathbb{F}^{m \times n}$ be a matrix. Note that both parties know matrix $\mathbf{M}$ as they share hash function H. The compression algorithm computes and outputs the matrix-vector multiplication $\hat{\mathbf{c}} = \mathbf{M} \cdot \tilde{\mathbf{c}}$.

The decompression algorithm takes in the vector $\hat{\mathbf{c}}$ and produces its decryption $\hat{\mathbf{p}}$. Next, we reconstruct the matrix $\mathbf{M}$ using the random function H. Let $I = \{i_1, ..., i_t\}$ be the set of non-zero plaintext entry indices, and let $\mathbf{M}_{\mathsf{c}(I)} = [\mathbf{v}_{i_1}, ..., \mathbf{v}_{i_t}] \in \mathbb{F}^{m \times t}$ be a sub-matrix of $\mathbf{M}$ consisting of all column vectors whose indices appear in I. Similarly, let $\hat{\mathbf{p}}_I = [\hat{p}_{i_1}, \ldots, \hat{p}_{i_t}]$ for entries of $\hat{\mathbf{p}}$ in I. The algorithm solves the linear system associated with $\mathbf{M}_{\mathsf{c}(I)}$ and $\hat{\mathbf{p}}$ to compute $\mathbf{p}_I$ satisfying $\mathbf{M}_{\mathsf{c}(I)} \cdot \mathbf{p}_I = \hat{\mathbf{p}}_I$ to recover the non-zero $p_{i_j} = (\mathbf{p}_I)_j$ for each $j \in [t]$.

We note that the decompression algorithm can correctly recover the plaintext vector if and only if the linear system $\mathbf{M}_{\mathsf{c}(I)} \cdot \mathbf{p}_I = \hat{\mathbf{p}}_I$ has a unique solution (that is, $\mathbf{M}_{\mathsf{c}(I)}$ has full column rank). For our choice of $\mathbf{M}$, this precisely happens when all hash outputs $H(i)$ are distinct for every $i \in I$.

3.2 Second Attempt: Random Matrices

Recall that in the first attempt, the generated matrix $\mathbf{M}$ consists of random column vectors with Hamming weight exactly one corresponding to the balls-into-bins process. This forced us to set the number of rows and the encoding size to $m = \Omega(t^2)$ to avoid collisions. Taking a closer look, we notice that the way we generate the column vectors are unnecessarily restrictive. Indeed, for our scheme to succeed, we only require the $\mathbf{M}_{\mathsf{c}(I)}$ to have a unique solution. There is no need to restrict rows to Hamming weight one vectors.

This crucial observation leads to the following approach. Instead of sampling random column vectors with Hamming weight 1, we instead sample column vectors uniformly at random from $\{0,1\}^m$. To do this, we can imagine the shared hash function $H : [n] \to \{0,1\}^m$ outputs random binary column vectors of length m. Then, the shared matrix is $\mathbf{M} = [H(1), \ldots, H(n)]$. This way, the generated column vectors will be linearly independent with high probability even when m is small. The rest of the algorithm stays identical.

Failure Probability and Compression Rate. The algorithm's failure probability and compression rate will be pa-

rameterized by ε and t. Let $m = (1+\varepsilon)t$ be the number of rows. Even when ε is very small, the generated $m \times t$ matrix $\mathbf{M}_{\mathsf{c}(I)}$ has a unique solution except with negligible probability. For example, setting $m = t + \lambda$ with very small $\varepsilon = \lambda/t$, the system has full rank with probability $1 - 2^{-\lambda-1}$ (see [33]). The compression rate is almost optimal as the encoding contains $t + \lambda$ ciphertexts that is only λ more than the optimal minimum.

Running Time. Let $m = (1+\varepsilon)t$. We start by analyzing the compression time. Generating a random column vector $\in \{0,1\}^m$ takes $O(m)$ time, so the entire matrix generation takes $O(mn)$ time during compression. Computing the matrix-vector product takes $m \cdot n$ homomorphic ciphertext additions. The compression algorithm performs $O(m \cdot t)$ ciphertext-ciphertext additions. For decompression, we note that solving the linear system associated to $\mathbf{M}_{\mathsf{c}(I)}$ requires $O(m \cdot t^2)$ time using Gaussian elimination.

Comparison to the First Attempt. While the new algorithm can give us very high compression rate, it is computationally very inefficient. Compression requires $O(mt)$ time and decompression requires $O(mt^2)$ time using Gaussian elimination. In practice, this may not be so problematic when $t << n$, but as t grows, the scheme is computationally expensive. Ideally, we would like compression to be close to linear in the number of ciphertexts, n, and decompression to be close to linear in t. In contrast, the first attempt has horrible compression rate of $m = O(t^2)$, but is computationally more efficient. The compression algorithm requires only $O(n)$ time. Furthermore, decompression only used $O(t^2)$ time.

This raises the following question: is it possible to get the best of both worlds - an algorithm that achieves high compression rate but is also practically efficient? We show that this is possible in the next subsection.

3.3 LSObvCompress: Random Band Matrices

In prior attempts, we generated random matrices uniformly at random from $\{0,1\}^{m \times n}$. This allowed the associated random linear systems to be uniquely solvable with high probability even when $m = (1+\varepsilon)t$ was very small. However, solving this linear system is very inefficient, which made the previous scheme impractical for larger t. This is not too surprising, because the generated matrix is very dense. The expected number of non-zero matrix entries is $mn/2$. This suggests that the algorithm for solving the linear system must also have at least $O(mn)$ running time as well.

Looking closely, we again realize that we never needed the generated matrices to be sampled uniformly at random from $\{0,1\}^{m \times n}$. That is, as long as the associated linear system is uniquely solvable with high probability, the distribution itself is irrelevant to the security of the scheme. Therefore, we only require a matrix generation algorithm that generates a "small" linear system that is uniquely and efficiently solvable. For LSObvCompress, we consider random matrices that satisfy these two properties.

Random Band Matrices. There has been extensive research on the core algorithmic problem of generating sparse random matrices that are efficiently solvable. For LSObvCompress, we utilize the random band matrices of Dietzfelbinger and Walzer [28] that is the most efficient to our knowledge.

Random band matrices are constructed such that each row consists of a random band with width w, and all entries outside of the band are zero. Formally, let m be the length of each row of the matrix. For each row, a band start index s is chosen randomly from $[m-w+1]$, and each entry within the band, i.e. in range $[s, s+w)$, is a uniformly random bit from $\{0,1\}$. All other entries outside the range $[s, s+w)$ remain 0.

Intuitively, random band matrices are solvable in $O(nw)$ time because the generated random matrix is "almost diagonal" after the rows are sorted by the band start positions. Furthermore, each row reduction operation maintains an invariant where the number of non-zero entries per rows is $O(w)$ making Gaussian elimination very efficient.

Adaptation for LSObvCompress. Unfortunately, we are unable to directly apply random band matrices for LSObvCompress. Going back to the linear system framework presented in Section 3.1, the client will solve the linear system associated with the matrix $\mathbf{M}_{\mathsf{c}(I)}$. Recall that I is the subset of non-zero plaintexts, $\mathbf{M}$ is the chosen random matrix and $\mathbf{M}_{\mathsf{c}(I)}$ is the sub-matrix of $\mathbf{M}$ consisting of all the column vectors whose indices appear in I. Suppose we chose $\mathbf{M}$ to be a random band matrix. Unfortunately, $\mathbf{M}_{\mathsf{c}(I)}$ is not guaranteed to be a random band matrix. In particular, it is possible that I (and, thus, the columns) are chosen such that each matrix row will have a band much smaller than length w or be all zero. In this case, it is unclear if the matrix $\mathbf{M}_{\mathsf{c}(I)}$ still has a unique solution.

Instead, we will choose our matrix $\mathbf{M}$ using an adaptation of random band matrices to ensure that $\mathbf{M}_{\mathsf{c}(I)}$ is still efficiently solvable for any choice of non-zero plaintext indices I. To do this, we will instead choose $\mathbf{M}$ to be the tranpose of random band matrices. In other words, we will generate each column vector of $\mathbf{M}$ to consist of a random band of width w. To do this, we imagine both parties share two hash functions $\mathsf{H}_1 : [n] \to [m-w+1]$ and $\mathsf{H}_2 : [n] \to \{0,1\}^w$. For the i-th column of the shared matrix $\mathbf{M}$, $\mathsf{H}_1(i)$ denotes the start of the band and $\mathsf{H}_2(i)$ chooses the random w-bit band.

Next, we can consider any subset of non-zero plaintexts I and the associated sub-matrix $\mathbf{M}_{\mathsf{c}(I)}$. As each column vector consists of a random w-length band, $\mathbf{M}_{\mathsf{c}(I)}$ remains a transpose of a random band matrix. As the column and row rank of any matrix is identical, we can rely on the analysis of Dietzfelbinger and Walzer [28] to see that $\mathbf{M}_{\mathsf{c}(I)}$ will have a unique solution with high probability for any choice of I.

The only caveat is that we cannot apply the running time analysis of the random band row matrix construction, as the bands are constructed column-wise instead of row-wise.

Algorithm 1 LSObvCompress.ObvCompress algorithm

Input: $\mathbf{pk}_{\mathcal{E}}, \tilde{\mathbf{c}}, t, R$: public additively homomorphic encryption key, vector of n ciphertexts, number of non-zero plaintext entries, and randomness.
Output: $\hat{\mathbf{c}}$: compressed encoding of $\tilde{\mathbf{c}}$.

$m \leftarrow (1+\varepsilon)t$
$\mathbf{M} \leftarrow 0^{m \times n}$
for $i = 1, \ldots, n$ **do**
  $\mathbf{v_i} \leftarrow \mathsf{GenRandVec}(i, m; R)$
  $\mathbf{M}[:][i] \leftarrow \mathbf{v_i}$ ▷ Set the ith column to $\mathbf{v_i}$
$\hat{\mathbf{c}} \leftarrow \mathbf{M} \cdot \tilde{\mathbf{c}}$ ▷ HE add using $\mathcal{E}$.Eval and $\mathbf{pk}_{\mathcal{E}}$
return $\hat{\mathbf{c}}$

Algorithm 2 GenRandVec algorithm

Input: i, m, R: column index, column vector length, and randomness
Output: $\mathbf{v_i}$: generated random column vector

$w \leftarrow$ band width
$s \leftarrow \mathsf{H}_1(R \,||\, i)$ ▷ Random value from $[m-w+1]$
$\mathbf{u} \leftarrow \mathsf{H}_1(R \,||\, i)$ ▷ Random w-bit band.
$\mathbf{v_i} \leftarrow 0^m$
for $j = 0, \ldots, w-1$ **do**
  $\mathbf{v_i}[s+j] \leftarrow \mathbf{u}[j]$
return $\mathbf{v_i}$

Nonetheless, we show that solving the system remains practically efficient with this modification in our experiments (see Section 7.1). Intuitively, this is because a transpose of a random band row matrix remains similar to a random band row matrix after the columns are sorted by the band start positions. The maximum band width across the entire rows is not much larger than the column band width w, which allows the linear system to be solved efficiently just as in the random band row matrix construction. See Figure 3 for an illustration. We prove the following theorem (see Appendix A for the proof):

Theorem 1. *Consider a $m \times t$ matrix with $m = (1+\varepsilon)t$ where each column consists of a single random w-bit band. For constant $\varepsilon > 0$ and band length $w = O(\lambda + \log t)$, the random band matrix has column rank n and executing Gaussian elimination after sorting the columns by the starting location of the band runs in time $O(tw)$ except with probability $2^{-\lambda}$.*

We now formally present LSObvCompress using random band matrices. See Algorithms 1 and 3 for the description of the oblivious compression and decompression algorithms.

Next, we analyze the properties of LSObvCompress showing that it combines the good compression rates and efficient encoding/decoding times of our prior two attempts.

Failure Probability and Compression Rate. For the failure probability, we note that LSObvCompress fails only when $\mathbf{M}_{\mathsf{c}(I)}$ does not have a unique solution or that unique solution cannot be found. By Theorem 1, we know this occurs with probability at most $2^{-\lambda}$ assuming that $w = O(\lambda/\varepsilon + \log n)$.

In our experiments, we will use concrete parameters for w and ε for various values of t to obtain 2^{-40} error probability. We point readers to Section 7.1 for more details. For the compression rate, our experiments show that ε may be as small as 0.05. As a result, LSObvCompress obtains compression rates that are only 5% larger than optimal.

Running Time. We start by analyzing the compression algorithm that computes the matrix multiplication of $\mathbf{M}$ and the input ciphertext vector $\tilde{\mathbf{c}} = [\tilde{c}_1, \ldots, \tilde{c}_n]^T$. As $\mathbf{M}$ is a binary matrix with at most nw non-zero entries, this can be performed using at most nw ciphertext-ciphertext additions. For decompression, we note that the main cost is solving the linear system $\mathbf{M}_{\mathsf{c}(I)}$ that requires $O(tw)$ time by Theorem 1 that is corroborated by our experiments (see Section 7.1).

Noise Growth for SHE. Recall that for the applications to

Algorithm 3 LSObvCompress.Decompress algorithm

Input: $\mathbf{sk}_{\mathcal{E}}, \hat{\mathbf{c}}, I, R$: secret additively homomorphic encryption key, compressed encoding of ciphertexts, set of non-zero plaintext indices, and randomness.
Output: $\{i, p_i\}_{i \in I}$: original non-zero plaintext values.

$m \leftarrow (1+\varepsilon)t$
$\mathbf{M}_{\mathsf{c}(I)} \leftarrow 0^{m \times t}$ ▷ Initialize all zero matrix.
for $i_j \in I = \{i_1, \ldots, i_t\}$ **do**
  $\mathbf{v}_{i_j} \leftarrow \mathsf{GenRandVec}(i_j, m; R)$
  $\mathbf{M}_{\mathsf{c}(I)}[:][j] \leftarrow \mathbf{v}_{i_j}$ ▷ Set the jth column to $\mathbf{v}_{i_j}$
$\hat{\mathbf{p}} \leftarrow$ decryption of $\hat{\mathbf{c}}$ using $\mathcal{E}$.Dec and $\mathbf{sk}_{\mathcal{E}}$
$p_I \leftarrow \mathsf{SolveLinearSystem}(\mathbf{M}_{\mathsf{c}(I)}, \hat{\mathbf{p}})$
if $p_I = \perp$ **then**
  return $\perp$
$\mathbf{p} \leftarrow \emptyset$
for $i_j \in I = \{i_1, \ldots, i_t\}$ **do**
  $\mathbf{p} \leftarrow \mathbf{p} \cup \{(i_j, (p_I)_j)\}$
return $\mathbf{p}$

Algorithm 4 SolveLinearSystem algorithm

Input: $\mathbf{M}, \hat{\mathbf{p}}$: LHS matrix, RHS values to solve for
Output: $\mathbf{p}$: solution to the linear system $\mathbf{M} \cdot \mathbf{p} = \hat{\mathbf{p}}$

$(\mathbf{M}^{\pi}, \pi) \leftarrow$ column sorting of the matrix $\mathbf{M}$ in ascending band start positions, along with the corresponding permutation that produces the column sorted matrix (e.g. $\mathbf{M}^{\pi}[:][i] = \mathbf{M}[:][\pi(i)]$)
$\mathbf{p}^{\pi} \leftarrow$ execute Gaussian elimination on $\mathbf{M}^{\pi}$ and $\hat{\mathbf{p}}$, $\perp$ if no unique solution
if $\mathbf{p}^{\pi} = \perp$ **then**
  return $\perp$
$\mathbf{p} \leftarrow 0^t$
for $i = 1 \ldots t$ **do**
  $\mathbf{p}[\pi(i)] \leftarrow p^{\pi}[i]$
return $\mathbf{p}$

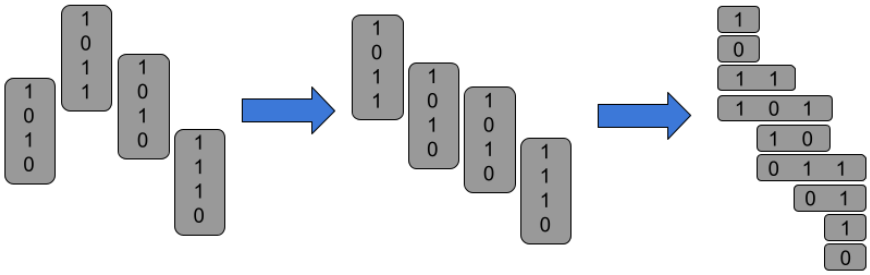

Figure 3: Example of a random band column matrix construction with band width $w = 4$. Second diagram shows the matrix after sorting the columns by the band start positions. Third diagram shows the random band row matrix view of the constructed matrix. In this example, the maximum band row width is 3.

batch PIR and labeled PSI, we will initialize LSObvCompress, using lattice-based SHE schemes. Therefore, noise growth is an important factor to consider. Suppose that the input ciphertexts $\tilde{\mathbf{c}} = [\tilde{c}_1, \ldots, \tilde{c}_n]^T$ each have error at most $\mathsf{Err}(\tilde{c}_i) \leq e$. We note that the compression algorithm requires computing the sum of at most w ciphertexts. Therefore, each ciphertext in the compressed output has error at most $O(w \cdot e)$ as ciphertext-ciphertext additions only incur linear noise growth (see the full version for more details). As decompression is done after decryption, we do not need to worry about noise growth for decompression.

3.4 Comparison with Sparse Random Linear Codes [45, 48]

Liu and Tromer [48] implicitly study oblivious ciphertext compression. They observe that Sparse Random Linear Codes (SRLCs) [45], which use matrices $\mathbf{M} \in \mathbb{F}^{m \times n}$ where each column has a small number of non-zero entries drawn randomly from $\mathbb{F}$ can be used. However, each entry is sampled independently, in an unstructured way, which results in larger encodings than with LSObvCompress. Indeed, they show that such matrices can be sampled with full rank with high probability only if $m = O(t \log^2 t \log \lambda)$, which is larger than $m = 1.05t$ of LSObvCompress. Moreover, because SRLCs are unstructured, Gaussian elimination takes $O(t^3)$ time, resulting in slower $O(t^3)$ decoding time, compared to the $O(t \cdot \lambda)$ decoding time of LSObvCompress. Finally, since SRLCs use elements drawn randomly from $\mathbb{F}$, when used with FHE, large parameters must be used to handle the noise when multiplying ciphertexts by these large elements. However, LSObvCompress only uses elements from $\{0, 1\}$, which means that ciphertexts are only added together, resulting in minimal noise growth.

4 Oblivious Ciphertext Decompression

We show that similar ideas that we used to solve the oblivious ciphertext compression problem may also be used to solve the oblivious ciphertext decompression problem. As a reminder, in this problem, the compressor is given a plaintext vector, $\mathbf{p} = [p_1, \ldots, p_n]^T$, and t relevant indices $I \subset [n]$. The goal is for the decompressor to decode ciphertexts $\tilde{\mathbf{c}} = [\tilde{c}_1, \ldots, \tilde{c}_n]^T$ such that $\tilde{c}_i$ is an encryption of p_i for all relevant indices $i \in I$. There are no requirements for any $i \notin I$.

Description of LSObvDecompress**.** Essentially, we will apply the ideas of LSObvCompress, but in reverse. That is, we will start with a matrix $\mathbf{M}$ of dimension $n \times m$ (that both the compressor and decompressor can generate based on shared randomness), where $m = (1+\varepsilon)t$ is the encoding length for some constant $\varepsilon > 0$. Then, based on relevant row indices $I = \{i_1, \ldots, i_t\} \subset [n]$, the compressor will solve the linear system formed by a $(t \times m)$-dimensional sub-matrix $\mathbf{M}_{\mathsf{r}(I)}$ of $\mathbf{M}$ and vector $\mathbf{p}_I = [p_{i_1}, p_{i_2}, \ldots, p_{i_t}]$, to obtain compressed plaintext vector $\hat{\mathbf{p}}$ of dimension m. Specifically, the compressor will solve the linear system for $\hat{\mathbf{p}}$ satisfying $\mathbf{M}_{\mathsf{r}(I)} \cdot \hat{\mathbf{p}} = \mathbf{p}_I$ using sub-matrix $\mathbf{M}_{\mathsf{r}(I)} = [\mathbf{M}_{i_1}^T, \ldots, \mathbf{M}_{i_t}^T]$.

Afterwards, the vector $\hat{\mathbf{p}}$ is encrypted entry-wise. The encrypted version of $\hat{\mathbf{p}}$ is the final encoding that we denote $\hat{\mathbf{c}}$. If the linear system according to $\mathbf{M}_{\mathsf{r}(I)}$ is not solvable, then the encoding fails and the compressor outputs any m encryptions. In applications, this is the point where we can utilize packing techniques where multiple plaintext values may be encrypted into a single ciphertext (as done in [14]).

For oblivious decompression, the decompressor computes $\mathbf{M} \cdot \hat{\mathbf{c}}$ homomorphically. Intuitively, this gives the decompressor ciphertext vector $\tilde{\mathbf{c}} = [\tilde{c}_1, \ldots, \tilde{c}_n]^T$ such that for each $i_j \in I$, the underlying plaintext of $\tilde{c}_{i_j}$ is $\mathbf{v}_{i_j} \cdot \hat{\mathbf{p}}$, which is exactly p_{i_j}, as desired. For every $\tilde{c}_{i_j}$ where $i_j \notin I$, the underlying plaintext will be some arbitrary linear combination of the entries of $\hat{\mathbf{p}}$, but recall that these values need not be correct.

For the choice of matrix $\mathbf{M}$, we can in fact generate it similarly as in LSObvCompress as a random band matrix of dimension $n \times m$, where each row consists of a single random band of length w. Note, this is the original random band matrix construction [28] without modification.

We present the pseudocode for LSObvDecompress in Algorithms 5 and 6.

Failure Probability. From above, we saw that the encoding is correct as long as the compressor can solve the linear system associated with $\mathbf{M}_{\mathsf{r}(I)}$. For the failure probability, we can simply calculate the probability that $\mathbf{M}_{\mathsf{r}(I)}$ does have a unique solution (or it cannot be found). As $\mathbf{M}$ is a random band matrix, we know that $\mathbf{M}_{\mathsf{r}(I)}$ is also a random band matrix. Therefore, if we set the band length $w = O(\lambda/\varepsilon + \log t)$ and

Algorithm 5 LSObvDecompress.Compress algorithm

Input: $\mathbf{sk}_{\mathcal{E}}, \mathbf{p} = [p_1, \ldots, p_n]^T, R$: secret additively homomorphic encryption key, plaintext values and randomness.
Output: $\hat{\mathbf{c}}$: compressed ciphertexts.

Compute $I = \{i \mid p_i \neq 0\} \subseteq [n]$.
If $|I| > t$, abort.
If $|I| < t$, arbitrarily add indices to I until $|I| = t$.
$m \leftarrow (1+\varepsilon)t$
$\mathbf{M}_{\mathsf{r}(I)} \leftarrow 0^{t \times m}$ ▷ Initialize all zero matrix.
for $i \in I$ **do**
  $\mathbf{M}_i \leftarrow \mathsf{GenRandVec}(i, m, R)^T$
$\hat{\mathbf{p}} \leftarrow \mathsf{SolveLinearSystem}(\mathbf{M}_{\mathsf{r}(I)}, \mathbf{p}_I)$
$\hat{\mathbf{c}} \leftarrow$ encryption of $\hat{\mathbf{p}}$ using $\mathcal{E}$.Dec and $\mathbf{sk}_{\mathcal{E}}$
return $\hat{\mathbf{c}}$

Algorithm 6 LSObvDecompress.ObvDecompress algorithm

Input: $\hat{\mathbf{c}}, R$: compressed ciphertexts and randomness.
Output: $\tilde{\mathbf{c}}$: decompressed ciphertexts.

$m \leftarrow (1+\varepsilon)t$
for $i \in [n]$ **do**
  $\tilde{c}_i \leftarrow \mathsf{GenRandVec}(i, m, R) \cdot \hat{\mathbf{c}}$
$\tilde{\mathbf{c}} \leftarrow [\tilde{c}_1, \ldots, \tilde{c}_n]$
return $\tilde{\mathbf{c}}$

$\mathbf{M}_{\mathsf{r}(I)}$ to be a $t \times (1+\varepsilon)t$, then $\mathbf{M}_{\mathsf{r}(I)}$ has a unique solution.

Compression Rate. We show that ε may be as small as 0.05 using experimental evaluation (see Section 7.1). Note, this is only 5% larger than the minimum of t ciphertexts since t plaintext values must be correctly encoded.

Running Time. The compression algorithm requires solving the linear system associated to $\mathbf{M}_{\mathsf{r}(I)}$ that is a $t \times (1+\varepsilon)t$ random band matrix. This can be done in $O(tw)$ time using only plaintext operations. Additionally, the resulting vector must be encrypted using $O(m) = O(t)$ time.

Decompression simply requires computing the matrix-vector multiplication $\mathbf{M} \cdot \hat{\mathbf{c}}$. As each row has at most w one entries, this requires $O(nw)$ homomorphic additions.

Obliviousness. Note that $\hat{\mathbf{c}}$ is always a length-m ciphertext vector. Reducing to the security of the underlying encryption scheme $\mathcal{E}$, we can replace each of these ciphertexts with encryptions of 0 meaning $\hat{\mathbf{c}}$ is independent of input plaintexts.

Noise Growth for SHE. Recall that for the applications to batch PIR and labeled PSI, we will initialize LSObvCompress, using lattice-based SHE schemes. Therefore, noise growth is an important factor to consider. We note that the compression algorithm is performed in plaintext without any homomorphic operations. Therefore, we only consider noise growth for decompression. The compressed input consists of m fresh SHE ciphertexts. Decompression adds at most w ciphertexts. If the input ciphertexts $\tilde{\mathbf{c}} = [\tilde{c}_1, \ldots, \tilde{c}_m]^T$ have error $\mathsf{Err}(\tilde{c}_i) \leq e$ for all $i \in [m]$, then each output ciphertext has error at most $O(w \cdot e)$. See the full version for further details.

5 Batch PIR

We will present three single-server PIR schemes using our compression techniques. We refer readers to Section 7.2 for our experimental evaluation to choose the best option for various settings of database size, entry size and batch size. We also present an improved two-server scheme.

5.1 Single-Server: Compressed Responses

In this section, we present our improved single-server batch PIR with compressed responses that apply for large entries that cannot leverage vectorization techniques [52].

Cuckoo Hashing Batch PIR Framework. In this section, we review the Cuckoo Hashing Batch PIR Framework by Angel *et al.* [14]. In a naive batch PIR scheme, the server would process each of the ℓ queries on the entire n database entries, resulting in a total of $O(n\ell)$ server operations. To reduce server computation, Angel *et al.* [14] presented a batch PIR framework that cleverly utilizes cuckoo hashing to encode both the batch query and the database entries. To date, this is the most practically efficient approach to constructing a batch PIR scheme. Our batch PIR will be built directly from this framework.

In this framework, the server setup works by creating $B \geq \ell$ independent single-query PIR servers and replicating each of the n database entries appropriately to a subset of $\alpha \geq 1$ servers. Consider a sparse database $D = \{(k_1, v_1), \ldots, (k_n, v_n)\} \in (\mathcal{K} \times \mathcal{V})^n$. Concretely, the choice of the α-subset is determined by the individual database entry (k_i, v_i) and α independent hash functions $H_1, \ldots, H_\alpha : \mathcal{K} \to [B]$ mapping keys to one of the B servers. In particular, (k_i, v_i) will be replicated to the servers indexed by $H_1(k_i), \ldots, H_\alpha(k_i)$. The total number of entries across all B servers will be $n\alpha$.

The hash functions that will be shared between the client and the server so that the client may also perform batch queries. Given a batch query $\{q_1, \ldots, q_\ell\}$, the client performs cuckoo hashing to map the ℓ query keys into the B buckets. In particular, each bucket will contain at most one query key after cuckoo hashing. Then, the client constructs a single-query PIR request for each of the B PIR servers. For empty buckets, the client will construct dummy "zero" requests such that the response to a dummy request will be a ciphertext that encrypts zero. Concretely, $B - \ell$ dummy requests. Finally, the server will process the B independent single-query PIR requests and send B responses back to the client.

Concrete Instantiation. Angel *et al.* [14] empirically determined that setting $B = 1.5\ell$ and $\alpha = 3$ results in an appropriate balance between the failure probability of the client allocation procedure, and efficiency. We notice that the request and response size in the cuckoo hashing framework is larger than

the naive approach. In the naive approach, the request and response size are merely ℓ ciphertexts whereas the framework requires 1.5ℓ ciphertexts. This is 50% larger than the number of responses in the naive approach.

Client Mapping or Keyword PIR. One subtlety of this framework is that each of the B independent single-query PIR servers consists of a sparse database. We note that this is true regardless of whether the original batch PIR problem consists of a dense database where $\mathcal{K} = [n]$ or a sparse database where $\mathcal{K}$ could be much larger. In earlier works (such as [14, 52]), it was suggested to use $O(n)$ client mappings to convert from database indices to bucket indices. Recent work [57] instead directly uses state-of-the-art keyword PIR schemes to avoid linear client storage. Throughout the rest of our work, we will follow this approach and use single-query keyword PIR protocols for each of the B buckets.

Keyword PIR Framework [57]. We provide a brief overview of the keyword PIR framework of [57] (used for each of the B buckets), paying special attention to those details relevant to our final batch PIR scheme.

- As in recent standard PIR schemes [13, 14, 51, 53], the framework represents the n-entry database as a $d_1 \times d_2 \times \cdots \times d_z$ hypercube, where $d_1 \cdots d_z \geq n$.
- The query algorithm for some key k creates z vectors of length $d_1, \ldots, d_z$, homomorphically encrypts them, then uploads them to the server.
- The server takes in an encoding $\mathbf{E}$ of the database, a two-dimensional matrix of size $d_1 \times \lceil n/d_1 \rceil$, and homomorphic encryptions of vectors $\mathbf{v}_1, \ldots, \mathbf{v}_z$. It first applies $\mathbf{v}_1$ to $\mathbf{E}$ to obtain a $\lceil n/d_1 \rceil$ vector, arranges this vector into a $d_2 \times \lceil n/(d_1 d_2) \rceil$ matrix and applies $\mathbf{v}_2$ to obtain a vector of size $\lceil n/(d_1 d_2) \rceil$, and repeats this for all z dimensions (where for the last dimension, the vector from the previous step will not be arranged into a matrix and instead, an inner product with $\mathbf{v}_z$ will be performed). At the end of this process, the server obtains a ciphertext encrypting the queried entry of the client.
- The server then sends this ciphertext to the client, who can decrypt it to obtain their queried entry.

Our Construction. To reduce communication in batch PIR, we will apply LSObvCompress to reduce the server response communication in the cuckoo hashing framework.

Namely, recall that for the $B - \ell$ buckets which do not have an associated key, the client will construct dummy "zero" requests such that the corresponding response ciphertext will encrypt zero. This can be done by setting, e.g., $\mathbf{v}_z$ to the zero-vector, since in the last step of the response algorithm, the server computes the inner product of $\mathbf{v}_z$ with some vector to obtain the final response ciphertext. Therefore, after the server processes the $B = 1.5\ell$ requests, it obtains $B = 1.5\ell$ responses of which ℓ consist of encrypted entries, and the rest are encrypted zeros. Thus, the server can apply the compression of LSObvCompress with $n = B$ and $t = \ell$ to obtain compressed ciphertexts. Of course, the client knows the indices of the ℓ real requests. As a result, the client can execute the decompression of LSObvCompress to obtain the requested entries.

Our construction therefore results in response size with overhead as small as $1.05\times$ the optimal, with minimal added computation, instead of the $1.5\times$ overhead in response size of [14].

Noise Growth. For noise growth, we will assume that the keyword PIR framework [57] is applied using recent PIR schemes from SHE composition [51, 53]. We perform the same noise analysis for prior PIR schemes in the full version and see that our new PIR scheme increases the noise growth by a $O(w)$ multiplicative factor.

5.2 Single-Server: Compressed Requests

Next, we apply LSObvDecompress to compress requests for single-server batch PIR schemes.

Our Construction. In our framework using the keyword PIR from [57], the client generates $B = 1.5\ell$ requests, each containing z vectors. However, we only need correct answers from ℓ requests. Thus, the client can combine all $B \cdot z$ request vectors into one long vector, and for relevant indices I consisting only of entries corresponding to the z vectors for each of the ℓ important requests, apply LSObvDecompress. This will result in a compressed request with size overhead only $1.05\times$ compared to the naive batch PIR, which the client can then encrypt and send to the server. This is in contrast to the $1.5\times$ overhead in request size of [14]. We also utilize in our construction the request packing techniques from [14] to fit multiple requests into a single ciphertext.

The server will first apply the request ciphertext packing decoding and, then run decompression from LSObvDecompress to obtain the B encrypted requests. Note, only the ℓ important requests will be correct. This is sufficient as the remaining 0.5ℓ dummy requests are ignored by the client anyways. The remainder of the server processing and client decrypting remains identical.

Noise Growth. We show that applying LSObvDecompress increases noise by an $O(w)$ multiplicative factor (see the full version for further details).

Why not both request and response compression? Theoretically, one can apply compression for both requests and responses simultaneously. In practice, the noise growth is $O(w^2)$ multiplicative factor (see the full version for the analysis) that is large. We were unable to find parameters where request and response compression beat either of the PIR schemes above. We leave it as an open problem to find better SHE/PIR schemes enabling both request and response compression. The full details of using both may be found in the full version.

5.3 Single-Server: Vectorized Responses

We present a method to compress responses in conjunction with the recent vectorization techniques of Mughees and Ren [52]. The vectorization techniques [52] utilize *Single-Instruction-Multiple-Data* (SIMD) techniques. SIMD encodes multiple database entries into a single ciphertexts (leveraging additional structure of the SHE scheme) and operates on all of them simultaneously.

Our Construction. The core idea of utilizing LSObvCompress to compress responses remains the same, but we wish to leverage that multiple entries fit into a single ciphertext. To do this, we present a vectorized version of LSObvCompress that optimally packs multiple entries into a single ciphertext. If d entries fit into a single ciphertext, our vectorized LSObvCompress sends only $\lceil 1.05\ell/d \rceil$ to the client. In contrast, $\lceil 1.5\ell/d \rceil$ ciphertexts are encoded in [52].

At a high level, vectorized LSObvCompress works nearly identically as the variant of LSObvCompress described in Section 3.3. The only difference is that we apply techniques from [52] to rotate ciphertexts and pack multiple entries into a ciphertext before performing compression. Due to lack of space, we defer the full description to the full version.

5.4 Two-Server: Compressed Responses

Next, we use LSObvCompress to compress responses for two-server batch PIR. In this setting, the client sends requests to both servers. Each server holds a copy of the database and cannot communicate with each other. They then send individual responses back to the client, who uses both to reconstruct the requested entry. The same correctness and privacy conditions are required. Privacy is considered with respect to each individual server assuming non-collusion.

Two-Server PIR. To date, the most concretely efficient two-server PIR schemes are built using distributed point functions (DPF) [19, 37, 40]. A point function $f_i : \mathcal{K} \to \{0,1\}$ satisfies $f_i(x) = 1$ if and only if $x = i$. DPFs enable secret sharing f_i amongst the two servers using two functions, f_i^0 and f_i^1, satisfying $f_i(x) = f_i^0(x) + f_i^1(x)$ for all $x \in \mathcal{K}$. Both f_i^0 and f_i^1 must not individually reveal anything about f_i.

To perform a two-server keyword PIR query for key k, the client uses DPFs to create secret shares of f_k, f_k^0 and f_k^1, that are sent to each of the two servers. Suppose the database consists of n key-value pairs, $D = \{(k_1, v_1), \ldots, (k_n, v_n)\}$. For each server $j \in \{0,1\}$, the j-th server computes

$$z_j = f_k^j(k_1) \cdot v_1 + \ldots + f_k^j(k_n) \cdot v_n.$$

Finally, the client receives z_0 and z_1 and computes the final answer $z_0 + z_1$. If $k = k_i$, then $z_0 + z_1 = v_i$. Otherwise, $z_0 + z_1 = 0$ when $k \notin \{k_1, \ldots, k_n\}$.

There is a small issue that the client cannot distinguish between $v_i = 0$ and $k \notin \{k_1, \ldots, k_n\}$. To fix this, we can ensure that zero is not a valid entry. For example, one can simply append a 1-bit to the end of each entry, $v_1, \ldots, v_n$.

Two-Server Batch PIR. To our knowledge, the most efficient two-server batch PIR remains the cuckoo hashing framework of Angel *et al* [14]. In the concrete instantiation, we use a two-server, single-query, keyword PIR for each of the $B = 1.5\ell$ buckets when performing a batch query for ℓ entries.

Our Construction. Our goal is to utilize LSObvCompress to reduce the number of responses from $B = 1.5\ell$ that are sent by both servers. We will use the two-server keyword PIR based on the DPF of [19]. Note that this PIR does not use encryption and, instead, relies on the non-collusion of the two servers for security. The encryption scheme $\mathcal{E}$ for LSObvCompress in this setting is additive secret sharing. Homomorphic additions will simply be addition operations by each server.

First, recall that in order to use LSObvCompress, the 0.5ℓ dummy requests must results in additive sharings (encryptions) of 0. We will add $(k_0, 0)$ is added to each of the B buckets for special key k_0. The client will issue a keyword PIR query for k_0 for each of the 0.5ℓ dummy buckets. The servers upon receipt of these requests for all B buckets will then compute the corresponding responses. Consider the i-th response z_i^0 and z_i^1 for both servers. Let $I' \subset [B]$ be the indices of the real, non-dummy requests. For all $i \in [B]$, $z_i = z_i^0 + z_i^1$ is the i-th requested entry. If $i \notin I'$, then $z_i = z_i^0 + z_i^1 = 0$.

We can thus apply LSObvCompress as follows. Both servers will use LSObvCompress to compress their responses $\mathbf{z}^0 = [z_1^0, \ldots, z_B^0]$ and $\mathbf{z}^1 = [z_1^1, \ldots, z_B^1]$. Recall that this is done by computing the matrix-vector multiplications $\hat{\mathbf{z}}^0 = \mathbf{M} \cdot \mathbf{z}^0$ and $\hat{\mathbf{z}}^1 = \mathbf{M} \cdot \mathbf{z}^1$ where $\mathbf{M}$ is the transpose of a random band matrix. The client will compute $\hat{\mathbf{z}} = \hat{\mathbf{z}}^0 + \hat{\mathbf{z}}^1 = \mathbf{M} \cdot (\mathbf{z}^0 + \mathbf{z}^1)$ that is a compression of the requested entries, $\mathbf{z}^0 + \mathbf{z}^1$. Finally, the client runs the decompression portion of LSObvCompress on $\hat{\mathbf{z}}$ to obtain the non-dummy queried entries, z_i for all $i \in I$.

6 Labeled PSI

In this section, we show our techniques may be used to build protocols for labeled PSI in the unbalanced setting. Recall that the receiver has a set X and the sender has a labeled set $\{(y, L_y) \mid y \in Y\}$. Note, that one may interpret this as batch keyword PIR with the receiver as the client and the sender as the server. The only difference is that PSI requires privacy for both party's input. Therefore, we need to also enable privacy for the sender (server) input. We present two improved constructions using our compression techniques.

Batch Keyword PIR and Oblivious PRF. We can use the generic transformation from [32] combining our single-server batch keyword PIR with any oblivious pseudorandom function (OPRF) to build our labeled PSI protocol. An OPRF allows the receiver to input set X and learn the set of pseudorandom outputs $\{F_k(x) \mid x \in X\}$, where F is a PRF, and k is known to the sender. For security, both the sender and receiver

should learn nothing else (beyond the size of $|X|$). Our scheme provides full security against a malicious receiver and privacy against a malicious sender, as in prior works [21, 25].

At a high level, the protocol goes as follows. First, the sender generates a private key k and evaluates the OPRF on its input set Y. The labels $\{L_y \mid y \in Y\}$ are encrypted using keys derived from the OPRF evaluation. The sender and receiver execute the OPRF protocol on the receiver's input and a sender's private key. Finally, the sender and receiver execute a batch PIR using the receiver's output of the OPRF protocol to retrieve the encrypted labels. Afterwards, the receiver may decrypts labels in the intersection. We point readers to the full version for more details and analysis.

As a side note, we point out that we must modify the keyword PIR construction from [57] slightly. In particular, the database encoding algorithm must have negligible failure to ensure database privacy. To do this, we can increase the band length parameter to ensure negligible encoding failures (using the analysis from [18]). See the full version for more details.

Improving Oblivious Polynomial Evaluation. Prior works [21, 22, 25] built labeled PSI using oblivious polynomial evaluation (OPE). We can apply LSObvDecompress to OPE protocols for reducing request sizes by 30%. Although, we note prior work [52] showed that batch PIR approaches result in more efficient labeled PSI protocols compared to OPE. Nevertheless, OPE is an interesting application of our compression algorithms. See the full version for more details.

7 Experimental Evaluation

We perform experimental evaluation for our new compression algorithms, LSObvDecompress and LSObvCompress, as well as their improvements to batch PIR and labeled PSI. Finally, we also benchmark our protocols for the real world application of anonymous messaging.

Experimental Setup. We implemented our experimental evaluations with around 3000 lines of C++ code. All our experiments are performed using Ubuntu PCs with 96 cores, 3.7 GHz Intel Xeon W-2135 and 128 GB of RAM with only single-threaded execution. The AVX2 and AVX-512 instruction sets with SIMD instructions are enabled. The results are the average of at least 10 experimental trials with standard deviation less than 10% of the averages. Our implementations will target error probability 2^{-40} and 128 bits of computational security. Server monetary costs are computed using Amazon EC2 savings plan pricing of t2.2xlarge instances [4] of \$0.09 per GB of traffic and \$0.021 per CPU hour at the time. We will utilize SHA256 as the hash function and AES-GCM-256 as the encryption scheme with 32 byte keys. Unless otherwise specified, we will use the compression parameter $\varepsilon = 0.05$ for our experiments.

Interpreting the Experimental Results. As our compression schemes are general schemes that can be instantiated on various protocols, they incur additional computational overhead compared to the ones that don't use our compression schemes. To assess concrete tradeoffs between the computational overhead and the communication reduction, we will use the Amazon EC2 server monetary cost model which measures the communication and computational efficiency as a dollar cost. We note that this model has been used in prior works [18, 57] for this exact purpose.

7.1 Oblivious Ciphertext Compression

We first evaluate the performance of LSObvCompress and LSObvDecompress in isolation and report results in Figure 4.

Setup. In our experiments, we will use Regev encryption [58] as the underlying scheme using the implementation from Spiral [9]. We fix the plaintext size to 8 KB and the ciphertext size to 20 KB. In the figure, t corresponds to the number of non-zero entries and n corresponds to the total number of entries including the zero entries. We fix the fraction of zero entries to $0.5t$ (thus $n = 1.5t$). Note that this corresponds to the fraction of dummy requests/responses in the cuckoo hashing framework from [14]. In our evaluations, we will target two compression sizes of $1.05t$ and $1.07t$. Note that this results in 30% and 29% request/response size reduction respectively.

Results. We see that computation time increases with better compression rate as well as larger t and n. However, we claim that our LSObvCompress and LSObvDecompress remain practically efficient for many applications; as we will show in the next sections, the additional computational cost is a relatively small fraction of the entire protocol's computation time, and the significant reduction in the communication cost will justify these small additional computational overhead.

7.2 Single-Server Batch PIR

We evaluate the single-server batch PIR schemes from Section 5 using our compression techniques to reduce communication. We report our results in Figure 5.

Setup. We implement our compression algorithms on top of the open-source Spiral implementation [9]. We use $n = 1$ million database entries for all of our results. Baseline corresponds to Angel *et al* [14]'s batch PIR framework implemented on top of Spiral [51] without our compression techniques. The parameters for the baseline were chosen using the script provided by their open-source implementation. In our evaluations, we consider three batch sizes $\ell \in \{512, 1024, 2048\}$ (in the context of ciphertext compression/decompression, the batch size ℓ corresponds to the number of non-zero entries). We follow the batch PIR setup from [14] and fix the fraction of dummy requests/responses (i.e. zero entries) to 0.5ℓ. We target compression size of 1.05ℓ.

Compression Size	Sizes & Schemes	Compression Time	Decompression Time	Total Time
1.05t	**t = 512, n = 768**			
	LSObvCompress	2.38 s	0.66 s	3.04 s

Figure 4: Evaluations of LSObvCompress and LSObvDecompress for different values of t (non-zero/relevant entries) and n (uncompressed input size). We fix the plaintext size to 8 KB and ciphertext size to 20 KB for all our results.

Results. Using our LSObvCompress, we see 30% response size reduction in exchange for a reasonable additional computational cost compared to state-of-the-art PIR for large entries without compression. We see that this small additional computation cost is justified by the reduction in the server monetary cost. In particular, LSObvCompress reduces the server monetary cost by up to 10% compared to the baseline.

Using our LSObvDecompress algorithm, we see 20-24% reduction in the request size with slight increase in computation and server monetary cost.

We were unable to integrate our vectorized version of LSObvCompress into the vectorized batch PIR protocol [52] as we are unaware of an open-source implementation. Nevertheless, we still implemented our vectorized version LSObvCompress from Section 5.3 using the SEAL library [59]. The results are presented in the full version.

Choosing the Right Protocol. In general, LSObvCompress provides the best communication and server monetary cost reduction. Thus, LSObvCompress will typically be the best option for most settings.

In certain settings, we note that LSObvDecompress may be useful where we wish to minimize upload communication from the client to the server. There are many natural settings where the upload costs/speed are more expensive/slower than the download costs/speed. For applications in these scenarios, it may be critical to save as much upload communication as possible that is achieved by LSObvDecompress.

Application: Anonymous Messaging. Angel and Setty [15] introduced Pung that built an anonymous messaging protocol using any single-server batch PIR (see the full version). In Figure 6, we report our results for retrieving 288-byte messages. We fix the number of database entries to $n = 1$ million and batch size to $b = 512$.

By using our improved batch PIR constructions, we obtain more communication-efficient versions of Pung. In particular, we see that LSObvCompress reduces the server monetary cost by 7% compared to the baseline.

7.3 Two-Server Batch PIR

We implement our response-compressed two-server batch PIR from Section 5.4 on top of the two-server single-query PIR implementation in [2]. We report our results in Figure 7.

Setup. We fix the number of database entries to $n = 1$ million where each database entry is 288 bytes large. As in the single-server batch PIR experiment (Section 7.2), we fix the fraction of dummy responses to 0.5ℓ and target compression size of 1.05ℓ. We omit evaluating request sizes as they are the same for both schemes.

Results. We observe that using LSObvCompress can reduce response size by 30% in exchange for a small additional computational cost. However, the small additional computational

Figure 7: Comparison of DPF based two server batch PIR protocol [2] with and without LSObvCompress ($\varepsilon = 0.05$). We fix the number of database entries to $n = 1$ million and each entry size to 288 B for all our results.

cost is justified by the savings in the server monetary cost. Compared to the baseline, LSObvCompress can reduce the server monetary cost by up to 24%.

7.4 Labeled PSI

Next, we evaluate our labeled PSI built from our batch PIR in Section 5.1 and an OPRF protocol (see the full version for details). We report our results in Figure 8.

Setup. Our implementation uses the single-server batch PIR implementation from Section 5.1 with the OPRF implementation from [1]. We fix the size of the sender's set to 1 million and receiver's set to 512 (note, in the context of batch PIR these corresponds to the number of database elements and the batch size respectively). We have used one of the default parameter sets available in their open-source implementations for Cong *et al* [25]'s scheme.

Results. Our scheme has 65-88% reduced communication over prior state-of-the-art works [25]. For smaller label size, our construction with Spiral [51] is slower, but we start to catch up and eventually outperform Cong *et al* [25] for larger label sizes. Note that even with these additional computation cost, we reduce the server monetary cost by 30-70%.

Due to the limitation of their open source implementation [1], we could not compare our construction on larger label sizes, but we expect our scheme to outperform significantly as the label sizes increase. In any case, our communication cost and server monetary cost is significantly smaller.

Label Size & Schemes	Total Online Comm.	Total Online Time	Server Monetary Cost
512 B			
Cong *et al.* [25]	33.2 MB	**169 s**	$0.00397
LSObvCompress	**11.4 MB**	304 s	**$0.00279**
1024 B			
Cong *et al.* [25]	66.1 MB	**331 s**	$0.00787
LSObvCompress	**11.6 MB**	355 s	**$0.00311**
1536 B			
Cong *et al.* [25]	103.6 MB	535 s	$0.01244
LSObvCompress	**11.9 MB**	**446 s**	**$0.00367**

Figure 8: Comparisons of Cong *et al.* [25]'s labeled PSI and our LSObvCompress-based PSI with $\varepsilon = 0.05$. We fix the size of the sender's set to 1 million and the receiver's set to 512.

8 Related Works

Ciphertext Compression. Variants of ciphertext compression have been studied in the past. Liu and Tromer [48] implicitly studied oblivious ciphertext compression without explicitly defining the primitive. In their scheme, they use sparse linear random codes that result in larger encodings and slower decoding time (see Figure 1), and, if instantiated with a FHE scheme, larger parameters for that scheme. Angel *et al.* [14] used packing and vectorization techniques to reduce request communication in PIR. Mughees and Ren [52] also showed vectorization techniques may be used to reduce response communication in batch PIR. Fleischhacker *et al.* [31] studied a more challenging variant of our setting where neither the decompressor (client) nor the compressor (server) know the identity of the the non-zero ciphertexts. As a result, their schemes have worse compression rate and more expensive compression and decompression algorithms. The same problem was implicitly studied in [23].

PIR. Single-server PIR was first studied by Kushilevitz and Ostrovsky [46]. Follow-up works constructed PIR from various other assumptions [20, 26, 35, 47, 55]. More recent works have studied concretely efficient protocols from lattice-based homomorphic encryption [11–15, 34, 50, 51, 53, 56, 57].

PIR has also been studied in the setting of multiple, non-colluding servers. A line of work has studied the communication efficiency with information-theoretic security (see [24, 29, 30] and references therein). Recent works have studied concretely efficient two-server PIR with computational security using distributed point functions [19, 37, 40].

Batch PIR. Batch PIR has been studied heavily in the past. Beimel *et al.* [17] presented a method to reduce server computation using matrix multiplication. Groth *et al.* [39] presented a communication-optimal scheme adapting the scheme in [35]. Another line of work (see [41, 43, 49, 60] and references therein) presented batch codes that transforms any single-query PIR into a batch PIR. More recent work [14, 15] introduced probabilistic batch codes that result in the most

concretely-efficient batch PIR schemes to date. Mughees and Ren [52] introduced vectorization techniques to reduce server responses for small database entries. Patel *et al.* [57] presented keyword PIR schemes that can remove the client mapping.

Labeled PSI. Labeled PSI is a variant where each identifier has an associated data label that should be retrieved. Labeled PSI is most often studied in the unbalanced setting where the receiver's set is much smaller than the sender's set. Many recent works [21, 22, 25, 27, 44] studied labeled PSI with sub-linear communication in the larger set. The same setting where the receiver only queries for a single item has been studied as symmetric PIR [13, 36].

9 Conclusions

In this work, we present state-of-the-art constructions for both batch PIR and labeled PSI with reduced communication costs compared to prior solutions. To do this, we identify a common task in both primitives that we denote as oblivious ciphertext compression where a compressor (server) is given n ciphertexts with only $t < n$ non-zero ciphertexts. The decompressor (client) knows the location of the t non-zero ciphertexts, but the compressor is unaware of this knowledge. We present LSObvCompress that enables compressions consisting of $1.05t$ ciphertexts that is only 5% larger than the minimum while requiring only additive homomorphism. Using LSObvCompress, we present batch PIR schemes with 30% smaller responses and labeled PSI protocols with 65-88% reduced communication and comparable computation.

A Random Band Matrix Analysis

In this section, we analyze the variant of random band matrices from Section 3.3 where each column is generated with a random w-bit band. As these are transposes of random band matrices, we know these variants will have unique solutions. It remains to show that the running time of these random band matrices runs in time $O(nw)$ similar to the original random band matrices from [28].

To do this, we show that each row will consist of exactly one continguous section of non-zero entries of length $O(w)$. We couple the process of generating random band matrices with random column vectors as two-dimensional balls-into-bins allocation (see [16] for more details). In particular, we model each of the t columns as t lists of w items. There exists $m = (1+\varepsilon)t$ entries corresponding to each of the m rows. Each of the t lists are assigned to a random entry from $[m-w+1]$. If the i-th list is assigned to entry $j \in [m-w+1]$, then one of the w items in the list are placed into each of the entries $\{j, j+1, \ldots, j+w-1\}$. Note, the maximum load of any of m entries is equivalent to the largest consecutive section of non-zero entries in any of the m rows of the generated random band matrix after sorting by column starting location.

Prior work [16] studied the setting where each of the t lists picked one of the m entries uniformly at random. We adapt the analysis for the slightly skewed distribution used for random band matrices in our work where only one of the first $m-w$ entries are chosen uniformly at random.

Proof of Theorem 1. We use the coupling described above. Therefore, it suffices for us to analyze only two-dimensional balls-into-bins allocations. We denote binary random variables $X_{i,j}$ to be whether the random band of the i-th column will overlap with the j-th row. Therefore, $X_{i,j} = 1$ if this event is true and $X_{i,j} = 0$ otherwise. Note, $X_{i,j} = 1$ if and only if the i-th column's random band starts in the set of row indices $\{j-w+1, j-w+2, \ldots, j\}$. In other words, $\mathsf{E}[X_{i,j} = 1] \leq w/(m-w+1)$. Let B_j be the total number of columns whose random bands overlap with the j-th row. By linearity of expectation, we get that

$$B_j = \sum_{i \in [t]} \mathsf{E}[X_{i,j}] \leq \frac{tw}{m-w+1}.$$

Note that each $X_{i,j}$ is an independent random variable. Therefore, we can apply Chernoff bounds to get that

$$\Pr\left[B_j > 3 \cdot \frac{tw}{m-w+1}\right] \leq 2^{-tw/(m-w+1)}.$$

Next, we apply a Union bound over all m rows to get that B_j for all $j \in [m]$ is upper bounded by the same value with probability at most $m \cdot 2^{-tw/(m-w+1)}$. Finally, by noting that $m = (1+\varepsilon)t$ for some constant $\varepsilon > 0$ and picking $w = O(\lambda + \log t)$, we get that each row has a band length of at most $O(w)$ except with probability $2^{-\lambda}$. □

Single Pass Client-Preprocessing Private Information Retrieval

Arthur Lazzaretti

Yale University

Abstract

Recently, many works have considered Private Information Retrieval (PIR) with client-preprocessing: In this model a client and a server jointly run a preprocessing phase, after which client queries run in time sublinear in the database size. However, the preprocessing phase is expensive—proportional to $\lambda \cdot N$, where λ is the security parameter (e.g., $\lambda = 128$).

In this paper we propose SinglePass, the first PIR protocol that is concretely optimal with respect to client-preprocessing, requiring exactly a *single* linear pass over the database. Our approach yields a preprocessing speedup ranging from $45\times$ to $100\times$ and a query speedup of up to $20\times$ when compared to previous state-of-the-art schemes (e.g., Checklist, USENIX SECURITY 2021), making preprocessing PIR more attractive for a myriad of use cases that are "session-based".

In addition to practical preprocessing, SinglePass features constant-time updates (additions/edits). Previously, the best known approach for handling updates in client-preprocessing PIR had complexity $O(\log N)$, while also adding a $\log N$ factor to the bandwidth. We implement our update algorithm and show concrete speedups of about $20\times$ over previous state-of-the-art updatable schemes (e.g., Checklist).

1 Introduction

Private Information Retrieval (PIR), as defined by Chor et al. [8] is a protocol between a client and a server where the server holds a public database DB of N bits and the client holds an index $i \in \{0,\ldots,N-1\}$. The goal of the protocol is for the client to learn $\mathsf{DB}[i]$ without revealing any information about i to the server. PIR has found many applications, such as in private contact tracing, oblivious ad serving, private movie streaming, among others [3, 4, 15, 17, 21]. A PIR protocol is non-trivial if its bandwidth is sublinear in N. For large N, it is desirable to also have $o(N)$ server computation. This was shown to be impossible by Beimel et al. [5] for a single query, posing a significant limitation for practical adoption.

Sublinear PIR through preprocessing. Due to the above limitation, Beimel et al. [5] defined a *server-preprocessing* PIR scheme, where the server runs a query-independent and client-independent preprocessing in the beginning of the protocol, after which it is possible to achieve $o(N)$ amortized server computation per query. However, all known protocols in this model are of theoretical nature due to large hidden constants (e.g., [5, 24]) or the use of trusted setup [7, 19].

In search for more practical schemes with sublinear server time, Corrigan-Gibbs and Kogan [9] recently introduced a slight modification of the above server-preprocessing PIR model: Here, the client and server *jointly* run a preprocessing phase, after which the client's queries run in $o(N)$ time. Interestingly, in this model the server does not store any additional information other than the database. Instead, the additional information used for future queries is stored client-side, allowing more efficient scaling to a large number of clients. We call this model the client-preprocessing PIR model. Client-preprocessing PIR has definitely brought PIR closer to practice, due to particularly fast online server times. For example, one of the fastest schemes, Checklist [21], can answer a PIR query on 3 million entries in less than a millisecond!

At a high level, Checklist (and all prior client-preprocessing PIR schemes [9, 21, 23, 30, 34]) works as follows (We assume here the two-server model where the database is replicated in two, non-colluding servers, Server 0 and Server 1.) During the *offline* phase, the client picks $\lambda \cdot \sqrt{N}$ independent random sets $S_1, S_2 \ldots,$. Each S_i is a subset of $\{0,\ldots,N-1\}$ and has size $\sqrt{N}$. These sets are sent to Server 0. Server 0 computes the parities/hints $p_1, p_2 \ldots,$ of these sets by setting

$$p_i = \bigoplus_{k \in S_i} \mathsf{DB}[k],$$

where DB is the public database. The hints are then sent to the client to be stored together with the sets S_i. During the *online* phase, on a query to some index x, the client finds a preprocesssed set S_i (and its corresponding parity p_i) such that S_i contains x, and sends $S_i \setminus \{x\}$ to Server 1.[1] The server

[1] Since Checklist sets do not have a fast membership testing mechanism,

Table 1: **SinglePass** compared to Checklist for PIR on updatable databases of N w-bit elements. $Q \in [N]$ is a parameter of our scheme.

Scheme	Preprocessing Time	Query Time	Query BW	Client Storage	Update Time
Checklist [21]	$O(\lambda \cdot N)$	$O(\sqrt{N})$	$O((\log N)(\lambda \log N + w))$	$O(N \log N + \lambda\sqrt{N} \cdot w)$	$O(\log N)$
SinglePass	$O(N)$	$O(Q)$	$O(Q \cdot w)$	$O(N \log N + (N/Q)w)$	$O(1)$

computes the parity p of $S_i \setminus \{x\}$ and sends p to the client. Then the client can retrieve $\mathsf{DB}[x]$ as $p \bigoplus p_i$. This basic outline can be extended to provide support for unlimited queries.

Limitation of client-preprocessing PIR schemes. The informal description above shows that the preprocessing phase of existing PIR schemes requires $\lambda\sqrt{N} \cdot \sqrt{N} = \lambda \cdot N$ database accesses. For $\lambda = 128$, preprocessing will have to access the entire database roughly 128 times before a single query can be issued! (The reason $\lambda\sqrt{N}$ sets are required is to ensure that one of these subsets contains any index with overwhelming probability.) For use cases where the database is dynamic, or the number of queries is small, such slow preprocessing can be hard to justify and leads to particularly slow implementations.

1.1 SinglePass

We propose SinglePass, the first client-preprocessing PIR scheme whose preprocessing is exactly one linear pass over the database, operating on each element exactly once— this is asymptotically optimal [5]. Using SinglePass, the first query requires a linear pass (namely the preprocessing) over the database. Subsequent queries run extremely fast, for the duration of a "session", after which we can potentially delete the state. In this way preprocessing becomes much more economical for applications that require a small amount of queries. In Table 1, we provide a table with the comparison between the asymptotics of SinglePass and Checklist. In addition, our SinglePass scheme also boasts of perfect correctness, and client storage size *independent* of λ.

Constant-time updates in SinglePass. SinglePass is the first protocol to support updates of the preprocessed client state in constant time. Previously, client-preprocessing schemes could only support edits and additions by using $O(\lambda\sqrt{N})$ time per update. Ma et al. [25] and Kogan et al. [21] studied different techniques to overcome this challenge, however both approaches incurred non-constant overhead per update. For example, [21] first maps the PIR scheme to keyword PIR and then uses a "waterfall technique" from hierarchical ORAM [14] to support edits and additions in $O(\log N)$ amortized time per operation, at the cost of an additional $\log N$ overhead in query bandwidth. Our new construction's technique allows us to naturally defineEdit and Add algorithms for our preprocessed client state that run in $O(1)$ time. This means that our scheme can not only improve PIR in the static "session-based" setting, but also greatly reduce server and client time for updates in the case where clients keep the preprocessed state in storage and wish to update it sporadically.

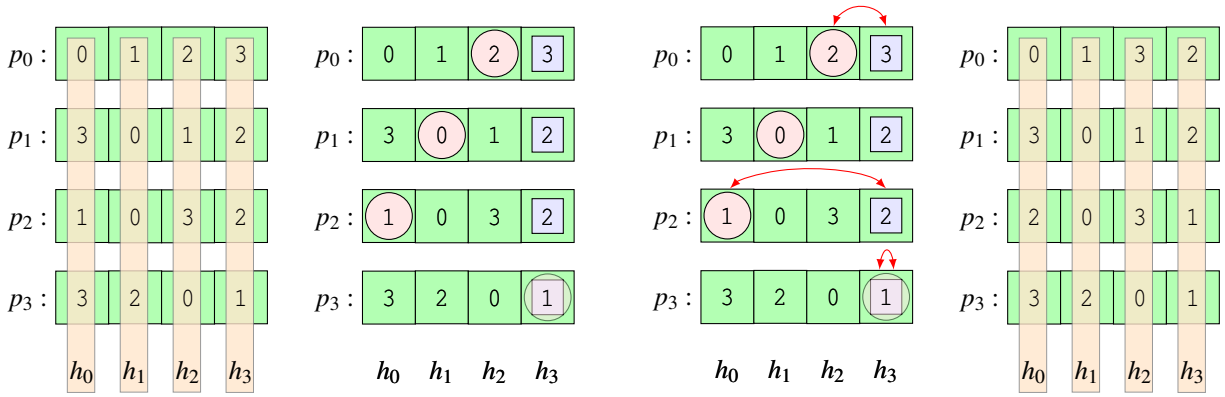
Evaluation. We implement SinglePass and show that it performs very well in comparison to previous schemes. In specific, we achieve preprocessing speeds ranging from 45-100x compared to all previous schemes, as well as a 10x speed up in query times when using comparable storage to other schemes, for the tests we benchmarked. Our scheme also provides, empirically, a speed up of approximately 20x in update time.

On linear client storage. Just like Checklist, SinglePass suffers from linear client storage. However, because there is no dependency on λ, SinglePass's client storage is only worse than the client storage of previous schemes [9, 21–23, 30] for N greater than one billion elements (This is for a word size of 1024 bytes.) In practice, databases with a size on the order of a million elements encompass a large array of PIR use cases, including private blocklists [21], metadata-hiding communication [2, 3], private movie streaming [15], private wikipedia [27], among others. This is the size of databases we focus on mainly in this work.

SinglePass working example. Below, we go through a short example of a preprocessing and query step of our scheme with visuals for intuition. Throughout the paper, we use

$$\alpha \xleftarrow{\$} \mathbb{S}$$

to indicate α being sampled uniformly at random from the set $\mathbb{S}$. For natural N, we use $[N]$ to denote the set $\{0, \ldots, N-1\}$ and $\mathcal{P}_N$ to denote the set of all permutations of $[N]$.



Let now $N = 16$ and $Q = 4$, where Q is a tunable parameter for the set size. Again, we work with two, non-colluding servers both storing DB. First, we organize DB as Q arrays of $N/Q = m$ elements. Let DB_i be the array $\mathsf{DB}[i \cdot m : (i+1) \cdot m]$.

We first describe how preprocessing works in SinglePass: Server 0 first samples a permutation p_i for each DB_i, $i \in [Q]$, where each p_i is a permutation of $[m]$. Then, for each $j \in [m]$, Server 0 computes $h_j = \bigoplus_{i \in [Q]} \mathsf{DB}_i[p_i(j)]$ and sends it to the client (along with the seed used to generate the permutations).

After the offline phase, the client state can be pictured as in Figure 1(a).

This picture shows what elements are contained in each hint given the permutations sampled by Server 0 were $p_0, \ldots, p_3$.

they instead keep a hashmap which maps indices to sets, which is processed offline, for faster queries. This incurs $O(N \log N)$ client storage.

(a) Initial state. (b) Chosen elements. (c) Swaps. (d) Final state.

Figure 1: Figures to aid our working example.

For example, $\mathsf{DB}_3[2]$ is contained in h_1 because $p_3(1) = 2$. Now, let us examine how we use this state to perform queries. Consider a query to $x = (1,2)$. First, we find position *ind* in p_1 such that $p_1(ind) = 2$. In this case, $ind = 3$. Notice that the hint h_3 contains $\mathsf{DB}[x] = \mathsf{DB}_1[2]$. After we find *ind*, we send the column that *ind* belongs to to Server 1, replacing $p_1(2)$ with a random element from $[N/Q]$. We also sample a random position $r_i \in [N/Q]$ for each p_i and send the array of $[p_i(r_i) : i \in [Q]]$ to Server 0. We name the arrays sent to Server 1 and Server 0 as S_{query} and S_{refresh}, respectively. The servers respond with A_b which is an array with all elements requested by the client (where the indices requested are of the form (i, j), where i is the position of the number if the array, and j is the number itself. This can be pictured in Figure 1(b).

The red circles represent $p_i(r_i)$ for $i \in [Q]$ and the blue squares represent $p_i(ind)$ for $i \in [Q]$. The client then builds S_{query} and S_{refresh}.

S_{query} :	3	~~2~~ $\to r$	2	1

S_{refresh} :	2	0	1	1

S_{query} will be sent to Server 1 as the elements needed to retrieve $\mathsf{DB}[x]$ using its hint (along with an additional random element) and S_{refresh} is sent to Server 0 in order for the client to be able to 'refresh' the client state back to a set of uniform permutations from Server 1's perspective. The client sends S_{query} and S_{refresh} to Server 1 and Server 0, respectively, and gets back A_1 and A_0.

A_1 :	$\mathsf{DB}_0[3]$	$\mathsf{DB}_1[r]$	$\mathsf{DB}_2[2]$	$\mathsf{DB}_3[1]$

A_0 :	$\mathsf{DB}_0[2]$	$\mathsf{DB}_1[0]$	$\mathsf{DB}_2[1]$	$\mathsf{DB}_3[1]$

The client has now enough information to both:

1. Recover $\mathsf{DB}_1[2]$ by simply taking the exclusive or of h_3 with every element in A_1 except $\mathsf{DB}[r]$.

2. Refresh the state by performing *swaps* between the elements sent to Server 0 and the elements sent to Server 1 for each permutation.

The purpose of (1) is clear, to retrieve the element of interest. The purpose of (2) is to *reset* the client state before the next query. For our example, the swapping depicted in Figure 1(c).

Since we have the value for each element on the permutation we wish to swap, we can update the hints accordingly by using exclusive or operations. Intuitively, these swaps make it so that each permutation is now completely unknown to the server again. If we can show that the first query is secure, and that after the swaps, each permutation is completely unknown to Server 1, then we can use induction to show that this scheme is secure for any number of queries. Looking ahead, we model and formally prove the statement on the swaps in Lemma 3.1. After the query, our new refreshed state can be seen in Figure 1(d).

Notice that no swap happened in p_1. This is simply because we don't show any information about p_1 to Server 1. After resetting its state, the client is ready to perform a new query.

We stress here also that although Server 0 sees the preprocessing, it only sees uniform random elements after that (since each r_i is picked independently from each other and from the query itself). Then, Server 0 also learns nothing from any sequence of queries. We formalize this intuition after introducing our full scheme.

2 PIR Preliminaries and Definitions

SinglePass works in the two-server model, where a database of N bits is replicated in two servers and at least one server

behaves honestly. SinglePass privacy holds for any adversary controlling either server and any number of clients, but does not capture an adversary controlling both servers. This can be realized in practice by having the servers be run by different parties. We now give the definition of client-preprocessing PIR (We use a slightly modified definition from the initial works on offline/online PIR [9, 21].)

Definition 2.1 (Client-Preprocessing PIR [21])**.** *A multi-query, 2-server client-preprocessing PIR scheme* Π *is a tuple of four polynomial-time algorithms:*

- *Hint*$(DB \in \{0,1\}^{N \cdot w}) \to (ck, h)$*:*
  A randomized algorithm that on input a database $DB \in (\{0,1\}^w)^N$ *outputs client keys* ck *and a client hint* h*.*
- *Query*$(ck, x) \to (ck', q_0, q_1)$*:*
  A randomized algorithm that on input ck *and index* $x \in [N]$ *outputs updated client keys* ck' *and queries* q_0, q_1*.*
- *Answer*$(DB, q_b) \to (A_b)$ *:*
  A deterministic algorithm that on input DB *a query* q_b *outputs an answer* A_b*.*
- *Reconstruct*$(ck, h, A_0, A_1) \to (h', y)$ *:*
  A deterministic algorithm that on input ck*,* h *and answers* A_b *outputs an updated hint* h' *and database value* y*.*

Using the above algorithms we can build a PIR protocol as follows. When a new client connects, Server 0 runs the Hint algorithm, and outputs the client keys and hint, which are returned to the client. After this, the client can use the client keys and query index x to output two queries, q_0 and q_1, each directed to Server 0 and Server 1 respectively. Notice that the client at this stage also updates its keys (in our context, the permutations). Each Server returns an answer A_b, which are then used by the client along with the hints to reconstruct $\mathsf{DB}[x]$, and update the hints for the next query.

Correctness. Correctness will model the fact that under a correct execution, the client should always retrieve the correct word $\{\mathsf{DB}[x_i]\}_{i \in t}$ for any sequence of t queries $x_1, \ldots x_t$ it desires to make. Correctness only needs to hold for honest servers, as opposed to privacy for which we will consider malicious servers. We given the formal definition below.

Definition 2.2 (Correctness)**.** *A multi-query 2-server client-preprocessing PIR* $\Pi = (Hint, Query, Answer, Reconstruct)$ *is* ***correct*** *if, for any* $\lambda, w, N, T \in \mathbb{N}$*, every* $DB \in (\{0,1\}^w)^N$ *and every* $x_0, \ldots, x_{T-1} \in [N]^T$*, the honest execution of the following game always outputs "1":*

- *Compute* $(h, ck) \leftarrow Hint(DB)$*.*
- *For* $t = 0, \ldots, T-1$*, compute:*
  - $(ck, q_0, q_1) \leftarrow Query(ck, x_t)$*.*
  - *For* $b \in \{0,1\}$*,* $A_b \leftarrow Answer(q_b)$*.*
  - $(h, y_t) \leftarrow Reconstruct(ck, h, A_0, A_1)$*.*
- ***If*** $\forall t \in [T]$*,* $y_t = DB[x_t]$*, output "1",* ***else*** *output "0".*

PrivGame^0 (Privacy for Server 0)	**PrivGame**^{1} (Privacy for Server 1)
• $b \xleftarrow{\$} \{0,1\}$.	• $b \xleftarrow{\$} \{0,1\}$.
• $(\mathsf{ck}, \_) \leftarrow \mathsf{Hint}(\mathsf{DB})$.	• $(\mathsf{ck}, \_) \leftarrow \mathsf{Hint}(\mathsf{DB})$.
• $\mathsf{st} \leftarrow \mathcal{A}(1^\lambda, \mathsf{ck})$.	• $\mathsf{st} \leftarrow \mathcal{A}(1^\lambda)$.
• For $t = \{0, \ldots, T-1\}$:	• For $t = \{0, \ldots, T-1\}$:
– $(\mathsf{st}, x_0, x_1) \leftarrow \mathcal{A}(\mathsf{st})$.	– $(\mathsf{st}, x_0, x_1) = \mathcal{A}(\mathsf{st})$.
– $(\mathsf{ck}, q_0, \_) \leftarrow \mathsf{Query}(\mathsf{ck}, x_b)$.	– $(\mathsf{ck}, \_, q_1) \leftarrow \mathsf{Query}(\mathsf{ck}, x_b)$.
– $\mathsf{st} \leftarrow \mathcal{A}(\mathsf{st}, q_0)$.	– $\mathsf{st} \leftarrow \mathcal{A}(\mathsf{st}, q_1)$.
• $b' \leftarrow \mathcal{A}(\mathsf{st})$.	• $b' \leftarrow \mathcal{A}(\mathsf{st})$.
• Output $b = b'$.	• Output $b = b'$.

Figure 2: Privacy games for PIR.

Privacy. Recall that Server 0 sees runs the preprocessing and sees q_0, for each queried index x. Also, Server 1 sees only q_1, for each query x, and does not run the preprocessing. Our privacy game models that under this behavior, no information is leaked to either server about x, even for a sequence of adaptively-chosed queries. Note that our assumption of no collusion allows us to prove that the information received by each server individually is independent from the issued queries issued—but there are no guarantees the joint view. We formalize this intuition in the definition below.

Definition 2.3 (Privacy)**.** *A multi-query 2-server client-preprocessing PIR* $\Pi = (Hint, Query, Answer, Reconstruct)$ *is* ***private*** *if, for security parameter* λ*, for all polynomially bounded* $N(\lambda), T(\lambda) \in \mathbb{N}$*, for any efficient stateful algorithm* $\mathcal{A}$*, for* $\sigma = \{0,1\}$

$$\Pr\left[PrivGame^{\sigma}_{\mathcal{A},\lambda,N,T} \to 1\right] \leq 1/2 + neg(\lambda),$$

where $PrivGame^0$ *and* $PrivGame^1$ *are defined in Figure 2.*

We reiterate that the definitions in this subsection are only slightly modified from the initial works on Offline/Online PIR [9, 21]. The modification is mainly with respect to including the word size w as part of the PIR definition. This helps us

better quantify the schemes' efficiency. The privacy of the scheme is computational, and the correctness is not.

A pseudorandom function can be used to produce a large number of pseudorandom outputs from a single truly random seed. In our construction, PRFs will be important for concrete efficiency, however, unlike previous schemes, they will not be necessary to argue security.

Sampling permutations. Our new PIR scheme relies heavily on permutations. Specifically, these permutations will be over "small" domains of at most a couple million elements. [2] Sampling pseudorandom permutations over small domains (for an adversary that can query the whole permutation) is a well-studied problem with a long line of work [18,26,28,29,31,32]. To date, we do not have representations of small domain permutations that are fast empirically and also succinct (like we have AES for larger domains). Therefore, in SinglePass we sample random permutations using the Fisher-Yates shuffle, also known as the Fisher-Yates-Durstenfeld-Knuth shuffle [10, 11, 20], which outputs an unbiased permutation over $[N]$ in $O(N)$ time, but requires storing the whole permutation explicitly after generating it to evaluate the permutation in sublinear time. We define this permutation in the following lemma.

Lemma 2.1 (Fisher-Yates Shuffle [10, 11, 20])**.** *For any positive integer N, there exists an algorithm Permute(N) that can output a permutation of the set $[N]$ sampled uniformly from the set of all permutations of $[N]$, $\mathcal{P}_N$, in $O(N)$ time.*

We can naturally define a computational version of the Fisher-Yates shuffle by using a PRG and a random seed to sample all the randomness used in the protocol—this is what we use in SinglePass. Using a seeded PRG allows us to concisely represent the permutation, but does not allow for point queries to the permutation in $o(N)$ time. Looking ahead, for our PIR scheme, we store the whole permutation at the client, since this storage turns out to be small in practice—however we still use the seed of the PRG to communicate the permutation to the server efficiently, i.e., without sending the whole permutation to the server.

3 Show and Shuffle Experiment

Before we present the SinglePass protocol in detail, we abstract a key concept necessary for SinglePass to work, through an experiment called *Show and Shuffle*—see Figure 3. The Show and Shuffle experiment captures the single-query security of SinglePass.

The experiment first samples L permutations $(P_1,\ldots,P_L)$ over $[K]$ uniformly. Then the adversary outputs a tuple $(\ell,k)\in[L]\times[K]$. The experiment then defines $j=P_\ell^{-1}(k)$, and outputs $(v_1,\ldots,v_L)$ where $v_i=P_i(j)$ **if** $i\neq\ell$ and v_j is chosen uniformly from $[K]$.

Show and Shuffle

Public Parameters: $L,K\in\mathbb{N}$.

Experiment:

1. Sample $(P_1,\ldots,P_L)\xleftarrow{\$}(\mathcal{P}_K)^L$.
2. Adversary $\mathcal{A}$ outputs $x=(\ell,k)\in[L]\times[K]$.
3. Find j such that $P_\ell(j)=k$.
4. Set $\mathbf{v}=(v_1,\ldots,v_L)$ such that for each $i\in[L]$:
   - $v_i=P_i(j)$ **if** $i\neq\ell$.
   - $v_i\xleftarrow{\$}[K]$ **if** $i=\ell$.
5. Let $b\xleftarrow{\$}\{0,1\}$.
6. **If** $b=0$: Output $\mathcal{R}_0=(F_1,\ldots,F_L)\xleftarrow{\$}(\mathcal{P}_K)^L$.
7. **Else:**
   - For each $i\in[L],i\neq\ell$, sample $r_i\xleftarrow{\$}[K]$, and let $P'_i=P_i$ except swapping $P_i(j)$ and $P_i(r_i)$.
   - Let $P'_\ell=P_\ell$, output $\mathcal{R}_1=(P'_1,\ldots,P'_L)$.
8. $\mathcal{A}(\ell,k,\mathbf{v},\mathcal{R}_b)\to b'\in\{0,1\}$.
9. Outputs 1 iff $b'=b$.

Figure 3: Show and Shuffle experiment.

Next the experiment flips a bit b, and either outputs a *swapped version* of $(P_1,\ldots,P_L)$ or freshly sampled permutations $(F_1,\ldots,F_L)$ dependent on b. To swap P_i into P'_i, the experiment samples a uniform r_i from $[K]$ and *swaps* the outputs of $P_i(j)$ and $P_i(r_i)$. We do not perform a swap for P_ℓ. Show and Shuffle models exactly one query of SinglePass, and will help us show that after each query, the resulting client hint is uniform. Looking ahead, to prove the security of SinglePass, we will apply the following Show and Shuffle Indistinguishability lemma (Lemma 3.1) T times.

Lemma 3.1 (Show and Shuffle Perfect Indistinguishability)**.** *For the Show and Shuffle game defined in Figure 3, denoted as SaS, for any adversary $\mathcal{A}$, for any $L,K\in\mathbb{N}$:*

$$\Pr\left[\mathsf{SaS}_{\mathcal{A},L,K}\to 1\right]=1/2.$$

[2] With "small", we refer to a domain of size on the order of 2^{20} as opposed to the AES permutation which has a domain size of 2^{128}.

Proof. It is

$$
\begin{aligned}
&\Pr[\mathsf{SaS}_{\mathcal{A},L,K} \to 1] \\
&= \frac{1}{2}\left(\Pr[\mathsf{SaS}_{\mathcal{A},L,K} \to 1 \mid b=1] + \Pr[\mathsf{SaS}_{\mathcal{A},L,K} \to 1 \mid b=0]\right) \\
&= \frac{1}{2}(\Pr[\mathcal{A}(\ell,k,\mathbf{v},\mathcal{R}_1) \to 1 \mid b=1] \\
&\qquad + \Pr[\mathcal{A}(\ell,k,\mathbf{v},\mathcal{R}_0) \to 0 \mid b=0]) \\
&= \frac{1}{2}(\Pr[\mathcal{A}(\ell,k,\mathbf{v},\mathcal{R}_1) \to 1 \mid b=1] \\
&\qquad + (1 - \Pr[\mathcal{A}(\ell,k,\mathbf{v},\mathcal{R}_0) \to 1 \mid b=0])) \\
&= \frac{1}{2} + \frac{1}{2}(\Pr[\mathcal{A}(\ell,k,\mathbf{v},\mathcal{R}_1) \to 1 \mid b=1] \\
&\qquad - \Pr[\mathcal{A}(\ell,k,\mathbf{v},\mathcal{R}_0) \to 1 \mid b=0]).
\end{aligned}
$$

To finish the proof it is enough to show that

$$Pr[\mathcal{A}(\ell,k,\mathbf{v},\mathcal{R}_1) \to 1 \mid b=1] = \Pr[\mathcal{A}(\ell,k,\mathbf{v},\mathcal{R}_0) \to 1 \mid b=0].$$

Note that in the above expression, the only difference in the adversary's view is $\mathcal{R}_b$. Therefore it is enough to show that the distributions of $\mathcal{R}_0$ and $\mathcal{R}_1$ are the same. Throughout, we implicitly condition on the other inputs the adversary has access to which are invariant in both schemes: $\ell, k, \mathbf{v}$.

Now, for any $p_1, \ldots, p_L$, where each p_i is a permutation of $[K]$, by construction of our experiment, it follows that

$$\Pr[(F_1, \ldots, F_L) = (p_1, \ldots, p_L)] = (1/K!)^L.$$

Then, it is enough to show that the same holds for set $\mathcal{R}_1$. Formally, we have to show that for any $p_1, \ldots, p_L$, where each p_i is a permutation of $[K]$ it is

$$\Pr[(P'_1, \ldots, P'_L) = (p_1, \ldots, p_L)] = (1/K!)^L.$$

First, notice the important fact that each P'_z for $z \neq \ell$ is only dependent on P'_ℓ and no other permutation. More formally, by construction, we have that

$$\Pr[P'_z = p_z | \{P'_i = p_i\}_{i \neq z}] = \Pr[P'_z = p_z \mid P'_\ell = p_\ell]. \quad (1)$$

This gives us that for each $P'_z, P'_y, z, y \neq \ell$, P'_z and P'_y are conditionally independent given P'_ℓ. Now, going back to our initial equation, we can decompose it as follows:

$$
\begin{aligned}
&\Pr[(P'_1, \ldots, P'_L) = (p_1, \ldots, p_L)] = \Pr[(P'_1, \ldots, P'_{\ell-1}, P'_{\ell+1}, \ldots, P_L) \\
&= (p_1, \ldots, p_{\ell-1}, p_{\ell+1}, \ldots, p_L) | P'_\ell = p_\ell] \cdot \Pr[P'_\ell = p_\ell] \\
&= \Pr[P'_\ell = p_\ell] \cdot \prod_{z \in [L], z \neq \ell} \Pr[P'_z = p_z \mid P'_\ell = p_\ell],
\end{aligned}
$$

where the first equality follows from a simple chain rule and the second equality follows because the set $\{P'_z\}_{z \neq \ell}$ is conditionally independent given P'_ℓ, from Equation (1).

Notice that the only element that affects P'_z out of P'_ℓ is $j = P'^{-1}_\ell(k)$, so we can condition only on j rather than the whole permutation. Now, for each $z \in [L], z \neq \ell$, pick any permutation of $[K]$, $p_z = [q_1, \ldots, q_K]$. We need to calculate $\Pr[P'_z = p_z \mid j]$. We consider two cases.

For the first case, when $q_j = v_z$ we have

$$\Pr[P'_z = p_z \mid j, q_j = v_z] \Pr[q_j = v_z] = \frac{\Pr[P_z = p_z \mid j, q_j = v_z]}{K} = \frac{1}{K!}.$$

The first equality holds since $\Pr[q_j = v_z] = \Pr[r_z = j] = 1/K$. The second equalily holds because since $r_z = j$ we did not perform any swaps and the rest of P_z (other than $P_z(j)$ which is fixed) is uniformly distributed by definition.

For the second case, when $q_s = v_z$ for some $s \neq j$ we have:

$$
\begin{aligned}
&\Pr[P'_z = p_z \mid j, q_s = v_z, P'_z(j) = q_j] \Pr[q_s = v_z, P'_z(j) = q_j] \\
&= \Pr[P'_z = p_z \mid j, q_s = v_z, P'_z(j) = q_j] \\
&\qquad \cdot \Pr[P'_z(j) = q_j | q_s = v_z] \Pr[q_s = v_z] \\
&= \frac{1}{K} \Pr[P'_z = [q_1, \ldots, q_K] \mid j, q_s = v_z, P'_z(j) = q_j] \\
&\qquad \cdot \Pr[P'_z(j) = x | q_s = v_z] \\
&= \frac{1}{K} \Pr[P_z = [q'_1, \ldots, q'_K] | j, q_s = v_z, P_z(s) = q'_s] \\
&\qquad \cdot \Pr[P_z(s) = q'_s | s \neq j] \\
&= \frac{1}{K}\left(\frac{1}{K-1}\right) \Pr[P_z = [q'_1, \ldots, q'_K] | j, q_z = v_z, P_z(s) = q'_s] \\
&= \frac{1}{K}\left(\frac{1}{K-1}\right)\left(\frac{1}{(K-2)!}\right) = \frac{1}{K!},
\end{aligned}
$$

where Lines 1 and 2 hold by just opening up the conditioning and Lines 2 and 3 hold because $\Pr[q_s = v_z] = \Pr[r_z = s] = 1/K$. Lines 3 and 4 hold by construction, if we redefine $q'_i = q_i$ for every $i \neq s$ and $i \neq j$, and let $q'_s = q_j$ and $q'_j = q_s$ (we are just inverting the swap on P'). Lines 4 and 5 hold because $P_z(s)$ cannot equal v_z conditioned on $s \neq j$, but is uniform among the rest of the elements. Finally, Lines 5 and 6 hold because when we fix $P_z(s)$ and $P_z(j)$, the rest of the elements are unchanged and uniform by definition of P_z. So, we have shown that for any $z \neq \ell$, $\Pr[P'_z = p_z \mid P'_\ell = p_\ell] = 1/K!$.

Plugging this back in to the equation we found before, we have that for any $p_1, \ldots, p_L$

$$
\begin{aligned}
&\Pr[(P'_1, \ldots, P'_L) = (p_1, \ldots, p_L)] \\
&= \left(\prod_{z \in [L], z \neq \ell} \Pr[P'_z = p_z \mid P'_\ell = p_\ell]\right) \Pr[P'_\ell = p_\ell] \\
&= \left(\prod_{z \in [L], z \neq \ell} \frac{1}{K!}\right) \Pr[P'_\ell = p_\ell] \\
&= \left(\frac{1}{K!}\right)^{L-1} \Pr[P'_\ell = p_\ell] = \left(\frac{1}{K!}\right)^L.
\end{aligned}
$$

Note that the last line just follows because $P'_\ell = P_\ell$ was sampled uniformly in the experiment. Then, tying back to the

beginning, we have

$$\Pr[\mathcal{A}(\ell,k,\mathbf{v},\mathcal{R}_1)\to 1\,|\,b=1]=\Pr[\mathcal{A}(\ell,k,\mathbf{v},\mathcal{R}_0)\to 1\,|\,b=0].$$

This proves our lemma. ■

4 The SinglePass Protocol

In this section, we first present the detailed algorithms of our SinglePass protocol—see Figure 4. Then, we present our main theorem (Theorem 4.1) and its proof. Our proof will be using the result we proved for the Show and Shuffle game—see Lemma 3.1.

We recall that in SinglePass, Server 0 is running Hint(DB), the client runs Query with its index and the keys output by the Hint algorithm and then sends q_0 to Server 0 and q_1 to Server 1. Then, each server runs Answer(DB, q_b), and returns the output to the client. Finally, the client runs Reconstruct to retrieve the answer at the queried index and update the hints. The privacy with respect to each server is modeled and explained in Section 2.

For the scheme, we assume that the client implicitly keeps track of x, ind, and $\{r_i\}_{i\in[Q]}$ in between Query and Reconstruct. The following theorem states our main result.

Theorem 4.1 (Single Pass Client-Preprocessing PIR)**.** *The scheme in Figure 4 is a client-preprocessing Private Information Retrieval scheme as defined in Definition 2.1, with parameters $N,Q,w\in\mathbb{N}$, where $Q|N$, where N is the database size, Q is the query size, and w is the word size, satisifes Correctness and Privacy according to Definitions 2.2 and 2.3 respectively, and has the following complexities:*

- *Hint(q_h, DB) runs in $O(N\cdot w)$ time and outputs a hint of size $(N/Q)\cdot w$ bits.*
- *Query(ck,x) runs in $O(Q)$ time.*
- *Answer(DB,q_b) runs in $O(Q\cdot w)$ time.*
- *Reconstruct(ck,h,A_0,A_1) runs in $O(Q\cdot w)$ time.*
- *The client stores state of $O(N\log N+(N/Q)\cdot w)$ bits.*
- *The server stores only DB.*

We prove Theorem 4.1 in the Appendix A. The crux of our proof is the Show and Shuffle experiment (Figure 3). We define a sequence of hybrids between our experiment and an idealized experiment, and can show each pair of this sequence to be indistinguishable by using Lemma 3.1.

SinglePass

Public Parameters: Let $Q,N\in\mathbb{N}$ such that $Q|N$. Let $m\in\mathbb{N}=N/Q$. Let DB be an array of N elements of size w. For $i\in[Q]$, let $\mathsf{DB}_i=\mathsf{DB}[i\cdot m:(i+1)m]$.

Hint(DB):

1. For $i\in[Q]$, $p_i\xleftarrow{\$}\mathsf{Permute}(N/Q)$.
2. Compute hints $h_0,\ldots,h_{m-1}$, where for $j\in[m]$:
$$h_j=\bigoplus_{i=0}^{Q-1}\mathsf{DB}_i[p_i(j)].$$
3. Output $h=\{h_j\}_{j\in[m]}$, $ck=\{p_i\}_{i\in[Q]}$.

Query(ck, $x=(i^*,j^*)\in[Q]\times[m]$):

1. Parse $x=(i^*,j^*)$. Find $ind\in[m]$ s.t. $p_{i^*}(ind)=j^*$.
2. Let $S=[p_j(ind):j\in[Q]]$. Set $S[i^*]=r^*\xleftarrow{\$}[m]$.
3. Sample $r_0,\ldots,r_{Q-1}$ independently and uniformly from $[N/Q]$.
4. Let $S_{\text{refresh}}=[p_i(r_i):i\in[Q]]$.
5. For $i\in[Q],i\neq i^*$, swap $p_i(ind)$ and $p_i(r_i)$.
6. Output ck, $q_0=S_{\text{refresh}}$, $q_1=S_{\text{query}}$.

Answer(DB, q_b):

1. Return $A_b=[\mathsf{DB}_i[q_b[i]]:i\in[Q]]$.

Reconstruct(ck, h,A_0,A_1):

1. Let $DB[x]=\mathsf{DB}_{i^*}[j^*]=\left(\bigoplus_{i\in[Q],i\neq i^*}A_1[i]\right)\oplus h_{ind}$.
2. For each $i\in[Q],i\neq i^*$, update:
$$h_{ind}=h_{ind}\oplus A_0[i]\oplus A_1[i].$$
$$h_{r_i}=h_{r_i}\oplus A_0[i]\oplus A_1[i].$$
3. Output $\mathsf{DB}[x]$, ck, h.

Figure 4: SinglePass algorithms.

5 SinglePass Evaluation

In this section, we present the evaluation of SinglePass. SinglePass is implemented in about 300 lines of Go code and 150 lines of C code, as an extension to the existing PIR frame-

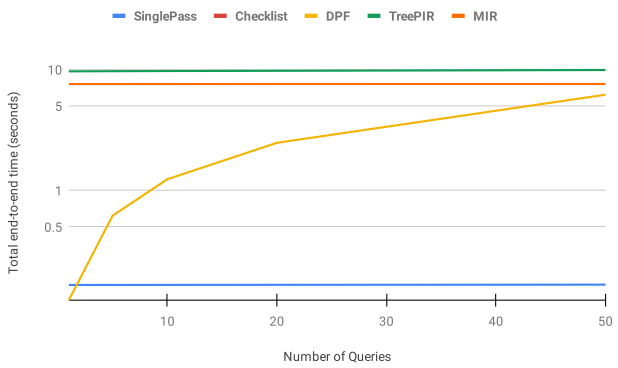


Figure 5: Comparison of end-to-end time for varying number of queries over a database of one million 512-byte elements (log scale).

work from Checklist [21]. Our code can be found in [1]. We compare SinglePass against Checklist [21], TreePIR [23] and MIR [30], three novel state-of-the-art client preprocessing PIR schemes, for a variety of parameters. Benchmarks are all run on an AWS EC2 instance of size t2.2xlarge, on a single thread. We recall that previous works have dependency on the security parameter for preprocessing and client storage.[3]

Here, along with the state-of-the-art client-preprocessing schemes, we also include comparisons against the state-of-the-art two-server PIR scheme with no preprocessing from [6, 12, 16], which we will denote as DPF.

The choice of parameters picked throughout the section reflect a sample use case of a private encyclopedia service, where a user would browse a private encyclopedia website, access a couple of articles privately, and afterwards leave and delete the local state. In this scenario, fast preprocessing is crucial so that the user does not have to wait too long to access the website. In our evaluations we include two sets of benchmarks.

First, we measure end-to-end time of SinglePass compared to end-to-end time of Checklist, TreePIR, MIR and DPF for a database of one million 512-byte elements. This is shown in Figure 5. (The line of TreePIR is hidden underneath the line for Checklist.) From various database sizes and entry sizes we found for encyclopedias online (up to two million entries of size 512 to 2048 bytes) we arbitrarily picked this one to be representative. We however note that the trend seen in Figure 5 holds across any set of parameters. This is because of the asymptotic improvement of a factor of λ in preprocessing time. Results show that whereas other schemes start beating DPF after 50+ queries, the total end-to-end time of SinglePass is already better even when performing two queries.

[3] In fact, because of this, as aforementioned in Section 1, even for a databases of 1 billion 1024 byte elements, our scheme concretely achieves less client storage than some of these scalable schemes, despite its worst asymptotics, for the same Q [23, 30, 34].

Second, in Figure 6, we provide a more fine-grained comparison of preprocessing time, per-query time, and bandwidth between SinglePass, Checklist,TreePIR and MIR, through the whole range of parameters mentioned above (We do not include DPF since it does not have preprocessing.) The parameter choices reflect our envisioned use case of a private encyclopedia service. For these tests, we *normalize the tests by client storage.* By this, we mean that we run the tests for MIR,TreePIR and Checklist, and subsequently run SinglePass picking the smallest Q such that our client storage does not exceed the storage of the previous schemes—therefore we can benchmark the performance of the schemes when given similar client resources. In this scenario we observe that SinglePass provides very favorable trade-offs in preprocessing time and query time, at a modest bandwidth cost with respect to MIR and Checklist. In Appendix B, we also include tests normalized by query time. In those tests, all schemes have very similar query times, and the other metrics vary. We discuss this further in Appendix B.

6 Extending SinglePass to Dynamic Databases

In this section we study how to slightly modify SinglePass to support updates in the database. In particular we wish to support edits, additions and deletions. Recall that SinglePass's hint consists only of a single (partitioned) permutation of the database. Therefore we can direclty update the hint data structure in $O(1)$ time, without any other additional overhead. Below, we give some intuition of how our updates work, and subsequently provide formal algorithms.

Edits/Deletions. To edit the value of index $x = (i, j) \in [Q] \times [N/Q]$, we compute $k = p_i^{-1}(j)$ and this indicates which hint contains x, h_k. Then, given the original preprocessed value at index x, denoted $\mathsf{DB}[x]_{old}$, and the new value at x, denoted $\mathsf{DB}[x]_{new}$, the client can updates the hint by simply setting $h_k = h_k \oplus \mathsf{DB}[x]_{old} \oplus DB[x]_{new}$, after computing k. Since all these steps take constant time, editing takes constant time. We also define a deletion to be an edit where $\mathsf{DB}[x]_{new}$ equals 0 (or a special delete value).

Additions. We can support additions in the end of the array in two steps. We first sample a new permutation p_Q, and then let $k = p_Q^{-1}(N)$. We let $h_k = \mathsf{DB}[N]$. Note that we only have to sample the permutation once for every N/Q additions, and sampling the permutation takes $O(N/Q)$ time. Every subsequent addition takes $O(1)$ time, since we just compute the exclusive or of this element and the appropriate hint (which we find by checking the inverse), giving us constant amortized time for addition. This can be deamortized by sampling a constant part of the permutation at each step.

The attentive reader will notice that the addition operation introduces a new permutation, and therefore a new element being sent on each query which may be out of bounds for the current database. The server can just choose to ignore indices

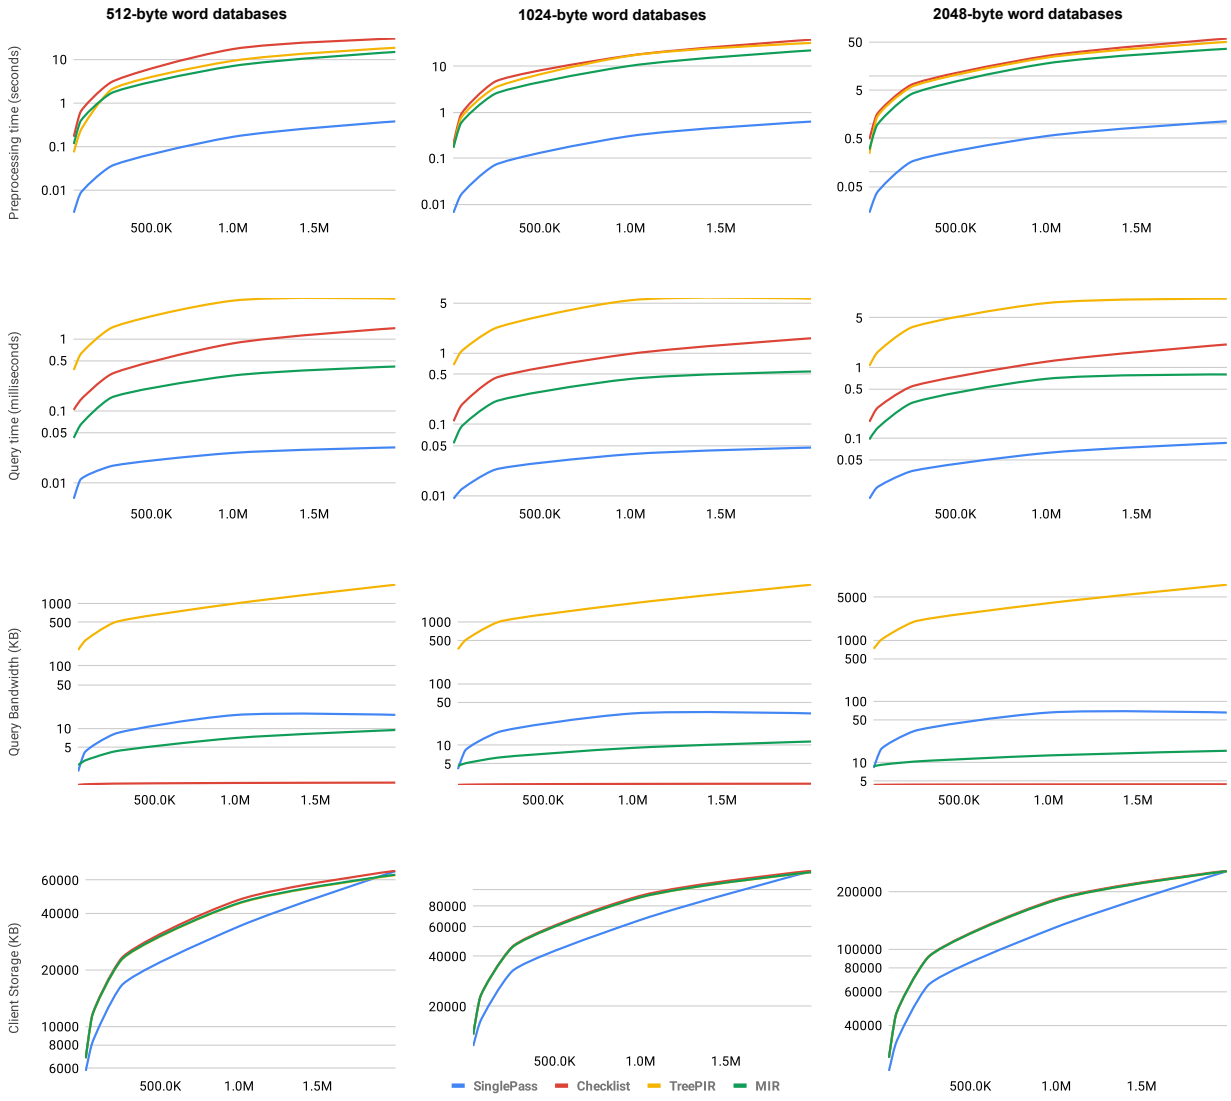

Figure 6: Comparison of benchmarking over preprocessing time, query time, bandwidth and client storageover increasingly sized static databases (x-axis) for different element sizes (on a log scale).

out of bounds. Furthermore, every N/Q additions increase the bandwidth by an additive factor of $2w$, by increasing our value of Q to be $Q+1$. After N additions, this means that our new bandwidth will be $2Q$ rather than our initially selected Q. After N additions, one can re-run the preprocessing step to again tune Q to a desired value while maintaining a constant update cost (since this is performed only every N updates). This step can also be de-amortized by running a constant amount of steps at each update. We give the full pseudocode for Edit and Add in Figure 7.

Previous work on dynamic PIR. Previous works in preprocessing PIR do not handle updates naturally in constant time. At a high level, this is because their preprocessing step involves sampling around $\lambda\sqrt{N}$ independent subsets of $[N]$. Updates then require checking each subset. To address this, previous works such as Checklist [21] and TreePIR [23] borrowed techniques from hierarchical ORAM [13] that support amortized $O(\log N)$ time updates by incurring overheads in both query time and client storage (this approach is also known as a *waterfall update* approach). The transformation from a static preprocessing PIR scheme into an updatable one in this manner requires two steps, a transformation from standard PIR to *keyword* PIR with indices as the keys [8] and a blackbox application of this waterfall preprocessing data structure approach to this keyword PIR. We cannot apply the waterfall approach directly to standard PIR since it involves storing a logarithmic number of databases of exponentially-increasing size , and as such we need a way to maintain the original indices.[4] Each of these steps adds some bandwidth overhead, communication, client and server time. Other approaches have been studied [25] but also incur significant overheads in comparison to the static preprocessing scheme.

Evaluation for dynamic databases. We implement the update algorithms for SinglePass in an additional 200 lines of Go code and 50 lines of C code. We run a complete test suite in Figure 8, with the same parameters as we picked in Section 5. All other dymamic schemes that we use in our comparison use the waterfall update approach as we discussed before. Unlike in Section 5, we do not include the DPF scheme in our benchmarks, since these use cases assume the client will run the preprocessing only once, or at least not very often. This could reflect a mobile app for the private encyclopedia service envisioned in Section 5, where it is fine to use some permanent storage. In this scenario, minimizing update times is crucial so as to impose as small as a burden as possible on the servers.

In Figure 8, we show the update time for a batch of 500 updates. Notice that while Checklist's update time scales logarithmically with the database size, the update time for SinglePass remains basically the same across all database sizes. Preprocessing time, query time and query bandwidth, follow mostly the same patterns identified in Section 5, with an

[4]The full approach is discussed in detail in the Checklist paper [21].

Edit$(\mathsf{ck}, h, i, \mathsf{DB}[i]_{old}, \mathsf{DB}[i]_{new})$:

1. Compute i_0, i_1 such that $i = (\lceil N/Q \rceil) i_0 + i_1$.
2. Let $k = p_{i_0}^{-1}(i_1)$.
3. Let $h_k = h_k \oplus \mathsf{DB}[i]_{old} \oplus \mathsf{DB}[i]_{new}$.

Add(ck, h, w):

1. Let $j = N \mod (N/Q)$.
2. If $j = 0$:
   (a) Sample $p_Q = \mathsf{Permute}([N/Q])$.
   (b) Let $Q = Q+1$.
3. Let $k = p_{Q-1}^{-1}(j)$.
4. Let $h_k = h_k \oplus w$.
5. Let $N = N+1$.

Figure 7: Update Operations for SinglePass.

improvement in the comparative bandwidth for SinglePass, because of the overhead incurred when mapping Checklist to its updatable version. For databases of up to 1 million elements, we notice that SinglePass has bandwidth which is at most 1.5× Checklist's bandwidth, while maintaining a query time reduction of roughly 20× on average across all experiments and a preprocessing time speed-up of up to 100×. As in Section 5, we pick Q for SinglePass accordingly, in order to benchmark both SinglePass and Checklist using comparable client storage. We include tests that fix query time in Appendix B.

In Table 2, we also provide a benchmark of SinglePass and Checklist for the blocklist application studied in Checklist, with the parameters picked in the original Checklist paper: a database of 3 million 32-byte elements that is updated in batches of 500. Our scheme achieves over 100× speed-up in preprocessing, over 47× speed-up in query time, an approximate 2× saving in bandwidth and a 19× faster update time. The saving stems primarily from not requiring a dependency on the security parameter for the preprocessing and storage. Because our client storage for using the same set size as Checklist is much smaller, we can tune Q such as to use about the same storage. For the scenario benchmarked in Table 2, this amounts to a set size of $Q = 10$. This is how the

λ saving in client storage and preprocessing can translate into improved query time. The update time discrepancy of about $20\times$ is due to the $O(\log N)$ additional overhead. [5]

[5] One caveat of the comparison is it is necessary for the updatable version of Checklist to support keyword queries in order to achieve the $O(\log N)$ amortized bandwidth. SinglePass is a pure PIR scheme that only supports index queries. However, using cuckoo hashing we can derive a keyword PIR scheme with a $2\times$ overhead [33].

A Proof of Main Theorem

In this section, we prove Theorem 4.1

Proof. Complexities: For Hint, by Lemma 2.1, we can sample the permutations needed in $O(N)$ time, and then use random access to compute the hints in $O(N \cdot w)$ time. Query to $x = (i^*, j^*)$ has to find the index ind such that $p_{i^*}(ind) = j^*$. Notice that given the expanded format of each permutation and its inverse, this can be done in $O(1)$ time, by simply taking $p_{i^*}^{-1}(j^*)$.[6] After, we just have to index $p_i(ind)$ for $i \in [Q]$ which takes $O(Q)$ time, and send that to the server (with a symmetric number of operations to generate the refresh hint).

[6] We can store the inverse along with the permutation with constant overhead. In practice, for some scenarios, it might be beneficial to not store the inverse in order to save space. In those cases, the client time would be $O(Q+N/Q)$. This is the only place where the inverse is used for that static scheme. For the updatable scheme, we require the inverse to get $O(1)$ update operations.

Answer only reads the array of size Q and accesses each element indexed by the array. Assuming random access costs constant time, this also runs in $O(Q)$ time. Finally, Reconstruct does $O(Q)$ operations to update the hint parities of the elements used (from the above complexities, only $O(Q)$ elements are sent/received on each query. The client storage is the hint it receives from Hint (and whatever refresh operations done on it, which don't increase its size) plus the expanded client keys (N indices of $[N]$, therefore, $N \log N$ space). Alternatively, the client can store only the seed used for the permutations and expand them at query time, but by Lemma 2.1 this would then require Query to run in $O(N)$ time.

Correctness: Follows by construction (we reiterate correctness is modeled for honest servers only).

Note that after a correct preprocessing, Server 0 sends back to the client $(ck, h) = (\{p_i\}_{i\in Q}, \{h_j\}_{j\in\lfloor N/Q \rfloor}$ where each p_i is a pseudorandom permutation of $[1, \lfloor N/Q \rfloor]$ and each $h_j = \bigoplus_{i\in Q} \mathsf{DB}[p_i(j)]$.

Then, for a query to $x = (i^*, j^*)$, first define *ind* to be the element of $[N/Q]$ such that $p_{i^*}(ind) = j^*$. If Server 1 responds to q_1 honestly, then it is clear to see that the client's output for the query is $\left(\bigoplus_{i\in Q, i\neq i^*} \mathsf{DB}_i[p_i(ind)]\right) \oplus h_{ind} = \mathsf{DB}_{i^*}[p_{i^*}(ind)] = \mathsf{DB}_{i^*}[j^*] = \mathsf{DB}[x]$.

For a subsequent query, what is left to show is that for every following query, for every $j \in [N/Q]$, $h_j = \bigoplus_{i\in[Q]} \mathsf{DB}_i[p_i(j)]$ after the swaps. Notice that for each swap between $p_i(k)$ and $p_i(v)$, we let $h_k = h_k \oplus \mathsf{DB}_i[p_i(k)] \oplus \mathsf{DB}_i[p_i(v)]$ therefore effectively removing the old element in this hint's position from the xor and adding the new one (this happens symmetrically on h_v). Then, at the beginning of the next query, each hint h_j is still equal to $\bigoplus_{i\in[Q]} \mathsf{DB}_i[p_i(j)]$. Then, by our argument for the first query, correctness holds as well (and holds for any T).

Privacy: We consider the privacy of each server separately according to the games defined in Figure 2.

Server 0: To show privacy for Server 0 for any $\lambda \in \mathbb{N}$ and any $N(\lambda), T(\lambda)$, for any PPT adversary $\mathcal{A}(\lambda)$,

$$\Pr\left[\mathsf{PrivGame}^0_{\mathcal{A},\lambda,N,T} \to 1\right] \leq 1/2 + \mathsf{neg}(\lambda).$$

Note that in **PrivGame**^{0}, which models the view of Server 0, Server 0 has access to both the client keys, and then for each query $t \in T$, it gets access to the corresponding q_0 for that query, which we will denote here as q_0^t.

Notice that as long as each p_i is bijection from $[N/Q]$ to $[N/Q]$, then each $p_i(r_i)$ is uniform and independent of the query being made, since by definition each r_i is uniform and independent of the query being made. Since for every step, the new swapped p_i is still a bijection, then this holds for any timestep t. So each q_0 is a set of elements in $[N/Q]$ independent of the query being made. Then, since each step q_0 is independent of the query being made, it follows that for any pair x_0, x_1, even conditioned on seeing the preprocessing, an adversary acting as Server 0 cannot distinguish between $b = 0$ and $b = 1$ on the **PrivGame**^{0} experiment. If we use pseudorandomness output by a PRG with security parameter λ rather than true randomness to sample each r_i, we incure a negligible probability of distinguishing, directly from the PRG security definition. Finally, we get that,

$$\Pr\left[\mathsf{PrivGame}^0_{\mathcal{A},\lambda,N,T} \to 1\right] \leq 1/2 + \mathsf{neg}(\lambda).$$

Server 1: To show privacy for Server 1 for any $\lambda \in \mathbb{N}$ and any $N(\lambda), T(\lambda)$, for any PPT adversary $\mathcal{A}(\lambda)$,

$$\Pr\left[\mathsf{PrivGame}^1_{\mathcal{A},\lambda,N,T} \to 1\right] \leq 1/2 + \mathsf{neg}(\lambda).$$

Notice that here, the adversary acting as Server 1 does not get access to the preprocessing (since it is run by Server 0), but it does see q_1 for every timestep $t \in T$.

Here, we use Theorem A.1. Note that Experiment 1 in Theorem A.1 is exactly equivalent to our PIR query at each timestep. Then, by Theorem A.1, we can replace each q_1 shown to Server 1 by uniform random elements of $[N/Q]$. This implies that for any x_0, x_1 picked by the adversary as inputs from **PrivGame**^{1}, the outputs at each timestep will be identically distributed and indistinguishable when using true randomness. Then, we can replace the randomness used by pseudorandomness sampled through a PRG with security parameter λ (which is what we do in our scheme), and it follows by the PRG security that this would be computationally indisinguishable from before. Then, it follows that:

$$\Pr\left[\mathsf{PrivGame}^1_{\mathcal{A},\lambda,N,T} \to 1\right] \leq 1/2 + \mathsf{neg}(\lambda).$$

■

A.1 Server 1 Indistinguishability

Theorem A.1 (Query indistinguishability)**.** *For any adaptive adversary $\mathcal{A}$, Experiment* 0 *and Experiment* 1*, as defined in Figure 9, are perfectly indistinguishable.*

Proof. We prove this through a series of hybrid experiments. Note that at each step t, the adversary can pick inputs and then see the outputs for that step before deciding its inputs for the next step. We start from H_0, in which at each step, rather than simply sampling uniformly as in Experiment 0, the experiment samples Q independent permutations of $[N/Q]$ uniformly. and behaves by using the adversary inputs to index these permutations. Since they permutations are uniformly and independently sampled, these are indistinguishable. We expand on this below.

Experiment 0

Public Parameters: $N, Q \in \mathbb{N}$, assume $Q|N$.

Experiment:

1. **For** $t \in \{0, \ldots T-1\}$:
   (a) Adversary outputs $x^t = (i^t, j^t) \in ([Q] \times [N/Q])$.
   (b) Output $(y_1^t, \ldots, y_Q^t) \xleftarrow{\$} [N/Q]^Q$.

Experiment 1

Public Parameters: $N, Q \in \mathbb{N}$, assume $Q|N$.

Experiment:

1. Sample $P_1^1, \ldots P_Q^1 \xleftarrow{\$} (\mathcal{P}_{N/Q})^Q$.
2. **For** $t \in \{0, \ldots, T-1\}$:
   (a) Adversary outputs $x^t = (i^t, j^t) \in ([Q] \times [N/Q])$.
   (b) Find *ind* s.t. $P_{i^t}^t(ind) = j^t$.
   (c) Output $S = (v_1^t, \ldots, v_Q^t)$ where:
   - $v_i^t = P_i^t(ind)$ **if** $i \neq i^t$.
   - $v_i^t \xleftarrow{\$} [N/Q]$ **if** $i = i^t$.

   (d) Let $\{r_i\}_{i \in Q} \xleftarrow{\$} [N]^Q$.
   (e) For $i \in Q$, let $P_i^{t+1} = P_i^t$ except we swap the values of $P_i^t(r_i)$ and $P_i^t(ind)$ for $i \neq i^t$.

Figure 9: Experiments

Experiment H_0

Public Parameters: $N, Q \in \mathbb{N}$, assume $Q|N$.

Experiment:

1. **For** $t \in \{0, \ldots T-1\}$:
   (a) Sample $(P_1^t, \ldots, P_Q^t) \xleftarrow{\$} (\mathcal{P}_N)^Q$.
   (b) Adversary outputs $x^t = (i^t, j^t) \in ([Q] \times [N/Q])$.
   (c) Find *ind* such that $P_{i^t}^t(ind) = j^t$.
   (d) Output $(v_1^t, \ldots, v_Q^t)$ where:

Experiment H_0 **(cont)**

- $v_i^t = P_i^t(ind)$ **if** $i \neq i^t$.
- $v_i^t \xleftarrow{\$} [N/Q]$ **if** $i = i^t$.

Experiment 0 and Experiment H_0 are indistinguishable: For each step, we sample fresh permutations, so consider each step independently. Now, consider the distribution of v_i^t for $i \in Q, t \in T$. Since our permutations are sampled uniformly, and each P_i^t for $i \neq i^t$ is independent from P_{i^t}, every $P_i(ind)$ is uniformly distributed over $[N/Q]$, for $i \in Q, i \neq i^t$. Then, it follows that for $i \in Q, i \neq i^t$, v_i^t is uniformly distributed. By definition $v_{i^t}^1$ is also uniformly distributed. Then, for any step $t \in [T]$, any $i \in [Q]$, v_i^t is distributed uniformly. Since the outputs of both experiments have the same distribution at each step, Experiment H_0 and Experiment 0 are indistinguishable.

Then, consider the following hybrid:

Experiment H_1

Public Parameters: $N, Q \in \mathbb{N}$, assume $Q|N$.

Experiment:

1. **For** $t \in \{0, \ldots T-2\}$:
   (a) Sample $(P_1^t, \ldots, P_Q^t) \xleftarrow{\$} (\mathcal{P}_N)^Q$.
   (b) Adversary outputs $x^t = (i^t, j^t) \in ([Q] \times [N/Q])$.
   (c) Output $(y_1^t, \ldots, y_Q^t)$ where $y_i^t = P_i^t(x^t)$.
2. Sample $(r_1^{T-2}, \ldots r_Q^{T-2}) \xleftarrow{\$} ([N/Q])^Q$.
3. Let $P_i^{T-1} = P_i^{T-2}$ except we swap the values of $P_i^{T-2}(r_i^{T-2})$ and $P_i^{T-2}(x^{T-2})$ for each $i \in [Q], i \neq i^t$.
4. Adversary outputs $x^{T-1} = (i^{T-1}, j^{T-1})$.
5. Find *ind* s.t. $P_{i^{T-1}}^T(ind) = j^{T-1}$.
6. Output $(v_1^{T-1}, \ldots, v_Q^{T-1})$ where:
   - $v_i^{T-1} = P_i^{T-1}(ind)$ **if** $i \neq i^{T-1}$.
   - $v_i^{T-1} \xleftarrow{\$} [N/Q]$ **if** $i = i^{T-1}$.

.

Notice that for the first $T-1$ steps of the experiment (iterations 0 through $T-2$), it runs exactly as H_0, so up to that point they are indistinguishable. The only difference is how we sam-

ple each P_i^{T-1}. In Experiment H_0, it is sampled uniformly at random, whereas in Experiment H_1, it is sampled by taking each P_i^{T-2}, swapping the only element shown of P_i^{T-2} with a uniform random point and denoting this new permutation as P_i^{T-1}. Notice that, by the indistinguishability of the Show and Shuffle experiment (Lemma 3.1), we can see that each the set of P_i^{T-1} in both experiments is identically distributed, since this is exactly the experiment proven in Lemma 3.1. Then, it follows directly that Experiment H_0 and Experiment H_1 are indistinguishable.

Now, define experiment H_k as follows, $k \in \{1,\dots,T-1\}$:

Experiment H_k

Public Parameters: $N, Q \in \mathbb{N}$, assume $Q|N$.

Experiment:

1. **For** $t \in \{0,\dots T-k-1\}$:
   (a) Sample $(P_1^t,\dots,P_Q^t) \xleftarrow{\$} (\mathcal{P}_N)^Q$.
   (b) Adversary outputs $x^t = (i^t, j^t) \in ([Q] \times [N/Q])$.
   (c) Output $(y_1^t,\dots,y_Q^t)$ where $y_i^t = P_i^t(x^t)$.
2. **For** $t \in \{T-k, T-1\}$:
   (a) Sample $(r_1^{t-1},\dots r_Q^{t-1}) \xleftarrow{\$} ([N/Q])^Q$.
   (b) Let $P_i^t = P_i^{t-1}$ except we swap the values of $P_i^{t-1}(r_i^{t-1})$ and $P_i^{t-1}(ind^{t-1})$ for each $i \in [Q]$.
   (c) Adversary outputs $x^t = (i^t, j^t)$.
   (d) Find ind^t s.t. $P_{i^t}^t(ind^t) = j^t$.
   (e) Output $(v_1^t,\dots,v_Q^t)$ where:
   - $v_i^t = P_i^t(ind)$ **if** $i \neq i^t$.
   - $v_i^t \xleftarrow{\$} [N/Q]$ **if** $i = i^t$.

   .

Notice that for every k, we can show that H_k is indistinguishable from H_{k-1} by the same argument above. The only difference between H_k and H_{k-1} is the $k-$th step, where instead of sampling a fresh random permutation at step $T-k+1$, we use a swapped version of the permutation sampled in the last step. Since distinguishing between H_k and H_{k-1} is exactly equivalent to breaking the Show and Shuffle experiment, we can conclude that this holds for every $k \in \{1,\dots,T-1\}$.

We define H_{T-1} explicity below. After $T-1$ hybrids (where each H_{k-1} and H_k are indistinguishable by the Show and Shuffle lemma), we only sample a permutation once, and swap at each step thereafter (rearranged for ease of reading):

Experiment H_{T-1}

Public Parameters: $N, Q \in \mathbb{N}$, assume $Q|N$.

Experiment:

1. Sample $(P_1^0,\dots,P_Q^0) \xleftarrow{\$} (\mathcal{P}_N)^Q$.
2. Adversary outputs $x_1 \in [N]$.
3. **For** $t \in \{0,\dots,T-1\}$:
   (a) Adversary outputs $x^t = (i^t, j^t) \in ([Q] \times [N/Q])$.
   (b) Find ind^t s.t. $P_{i^t}^t(ind^t) = j^t$.
   (c) Output $(v_1^t,\dots,v_Q^t)$ where:
   - $v_i^t = P_i^t(ind)$ **if** $i \neq i^t$.
   - $v_i^t \xleftarrow{\$} [N/Q]$ **if** $i = i^t$.

   .
   (d) Sample $(r_1^t,\dots r_Q^t) \xleftarrow{\$} ([N/Q])^Q$.
   (e) Let $P_i^{t+1} = P_i^t$ except we swap the values of $P_i^t(r_i^t)$ and $P_i^t(ind^t)$ for each $i \in [Q]$.

Notice that Experiment H_{T-1} and Experiment 1 are the same, except for the reordering of when each P_i^1 is sampled and therefore they are indistinguishable. We conclude that Experiment 1 and Experiment 0 are perfectly indistinguishable. ■

B More Benchmarks

In this section, we include benchmarks for the same tests as those already performed, however, normalizing by *number of operations performed by the server online*, or in other words, the number of elements the online server has to read. In this case, for both static and dynamic cases, we will see that SinglePass achieves 50-100x better preprocessing time and approximately 80x better storage across the board, with similar query time. The price we pay is that the query bandwidth with comparison to MIR and Checklist is much increaased. However, with query sizes hovering around 150KB-3MB, we find that it still is not an impediment for usage, since 3MB is the size of an average web page. We provide the charts in Figure 10 and Figure 11. As seen in Section 5, we can decrease query bandwidth and query time by using more storage.

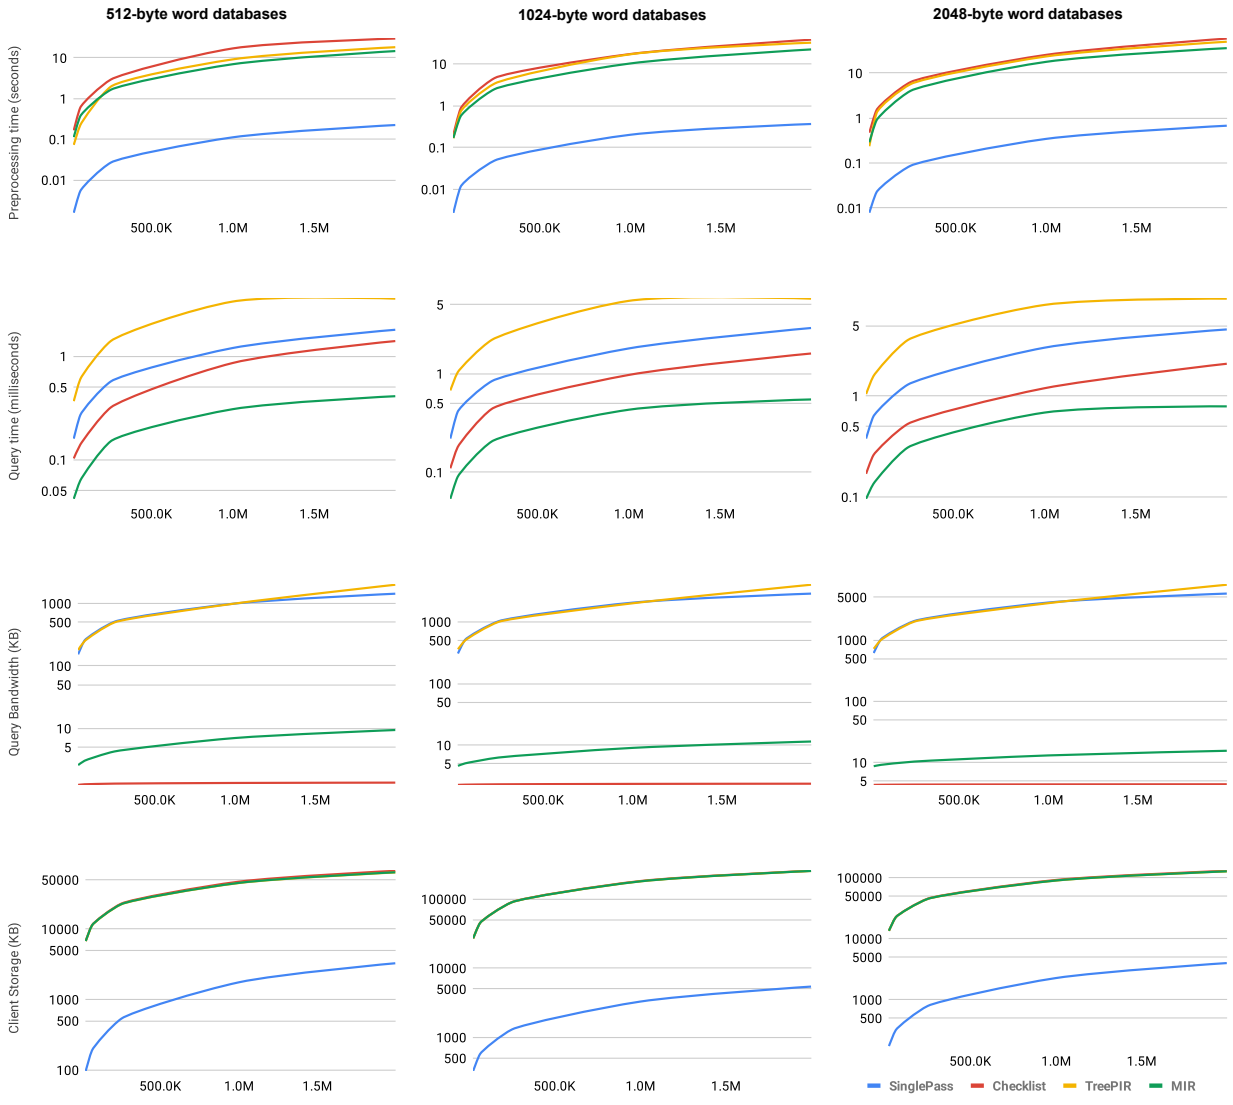

Figure 10: Comparison of benchmarking over preprocessing time, query time, bandwidth and client storageover increasingly sized static databases (x-axis) for different element sizes (on a log scale) when fixing query time.

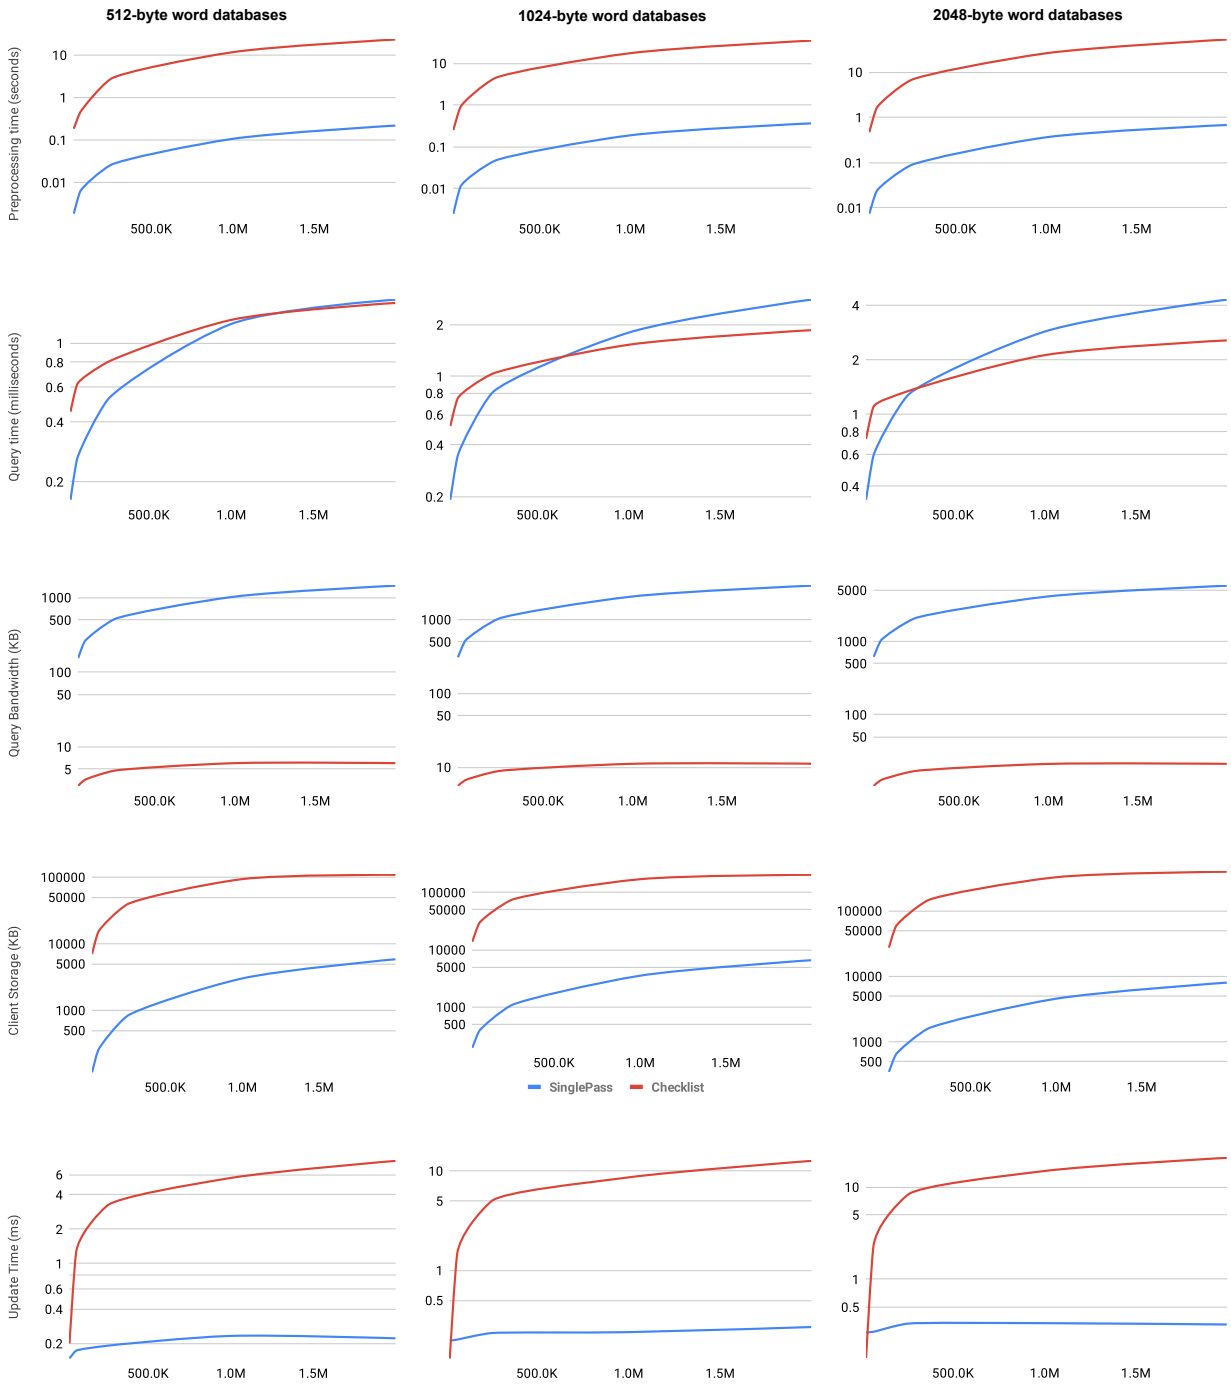

Figure 11: Comparison of benchmarking over preprocessing time, query time, bandwidth, client storage and update time over increasing updatable databases sizes (x-axis) for different element sizes (on a log scale) for fixing query time.

YPIR: High-Throughput Single-Server PIR with Silent Preprocessing

Samir Jordan Menon
Blyss

David J. Wu
UT Austin

Abstract

We introduce YPIR, a single-server private information retrieval (PIR) protocol that achieves high throughput (up to 83% of the memory bandwidth of the machine) *without* any offline communication. For retrieving a 1-bit (or 1-byte) record from a 32 GB database, YPIR achieves 12.1 GB/s/core server throughput and requires 2.5 MB of total communication. On the same setup, the state-of-the-art SimplePIR protocol achieves a 12.5 GB/s/core server throughput, requires 1.5 MB total communication, but *additionally* requires downloading a 724 MB hint in an offline phase. YPIR leverages a new lightweight technique to remove the hint from high-throughput single-server PIR schemes with small overhead. We also show how to reduce the server preprocessing time in the SimplePIR family of protocols by a factor of 10–15×.

By removing the need for offline communication, YPIR significantly reduces the server-side costs for private auditing of Certificate Transparency logs. Compared to the best previous PIR-based approach, YPIR reduces the server-side costs by a factor of 8×. Note that to reduce communication costs, the previous approach assumed that updates to the Certificate Transparency log servers occurred in *weekly* batches. Since there is no offline communication in YPIR, our approach allows clients to always audit the most recent Certificate Transparency logs (e.g., updating once a day). Supporting daily updates using the prior scheme would cost 48× more than YPIR (based on current AWS compute costs).

1 Introduction

A private information retrieval (PIR) [23, 50] protocol allows a client to privately retrieve a record from a database without revealing to the database which record was requested. PIR is a useful building block in systems for metadata-hiding messaging [71, 51, 5, 4], private database queries and web search [82, 41], password breach alerting [57, 81, 3], Certificate Transparency auditing [43], private media consumption [39], private ad delivery [47, 7, 37], and more.

Recently, there has been a flurry of works pushing the limits on the concrete efficiency of *single-server* PIR. Most concretely-efficient PIR constructions rely on an initial *offline phase* where the client either uploads or downloads some information to or from the server:

- **Downloading a hint:** The fastest single-server PIR schemes [26, 43, 86, 74] rely on the client first downloading a query-independent "hint" in an offline phase. With a $\sqrt{N}$-size hint (where N is the size of the database) the SimplePIR scheme [43] achieves a throughput (i.e., the ratio of the database size and the time needed to answer a query) that is comparable to the memory bandwidth of the system (i.e., the speed at which the PIR server can read the database from memory; this is 14.6 GB/s on our machine). Moreover, if the client can *stream* the entire database in the offline step (and cache $O(\sqrt{N})$ bits), then schemes like [86, 74, 35] even allow the server to answer queries with *sublinear* online computation; this enables protocols that can easily handle databases with hundreds of GB of data (e.g., in an application to private DNS lookups). Of course, this assumes that clients can perform a streaming download of this size.
- **Uploading client-specific state:** In an alternative model [4, 1, 72, 67], clients instead upload a "public key" to the server in the offline phase. The public key is typically used to "compress" the query and response. For retrieving large records (e.g., tens of KB long), these protocols currently achieve the best communication. However, the highest server throughput [67] achieved by these approaches is much smaller (over 10×) than the throughput of their hint-based counterparts.

Challenges of offline communication. While moving some of the communication to the offline phase has been critical to the concrete efficiency of PIR, it also imposes challenges for practical deployments. In the hint-based approach, the offline download is large: for an 8 GB database such as the one used in the application to signed certificate timestamp (SCT) auditing in Certificate Transparency from [43], the size

of the hint is over 200 MB using the SimplePIR scheme and 16 MB using the DoublePIR scheme. This is problematic for dynamic databases, since each time the database updates, every client must re-download portions of the hint. When using DoublePIR for private SCT auditing, the protocol of [43] compromised by having clients update their hints on a *weekly* basis, even though Certificate Transparency log servers typically update their databases *daily*. Such a scheme sacrifices real-time monitoring for efficiency. Indeed, if the log database updates daily and the client always audits against the most recent version of the database, the hint downloads and updates are more than 90% of the total cost (see Section 4.4). Dynamic databases are common to many other applications of PIR, such as metadata-hiding messaging or private DNS lookups. Moreover, if a client uses PIR to access multiple databases, it would need to cache hints from each database, which imposes storage burdens for the client.

The client-specific state used by OnionPIR [72], Spiral [67], and similar schemes [4, 1] introduces its own share of challenges. In these schemes, the server must store a (large) public key for each client, imposing high storage requirements for the server and also requiring additional infrastructure to support efficient client state lookups and retrieval. Reuse of client-specific public keys can also enable active attacks on the application [43].

Silent preprocessing. High offline communication costs and large client-side or server-side storage requirements are major bottlenecks in the most concretely-efficient single-server PIR protocols. A natural question is whether we can achieve good concrete efficiency with preprocessing, but *without* offline communication (i.e., a protocol with *silent* preprocessing). In fact, two recent works have already made great strides in this direction: Tiptoe [41][1] and HintlessPIR [55]. Both schemes essentially leverage a form of "bootstrapping" [32] to remove the hint from the SimplePIR protocol [43], where the server *homomorphically* compresses the SimplePIR hint using an encoding of the client secret key. We refer to the full version of this paper [68] for a more detailed summary of these two schemes. While these protocols eliminate the client's need to download the hint, they incur a computation and communication penalty. For example, the throughput of the Tiptoe system on a 32 GB database is over 7× slower than SimplePIR, and the communication cost (for retrieving a 1-bit record) is over 35× greater than the online communication of SimplePIR. HintlessPIR is more lightweight, but still requires 4× more online communication than SimplePIR and has a throughput that is at most 62% of the SimplePIR throughput. We provide a more detailed comparison of the bootstrapping-based approach from Tiptoe and HintlessPIR with our "key-switching-based" approach in Section 4.2, and an overview of the design of Tiptoe and HintlessPIR in the full version of this paper [68].

[1]Tiptoe is a system for performing private web queries, but as part of their design, they introduce a hintless variant of SimplePIR. In this work, when we refer to Tiptoe, we refer specifically to their hintless PIR scheme.

1.1 Our Contributions

In this work, we introduce YPIR, a new single-server PIR protocol with silent preprocessing. Like Tiptoe [41] and HintlessPIR [55], we build on SimplePIR and its recursive variant, DoublePIR. However, instead of using bootstrapping, we take a *packing* approach (which has a conceptually-similar flavor to the response packing techniques from [67]) and "pack" the DoublePIR response into a more compact representation using polynomial rings.[2] We provide a technical overview of YPIR in Section 1.2 and the full construction in Section 3.

High throughput with silent preprocessing. The YPIR protocol can be viewed as appending a lightweight post-processing step to DoublePIR to "compress" the DoublePIR response. When retrieving a single bit from a 32 GB database, YPIR achieves a throughput of 12.1 GB/s, which is 97% of the throughput of SimplePIR (and 83% of the memory bandwidth of the machine). In contrast, HintlessPIR achieves a maximum throughput that is only 62% of SimplePIR (and concretely, 6.4 GB/s on our machine) [55]. For database sizes ranging from 1 GB to 32 GB, the YPIR response size is the same as that in DoublePIR, 9–37× shorter than the response size in SimplePIR, and over 100× shorter than that of HintlessPIR and Tiptoe. On the flip side, YPIR queries are 1.8–3× larger than those in DoublePIR, 3–7× larger than SimplePIR, and similar to those in HintlessPIR. We refer to Section 4 for a more detailed breakdown and comparison. In short, for retrieving small records from a large database, YPIR achieves 97% of the throughput of one of the fastest single-server PIR schemes while fully eliminating *all* offline communication and only incurring a modest increase in query size.

Faster server preprocessing. While YPIR requires no offline communication, it still relies on an offline server preprocessing step (the same as that in SimplePIR). In Section 4.1, we describe a simple approach to improve the server preprocessing throughput by a factor of 10–15×. For instance, while preprocessing a 32 GB database in SimplePIR requires two hours, it just requires 11 minutes with the YPIR approach. Asymptotically, our approach reduces the offline preprocessing cost by a factor of $n/\log n$, where n is the lattice dimension (in SimplePIR-based systems, $n \geq 1024$). Our technique can be used to reduce the preprocessing costs of any of the protocols in the SimplePIR family.

Cross-client batching. The throughput of protocols like SimplePIR is bounded by the memory bandwidth of the system. Since the server throughput is memory-bounded rather than CPU-bounded, we can achieve higher *effective* throughput by

[2]The Y in YPIR is to reflect the fact that the protocol design combines the high-throughput capabilities of PIR based on integer lattices (i.e., the LWE assumption [80]) with the response compression techniques from PIR based on ideal lattices (i.e., the RLWE assumption [62]).

increasing the number of CPU operations per byte of memory read. In Section 4.1, we describe a simple *cross-client batching* approach where the PIR server uses a single scan over the database to answer multiple queries from *non-coordinating* clients.[3] In this work, we show that it is straightforward to tweak SimplePIR (and generalizations like DoublePIR and YPIR) to allow the server to answer a small batch of k queries using a single linear scan through memory. While cross-client batching does *not* reduce the raw number of instructions performed by the CPU, it achieves better utilization of the CPU. With just 4 clients, cross-client batching improves the effective server throughput for a protocol like SimplePIR by a factor of 1.4× to 17 GB/s; applied to YPIR, we achieve an effective throughput of 16 GB/s. In typical applications where servers routinely process queries from multiple clients simultaneously, cross-client batching provides a way to increase the effective throughput for the server and make better use of the available computing resources on the server.

Application to Certificate Transparency. In Section 4.4, we compare the server-side costs of using YPIR to realize an application to private SCT auditing in Certificate Transparency [52, 53]. In this setting, a log server holds a set of SCTs and a client (e.g., a web browser) periodically checks that the SCTs it received from web servers are contained in the log. In private SCT auditing, the goal is to perform these audits without requiring clients to reveal their browsing history to the log server. Henzinger et al. [43] designed an elegant solution for private SCT auditing by combining PIR with Bloom filters. In their protocol, an SCT audit translates to a single PIR query to the log server. A major challenge in this setting is that Certificate Transparency logs update on a daily basis (with millions of certificates added daily). When built from protocols like DoublePIR, clients will frequently need to download hint updates when performing an audit. To mitigate these communication costs, the work of [43] compromises by updating the database on a *weekly* basis. Thus, their approach does not support real-time auditing.

Based on current AWS computation and communication costs, YPIR has 8× lower server costs compared to the DoublePIR system that could only support *weekly* updates to the log server (i.e., the cost drops from $1822 per million clients for DoublePIR to $228 per million clients for YPIR). The cost of YPIR further drops to $183 per million clients if we leverage cross-client batching with a batch size of 4 (i.e., assume that the server always has a saturated queue of at least 4 queries). Moreover, with YPIR, the client always audits the latest version of the log server. In fact, the *total* communication incurred by YPIR each week is smaller than the total communication of the DoublePIR approach. In other words, YPIR reduces the total communication even after accounting for the fact that the cost of downloading the DoublePIR hint can be amortized over the course of a week. Conversely, if we were to use DoublePIR to support *daily* log updates, the weekly server cost balloons to over $10,000 per million clients, which is 48× higher than using YPIR. Compared to other hintless PIR schemes such as Tiptoe and HintlessPIR, we estimate YPIR achieves a cost savings of 16–84× for private SCT auditing (see Table 6).

Limitations. The main limitation of YPIR is the larger query sizes compared to SimplePIR and DoublePIR. Specifically, a YPIR query is 1.8–3× larger than a DoublePIR query (for an 8 GB database, YPIR queries are 1.5 MB while DoublePIR queries are 724 KB) and 3–7× larger than a SimplePIR query. If the application setting has a small, fixed communication budget, YPIR may not be appropriate; for example, for a 32 GB database, the minimum YPIR query size is 1.1 MB. We refer to Section 4.2 for more details on the communication-computation trade-offs in YPIR, HintlessPIR, SimplePIR, and DoublePIR.

1.2 Overview of YPIR

The starting point for this work is the SimplePIR/DoublePIR schemes from [43] based on the learning with errors (LWE) problem [80]. First, an LWE encryption of $\mu \in \mathbb{Z}_p$ is a pair $\mathsf{ct} = (\mathbf{a}, b) \in \mathbb{Z}_q^{n+1}$ where $b = \mathbf{s}^\top \mathbf{a} + e + \Delta \cdot \mu$. Here, n is the lattice dimension, $\mathbf{s} \in \mathbb{Z}_q^n$ is the secret key, $e \in \mathbb{Z}$ is a (small) error term, and Δ is a scaling factor (typically, $\lfloor q/p \rfloor$). Given ct and the secret key $\mathbf{s}$, the user can compute $b - \mathbf{s}^\top \mathbf{a} = \Delta \cdot \mu + e \bmod q$. If e is small relative to the scaling factor Δ (i.e., $|e| < \Delta/2$), the user can recover $\mu \in \mathbb{Z}_p$ from ct by rounding.

In SimplePIR and DoublePIR, the database is represented by a matrix $\mathbf{D} \in \mathbb{Z}_p^{\ell_1 \times \ell_2}$ and records are indexed by a row-column pair (i, j). The query consists of LWE encryptions of the components of the indicator vectors $\mathbf{u}_i$ and $\mathbf{u}_j$ (i.e., $\mathbf{u}_i$ is the vector that is 0 everywhere and 1 in index i). In SimplePIR, the response consists of ℓ_2 ciphertexts $\mathsf{ct}_1, \ldots, \mathsf{ct}_{\ell_2} \in \mathbb{Z}_q^{n+1}$ which encrypt the ℓ_2 entries of row i of the database. In DoublePIR, the response is an LWE encryption of ct_j, which is itself an encryption of the element in row i, column j of $\mathbf{D}$.

An LWE encryption of an element of $\mathbb{Z}_p$ consists of $(n+1)$ $\mathbb{Z}_q$ elements. Since $\mathsf{ct}_j \in \mathbb{Z}_q^{n+1}$ is a vector over $\mathbb{Z}_q$, an encryption of ct_j (i.e., the DoublePIR response) contains $\kappa(n+1)^2$ elements over $\mathbb{Z}_q$, where $\kappa = \log q / \log p$. The extra factor of κ comes from the fact that the plaintext space for the LWE encryption scheme is $\mathbb{Z}_p$, so to encrypt the components of ct_j over $\mathbb{Z}_q$, DoublePIR first decomposes each $\mathbb{Z}_q$ element into its base-p representation (consisting of κ digits in $\mathbb{Z}_p$). For security, the lattice dimension n is around $2^{10} = 1024$, so the response is very large. The insight in [43] is that most of the components in the response only depend on the database and *not* the query. Thus, these can be prefeteched as a hint in the

[3] We contrast this with single-client batching [9, 46, 38, 4], which seeks to amortize the cost over multiple queries from a single client. Our cross-client batching applies even if each client makes a *single* query and is entirely transparent to the client (i.e., requires no client-side changes). Cross-client batching was also used in [60] to improve the effective throughput of PIR in the multi-server setting.

offline phase. For example, for an 8 GB database with 2^{36} 1-bit records, the query-independent portion of the response is 16 MB while the query-dependent portion is just 32 KB.

Packing the DoublePIR responses. The YPIR protocol eliminates the offline hint from DoublePIR by *compressing* the *full* DoublePIR response using ring LWE [62]. Specifically, we work over the polynomial ring $R = \mathbb{Z}[x]/(x^d + 1)$ where d is a power-of-two. RLWE ciphertexts have the advantage of having a much smaller ciphertext expansion factor. With vanilla LWE, encoding a single value $\mu \in \mathbb{Z}_p$ requires a vector of $(n+1)$ elements over $\mathbb{Z}_q$ whereas encoding a *ring* element $\mu \in R_p$ only requires two elements in R_q (where $R_q := R/qR$). If we consider the ciphertext expansion factor (i.e., the ratio of the ciphertext size to the plaintext size), RLWE decreases the expansion factor from $(n+1)\log q/\log p$ to $2\log q/\log p$. For concrete values of $n \approx 2^{10}$, this is a $1000\times$ reduction in ciphertext expansion factor.

In YPIR, we use the LWE-to-RLWE packing technique from [21]. This transformation takes a collection of d LWE ciphertexts $\mathsf{ct}_1, \ldots, \mathsf{ct}_d \in \mathbb{Z}_q^{d+1}$ that encode messages $\mu_1, \ldots, \mu_d \in \mathbb{Z}_p$ (under a secret key $\mathbf{s}$) and packs them into an RLWE ciphertext that encrypts the polynomial $f(x) := \sum_{i\in[d]} \mu_i x^{i-1} \in R_p$ (under a key $s \in R_q$ derived from $\mathbf{s}$). Note that we assume the lattice dimension n in LWE coincides with the ring dimension d in RLWE. Critically, the transformation takes $d(d+1)$ elements over $\mathbb{Z}_q$ and compresses them into just $2d$ elements over $\mathbb{Z}_q$. This yields a factor $(d+1)/2$ reduction in ciphertext size.[4] For an 8 GB database, this packing approach compresses the full 16 MB DoublePIR response into a 12 KB response (see Table 1). The cost is that the query must now include a "packing key" for the transformation from [21] (which essentially consists of RLWE key-switching matrices). This increases the query size from 724 KB in DoublePIR by a factor of $2\times$ to 1.5 MB. We additionally note that most of the computational costs of the [21] transformation can actually be moved to an offline preprocessing phase (because it is applied to *query-independent* components). In our experiments, we observed a $9\times$ reduction in the online computational cost by having the server perform a modest amount of additional work in the offline phase. We describe this approach in Section 4.1.

Supporting large records. A limitation of DoublePIR is that it only supports retrieving small records (i.e., a single element of the plaintext space $\mathbb{Z}_p$). This is sufficient for some applications like private SCT auditing (see Section 4.4), but other PIR applications may require support for large records. In Section 4.3, we show that we can also apply the same packing approach to SimplePIR to obtain a PIR protocol (YPIR+SP) that supports queries to databases with large records. This is a similar setting considered in HintlessPIR (i.e., composing SimplePIR with a LWE-to-RLWE transformation) [55]. As we describe in Section 4.3, our YPIR+SP protocol achieves a $2.2\times$ reduction in total communication with only a 5% reduction in throughput compared to HintlessPIR when considering databases with 32–64 KB records.

Faster preprocessing. YPIR relies on the same preprocessing as SimplePIR (and DoublePIR). The main cost of this preprocessing is computing a product of the form $\mathbf{AD}$ where $\mathbf{A} \in \mathbb{Z}_q^{n\times \ell_1}$ is a (random) matrix and $\mathbf{D} \in \mathbb{Z}_p^{\ell_1 \times \ell_2}$ is the database. While this process only needs to be performed once, it is a very expensive process for large databases: on a single core, this precomputation has a throughput of under 4 MB/s; for a 32 GB database, the SimplePIR preprocessing takes over two hours. In this work, we observe that we can replace $\mathbf{A}$ with a *structured* matrix and use number-theoretic transforms (NTTs) to compute the matrix-vector product. Asymptotically, this yields a $n/\log n$ improvement to preprocessing, and concretely, we observe a 10–$15\times$ increase in the throughput. The only cost of this is that security of the scheme now rests on the ring LWE assumption rather than the LWE assumption. Note that this optimization *only* changes the preprocessing and *not* the online server computation. In particular, the online server computation is still over $\mathbb{Z}_q$ (and *not* over a polynomial ring). We describe our approach in more detail in Section 4.1. We also stress that our approach is *not* just lifting SimplePIR to work over polynomial rings. While this works in theory, the performance bottleneck in practice is the *memory bandwidth* of the system. As we discuss in Section 4.1, a ring-based SimplePIR has higher memory requirements, which is enough to reduce throughput from 11.5 GB/s to just 3.2 GB/s.

2 Preliminaries

We write λ for the security parameter. For a positive integer $n \in \mathbb{N}$, we write $[n]$ for the set $\{1, \ldots, n\}$. For integers $a, b \in \mathbb{Z}$, we write $[a, b]$ for the set $\{a, a+1, \ldots, b\}$. For a positive integer $q \in \mathbb{N}$, we write $\mathbb{Z}_q$ to denote the integers modulo q. We use bold uppercase letters to denote matrices (e.g., $\mathbf{A}, \mathbf{B}$) and bold lowercase letters to denote vectors (e.g., $\mathbf{u}$, $\mathbf{v}$).

We write $\mathsf{poly}(\lambda)$ to denote a function that is $O(\lambda^c)$ for some $c \in \mathbb{N}$ and $\mathsf{negl}(\lambda)$ to denote a function that is $o(\lambda^{-c})$ for all $c \in \mathbb{N}$. We say an algorithm is efficient if it runs in probabilistic polynomial time in its input length.

Rounding. For an input $x \in \mathbb{R}$, we write $\lfloor x \rceil$ to denote the rounding function; that is $\lfloor x \rceil$ outputs the nearest integer to x (rounding up in case of ties). For integers $q > p$, we write $\lfloor \cdot \rceil_{q,p} \colon \mathbb{Z}_q \to \mathbb{Z}_p$ to denote the rounding function that first takes the input $x \in \mathbb{Z}_q$, lifts it to an integer in the interval $x' \in (-q/2, q/2]$, and outputs $\lfloor p/q \cdot x' \rceil$ as an element of $\mathbb{Z}_p$. Here, the division and the rounding are performed over the

[4] It is also possible to pack LWE encodings (e.g., using the SPIRAL approach for response compression [67]) into a packed LWE ciphertext [79], but this requires $O(d)$ key-switching matrices. Since these key-switching matrices must now be communicated with the query, this does not help reduce communication. The LWE-to-RLWE transformation only requires $O(\log d)$ key-switching matrices, which can be included as part of the query with only modest communication overhead.

rationals. We extend $\lfloor \cdot \rceil_{q,p}$ to operate component-wise on vector-valued and matrix-valued inputs.

Polynomial rings. Our construction will use the cyclotomic ring $R = \mathbb{Z}[x]/(x^d+1)$ where d is a power of two. For a positive integer $q \in \mathbb{N}$, we write $R_q := R/qR$. We now define the Coeffs and NCyclicMat functions over R (and by extension, R_q). Let $g = \sum_{i=0}^{d-1} \alpha_i x^i \in R$ be a ring element.

- Let $\mathsf{Coeffs}\colon R \to \mathbb{Z}^d$ be the mapping $g \mapsto [\alpha_0, \ldots, \alpha_{d-1}]^\mathsf{T}$ that outputs the vector of coefficients of g.
- Let $\mathsf{NCyclicMat}\colon R \to \mathbb{Z}^{d\times d}$ be the linear transformation over $\mathbb{Z}^d$ associated with multiplication by $g \in R$. Namely, for all $f \in R$, it holds that $\mathsf{Coeffs}(f)^\mathsf{T} \cdot \mathsf{NCyclicMat}(g) = \mathsf{Coeffs}(fg)^\mathsf{T}$. Specifically,

$$\mathsf{NCyclicMat}(g) := \begin{bmatrix} \alpha_0 & \alpha_1 & \alpha_2 & \cdots & \alpha_{d-1} \\ -\alpha_{d-1} & \alpha_0 & \alpha_1 & \cdots & \alpha_{d-2} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ -\alpha_1 & -\alpha_2 & -\alpha_3 & \cdots & \alpha_0 \end{bmatrix}.$$

  We extend NCyclicMat to operate on vectors in a component-wise manner. In particular, this means that for all $f \in R$ and $\mathbf{g} = (g_1, \ldots, g_m) \in R^m$,

$$\begin{aligned} \mathsf{Coeffs}(f \cdot \mathbf{g})^\mathsf{T} &= [\mathsf{Coeffs}(fg_1)^\mathsf{T} \mid \cdots \mid \mathsf{Coeffs}(fg_m)^\mathsf{T}] \\ &= \mathsf{Coeffs}(f)^\mathsf{T} \cdot \mathsf{NCyclicMat}(\mathbf{g}^\mathsf{T}). \end{aligned} \tag{2.1}$$

We define both operators over R_q in the identical manner. When $q = 1 \bmod 2d$, we say that q is "NTT-friendly;" in this case, polynomial multiplication in R_q can be implemented using a negacyclic convolution [61, 59], which can in turn be computed using fast radix-2 number-theoretic transforms (NTTs). For $f \in R$, we write $\|f\|_\infty$ to denote the ℓ_∞ norm of the vector of coefficients $\mathsf{Coeffs}(f)$.

Gadget matrices. Next, we recall the notion of the gadget matrix from [70]. For a modulus $q \in \mathbb{N}$ and a decomposition base $z \in \mathbb{N}$, we write $\mathbf{g}_z = [1, z, z^2, \ldots, z^{t-1}] \in \mathbb{Z}_q^t$ where $t = \lceil \log q / \log z \rceil$. For a dimension $n \in \mathbb{N}$, we define $\mathbf{G}_{n,z} := \mathbf{I}_n \otimes \mathbf{g}_z^\mathsf{T} \in \mathbb{Z}_q^{n\times nt}$ to be the gadget matrix. We write $\mathbf{G}_{n,z}^{-1}\colon \mathbb{Z}_q^n \to \mathbb{Z}^{nt}$ to denote the base-z digit decomposition operator that expands each component of the input vector into its base-z representation (where each output component is an integer between $-z/2$ and $z/2$). We write $\mathbf{g}_z^{-1}\colon \mathbb{Z}_q \to \mathbb{Z}^t$ for the 1-dimensional operator $\mathbf{G}_{1,z}^{-1}$. We extend $\mathbf{G}_{n,z}^{-1}$ to operate on matrices $\mathbf{M} \in \mathbb{Z}_q^{n\times k}$ by independently applying $\mathbf{G}_{n,z}^{-1}$ to each column of $\mathbf{M}$.

Ring learning with errors. Like many lattice-based PIR schemes [66, 4, 33, 72, 67, 55], the security of our protocol relies on the ring learning with errors (RLWE) problem [80, 62]. We state the "normal form" of the assumption where the RLWE secret is sampled from the error distribution; this version reduces to the one where the secret key is uniform [6].

Definition 2.1 (Ring Learning with Errors [62])**.** Let λ be a security parameter, $d = d(\lambda)$ be a power-of-two, and $R = \mathbb{Z}[x]/(x^d+1)$. Let $m = m(\lambda)$ be the number of samples, $q = q(\lambda)$ be a modulus, and $\chi = \chi(\lambda)$ be an error distribution over R. The ring learning with errors (RLWE) assumption $\mathsf{RLWE}_{d,m,q,\chi}$ in Hermite normal form states that for $\mathbf{a} \xleftarrow{R} R_q^m$, $s \leftarrow \chi$, $\mathbf{e} \leftarrow \chi^m$, and $\mathbf{v} \xleftarrow{R} R_q^m$, the following two distributions are computationally indistinguishable: $(\mathbf{a}, s\mathbf{a}+\mathbf{e})$ and $(\mathbf{a}, \mathbf{v})$.

LWE and RLWE encodings. We say that a vector $\mathbf{c} \in \mathbb{Z}_q^{n+1}$ is an "LWE encoding" of a value $\mu \in \mathbb{Z}_q$ with respect to a secret key $\mathbf{s} \in \mathbb{Z}_q^n$ and error $e \in \mathbb{Z}$ if $[-\mathbf{s}^\mathsf{T} \mid 1] \cdot \mathbf{c} = \mu + e$. For a ring $R = \mathbb{Z}[x]/(x^d+1)$, we say that $\mathbf{c} \in R_q^2$ is an "RLWE encoding" of a value $\mu \in R_q$ with respect to a secret key $s \in R_q$ and error $e \in R$ if $[-s \mid 1] \cdot \mathbf{c} = \mu + e$. In our setting, it will typically be the case that $\mu = \lfloor q/p \rfloor v$ for some $v \in \mathbb{Z}_p$ (or $v \in R_p$). Given $\mu + e$ for sufficiently small e, it is then possible to recover the value of v by rounding.

Packing LWE encodings. Observe that RLWE encodings have better *rate:* namely, an encoding of $\mu \in R_q$ consists of just two elements of R_q, whereas an LWE encoding of $\mu \in \mathbb{Z}_q$ requires a vector of $(n+1)$ elements, where n is the lattice dimension (i.e., the security parameter). Chen, Dai, Kim, and Song [21] described a general transformation to "pack" multiple LWE encodings into a single RLWE encoding. This is the main technique we use to remove the hint from DoublePIR. We give an informal overview of the transformation here and defer the formal description to the full version of this paper [68]. Informally, there are two algorithms $(\mathsf{CDKS.Setup}, \mathsf{CDKS.Pack})$ with the following properties:

- $\mathsf{CDKS.Setup}(1^\lambda, s, z) \to \mathsf{pk}$: On input the security parameter λ, a secret key $s \in R_q$, and a decomposition base $z \in \mathbb{N}$, the setup algorithm outputs a packing key pk.
- $\mathsf{CDKS.Pack}(\mathsf{pk}, \mathbf{C}) \to \mathbf{c}'$: On input the packing key pk and LWE encodings $\mathbf{C} \in \mathbb{Z}_q^{(d+1)\times d}$, the packing algorithm outputs an RLWE encoding $\mathbf{c}' \in R_q^2$.

Correctness says that if the columns $\mathbf{c}_1, \ldots, \mathbf{c}_d \in \mathbb{Z}_q^{d+1}$ of $\mathbf{C}$ are LWE encodings of $\mu_1, \ldots, \mu_d \in \mathbb{Z}_p$ with respect to the secret key $\mathbf{s} = \mathsf{Coeffs}(s) \in \mathbb{Z}_q^d$, then the $\mathbf{c}' \in R_q^2$ output by CDKS.Pack is an RLWE encoding of $\sum_{i\in[d]} \mu_i x^{i-1} \in R_p$ (with respect to the secret key $s \in R_q$). Namely, the transformation takes $d(d+1)$ elements over $\mathbb{Z}_q$ and packs them into just $2d$ elements over $\mathbb{Z}_q$ (which encode a polynomial with $\mu_1, \ldots, \mu_d$ as its coefficients). We do assume that the lattice dimension of the LWE encodings coincide with the ring dimension.

Modulus switching. A standard technique to reduce the size of lattice-based encodings after performing homomorphic operations on them is to use *modulus switching* [17, 16]. Modulus switching takes an (R)LWE encoding mod q and rescales it to an encoding mod q_1 where $q_1 < q$. This reduces the size of the encoding. Here, we describe a more fine-grained variant from [67] where two different moduli are used. We describe

the approach for encodings over any ring $R = \mathbb{Z}[x]/(x^d+1)$; the case where $d = 1$ corresponds to the case of the integers.

- $\mathsf{ModReduce}_{q_1,q_2}(\mathbf{c})$: For integers $q > q_1 \geq q_2$ and on input an encoding $\mathbf{c} \in R_q^{n+1}$ where $\mathbf{c} = \begin{bmatrix}\mathbf{c}_1 \\ c_2\end{bmatrix}$ for $\mathbf{c}_1 \in R_q^n$ and $c_1 \in R_q$, output $(\lfloor \mathbf{c}_1 \rceil_{q,q_1}, \lfloor c_2 \rceil_{q,q_2}) \in R_{q_1}^n \times R_{q_2}$.

When there is a single modulus q_1, we write $\mathsf{ModReduce}_{q_1}(\mathbf{c})$ to denote $\mathsf{ModReduce}_{q_1,q_1}(\mathbf{c})$. We extend $\mathsf{ModReduce}_{q_1,q_2}$ to matrices by column-wise evaluation. We give the formal correctness property in the full version of this paper [68].

Private information retrieval. We now recall the formal definition of a (two-message) single-server PIR protocol [50]. We work in the model where there is an initial database-dependent preprocessing algorithm that outputs a set of public parameters (assumed to be known to the client and to the server) and an internal server state.

Definition 2.2 (Private Information Retrieval [50, adapted])**.** Let $N \in \mathbb{N}$ be an integer. A (two-message) single-server private information retrieval (PIR) scheme $\Pi_{\mathsf{PIR}} = (\mathsf{DBSetup}, \mathsf{Query}, \mathsf{Answer}, \mathsf{Extract})$ with message space $\mathbb{Z}_N$ is a tuple of efficient algorithms with the following properties:

- $\mathsf{DBSetup}(1^\lambda, \mathbf{D}) \to (\mathsf{pp}, \mathsf{dbp})$: On input the security parameter λ and a database $\mathbf{D}$, the setup algorithm outputs a set of public parameters pp and database parameters dbp.
- $\mathsf{Query}(\mathsf{pp}, \mathsf{idx}) \to (\mathsf{q}, \mathsf{qk})$: On input the public parameters pp and an index idx, the query algorithm outputs a query q and a query key qk.
- $\mathsf{Answer}(\mathsf{dbp}, \mathsf{q}) \to \mathsf{resp}$: On input the database parameters dbp, a query q, the answer algorithm outputs a response resp.
- $\mathsf{Extract}(\mathsf{qk}, \mathsf{resp}) \to D_i$: On input the client state qk and a response resp, the extract algorithm outputs a database record $D_i \in \mathbb{Z}_N$.

The PIR scheme is correct if for all $\lambda \in \mathbb{N}$, all databases $\mathbf{D}$, and all indices idx, if we sample $(\mathsf{pp}, \mathsf{dbp}) \leftarrow \mathsf{DBSetup}(1^\lambda, \mathbf{D})$, $(\mathsf{q}, \mathsf{qk}) \leftarrow \mathsf{Query}(\mathsf{pp}, \mathsf{idx})$, and $\mathsf{resp} \leftarrow \mathsf{Answer}(\mathsf{dbp}, \mathsf{q})$, then

$$\Pr[\mathsf{Extract}(\mathsf{qk}, \mathsf{resp}) = \mathbf{D}[\mathsf{idx}]] \geq 1 - \delta,$$

where $\mathbf{D}[\mathsf{idx}]$ denotes the element of $\mathbf{D}$ indexed by idx. Here, δ denotes a correctness error. The scheme satisfies query privacy if no efficient adversary can distinguish a query to an index idx_0 from a query to an index idx_1. We provide the formal correctness and security definitions for PIR in the full version of this paper [68].

3 The YPIR Protocol

In this section, we describe the YPIR protocol. As described in Section 1.2, the YPIR protocol first invokes DoublePIR [43] over the database, and then packs the DoublePIR response (a collection of LWE encodings) into a small number of RLWE encodings.

Construction 3.1 (YPIR Protocol)**.** Let λ be a security parameter. We model the database as a matrix $\mathbf{D} \in \mathbb{Z}_N^{\ell_1 \times \ell_2}$. In the scheme, we associate the records in $\mathbf{D}$ with its integer representative in the interval $(-N/2, N/2]$. We index records by a row-column pair $(i_1, i_2) \in [\ell_1] \times [\ell_2]$. YPIR uses different sets of lattice parameters for the initial pass (i.e., the linear scan over the database—"SimplePIR") and for the second pass (i.e., recursing on the output of the first step—"DoublePIR"). This is because the parameters for the second pass must be compatible with the LWE-to-RLWE packing transformation. We define the parameters below:

- Let $d_1 = d_1(\lambda), d_2 = d_2(\lambda)$ be ring dimensions, where each is a power of two. We write $R_{d_1} := \mathbb{Z}[x]/(x^{d_1}+1)$ and $R_{d_2} := \mathbb{Z}[x]/(x^{d_2}+1)$. For $j \in \{1,2\}$ and a modulus q, we write $R_{d_j,q} := R_{d_j}/qR_{d_j}$.
- Let $q_1 = q_1(\lambda), q_2 = q_2(\lambda)$ be the encoding modulus and $\tilde{q}_1 = \tilde{q}_1(\lambda)$, $\tilde{q}_{2,1} = \tilde{q}_{2,1}(\lambda)$, and $\tilde{q}_{2,2} = \tilde{q}_{2,2}(\lambda)$ be a set of reduced modulus (for modulus switching). We require that $\gcd(d_2, q_2) = 1$.
- Let $\chi_1 = \chi_1(\lambda), \chi_2 = \chi_2(\lambda)$ be error distributions over R_{d_1} and R_{d_2}, respectively.
- Let $z = z(\lambda)$ be a decomposition parameter (for the LWE-to-RLWE packing).
- Let $p = p(\lambda)$ be an intermediate modulus and let $\kappa = \lceil \log \tilde{q}_1 / \log p \rceil$.
- Let $(\mathsf{CDKS.Setup}, \mathsf{CDKS.Pack})$ be the LWE-to-RLWE packing algorithms (see the full version of this paper [68] for the precise parameter instantiation).

The $\mathsf{YPIR} = (\mathsf{DBSetup}, \mathsf{Query}, \mathsf{Answer}, \mathsf{Extract})$ scheme is defined as follows:

- $\mathsf{DBSetup}(1^\lambda, \mathbf{D})$: On input the security parameter λ and a database $\mathbf{D} \in \mathbb{Z}_N^{\ell_1 \times \ell_2}$, where $\ell_1 = m_1 d_1$ and $\ell_2 = m_2 d_2$ for integers $m_1, m_2 \in \mathbb{N}$,[5] the setup algorithm samples $\mathbf{a}_j \xleftarrow{R} R_{d_j,q_j}^{m_j}$ and sets $\mathbf{A}_j = \mathsf{NCyclicMat}(\mathbf{a}_j^\mathsf{T}) \in \mathbb{Z}_{q_j}^{d_j \times \ell_j}$ where $j \in \{1,2\}$. Finally, the setup algorithm computes

$$\begin{aligned} \mathbf{H}_1 &= \mathbf{G}_{d_1,p}^{-1}(\lfloor \mathbf{A}_1 \mathbf{D} \rceil_{q_1,\tilde{q}_1}) \in \mathbb{Z}^{\kappa d_1 \times \ell_2} \\ \mathbf{H}_2 &= \mathbf{A}_2 \cdot \mathbf{H}_1^\mathsf{T} \in \mathbb{Z}_{q_2}^{d_2 \times \kappa d_1}. \end{aligned} \tag{3.1}$$

  The setup algorithm then outputs the public parameters $\mathsf{pp} = (1^\lambda, \ell_1, \ell_2, N, \mathbf{a}_1, \mathbf{a}_2)$ together with the server state $\mathsf{dbp} = (1^\lambda, \mathbf{D}, \mathbf{H}_1, \mathbf{H}_2)$.
- $\mathsf{Query}(\mathsf{pp}, \mathsf{idx})$: On input the public parameters $\mathsf{pp} = (1^\lambda, \ell_1, \ell_2, N, \mathbf{a}_1, \mathbf{a}_2)$ and an index $\mathsf{idx} = (i_1, i_2) \in [\ell_1] \times [\ell_2]$, the query algorithm proceeds as follows:

[5] For ease of exposition, we describe our construction for the setting where the database dimensions are a multiple of the ring dimensions d_1 and d_2. This can be ensured by padding the database with dummy rows and columns. It is straightforward to extend the scheme to support arbitrary dimensions *without* padding, but this introduces additional notational burden. We defer the description of the modified scheme to the full version of this paper [68].

1. **Key generation:** Sample two secret keys $s_1 \leftarrow \chi_1$ and $s_2 \leftarrow \chi_2$. Compute the packing key $\mathsf{pk} \leftarrow \mathsf{CDKS.Setup}(1^\lambda, s_2, z)$.
2. **Query encoding:** Define the scaling factors $\Delta_1 = \lfloor q_1/N \rfloor$ and $\Delta_2 = \lfloor q_2/p \rfloor$. The query encodings are then constructed as follows:
   (a) For $j \in \{1,2\}$, let $m_j = \ell_j/d_j$ and $i_j = \alpha_j d_j + \beta_j$ where $\alpha_j \in [m_j]$ and $\beta_j \in [d_j]$. Let $\boldsymbol{\mu}_j = x^{\beta_j}\mathbf{u}_{\alpha_j} \in R_{d_j,q_j}^{m_j}$, where $\mathbf{u}_j$ denotes the j^{th} elementary basis vector (of the appropriate dimension).
   (b) For $j \in \{1,2\}$, sample $\mathbf{e}_j \leftarrow \chi_j^{m_j}$ and construct the encoding $\mathbf{c}_j = \mathsf{Coeffs}(s_j\mathbf{a}_j + \mathbf{e}_j + \Delta_j\boldsymbol{\mu}_j) \in \mathbb{Z}_{q_j}^{\ell_j}$.

   Output the query $\mathsf{q} = (\mathsf{pk}, \mathbf{c}_1, \mathbf{c}_2)$ and the query key $\mathsf{qk} = (s_1, s_2)$.

- $\mathsf{Answer}(\mathsf{dbp}, \mathsf{q})$: On input the database parameters $\mathsf{dbp} = (1^\lambda, \mathbf{D}, \mathbf{H}_1, \mathbf{H}_2)$ and the query $\mathsf{q} = (\mathsf{pk}, \mathbf{c}_1, \mathbf{c}_2)$, where $\mathbf{D} \in \mathbb{Z}_N^{\ell_1 \times \ell_2}$, $\mathbf{H}_1 \in \mathbb{Z}^{\kappa d_1 \times \ell_2}$, $\mathbf{H}_2 \in \mathbb{Z}_{q_2}^{d_2 \times \kappa d_1}$, $\mathbf{c}_1 \in \mathbb{Z}_{q_1}^{\ell_1}$, and $\mathbf{c}_2 \in \mathbb{Z}_{q_2}^{\ell_2}$, the answer algorithm proceeds as follows:

  1. **Compute the SimplePIR response:** Let $\mathbf{T} = \mathbf{g}_p^{-1}(\lfloor \mathbf{c}_1^\mathsf{T}\mathbf{D} \rceil_{q_1,\tilde{q}_1}) \in \mathbb{Z}^{\kappa \times \ell_2}$.
  2. **Compute the DoublePIR response:** Let
  $$\mathbf{C} = (d_2^{-1} \bmod q_2) \cdot \begin{bmatrix} \mathbf{H}_2 & \mathbf{A}_2\mathbf{T}^\mathsf{T} \\ \mathbf{c}_2^\mathsf{T}\mathbf{H}_1^\mathsf{T} & \mathbf{c}_2^\mathsf{T}\mathbf{T}^\mathsf{T} \end{bmatrix} \in \mathbb{Z}_{q_2}^{(d_2+1)\times\kappa(d_1+1)}. \tag{3.2}$$
  3. **Pack encodings:** Let $\rho = \lceil \kappa(d_1+1)/d_2 \rceil$ and parse $[\mathbf{C} \mid \mathbf{0}^{(d_2+1)\times(d_2\rho - \kappa(d_1+1))}] = [\mathbf{C}_1 \mid \cdots \mid \mathbf{C}_\rho]$ where each $\mathbf{C}_i \in \mathbb{Z}_{q_2}^{(d_2+1)\times d_2}$. Namely, $\mathbf{C}_1, \ldots, \mathbf{C}_\rho$ are the blocks of $\mathbf{C}$ and $\mathbf{C}_\rho$ is padded to the required dimension with columns of all-zeroes. Then, for each $i \in [\rho]$, compute $\tilde{\mathbf{c}}_i \leftarrow \mathsf{CDKS.Pack}(\mathsf{pk}, \mathbf{C}_i) \in R_{d_2,q_2}^2$.
  4. **Apply (split) modulus switching:** For each $i \in [\rho]$, let $(c_{i,1}, c_{i,2}) = \mathsf{ModReduce}_{\tilde{q}_{2,1},\tilde{q}_{2,2}}(\tilde{\mathbf{c}}_i)$.

  Output $\mathsf{resp} = ((c_{1,1}, c_{1,2}), \ldots, (c_{\rho,1}, c_{\rho,2}))$.

- $\mathsf{Extract}(\mathsf{qk}, \mathsf{resp})$: On input the client state $\mathsf{qk} = (s_1, s_2)$ and the response $\mathsf{resp} = ((c_{1,1}, c_{1,2}), \ldots, (c_{\rho,1}, c_{\rho,2}))$ where $c_{i,1} \in R_{d_2,\tilde{q}_{2,1}}$ and $c_{i,2} \in R_{d_2,\tilde{q}_{2,2}}$, the extract algorithm computes $v_i' = \lfloor -s_2 c_{i,1} \rceil_{\tilde{q}_{2,1},\tilde{q}_{2,2}} + c_{i,2} \in R_{d_2,\tilde{q}_{2,2}}$ and $v_i = \lfloor v_i' \rceil_{\tilde{q}_{2,2},p} \in R_{d_2,p}$ for each $i \in [\rho]$. Let
  $$\bar{\mathbf{w}} = \begin{bmatrix} \mathsf{Coeffs}(v_1) \\ \vdots \\ \mathsf{Coeffs}(v_\rho) \end{bmatrix} \in \mathbb{Z}_p^{d_2\rho}.$$
  Parse $\bar{\mathbf{w}} = \begin{bmatrix} \mathbf{w} \\ \mathbf{w}' \end{bmatrix}$ where $\mathbf{w} \in \mathbb{Z}_p^{\kappa(d_1+1)}$ and $\mathbf{w}' \in \mathbb{Z}_p^{d_2\rho - \kappa(d_1+1)}$. Compute
  $$\mathbf{c}' = \begin{bmatrix} \mathbf{G}_{d_1,p} & \mathbf{0}^{d_1\times\kappa} \\ \mathbf{0}^{1\times\kappa d_1} & \mathbf{g}_p^\mathsf{T} \end{bmatrix} \mathbf{w} = \mathbf{G}_{d_1+1,p}\mathbf{w} \in \mathbb{Z}_{\tilde{q}_1}^{d_1+1}$$
  and the scaled message $\mu' = \lceil -\mathsf{Coeffs}(s_1) \mid 1 \rfloor \cdot \mathbf{c}' \in \mathbb{Z}_{\tilde{q}_1}$. Compute $\mu = \lfloor \mu' \rceil_{\tilde{q}_1,N} \in \mathbb{Z}_N$ and output the representative of μ in $\mathbb{Z}_N$.

Remark 3.2 (Silent Preprocessing)**.** As described, the public parameters pp in Construction 3.1 are very long (specifically, the vectors and $\mathbf{a}_1$ and $\mathbf{a}_2$). However, the vectors $\mathbf{a}_1$ and $\mathbf{a}_2$ are *uniformly random*, and could be derived from a random oracle. This is a standard technique used in lattice-based PIR [72, 67, 43, 26]. With this modification, the public parameters in Construction 3.1 only consist of the *meta-parameters* for the database itself (i.e., the database dimensions and the record size). Thus, we say YPIR supports *silent* preprocessing (in the random oracle model).

Supporting arbitrary dimension. Construction 3.1 assumes that the database dimensions are multiples of the ring dimensions d_1 and d_2. We describe in the full version of this paper [68] a straightforward way to adapt the scheme to support databases with arbitrary dimensions (and without padding).

Correctness and security. We now give the formal correctness and security theorems for the YPIR protocol, but defer their proofs to the full version of this paper [68]. To summarize, the security of YPIR relies on the hardness of the RLWE assumption as well as a standard circular security assumption (for the use of key-switching matrices in the LWE-to-RLWE packing). The circular-security assumption is common when working with lattice-based homomorphic encryption schemes [32, 17, 16, 15] and also used in many previous RLWE-based PIR schemes [4, 1, 72, 67, 55].

Theorem 3.3 (Correctness)**.** *Let $N \in \mathbb{N}$ be the record size and $\ell_1, \ell_2 \in \mathbb{N}$ be the database dimensions. Let d_1, d_2, q_1, q_2, $\tilde{q}_1$, $\tilde{q}_{2,1}$, $\tilde{q}_{2,2}$, χ_1, χ_2, z, p be the scheme parameters from Construction 3.1. Suppose χ_1 and χ_2 are subgaussian with parameters σ_1 and σ_2, respectively. Let $\kappa = \lceil \log \tilde{q}_1 / \log p \rceil$, $\rho = \lceil \kappa(d_1+1)/d_2 \rceil$, and $t = \lfloor \log_z q_2 \rfloor + 1$. Then, under the independence heuristic, Construction 3.1 has correctness error*

$$\delta \le 2d_2\rho \exp(-\pi\tau_{\mathsf{double}}^2/\sigma_{\mathsf{double}}^2) + 2\exp(-\pi\tau_{\mathsf{simple}}^2/\sigma_{\mathsf{simple}}^2),$$

where the parameters τ_{double}, σ_{double}, τ_{simple}, and σ_{simple} are given in Fig. 1.

Theorem 3.4 (Security)**.** *Under the $\mathsf{RLWE}_{d_1,m_1,q_1,\chi_1}$ assumption and assuming the LWE-to-RLWE packing scheme $(\mathsf{CDKS.Setup}, \mathsf{CDKS.Pack})$ satisfies pseudorandomness given the packing key (see the full version of this paper [68]), then Construction 3.1 satisfies query privacy.*

4 Implementation and Evaluation

In this section, we describe our implementation and experimental evaluation of the YPIR protocol (Construction 3.1).

$$\tau_{\mathsf{double}} = \frac{\tilde{q}_{2,2}}{2p} - (\tilde{q}_{2,2} \bmod p) - \frac{1}{2}\left(2 + (\tilde{q}_{2,2} \bmod p) + (\tilde{q}_{2,2}/q_2)(q_2 \bmod p)\right)$$
$$\sigma^2_{\mathsf{double}} \leq (\tilde{q}_{2,2}/\tilde{q}_{2,1})^2 d_2 \sigma_2^2/4 + (\tilde{q}_{2,2}/q_2)^2(\sigma_2^2/4)(\ell_2 p^2 + (d_2^2-1)(t d_2 z^2)/3)$$
$$\tau_{\mathsf{simple}} = \frac{\tilde{q}_1}{2N} - (\tilde{q}_1 \bmod N) - \frac{1}{2}\left(2 + \tilde{q}_1 \bmod N + (\tilde{q}_1/q_1)(q_1 \bmod N)\right)/2$$
$$\sigma^2_{\mathsf{simple}} \leq d_1 \sigma_1^2/4 + (\tilde{q}_1/q_1)^2 \ell_1 N^2 \sigma_1^2/4$$

Figure 1: Parameters for Theorem 3.3 (Correctness of YPIR).

Parameter selection. Theorem 3.3 bounds the correctness error δ of YPIR as function of the scheme parameters. We now describe how we instantiate the different parameters to achieve a correctness error $\delta \leq 2^{-40}$ and 128-bits of security (as estimated by the Lattice Estimator [2][6]). We select a single parameter set for YPIR using the following procedure:

- Like SimplePIR [43], we set $d_1 = 2^{10} = 1024$ and $q_1 = 2^{32}$. We set χ_1 to be a discrete Gaussian distribution[7] with parameter $s_1 = 11\sqrt{2\pi}$ (to achieve 128-bits of security for this choice of ring dimension and modulus).
- For the DoublePIR and LWE-to-RLWE packing steps, we work over a larger ring, to allow for the extra noise added by the LWE-to-RLWE transformation. Here, we choose $d_2 = 2^{11} = 2048$ and q_2 to be a 56-bit modulus that splits into a product of two (28-bit) NTT-friendly modulus (specifically, $q_2 = (2^{28} - 2^{16} + 1) \cdot (2^{28} - 2^{24} - 2^{21} + 1)$). Using two 28-bit NTT-friendly modulus allows us to use native 64-bit integer arithmetic to implement arithmetic operations modulo each of the prime factors of q_2.[8] We choose χ_2 to be a discrete Gaussian distribution with parameter $s_2 = 6.4\sqrt{2\pi}$ (to achieve 128-bits of security for this choice of ring dimension and modulus).
- We choose parameters to support any choice of $\ell_1, \ell_2 \leq 2^{18}$ (recall that the database in YPIR is represented as an ℓ_1-by-ℓ_2 matrix). This is sufficient to support databases with up to 2^{36} records (and for our choice of N, up to 64 GB in size).
- We choose the largest value for the gadget decomposition base $z \in \mathbb{N}$ that achieves correctness error at most $\delta \leq 2^{-40}$. This allows for faster computation.
- We choose the largest value of N and the largest intermediate decomposition base p that achieves correctness error at most δ when $\tilde{q}_1 = q_1$ and $\tilde{q}_{2,1} = \tilde{q}_{2,2} = q_2$. This minimizes the communication overhead of the scheme. We constrain N and p to be powers-of-two so elements can be represented by a single machine word.
- After fixing N and p, we choose the smallest modulus switching parameters $\tilde{q}_1, \tilde{q}_{2,1}, \tilde{q}_{2,2}$ that achieve correctness error at most δ. This minimizes the size of the responses.

We summarize the lattice parameters we select in the full version of this paper [68]. When the database consists of ℓ one-bit records, we let $\ell' = \lceil \ell / \log N \rceil$, and set $\ell_1 = 2^{\lceil \log \ell'/2 \rceil}$ and $\ell_2 = 2^{\lfloor \log \ell'/2 \rfloor}$.

4.1 Additional Optimizations

In the full version of this paper [68], we describe some additional techniques to improve the concrete efficiency of YPIR. We provide a brief overview of these here.

NTT-based hint computation. First, we show that using structured matrices (specifically, negacyclic matrices; see Section 2), we can significantly reduce the computational cost of computing the hints $\mathbf{H}_1$ and $\mathbf{H}_2$ in Eq. (3.1) of YPIR. Specifically, in YPIR, the matrices $\mathbf{A}_1$ and $\mathbf{A}_2$ are defined to be $\mathbf{A}_i := \mathsf{NCyclicMat}(\mathbf{a}_i^\top)$. In SimplePIR/FrodoPIR, the corresponding matrices $\mathbf{A}_1$ and $\mathbf{A}_2$ were uniformly random. By using a structured matrix, we can leverage NTTs to more efficiently compute the hints $\mathbf{H}_1$ and $\mathbf{H}_2$ in Eq. (3.1). In particular, the YPIR approach is asymptotically faster (by a factor $d/\log d$, where d is the lattice dimension) and concretely faster (10–15×) compared to the preprocessing approaches of protocols like SimplePIR [43] or FrodoPIR [26]. Our approach directly applies to reduce the preprocessing cost in any system that builds on SimplePIR/FrodoPIR (e.g., [24, 41, 55, 27]) with *zero* impact to the online costs of the protocol (the online server processing is unchanged). The only difference is security now relies on RLWE (due to the use of structured $\mathbf{A}_i$) rather than LWE.

Preprocessing the CDKS transformation. We show how to speed up the [21] LWE-to-RLWE packing transformation by moving a large portion of the online packing computation to the *offline* preprocessing stage (i.e., from Answer to Setup). Specifically, our approach reduces the number of NTTs that must be performed in Answer from $O(\kappa d_1 + \log d_2)$ to $O(\kappa + \log d_2)$. Concretely, this reduces the online cost of the packing transformation by 9× (see Table 4).

Cross-client batching. Protocols like SimplePIR and YPIR are ultimately constrained by the memory bandwidth of the

[6] We use commit 4195c66 (2024/02/06) from https://github.com/malb/lattice-estimator for our security estimates.

[7] We refer to the full version of this paper [68] for a definition of the discrete Gaussian distribution.

[8] Since we use 64-bit integer arithmetic to implement arithmetic operations with respect to a 28-bit modulus, we do *not* need to perform a modulus reduction after *every* arithmetic operation. In our implementation, we reduce only when the computation might "overflow" the 64-bit integer.

system (see Section 4) and not the cost of evaluating the underlying arithmetic operations during query processing. One approach to increase the *effective* throughput in these protocols is to perform additional computation for each byte of memory accessed. A natural approach to overcome the memory bandwidth barrier is to support "cross-client batching" [60] where the server uses a single scan through memory to answer requests from multiple *independent* clients.

The structure of SimplePIR makes it amenable for cross-client batching as the core computation is a matrix-vector product $\mathbf{q}^T\mathbf{D}$ between the query $\mathbf{q}$ and the database $\mathbf{D}$. If a batch of k queries $\mathbf{q}_1, \ldots, \mathbf{q}_k$ arrive simultaneously, then the computation becomes a matrix-vector product $\mathbf{QD}$, where the rows of $\mathbf{Q}$ are the queries $\mathbf{q}_1, \ldots, \mathbf{q}_k$. In this way, the server performs more arithmetic operations per byte of memory fetched, which in turn increases the effective throughput of the protocol. We provide the full details in Section 4.1. As we show in Section 4.2, cross-client batching can increase the effective server throughput of many PIR schemes by 1.5–1.7×. A benefit of our approach is that it is entirely transparent to the client (i.e., requires no changes client-side) and applies even if the clients are each making a single query.

Our technique is similar to the cross-client batching technique of Lueks and Goldberg [60] who used faster matrix-vector multiplication algorithms to obtains asymptotic and concrete server speed-ups. In our setting, we leverage batching as a means to improve CPU utilization and as such, our approach only provides a concrete (but not asymptotic) improvement to server throughput.

4.2 Experimental Evaluation

In this section, we describe our experimental evaluation of the YPIR protocol and compare it against other PIR protocols. We compare against the state-of-the-art high-throughput single-server PIR schemes: SimplePIR/DoublePIR [43] as well as the hintless schemes proposed in Tiptoe [41] and HintlessPIR [55]. We refer to the full version of this paper [68] for a more detailed summary of the design of the PIR scheme from Tiptoe as well as the HintlessPIR scheme. We do not benchmark schemes in alternative models such as the sublinear schemes that require streaming the database in the offline phase [86, 74, 35] or the RLWE-based schemes that require maintaining client-specific keys [4, 1, 3, 72, 67].

Experimental setup. We implement YPIR in 3000 lines of Rust, with a 1000 line C++ kernel for fast 32-bit matrix-multiplication adapted from the public SimplePIR implementation [43].[9] We use the approach from Section 4.1 to implement the server hint precomputation, and use the approach from Section 4.1 to speed up the LWE-to-RLWE packing transformation. As discussed in Remark 3.2, we compress the vectors $\mathbf{a}_1$ and $\mathbf{a}_2$ in the public parameters pp as well as the pseudorandom components of the packing key pk using the output of a stream cipher (ChaCha20 in counter mode). We benchmark YPIR against the public implementations of SimplePIR, DoublePIR [43] (commit `e9020b0`), the PIR scheme from Tiptoe [41] (commit `f053a81`), and HintlessPIR [55] (commit `4be2ae8`). When relevant, we compile each scheme with support for the Intel HEXL [11] acceleration library. We use an Amazon EC2 `r6i.16xlarge` instance running Ubuntu 22.04, with 64 vCPUs (Intel Xeon Platinum 8375C CPU @ 2.9 GHz) and 512 GB of RAM. We use the same (single-threaded)[10] benchmarking environment for all experiments, and compile all of the implementations using `GCC 11`. The processor supports the AVX2 and AVX-512 instruction sets, and we enable SIMD instruction set support for all schemes. We write KB, MB, and GB to denote 2^{10}, 2^{20}, and 2^{30} bytes, respectively. All of our runtime measurements are averaged from a minimum of 5 sample runs and have a standard deviation of at most 5%.

Server throughput. In Table 1, we report the different computational and communication costs for retrieving a 1-bit record from databases of varying sizes. We focus on single-bit retrieval since this is the setting of interest in private SCT auditing and provides a common baseline for comparing different schemes. Each YPIR response actually encodes an element of $\mathbb{Z}_N$ (for our parameters, each record is 8 bits long).

For small databases (e.g., 1 GB), the throughput of YPIR is 43% slower than SimplePIR and 26% slower than DoublePIR. This is because a significant portion of the query-processing time is spent on the LWE-to-RLWE transformation (30%; see Table 2). However, since the cost of this transformation is essentially *independent* of the size of the database, the throughput of YPIR quickly approaches that of DoublePIR as the size of database increases. With an 8 GB database, the throughput is 3–18% *faster* than the reference implementations of SimplePIR and DoublePIR and 79% of the memory bandwidth of the system. The efficiency gain over SimplePIR and DoublePIR is due both to a different choice of parameters in YPIR compared to the reference implementation [44] and to a more optimized implementation. To compare the schemes on an even footing, we include measurements against *our* implementation of these protocols (denoted SimplePIR* and DoublePIR*) with our lattice parameters. Compared to our SimplePIR* and DoublePIR* implementations, the throughput of YPIR on a 8 GB database is only 10% slower, and for a 32 GB database, only 1% slower. Thus, for moderate-size databases, YPIR achieves similar throughput to SimplePIR/DoublePIR *without* any offline hints. We provide more details in Fig. 2.

Compared to the Tiptoe approach [41], YPIR achieves 8–

[9] Our code is available at `https://github.com/menonsamir/ypir`.

[10] The primary computational cost in the SimplePIR-family of protocols (including YPIR and HintlessPIR) is computing a matrix-vector product. This is a highly parallelizable operation. However, for ease of comparison, we focus on a single-threaded execution in our evaluation.

Database	Metric	SimplePIR	DoublePIR	Tiptoe	HintlessPIR	YPIR

	Throughput	10.4 GB/s	9.9 GB/s	1.5 GB/s	6.4 GB/s	12.1 GB/s

Table 1: Communication and computation needed to retrieve a single bit for databases of varying sizes. For each scheme, we also measure the speed of the preprocessing algorithm ("Prep. Throughput") that the server must run upon each database update, and if applicable, the size of the hint that the client must download in the offline phase ("Off. Download"). The measurements for SimplePIR, DoublePIR, [43], Tiptoe [41], and HintlessPIR [55] are all obtained by running their *official* reference implementations on our test system [44, 42, 56]. We refer to the full version of this paper [68] for a direct comparison with *our* implementations of SimplePIR and DoublePIR (derived from the subprotocols of YPIR), which achieve higher throughput than the provided reference implementation.

19× higher throughput. This is because over 85% of the server processing time in Tiptoe is spent on the LWE-to-RLWE conversion algorithm (based on homomorphic decryption). In YPIR, for large databases, the LWE-to-RLWE packing is only 1–10% of the total server processing time (see Table 2).

Compared to HintlessPIR, YPIR achieves 2–6× higher server throughput. Notably, the HintlessPIR reference implementation peaks at 6.4 GB/s while YPIR peaks at 12.1 GB/s. One reason underlying this performance gap is because HintlessPIR applies the LWE-to-RLWE transformation to pack $O(\sqrt{N})$ encodings, where N is the number of records in the database. In contrast, YPIR only needs to pack a fixed number of LWE encodings (independent of the number of records). For a 32 GB database, HintlessPIR spends roughly 50% of its time performing packing (because it packs $O(\sqrt{N})$ encodings), whereas YPIR spends only 1% of its time packing.

Communication. Comparing the communication requirements of YPIR to hint-based schemes, the queries in YPIR are about 1.8–2.7× larger than DoublePIR and 3.5–7× larger than SimplePIR (with smaller overheads for larger databases). The larger queries are due to the key-switching matrices needed for the LWE-to-RLWE packing. On the flip side, the response size for YPIR is 2.7× *smaller* than DoublePIR and 10–60× smaller than SimplePIR. This is due to the better *rate* of RLWE encodings compared to LWE encodings, as well as the use of modulus switching in our implementation. The response size of YPIR and DoublePIR depend only on the lattice parameters and *not* the database size. If we look at total *online* communication (both upload and download), the cost of YPIR is only 1.8–3.6× larger compared to SimplePIR and 1.8–2.5× larger compared to DoublePIR. The key advantage, of course, is that YPIR does not require the client to download a hint. In the case of a 32 GB database, the size of the hint is 724 MB for SimplePIR and 16 MB for DoublePIR.

Compared to HintlessPIR, YPIR queries are 1.7–3× larger and responses are 125× smaller. The YPIR response size is significantly smaller because the HintlessPIR response size scales with the square root of the database size (like SimplePIR). On the other hand, YPIR queries are larger than in HintlessPIR due to needing more key-switching matrices for the LWE-to-RLWE packing. Compared to Tiptoe, YPIR has 13–39× smaller queries and 175–1417× smaller responses. The *total* communication cost for a issuing a single query for an 8 GB database is 1.5 MB for YPIR, 2 MB for HintlessPIR, and 42 MB for Tiptoe.

Preprocessing cost. Our NTT-based precomputation (Section 4.1) is about 10–15× faster than that of SimplePIR or DoublePIR and 8× faster than HintlessPIR. For a 32 GB

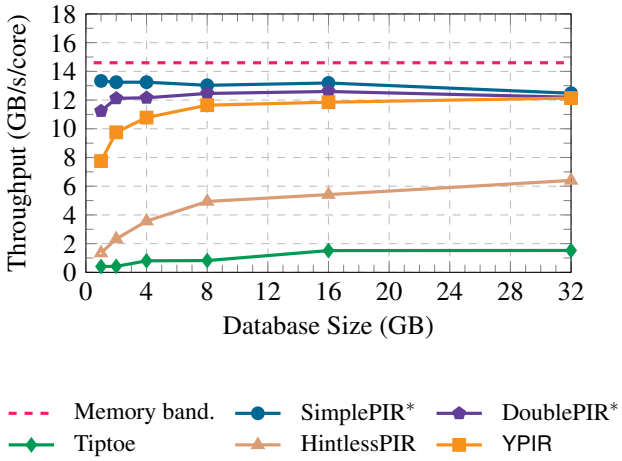

Figure 2: Server throughput for retrieving a single bit from different databases. For SimplePIR and DoublePIR, we report throughput using our reference implementation and parameter choices (denoted SimplePIR* and DoublePIR*), since these were faster than those of the reference implementation [44] in our test setup. For HintlessPIR [55], we report the bandwidth measured on our system with the reference implementation [56]. We measure the memory bandwidth of the system using STREAM [65].

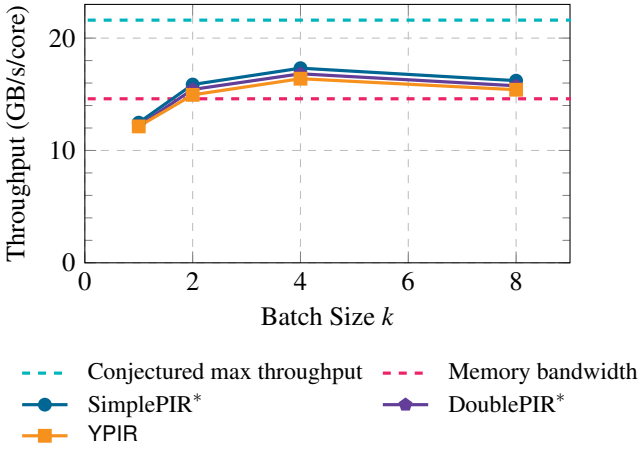

Figure 3: Effective per-query server throughput for retrieving a single bit from a 32 GB database with cross-client batching. As in Fig. 2, we use *our* implementation of SimplePIR and DoublePIR (i.e., SimplePIR* and DoublePIR*) for the comparisons. We measure the memory bandwidth of the system using STREAM [65]. We compute the conjectured maximum possible throughput for these schemes based on the assumption that processing each database byte requires a *minimum* of two 32-bit arithmetic operations and using the clocks-per-instruction values provided by the CPU vendor [45].

database, the offline precomputation of YPIR would take about 11 CPU-minutes, whereas for SimplePIR/DoublePIR, it would take roughly 144 CPU-minutes, and for HintlessPIR, it would take 95 CPU-minutes.

Server microbenchmarks. Table 2 provides a fine-grained breakdown of the server computation costs of YPIR (i.e., the Answer algorithm in Construction 3.1). First, we observe that the packing transformation essentially incurs a *fixed* cost to the server processing time. This is because the LWE-to-RLWE packing transformation in YPIR is applied to the DoublePIR responses, which does *not* scale with the size of the database. For small databases (e.g., 1 GB), the packing transformation represents 30% of the server processing time, but as the size of the database grows, the cost of the linear scan over the database (i.e., the SimplePIR step) dominates. With a 32 GB database, the packing transformation is only 1% of the overall cost of the server processing. In this case, the throughput of YPIR quickly approaches that of DoublePIR.

Size	SimplePIR	DoublePIR	Packing	Total
1 GB	0.07 s (59%)	14 ms (11%)	39 ms (30%)	0.13 s
4 GB	0.30 s (82%)	27 ms (7%)	38 ms (10%)	0.37 s
16 GB	1.21 s (93%)	57 ms (4%)	39 ms (3%)	1.31 s
32 GB	2.56 s (96%)	58 ms (2%)	39 ms (1%)	2.66 s

Table 2: Breakdown of YPIR server computation time for retrieving a single bit from databases of varying sizes. For each database size, we report the time spent in the SimplePIR step (Step 1), the DoublePIR step (Step 2), and the LWE-to-RLWE packing step (Step 3) for the Answer algorithm in Construction 3.1. In parentheses, we report the percentage of the total time spent on the associated step.

Query size breakdown. In Table 3, we provide a breakdown of the different components of the YPIR query. From Construction 3.1, the YPIR query consists of two sets of LWE encodings $\mathbf{c}_1, \mathbf{c}_2$ (that encode indicator vectors of the row and column of the desired database record) as well as the packing parameters pk (i.e., the key-switching matrices) for the LWE-to-RLWE packing transformation. The size of the packing parameters matrices are *fixed* (concretely, these are 462 KB), while the encodings of the indicator vectors for the row and the column scale with the number of rows and columns, respectively. In our experiments, the database is arranged as a square with an equal number of rows and columns. As such, the number of LWE encodings needed to encode the indicator vectors for the row ($\mathbf{c}_1$) and for the column ($\mathbf{c}_2$) are the same. However, we use larger parameters for the second set of encodings $\mathbf{c}_2$ (to support the LWE-to-RLWE packing transformation). As such, the encoding $\mathbf{c}_2$ is roughly $(\log q_2 / \log q_1) \approx 2\times$ larger than the encoding $\mathbf{c}_1$.

Cross-client batching. We modify SimplePIR, DoublePIR, and YPIR to support cross-client batching as described in Section 4.1. For a database of size ℓ, we define the effective

Database Size	$\lvert \mathbf{c}_1 \rvert$	$\lvert \mathbf{c}_2 \rvert$	$\lvert \mathsf{pk} \rvert$	Total Size
1 GB	128 KB (15%)	256 KB (30%)	462 KB (55%)	846 KB
4 GB	256 KB (21%)	512 KB (42%)	462 KB (38%)	1.2 MB
16 GB	512 KB (26%)	1.0 MB (51%)	462 KB (23%)	2.0 MB

Table 3: Breakdown of YPIR query size for retrieving a single bit from databases of varying sizes. Recall from Construction 3.1 that the query consists of three components: (1) the LWE encoding $\mathbf{c}_1$ of the row of interest (processed in the initial SimplePIR step), (2) the LWE encoding $\mathbf{c}_2$ of the column of interest (processed in the DoublePIR step), and (3) the key-switching parameters pk for the LWE-to-RLWE packing. We report the size of each of these components. In parenthesis, we report the percentage of the total query size associated with each component.

(per-query) server throughput to process a batch of k queries to be $k\ell/T$, where T is the time it takes to answer all k queries. We consider batch sizes ranging from $k = 1$ to $k = 8$ and measure the effective throughput of the scheme for retrieving a single bit from a 32 GB database in Fig. 3. In all cases, using cross-client batching increases the effective throughput by a factor of up to 1.4×. In the case of SimplePIR and DoublePIR, processing a batch of 4 queries yields a 1.4× improvement (an effective throughput of over 17 GB/s). This is higher than the *memory throughput* of the machine. With YPIR, the effective throughput for a batch size of 4 is over 16 GB/s, which is 1.3× larger than the single-query throughput. The gap in effective throughput between YPIR and SimplePIR widens as we increase k, since the fixed cost of the LWE-to-RLWE packing (see Table 2) does not benefit from cross-client batching. These results show that for setting where a server needs to process concurrent queries from different clients, it is advantageous to process them in a batch rather than sequentially, even though there is no reduction in the total number of arithmetic operations the server performs.

LWE-to-RLWE translation. Tiptoe [41], HintlessPIR [55], and YPIR all apply some form of LWE-to-RLWE translation to *compress* the SimplePIR/DoublePIR hints and eliminate the need for an offline hint download. Here, we provide a more detailed discussion of the different approaches.

Tiptoe and HintlessPIR rely on a bootstrapping-like approach where the client provides an RLWE encoding of the secret key in its query. The server then treats the LWE encodings in the SimplePIR hint as a vector of *plaintexts*. Then, using the RLWE encoding of the LWE secret key, it homomorphically evaluates the inner product between the encodings in the SimplePIR hint and the secret key. This yields an RLWE encoding of the desired database record. Since both of these approaches essentially implement homomorphic decryption, they set the *plaintext* modulus of the RLWE encoding scheme to be at least as large as the LWE encoding modulus. This results in needing to use a much larger RLWE encoding modulus to achieve correctness. For example, HintlessPIR uses a 90-bit RLWE modulus to implement this step (whereas the LWE encoding modulus in the SimplePIR hint is just 32 bits).

In contrast to the previous approaches, YPIR applies the Chen-Dai-Kim-Song packing transformation [21]. While this could also be viewed as a type of "bootstrapping" (since the transformation relies on key-switching, which is in some sense a homomorphic decryption operation), it does *not* require us to "re-encode" the LWE encodings under RLWE. Like most key-switching transformations, the Chen et al. transformation allows us to use the same modulus for the LWE encoding and for the RLWE encodings. Moreover, the noise introduced by key-switching is additive and is *not* scaled up by the magnitude of the LWE encoding modulus. A downside of this approach is that the LWE and RLWE encodings share a common modulus, so we cannot use a power-of-two modulus, as such moduli are not NTT-friendly.

	Tiptoe	HintlessPIR	Chen et al.

Table 4: Concrete costs of packing 2^{12} input LWE encodings into RLWE encodings using the Tiptoe [41], HintlessPIR [55], and the Chen et al. [21] approach used in YPIR. We report the lattice parameters for the input LWE encodings considered in each construction: n is the lattice dimension, q is the encoding modulus, and p is the plaintext modulus. We also report the size of the parameters the client must upload to the server, and the size of the output RLWE encodings. To normalize for the differences in the lattice parameters, we also report the rate (the ratio of the plaintext size in the packed encoding to the size of the encoding). Finally, we measure the offline and online server computation times. We report the Chen et al. packing approach with the preprocessing technique described in Section 4.1.

In Table 4, we provide microbenchmarks for packing 4096 LWE encodings (of dimension n) into RLWE encodings (of dimension $d \geq n$) using the different approaches. HintlessPIR has the smallest public parameters because it only requires a single key-switching matrix. The Chen et al. approach uses $\log d$ key-switching matrices. Tiptoe uses a separate RLWE

encoding for each component of the LWE secret, so its parameters have size $O(nd)$ and are concretely larger than both approaches. The size of the packed encodings is 7.5× smaller using our approach than HintlessPIR (and 21× smaller than Tiptoe). The reduction in size is because the Chen et al. approach can use a smaller RLWE modulus and ring dimension (concretely, a 56-bit modulus and $d = 2048$, compared to a 90-bit modulus and $d = 4096$ in HintlessPIR). We can also apply modulus reduction to further reduce the size of the encodings. If we factor in the different lattice parameters considered in each construction and focus on the rate (i.e., the ratio of the size of the plaintext in the packed encoding to the size of the packed encoding), the Chen et al. approach is over 15× higher than the approach from HintlessPIR. In terms of computation, the Chen et al. procedure with preprocessing is roughly 2.7× faster than the approach taken in HintlessPIR and 11× faster than the approach in Tiptoe.

4.3 Supporting Larger Records

The basic YPIR protocol is tailored for retrieving a single bit (or byte) from a database. To support larger database records, we consider a variant of YPIR where we apply the LWE-to-RLWE packing procedure to the SimplePIR output rather than the DoublePIR output. Recall that the SimplePIR output encodes an entire column of the database (as opposed to just a single record). Thus, the SimplePIR output is already naturally encoding a "large record." Note that this version of YPIR is similar to the approach taken in HintlessPIR, where they apply bootstrapping to pack the SimplePIR hint into a small number of RLWE encodings.

In Table 5, we compare the performance of our YPIR with SimplePIR (denoted YPIR+SP) approach with SimplePIR and HintlessPIR for retrieving large records from various databases. For sake of comparison, we consider the database configurations from [55]. Overall, YPIR with SimplePIR has a similar query size to HintlessPIR, but 7–14× smaller responses. As discussed in Section 4.2, HintlessPIR has larger responses because the bootstrapping approach requires it to embed the SimplePIR encoding modulus (32 bits) within the plaintext space of the output RLWE encodings. This leads to a much larger RLWE encoding modulus (and thus, response size). In contrast, the approach used by YPIR applies packing *directly* to the input LWE encodings, rather than treating them as plaintexts; this allows the RLWE ciphertext modulus to be the same as the LWE ciphertext modulus.

The throughput of YPIR+SP is similar to that of HintlessPIR, ranging from 1.8× faster for small databases, to 5% slower for large databases. YPIR is faster for small databases because it uses a lighterweight LWE-to-RLWE packing procedure (see Section 4.2 and Table 4). However, the conversion step is only applied to an input of size $O(\sqrt{N})$ whereas the SimplePIR step is applied to an input of size $O(N)$, where N is the size of the database. This makes the difference in overall throughput less substantial when N is large but noticeable when N is small. Because YPIR+SP performs packing directly on the result of the SimplePIR step, it uses an NTT-friendly modulus that is not a power-of-two in the SimplePIR step. This makes the SimplePIR step of YPIR+SP about 1.4× slower than the SimplePIR reference implementation. Since HintlessPIR can be directly applied to SimplePIR, it is able to achieve higher throughput than YPIR+SP when the database is large (e.g., HintlessPIR is 5% faster for a 32 GB database). Thus, for large databases with big records, YPIR+SP has substantially smaller total communication, but comes at a small reduction in throughput relative to HintlessPIR.

4.4 Application to Private SCT Auditing

Certificate Transparency (CT) [52, 53] is a standard for monitoring and auditing the issuance of digital certificates by maintaining a public append-only log of every certificate issued by every certificate authority. In this model, whenever a certificate authority (CA) issues a certificate, it also deposits the certificate into one or more CT logs. The log operator responds with a *signed certificate timestamp* (SCT). The SCT is embedded within the certificate and represents a commitment from the log operator to include the certificate in its log within a certain timeframe (e.g., typically 24 hours). Whenever a client receives a certificate with an embedded SCT, the client can verify the SCT with the log server to confirm that the server has indeed received the associated certificate. In turn, domain owners can check with log servers to obtain the certificates that have been issued for their domain, and identify any fraudulent certificates.

To defend against log operators falsifying SCTs (i.e., issuing an SCT but *not* depositing the certificate into the log), clients must regularly verify that (a subset of) the SCTs they receive from web servers are actually contained in the CT log. A naïve implementation of this would have the client simply reveal the SCTs they are auditing to the log operator, which in turn, reveals the client's browsing habits to the log operator. Several methods for privacy-preserving SCT auditing are based on matching hash prefixes [28] or accessing the log server via an anonymizing proxy [25], but these approaches do not provide formal cryptographic guarantees to privacy.

Private SCT auditing. Several works have proposed to use PIR for private SCT auditing [60, 48, 43]. In this work, we focus on the recent approach of Henzinger et al. [43] that leverages single-server PIR to construct a *private* SCT auditing protocol. In their approach, each log operator prepares a data structure (based on Bloom filters) representing the set of active SCTs in the log. To test whether a particular SCT is contained in the log, the client privately reads a single bit from this data structure using PIR.

To represent the set of 5 billion currently-active SCTs, the Henzinger et al. approach encodes the SCTs as a database of

Database	Metric	SimplePIR	HintlessPIR	YPIR+SP
$2^{15} \times 32$ **KB (1 GB)**	**Prep. Throughput**	3.7 MB/s	4.8 MB/s	63 MB/s

Table 5: Communication and computation needed to retrieve larger records from databases of varying configurations.

size 2^{36} bits (8 GB). Each SCT audit in turn corresponds to a single PIR query to this database. In [43], the underlying PIR protocol is instantiated using DoublePIR.

Cost of private SCT auditing. A limitation of using DoublePIR for private SCT auditing is the need to download (and store) the large hint. SCT databases are constantly updated, with roughly 10 million certificates issued each day [69]. To audit against the latest version of the log, the clients must first download the hint for the current log state.[11] To mitigate this, the approach in [43] is to have clients download the hints on a *weekly* basis and wait to test an SCT if its validity falls outside the time window associated with the current hint. While this reduces the protocol's communication costs, it also introduces delays in detecting malicious log behavior. The log server must also maintain multiple copies of the SCT database to support PIR queries for hints issued at different times.

A PIR scheme with silent preprocessing avoids these deployment issues. Following [43], we assume a client makes 10^4 TLS connections each week and performs two audits for a $1/1000$-fraction of connections (this is also the setting Chrome uses [28]). In Table 6, we report the monetary costs of the outbound communication[12] and the server computation based on current AWS pricing when instantiating the [43] approach with DoublePIR, Tiptoe, HintlessPIR, and YPIR.

When the client downloads weekly hints, the DoublePIR approach [43] has a weekly server cost of $1822 per 1 million clients. Over 80% of this cost is from clients downloading the 16 MB hint. If we consider daily updates,[13] and have clients audit the most recent version of the log, the weekly cost of DoublePIR balloons to $10,863 per 1 million clients.

A system based on YPIR would have a weekly cost of $228 per 1 million clients. This is 8× cheaper than using DoublePIR with *weekly* updates and over 48× cheaper than using DoublePIR with daily updates. Most of YPIR's costs are from server computation, not communication. If we apply cross-client batching with a queue of size 4, YPIR's estimated weekly server cost drops to just $183 per 1 million clients.

Scheme likes HintlessPIR, Tiptoe, and YPIR that do not require hints are unaffected by update frequency. The upload in YPIR is just 1.07× larger than HintlessPIR, and 23× smaller than Tiptoe. Since AWS only charges for *outgoing* communication, and Tiptoe and HintlessPIR have larger responses than YPIR, they have substantially higher AWS costs (84× and 16×, respectively). Overall, the total communication required by YPIR is 2× lower than HintlessPIR, 28× lower than Tiptoe, and 4.3× lower than DoublePIR with daily updates. In fact, YPIR's total communication with daily updates is *smaller* even compared to DoublePIR's total communication with *weekly* updates. So even if the client amortizes the DoublePIR hint across multiple queries over the course of the week, YPIR still achieves smaller end-to-end commu-

[11] Instead of downloading the full hint each time, the client could download an update instead. The size of the update scales roughly with the number of rows in the database that has changed. Since the bits of the database correspond to the bits of a Bloom filter, updates will typically occur in random positions. Since the number of insertions each day is significantly larger than the number of rows, the size of a daily hint update is comparable to the size of the entire hint.

[12] AWS only charges for *outbound* communication.

[13] Since SCTs are promises to include certificates in logs within a 24-hour period, the maximum useful frequency of database updates is daily.

	DoublePIR	DoublePIR	Tiptoe	HintlessPIR	YPIR
Update Frequency	*Weekly*	*Daily*	—	—	—
Offline Download	16 MB	112 MB	—	—	—
Upload	14 MB	14 MB	659 MB	27 MB	29 MB
Download	640 KB	640 KB	172 MB	34 MB	240 KB
Computation	16.90 s	16.90 s	194.96 s	32.40 s	13.74 s
Communication Cost	\$0.001569	\$0.010610	\$0.016215	\$0.003222	\$0.000022
Computation Cost	\$0.000253	\$0.000253	\$0.002924	\$0.000486	\$0.000206
Total Cost	\$0.001822	\$0.010863	\$0.019139	\$0.003708	\$0.000228

Table 6: Weekly server costs per client needed to support private SCT auditing using the PIR-based approach of Henzinger et al. [43]. Following [43, 28], we assume the client performs 20 SCT audits each week, where each audit corresponds to retrieving a single bit using a PIR query over an 8 GB database. For DoublePIR [43], the client needs to download a hint associated with the current state of the SCT database. We consider the setting where the client downloads the hint once each week and the case where the client downloads the hint (or a hint update) each day. The other schemes (Tiptoe [41], HintlessPIR [55] and YPIR) do not require hints. We measure the cost of running such a service based on current AWS costs: (\$0.09 per outbound GB and $\$1.5 \cdot 10^{-5}$/core-second; inbound communication is free) [43].

nication costs. Compared to the communication needed by Chrome's k-anonymity-based approach for private SCT auditing [28], (which does not provide cryptographic privacy), the communication requirement using YPIR is only 12.6× higher. Concretely, the *weekly* communication costs are 2.3 MB for the k-anonymity approach, and 29 MB for YPIR.

5 Related Work

Private information retrieval was first introduced in [23]. The original construction considered the multi-server model where the database is replicated across multiple (non-colluding) servers. The reliance on non-colluding servers enables lightweight constructions (based on symmetric cryptography or even no cryptography at all) [85, 31, 8, 36, 13, 40].

Kushilevitz and Ostrovsky [50] gave the first single-server PIR scheme based on additively homomorphic encryption. Subsequently, single-server PIR has been constructed from many number-theoretic assumptions [18, 34, 30, 20, 12]. Of particular note are the lattice-based constructions, which yield the most (concretely)-efficient constructions of single-server PIR [66, 5, 4, 33, 76, 3, 1, 72, 73, 67, 26, 43, 41, 55].

Reducing the computational cost of PIR. There are many techniques to reduce the computational burden of PIR. Batch PIR [9, 46, 38, 4, 73] allows a client to retrieve many elements from the database with low overhead relative to the cost of a single query. In *stateful PIR* [77, 49, 72, 63], the client retrieves *private* state from the server in an offline phase in order to reduce the cost of the online phase. Recently, several works have also shown how to construct single-server PIR protocols with amortized sublinear online computation [54, 74, 84, 86]. Notably, several of these constructions only rely on symmetric cryptography [74, 84, 86] and can plausibly handle queries to extremely large databases (on the order of hundreds of GB). However, these systems have the limitation that the client has to stream the *entire* database in the offline phase, which may be infeasible for large databases.

In *doubly-efficient PIR* [19, 14], the server locally preprocesses the database in a way that allows it to answer queries in sublinear time. Notably, no communication is needed in the offline phase. A recent breakthrough [58] gives a construction of doubly-efficient PIR from the RLWE assumption; however, the concrete costs of this protocol still seem too high to be practically viable for realistic database sizes [75].

PIR variations. A number of recent works have also sought to strengthen PIR to provide security in the presence of *malicious* servers [83, 10, 24, 29, 27]. Other extensions of PIR include retrieving records by keyword instead of index [22]; this case can be reduced to standard PIR [22, 3, 64, 78].

Acknowledgments. We thank Alexandra Henzinger for helpful pointers on the Tiptoe implementation, Baiyu Li for advice on parameter selection and benchmarking for HintlessPIR, and Kevin Yeo for suggestions related to keyword PIR. We thank the Usenix Security reviewers for their helpful comments. David J. Wu is supported in part by NSF CNS-2140975, CNS-2318701, a Microsoft Research Faculty Fellowship, a Google Research Scholar award, and a grant from Protocol Labs.

Abstract

Many online services deal with sensitive information such as credit card data, making those applications a prime target for adversaries, e.g., through Cross-Site Scripting (XSS) attacks. Moreover, Web applications nowadays deploy their functionality via client-side code to lower the server's load, require fewer page reloads, and allow Web applications to work even if the connection is interrupted. Given this paradigm shift of increasing complexity on the browser side, client-side security issues such as client-side XSS are getting more prominent these days. A solution already deployed in server-side applications of major companies like Google is to use type-safe data, where potentially attacker-controlled string data can never be output with sanitization. The newly introduced *Trusted Types* API offers an analogous solution for client-side XSS. With Trusted Types, the browser enforces that no input can be passed to an execution sink without being sanitized first. Thus, a developer's only remaining task – in theory – is to create a proper sanitizer. This study aims to uncover roadblocks that occur during the deployment of the mechanism and strategies on how developers can circumvent those problems by conducting a semi-structured interview, including a coding task with 13 real-world Web developers. Our work also identifies key weaknesses in the design and documentation of Trusted Types, which we urge the standardization body to incorporate before the Trusted Types becomes a standard.

1 Introduction

The effect of Cross-Site Scripting (XSS) and its mitigation techniques have been studied extensively in recent years. For more than two decades XSS has been present in the OWASP Top 10 Web Application Security Risks [44], showing that XSS is here to stay. While the server-side part of the problem already has proper mitigation techniques, such as type safety [27] or automatic encoding [14], client-side XSS lacks proper solutions. However, prior work [26, 39, 41, 55, 56, 57, 59] has shown that client-side XSS vulnerabilities are on the rise.

A common mitigation strategy for XSS is the usage of a Content Security Policy (CSP). However, prior work has already shown that deployment of this lacks behind [9, 50, 66, 67] and developers even are unaware of the differences between client- and server-side XSS when attempting to grasp the threat models covered by CSP [51]. Nevertheless, to transfer the concept of type safety to the client side, Google proposed the Trusted Types API [33], a new addition to CSP. With this mechanism, it is not possible to invoke dangerous JavaScript APIs without passing the input through sanitization functions that the developers need to specify themselves. However, at the point where the World Wide Web Consortium (W3C) has discussed shipping Trusted Types as a First Public Working Draft (FPWD) [16], browser vendors raised concerns. Specifically, they noted that the complexity of self-creating sanitization functions for HTML, JavaScript, and script URLs, may be too difficult for the majority of developers. However, the claim of the browser vendors lacks a scientific foundation because the actual usability of Trusted Types deployment has not yet been evaluated. Still, in December 2023, Mozilla changed their opinion on Trusted Types such that it now will become a Technical Specification [4]. A timeline of the events around TT is depicted in Table 4.

To close the research gap regarding TT's deployment process and provide valuable input in the ongoing standardization process, the objective of our work is to get insights into each step of the deployment process of Trusted Types and investigate the developer's knowledge about the underlying issue, namely client-side XSS. Therefore, we designed a qualitative interview study in a "bottom-up" approach [24] that includes a coding task where the participants deploy Trusted Types for a small Web application. Throughout our study, we evaluate the participant's knowledge of the different dimensions of XSS and their knowledge of existing mitigation techniques. In addition, our iterative study process allowed us to get fine-grained insights into all deployment steps, allowing us to evaluate the entire deployment process of Trusted Types.

Our work first presents a comprehensive qualitative interview study methodology to evaluate the usability of Trusted

Types (Section 3). With 13 participants, we were able to uncover important roadblocks of Trusted Types deployment, such as misconceptions introduced by information sources or problems caused by same-origin iframes (Section 4). Based on our findings, we discuss and propose strategies on how to successfully deploy Trusted Types, while highlighting the pitfalls developers might face. Also, we present general improvement suggestions for the Trusted Types standard, like the inheritance of Trusted Types sanitizers for same-origin iframes (Section 5). With the improvement suggestions, we want to ease the deployment process of Trusted Types and influence the W3C's standardization process. Also, we hope that the W3C and research community sees this work as a role model to test working drafts with real-world Web developers before releasing them and fully implementing them in browsers.

Availability. For transparency and reproducibility, we provide a full replication package [11], including our survey and coding task (incl. custom third parties) Web apps.

2 Background & Related Work

This section describes details about the underlying threat model of Trusted Types, the security mechanism itself, as well as a brief overview of qualitative methodologies used in usable security research.

2.1 Cross-Site Scripting

To protect the content of a Web page, the Same Origin Policy (SOP) ensures that only documents with the same origin [3], i.e., same protocol, hostname, and port, can access each other. Notably, if attackers manage to execute JavaScript in the origin of a vulnerable Web site, this script has the same capabilities as a script that is served legitimately by the page itself. Thus, the attacker's script can steal sessions or login credentials, impersonate user actions, or change the page content to distribute fake news. Since its initial discovery back in 1999 [48] numerous publications and blog posts investigated the different types of Cross-Site Scripting, such as XSS through content sniffing [47], client-side (also called *DOM-based*) XSS [29], universal XSS [23], self XSS [52], scriptless XSS [20], mutation-based XSS [21], same-origin method execution [19], gadget-based XSS [40], or persistent client-side XSS [57]. In general, however, XSS can either be persistently stored or only reflected per request, while the vulnerable code is either located on the server or the client side. The plethora of different types of XSS, as well as its omnipresence in annually published OWASP Top 10 Web Application Security Risks [44], shows that XSS is a problem that is still not solved nowadays.

2.1.1 Server-Side Cross-Site Scripting

The first discovered type of XSS flaw was server-side XSS [48], i.e., the vulnerable code is located on the server side. In this case, parts of the request, such as the URL parameters (reflected), or stored user content, such as profile descriptions (persistent), are mixed up with the developer-specified markup in the response. This way, an attacker can inject malicious markup such as *script* tags that are then delivered via the server of the vulnerable application, which causes the script to run in the context of this Web application.

Notably, server-side XSS can be mitigated or even defended against by enforcing type safety on the backend such that a string (or XSS payload) can never end up in a response unfiltered [27]. Also, many popular frameworks, such as the Python Django Framework, automatically encode, and thus sanitize, every string that is programmatically passed to the template rendering engine [14]. Thus, a developer needs to explicitly use the `mark_safe` method to cause a server-side XSS vulnerability. Also, academic solutions such as Noxes [28] can be used to prevent XSS. Noxes uses a set of rules to detect XSS attempts. For example, it requires user interaction for all dynamically crafted links to enable the user to make either temporary or permanent security decisions.

2.1.2 Client-Side Cross-Site Scripting

With the advent of more complex client-side JavaScript code, XSS vulnerabilities can also occur in vulnerable client-side code. Also here, an injection can happen either in a reflected fashion (e.g., by using data from the URL via `location.href`) or payloads can originate from a persistent client-side storage such as cookies or the `localStorage` API. Either way, the vulnerability is that the attacker code from these locations at some point ends up in a JavaScript sink that can execute code such as `innerHTML` or `eval`.

For reflected client-side XSS, multiple works [39, 41, 59] used a modified browsing engine to taint dangerous flows from a URL into executing sinks, to show that client-side XSS is a prevalent problem even in the top most visited Web applications. Steffens et al. [57] also used taint-tracking to show the prevalence of persistent client-side XSS vulnerabilities in the top 5,000 Web sites. They showed that 21% of the sites that make use of data originating from client-side storages are vulnerable to persistent client-side XSS.

2.2 Content Security Policy

A Web site's operator can also deploy a proper Content Security Policy header to mitigate XSS [68]. CSP allows the developer to specify the sources from which scripts can be loaded through the `script-src` directive. This way, even in the presence of an injection flaw, the attacker is limited to relying on scripts that are allowed by the developer. By default, CSP also forbids the usage of inline scripts, event handlers,

and the dreaded `eval` functionality. However, setting up a restrictive and functional CSP has shown to be a hard task due to third-party behavior [58], or the unusability [51] of the mechanisms itself. Over the years, numerous papers have shown that the vast majority of all policies in the wild are trivially bypassable [9, 50, 66, 67]. And even those policies that are considered meaningful can be bypassed via JSONP [66], script-gadgets [40], or open redirects [49].

While in theory, a perfect CSP would mitigate the effect of server- and client-side XSS attacks alike, such a policy is hard — if not impossible — to craft for real-world Web applications. In particular, for client-side code, sites often rely on third parties for important functionality such as maps or ads. However, as shown by Steffens et al. [58], these third parties often require the usage of, e.g., `eval`. However, with CSP, developers lack fine-grained per-party control over such features: they can only decide to either allow all executions of `eval`, which makes the application prone to client-side XSS if the string-to-code conversion happens with attacker-controlled input or to deny all string-to-code conversions, which results in the loss of functionality. While academic approaches to overcome this issue exist [43], these are limited in both functionality and security and lack deployment in the wild.

2.3 Trusted Types

Although the problem of client-side XSS and its prevalence in Web applications is well understood, a proper defense or mitigation technique is still missing. For example, Google engineers enforce type safety on the backend such that dangerous markup can never end up in the body of a response without explicit sanitization [27]. To transfer this defense idea to the client side, Google suggested Trusted Types [33] to filter values before they flow into dangerous JS sinks such as `eval` or `innerHTML`. To deploy Trusted Types, a developer needs to set the CSP's `require-trusted-types-for` directive to `'script'`, enabling the enforcement by the browser. In addition, they can provide a list of allowed sanitizer policy names through the `trusted-types` directive to control the number of sanitizers. Thus, enabling Trusted Types via the CSP header only requires a fixed header to be deployed and does not require additional configuration of the header.

In addition, as shown in Listing 1, the boilerplate code for registering a sanitizer is simple. The challenging part is to implement the actual functional yet secure sanitizers (here `sanitize{HTML,JS,URL}`). Because we want our participants to focus on the implementation of the sanitizers, and because our prestudy (see Section 3.5) showed that deploying the header is just a copy & paste task, we set the fixed header value for the participants in our main study. Notably, Klein et al. [30] have already investigated the quality of deployed HTML sanitizers in the wild and classified 88 sanitizers used on 102 different domains as bypassable and thus insecure,

```
window.TT = trustedTypes.createPolicy('default', {
    createHTML: rawHTML => sanitizeHTML(rawHTML),
    createScript: rawJS => sanitizeJS(rawJS),
    createScriptURL: url => sanitizeURL(url)
});
```

Listing 1: Trusted Types API example.

emphasizing the importance of focussing on the sanitizers. We want to extend this by investigating why developers fail to deploy sanitizers for HTML, JS, and URLs in order to reveal possible deployment roadblocks for TT. The results of Klein et al. [30] and several vulnerabilities in the wild caused by manually crafted and broken sanitization have shown that developers should rather use established sanitizer libraries instead of self-crafted sanitizers. However, in many cases, custom sanitization is the only viable approach for deploying TT. Ready-made sanitizers like DOMPurify [13] or the upcoming HTML Sanitizer API [5] can only remove all code. This lack of customization paired with the behavior of third parties to inject content that contains (inline) JavaScript [58] requires the developer to write custom sanitizer functions as TT requires them to allow the specific code from their third parties but disallow malicious code. Each site has unique requirements caused by the first- and third-party code it runs, requiring a TT sanitizer to be highly custom per site.

When enabled, Trusted Types enforces that *all* dangerous client-side APIs that might lead to code execution can only be used with a Trusted Types Object. To create those objects, the developer can explicitly call the corresponding Trusted Types sanitizer function, e.g., `TT.createHTML(input)`. Alternatively, they can define the special *default* policy, whose respective sanitizers are implicitly invoked by the browser when unsanitized data is passed to a dangerous sink. In a 2021 document, Kotowicz [32] reported on Google's success in deploying Trusted Types on 130 of their services. Furthermore, the report mentions that Google faced no client-side XSS in their Trusted Types protected applications. The report also mentioned that new tools and better framework support can ease the deployment. In fact, Wang et al. [65] showed how Trusted Types can be incorporated into Web frameworks such as AngularJS. Hence, Trusted Types seem to have the potential to be the panacea that client-side XSS requires.

2.4 Qualitative Methods

Given that we aim to explore the origins of behaviors and misconceptions of a new mechanism, we chose the "bottom-up" approach of a qualitative study design [24].

In the area of IT security, the qualitative analysis of semi-structured interviews was already used to better understand problems, misconceptions, and mindsets of developers [37, 51], users [22, 25], or administrators [36] of IT systems. Also qualitative analysis of online discussions about code in

different languages [12] or the usage of cryptography libraries [45], or an analysis of Rust-related Stack Overflow questions [69] have shed light on those problems.

While the qualitative analysis of interviews or online resources is suitable for exploring a topic and investigating concepts and trains of thought of participants on topics that they are already familiar with, the investigation of previously unknown scenarios needs a more controllable study setting, namely lab studies. Here, the researcher can adjust the settings of the study to observe if certain changes have possible effects on the investigated scenario. In order to get qualitative data out of those lab tasks, the participants can be asked to think aloud such that the process sheds light on, for example, the motivations behind certain decisions. For example, Acar et al. [1] conducted an online coding task to access the usability and security of cryptographic libraries. While Krombholz et al. [35] performed a lab study and interviews to assess challenges in deploying TLS, Tiefenau et al. [61] conducted a lab study to evaluate the usability and security benefits of using a semi-automated certificate generation for TLS, and Mindermann et al. [42] conducted a lab study to evaluate the usability of Crypto APIs in Rust.

To the best of our knowledge, the only other work that specifically tackled the challenges of deploying a client-side Web security mechanism has been conducted by Roth et al. [51]. They used a lab study to investigate the deployment process of a widely used security mechanism, namely CSP. They conducted remote coding interviews with twelve developers to find strategies, roadblocks, motivations, and misconceptions regarding CSP deployment through a rather artificial setting with an application intentionally containing CSP-hindering features. Instead of artificially increasing the task's complexity, we instead rely on the usage of real-world third parties to maximize the ecological validity of our results. Also, in contrast to the fully standardized CSP, Trusted Types is still a Working Draft. Thus, a usability evaluation of this new mechanism has the potential to improve the mechanism before its widespread deployment would cause breaking changes.

3 Methodology

A GitHub discussion [16] of the World Wide Web Consortium (W3C) showed that some browser vendors oppose the standardization and deployment of Trusted Types because they claim it is too complicated for the long tail of sites. Therefore, Trusted Types, as a new mechanism, is currently only supported by Chromium-based browsers (from version 83, May 2020) [10]. This work aims to uncover problems with the current version of the mechanism and evaluate its ease of deployment. This can aid the W3C to improve the mechanism to enable developers to mitigate client-side XSS attacks.

Due to the youth of the mechanism and its limited support in modern browsers, the adoption rate of the mechanism is negligible. Therefore, the targets for our study are not Web developers with experience with the mechanism, as it is nearly non-existent, but rather the average Web developer who might potentially use Trusted Types in the future. Together with them, we want to get detailed insights into the deployment process of Trusted Types from a controlled coding task. In this way, we can uncover roadblocks and develop deployment strategies for the mechanism.

Thus, our work has the following research goals: **(1)** What roadblocks do developers face when implementing Trusted Types sanitizers and which strategies do they apply? (Section 4), and **(2)** How can the standard and overall deployment process of Trusted Types be improved and what are the biggest challenges? (Section 5)

3.1 Recruitment and Participants

To maximize the ecological validity of our results, the target population for our study is real-world Web developers who have experience with the development and deployment of Web sites. Given that we want to study the deployability of Trusted Types for all sorts of Web applications and given that Trusted Types is not widely used by Web sites anyways, we not only considered professional Web developers but also non-professional Web developers, for example, students, as long as they mention prior Web development experience during the screening survey. Since Web developers are a hard-to-recruit population [51], we relied on a combination of different recruitment strategies to optimize outreach. First, we posted a recruitment flyer on our institution's social media channels. The flyer contains details and timelines of the study procedure as well as information about us and the compensation for the study [53]. In addition to that, multiple researchers from our team presented talks about Web security at multiple industry-focused developer conferences. Those talks included a call for participants for this study so that we could have direct contact and immediately answer questions from the Web developers who showed interest. Also, we used contacts of researchers of our institution to industry and asked those people to forward our recruitment Web site to their internal team chat or in their Web development communities. We also posted our call for participation on the platforms `freelancer.com` and `upwork.com` to also get hands-on Web developers who are not permanently employed in a development team. In general, irrespective of the recruitment procedure, we always mentioned that in addition to the monetary compensation of 50€, the participants could learn something about client-side XSS vulnerabilities and how they can mitigate this issue for their Web applications.

3.2 Screening Survey

To ensure a homogeneous set of participants who are all security aware and have sufficient experience in Web development, we conducted a screening questionnaire before inviting

selected participants to the actual interview. This survey included 12 fields, where ten were actual questions about the demographics of the participant, plus a field for the contact email address as well as a feedback/issue field for the survey. We developed the corresponding survey app ourselves and self-hosted it under a subdomain of our institution to ensure full and exclusive control over the data entered into the survey.

The landing page of the survey informs the participants about the approximate time required for the survey (1-2 minutes) and the number of questions. Furthermore, they are informed that all data will be treated confidentially and that we will at no point disclose their identities or the sites they operate. The page also includes information on who we are and the terms and conditions of participating in the survey. In the survey itself, the participants are asked to (optionally) provide age, gender, current occupation, highest education, country of living, and the size of the company that they are working at. In addition to that, we also ask questions about their experience in deploying or maintaining Web security mechanisms, their IT security background, the Web presence of their company, and questions regarding the development team. With that information, we are then able to better assess the participant's eligibility for the study. Notably, all of the input fields, except for the contact email, are optional.

After the survey, we manually check the eligibility of the participants, and in case of a positive evaluation, invite them to the actual interview via email. To be eligible, participants must be a non-bot user, and their occupation should be related to Web development or one of the other answers (e.g., "Do you have any experience in deploying or maintaining Web security mechanisms? If yes, which?") should show that they have experience as a Web operator. The email consists of a short reminder regarding the schedule for the interview process, a link to the interview scheduling system of the Nextcloud instance hosted by our institution, and information about the interview setup. To give the participants a comfortable environment, we offer them the option to use any video conference software that they want, as long as it allows for screen sharing for the coding task. We also offer them different ways of setting up the Web application for the coding task. They can either use a docker image provided by us, can directly execute the Python Django code, or can remotely control the interviewer's machine (e.g., via Zoom or TeamViewer) to conduct the coding task.

3.3 Interview

In the first few minutes of our interview, the researcher gives the participant an introduction to the timeline of our interview session. The interview is partitioned into questions regarding the participant's working environment, some questions about Web security, the coding task, and a debriefing. The question set about the working environment is to check the security and Web development background of the participant but also to get the chat between researcher and participant rolling.

After the general questions, we bring the conversation to XSS to answer our question regarding the understanding of this vulnerability and the differences between client- and server-side XSS. Therefore, we explicitly asked our participants if they could explain to us how the vulnerability happens and about the differences between client- and server-side XSS. Here, we also try to find out if the participant knows client-side execution sinks for XSS attacks. Next, we chat about Web security mechanisms that come into the mind of the participants when they want to defend against XSS, which then transitions into questions regarding Trusted Types and its method of operation. The question block is topped off with questions about the impression of Trusted Types and if they would use it in one of their Web applications. Then, the coding task is performed, which we explain in detail in Section 3.4. After the coding task, a set of debriefing questions will follow. Based on the recent interactions with the deployment of Trusted Types the impression of the mechanism might have changed, which is why we ask about the feasibility of Trusted Types as a defense mechanism against XSS. The last question that we ask is about improvement suggestions for Trusted Types, to assess which is the biggest problem that currently hinders the successful deployment of Trusted Types. Finally, the participant needs to fill out a System Usability Scale (SUS) [7] to assess the usability of deploying Trusted Types. The SUS questionnaire contained ten questions on a five-point Likert scale.

3.4 Coding Task

In our coding task, we ask the participants to deploy Trusted Types for a small Web application, while the main work in the case of the deployment process is the implementation of the sanitizer functions. The Web application itself uses features, libraries, and frameworks that are frequently used by real-world Web applications to increase the ecological validity of the data we gathered throughout the coding task. We explain details of how we chose those in Section 3.4.1. Notably, throughout the coding interviews, the functionality of the Web application had to be changed to ease the initial deployment process such that we could get more fine-grained insights into the later deployment steps, but also to lower the level of frustration of the participants because they could get nowhere near to a proper solution. Due to our usage of real-world third parties for a better ecological validity of our results, we also had changes in the functionality of the application that were not driven by us but by third parties that changed the way their libraries operate during our study. We explain the exact changes of this iterative interview process in detail in Section 4.2.

Third-Party Site (eTLD+1)	Inclusions (# Sites)
google-analytics.com	2,626
googletagmanager.com	2,329
gstatic.com	2,311
doubleclick.net	2,162
google.com	2,132
facebook.net	1,632
youtube.com	1,571
googleadservices.com	1,359
googleapis.com	1,233
twitter.com	988

Table 1: Top 10 third parties by inclusions

Framework	Usage (# Sites)
jQuery	1,005
Bootstrap	358
Dojo Toolkit	79
Vue.js	75
Angular	68
Backbone.js	19
Ember.js	1

Table 2: Usage of JS frameworks

3.4.1 Web Application

The Web application's backend is written in Python 3.10 using the Django Framework. For Trusted Types, the actual backend language is less important because of the main work, i.e., the Trusted Types sanitizer being implemented in JavaScript. Also, as Trusted Types is enforced on the client side, client-side technologies used by Web sites are more important for our demo application than the server-side technologies.

To gather data about the usage statistics of third-party JavaScript we crawled the Tranco Top 5k sites [38, 62] with a Chromium browser instrumented by puppeteer [18]. Our crawl also collected the URLs present on the loaded page and visited those up to two levels of links from the start page, while crawling at most 500 URLs per site. During a page load, we waited a maximum of 20 seconds for the load event to be fired and then an additional 5 seconds before we continue. During this time, we capture all loaded script URLs.

In Table 1, we show the top 10 sites, by the number of including sites, that were loaded during our crawl. The most requested site by far was `google-analytics.com`, with 2,626 sites that included scripts from it. Due to this prevalence of the service in real-world Web applications, our demo application also uses Google Analytics.

Advertisements, specifically those from `doubleclick.net`, were also used frequently (on 2,162 sites). However, showing real advertisements to our participants would put costs without benefits on those who ordered the advertisement. These costs would not only be problematic from an ethical point of view but could also make us accountable for ad fraud. Therefore, instead of just ignoring the prevalence of advertisements in real-world applications, we decided to create a custom advertisement service for the Web application. Notably, a Trusted Types policy consists of three sanitizer functions. Thus, our coding task should require the participants to implement all three sanitizers. No other third-party service that we included used `eval` conversion (which requires the createScript sanitizer), although Steffens et al. [58] showed that in 58.5% of the sites, their third parties mandate the usage of unsafe-eval in the sites CSP. To not lose this part of the deployment, we designed an ad service that uses `eval` to ensure a realistic setting even without including actual real-world ads.

The biggest player in terms of social media integration was `facebook.net`. The majority of those page loads (742/1,632) were inclusions of the script that includes their widget. This is why we also included this feature in our application. Notably, 336 of the sites that used the Facebook integration also used the Twitter widget at the same time, which is why we also incorporated the Twitter widget in our Web application.

Another common third-party service used in Web sites is the integration of maps. Because the most widely used service here (Google Maps) needed a domain name to properly use all features – yet we only used a local setup for our study – we had to use a different service that supported our use case. Therefore, we used `openstreetmap.org` as maps integration. In addition to that, we also showed a news blog that used the third-party comment system `disqus.com`. As we discuss in Section 3.5, we removed these after the pre-study.

To determine the most frequently used client-side frameworks, we investigate both the included URLs as well as the script content to detect libraries. Table 2 shows that jQuery is by far the most used framework with over 1k sites that use it. Notably, the intersection of those sites with those from the second most used framework (Bootstrap) shows that 62.8% (225/358) of the sites that are using Bootstrap are also using jQuery. Thus, we used a combination of Bootstrap and jQuery to build our Web application.

3.5 Pre-Study

To ensure that our coding task and its setup do not contain errors and can be solved, such that no participant is frustrated after the interview, we conducted a pre-study involving two participants (P1 & P2). Both worked for an IT company, one as a developer and the other one in their security incident response team. Notably, both took Web-related university courses. By selecting participants who are presumably less trained in deploying features for real-world Web sites, we want to find a lower bound for the scope of our coding task.

Given that neither of the participants of the pre-study was close to sufficiently deploying Trusted Types for the Web application, we decided to remove some features from the Web site to ease the deployment. We based the decision of which of the third parties to drop on the results presented in Table 1. Thus, we removed the subpages that use *maps* integration and the `disqus.com`. We also added code snippets in the coding task to speed up the deployment. The pre-study showed that participants copy-paste the CSP header that enables Trusted Types and the skeleton for the sanitizer functions from online resources. As mentioned in Section 2.3 the header has a fixed value and does not require sophisticated configuration. Thus, by adding them to the source code files, we put the focus on the challenging part, the creation of the sanitizer functions, and at the same time we reduce the setup time for the coding task. The pre-study also showed that our interview guideline (see Appendix A) was sufficient to answer our research questions. From the transcribed interviews we were able to learn more about the developer's mental model of XSS, especially client-side XSS, and uncover roadblocks as well as strategies for Trusted Types deployment. In addition to that, the interviews also shed light on the participant's perceptions of Trusted Types and motivations and disincentives to deploy it.

3.6 Data Analysis

For the analysis of the collected data, we used the GDPR-compliant online transcription service `amberscript.com`. Here we used the *Human-made* mode which ensures that the transcriptions are created by professional transcribers and captioners. The first author who conducted the study discussed interesting concepts that arose during interviews or coding tasks with the others. Based on these, the first author built the codebook iteratively, with a technology-centric lens of analysis in an open coding approach [60]. To better analyze the results of the coding task and not miss important information, the recordings of the shared screen during the coding task were also considered during the analysis. We continued conducting interviews and analyzing them until no new concepts were added to the codebook from the latest two interviews. After reaching our criteria for saturation of our dataset, the main author handed over three interviews with the saturated version of the codebook (see Replication Package [11]) to two other authors to calculate the inter-coder reliability of our results. We selected three interviews that provide the broadest coverage of codes. The average inter-coder reliability Krippendorff α [34] was 0.987. We assume the near-perfect score is due to our codes capturing technical concepts, which does not leave much room for interpretation.

To better evaluate the mindset of our participants and to get a better understanding of the occurring roadblocks and the strategies that the developer chooses, our codes are segmented into high-level categories and more detailed low-level information. If, for example, a participant struggled with Trusted Types deployment due to a programmatically added sourceless iframe, we assigned the code "Roadblock: Same-Origin Iframe", where *Roadblock* is our high-level category and *Same-Origin Iframe* the low-level description. Following the methodology of previous research [45, 51, 54] to identify emerging concepts, patterns, and themes, we analyzed our data using thematic analysis [6]. We then used axial coding [60] to find relations between those concepts and patterns. For example, we analyzed the connection between roadblocks and the applied strategy to explore which factors in the deployment process can lead to the success or failure of the deployment of Trusted Types.

3.7 Ethical Considerations

To the best of our knowledge, we designed our interview, the coding task, and the data collection process always with the risks and benefits for the participant in mind. The participants had the freedom of choice to use their own machine for the coding task or to remote control the interviewer's machine. While using their own device is closer to the participant's normal and familiar coding behavior, the required installation of Python and Django might be perceived as invasive. However, they could have used the Dockerfiles to create an easy-to-remove docker image that runs our code.

In case the participants used a browser on their own device to access the Web application, the current IP address of the user is leaked to third parties as the app performs requests to Google Analytics, Twitter, and Facebook. We decided to still use those real-world third parties to maximize the ecological validity of our results.

Also, our participants, especially those from the pre-study, may have become exceedingly frustrated when they, after 90 minutes, were not even close to a proper solution. This was one of the main reasons why we cut down some of the features of our application so that we do not leave behind a long-lasting bad feeling of working with Trusted Types or deploying security features.

As noted before, we used Amberscript to transcribe the audio of our interview sessions. Notably, we uploaded the audio (not the video) track to only reveal the necessary minimum to the service. Also, Amberscript is fully compliant with GDPR and advertises their service by guaranteeing full confidentiality, transparency, and non-disclosure agreements of all the transcribers [8]. In addition to that, all participants gave their electronic consent in the initial survey and again verbal consent to our data collection and processing methods at the beginning of the interview. All data (on our side and on Amberscript) was processed and stored in compliance with the General Data Protection Regulation (GDPR), and the entire methodology of our study and data collection processes have been approved by our Ethical Review Board (ERB).

4 Results

In this section, we present the results of our analysis, starting with the demographics of our participants. We then elaborate on the participant's mindset regarding the difference between client- and server-side XSS, highlight the different roadblocks that we investigated for Trusted Types deployment, and shed light on different deployment strategies and their success.

Without the pre-study participants, the average length of an interview was 01h 23min 09s (Median: 01:24:20, Min: 01:02:25, Max: 01:44:50). The first non-pre-study interview was conducted in July 2022, the last one in April 2023.

4.1 Participant Demographics & Background

Our main study population consisted of 13 participants (12 male + one female). Their age ranged from 20 to 50 years. Although we posted our call for participation on the platforms freelancer.com and upwork.com, we have not received any offers from users on those platforms. Therefore, all participants found out about our study either based on talks at industry conferences, social media channel postings (5 participants), or direct contacts who forwarded the recruitment flyer to their web development teams (8 participants). Our survey asked the age in intervals of ten, e.g., 30-40, to not be too privacy-invasive. Appendix B shows an overview of the demographics of all interview participants.

In total, the survey received 50 submissions, of which 28 were eligible and invited to the study. 13 answered our invitation emails or the reminders we sent after one week and later participated in the interview.

Three participants are working in an IT security field, e.g., an Incident Response Team, while one of them also considered themselves as casual Web developer because they created small Web applications, e.g., for personal use. Eleven are working as Web developers, where one of them also mentioned IT security as one of his work areas. Also, one of the Web developers is at the same time working in DevOps, which was also mentioned by one other participant.

Regarding security education, seven participants mentioned that they took security-related courses during their studies. The other six participants had taken courses or certificates for IT security but reported to have self-taught knowledge about the topic via videos and blog posts. Thus, we reached our target to conduct this study with a homogeneous set of participants who are security aware and familiar with Web development. We also had two participants who admitted that they were not educated in the area of Web security but only read a few articles about XSS.

During the chat about Trusted Types, eight participants stated that they had never heard about the mechanism before, while the others did not explicitly mention knowing (or not knowing) Trusted Types before participating in our study. We also asked the participants about their knowledge of XSS mitigation techniques. Here, seven participants mentioned CSP, ten mentioned proper sanitization and/or filtering of user-controlled input, and one considered Web Application Firewalls (WAF) a mitigation for XSS. Notably, many of the participants mentioned multiple mitigation techniques here, so our participants proved to be knowledgeable regarding the mitigation of XSS attacks.

4.2 Strategies & Roadblocks for Trusted Types

Based on the approaches that we had observed throughout the coding tasks, we created a workflow diagram (shown in Figure 1) that we use in this section to shed light on the different roadblocks that we investigated in the different deployment stages. We also explain in detail the changes in the Web application and the reasons for those changes. In addition to that, we discuss the implications of the decisions and strategies on the success of the deployment process. We mitigate bias by carefully introducing participants to the task, starting by explicitly telling them to act as if they were doing this in their company or for their own projects and that they can and should use any resources and libraries (see Appendix A).

Stage 1: Enforcement and Initial Deployment

Participants P3 & P4 deployed CSP very late, after writing at least one sanitizer such that they were overwhelmed by the number of errors that were caused. Also, participants P5 & P6 did not manage to deploy a CSP. To get deeper insights into the deployment process, we tried to ease this part of the process. Thus, we added commented-out boilerplate code to set a CSP header that enabled Trusted Types for scripts and enforced a *default* policy. Also, the participants were confused about using named policies, because one of the information sources recommended their usage.

> *"Is this the default policy? Because they had something written here, you should not always take the default, but tinker with the specific one."*
> – Participant 12

However, this is impossible for third-party code that is unaware of Trusted Types deployment since that would have to explicitly invoke the named sanitizer (rather than implicitly invoke the default one). Therefore, we added boilerplate code for a *default* Trusted Types policy, which simply returns the input without modifications for all sanitizers after P5.

With the new changes, participant P7 managed to deploy the CSP that enforces the default policy with a sanitizer, which simply returns its input and therefore does not add security. However, the enforcement of this default policy resulted in errors caused by Twitter's usage of source-less same-origin iframes for their timeline widget. Those kinds of iframes inherit the CSP policy that mandates the usage of Trusted Types, but they do not inherit the sanitizer functions. Requiring the usage of those functions without them being present then results in multiple errors. Notably, Twitter's behavior

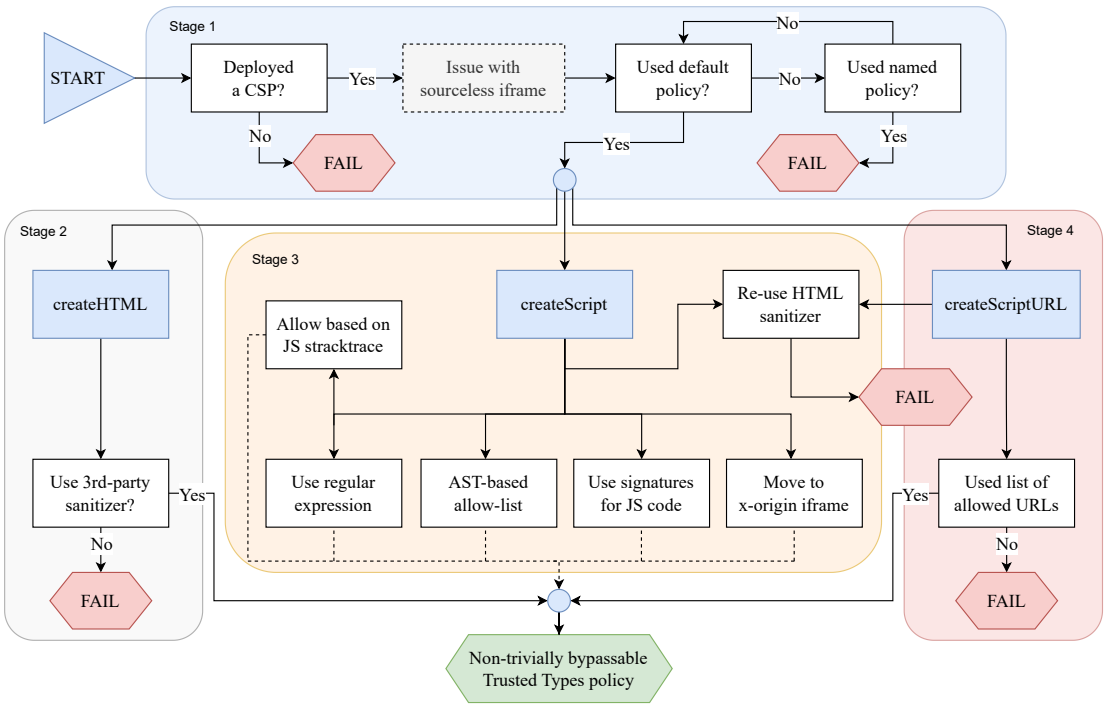

Figure 1: Diagram of the deployment workflow based on our participants.

regarding how the widget is built changed throughout the process of this study. To our question in the Twitter Community Hub [63], they acknowledged that this change is more of a usability/accessibility-driven change because the server-side rendering of the timeline is reducing the loading time of the widget rather than easing Trusted Types deployment.

Stage 2: HTML Sanitizer

All participants started with implementing the *createHTML* sanitizer. Participants P4, P7, P8, P11, and P12 used a third-party HTML sanitizer (DOMPurify [13]) to implement the *createHTML* function. Because none of the third parties that we used required the usage of adding JavaScript in any form into the DOM, this path led to a successful deployment of the *createHTML* sanitizer.

> *"There was also a library recommended here. If OWASP recommends DOMPurify, then I'll take it!"*
>
> – Participant 11

The other participants (P3, P5, P6, P9, P10) implemented the sanitizers themselves, which in all cases led to an easily bypassable filter. Most participants started by copy-pasting the example sanitizer from one of the information sources. This sanitizer, however, replaces all < with their HTML equivalent (`<`); thus, all inserted tags are destroyed, which causes Twitter and Facebook not to work anymore. Some of them (P6, P10) then changed this code to only remove `<script`. This is utterly insecure since an attacker can still inject an inline event handler (`<img src=foo onerror=alert(1)>`). Thus, in total, all custom sanitizers were trivially bypassable, so only seven out of 13 participants managed to implement a secure HTML sanitizer function for Trusted Types.

Stage 3: JS Sanitizer

Five of our participants (P4, P7 & P10-12) first reused their `createHTML` sanitizer to also sanitize JavaScript. Both the participant's custom HTML sanitizers as well as DOMPurify replace an opening HTML tag (<) with its encoded equivalent (`<`) or the empty string. The evaluated code from the custom advertisement widget contains the following snippet:

```
for (let i = 1; i <= 5; i++) { ... }
```

With the HTML sanitizer function, this code was therefore changed to, for example:

```
for (let i = 1; i &lt;= 5; i++) { ... }
```

Thus, the change causes a syntax error during the `eval` call. The participants that took this path needed quite a bit to notice this, as Chromium only pointed to the call of the `eval` for the syntax error. To find the root cause of the error, the developers were required to investigate how this functionality works in detail, determine the source of the evaluated source code, and compare it with the result of the sanitizer.

Those participants who did not re-use their `createHTML` and those who afterward changed their sanitizer due to the errors mentioned above mentioned diverse ways how to implement the `createScript` sanitizer. Participants 6, 8 & 13

mentioned that Regular Expressions could be used to differentiate between benign and attacker-controlled code. The possibility to base the `createScript` sanitizer on cryptographic signatures to only evaluate benign code was mentioned by participant 11. Another solution mentioned by two of our participants (P7 & P11), tried to circumvent the problem by moving the code that required the usage of eval into cross-origin iframes such that their execution context differs and Trusted Types are not inherited into the iframe. Participant 13 also mentioned the possibility of raising and catching a custom JavaScript Exception in order to use the stack trace of the JS execution to allow specific code snippets to run, while participant 10 thought about an allowlist-based on the Abstract Syntax Tree (AST) of the code snippet. We discuss the (in)feasibility of those sanitization approaches in Section 5.3.

Stage 4: URL Sanitizer

Also, here five participants re-used the HTML sanitizer, but because the URLs in our application did not contain any HTML characters, like $<$, they did not recognize that this might be an issue. The five participants that noticed or directly created a sanitizer themselves used an allowlist-based approach. Throughout that process, some participants noticed that the dynamically added URLs contained a changing string.

"It is a hash here. I could well imagine that it changes with every refresh or so."
– Participant 8

In those cases, the participants changed their implementation to an allowlist based on hostnames rather than URLs or used the `startsWith` function to check for the URL without considering the seemingly random string. As ignoring the URL path might lead to JSONP-based script executions [66] or open redirects [49] being possible, the `startsWith` or host-based allowlist is still trivially bypassable.

Notably, we also had three participants who gave up or ran into time issues during the implementation of the createScript sanitizer and did not implement the createScriptURL sanitizer.

Using AI for a solution:

During the introduction of the coding task, we mentioned that the participants could freely choose their information sources and that they could use anything during the coding task that they considered helpful. One participant used the AI-based GitHub Copilot to write the Trusted Types sanitizer functions.

"I could actually be quite bold here once and say: '// Generate Trusted Types using DOMPurify"'
– Participant 12

The generated code for the `createHTML` sanitizer was correct because it simply used DOMPurify (without actually importing it, though). However, the generated code for the other two sanitizers also used DOMPurify, which not only resulted in trivially bypassable sanitizers as the library is not designed to sanitize JavaScript code or URLs, but it also caused the ad feature of the application to not work anymore due to the reasons explained in Section 4.2. See Listing 2 for the entire output of the GitHub Copilot.

4.3 Client- vs. Server-side XSS

While eleven participants properly explained the concept of server-side XSS, only eight of those managed to describe client-side XSS and the difference between them. Notably, the participants who did not know the difference between the different XSS types failed to create a proper sanitizer as they, for example, tried to write a customized sanitization function.

"In the real world, if I wanted to protect against XSS attacks, I wouldn't just use JavaScript, I would use PHP, which has much more functions!"
– Participant 6

Those custom HTML sanitizers also ignored the fact that JS cannot only be executed by script tags but also via event handlers or URLs, as they only removed script tags but nothing else. Therefore, JavaScript URLs (URLs using the `javascript:` schema), or `onload`/`onerror` JavaScript handlers of, for example, HTML image tags, can be used to execute malicious code. Also, those participants spent quite some time creating those trivially bypassable filters and, therefore, did not manage to work on sanitizing JavaScript code or script URLs.

4.4 Perceptions on XSS and Trusted Types

From the seven participants that used third-party sanitization libraries to implement the `createHTML` sanitizer, four explained that they are doing this because self-created sanitization functions or custom security solutions, in general, are prone to be bypassable.

"Looks like a lot of manual work and gives the user many possibilities to do things wrong with this API"
– Participant 10

While this perception of sanitization seemingly pushed the participants into using proper sanitization libraries instead of creating a sanitizer themself, others might cause them to incautiously write dangerous code, as five participants mentioned that if you use common frameworks, XSS attacks cannot happen anymore or are at least mitigated by default.

"I don't know how all these frameworks, like React or something do that, that they don't have XSS."
– Participant 4

However, although React automatically escapes string variables in views if added to the DOM, there are still XSS vectors that are not secured per default. Despite the trivial exploitability if functions like `dangerouslySetInnerHTML` are present, it is also possible to execute JavaScript by setting `href` or `src` attributes of HTML tags to `javascript:` or `data:` URIs [46]. Even if frameworks would secure all first-party code,

the common practice in the Web to include third-party code, which might contain client-side XSS vulnerabilities, can still cause harm to the users of the Web application.

4.5 Usability Perspective

In total ten of our participants sent us the filled-out SUS survey. The highest SUS score was 80, the lowest 32.5, and the average was 58.75. The average score indicates that people rate Trusted Types as only marginally acceptable [2].

During the interviews, all participants mentioned that they see XSS as a big problem in modern Web applications. We also asked the participants before and after the coding task if they would use Trusted Types for one of their Web applications. Ten of the 13 participants rated TT more negatively after having completed the coding task. For five of those, the engineering effort of the deployment was the main concern. They especially mentioned that the deployment of Trusted Types into an existing application is hard due to existing code that needs to be restructured or third parties that need to be replaced. They claim that this would be considerably easier if security was considered from the planning phase of a project. Three participants explicitly mentioned this was a reason to only consider Trusted Types for private projects and that they would not use it in their company. Nearly all participants also explicitly mentioned the massive time and engineering effort in properly filtering or sanitizing JavaScript via the createScript sanitizer. This indicates that developers want to defend against XSS attacks; however, they think it requires time and engineering effort.

Key roadblocks for Trusted Types

Misconceptions about third-party sanitizers are causing disfunctional or bypassable sanitizers, as, e.g., HTML sanitizers are used for JS or URL sanitization.

As depicted in Stage 1, **Information Sources** provide misleading/superficial information, which is why, e.g., the choice between a **Named or Default policy** caused troubles during the deployment as only default policies work in real-world settings with third-parties.

Stage 2 of the deployment process reveals that **JavaScript sanitization** is hard up to impossible and requires heavy engineering effort.

5 Discussion

This section explains in detail some of the problems that our participants faced and discusses ways how those issues can be fixed or mitigated. Additionally, we discuss improvement suggestions that our participants mentioned after the coding task. Also, we discuss the limitations of this work at the end of this section.

5.1 Sourceless iframe Problem

CSP inheritance rules dictate that when a sourceless iframe (i.e., one without a `src` property) is encountered by the browser, the parent's CSP is enforced. This is necessary since, otherwise, an adversary could trivially bypass CSP's protection. In this scenario, assume an attacker capable of injecting markup into a page. They could then inject an iframe tag with a `srcdoc` attribute, which allows to specify the HTML (and thus JavaScript) rendered in the iframe. If now the parent's CSP would *not* be inherited, the attacker's code could run unimpaired in the origin of the parent's execution context.

For the first seven interviews, Twitter's timeline widget was loaded via a script that created a sourceless iframe, which then contains the requested timeline. This comes with a specific issue, which was identified and explicitly noted by one of the participants. Since the sourceless iframe is a different JavaScript context, none of the defined functions of the parent's document are available in the iframe. Since the actual sanitizers are implemented in JavaScript, this also means they are *not* present in the iframe. As a result, the iframe enforces the usage of a Trusted Types policy for which no default sanitizer exists, which, therefore, will result in errors and malfunction of the Twitter timeline widget.

One way for developers to fix this issue themself is to hook calls to all of the functions that can be used to append elements to the DOM (e.g., `insertBefore` or `appendChild`) and in case of an iframe being added directly inject the Trusted Types sanitizer into this frame (see Listing 3). We cannot hook the element creation of the iframe here as we can only script into iframes that are already added to the DOM. If now, however, code in these iframes again creates sourceless iframes, the problem will reoccur such that the JavaScript snippets that inject the sanitizers into added iframes need to be aware of their source code and inject themselves into the iframe such that all iframes are covered.

The above-mentioned solution can be solved through proper boilerplate code, yet developers should not have to deal with this issue in the first place. Instead, we propose that the standard be adjusted such that all registered sanitizers are passed on to sourceless iframes automatically. This way, the code in the iframe can make use of explicit sanitization through the named sanitizers, but more importantly, any code that is agnostic to Trusted Types still works as the default sanitizer is called implicitly. We note that if the iframe requires the usage of a *separate* sanitizer, it suffices for the main page's CSP to specify an allowed name for a sanitizer yet not register it. This way, the iframe's code can register and use the sanitizer with the previously unused name.

5.2 Standardized & Customizable Sanitization

Third-party sanitization libraries such as DOMPurify were used by seven of our participants. Notably, six of them then used this sanitizer for HTML content, also for JavaScript code and URLs, but three of them later noticed that this could not work. Thus, the initial misconception of DOMPurify as a general-purpose sanitizer was problematic. One participant also noted that leveraging a third-party library can be beneficial, yet requires this third-party sanitizer to be updated constantly in the face of potentially new variants of XSS.

"XSS attacks, they are always evolving. I'm not sure if Trusted Types can also keep up."
– Participant 6

Notably, the planned Web Sanitizer API [5] would fix those issues or at least shift the responsibility from the operators to the browser vendors' side. However, the Web Sanitizer API can only be used for `createHTML`, but not for `createScript`, as it can also only sanitize HTML content. Also, at the time of writing, the Web Sanitizer API is all-or-nothing – it can only remove all dangerous constructs but has no way to exempt certain scripts required by the page to function properly. While it might be feasible for the first party to update their code to not dynamically add script tags and hence be compliant with usage of the Web Sanitizer API, functionality of third parties depends on the coding practice of parties beyond the control of the site's developer.

5.3 Sanitizing JavaScript

As mentioned earlier, but also pointed out by our participants, the `createScript` sanitizer is the hardest part as it can neither be solved properly by an allowlist nor are there existing sanitization libraries or APIs for that task.

"createScript is another beast, because it checks the created JavaScript strings. Of course, it is difficult to ensure that this is valid at all, whether it is secure or not."
– Participant 8

Nevertheless, our participants mentioned or even implemented some ways how we might be able to sanitize or distinguish attacker code from benign code (see Section 4.2). During the implementation of the `createScript` sanitizer, participant 10 thought about an allowlist based on the Abstract Syntax Tree (AST). However, an attacker could then still create malicious JavaScript with the same AST [17] as the benign and allowed snippets and thus bypass the sanitizer.

Participant 11 mentioned that one way to allow specific scripts to be executed is signatures to ensure that the origin of that script is trusted. However, while this works for external resources under the control of the operator, it will only work for third-party scripts if the developer convinces this party to change their functionality to also sign the code that they deliver to the application.

Participants 6, 8 & 13 suggested Regular Expressions to only allow code with a certain pattern. Besides this only being maintainable at a small scale, it might be bypassable as attackers may be able to write their attacker code in the benign and allowed pattern.

"We can not insert a general-purpose sanitizer here now. Maybe Regex, but how efficient is that, then? And if-else stories about plain text comparisons of any script content is also kind of difficult."
– Participant 8

Notably, participant 13 mentioned the possibility to raise and catch exceptions in order to create an allowlist based on the caller of the function. This was also our sample solution (see Listing 4) for `createScript`. Here, we used the call stack to allow JavaScript execution from specific functions or parties via the stacktrace. While this might yield a functional solution, it shifts the trust to the third-party developer: if their JavaScript code has an exploitable XSS flaw, an adversary can simply exploit that to attack the including site.

Participants 7 & 11 mentioned that instead of somehow implementing the sanitizer, they would rather move the content that requires the usage of string-to-code conversion into an iframe that runs under a different origin. While this works for the third parties that we used, others will not work properly anymore as some advertisements require access to the Web page (including its DOM) [15]. Also, this solution is more of a compartmentalization than an actual sanitization, hence somewhat beside the point of Trusted Types.

5.4 Impact of Information Sources

The information sources at the time of writing focused on named policies rather than default policies. One of the information sources [31] suggested to "[u]se the default policy sparingly, and prefer refactoring the application to use regular policies instead". For four of our participants (P5, P5, P8 & P9), this suggestion caused problems as they first tried to use named policies and then later on noticed that they needed to implement a default policy anyway because they could not change the JS code provided by third parties.

"I found it difficult in the explanations how to handle own policies or how to set default policies."
– Participant 8

While the usage of named policies enables the developer to create sanitizer functions that are customized towards the data that flows into the respective sink, creating the policies and refactoring the code is work that should be done after having the default policy as a fallback, such that the developer is not overwhelmed by the number of errors. Thus, we argue that information sources should advertise the usage of a default policy as a first step and then the usage of named policies for certain parts of the application to harden the protection offered by Trusted Types.

"I could imagine, for example, would be to somehow outsource that into an iframe or something. So, to sandbox that, if I already have such a case. But that would be a completely different topic."
– Participant 11

Seven participants also complained about insufficient examples, especially for the usage of a default policy and the `createScript` and `createScriptURL` sanitizer functions. The examples on the information sources only contain explicit examples where strings are sanitized but only superficial examples of the sanitizers.

"In the examples here, there are just the strings that can be escaped and then appended, but I don't have any strings here to work with"
– Participant 3

The missing examples for the non-HTML sanitizer might be one of the reasons why seven participants initially used the examples for the `createHTML` sanitizer for all three sanitizers. Using the HTML sanitizer for JavaScript and URLs is not only insecure as it does not really sanitize anything for those strings but also leads to a loss of functionality depending on the third-party JavaScript code, as we have pointed out in Section 4.2. To ease the debugging process for code that is evaluated through string-to-code conversation, browser vendors might consider changing their error output for those functions to point to the evaluated string.

In general, our participants (P3, P5) mentioned that the information sources for Trusted Types only provide superficial information on the use case and the deployment process.

"Just with the half-hour now, I understood it much better than just in the article, and it makes complete sense to me now why I would use those."
– Participant 5

To improve the situation, we used our results to create an information source [11] with a roadmap for successful Trusted Types deployment with explanations and code examples for each of the individual deployment steps. We also plan to incorporate edge case examples, like the hook for dynamic iframe additions or an HTML parser that preserves specific event handlers.

5.5 Implications for the Trusted Types Design

Based on the roadblocks that we have seen and our participants' improvement suggestions and feedback, we elaborate on different implications for the design of Trusted Types in order to improve the mechanism.

One root cause of the roadblocks was that the information sources only provided superficial information about Trusted Types, such as only explaining the CSP header but not providing information about the sanitizers. But even in those cases where the information source tried to explain the sanitizers, participants noted insufficient or misleading examples. The focus on named policies, with the reason of a more explicit way of securing a Web application, misled participants to use only named policies, but not default ones, which resulted in the failure of third-party code. Thus, we recommended that Trusted Types need to have high-quality information sources with guidelines, examples, and detailed explanations.

Also, the rather technical problems of same-origin iframes or complicated workarounds to get more contextual information about the script execution can be at least eased by automating those workarounds. Given that the policies are registered using a centralized API call, it should be easy to automatically inherit all policies to same-origin iframes, such that those are not causing any issues anymore. In addition to that, the sanitizers could get an additional argument that gives contextual information, such as the call stack, that developers can then use to create an allowlist.

To further ease the creation of sanitizers, pre-configured sanitizing APIs, such as the planned Web Sanitizer API [5], should be provided. Notably, those APIs should provide the capability to allow specific inline scripts and/or events inside the injected HTML in order to enable the sanitization of third-party code. This could be done by either using code hashes or context information from the developer or, even better, the createHTML sanitizer could invoke the createScript sanitizer for inline script tags and inline events to not mix up the different steps, as suggested by participant 13.

Similar to CSP [51, 58], third-party scripts are also a big problem for the deployment of Trusted Types. It is hard to find a technical solution for this problem, which is why we argue that a political solution, e.g., by the W3C has to be elaborated to encourage third parties to be compliant with security mechanisms. One idea would be to have a warning icon similar to those for unencrypted connections if the Web site is not deploying properly configured security mechanisms. This way, companies would choose their partner services with care, and those that do not adhere to compliant coding styles will lose customers and, thus, revenue. Of course, this idea first should be tested and scientifically evaluated by us as a research community, e.g., by creating such a system in a study that follows a participatory design approach.

Key problems for each sanitizer

createHTML: As the example of DOMPurify and the Sanitizer API show, current libraries make it hard up to impossible to preserve JS code in HTML as they remove *all* existing JS code from the HTML.

createScript: There is (currently) no proper way of sanitizing JS code, as Stage 2 has shown that all sanitization ideas from the participants are bypassable. The only secure but hard-to-maintain solution would be using code hashes, which are hard to use here due to WebCrypto not being available in synchronous contexts.

createScriptURL: Randomness in URLs causes the use of startsWith (or RegEx), as shown by our participants. This, however, may cause bypasses through JSONP or Open Redirects.

5.6 Recommendations

This section provides a clear list of recommendations for all parties involved in the development or deployment of TT.

5.6.1 For Browser Vendors

(1) Ease the implementation of the HTML sanitizer, e.g., by introducing an allow list of not removed scripts or by calling the other sanitizers as soon as script tags or inline JS handlers are faced. **(2)** To get rid of the sourceless iframe problem, browsers could think about inheriting all registered TT sanitizers if a CSP containing the trusted-types keyword is inherited, which would also fix other security issues regarding TT and iframes [64].

5.6.2 For Developers

(1) Think about TT integration from the beginning of a project, as certain coding practices (e.g., sourceless iframes) make it hard to deploy TT. **(2)** Although named policies are more descriptive, developers should use default policies for existing projects such that they do not need to change the entire code base, but the sanitizer is automatically called.**(3)** As in the case of other CSP features [51], developers should, if possible, choose third parties with care as they might have behavior that makes it hard to deploy TT (e.g., injecting content with inline JS handlers).

5.6.3 For the Community

(1) As information sources and descriptions of sanitizers are causing misconceptions that lead to dysfunctional sanitizers, the security community needs to work on better materials to adhere to real-world scenarios. **(2)** The sanitization of JS code seems to be one of the biggest roadblocks for deploying TT. Here, we need to work on better tools and evaluate them to allow developers to easily distinguish between benign and malicious code.

5.7 Limitations

In addition to the expected limitations of self-reported data in interview studies (e.g., recall bias, social desirability bias), we acknowledge observer bias during the coding task. To mitigate this, we emphasized that we are not testing participants' knowledge or ability to deploy Trusted Types but are relying on their help to evaluate the header. Further, restricting the coding task to 90 minutes may limit how participants engage with Trusted Types. However, we argue that if a security mechanism needs massive engineering effort even for a small Web application, the deployment for complex Web applications in the wild will be challenging due to monetary and time constraints. Also, we acknowledge that supervised coding tasks in lab settings lead to lower ecological validity compared to field studies. In our analysis, the first author, who conducted the interviews, built the codebook iteratively after discussing interesting concepts from interviews with the other authors. Given that the first author might have missed concepts that arose during the interview that a second initial coder might have caught, the set of concepts described in this paper might not be exhaustive. However, with the final codebook, the second and third author codings were used to check for inter-coder reliability, and based on the final coding and codebook, all coders discussed possible themes such as deployment strategies and roadblocks. Last, we do not claim generalizability to the overall population of Web developers. We reached saturation with respect to high-level roadblocks participants encountered for the given Web application. However, we do not claim completeness with regard to low-level misconceptions that may be influenced by educational level or cultural background. Seven participants have an IT Security background, suggesting our sample is more educated than the general Web developer population. Thus, we position our results as a lower bound for problems that occur during the deployment of Trusted Types.

6 Conclusion

Our work presents the first qualitative study involving 13 real-world Web developers to evaluate the usability of Trusted Types deployment. With our qualitative interview study, and especially the coding task, we were able to uncover important roadblocks to Trusted Types deployment and the strategies that lead to successful sanitizers. Based on those, we elaborate on improvement suggestions for the mechanism so that we can ease the deployment of Trusted Types for developers. As the quality of the available information sources was one of the major problems that developers faced or mentioned during the study, we as a community need to work on better-quality information sources that need to contain examples and detailed explanations. In addition to that, technical issues like the inheritance of Trusted Types to same-origin iframes need to be fixed to ease the deployment of the mechanism.

Acknowledgments

We want to thank the reviewers for their feedback regarding our paper's presentation and all our participants for their time and insights that ultimately made this work possible.

A Interview Guideline

Introduction:

Hi $Name,
I'm Sebastian, first of all thank you for participating in our Interview such that we can improve the security and usability of Trusted Types. Also, please note that we want to find general strategies and roadblocks of Trusted Types, so we are not evaluating the correctness of your answers we only want to improve the security mechanism. We first start with few questions regarding your working environment and some Web topics. Those will take around 15 minutes, and if you don't want to answer a question, feel free to say it, and we'll skip it. Afterwards, we will do the coding task, where you are asked to implement Trusted Types sanitizers for a small Web application. We can offer you the App as a Docker, you can run the code directly on your machine, or you can remote control one of our machines. Which would be the option you prefer? Any other questions before we start?

General Questions:

- In your company, what is the specific area that you cover with your work? If you are in a team, what is your specific task in this team?
- Are you considering yourself a Web developer? If yes, since: ...
- Do you have an IT-Security background? If yes, please specify: ...
- Was Web Security part of your education? If yes, briefly outline the basic content / topics covered?
- How familiar are you with XSS? How did you learn about it?

Web Security Questions:

- How would you explain Cross-Side Scripting?
  - How does the vulnerability happen?
  - Client- vs. Server-side XSS?
  - Client-side execution sinks?
- What kind of Web security mechanisms come into your mind when you want to defend against XSS?
- In preparation for this study, you were asked to inform yourself about Trusted Types. Did you already know about this mechanism?
  - How have you found/searched for information?
  - Which Information Sources did you find?
  - How would you rate the quality of those sources?
- After reading the information sources: How would you explain Trusted Types?
  - How is it enforced?
  - How does it defend against XSS?
- What is you impression of TT at this point? Any concerns?
- Would you use Trusted Types for one of your Web applications?

Coding Task / Knowledge Validation:

Your task is to create Trusted Types sanitizers that defend the given Web application against client-side XSS. The application itself is written in python using the Django Framework. However, you do not need to know any details about Django as you only need to write the sanitizer in JavaScript. During the coding task, it would be awesome if you could think aloud about your decisions such that we can learn from them. Also, it would be nice if you could share your screen such that we can see the roadblocks that you face during deployment. Notably, you can develop just like you wish, so feel free to use any online resources, textbooks, and so on. So let's have a look into the source code...
As said, we are using the Python Django Framework. In `app/templates/*` are the HTML files that are used as templates for rendering the content. In `app/views.py` you can find the logic / implementation behind every endpoint. In `app/static/*` all static files such as JavaScripts that are used by the application are located. In `app/static/js/trusted-types.js` we already have boilerplate code for the sanitizers. Explain the TT code and ask "While I'm preparing the application/the docker is building think about this code and if **you would say this code already prevents some XSS attacks?**. Before starting, let's quickly take a look at the Front end.

Debriefing:

- What is you impression of TT after working with it?
- Do you think TTs are a feasible defense against XSS?
- What would have to change for you to use the mechanism? / What would an ideal mechanism look like for you?

Ending: Send the SUS, and the voucher form.

B Participant Demographics

Part.	Age	Gen.	CC	Edu.	Occupation
P1 (*pre*)	20-30	M	DE	-	Student
P2 (*pre*)	20-30	M	DE	-	Student
P3	20-30	M	DE	Master	Security Operator
P4	20-30	M	DE	Bachelor	Research Assistent

P13	20-30	M	DE	Bachelor	Freelance Developer
P14	20-30	M	DE	Master	Web-Developer
P15	20-30	F	DE	Master	Web-Developer

Table 3: Overview of the participants demographics.

C Additional Listings and Table

April 2010	Stamm et al. presented their work on a novel XSS mitigation, the Content Security Policy (CSP), at TheWebConf
November 2011	CSP becomes a First Public Working Draft by the WorldWideWeb Consortium (W3C).
since 2014	The research community extensively evaluated CSP and it became clear that for certain types of XSS, especially client-side XSS, it is not working.
15th Sep. 2017	Google engineers proposed Trusted Types as an addition to CSP to defend against client-side XSS.
19th May 2020	First full support for Trusted Types in the Chromium Engine.
06th Sep. 2021	Trusted Types support added to AngularJS by Wang et al. in the process of their IEEE EuroS&P Workshop paper.
17th Jun. 2021	Mozilla called a “Formal Objection” to TrustedTypes becoming a technical specification in the W3C.
06th Jul. 2021	Google published a Report on Google’s success in deploying Trusted Types on 130 of their services.
January 2022	Start with the design of the study followed by pre-tests and pre-studies for this work.
July 2022	The first interview with a non-pre-study participant has been conducted.
April 2023	The final interview has been conducted followed by a coding / evaluation process.
13th Dec. 2023	Mozilla change their standards position to *positive* such that Trusted Types can become standardized.
August 2024	This work is presented and published at the USENIX Security Symposium 2024.

Table 4: Timeline of Trusted Types (incl. this work)

```
// generate trusted types using dompurify
var trustedHTML = DOMPurify.sanitze(dirtyHTML,
↪ {RETURN_TRUSTED_TYPE: true});
var trustedScript = DOMPurify.sanitze(dirtyScript,
↪ {RETURN_TRUSTED_TYPE: true});
var trustedScriptURL = DOMPurify.sanitze(dirtyScriptURL,
↪ {RETURN_TRUSTED_TYPE: true});

// assign trusted types to DOM elements
document.getElementById('trustedHTML') .innerHTML =
↪ trustedHTML;
document.getElementById('trustedScript') .innerHTML =
↪ trustedScript;
document.getElementById('trustedScriptURL') .innerHTML =
↪ trustedScriptURL;

// assign trusted types to attributes
document.getElementById('trustedScriptURL') .src =
↪ trustedScriptURL;
document.getElementById('trustedScriptURL') .href =
↪ trustedScriptURL;
document.getElementById('trustedScriptURL') .onclick =
↪ trustedScriptURL;
```

Listing 2: GitHub Copilot output

```
let TTCode = `(${addTTFunc.toString()})();`;

let ogFunc = Node.prototype['appendChild'];
Node.prototype['appendChild'] = function () {
    let el = ogFunc.apply(this, arguments);
    if (el.tagName && el.tagName.toLowerCase() ===
    ↪ "iframe" && el.contentWindow) {
        let trusted = window.defaultPolicy
        ↪ .createScript(TTCode);
        el.contentWindow.eval(trusted);
    }
    return el;
};
```

Abstract

Virtual Private Networks (VPNs) are a crucial Privacy-Enhancing Technology (PET) leveraged by millions of users and catered by multiple VPN providers worldwide; thus, understanding the user preferences for the choice of VPN apps should be of importance and interest to the security community. To that end, prior studies looked into the usage, awareness and adoption of VPN users and the perceptions of providers. However, no study so far has looked into the user preferences and underlying reasons for switching among VPN providers and identified features that presumably enhance users' VPN experience. This work aims to bridge this gap and shed light on the underlying factors that drive existing users when they switch from one VPN to another. In this work, we analyzed over 1.3 million reviews from 20 leading VPN apps, identifying 1,305 explicit mentions and intents to switch. Our NLP-based analysis unveiled distinct clusters of factors motivating users to switch. An examination of 376 blogs from six popular VPN recommendation sites revealed biases in the content, and we found ignorance towards user preferences. We conclude by identifying the key implications of our work for different stakeholders. The data and code for this work is available at https://github.com/Mainack/switch-vpn-datacode-sec24.

1 Introduction

Virtual Private Networks (VPNs) are a Privacy Enhancing Technology (PET) that has become increasingly popular over the last two decades. With the advent of commercial VPN services, VPNs are adopted by millions of users [9]. Today, VPN usage ranges from accessing geo-restricted content to accessing the web securely through public wifi [1, 15].

Prior work looked into the end-user's awareness and usage of VPNs [43, 54]. They found that end-users have varied expectations from VPN services. People who are emotionally invested in protecting their privacy are generally resilient VPN users. Some users might expect that a VPN can help them access Netflix US while they are on vacation in China, and they may not care much about privacy, while others might want to use a VPN to securely connect to their offices, protecting them from potential privacy threats. Intuitively, this variation in expectation, combined with massive growth in the user base and ecosystem with multiple key players [17], provides users with the choice to use the VPN service that best caters to their needs. In fact, VPN users today have the obvious option of switching between VPN providers [1].

However, a user who is adopting a VPN and a user who is switching between VPN service providers are potentially different in terms of enhanced awareness resulting from previous VPN usage (and perhaps due to facing associated problems). Thus, recent work has reviewed and investigated the technical aspects of VPN infrastructure (e.g., for finding vulnerabilities) and the adoption of VPNs [43, 54]. However, it is unclear whether users switch between VPN providers and what are their key motivators (e.g., specific VPN usage preferences). This issue is further complicated due to the unclear impact of VPN-review websites on this VPN-switching behaviour. According to recent work, most of the users consider the VPN review blogs available online to choose from a large number of VPNs during VPN adoption [50]. These prior works also noted that these websites could be biased towards particular VPN service providers. However, it is unclear how these websites might cater to a more experienced VPN user who wants to switch between VPNs. This question of the requirements of existing VPN users and whether the current VPN apps and VPN review blogs cater to those desired preferences has serious implications for VPN providers, VPN-review blogs, and the general research community. Unfortunately, there is not much work focusing on understanding end-users' behaviour and preferences regarding VPN switching. Thus, in this work, we fill this gap and investigate VPN-switching behaviour and

An extended version of this paper that includes the appendices is available for interested readers at arXiv. All references to Appendix in this paper refers to the Appendix included in that arXiv version.

[1] Since VPNs are often used as applications (or apps), in this work, we use VPN, VPN-provider and VPN-app interchangeably.

preferences of end-users in the wild.

We focus on mobile VPN apps (due to the ubiquity of smartphones and additional metadata like reviews and # downloads provided by the app stores). We systematically selected 20 popular VPN apps on the Android and iOS platforms. Then, we collected 1,333,160 user-generated reviews for these apps from the Google Play Store and Apple App Store. Next, we created a systematic keyword search, manual labelling and automated text-classification-driven approach[2] to identify 185,399 reviews where users intended to switch between VPN providers (often with reason). Next, we took a deep dive into the why question—our in-depth qualitative analysis of these reviews uncovered a hierarchy of reasons for VPN-switching—we synthesized these reasons into the most desirable and undesirable properties of VPNs as indicated by users in the wild. Furthermore, we demonstrate that these reasons for VPN switching have interesting differences from prior work on VPN adoption reasons. Finally, we collected 376 VPN-review blogs and checked in detail if they potentially covered user-desired features of VPNs during switching. Specifically, we answer five key research questions.

RQ1 *Do users switch between VPNs? Is the switching uniform across different VPN providers?*

RQ2 *What are the key reasons driving VPN-switching?*

RQ3 *Are the features desired during VPN-switching, by existing VPN users, different from features desired during VPN adoption?*

RQ4 *What are the concrete features desired by users during VPN-switching?*

RQ5 *Does information by VPN review websites align with desired requirements of users during switching VPNs?*

During our endeavour to answer the above-listed questions, we found that VPN switching is a very common phenomenon among users, and there is a clear hierarchy of factors that primarily contribute to user switching between VPNs. We also found that users have different preferences while *choosing* VPNs vs. *switching* between VPNs. This can be clearly attributed to the fact that with the usage of VPN, users' expectations and requirements change, and hence, the factors they consider. Thus, we tried to enlist and group users based on factors they primarily consider while deciding to switch VPNs. Finally, to complete the study of user switching, we looked into primary sources which users refer to aid in their VPN switching decisions, i.e. VPN recommendation blogs and found that there are multiple ways in which VPN review websites fail to address the themes which are most relevant to users when switching between VPNs. In line with earlier literature, we also found that these websites show bias towards particular VPN providers and misguide the users in their search for the right VPN service (Section 10).

[2]The dataset and code for this work can be found at https://github.com/Mainack/switch-vpn-datacode-sec24.

Limitations. One of our study's key limitations is the potential of our approach to miss users who indeed switched VPNs but did not write a review. Furthermore, we used keyword search to identify reviews relevant to user switching context for manual analysis, but during this, we will miss some reviews due to the limited number of VPN names used as keywords and not using terms like "switching" for the search, as that might lead to a large number of false positives making the manual process more tedious. However, this limitation won't affect the results significantly since we added ML models in the pipeline to further identify relevant reviews. However, some inaccuracy is associated with models used to identify potential VPN-switching reviews and themes mentioned in any review. We have tried to reduce this error through hyperparameter tuning and model selection. We also established the correctness and suitability of our VPN-switching review dataset with additional manual analysis. We also acknowledge that ML models used for the identification of themes in reviews will not be able to identify new themes, but thematic saturation attained during thematic analysis suggests that there will be a very small number of such unidentified themes and potentially have a small impact on the validity of presented results. Furthermore, we did not conduct a survey—rather, we preferred collecting and analysing an ecologically valid dataset posted by users of their own volition. However, this limitation of data also indicates that our reported results are a lower bound on the identified reasons. Another limitation is posed by fake reviews on the App Store or Play Store, but as indicated in [48], the fraction of such reviews is too small to impact our results. Yet another limitation is that we will miss the users who only used desktop VPN apps.

We uncovered interesting and potentially generalizable reasons for VPN-switching using our ecologically valid dataset despite these limitations. We also acknowledge the lack of generalizability of results associated with review blogging websites, as we have only considered 6 popular websites, but since these are top recommendation websites used by users, the results are still relevant. In fact, our blog post analysis results might be impacted by SEO techniques employed by VPN recommendation websites [60], but we still used these blogs as a data source since a regular user looking for VPN recommendation will also be subject to these SEO techniques and hence, will see these same websites.

Ethical considerations. In this work, we collected data from the Google Play and Apple App Store and conducted a qualitative (thematic) analysis of these reviews. Since we analysed user-generated data from the wild, we tried our best to conduct our study ethically and protect users' privacy in our dataset. Our Institute does not have a formal IRB, so we carefully reviewed and followed best ethical practices while conducting this study. In line with earlier work, we noted that no registration was necessary to view App Store or Google Play store reviews [16], signifying it's an open forum. Our analyzed reviews did not divulge any personally identifiable

information. Also, as advised by earlier work to protect user privacy, we further hashed user names (thus anonymizing them) in our dataset to protect user privacy [10].

Next, we discuss related work regarding adopting and using VPN apps. Then, in section 3, we discuss our methodology involved in the collection and filtering of data, followed by details of thematic analysis (Section 4). Section 7 describes the results of our thematic analysis, and Section 8 compares desired features during VPN-switching and VPN adaptation. Section 9 describes the in-depth set of desirable features expressed by users during VPN-switching. Section 10 describes our analysis of VPN review websites. We discuss the implications in Section 12 and conclude in Section 13.

2 Related Work

We discuss related work on the user-centric view of VPNs in two broad directions.

Prior research of VPN awareness and usage. Virtual Private Network (VPN) has been studied rigorously by prior research because of their vital role as Privacy Enhancing Technology (PET) and for other purposes like censorship circumvention, bypassing geo-blocking, etc. Most studies have focused on people's awareness about the existence/usage of VPN [5, 29, 33] and on security-related concerns associated with VPN like anonymization, DNS leaks, etc [7,28,31,32,46]. A recent study by Dutkowska-Zuk et al. [14] conducted a study of 349 university students. They found that the students were mainly motivated to use VPNs to access restricted content rather than privacy. These studies about awareness and usage of VPNs were conducted through interviews [5] and surveys [29] while later were studied either by developing a pipeline for testing VPN apps [46] or by installing the app on a target device and then running tests on it [58] (an inherently invasive approach). Our study is complementary to this prior research as we focus on existing VPN users and identify their desired VPN characteristics that resulted in VPN-switching. Furthermore, contrary to the prior studies, we did not leverage user interviews or surveys [29]. Rather, we leveraged app reviews of popular VPN apps from the Google Play and Apple App stores, where users organically present their opinions and attitudes without researcher intervention, enhancing the ecological validity of results.

Prior research of VPN adoption. On the user side, data leaks, geoblocking services and awareness of privacy risks gave way to the wide adoption of VPNs [40]. Namara et al. [43] conducted a study about the adoption and usage of VPN apps and the barriers users encountered towards their adoption. Their survey of 90 participants found users' emotional reasons to adopt VPNs—like surveillance or desire for privacy. A closely related study by Sombatruang et al. [54] checked factors influencing users' decision to adopt a particular VPN application. They found user review ratings and pricing significantly affected the user's decision to choose a specific VPN app. Their results align with ours, with financial incentives and user reviews also playing a role in users' VPN-switching decisions. However, other factors like Geographic location and interaction of the VPN providers with users also played a significant role in our case. Overall, our work is complementary to these earlier studies. They investigated why users adopt VPNs. On the other hand, our study we investigated what factors motivate users of a current VPN app to switch to another VPN app. In fact, we demonstrate that these users seek more advanced and customized features than those uncovered in previous work. Our work also builds upon work by Ramesh et al. [50], which conducted end-user surveys and interviews with VPN service providers. They investigated users' dependence on VPN review websites for selecting VPNs and how these websites are not good sources of information. In that line, we unearth underlying reasons for VPN-switching and investigate VPN service recommendation websites to find the misalignment of user requirements and content provided by these websites. Next, we present our semi-automated approach of creating a review dataset mentioning VPN-switching in the wild.

3 Collecting VPN App Reviews Corresponding to VPN Service Switching

Our study's first step was collecting app reviews of the most popular VPN apps. To that end, we turn our attention towards the Google Play Store and Apple App Store, which host all available VPN mobile apps for the Android and iOS platforms, respectively and also contain a user review section where users post their perceptions and attitudes towards these apps. This section describes the stages associated with collecting and filtering reviews in detail.

3.1 Collecting reviews for popular VPN apps

Selecting VPN apps. We started with Google Play Store and we first searched for "VPN" in app stores. However, the search results repeatedly contained the same VPN providers (e.g., VPN app, VPN-enabled browser app, lite versions). On the contrary, searching for "best VPN 2023" gave the most popular versions of individual apps. So, we searched for "best VPN 2023" and noted the top 50 VPN apps (in terms of downloads) which appeared in the search results. To ensure the diversity of the user base of VPN apps, We bucketed these apps by their number of downloads into 5 buckets—50K to 100K, 100K to 500K, 500K to 1M, 1M to 5M and 5M to 100M or more. and in order to study the variation of VPN-switching with popularity, instead of checking only top VPNs, we did stratified sampling from popularity buckets and ended up with 20 VPNs; they are—Hotspot Shield, Nord, Express, Vypr, Freedome, Tunnelbear, Windscribe, HideMyAss, Surfshark,

Surfeasy, VPN Unlimited, Zenmate, Proton, Hola, Cyberghost, IP Vanish, Strong VPN, Private Internet Access (PIA), Super VPN, Turbo VPN. To further test the popularity of these VPN apps, we compiled a list of the most discussed VPNs from VPN market report statistics [42, 59]—our set of 20 VPNs have a 75% overlap with this list.

Collecting reviews for the VPN apps. We used open-source tools to collect public reviews written in English (for simplifying analysis) from the Google Play store and Apple app store [37, 47]. In total, we collected 1,333,160 unique reviews during our data collection. The selected VPN apps, the number of downloads on Google Play Store and the number of reviews (on both platforms) are in Table 7 (Appendix A).

3.2 Identifying reviews mentioning VPN-switching

First, we pre-processed the review dataset (to retain only meaningful ones) and then used a simple heuristic to identify reviews explicitly revealing VPN app-switching.

Table 1: Number of VPN app reviews identified after our preprocessing step and application of heuristic.

Number of VPNs used	20
#reviews	1,333,160
#reviews with #words > 5	411,751
#reviews containing multiple VPN names	4,403

Pre-processing reviews. Guzman et al. [21] shows that short reviews are often non-informative and contain praise or dispraise without reason. Thus, we removed all reviews with fewer than five words to retain only meaningful reviews. Finally, we ended up with 266,895 reviews from the Google Play Store and 144,856 reviews from the Apple App Store.

Detecting reviews possibly mentioning VPN-switch. Note that most of the 411,751 reviews are likely written about a particular VPN app. To that end, to uncover potential reviews, we used a simple idea: *the reviews that contain names of multiple VPNs might indicate that the user is comparing them*. Thus, they might have used or considered using both apps (signalling switching). We leverage this idea to filter the reviews via a simple keyword search—we extracted keywords from each VPN app name (Table 9 of Appendix B contains the full list of keywords) identified reviews with keywords from multiple VPN apps. We identified 4,403 such reviews. Table 1 summarizes the number of VPN app reviews at each step of our process.

Manual analysis to create final review dataset mentioning VPN-switch. Since mentioning multiple VPN app names might not be enough to actually mention VPN-switching, at this point, we resorted to manual analysis. We randomly sampled 1,600 reviews out of these 4,403, and one researcher manually reviewed each of these reviews to classify the reviews into three categories—Actual switch, Potential Switch and Irrelevant. For *Actual switch* reviews, a user explicitly mentioned that they switched between VPNs. For example, P661 mentioned *"I left [VPN1] for these guys! [VPN1] was slow.. and i mean slow... tried [VPN2]...and never looked back. love the speed and security!!"*. P2496 also mentioned *" Not able to connect to campus from dubai... bye to incompetent customer team.."*. In *potential switch* reviews, users showed intent of switching by comparing two VPNs but did not confirm switching VPN providers (however, we consider that if these users switched, they would switch from the VPN, which they are talking negatively about in the review). This comparison can be there without mention of a second VPN; for example, P1459 mentioned *"This is so stupit vpn I'll connect from Pakistan... unable to Netflix... frnds able to watch!! useless!!"*. Irrelevant reviews are the ones that neither compared multiple VPNs nor mentioned switching. Out of 1,600 reviews, 1,305 (81.3%) indicated either an actual or potential switch. To check the correctness of annotation, we randomly sampled 100 reviews out of 1600 reviews and had them re-annotated by another independent annotator, and found Cohen Kappa between these two annotations to be 0.74, indicating a substantial agreement. Table 2 summarizes the number of reviews in each category as well as the average number of words and characters for each of these types of reviews. Interestingly, both the actual and potential reviews have a considerably higher number of words and characters than the irrelevant reviews. This observation hints that users provide detailed and potentially better explanations in actual-switch and potential-switch reviews. Next, we perform a multi-stage qualitative analysis to identify the reasons for VPN-switching revealed in these 1,305 reviews.

Table 2: #reviews stating Actual switch, potential switch and neither (irrelevant) after our manual analysis of reviews mentioning multiple VPN app names.

Review type	**# Reviews**	**#words**		**#characters**	
		Avg.	s.d	Avg.	s.d
Actual switch	454	59.6	45.8	318.7	206.1
Potential switch	851	47.8	38.2	257.9	209.1
Irrelevant	295	25.3	39.1	132.8	203.2

4 Identifying Reasons of VPN-switching Using Qualitative Analysis

We leveraged our dataset of 1,305 VPN-switching reviews to investigate the reasons for VPN-switching via qualitative analysis. To that end, two researchers together extracted explanatory quotes from these 1,305 reviews—in total, there were 2,808 final quotes for our analysis, which at least one researcher deemed explanatory for VPN-switching. Next, we use open coding and affinity diagram [53] to develop a hierarchy of themes explaining reasons for VPN-switching.

Table 3: First three levels of our hierarchical themes explaining the reasons for switching VPNs.

A Network	B.5 Deciet	F.1.1 Payment medium
A.1 Network speed	B.5.1 Removal of app reviews	F.1.2 Subscription options
A.1.1 Network speed	B.5.2 Financial Fraud	F.2 Price of VPN
A.1.2 Ping value	B.5.3 False claims	F.3 Refund
A.2 Server count	B.5.4 User data usage	F.4 Premium version of app
A.3 Server switching	B.6 Reliability	F.5 Free version of app
A.3.1 Ease of switching server	B.7 Reputation	G Dynamic data services
A.3.2 Manual switching required	B.7.1 Branding	G.1 OTT
A.3.3 Issues with server selection	B.7.2 Online reviews	G.2 Games
A.3.4 Issues with country selection	B.7.3 History	G.3 Ads
A.4 Network Protocol	C Connection	G.4 Streaming
A.4.1 Port forwarding	C.1 Connection speed	H Software
A.4.2 Support for IPv6	C.2 Connection stability	H.1 Updates
A.4.3 Wireguard	C.3 Split tunneling	H.2 Features
A.4.4 Issues with TCP/UDP	C.4 Ease of reconnection	H.2.1 Number of features
B User Interaction	C.5 Auto-connect feature	H.2.2 Presence/Absence of features
B.1 Assistance	D Geography	H.3 Devices
B.1.1 Technical support	E Security and privacy	H.4 Bypassing capabilities
B.1.2 Customer support	E.1 Security	H.5 Resource consumption
B.2 Services Provided	E.1.1 Encyption standard	H.5.1 Battery consumption
B.2.1 Amount of data available	E.1.2 App security	H.5.2 System resources consumption
B.2.2 Support for multiple devices	E.1.3 Server security	H.6 Self sufficiency of software
B.2.3 Cross OS support	E.1.4 DNS leaks	H.7 Software stability
B.2.4 Compatibility with environment	E.1.5 Headquater country of VPN	
B.2.5 Issues with third-party apps	E.1.6 User activity logs	
B.2.6 Support for Always-On-VPN	E.1.7 Kill switch	
B.3 UI/UX	E.2 Privacy	
B.3.1 Mobile app	E.2.1 RTC leaks	
B.3.2 General UI issues	E.2.2 Usage access Permission	
B.3.3 General UX issues	E.2.3 Privacy policy of VPN	
B.4 User friendliness	E.2.4 SSH issues	
B.4.1 Ease of setup	E.2.5 Obfuscated servers present	
B.4.2 Ease of use	F Financial Aspects	
B.4.3 Accessibility	F.1 Payment	

Open coding. First, we applied open coding on the quotes. We randomly sampled 200 quotes, and using these quotes, two researchers collaboratively created a codebook. Apart from this, we set aside 50 quotes initially to check the saturation of themes. Next, using this codebook, those two researchers independently coded all the reviews. Inter-rater agreement (Cohen's kappa) at the end of the open coding round was 0.81, indicating almost perfect agreement. At the end of the open coding round, the two researchers met to discuss the specific user quotes whose codes were mismatched and assign a final code to each quote (if necessary, creating new codes). After completing coding all quotes (apart from the random 50 quotes we set aside earlier), one researcher verified that the identified themes are sufficient to code those 50 quotes, indicating thematic saturation of our open coding. Finally, the coders assigned a total of 217 codes to 1,305 user quotes.

Affinity diagramming to identify the hierarchy of themes. After this open coding round, the two researchers collaboratively analyzed the uncovered codes using *affinity diagramming* where they together looked into the set of quotes for each code, not only the code itself [22]. First, we set aside 10 random codes to check the saturation of hierarchy. Then, the coders collaboratively created a set of higher-level themes from the rest of the open codes. They continued this process on the newly developed higher-level themes for two more rounds when the coders felt no new higher-level theme could emerge. At the end of the process, we identified a 4-level hierarchy where Level-1 contains abstract highest-level themes created in the third (final) round of affinity diagramming, and Level-4 contains the very specific codes specified by the open coding step. Finally, we checked that including the 10 random codes did not add any new Level-1 and Level-2 themes, indicating thematic saturation of affinity diagramming. Our hierarchy of themes (first three levels) explaining the themes for reasons of VPN-switching is shown in Table 3. Level 1 contains the eight highest-level themes—Network, User interaction, Connection, Geography, Security and Privacy, Financial aspects, Dynamic data services and Software. However, we note that, so far, our analysis primarily considered only 1,305 semi-automatically filtered reviews (the complete hierarchy of themes is in Table 10 of Appendix C). Now, we scale our VPN-switching review dataset with themes using automated classification.

5 Scaling VPN-switching Review Dataset and Theme Annotation

We note that our VPN-switching review dataset comprises only 1,305 reviews (0.3% of a total of 411,751 reviews). To that end, we hypothesize that we might be missing a large-number of VPN-switching reviews which do not mention names of multiple VPNs. One such review in our corpus is *"[VPN1] had been working great for me in the past but after last*

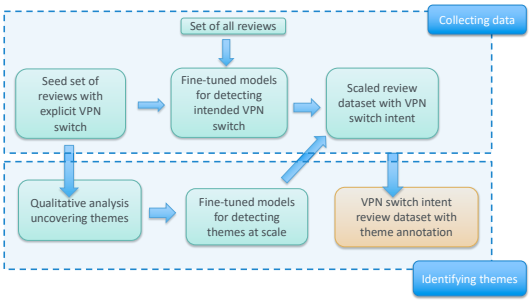

Figure 1: Pipeline for filtering review and identifying themes occurring in the reviews.

update it sucks...will look for other vpn if bug not fixed". Thus, to identify such reviews, we designed a machine learning pipeline presented in figure 1. This section will describe the pipeline's working and the resultant dataset.

5.1 Leveraging text-classification to extend VPN-switching review dataset

Originally, we manually divided 1,600 reviews into three categories—Actual switching, Potential switching and Irrelevant (Section 3.2). We note that we can consider these as three distinct classes assigned to the reviews—based on this idea, we model the problem of finding reviews mentioning VPN switching as a three-class classification problem. To that end, we tried multiple models as classifiers, including recent models like LLAMA2 [57], and FLAN-T5 [8]. The performance of individual models has been shown in Table 4. We used the fine-tuned DeBERTa model for further analysis since it offered best performance (F1-score of 0.85).

Model Architecture. Given the small number of labelled data points, we primarily used following pre-trained models, LLAMA-2 [57], FLAN-T5 [8], BERT [13], DeBERTa [23] and GAN-BERT [11]. We fine-tuned these model weights on the dataset for the downstream task of review classification. We used Optuna framework [26] for systematic hyperparameter tuning. Given the varying spectrum of models, the usage method also varied among the models (details in Appendix D).

Model Performance. We randomly split the dataset into 80% training and 20% validation subsets and post-training observed 85% accuracy and 84.73% F1-score on the validation dataset using DeBERTa model (presented in Table 4).

To further investigate the performance and misclassification of our model, we randomly selected an additional 100 reviews mentioning multiple VPN names (excluding the 1,600 annotated reviews), and one annotator manually annotated the selected reviews to create ground truth. Next, we used our text classification on these 100 reviews and constructed the confusion matrix (Table-5). We note that, in this confusion matrix,

Table 4: Performance of our fine-tuned models on the validation dataset for classifying reviews into Actual/Potential switch and irrelevant. Since the problem of review classification was a multi-class classification problem so metrics are computed using the methodology described in [19], where we compute model prediction using argmax among scores assigned by the model to all classes.

Model	Accuracy	Macro avg F1
FLAN T5	0.77	0.77
DeBERTa	**0.85**	**0.85**
LLAMA2	0.69	0.65
BERT	0.81	0.79
GANBERT	0.83	0.75

Table 5: Confusion matrix for our DeBERTa text-classifier annotation and ground truth for previously unseen 100 reviews. For only 9 reviews Actual/Potential switch is misclassified as irrelevant or vice-versa (marked in gray).

		Predicted		
		Actual switch	**Potential switch**	**Irrelevant**
Ground Truth	**Actual switch**	33	3	1
	Potential switch	13	20	2
	Irrelevant	2	4	22

in only 9 cases, a review mentioning an Actual or potential switch is misclassified as irrelevant. Thus, we identify actual or potential VPN-switching reviews in 91% of cases. Many misclassified reviews with strong negative/positive sentiments were not directed towards VPN features. Finally, we used this validated text-classified model on our dataset of 411,751 reviews to identify a total of 185,399 reviews mentioning actual or potential VPN-switching as presented in Table 6.

5.2 Identifying themes mentioned in extended dataset

Next, we wanted to assign themes to the reviews in our extended dataset of 185,399 reviews. To that end, we leveraged a similar idea as before—we modelled this problem as a theme identification problem and multi-label classification problem. Specifically, we model the Level-2 themes as labels assigned to each review . We chose to build our analysis based on L-2 themes—L-1 themes appeared too broad for granular analysis. Also, L-3 and L-4 themes might be more granular than L-2

Table 6: Final size of our extended dataset for VPN-switching reviews.

	Apple App Store reviews	**Google Play Store reviews**	**Total reviews**
Actual switch	38,139	52,166	90,305
Potential switch	35,614	59,480	95,094
Irrelevant	71,103	119,685	190,788

themes, but we have a relatively low amount of labelled data per L-3/L-4 theme. Thus automated theme identification with high accuracy would have been very difficult for them.

Model Architecture. We again used the following pre-trained models, LLAMA-2 [57], BART [35], FLAN-T5 [8], BERT [13], DeBERTa [23] and GAN-BERT [11]. Given the different architectures of these models, we fine-tuned BERT and GAN-BERT with multi-head classification layers on top of the pre-trained model. FLAN-T5 and BART were fine-tuned on the seq2seq task, and LLAMA2 was fine-tuned on the CausalLM task. We used Optuna framework [26] for systematic hyper-parameter tuning (details in Appendix E).

Model Performance. To measure the performance of the fine-tuned models, we split the labelled dataset into 80% training and 20% validation subsets. We found that the BART model outperformed other models, identifying more than 80% of themes correctly in the reviews. The accuracy of all models on the validation set is shown in Table 20 of Appendix E. To further ensure the correctness of the model, we also performed a manual analysis—we selected 100 random reviews (excluding the original 1,305 annotated) and manually annotated them with Level-2 themes. Then, we compared the correctness of our predicted themes against this ground truth. The result of the manual analysis is detailed in Table 21 of Appendix E. Our classifier was correct for the majority of the reviews (more than 80%) in both the validation set and additional ground truth dataset. Next, we will leverage this extended dataset of theme-annotated reviews to explore our research questions.

6 Do Users Switch Between VPN Apps? (RQ1)

In our extended dataset, we found that 185,399 reviews contain user intent of VPN-switching out of 411,751 reviews, i.e., for a significant fraction of 45% of reviews. We further ask if unique users contribute these reviews and if the VPN-switching behaviour is uniform across different VPN apps.

How many users are switching VPN apps? We consider usernames as proxies for user accounts. Our collected dataset shows that the 185,399 VPN-switching reviews were posted by 169,201 unique usernames. The only exception is the "A google user" tag in place of the name, which represents user accounts that have either been deleted or anonymized due to the user's privacy settings. Thus, these actual or potential VPN-switching reviews are posted mainly by individual user accounts (as opposed to a small subset of userbase).

Are VPN apps uniformly affected by VPN-switching? We further checked if the phenomena of VPN-switching is uniform across all VPN apps. To investigate, we checked what fraction of reviews per VPN app mention VPN-switching. Interestingly, there is a wide variation. Super VPN has only 2.0% of the reviews mentioned VPN-switching, and for VPN unlimited 61.9% of the reviews mentioned VPN-switching—showing a 30 times increase. The percentage of VPN-switching reviews for each of our VPN apps is in Table 8 (Appendix A). To that end, we computed the Pearson product-moment correlation coefficient between the number of downloads for each VPN and the percentage of reviews mentioning VPN-switch. We found there is a statistically significant negative correlation ($R = -0.5842$, $p = 0.006858$) between these two variables. Thus, VPN apps with smaller user bases have a higher chance of their users switching to other apps. Next, we investigate why users switch VPNs.

7 Reasons of VPN-Switching (RQ2)

In this section, we delve into each of the eight level-1 themes (i.e., highest-level themes) to understand how the switching of users can be explained based on that theme. According to our study, the reason for the switch can be among a large number of causes ranging from Geography, i.e. the country in which the user resides or visits, to User interaction, i.e. how VPN service provider interacts with users through channels like customer service or through software/app. In this section, we will not use the names of VPNs in this section, as our goal is to understand the high-level reasons for users to switch VPNs, not to identify the specific shortcomings/superiority of any VPN. In this section, we will discuss the themes which have been identified in the manual analysis.

7.1 Security and privacy

VPN userbase comprises users who want to protect their privacy against hackers and government agencies. Thus, switching from one VPN to another seems evident for users who think their security is under threat. In our manual analysis, security and privacy appeared in 196 reviews out of 1,305 manually coded reviews. In this theme, we described particular aspects of security and privacy that were most dominant in motivating users to switch from one VPN to another.

Hiding IP address: Commercial VPNs typically function by tunnelling the user's Internet traffic through a trusted remote server before it is forwarded to its final destination. This achieves the goal that the destination server does not learn the real IP address of the client [7]. Still, sometimes this fails to happen, and the actual IP address becomes visible to the destination server making the client vulnerable. This seemed to be a very relevant thing motivating users to switch from one VPN to another. For example, *P148 mentions, "Doesn't work. Currently in Germany, and prime video knows I'm in Germany. After selecting US- New York or Washington DC, still knows I'm in Germany... [VPN1] had been the only one that works for me"*, i.e. user feels their current VPN fails to hide their IP as Prime Video knows their correct location; thus, this user may switch to VPN1. We found quotes related to this theme in 40 reviews during our manual analysis.

User logs: User activity logs were another essential thing which users seemed to be concerned about because it was observed by users that VPN stored logs even if VPN service providers claimed that no logs were kept. In our manual analysis, user activity logs-related quotes appeared in 19 reviews. Also, many users expressed concerns about cases of selling logs, which threatened their privacy. One such example can be seen when *P10 mentioned, "It (VPN1) was caught selling user's data and logs in 2017. Use at ur own risk. Use [VPN2] instead of this"*, clearly warning users against VPN1 as it has a history involving the sale of user logs and data.

Headquarter country of VPN: One surprising yet recurring reason (found in 20 reviews during the manual analysis motivating users to switch from one VPN to another was the country where the VPN is headquartered. Many users felt that companies with headquarters in some countries were more likely to betray them than other companies. For example, *P899 mentioned, "...I let it run out. Why? Because [VPN1] is AMERICAN, and I'm done trusting Americans with my data...I've switched to [VPN2], a Swiss company. So far so good"*, where the user switched from VPN1 to VPN2 just because VPN1 is an American country while VPN2 is not. In our corpus, users were often against companies headquartered in "14 eyes countries".

App usage access: Permission control is one of the major Android privacy mechanisms. When an application is to be installed, a user has a choice whether to allow specific permissions or not [18]. While getting installed, many apps ask for "Usage Access" permission, allowing the app to track what other apps you're using and how often, as well as your carrier, language settings, and other details [56]. This appeared as a concern to some users. We found quotes related to this theme in 6 reviews. For example, *P30 mentioned, "Why does it need "App Usage Access" permission? [VPN1] doesnt ask for it..."*.

DNS leaks: The Domain Name System (DNS) is an essential Internet service that translates domain names into IP addresses [41]. Information leakage of DNS servers may cause the disclosure of users' behaviour or network zone structure and may even induce phishing or intranet penetration attacks [38]. DNS leaks were also raised as concerns in reviews mentioning them as reasons for switching from VPN. Other fundamental issues raised by users were related to issues with SSH, webRTC leak, etc. During our manual analysis, we found this concern in 10 reviews.

7.2 User demographics

Now we check how user demographics, such as place of residence, financial constraints, etc., are also responsible for making users switch between VPNs.

7.2.1 Geographic location of user

Due to the increase in awareness about the usage of VPNs as a Privacy Enhancing Technique and the rise in geoblocking imposed by various governments, there has been a worldwide increase in usage of VPNs, but this is sometimes constrained due to poor performance of VPNs in certain countries. In our study, we found this lack of performance in certain locations to be one of the reasons why users switch from one VPN to another (expressed in 88 out of 1,305 manually-coded reviews). For example, *P818 mentioned, "[VPN1] hasn't worked in China for a year. The app is useless on the phone and computer. The back up open listings are inadequate... Will never subscribe again. [VPN2]'s free service has worked better"*. Apart from the lack of customer care service, the failure of [VPN1] to work properly in China was an important reason why users were willing to switch to [VPN2].

User residing in China: Among the censorship regimes on the Internet, China is one of the most notorious, having developed an advanced filtering system known as the Great Firewall (GFW) to control the the flow of online information [24]. The strength of this firewall was also reflected in our study, as most reviews related to this theme were related to China (50 out of 88 Geography-related reviews), followed by Middle East countries like Saudi Arabia and UAE. In China, users complained of VPNs not upgrading their services as their servers were blocked as reflected in *review of P835 mentioning "anywhere else, hong kong for instance, connect right away. Now in nanchang, china, seldom succeed, because censors keep attacking and cutting access. [VPN1] stays ahead by highly frequent updates. perhaps [VPN2] could do something similar"*, where the user is currently using [VPN2] and expects [VPN2] to introduce updates frequently, like [VPN1], to fight censorship.

User residing in Middle East countries: Similar patterns were observed in Middle East countries, according to [45], blocked content often contains messaging that opposes the censoring government's own narrative of the conflicts, and that governments block content that could potentially spark internal dissent.We found quotes mentioning these countries in 12 reviews under this theme. Thus, VPN users in these regions face the unavailability of proper services and switch from one VPN to another. For example, *P139 mentioned in their review, "Cannot get the app to connect from UAE to USA. The chrome extensions says unable to load. Tried [VPN1] and that one worked. It even made [VPN1] run. Looks like [VPN1] is blocked in UAE. Otherwise it worked great in Europe"*.

Other locations: Other than these two regions, reviews also mentioned problems faced by users in Australia, Europe and South East Asia. One reason was the inactivity of VPN after government intervention, e.g., in Turkey the government blocked some servers as expressed by *P529 mentioning "Works Flawlessly. I'm in Turkey and the government blocked [VPN1] so I tried [VPN2]. It is fast and always works. Highly*

recommend". Within this theme, we noted that this inaction of VPNs towards government policies (e.g., blocking specific services) was the main motivation to switch VPNs.

7.2.2 Financial constraints of user

Most VPN services worldwide provide either premium or free service, or both leaving the choice to the user about the type of service they want to procure. Companies that provide users with the option of both free and premium versions of their VPN incentivize users to buy the premium version by increasing the daily usage limit or the number of simultaneous connections users can have. Some VPNs also come with a free trial period where users can try the premium features for a limited period (typically 7 days) and then evaluate if the user's needs are satisfied by this VPN. The sub-themes for this theme cover the contribution of these aspects of VPN service in motivating the user to switch. In our manual analysis, we found quotes related to this theme in 294 reviews out of 1,305 manually-coded reviews. Specifically, users mentioned the following reasons.

Pricing of VPN: High pricing of VPN was a recurring theme for some VPNs and sometimes served as the primary reason for users switching to another VPN. During our manual analysis, we found quotes related to this theme in 182 reviews. *P559 mentioned, "Good service but just too expensive. I have switched to [VPN1] and saved a fortune. I'm afraid that with such capable competitors offering such good value, [VPN2] will have to tidy up their pricing"*. Here, it is clear that the user switched from VPN2 to VPN1 even though the user feels that the service provided by VPN2 is good. While the pricing of VPN was a big issue for some users, a proportion of users cared more about the service provided than the price, for example, in *"This is probably the best VPN on the market. It costs more than other 'budget' VPNs but you get what you pay for. The speeds are phenomenal, especially for someone like me coming from [VPN] where I was paying to sit and look at the buffering symbol on YouTube..."*, where the user is ready to pay more and believes the service justifies the cost.

Free trial: Companies often provide free trial to lure users towards buying a premium version of VPN. However, it sometimes backfires—*review of P1478 mentioned "I tested this as an alternative to [VPN1] when my subscription ended, however they did not give the full 7 day trial, which instead ended after 5 days. The performance was okay, but that trial bug madee trust them less and in the end I went back to [VPN1]"*, here the bug in the free trial was disappointing for the user; thus, the user moved back to the previous VPN. Some companies ask users to enter payment information or make some initial payment for accessing a free trial but it also has some repercussions, as in, *review of P145 mentioning "Expensive and the Free Trial isnt a free trial. It still makes you put in billing information. That's just wrong. Never try this. They shouldnt have your info until you're ready to commit. Thats not a free trial idc if it allows you 7 days to cancel. Most people forget and thats what they're counting on"*. Here, we can see that the user is just switching due to distrust that VPN3 might be a fraud, and that's why they are asking for payment, which isn't what these payments are intended for. We found quotes related to this theme in 41 reviews during our analysis.

User finding no perk of paying for premium: One interesting theme observed from reviews is some users, after buying premium features, felt no difference from the free version of the VPN. During our manual analysis, we found quotes related to this theme in 10 reviews. *P745 mentioned, "from the first day I buy a one month premium subscription I felt like it was the same as the free version of the app. now I regret buying this piece of junk and thinking that I have to deal with it for the whole month. makes me angry and I feel like a stupid not going for the [VPN1]"*. Thus some VPN services are either not able to convey all features of the premium version to the users or it is not providing anticipated features to users.

General issues related to finances: Problems with a payment portal, lack of subscription options, lack of offers for existing users, etc. were other factors noted in our study as visible in reviews, for example, *P340 mentioned, "The description states that it has in app purchases but there is no way to pay from your Google play account. I had been saving money in my account for this purchase and now I find out I can't use it for this app. if you want to use your Google Play balance look into "[VPN1]" they will let you pay with your Google play balance"*. Apart from these, some positive factors also motivate users to switch from their current VPN to that particular VPN, for example, the availability of more subscription options or lower price as in their review, *P258 mentioned "Love it. Cheaper than [VPN], more subscription options than [VPN]. So easy to use"*. During our manual analysis, we found quotes related to this theme in 57 reviews.

7.3 Software usability

While the primary purpose of VPNs is to protect the user from privacy attacks while maintaining anonymity but usability is also an important factor considered by users. Our study found that many users switched among VPNs due to usability issues like poor UI, lack of required features, etc. In our manual analysis, we found quotes related to this theme in 524 reviews out of 1,305 reviews. Out of many recurring reasons, we have described a few of the most frequently appearing reasons responsible for users switching between VPNs.

UI/UX: User experience covered under UI/UX also appears as an essential aspect of this theme. Better UI serves as an important reason motivating users to switch between VPNs. During our manual analysis, we found quotes related to this theme in 129 reviews. Also, we observed that many users admired the UI features provided by other VPNs. For example, *P360 said, "Pretty basic app but it works well. I would like*

a quick toggle in the notification to pull down like [VPN1]", where the user admires the feature provided by VPN1. In some cases, we also observed that this admiration is so extreme that users tend to switch just because of them. Bugs in the user interface also seemed to matter for users motivating them to switch if not solved. For example, *P491 mentioned, "I just installed your VPN on my phone. However, I am uninstalling it now. There is no way to go back to the home screen once you connect to [VPN1]. If you go back, you get disconnected. This is disgusting. Take some cue from [VPN2] where there is an on or off switch..."*, where this bug in UI makes the VPN useless for the user and hence the switching.

Presence of too many features: While the lack of some basic features bothered users, the presence of too many features was also mentioned as the reason for switching between VPNs by some users, as with the number of features available in a software increase, resource consumption of software is also generally observed to increase. For example, *P54 said, "So sick of this VPN, they keep adding intrusive and unwanted features. I never wanted a file cleaner or task killer in my VPN app. Uninstalling and switching to [VPN2]"*, here the user is switching to VPN2 primarily because the current VPN has a lot of overhead in terms of features like file cleaner, task cleaner, etc. A similar pattern was observed in User Interface, where we found both very simple and very complex UI motivating users to switch VPNs. We found quotes related to this theme in 17 reviews.

Connection speed: We found speed is a significant factor for users switching between VPNs. While network speed is related to the latency experienced by users when the user is connected with a VPN, the connection speed is the time the VPN takes to connect to the desired service (e.g., a webpage). Some users mentioned slow connection speed as a primary motivation for VPN-switching. For example, *P769 mentioned, "You better take this review because I have used [VPN1] for three years with friends who use the same...[VPN1] is the worst at connecting & also log in...Connecting to country take hours. Other vpn connects in 5 sec. Just downgrade ur app, man"* Clearly, the user mentioned [VPN1] has issues with logging in, and the connection speed was not up to the mark. During our manual analysis, we found quotes pertaining to this theme in 39 reviews.

Network speed: Network speed has emerged as the most commonly cited metric for characterizing the quality of network offerings [3]. Numerically speaking, this was the most common theme that arose from our corpus study. For example, *P103 mentioned in their review "Nice app. The one thing that this app(VPN1) is lacking is the speed of the vpn. I've used [VPN2] for quite a while but this speed is pretty slow..."*— the user was directly comparing speeds provided by VPN1 and VPN2. During our manual analysis, we found quotes pertaining to this theme in 375 reviews.

Software updates: Software updates are essential to keeping systems and programs up-to-date. These updates fix bugs and improve performance and usability, but arguably their most important function is enhancing system security by fixing vulnerabilities [39]. In our study, we observed that infrequent updates are criticised by users as *P963 mentioned in their review "...It's been unreliable for weeks and the last mobile update was more than a fortnight ago. During the China blockages, [VPN2] had version updates and information for customers on their website"*. Here the user felt VPN2 is superior because of their frequent updates.

Another important aspect arising in our study related to updates is when users think that updates introduced in apps make service worse for them. For example, in *P1 says, "There are better VPN Apps. [VPN1] become dead. Try [VPN2]...[VPN1] they still old school and now these frequent updates, its get worse"*, where users feel that the updates introduced in the app are making their user experience even worse. Also, we found certain reviews where, according to users, no persisting problems were solved by updates—*P227 mentioned, "Users in China, don't bother. I've had [VPN1] for 2 years, no idea why I renewed my subscription. You can't connect more than half of the time. Constant updates that never seem to fix anything..."*, where constant updates don't seem to solve the network issues faced in China by the user. During our manual analysis, we found quotes related to this theme in 54 reviews.

7.4 Other frequently appearing factors motivating users to switch

In this sub-section, we will discuss other factors that frequently pop up in many user reviews. These themes are mostly related to the specific purposes for which users use VPNs, like accessing OTT platforms from restricted regions. The frequent appearance of these factors showed the extent to which VPN technology has been democratized.

OTT Platforms: The OTT service providers deliver audio, video and other media over the internet and bypass the traditional operator's network. Since the OTT players do not require any business or technology affiliations with network operators to provide such services, they are often known by the term 'Over-The-Top' (OTT). Some popular OTT platforms were mentioned quite frequently in our study— Netflix, Amazon Prime Video, Hulu and Hotstar [2,25,27,44]. During our manual analysis, we found quotes pertaining to this theme in 51 reviews.

Many users whose primary purpose was accessing the content of another country on these OTT platforms, which are generally blocked due to policies of government or OTT service providers, switch between VPNs if their current VPN does not provide expected access. One such example is seen when *P1400 mentions in their review, "There is no streaming Netflix server for another country than the US as US don't necessary have all title. [VPN1] has that..and able to con-*

nect to any region might consider jumping back to [VPN1]", where the user is considering switching from the current VPN to VPN1 because of restricted access to Netflix.

Gaming issues: By encrypting the internet connection and hiding the IP address, using a VPN for gaming can potentially help in several ways — granting access to different servers, improving ping and reducing lag, or even protecting you against DDoS attacks [34]. Thus, many gamers nowadays look forward to VPNs for a better and more secure gaming experience. Our study also found that many users switch between VPNs to get the expected gaming experience. For example, *P1395 mentioned in their review, "I was happy with this service until I realize that this service dosen't work with online games. The games keep disconecting. I though it was game issues until I switch to [VPN1]. taa daa, no more online games disconections..."*—the user switched VPNs because of disconnections in online games. During our manual analysis, we found quotes related to this theme in 8 reviews.

Streaming issues: Under this theme (included in 34 reviews), we also studied the importance of ease of streaming using VPNs in motivating users to switch from one VPN to another. Many streamers use a VPN to protect their actual IP address for privacy and performance reasons. Some use it to access Twitch or unblock content and games [12]. From the collected reviews, we found that many users considered switching to another VPN just because their current VPN doesn't perform well with streaming. For example, *P126 mentioned, "...I found it unreliable for video streaming. It was extremely slow and videos often just stopped playing and I couldn't get them to restart. I've switched to [VPN1]..."*, where the user switched to VPN1 because of issues with streaming videos.

Technical and customer support offered: Assistance provided by the company through technical support and customer support are the most common ways through which a company interacts with its current and potential customers. In our study, we discovered that poor knowledge of technical support, which made it difficult for users to solve the problems they faced while using VPNs, was an important reason for motivating users to switch. During our manual analysis, we found quotes related to this theme in 151 reviews. As *P146 mentioned, "I used [VPN1] for around 7 years. However, during the middle of 2020 I was unable to view TV anymore. After five months and numerous emails and promises that technicians were working on the issue, I gave up! I had read positive reviews of [VPN2] and decided to give it a go..."*, the inefficiency of technical support was a reason why the user switched from VPN1 to VPN2.

Next, we will discuss how these factors differ from those identified in the previously published literature on factors influencing the choice/usage of VPNs. We will analyze the impact of these factors on users' decisions to choose VPNs while switching.

8 Comparison of Features influencing VPN-adaption and VPN-switching (RQ3)

Our study identified reasons for VPN-switching, however, it is not obvious if these reasons for VPN-switching are different from the general VPN adoption motivation of users. Especially since Sombatruang et al. examined factors which users consider while choosing a VPN app which suits their purpose and preferences [54], to that end, we contrasted those factors from earlier work with the ones identified in our study to find how user requirements and concerns regarding the choice of VPN change with prior usage of VPNs.

Sombatruang et al. found that factors like device battery consumption, change in internet speed due to VPN, connection stability, ease of connection-establishment of connection, etc., are primary considerations of users while choosing a VPN [54]. They also highlighted the importance of app store reviews and star ratings of apps in the user app selection procedure. The subscription price and User personality are also crucial in the VPN adaption process [43]. These themes are also present in reviews exhibiting intent to switch, but there are some key differences, possibly due to users' experience.

Advanced user requirements for VPN: Unlike prior work, in our study, one recurring theme was that users complained about the lack of advanced features like split tunnelling, kill switch, better UI, streaming support while playing specific games, etc. Out of these, kill switch and split tunnelling security features are more common—we can infer that existing users understand the importance of these features after facing associated problems in their existing VPN. This informed understanding strongly influenced the VPN selection criteria during switching.

Dependence on user Demographics: Prior work found that the purpose of using a VPN is an important factor in the VPN selection process. We found that while this was still true, user demographics (specifically the geographical location of users) also played an important role in VPN switching. This was particularly visible in reviews from users residing in China and the Middle East, where web censorship is very high and VPNs are often blocked. In those situations, users are forced to switch between VPNs frequently if the app prevents them from evading geographical constraints.

Reduced weightage to ratings and reviews: Sombatruang et al. identified that ratings and reviews are most significantly correlated with VPN adaption, indicating herding attitude among users [54]. In contrast, our dataset had only 4.15% of reviews in which users talked about app ratings and user reviews of the VPN app, while other factors like geography, security, etc., are mentioned in significantly more reviews. Thus, our results hint that user experience with existing VPN apps often reduces the weightage of "ratings and reviews" as a factor during VPN-switching. Next, we will check the key features desired by users during VPN-switching.

9 VPN Features Desired By Users During VPN-switching (RQ4)

In this section, we check what features are desired by existing users during VPN-switching and if users desire multiple features together while switching their VPN providers.

Top desirable features in a VPN. We use our identified level-2 themes as features desired by users while switching their VPNs. To that end, we simply searched for these themes in the reviews and took the frequency of occurrence as importance for these features. The top-5 most mentioned features in VPN-switching reviews are Connection, Network speed, User-friendliness, Service Provided, and UI/UX appearing in 41,020, 28,406, 22,402, 21,689, 19,406 reviews, respectively (top-10 of such features with their frequency is in Table 25 of Appendix F). We noted that privacy is not among the top 10 mentioned features in VPN-switching reviews. This finding aligns with earlier work [54]. Next, we moved beyond only the most popular features and checked if these popular features also co-occurred with not-so-popular ones for specific VPN-switching reviews.

Co-occurrence of desired features in VPN-switching reviews. For checking the co-occurrence of multiple desired factors, in line with prior work, which examined the co-occurrence of tokens in the same posts [52], we created a co-occurrence network [36] of level-2 themes where themes served as nodes of the network and weights of edges were calculated using the formula: $W_{ij} = F_{ij}/(F_i * F_j)$ where F_{ij} are #reviews in which both theme i and j occur, F_i is the number of reviews in which theme i occurred, and F_j are #reviews in which theme j occurred. After constructing the co-occurrence network, we used the clique-based Louvain algorithm [4, 20] to find 10 overlapping communities in the graph.

Specific subsets of desired features co-occurred in VPN-switching reviews. In our detected communities, we found that the most frequent factors in user reviews about switching VPN and network speed co-occurred with non-frequent factors like streaming. This shows that user requirements often encompass multiple features, and furthermore, there are distinct feature sets that are desired together in VPN-switching reviews, signifying a concrete spectrum of needs which led to VPN-switching. One interesting observation is that 7 out of 10 communities have "Security" (3 communities) and "Privacy" (5 communities) in them even though privacy did not occur most frequently in reviews—signifying at least a non-trivial subset of users still consider better security and privacy as a valid reason for switching VPNs. We provide the complete list of the feature co-occurrence communities for interested readers in Table 24 (Appendix F). Next, we finally check if the current VPN review blogs identify and cater to these distinct user requirements.

10 Alignment of Information in VPN Review Websites with User Requirement During VPN-switching (RQ5)

We previously noted in Section 8 that users switching among VPNs put lesser emphasis on reviews and ratings while switching. However, as previous work found, general users still rely on VPN review blog websites for information regarding VPNs [50]. To that end, we ask if these VPN-review blog articles can help the users who want to switch VPNs.

10.1 Collecting data from VPN-review blogs

In order to identify popular VPN-review websites and their relevant blog articles, first, we queried Google with the term "best VPN" and collected the top 10 results. Four out of these ten websites prohibit automatically collecting their articles, so we focus on the rest. We searched each website domain using Google's site search with the keywords "Best VPN recommendation blogs", "VPN review blogs", and "VPN comparison blogs", which resulted in 583 blog articles. We manually reviewed these articles to identify 376 blog articles related to VPN or its uses. Out of these, 176 are VPN review blogs, and 200 are VPN best-pick blogs (i.e. blogs which either recommend a ranked list of best VPNs or compare VPNs). For ethical reporting of results, this section will refer to individual sites with alphabets A to F.

10.2 Topic analysis of VPN-review blogs

Topic Modelling: To identify the content available in the blogs, we started with Topic Modelling implemented using LDA algorithm [30]. Firstly, we applied LDA to the text of the entire 376 blog corpus, followed by applying it to the corpus formed by only the VPN review blogs and VPN best-pick blogs separately.

Identifying themes in reviews: Apart from topic modelling, we also applied the BART model fine-tuned for identifying themes in reviews on the blogs corpus. Given the input length constraint of the BART model, we fed the blogs to the model in small chunks followed by a union of identified themes. This provided us with the themes covered by blogs from these VPN recommendation websites.

Blogs do not give information on important and desired VPN features: We started by applying the LDA topic modelling algorithm on our blog dataset corpus [30]. LDA output word clusters as topics. Following the method described in prior work, we identify the optimal number of topics and assigned semantic labels to these word clusters via manually checking the blogs where words from a cluster appear [6]. Finally, we identified ten topics in the blogs, out of which four topics were related to VPN features. Two topics primarily contained terms related to streaming services like "Hulu",

"Netflix", etc. The other two topics were related to "Security and Privacy" and "Connection and Network speed". These are in line with the themes identified in our qualitative analysis.

We also noted a lack of coverage of other important aspects mentioned by users in reviews like financial aspects (like price, free version availability, etc.) and Geography. We also applied topic modelling on subsets of blog articles—VPN review blogs and VPN best-pick blogs separately. Topic analysis of VPN reviews and best-pick blogs yielded 10 topics each. Most of the topics in VPN-review blogs were related to Streaming and Speed, while topics in VPN best-pick blogs were mainly related to the Speed and Pricing of VPNs. However, these topics did not touch upon a plethora of features mentioned in Section 9—these blogs might provide information about a significant number of desired features which users consider during VPN-switching. The topics (semantic labels with word cluster) are in Table 28, 29 and 30 of Appendix F.

Then, we identified themes covered in the blogs using the BART model fine-tuned to identify themes in reviews to understand the coverage of user requirements by these blogs. The top themes identified by the model are listed in Table 27. Among the top themes, we can see "Privacy" and "Features", which, according to our findings, are also the top aspects users look at when making the decision to switch VPNs, but we see no coverage of important themes like "Geography" or "User Friendliness" or "Reliability" which is also important for users. We also checked the variation of topics covered in VPN review blogs and VPN best-pick blogs and saw a similar trend as before. Best-pick blogs mostly focused on Speed and Pricing, and VPN review blogs focused on features but lacked coverage of other important aspects related to VPN switching.

10.3 Entities mentioned in VPN-review blogs

We Performed an off-the-shelf Named Entity Recognition technique (NER) [51] on individual blogs and then calculated the frequency of these entities in blogs from different websites as well as in the whole blog corpus. The full list of the top 10 most frequently occurring entities for each of the websites is presented in Table 22 of Appendix H.

Information in blogs is heavily biased towards specific VPN apps and services: Our frequency analysis of entities reveals that there are 1 to 5 specific VPN app names in the top 10 most occurring entities across websites. Out of these two entities occur very frequently—"Netflix" and "Surfshark" (Table 22 of Appendix H). We make two observations from this analysis. First, these websites focus disproportionately more on streaming services like Netflix, backing our observation in Topic modelling. Second, these websites primarily mention a few VPNs like Nord or SurfShark while ignoring other VPNs. However, interestingly, a Pearson correlation coefficient analysis did not find any statistically significant correlation between the frequency of the entities (which are VPN apps) and the number of downloads. Finally, we do a word association analysis to check (i) if these mentions of specific entities in blogs (i.e., co-occurred) are biased (e.g., overwhelming praise or criticism) and (ii) if the themes identified in Section 9 (which are also user-desired features) are at all mentioned in any form in these blogs.

11 Bias towards specific entities and coverage of features in VPN-review blogs

Word association analysis: We leverage a technique developed in prior work to perform a word association analysis, i.e., given a set of words, what are similar or associated words appear in a corpus? [55]. We first created two sets of keywords. The first set contains keywords that are not related to any specific themes, and rather, they contain general terms describing desired VPN characteristics like "best", "fastest" and "Cheapest". The second set contained a set of keywords which are related to themes (i.e., features) desired in VPN-switching reviews. Next, to capture words used in similar contexts, we used a pre-trained BERT model [13] and fine-tuned it using the blog corpus on a Masked Language Modelling task to get a model acquainted with the context used in blogs. Then, we generated embeddings for keywords using this BERT model. Finally, we analysed embedding of which words are similar (as described in prior work [55]) to embeddings of our sets of keywords. This approach helped us to capture the context of input keywords within the blogs while also taking the general meaning of words into context due to the nature of the pre-trained model. All keywords are in Table 26 of Appendix H.

Bias towards specific VPN apps in blogs: For the keyword "best", in most websites, the names of popular VPNs like Nord and Proton are among the most similar words. We made similar observations when we tried to find similar words for terms like "fastest" or "cheapest", indicating a bias towards selected VPNs corresponding to all words in our first set of keywords—signifying desired VPN characteristics are always associated with these VPN apps in the blogs.

Lack of coverage for user-desired features in VPN-blogs: Leveraging our second set of theme-related keywords, we checked if VPN blogs used keywords related to user-desired themes (in VPN-switching reviews). Specifically, for each keyword in our set (e.g., "logs", "free", or "price"), we checked top 10 most similar words in the corpus (in terms of our fine-tuned BERT model embedding). However, for most themes, these words are not relevant—possibly because most of these themes are not discussed in depth in the VPN blogs.

12 Implications

Our first-ever study of VPN-switching study unearths a number of important observations. To that end, in this section,

we examine the implications of our study for VPN providers, VPN-review blogs and the security community in general.

VPN-switching is intended by a non-trivial fraction of users: We note that VPN-switching, although not studied before, is a significant phenomenon. More specifically, out of 411,751 reviews from 20 popular VPN apps, 185,399 (45%) indicated towards VPN-switching. This observation heavily emphasizes the need to assist these users from the VPN-review blogs as well as from VPN providers by providing them services that cater to these users' desired preferences.

Users desire advanced and more customized features while switching VPN: As opposed to VPN adoption, the users who want to switch VPNs are more knowledgeable. Thus, they seek more advanced security features and customized options (e.g., for evading the censorship employed in specific countries). Thus, VPN providers might want to provide customized solutions to these experienced users.

Users desire sets of features while switching VPN: Our cluster analysis revealed that, interestingly, the VPN-switching reviews often desire multiple features for their new VPN app. In fact, these features form distinct clusters, hinting at separate user bases (since mostly unique users posted these reviews) with distinct requirements. In fact, often during VPN-switching, security and privacy is an important factor, but it is accompanied by additional requirements in a VPN. This finding provides a roadmap for VPN providers and researchers to create customized VPN solutions which can cater to these distinct user bases with different sets of requirements.

Current VPN-review blogs are insufficient for VPN-switching for bias toward specific VPNs and low coverage of user-desired features: Finally, our analysis reveals a huge gap and opportunity for researchers and the general security education community. Currently, VPN review blogs paint a biased picture of VPN apps and manipulate users to switch to specific VPNs. In fact, presumably, due to this reason, the users who want to switch VPNs did not mention these reviews and ratings as significant factors for choosing a new VPN. Furthermore, these blogs are insufficient to provide information to users regarding their desired privacy, security and usability features. Hence, our findings imply that the security community should develop more tools like Vpnalyzer [49] and make them user-friendly so that users can check the VPNs and switch to a VPN according to their requirements.

12.1 Recommendations for stakeholders

Finally, we synthesize a list of recommendations for important stakeholders in the context of VPN switching—VPN providers, VPN recommendation websites, the Security Research Community, and finally, the users themselves.

Recommendations for VPN service providers: Our findings indicate that there is no one-size-fits-all thing in the case of VPN. Hence, service providers need to provide users with options to customize VPN features based on users' priorities and requirements. The providers can also aid users by customizing their products according to user geography and demographic groups. In our study, we found that there is a large section of VPN users who expressed "Potential Shift" in their reviews. These users are basically giving their existing VPNs a chance to satisfy their need. Thus sensing these needs and establishing a smoother communication channel between user and providers (e.g., via customer or technical support) can help the company retain these users.

Recommendations for VPN recommendation websites: We identify that VPN recommendation websites are biased towards particular VPN service providers and do not cover important themes that users consider while switching VPNs. Therefore, coverage of such topics in blogs can help users make more informed decisions. We also noted a difference in factors responsible for VPN adoption and switching, which can guide these websites to tailor their blogs according to users' VPN usage experience. These websites can also provide automated VPN recommendation systems according to users' experience and requirements.

Recommendations for the security research community: Our results show that users sometimes compromise their security for their requirements, like watching Netflix. Thus the security community might consider developing more tools like Vpnalyzer [49] and make them usable so that users can test the VPNs by themselves.

Recommendations for the users: Finally, from previous literature, we found that users rely a lot on VPN recommendation websites [50], which is a problem. In our study, we found that these websites are biased towards and selected VPNs and hence, users should rely on more reliable sources like academic tools or materials to select the VPN. Also, users need to acknowledge that their peers or even families will have different requirements compared to theirs; hence, just relying on word-of-mouth might not work while selecting VPNs.

13 Conclusion

This study delved into the VPN-switching behaviours of users through an analysis of 185,399 app reviews from 20 popular VPN apps across Google and Apple stores. Our findings revealed a significant number of users intending to switch between VPNs, with varied rates among providers. Notably, the size of a VPN provider's user base exhibited a statistically significant negative correlation with the frequency of VPN-switching mentions in reviews. Our qualitative analysis identified a hierarchy of reasons motivating users to switch, encompassing technical factors such as network speed and non-technical considerations like financial aspects.

Furthermore, our research introduced a novel exploration of VPN review blogs, exposing biases towards certain VPNs and a notable absence of information regarding user requirements. By shedding light on the reasons behind user retention

and loss for VPN providers and unveiling patterns in user preferences, this study offers valuable insights for enhancing VPN services and addressing user needs more effectively.

Abstract

Decentralized Finance (DeFi) offers a whole new investment experience and has quickly emerged as an enticing alternative to Centralized Finance (CeFi). Rapidly growing market size and active users, however, have also made DeFi a lucrative target for scams and hacks, with 1.95 billion USD lost in 2023. Unfortunately, no prior research thoroughly investigates DeFi users' security risk awareness levels and the adequacy of their risk mitigation strategies.

Based on a semi-structured interview study ($N = 14$) and a follow-up survey ($N = 493$), this paper investigates DeFi users' security perceptions and commonly adopted practices, and how those affected by previous scams or hacks (DeFi victims) respond and try to recover their losses. Our analysis shows that users often prefer DeFi over CeFi due to their decentralized nature and strong profitability. Despite being aware that DeFi, compared to CeFi, is prone to more severe attacks, users are willing to take those risks to explore new investment opportunities. Worryingly, most victims do not learn from previous experiences; unlike victims studied through traditional systems, DeFi victims tend to find new services, without revising their security practices, to recover their losses quickly. The abundance of various DeFi services and opportunities allows victims to continuously explore new financial opportunities, and this reality seems to cloud their security priorities. Indeed, our results indicate that DeFi users' strong financial motivations outweigh their security concerns – much like those who are addicted to gambling. Our observations about victims' post-incident behaviors suggest that stronger control in the form of industry regulations would be necessary to protect DeFi users from future breaches.

1 Introduction

Decentralized Finance (DeFi) is a financial ecosystem built on blockchain platforms like Ethereum. It provides a variety of financial services, mainly executed through smart contracts [48], such as Decentralized Exchanges (DEXs) and lending services. This emerging field has attracted substantial interest, with its Total Value Locked (TVL) reaching a record high of 180 billion USD in November 2021 [17].

With its growing popularity, DeFi has become an attractive target for hacks and scams, which we also refer to as DeFi incidents. The total loss resulting from DeFi incidents in 2023 exceeded 1.95 billion USD [16]. Popular DEXs such as Balancer, Curve Finance, and dYdX were breached due to smart contract vulnerabilities [3, 14, 20]. Additionally, over 263 rug-pull scams were reported in 2023 [16]. The infamous LUNA meltdown (reported in 2022) failed to protect its stablecoin values, incurring a total loss of 60 billion USD [4].

Despite reports being published about numerous DeFi incidents and their losses, people are still heavily using DeFi, and its TVL remains at 130 billion USD in 2024 [17]. Such trends motivated this work and two intriguing aspects: (1) despite the prevalence of security breaches being reported, why do people continue to use DeFi services, and (2) whether people make decisions based on an adequate understanding of security risks and mitigation practices. To date, there is no prior research that thoroughly investigates DeFi users' perceptions of security risks. Prior efforts often focused on smart contract security [10, 26, 38, 49]. Wang *et al.* [46] studied user perceptions of DeFi incidents. However, their investigations were limited to the scope of sandwich attacks.

To bridge this gap, we conducted a semi-structured interview with 14 DeFi users, including real-world victims, and a follow-up online survey ($N = 493$), investigating DeFi users' security risk awareness levels and the adequacy of commonly employed security practices, and how real-world victims respond to DeFi breaches and mitigate risks. These studies have been designed to address the following four research questions:

RQ1: Why do people continue to use DeFi despite numerous DeFi incidents being reported? Traditional Centralized Finance (CeFi) or bank users typically abandon their banks if serious incidents are reported [24]. Our curiosity lies in understanding why DeFi users behave differently.

RQ2: What DeFi risks are users concerned about, and how do they mitigate these risks? DeFi systems introduce unique security risks [52]. Our objective is to understand whether DeFi users have sufficient knowledge about the overall threat landscape, and the security controls that need to be used.

RQ3: How do victims respond to DeFi incidents? Another objective is to understand what actions are taken by victims after experiencing scams or hacks, and investigate the adequacy of their actions in recovering their losses. Our investigation extends to understanding how victims' perceptions change after the incident.

RQ4: How do DeFi users perceive regulation? Regulatory controls may be considered in the future to better protect DeFi users. To that end, we were driven to understand DeFi users' perceived benefits and concerns with respect to introducing regulatory controls.

Our qualitative and quantitative studies reveal that people choose DeFi services because they appreciate its decentralized nature, and the unique investment opportunities they offer (**RQ1**). Many participants consider DeFi to be less secure than CeFi. However, such participants still appreciate the transparency and trustworthiness guarantees of DeFi services, and continue using them anyway. Participants are mainly concerned about rug-pull scams, volatility of crypto prices, and smart contract exploitation (**RQ2**). However, many of them do not know how to effectively mitigate such threats. They often believe that traditional security systems are applicable and equally effective in protecting them from DeFi threats. For instance, many participants falsely believe two-factor authentication (2FA) will mitigate rug-pull or smart contract exploitation types of breaches. Worryingly, many victims simply find other DeFi services, and continue to use them to recover their losses (**RQ3**). Such victims fail to take any other remedy actions, and do not revise their security practices. Surprisingly, more than half of the studied victims explained that their security perceptions did not change after the incident. It seems like their overwhelming financial motivations cloud their security priorities: many participants fall victim to multiple scam or hack incidents, and still use DeFi without carefully considering the security risks. As expected, more participants oppose the idea of regulating DeFi services (**RQ4**) – mainly due to their concerns about paying additional tax and regulatory controls possibly jeopardizing the decentralization benefits of DeFi. Considering that paying tax is a civil obligation, however, and users' tendency to ignore security risks in pursuit of financial gains, our recommendation is to explore decentralized regulations and mandate strong security controls and practices to better protect DeFi users.

Taken together, these key findings represent the major contributions of the paper: a first formal study investigating DeFi users' security concerns and risk mitigation strategies, a list of security misconceptions that need to be addressed, and a thorough report on the security behaviors of DeFi victims and how they can be better protected in the future.

2 Background

In this section, we begin by reviewing DeFi with its characteristics and financial services. We then introduce the hacks and scams that have occurred in the DeFi realm.

2.1 Decentralized Finance (DeFi)

DeFi is a financial ecosystem backed by a blockchain such as Ethereum. These blockchains empower DeFi to have unique characteristics compared to Centralized Finance (CeFi), giving rise to the emergence of distinct DeFi services.

DeFi characteristic. Most DeFi services are implemented as smart contracts [48] on top of a blockchain. DeFi developers encode their protocols and functionalities into smart contracts and deploy them on the blockchain by sending smart contract creation transactions (txs). DeFi users then interact with DeFi services by sending txs to smart contracts of DeFi services. This makes DeFi services inherit characteristics of blockchain such as *decentralization*, *transparency*, and *accessibility*.

In particular, DeFi is *decentralized* due to its foundation on blockchain, which operates in a decentralized manner. Furthermore, the use of smart contracts as the backbone of DeFi implementations, along with recording of all tx histories on the blockchain, ensures the *transparency* of DeFi. Lastly, DeFi employs blockchain accounts, which anyone can create with a private key. DeFi operates through txs, and any account owner can initiate txs. These enhance the *accessibility* of DeFi.

DeFi service. DeFi offers many financial services inspired by CeFi while demonstrating the DeFi characteristics. Similar to CeFi, DeFi provides financial services such as exchanges and lending services. However, DeFi services operate with distinct mechanisms. For example, DEXs often utilize an automated market maker (AMM) mechanism [50], which automatically determines the exchange ratio based on the quantities of tokens in liquidity pools. Additionally, DeFi lending services introduce a unique feature called flashloan [47]. By leveraging the atomicity of blockchain transactions and the programmability of smart contracts, a flashloan allows borrowers to obtain a loan only if they repay it along with its interests within a single transaction. Notably, DeFi offers other various services such as NFTs, insurance, governances, stablecoins, and cross-chain bridges.

2.2 DeFi Hacks

Although the blockchain, the basis of DeFi, is secure, DeFi services might be insecure because of vulnerabilities in their implementations. In this paper, we categorize DeFi hacks into four categories based on the exploited components in DeFi.

Smart contract exploit. Due to the fact that most DeFi protocols are implemented through smart contracts, numerous DeFi hacks have happened by smart contract exploits, resulting in at least 1.57 billion USD losses until May 1, 2022 [51]. For

example, the DAO attack [15] exploited a *re-entrancy* vulnerability, which caused inconsistent state updates. Furthermore, attackers have actively exploited *price oracle manipulation* vulnerabilities, resulting from developers misusing price oracle APIs to get token prices in DeFi services.

Cross-chain bridge exploit. To connect DeFi services operating on different blockchains, DeFi employs *cross-chain bridges*, which facilitate the exchange of assets between two blockchains. Unfortunately, some attackers have identified vulnerabilities within these bridges and exploited them to manipulate tokens without providing assets on the other blockchain. For instance, the Wormhole bridge was exploited by this vulnerability and lost 320 million USD [7].

Private key leakage. Some DeFi hacks occurred due to private key leaks, as these private keys serve as passwords of DeFi accounts. For example, Ronin network's private keys were stolen, resulting in 625 million USD losses [11].

DeFi front-end attack. DeFi services are typically based on smart contracts and DeFi users should send txs on blockchain to interact with them. This might be a big hurdle for regular DeFi users, and DeFi developers provide some web pages (front-ends) to improve their usability. However, some attackers exploited the web pages to make users interact with the web pages to send tokens to attackers rather than trading with DeFi services [12].

2.3 DeFi Scams

Similar to CeFi users, DeFi users are also susceptible to various scams, including phishing. However, DeFi scams differ from CeFi scams due to the unique characteristics of DeFi.

Rug-pull. In DeFi ecosystems, anyone, including scammers, can launch their own DeFi services. Therefore, scammers create fraudulent services and persuade DeFi users to invest their money in these scams. In the end, scammers abandon their projects and disappear with the funds from DeFi users. We call such scams *rug-pulls*. In particular, there have been numerous rug-pulls involving DeFi scam tokens, resulting in losses exceeding 240 million USD [6].

Stablecoin meltdown. To connect DeFi with CeFi, DeFi developers introduced *stablecoins* [30], which are pegged to fiat currencies – stablecoins such as USDT and USDC are pegged to the USD. DeFi users believe that stablecoins are backed by an adequate reserve of fiat currencies or certain algorithms to uphold their values. However, some stablecoins failed to maintain their values, leading DeFi users to panic sell significant amounts of these stablecoins, ultimately resulting in a stablecoin meltdown. For instance, the "LUNA meltdown" failed to keep the value of its stablecoin, UST, which was backed by an algorithm, resulting in 60 billion USD losses [4].

Phishing. DeFi ecosystems are not immune to phishing attacks, similar to the CeFi ecosystems. DeFi phishers often reach out to potential victims via email or social media, attempting to obtain the victims' private keys or tricking them into initiating specific txs. Specifically, DeFi phishers may deceive victims into sending txs that include hidden token approval txs, thereby granting the phishers access to drain tokens from the victims' wallets.

Airdrop scam. One particular phishing method in DeFi involves using airdrops, where developers distribute tokens to DeFi users to advertise their services. Airdrop scammers exploit this process by sending their tokens to wallets of potential victims. These potential victims, upon receiving these unexpected tokens, may visit phishing websites or DeFi services to investigate the activities happening in their wallets. While they interact with phishing websites or DeFi services, they may leak their private keys or initiate some fraudulent txs as mentioned. Therefore, they are more likely to fall victim than to traditional phishing via email or social media.

3 Methodology

To investigate the motivations and risk perceptions of DeFi users relevant to our research questions, we conducted a two-phase study. Initially, we performed in-depth interviews with 14 users, obtaining qualitative insights into their experiences. Based on the findings from the first study, we executed a quantitative survey with 493 DeFi users to validate and expand our understanding. Ensuring ethical and responsible research practices, both study designs received thorough review and approval from our Institutional Review Board (IRB). Minimizing data collection, we only gathered necessary personal information and stored responses under pseudonyms to ensure anonymity. Importantly, participants were informed of their right to withdraw at any time. Supplementary study materials, including the interview guide, codebook, and survey questionnaire, are available in a GitHub repository[1].

3.1 Study 1: Semi-structured Interview

We aimed to gain a comprehensive understanding of user perceptions of DeFi, including their views on hacks and scams. To achieve this objective, we conducted semi-structured interviews with DeFi users ($N = 14$).

Design. The interview protocol was designed with four sections to sequentially address our research questions. (1) For **RQ1**, we asked participants about their perceptions of DeFi. Specifically, participants discussed their *preference* between DeFi and CeFi, along with justifications for their choices. (2) For **RQ2**, we explicitly inquired about participants' perceived DeFi risks and their mitigation strategies. (3) For **RQ3**, participants who were victims shared their experiences and reactions to DeFi hacks or scams. We also explored whether these incidents affected their perceptions of DeFi. (4) For **RQ4**, we

[1] https://github.com/mingyiliu95/defi-user-study

gathered participants' opinions on regulations that could mitigate DeFi hacks and scams. Notably, to ensure the accuracy and coherence of our interviews, we conducted three pilot interviews and primarily revised wording for clarification based on their feedback. We excluded these pilot interviews from our data analysis.

Recruitment. To ensure we interviewed actual DeFi users, we implemented a rigorous two-step recruitment process. Firstly, we advertised our study through popular channels within active DeFi communities like Twitter, Telegram, Discord, and through word-of-mouth. In our recruitment advertisement, we stated that the purpose of our study was to understand user perceptions of cryptocurrency trading. Secondly, potential participants completed a screening questionnaire designed to filter for active DeFi users over the age of 18. This questionnaire included questions about the decentralized application (dApp) usage, community involvement, and experiences with DeFi hacks or scams. Specifically, participants were asked: a) if they had interacted with dApps; if so, b) the names of the dApps they used most frequently; c) their role in the DeFi community (e.g., regular users, dApp developers); and d) if they had experienced DeFi hacks or scams. We then invited participants who accurately listed dApps, including those who identified themselves as victims of DeFi incidents, for interviews. Each participant received 20 USD as compensation.

Data collection and analysis. We conducted 14 online interviews via recorded video calls, averaging 65 minutes in length. After transcribing the videos, two researchers independently coded each interview and discussed their codes to reach a consensus. This coding process was iterated for all 14 interviews, resulting in 148 codes and a Cohen's κ inter-coder reliability score [22] of 0.89. As appended in Appendix A, the interview study was deemed complete once code saturation was reached without new codes emerging that addressed the research questions.

Demographics. Table 1 presents the detailed demographics of our interview participants ($N = 14$). The sample was predominantly male and younger, but there was a varied representation in terms of income and educational background. Participants ranged from newcomers to seasoned users in their cryptocurrency experience. Additionally, we disclosed whether participants were DeFi developers, considering the potential for bias from them. Lastly, we specifically targeted participants who had experienced DeFi misconduct, resulting in eleven self-identified victims in our interviews.

Table 1: The demographics of interview participants.

ID	Gender	Age	Education	Income	Crypto YoE[1]	Dev[2]	Victim
P1	Female	18-24	Bachelor's	$50k-75k	3-5	No	Yes
P2	Female	18-24	Bachelor's	$50k-75k	1-3	No	Yes
P3	Male	18-24	Bachelor's	$25k-50k	1-3	No	Yes
P4	Male	25-34	After bachelor's	$200k+	7-9	Yes	Yes
P5	Male	25-34	After bachelor's	$50k-75k	3-5	No	Yes

[1] Abbreviated for *Years of Experience*; [2] Abbreviated for *Developer*.

3.2 Study 2: Large-scale Survey

Based on the results of the interview study, we conducted a quantitative study via an online survey ($N = 493$) on Prolific[2] to statistically validate our observations from the interviews on a large scale.

Design. We structured the survey into four sections, mirroring our interview design. (1) For **RQ1**, we inquired about participants' positive and negative experiences with DeFi, and their *preference* for DeFi over CeFi. Specifically, we assessed factors such as *security*, *usability*, *transparency*, and *trust*, identified in the interviews as influencing DeFi preferences. (2) Addressing **RQ2**, we asked participants to select and rank the most concerning DeFi risks identified from interviews. We then queried about the countermeasures they had adopted to mitigate these risks. (3) When tackling **RQ3**, we probed participants' unfortunate experiences with DeFi hacks or scams, including the type of incident, their remedial actions, and any changes in perception. We did not pre-select victims for our survey to accurately represent the real-world proportion of users affected by DeFi incidents. (4) For **RQ4**, we gathered participants' views on DeFi regulations, asking them to express their support or opposition to regulatory oversight and explain their reasons. We included demographic questions at the survey's start and inserted two attention-checking questions within the sections on RQ1 and RQ3.

Recruitment. Because there was no pre-defined filter on Prolific to screen DeFi users, we used a screening questionnaire to recruit DeFi users for the full survey. Initially, we applied three built-in Prolific filters to ensure participants a) had used cryptocurrencies, b) maintained an approval rate above 95% for past submissions, and c) were U.S. residents to minimize cultural and regulatory differences. In the screening questionnaire, we asked if participants considered themselves DeFi users and, for validation, to name the dApp they most frequently used along with its smart contract address. Respondents who accurately listed dApps were deemed eligible and invited to participate in the full survey. We added the Prolific IDs of eligible participants to an allowlist, ensuring only those selected could take the survey. Despite a significant drop-off,

[2] https://www.prolific.com/

this screening process was necessary to ensure the validity of the participants. Compensation was set at 0.30 and 2.50 USD for completing the screening questionnaire and full survey, respectively.

Data collection and analysis. From June to October 2023, we received 4,380 responses to the screening questionnaire. We invited 1,134 eligible participants, of whom 550 submitted the full survey, averaging a completion time of 15 minutes. We analyzed 493 valid responses, excluding incomplete submissions, failed attention checks, or non-compliant responses (e.g., out-of-range ranks). Due to the non-normal distribution of the collected data, we employed non-parametric statistical tests for our analysis. We performed Mann-Whitney U tests and Chi-squared tests of independence (each at a significance level of $\alpha = 0.05$) to compare two answers (questionnaire options). Since each answer was compared to every other answer pairwise, we applied Bonferroni correction. In addition to p-values, we computed rank-biserial correlation r[3] to report the effect size.

Demographics. The demographics of our survey participants ($N = 493$) are presented in Table 2. Our sample predominantly consisted of males (82.4%) and individuals under 44 years old (78.0%), with average and median ages of 37.75 and 35, respectively. Furthermore, 77.0% held a degree at or above a Bachelor's level. Although we omitted specific occupation distribution due to diverse responses, "Computer and Mathematical" occupations were the most common (15.6%).

To assess the representativeness of our participants, given the scarcity of quantitative user studies in the DeFi arena, we compared our demographics with those from research targeting general crypto-asset users [2]. Our study had a higher proportion of male participants than the reference (77.5%) and a younger demographic, with the majority aged between 25 and 34 years (38.3%), as opposed to the reference study's primary age group of 35-44 years (36.2%). Our respondents also had higher educational attainment than the general U.S. population [43], aligning closely with the referenced study, where 77.2% of participants had at least a Bachelor's degree.

Table 2: The demographics of survey participants.

Item	Property	All (N=493) % of participants
Gender	Male	82.4
	Female	16.0
	Non-binary	1.2
	No answer	0.4

	No answer	1.4

4 Results

This section presents the study results addressing our research questions. We report qualitative findings in §4.1, quantitative validations in §4.2, and summarize key takeaways in §4.3.

4.1 Interview Study Results

4.1.1 Perceptions of DeFi

Focusing on tackling **RQ1**, we compared users' perceptions of DeFi and CeFi and analyzed why users prefer or do not prefer DeFi over existing CeFi services.

[3]The thresholds for interpreting effect sizes as small, medium, and large are 0.10, 0.30, and 0.50, respectively.

Preference. Most interview participants preferred DeFi over CeFi for various reasons: a few participants highlighted ease of access and use as the main reason, while some cited additional features, transparency, and reliability as the reasons for preferring DeFi. For example, P14 highlighted accessibility benefits: "*I don't have to open up an account. I just need a unique wallet.*" A small number of participants shared neutral or more negative feedback on DeFi, explaining their concerns related to security issues, excessive fees, and lack of experience. P2, for instance, explained "*Since I'm a beginner [in trading], I would go with traditional [fiat CeFi].*" We identify security, usability, transparency, trust, and profitability as common themes affecting preference to use DeFi, and provide example quotes below.

Security. Only a few interview participants mentioned security as a reason for preferring DeFi: "*DeFi is a more secure way to make transactions*" (P3). Half of those who did not prefer DeFi emphasized its insecurity. P13 explained "*Because [of] the amount of hacks... it sounds like it would be very difficult to secure [DeFi].*"

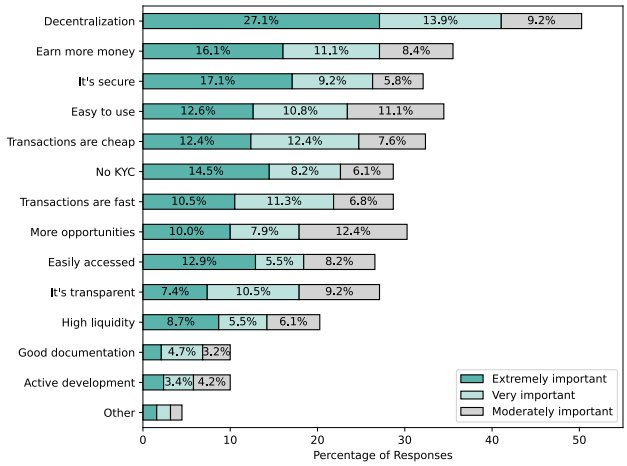
Usability. In response to the question about reasons for preferring to use DeFi, some interview participants mentioned that DeFi is easier to use, referring to fast transaction and interoperability advantages. For example, P5 explained "*[DeFi is] easier to use... You can go to DeFi and actually make quick transactions.*" P10 mentioned the ease in which crypto assets can be transferred: "*exchange from one protocol to*

another [is] easier compared to stock exchange." Several participants also mentioned the convenience factor associated with not having to verify their identity to set up and activate accounts. Among those who preferred DeFi for reasons other than usability, some mentioned their concerns about the steep learning curve.

Transparency. Half of those interview participants who preferred to use DeFi mentioned transparency. P4 explained "*No backroom dealings... Everything is public.*" These participants expressed concerns about the opaqueness of the practices employed by crypto and fiat CeFi services: "*You don't know what the bank's security is [but] you know what the DeFi security is... it's all on chain*" (P11).

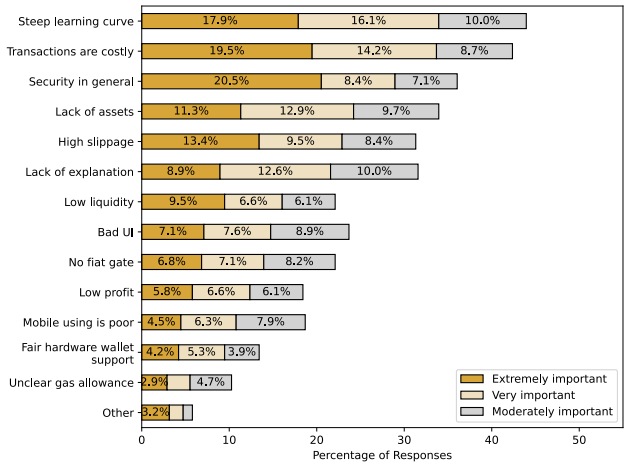
Trust. Some preferred to use DeFi because they do not trust the operations of fiat CeFi services, "*[Fiat CeFi] is not nearly as safe as everybody thinks it is. I don't trust the regular financial system*" (P11). On the contrary, one interview participant explained that he lost trust in DeFi and stopped using it: "*I don't use any of them [dApps] anymore... I don't really trust them apart from hacks*" (P8).

Profitability. Many participants acknowledged the profitability side of DeFi as the main reason for preferring to use DeFi. P7, for example, explained financial opportunities: "*There are a lot of opportunities to have a twenty percent APY income, so I put my money to the DeFi and earn the yield.*" However, there were also several participants who expressed expensive transaction fees as a reason for carefully choosing dApps: "*Fees are important. If I see competitive [tx] fees, I like to use them [more] often*" (P6).



4.1.2 Perceptions of DeFi risks and mitigation

This section explores **RQ2**, and reports details about DeFi users' security concerns and mitigation strategies.



Perceived risks. With respect to the perceived risk questions, many participants expressed concerns about `smart contract exploitation`, some mentioned specific vulnerabilities: "*There are a lot of risks in the lending protocol like oracle price manipulation*" (P7). Several participants were concerned about cryptocurrency price volatility and associated `financial risks`. The third most frequently mentioned risk was `rug-pull`, a common pump-and-dump exit scam orchestrated by the project owners. P6 expressed concerns about the lack of regulations to protect DeFi users from rug-pulls: "*Without it being regulated by someone, there's always the risk of investing in a rug-pull project.*"

Other frequently noted risks include `theft of private key` from wallets, `instability of stablecoins` (risk of de-pegging from 1 USD), and `airdrop scam` related to malicious tokens stored in wallets, each of which was mentioned by a few participants. `Phishing` and `regulatory uncertainty` were each mentioned once.

Risk mitigation. Participants reported mitigation strategies

(a) The survey results about love points of DeFi.

(b) The survey results about pain points of DeFi.

Figure 1: The survey results about love/pain points of DeFi.

and security practices they have employed to mitigate the risks they were concerned about. To deal with the risk of rug-pull and smart contract exploitation, most participants explained they perform thorough research on a given crypto project before investing. For instance, P9 said "*We do our research about the token [first]... and make sure it's a safe and reliable token before we buy [them].*" To address the risks associated with private key compromise, some participants said they rely on hardware wallets to safeguard private keys. P7 explained "*A hacker can't take my crypto private key because I use a hardware wallet.*"

P4 and P6 explained that they regularly revoke token approvals to mitigate rug-pull risks. Token approval allows dApps to access users' wallets, and transfer tokens on users' behalf. This reduces users' re-approval efforts and txs costs. However, token approval is often configured to allow unlimited token transfers, and such configurations could be ex-

ploited by malicious dApps to transfer the entire balance. To that end, P4 shared thoughts on the risk of failing to revoke token approvals in a timely manner: "*If you leave them approved, you could have a bad upgrade [with] a vulnerability that might be exploited. And if you've approved unlimited amounts, then they can just spend all [of] your tokens...*"

Overconfidence in two-factor authentication. P2 and P10 shared their strategy of using two-factor authentication (2FA) to mitigate many of the DeFi risks, including rug-pull and smart contract exploitation. P10 mentioned "*Two-factor authentication has been one of the best solutions for keeping wallets safe.*" Although 2FA is an integral security practice for protecting user accounts in CeFi platforms, it is not supported on non-custodial (decentralized) wallets [33]. We report this as a critical security misconception: DeFi users being overly confident in the use of 2FA to protect their wallets, and, as a result, paying less attention to other important security practices.

4.1.3 Real-world experience with DeFi breaches

To address **RQ3**, we study real-world victims' experiences and how they responded to a scam or hack.

Type of breaches. DeFi scams were reported more often than hacks by the interviewed victims. Among those who experienced DeFi hacks, several victims mentioned being affected by smart contract exploits, while some mentioned suffering from private key compromise. For example, P4, who is a dApp developer, shared an incident that involved the exploitation of a re-entrancy vulnerability in their smart contract: "*We lost million[s of dollars], it was not a good time... It was a re-entrancy vulnerability, and the audit completely missed it.*"

With respect to DeFi scam experiences, many participants encountered rug-pull incidents: "*He [the founder] deployed two smart contracts. One was fine [but] another was a rug-pull*" (P7). Several participants fell victim to phishing scams: "*I was DM-ed [direct messaged] by somebody who said, you just joined this channel, click this link to verify your account... I logged into my MetaMask... [and] half an hour later... everything was gone*" (P12).

Response actions. We asked interview participants about the immediate actions taken after experiencing the last scam or hack incident. Their responses include adopting new security practices, asking the support or development team for assistance, or not taking any action. Some victims mentioned they increased the net investment size, and moved to other DeFi services to quickly recover their loss. Among those who adopted a new security practice, P12 responded to a phishing scam by "*... disconnecting my wallet from every site, and revoking every [token] approval that I had out there.*" Several victims who contacted the development team received no response, or a premature response that was not particularly helpful. P3, for instance, said "*I sent an email... but I did not get any reply, [and] I moved on.*" P5 shared a similar experience: "*[They said] they will get back to me, but I never heard from them again.*" One victim, who experienced rug-pull, contacted an IP lawyer in an attempt to sue the development team but stopped after learning about the low probability of getting anything back. Some of the victims, who were affected by phishing and rug-pull breaches, did not take any action.

Perception changes. Our objective was to understand how victims' security perceptions may have been affected by the breaches. We asked "*has your belief or perception of DeFi changed after experiencing the DeFi hack or scam*?" Surprisingly, most interview participants explained their security perceptions of DeFi did not change; some even mentioned that their confidence in DeFi platforms increased despite the breach, praising the previously realized profits, and often blaming themselves for being careless. P3, for instance, lost about 4,700 USD in a recent rug-pull incident but said "*my belief in cryptocurrency has grown stronger after [experiencing] that [DeFi scam] because I made good money from it... An opportunity to make money is something I believe in.*" P9 blamed themselves: "*Oh, my belief did not change! I just felt like I was the victim of my own circumstance... Not doing enough research before diving into it... it was my fault basically.*" P11 explained that it was a risk that they were willing to take for financial gain.

Blame distribution. Lastly, we analyzed the distribution of stakeholders that the victims held accountable for the experienced breaches. A few interview participants simply blamed hackers and scammers. About half of the participants blamed developers: "*It is the responsibility of the developers to spot their loophole [first]... and make amendments for investors' security*" (P3). Most participants held themselves accountable, and explained that they should have done more research prior to using a DeFi service.

4.1.4 DeFi regulation preferences

This section delves into **RQ4** and investigates DeFi users' perceptions of regulations. The U.S. Securities and Exchange Commission (SEC) issued a statement [13] in 2021 outlining "pseudonymity" and "lack of transparency" issues associated with DeFi. In 2022, the SEC amended "Rule 3b-16" of the Exchange Act [40] to include all DeFi platforms in the "exchange" category. In the latest 2023 statement [23], the SEC explained that DeFi platforms need to conform to laws governing securities.

Given this background, our interview participants shared mixed feelings about regulation. Many participants shared positive feedback whereas the majority provided opposing feedback. Participants who endorsed DeFi regulation believed that it would promote DeFi security, reduce financial loss, and protect them from adversaries. P6, for example, explained "*A malicious user should be punished... there needs to be some justice...*" Opposing participants were worried that regulation efforts sit uneasily with the decentralized and unregulated

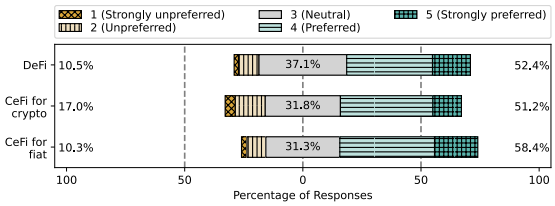
fundamentals of DeFi. Some were also concerned about regulations discouraging innovation, and tax implications.

4.2 Online Survey Results

4.2.1 Perceptions of DeFi

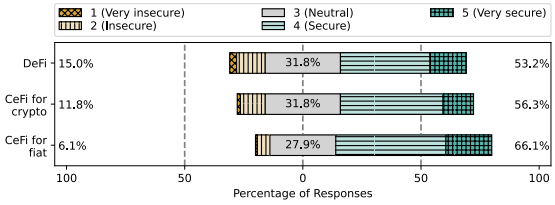
We focus on validating the interview results for **RQ1** in this section. The survey was designed to distinguish exchanges and lending platforms as two different DeFi services. However, because the user perceptions were not too different between the two services, we decided to simplify the analysis and report the aggregated results.

First, we derived and coded the aspects of users' enjoyment and frustration in DeFi, based on our interviews and a preliminary industry study [19]. From the initial pilot study, we noticed that people take too long and find it difficult to rank all given options based on relative importance. Hence, in the final survey design, we asked survey respondents to select and rank no more than three *love/pain points*. Figure 1 shows the results sorted by weighted scores, where "Extremely important," "Very important," and "Moderately important" represent 3, 2, and 1 scores, respectively. The detailed results of the statistical tests are presented in Appendix C. Due to page limits, we only report and discuss highly ranked love/pain points.



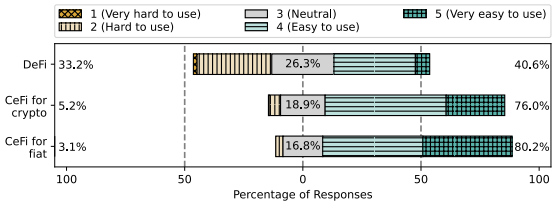
Love points. `Decentralization` was considered to be the most important love point. Our subsequent security analysis, however, revealed that many participants have an inadequate understanding of decentralization and thus are optimistic about this characteristic contributing to security. `Earn more money` ranked second, indicating that financial gains are important motivations for using DeFi services [19].

Pain points. Participants regarded steep learning curves and high transaction (tx) costs, which are classified as *usability*, and *security* issues, as the most important pain points. It's understandable that users deem DeFi tx fees expensive because, in addition to the inevitable gas fee[4], dApps may also impose liquidity taker fee on tx to reward market creators who provide liquidity, and this fee varies among dApps. In this case, some developers lowered their tx fees to offer a more cost-friendly environment [1, 42].

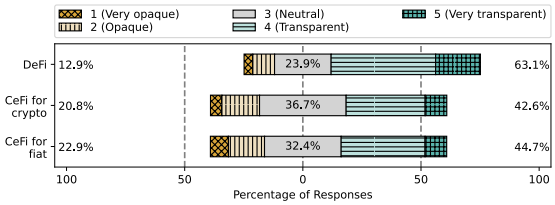


Second, from the interview responses, we identified *security*, *usability*, *transparency*, and *trust* as the most common reasons (thematic codes) influencing users' *preference* for DeFi and CeFi systems. We report our Likert scale question results from the survey, which has been designed to investigate users' comparative perceptions.

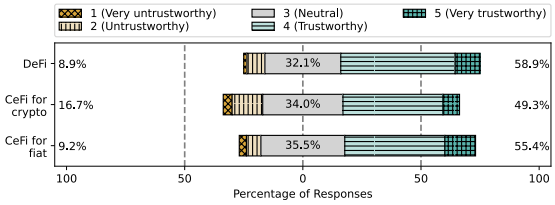
Preference. In contrast to the interview responses, our survey results did not show a dominant preference for DeFi. Participants' preference rates are summarized in Figure 2a. We observed a statistically significant difference in preference rates between crypto CeFi and fiat CeFi ($p < 0.01$) but the effect size was small ($|r| = 0.12$).



[4] Blockchain miners' reward for executing transactions.



(a) The comparison in terms of *preference*



(b) The comparison in terms of *security*

(c) The comparison in terms of *usability*

(d) The comparison in terms of *transparency*

(e) The comparison in terms of *trust*

Figure 2: The comparison of survey participants' perceptions between DeFi, CeFi for crypto, and CeFi for fiat.

Security. Unsurprisingly, Figure 2b shows that users perceive DeFi as slightly less secure than CeFi. Statistical tests in Table 3 revealed significant differences in security perception between DeFi and fiat CeFi ($p < 0.001$), and between crypto CeFi and fiat CeFi ($p < 0.01$). The effect sizes were small in both cases ($|r| = 0.15$ and $|r| = 0.13$).

We also asked an open-ended question about the reasons for their perceived security ratings: 39.8% considered DeFi to be secure due to its `decentralization` characteristic; this observation is well aligned with the love points explained before,

Table 3: Results showing significant differences in Mann-Whitney U tests under Bonferroni correction for DeFi's and CeFi's rate distributions of *preference*, *security*, *usability*, *transparency*, and *trust*. The p-values and effect sizes in rank-biserial correlation r are reported.

Item	*Preference*		*Security*		*Usability*		*Transparency*		*Trust*	
	DeFi	CeFi_C	DeFi	CeFi_C	DeFi	CeFi_C	DeFi	CeFi_C	DeFi	CeFi_C
CeFi_C[1]		–		–	p = 2.2e-30 r = 0.46	–	p = 1.1e-8 r = – 0.23	–	p = 8.4e-4 r = – 0.13	–
CeFi_F[2]		p = 9.0e-3 r = 0.12	p = 4.4e-4 r = 0.15	p = 2.1e-3 r = 0.13	p = 6.0e-35 r = 0.55	p = 2.1e-3 r = 0.13	p = 3.1e-7 r = – 0.23			p = 1.1e-2 r = 0.11

[1] Abbreviated for *CeFi for cryptocurrency*; [2] Abbreviated for *CeFi for fiat currency*.

in which the `it's secure` love point also recorded a high ranking. However, some explanations were not particularly convincing. For example, one participant believed that "*decentralized [service] is always more safe than centralized [service]*" (S512). Some participants mistakenly equated the decentralization of DeFi with that of the underlying blockchain and thus reported a misbelief about the security guarantees: "*[DeFi is] more secure because a hacker would have to override an entire blockchain [to steal funds in DeFi]*" (S12). `Self-custody of private keys` was also mentioned frequently (23.9%). One participant explained "*[DeFi is] secure if the private keys are well stored*" (S20), which is not the case. Some participants (19.3%) considered DeFi to be secure simply due to `no hack or scam experience`.

Among those who considered DeFi to be insecure, 55.8% of such participants mentioned `rampant hacks or scams` as the main reason. One participant explained "*I have [used] malicious smart contracts that steal your funds before*" (S398). `Decentralization` was the second most frequently mentioned reason (23.3%) for feeling insecure. For example, S224 explained "*[DeFi services] are easier to exploit than centralized [services].*" Furthermore, some participants associated decentralization with a lack of regulations and controls, and emphasized such liberal aspects as a reason for feeling less confident about DeFi.

Taken together, we report that a significant portion of participants over-estimate DeFi's security due to their limited understanding of the concept of `decentralization`. Such participants do not seem to be aware of the new attack vectors introduced through the use of smart contracts [52].

Usability. The overall sentiment, as shown in Figure 2c, was that both crypto and fiat CeFi are easier to use than DeFi ($p <$ 0.001 in both cases). Near-large and large effect sizes further emphasize the magnitude of differences ($|r| = 0.46$ and $|r| =$ 0.55) which was somewhat unexpected since our interview results revealed some participants prefer DeFi due to its fast transaction and interoperability benefits (See §4.1.1).

We asked survey participants to explain the usability scores they assigned to DeFi. Among 60.1% of explanations that provided negative feedback, 40.2% mentioned `steep learning curve`. Many participants felt overwhelmed by the new technologies they had to learn and use, including the concept of dApps, blockchains, and the interactions with non-custodial wallets. 11.8% of such participants explained `it's complex`, and 8.3% mentioned the learning curve associated with `blockchain knowledge required`. However, among those negative feedback, a noticeable 14.4% mentioned that using DeFi was `easy after education`. These observations indicate that users may struggle initially and face various learning challenges but through continued use and some educational support, DeFi could become an easier platform to use.

Transparency. We defined *transparency* in our survey as the extent to which a subject discloses operational and transactional details. Evidence gathered through Figure 2d and Table 3 validates that participants perceive DeFi to be more transparent: distribution of perceived transparency differed significantly between DeFi and other two CeFi services ($p <$ 0.001 in both cases), demonstrating small to medium effect sizes ($|r| = 0.23$ in both cases).

Trust. Survey results, summarized in Figure 2e and Table 3, indicate that users consider crypto CeFi to be the least trustworthy platform – its perceived trust level distribution showed statistically significant differences compared to both DeFi ($p <$ 0.001, $|r| = 0.13$) and fiat CeFi ($p < 0.05$, $|r| = 0.11$).

4.2.2 Perceptions of DeFi risks and mitigation

This section presents large-scale validation for **RQ2**, focusing on DeFi users' security concerns and preventive measures.

Perceived risks. The survey questions about risks were constructed based on those frequently mentioned codes. We asked survey participants to select three most concerning risks and rank them based on concern levels. The concern level distributions (ordered by weighted scores) are shown in Figure 3, and the statistical significance between the distributions is measured and reported in Appendix D. In line with the interview findings, `rug-pull`, `financial risks`, and `smart contract exploitation` were the top three DeFi risks that survey participants were concerned about.

Risk mitigation. Figure 4 presents the security practices commonly employed by our survey participants to mitigate the originally reported three security concerns. First, in line with

Table 4: The preventive measures adopted by survey participants against *rug-pull*, *financial risk*, and *smart contract exploitation*.

Preventive Measures	Rug-pull				Financial Risk				Smart Contract Exploit			
	Non-victim N=250		Victim N=74		Non-victim N=237		Victim N=53		Non-victim N=138		Victim N=64	
I do my own research	155	(62.0%)	42	(56.8%)	118	(49.8%)	34	(64.2%)	59	(42.8%)	37	(57.8%)
I only invest how much I am willing to lose	144	(57.6%)	48	(64.9%)	156	(65.8%)	32	(60.4%)	59	(42.8%)	38	(59.4%)
I check crypto news almost daily	85	(34.0%)	26	(35.1%)	83	(35.0%)	14	(26.4%)	38	(27.5%)	13	(20.3%)
I enable two-factor authentication to secure my wallets	49	(19.6%)	16	(21.6%)	106	(44.7%)	25	(47.2%)	45	(32.6%)	22	(34.4%)
I deal more with stablecoins	44	(17.6%)	8	(10.8%)	53	(22.4%)	9	(17.0%)	16	(11.6%)	12	(18.8%)
I store my crypto in several wallets	39	(15.6%)	15	(20.3%)	69	(29.1%)	15	(28.3%)	39	(28.3%)	28	(43.8%)
I have cold/hardware wallets	31	(12.4%)	14	(18.9%)	61	(25.7%)	7	(13.2%)	33	(23.9%)	17	(26.6%)
I bookmark official sites and smart contract addresses	26	(10.4%)	12	(16.2%)	37	(15.6%)	8	(15.1%)	28	(20.3%)	14	(21.9%)
I regularly check and revoke token approvals	22	(8.8%)	13	(17.6%)	27	(11.4%)	10	(18.9%)	20	(14.5%)	13	(20.3%)
I use a strategy that averages my buy-in price	18	(7.2%)	9	(12.2%)	37	(15.6%)	16	(30.2%)	15	(10.9%)	5	(7.8%)
I audit smart contract myself	16	(6.4%)	8	(10.8%)	15	(6.3%)	6	(11.3%)	19	(13.8%)	7	(10.9%)
I use a separate browser for my wallets	16	(6.4%)	7	(9.5%)	28	(11.8%)	8	(15.1%)	20	(14.5%)	11	(17.2%)
I don't think there are preventive measures to mitigate this risk	10	(4.0%)	4	(5.4%)	7	(3.0%)	0	(0%)	5	(3.6%)	0	(0%)
I don't have preventive measures to mitigate this risk	6	(2.4%)	1	(1.4%)	3	(1.3%)	0	(0%)	10	(7.2%)	2	(3.1%)
Other	5	(2.0%)	4	(5.4%)	2	(0.8%)	0	(0%)	0	(0%)	1	(1.6%)

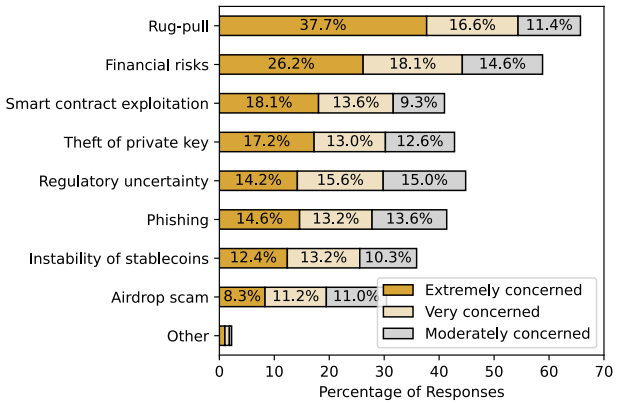


Figure 3: The DeFi risks that concern survey participants.

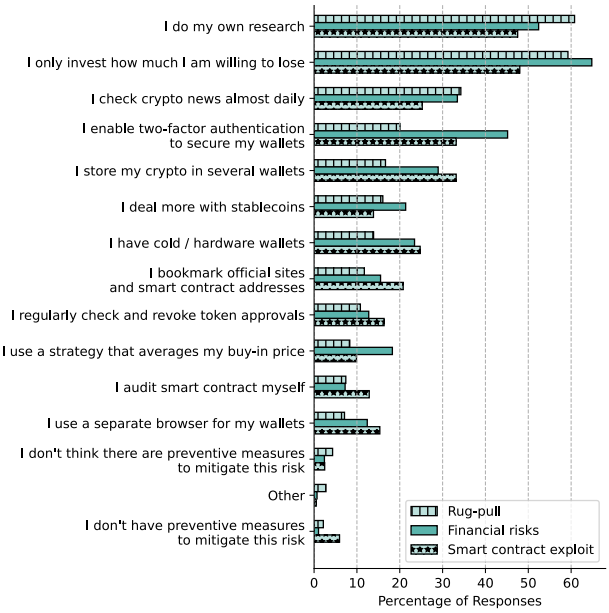

Figure 4: The survey results about how they mitigate *rug-pull*, *financial risks*, and *smart contract exploitation*.

the interview responses, the most commonly practiced strategy involved `I do my own research` and `I only invest how much I am willing to lose`, which are somewhat general investment strategies. Second, token approvals are a critical attack vector. Yet, the adoption rate of the most appropriate countermeasure, `I regularly check and revoke token approvals`, was only practiced by 10.8% of participants who shared their concerns about rug-pull scams. Although 2FA is not suitable for preventing rug-pulls, financial loss, and smart contract exploits, participants reported high adoption rates of 2FA for those three risks: recording 20.1%, 45.2%, and 33.2% adoption rates. Among participants who adopted at least one *technical* solution (2FA, hardware wallet, or revoking token approvals) for each risk, 62.4%, 80.4%, and 65% were using 2FA, respectively. Among such 2FA users, 57.1%, 56.5%, and 49.3% were using 2FA as the *only* technical countermeasure – indicating that the majority may be overconfident in the security guarantees offered by 2FA.

Influence of DeFi incidents. We also investigated whether falling victim to DeFi hacks or scams affects users' security perceptions and practices. Table 4 compares practices employed by non-victims and victims to mitigate their top three concerns. Noticeably, the victims' adoption rate for "revoking token approvals" was slightly higher in all three risks. Victims used the `I store my crypto in several wallets`

Table 5: DeFi Hack type encountered by survey participants, and whether they had a loss to that incident.

DeFi Hack Type	Occurrence	Loss
Smart contract exploitation	22 (37.9%)	14 (63.6%)
Cross-chain bridge attack	11 (19.0%)	9 (81.8%)
Theft of private key for my own wallets	9 (15.5%)	6 (66.7%)
Protocol front-end attack	6 (10.3%)	5 (83.3%)
Theft of private key for protocol smart contract	4 (6.9%)	2 (50.0%)
Other	3 (5.2%)	1 (33.3%)
I have no idea	3 (5.2%)	1 (33.3%)

Table 6: DeFi Scam type encountered by survey participants, and whether they had a loss to that incident.

DeFi Scam Type	Occurrence	Loss
Rug-pull	40 (54.8%)	31 (77.5%)
Phishing	16 (21.9%)	8 (50.0%)
Wallet dusting/Airdrop scam	9 (12.3%)	5 (55.6%)
Stablecoin meltdown	4 (5.5%)	2 (50.0%)
Other	3 (4.1%)	3 (100%)
I have no idea	1 (1.4%)	0 (0%)

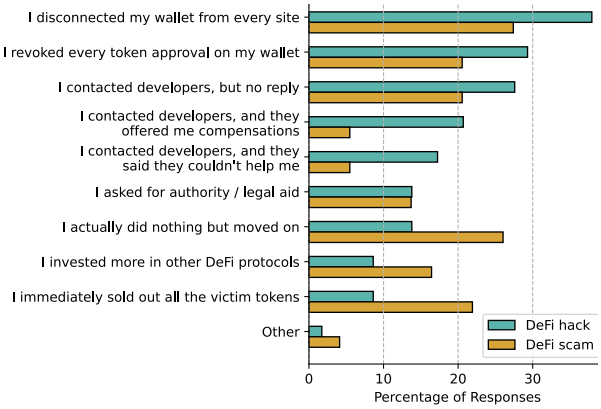

Figure 5: The actions that victims in survey participants took after the latest DeFi incident that they experienced.

strategy more frequently than non-victims to prevent rug-pull and smart contract exploits. Hence, there may be some tendency for victims to become more vigilant. Chi-squared tests, however, did not show significant differences between the two groups in all three risks ($p = 0.51$, $p = 0.23$, and $p = 0.46$).

There were also a few concerning trends: integral practices such as timely checking and revoking token approvals and opting for hardware wallets were not sufficiently adopted by victims. Further, the misconception about 2FA being adequate in mitigating the top three concerns was also prevalent among the victims.

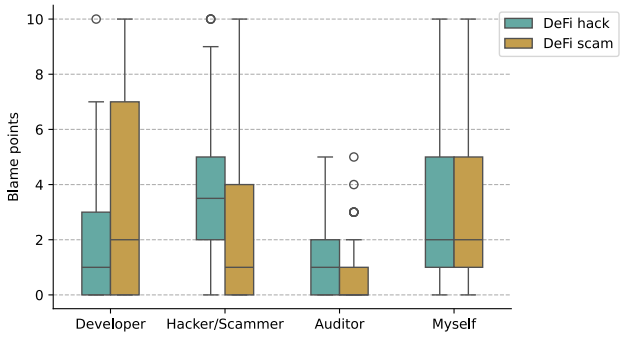

Figure 6: The blame distribution by victims in the latest DeFi incident that they experienced.

4.2.3 Real-world experience with DeFi breaches

To address **RQ3**, we validated the interview results on real-world victims' experiences, perceptions, and responses to scams or hacks.

Being affected multiple times. In the online survey, we defined a DeFi hack as "*the act of identifying and then exploiting vulnerabilities in the DeFi domain*", and provided unauthorized wallet access and dApp exploit as two examples. 11.8% of the participants reported having previously experienced a DeFi hack at least once – we refer to such participants as "victims". We then inquired victims about the number of times they have experienced DeFi hacks: the mean number of hacks was 1.8 ($\sigma = 1.6$). Similarly, we defined a DeFi scam as "*the act of tricking users or pretending to be a valid dApp, and stealing users' crypto assets*", and hinted that common DeFi scams include transferring malicious cryptocurrency to victims' wallets or being affected by rug-pulls. In line with the interview results, more participants seem to have fallen victim to DeFi scams than hacks: 14.8% of participants reported having experienced DeFi scams at least once. Surprisingly, the mean number of experienced scams was 4.7 ($\sigma = 12.5$). Worryingly, some participants mentioned experiencing more than 10 scams in the past. We contacted the victims again to confirm those numbers.

Type of breaches. Victims reported the category of the DeFi hack they recently fell into, which is presented in Table 5. `Smart contract exploitation` was the most prevalent attack, experienced by 22 victims. 9 victims suffered private key theft on their wallets. Other breaches are related to different vulnerabilities as discussed in §2. Regarding DeFi scams, Table 6 confirms that `rug-pull` is the most dominant scam: more than half of the victims were affected. `Phishing` ranked second. Despite the prevalence of phishing attacks and the number of affected victims, the overall concern level for phishing (as reported in Figure 3) was much lower than other risks such as financial risk or private key theft. We surmise this may be due to the fact that phishing incidents do not always result in a direct financial loss: indeed, just 50.0% of `phishing`

Table 7: The number of survey participants choosing each reason for unchanged or strengthened belief in DeFi after the incidents.

DeFi Hack		DeFi Scam	
Reason	Count	Reason	Count
`It was a risk that I was willing to take`	16 (55.2%)	`It was a risk that I was willing to take`	23 (59.0%)
`I am making profits regularly from DeFi`	12 (41.4%)	`It was my fault, I could have been smarter`	21 (53.8%)
`It was my fault, I could have been smarter`	11 (37.9%)	`The technology outweighs the downside of scams`	17 (43.6%)
`I made more research after the hack`	11 (37.9%)	`I made more research after the scam`	15 (38.5%)
`The technology outweighs the downside of hacks`	10 (34.5%)	`I can use trustworthy DeFi apps`	14 (35.9%)
`I can use trustworthy DeFi apps`	9 (31.0%)	`I am making profits regularly from DeFi`	13 (33.3%)
`I am a full-time DeFi trader`	3 (10.3%)	`Other`	2 (5.1%)
`Other`	0 (0%)	`I am a full-time DeFi trader`	0 (0%)

victims reported losing money as a result of the incident; in comparison, a significantly larger proportion of victims reported financial implications in the case of `rug-pull` (77.5%) and `smart contract exploitation` (63.6%).

Response actions. Figure 5 presents a summary of the victims' response actions and the frequency of occurrence. The most frequent response action was "disconnect wallet" and "revoke token approval" – however, their overall adoption rates were just 27.4% and 20.5% after scams, respectively. Worryingly, 13.8% of hack victims and 26.0% of scam victims failed to take any action. These findings are in line with the observations reported in §4.2.2: users generally lack knowledge about appropriate security practices that need to be considered after being affected by a breach. Another concerning trend entails several victims (16.4% after scams) increasing the net investment amount, and using other DeFi services to quickly recover their loss. Such victims may not have put in any effort to improve their security practices even after experiencing various hacks and scams, including rug-pull (23.5%) and smart contract exploitation (11.8%), and merely focused on finding new DeFi services to generate profit again.

Perception changes. The survey results confirmed interview observations at a larger scale: 50.0% of hack victims and 53.4% of scam victims indicated that their security perceptions did not change or confidence increased despite experiencing the hack or scam. Their reasons are summarized in Table 7. For both scams and hacks, "willingness to take risks" was the most prevalent reason for unchanged perceptions, followed by "making regular profits" and "self-blaming". Taken together, these results suggest that DeFi users' financial motivations are very strong, and previous experiences and educational support may have minimal impact on improving their security practices.

Blame distribution. For validation, we asked our survey participants to compose blame points, with a sum of ten, for developers, hackers/scammers, auditors, and themselves, regarding the most recent incident they fell into. The survey results are summarized in Figure 6. In line with the interview results, self-blame was prevalent in both incidents. Even the victims held themselves more accountable than developers for being affected by a DeFi hack. We observed a very wide interquartile blame range for developers in the scam scenario: this may be due to the prevalence of `rug-pull` experiences, in which the developers often play the role of scammers.

4.2.4 DeFi regulation preferences

The survey responses confirmed interview observations. 46.9% of the participants disagreed with the statement "*I am in favor of DeFi being regulated by authorities.*" 35.3% agreed, and the rest were neutral. The top three reasons for endorsing regulation were `contribute to making DeFi secure` (46.2%), `less financial loss for users` (37.7%), and `penalize nefarious persons` (34.3%). In comparison, the most prevalent reason for opposing regulation was `regulation brings in taxes` (53.1%), followed by `regulation hinders innovation` (48.5%) and `nefarious persons' misconduct still` (34.3%).

We also examined how the number of adopted mitigation techniques (RQ2) and DeFi scam/hack experiences (RQ3) influence users' regulation preferences. The first investigation involved dividing participants into three groups for each of the top three risks: those who did not adopt any mitigation technique, those who adopted one or two techniques, and those who adopted more than two. We did not, however, find any statistically significant difference in the regulation preference rates between those three groups. The second investigation involved comparing regulation preference rates between victims and non-victims: again, we did not identify any significant difference between the two groups.

Defining an adequate level of regulation is a complicated issue, and warrants further investigation. However, considering that security risks are often being ignored by DeFi users due to their strong financial motivations, and the most concerning implication of regulation is related to paying additional tax (this is a civil obligation anyway), we carefully hint toward developing an appropriate level of regulations to mandate strong security practices, and help victims protect their assets.

4.3 Key Takeaways

In this section, we highlight the key findings based on the evidence gathered from the two studies. First, profitability and

decentralization, as one would expect, are the two key factors contributing to users' preference for DeFi. Users often blindly believe that decentralization alone translates to strong security and reliability. However, despite this common misconception, users still perceive DeFi as less secure compared to other CeFi services (See §4.1.1 and §4.2.1). Second, similar to security behaviors observed in cryptocurrency systems [2], DeFi users do not employ adequate security controls to mitigate their top concerns. Alarmingly, DeFi users appear overly confident that 2FA will effectively protect them from common DeFi threats. In contrast to the victim characteristics reported in [9], DeFi victims did not show significant improvement in employed security practices compared to non-victims, implying that experience and education may have a limited impact (See §4.1.2 and §4.2.2). Third, `rug-pull` was the most prevalent breach experienced by the victims, and this observation aligns with the overall concern levels and the findings in [6]. `Phishing` was another prevalent attack among the victims, but the perceived concern levels were ranked among the bottom three risks. This contrasting trend may be explained by the fact that phishing does not always result in a direct financial loss (See §4.1.3 and §4.2.3). Fourth, contrary to CeFi victim behaviors [24], prior hack or scam experiences do not seem to affect many DeFi users' security perceptions and confidence in DeFi services. Their strong financial motivations seem to outweigh security priorities and concerns. These observations also suggest that experience and education may be insufficient to help users employ better security practices (See §4.1.3 and §4.2.3). Last, the primary concern for opposing DeFi regulation was paying tax. Considering that the primary objective of DeFi users is to maximize profit, this observation is unsurprising. Many expressed a willingness to sacrifice the potential security benefits of regulation (See §4.1.4 and §4.2.4).

5 Discussion

We present actionable recommendations based on our key findings, and discuss the limitations of the two studies.

5.1 Recommendations

Regulating DeFi to protect users. DeFi victims have a tendency to ignore security risks and pursue financial gains – some victims experienced multiple scam or hack incidents as a result. Such behaviors diverge significantly from previous findings related to internet scams [5, 9] where victims typically employ stronger protective measures after encountering frauds. Perhaps this difference can be explained partially by the analogy developed by Mills *et al.* [36], Delfabbro *et al.* [18], and Johnson *et al.* [28]: they present the idea that cryptocurrency users' trading practices and addictions often resemble gambling behaviors. Our results support their analogy. P13 mentioned "*Some of these DeFi projects are, in my opinion, basically [like] gambling*." If this analogy is accurate, then providing educational support and gaining more experience alone may not be effective in protecting DeFi users. Similar to how the internet gambling industry is heavily regulated to protect gamblers [35], the DeFi industry may also need to mandate strong security controls through regulation and regular audit requirements.

Regulating DeFi is a complicated issue: 46.9% of survey participants opposed the idea, expressing concerns about decentralization benefits being jeopardized through heavy regulation practices. Hence, the community must collectively work toward a decentralized form of regulation. For instance, the concept of a decentralized organization could be employed to facilitate autonomous management of DeFi project memberships [44]. Such organizations would conduct audits and enforce compliance through the means of verifying project team identity, analyzing whitepapers and roadmaps, and auditing project codes. Scam projects or projects that lack security controls would be rejected. Only those that pass the audits and compliance checks would be issued, e.g., a membership certificate – users can check this information before safely engaging with a reliable DeFi service.

Correcting security misconceptions. We identified several security misconceptions. First, many users underestimate the importance of reviewing and revoking token approvals. Educational support and regular reminders are necessary to help users adopt best practices for re-configuring token grant limits to minimize risks. MetaMask wallet, for example, offers comprehensive educational materials related to revoking token approvals [34]. In addition, we imagine a reminder feature that regularly prompts users to review their current approvals would also be effective. Second, users often believe that DeFi platforms provide an equal level of security as the underlying blockchain technology – such an inadequate security mental model needs to be improved, and users need to understand that DeFi platforms are just as prone to common online attacks. Last, many users seem to believe that 2FA is consistently effective against various DeFi threats. To help users understand the security protections offered through 2FA and its limitations, we suggest clarifying the covered threats in the 2FA settings of custodial wallets (e.g., Coinbase 2FA setting[5]) that users use to access DeFi services.

5.2 Limitations

This work has limitations because of its empirical nature. Though applied validation questions about DeFi usage, we relied on self-reported data to recruit DeFi users, which could not prevent participants from giving desirable or repetitive survey responses. In addition, participants' awareness and understanding of different DeFi hacks and scams may influence the self-reported type of incidents they suffered. Another key limitation of our study is the absence of a standardized frame-

[5] https://accounts.coinbase.com/security/settings

work for analyzing the diverse range of DeFi services and applications, which may result in significant variations in user perceptions of their usefulness and security. This limitation restricts our ability to understand how specific DeFi users, such as borrowers or lenders, perceive these factors compared to others. Future studies need to consider these compound factors through the control of demographics. Furthermore, to best accurately reflect the real-world distribution, we did not control the number of victim and non-victim participants. Therefore, we lacked sufficient responses from victims for more in-depth statistical analysis. We also note that we did not ask victims about their net profit or loss. Without this information, we cannot strongly claim that all victims are making short-sighted investment decisions – some victims, despite being affected by several scams or hacks, may be accepting carefully calculated risks to continue investing in DeFi and generating net profit. Investigation of such a strategic group of victims would be an intriguing future work. Lastly, Table 2 and Appendix B show our survey participants' yearly income and their asset distribution percentages in the crypto market and DeFi, respectively. The risk-taking behavior revealed in this paper may not apply to users who are wealthy or arrange a significant percentage of income in DeFi.

6 Related Work

User studies in DeFi. With the increasing popularity of DeFi, researchers have conducted various user studies within the DeFi ecosystems. For instance, Wang *et al.* [46] discovered that many DeFi users lack awareness of sandwich attacks and exhibit a high tolerance for them even after being educated about these attacks – this observation is similar to our report about users' attitudes toward DeFi incidents. However, they also explain that DeFi traders believe they would learn "how to avoid further losses" from losing money, and by being attacked once, they will be motivated to learn and protect themselves next time. These perceptions, studied in the context of a single sandwich attack and non-victims, conflict with our analysis on real-world victims: despite being affected by various DeFi scams and hacks, many victims continued to use DeFi services without revising their security practices. Additionally, Guan *et al.* [25] identified misconceptions among DeFi users, such as the belief that stablecoin developers collaborate with regulatory entities like governments. They also reported various perceived risks related to stablecoins. Our risk concern analysis, however, revealed that the aggregated stablecoin risk is one of the least concerning risks.

Feng *et al.* [21] explored users' perceptions of DeFi auditing and found that interview participants had difficulties interpreting technical audit reports, indicating a gap in the effectiveness of DeFi auditing. Chaliasos *et al.* [8] conducted user studies with DeFi security practitioners to evaluate whether DeFi security tools meet their needs. Notably, these related works do not address our research questions, thereby motivating this paper.

Mitigations of DeFi incidents. Several research approaches have been pursued to prevent DeFi hacks and scams before they occur. A significant direction includes identifying smart contract vulnerabilities through techniques such as fuzzing [10, 26, 38, 49], symbolic execution [31, 32, 37], and static analysis [29, 39, 41]. These methods have successfully detected numerous smart contract vulnerabilities before they could be exploited. Regarding efforts to mitigate scams, Cernera *et al.* [6] discovered that 60% of tokens on Ethereum and Binance Smart Chain last less than one day and highlighted patterns of rug-pulls. Huang *et al.* [27] developed a prediction model to identify NFT rug-pull projects before incidents occur. Conversely, Wang *et al.* [45] focused on recovery from DeFi incidents. To revert exploit txs, they introduced new types of tokens and NFTs, named ERC-20R and ERC-721R, which allow for transaction reversal.

7 Conclusion

Based on a semi-structured interview and a follow-up large-scale survey, we investigated DeFi users' security perceptions and the adequacy of commonly employed security practices. Our results showed that DeFi users tend to have inadequate understanding of the security controls, and ignore security risks to pursue financial motivations. Many participants falsely believed 2FA (not supported in non-custodial wallets) can protect them from most of the common DeFi threats. Our investigation of victims revealed more worrying behaviors: many victims' security perceptions did not change after experiencing scams or hacks, and they continued to use other DeFi services to quickly recover their losses without revising security practices. The majority of such victims failed to take any remedy actions after the incident. Victim behaviors indicate that educational support and gaining more experience may have a limited impact – a much stronger control, such as decentralized regulation, may be necessary to mandate adequate security practices and protect users.

Towards Privacy and Security in Private Clouds: A Representative Survey on the Prevalence of Private Hosting and Administrator Characteristics

Lea Gröber [†‡] Simon Lenau[†] Rebecca Weil[†] Elena Groben[‡]
Michael Schilling[†] Katharina Krombholz[†]

[†]*CISPA Helmholtz Center for Information Security*
[‡]*Saarland University*

Abstract

Instead of relying on Software-as-a-Service solutions, some people self-host services from within their homes. In doing so they enhance their privacy but also assume responsibility for the security of their operations. However, little is currently known about how widespread private self-hosting is, which use cases are prominent, and what characteristics set self-hosters apart from the general population. In this work, we present two large-scale surveys: (1) We estimate the prevalence of private self-hosting in the U.S. across five use cases (communication, file storage, synchronized password managing, websites, and smart home) based on a representative survey on Prolific ($\mathbf{n = 1505}$). (2) We run a follow-up survey on Prolific ($\mathbf{n = 589}$) to contrast individual characteristics of identified self-hosters to people of the same demographics who do not show the behavior.

We estimate an upper bound of 8.4% private self-hosters in the U.S. population. Websites are the most common use case for self-hosting, predominately running on home servers. All other use cases were equally frequent. Although past research identified privacy as a leading motivation for private self-hosting, we find that self-hosters are not more privacy-sensitive than the general population. Instead, we find that IT administration skills, IT background, affinity for technology interaction, and "maker" self-identity positively correlate with self-hosting behavior.

1 Introduction

In the past decade, both end users and companies have migrated to public clouds [23, 28, 44, 61, 69]. Due to an abundance of Software-as-a-Service (SaaS) offerings, clouds are not only used for file storage but also for a broad set of use cases, effectively putting users' data in the hands of third parties. As an alternative, some people set up and maintain their own services on hardware they control. This behavior has distinct security and privacy implications for these so-called "self-hosters": (1) There is a privacy benefit in taking control of data by hosting services on controlled premises [32, 62, 63]. Nonetheless, this benefit is negated if the self-hosted service lacks proper configuration, maintenance, and backup procedures, thereby rendering it vulnerable to attacks or data loss. Accordingly, (2) self-hosters need to take responsibility for securing their operations, a task that requires technical knowledge that not all people who self-host have [26]. Some see a security advantage in self-hosting because they believe small instances are unattractive targets [26], while cloud providers are more prone to be attacked due to the centralization of user data [45]. Yet, big providers usually have the means to invest in experts to secure their operations. Having the means still does not imply that commercial clouds are secure [31, 48, 70] or that individuals without these means fail to secure their self-hosted services [46].

Currently, assessing the security and privacy implications of self-hosting is challenging given the diverse interplay of configurations, use cases, and operator capabilities that have not yet been thoroughly studied. Additionally, there is a lack of comprehensive data on the scale of self-hosting and how many people are impacted by its security and privacy implications. Moreover, to design context-specific solutions that make securing private data easy, we first need to understand the distinct disposition of the self-hoster population.

Accordingly, we propose the following research questions as first steps towards gauging the security impact of self-hosting and laying the foundations for designing effective solutions:

RQ1: *How widespread is self-hosting for private use cases? What kind of people are self-hosting?* Estimating the prevalence of self-hosting is a first step towards understanding its security and privacy impact. Characterizing self-hosters' demographics lays the foundations for constructing personas that are representative of the population and valuable for any kind of security-focused design efforts.

RQ2: *Which tools are self-hosted and how?* Understanding technologies and server-type choices enables us to concentrate research efforts on common security-

relevant and potentially high-risk use cases.

RQ3: *In which characteristics do self-hosters differ from the average U.S. population?* Investigating what distinguishes self-hosters from the general U.S. population contributes to a better understanding of enabling and constraining individual characteristics relevant to system administration work. It also hints at roadblocks in the hosting ecosystem.

We addressed these questions by using a sequential two-survey design. First, we identified self-hosters in a demographically representative U.S. sample with $n = 1505$ participants and analyzed which services they self-hosted. Second, we ran a follow-up survey with $n = 589$ participants and compared the identified self-hosters against a socio-demographically matched control group with regard to 14 characteristics suggesting a relationship with self-hosting. We selected characteristics that we hypothesized would predict self-hosting behavior, based on qualitative insights from focus groups we ran prior to survey construction. This work makes the following core contributions:

1. We estimate the prevalence of self-hosting for private use in the U.S. with an upper bound of 8.4 % CI [7, 9.6]. Based on this we suggest that self-hosting is not a niche phenomenon and that research efforts are worth investing to understand and support a population that is assumed to be strongly motivated by security and privacy concerns.

2. We compile demographic data and individual characteristics that describe the self-hoster population. This information may inform future design studies focused on developing security-enhancing solutions.

3. We provide an overview of prominent use cases and server-type choices highlighting potential high-risk scenarios. Understanding common self-hosting practices helps to identify critical use cases and informs future research and development efforts.

4. We highlight individual characteristics that are positively and negatively associated with self-hosting behavior. This yields insights about which factors could be roadblocks to self-hosting and helps concentrate efforts to support future administrators.

Replication Package. We provide a full replication package including survey instruments, anonymized data, and evaluation artifacts.[1]

2 Related Work and Self-Hosting Definition

Self-Hosting. Self-hosting falls within a spectrum of hardware as well as software control and maintenance responsibility. For the scope of this paper, we define self-hosting as (1) user control over the hardware, i.e., using own hardware or renting said hardware, (2) control over the software, i.e., the operating system, configuration, and applications, (3) the self-hosted service needs to be available over a network, and (4) responsibility for the service, e.g., not relying on a third party for set-up and maintenance.

The research community has been looking at self-hosting from the angle of people administrating their own home networks [6, 8, 20, 25, 65]. This line of work focuses on the growing complexity of home networks due to the increasing number of IoT devices. Problems arise when people have to deal with hardware and software failures and when expectations of usefulness are defied (e.g., mismatches between what a person expects to be able to do and specific device capabilities) [6]. Moreover, recent work investigated private and organizational self-hosting in the case of a popular file-sharing and content collaboration platform. Here, Gröber et al. [26] found that privacy, autonomy, and security are prominent motivational factors when people decide to self-host services for private use. These self-hosters are diverse in terms of technical background and face challenges when it comes to maintenance and security choices.

Security Practices of Administrators. We place our work in the broader context of the security and privacy challenges administrators face. Self-hosters become admins without necessarily having the relevant expertise, however, even experts face challenges when working with security-relevant technology. In this regard, various studies examined root causes and usability challenges for transport layer security misconfigurations [22, 36, 37]. Similarly, Kraemer et al. [35] shed light on the influence of human error on network administration and information security. Li et al. [40] uncover challenges administrators face when updating servers. Dietrich et al. [15] investigated system operators' perspectives on security misconfigurations. They find that mitigations often exist but are not put to effective use. Moreover, recent research started investigating the social embeddedness of system administration work. Kaur et al. [34] uncovered structural challenges marginalized genders face when working in IT administration. Gröber et al. [26] categorized five different constellations in which operators work together to maintain IT infrastructure across organizational and private use. They found that individual characteristics such as operators' level of expertise and use case requirements influence how system administration work is carried out. These works highlight the relevance of the human-centric approach and justify our focus on individual characteristics.

Representative Studies in Security. We join the ranks of representative user studies in the area of security and privacy enabling researchers to draw generalizable conclusions. Redmiles et al. conducted a series of representative studies, such as a U.S.-census-representative survey via Survey Sampling International panel to investigate how demographics, knowledge, and beliefs correlate with security advice and be-

[1] https://projects.cispa.saarland/lea.groeber/usenix24-sh-prevalence

havior of end users [51]. Further, Redmiles et al. ran a census-representative telephone survey to understand how socioeconomic status correlates with security incidents [52]. Finally, Redmiles et al. investigated if data gathered on Amazon Mechanical Turk (MTurk) about security and privacy issues generalize to a broader population [53]. To this end, the authors compared an MTurk sample with a census-representative web panel and a probabilistic telephone sample. They found that MTurk responses regarding security and privacy tasks are actually more representative of the U.S. population than the web panel. This study has been replicated by Tang et al. on MTurk and Prolific and was compared against a probabilistic survey obtained through a service provider [64]. All studies above focus on the U.S. population. Recent research broadened the scope to German citizens [56], and a large-scale international study compared representative samples from 12 countries on four continents [30]. Both studies obtained their sample through online panelists carried out by a service provider. Research showed that online sampling platforms (including the one we used) are suitable tools for representative studies.

We offer a reflection on our study design and share takeaways from preparing and running large-scale representative studies on technical topics in Appendix A.

3 Methods Overview

This work comprises two quantitative surveys that we conducted consecutively. Thereby the self-hoster classification of Survey 1 informed the sampling of Survey 2. This way we were able to recruit a demographically matched control group for the self-hosters and study which characteristics distinguish them from non-self-hosters. Our team of researchers constructed both survey instruments simultaneously in an iterative process starting with paper prototypes. We continuously reviewed them for survey flow, potential biases, survey length, and attention checks and refined survey items (e.g., wording) and measurement details (e.g., scale anchors) to minimize misunderstandings or complications for participants. Two in-depth cognitive walkthroughs where we critically reviewed paper prototypes and the final instruments served as an internal quality check. We outline the final wordings and survey flows in the replication package. Both surveys also underwent technical pre-testing to ensure data collection quality and a smooth experience for participants.

We preregistered the study design including hypotheses.[2] Hypotheses for Survey 2 were grounded in qualitative data of two focus groups we ran prior to survey construction. Thus, we explain the focus groups as a methodological aspect of Survey 2 in Section 7.1.1. In the following, we present both studies in sequential order including details on methodology, results, and discussion.

4 Prevalence Survey 1 - Methods

To allow for valid estimation of the prevalence of self-hosting behavior in the U.S., we aimed to recruit a representative sample of the U.S. population and administer a survey based on which responses we could identify self-hosters. Representativeness in the context of our study refers to meeting the census distribution of age, sex, and ethnicity and, due to sampling via Prolific, is restricted to individuals who have internet access via a computer or mobile device. We assume the influence of this restriction to be minimal because access to such devices exceeded rates of 94% for heads of household up to 64 years old in 2018. For heads of household aged 65 and older, the rate was 80% [43]. With a continuous positive trend in recent years, the influence today can be assumed to be even less [57]. There might be other restrictions (beyond device and internet access) with respect to representativeness we can only speculate about. For example, data collected with Prolific suffer less from unattentive, low-motivated participants compared to other online platforms [17], but we do not have data about distributions of, e.g., motivations or attentiveness of the population and can thus not adjust for it. Each form of assessment (e.g., online, face-to-face, telephone) may introduce biases [55], and representativeness is limited to the assessment methods, their confounds and the selected characteristics for representativeness. Accordingly, our results should be interpreted as such. Our measurements, sampling method, and identification strategy are detailed in the following.

4.1 Measurements

We introduced our survey as a part of research about software and application use in private and professional contexts to avoid biasing participants toward the subject of self-hosting. As a basis for an operational identification strategy of self-hosting behavior, we presented participants with 5 use case categories (i.e., file storage - synchronization, file transfer; Web sites - CMS, blogging; communication - messaging, voice/video telephony; synchronized password managing; smart home) and lists of 5 self-hostable and 6 non-self-hostable tools within each category (see Table 3), in random order. We determined use cases with a crowd-sourced list "Awesome-Selfhosted" on GitHub and narrowed them down according to focus group insights and our research questions. "Smart-home" is included as an edge-case for devices that are available over the network and connected to a self-hosted home automation service in a server-client model. We included tools based on their popularity on GitHub for self-hostable tools [7, 27] and on Google Trends (https://trends.google.com) for non-self-hostable tools. We defined exclusion criteria to ensure self-hostable software tools match our definition of self-hosting. The replication package contains a detailed write-up of the process. In the survey,

participants also had the opportunity to add other tools not mentioned in the pre-selected lists. We asked them to indicate for each tool whether they use it in a private or work context.

For each self-hostable tool, and for each tool entered via the "other" option that was being used in a private context, we asked participants whether the tool was set up for them or whether they had set it up themselves on a server. All participants indicating that they had set up the tool themselves were subsequently asked on which type of server they had set it up (i.e., home server, virtual private server, dedicated server, or other). This was identical for all use case categories, except the smart home category. Here, we asked participants if they had enabled remote access from outside the local network (i.e., accessible via the internet, accessible via a virtual private network, only on the local network).

To reduce the number of false positives (i.e., participants incorrectly identified as self-hosters based on their response in the tool selection) we introduced a definition of private self-hosting in the second part of Survey 1. We distinguished it from commercial cloud services and asked participants if they had come into contact with self-hosting before, providing us with a short description of how they had come into contact via a free text field. We used this information later on as a sanity check for the identification of self-hosters based on their tool selection. To further ensure data quality, we used two attention checks in the survey to identify inattentive participants [47].

In the last part of Survey 1, we collected demographic data and final comments on the survey, and we announced the follow-up survey (Survey 2) for which we might contact some of the participants again. Compensation was estimated based on Prolific's best practice (>= 9 GBP/hour) and pretest duration (~360 seconds). The median response time of 499 seconds ended up higher than our estimate, resulting in a lower hourly wage of 6.49 GBP.

4.2 Sampling

Based on the data available to us at the time of sampling in the U.S. Decennial Census of Population and Housing [67] we defined target sub-samples, representing the U.S. population in terms of sex, age, and ethnicity. Because census data only contain information about the distribution of sexes (i.e., male, female) but not gender, we sampled based on the information available to us. However, because we assessed self-reported gender (i.e., man, including trans man/trans male; woman, including trans woman/trans female; non-binary; self-described) in our surveys, we report this information in the result sections. Moreover, we used the brackets 18-28; 28-38; 38-48; 48-58, and $>$ 58 for the target age and Asian, Black, Mixed, Other, and White for the target ethnicity.

For data collection we used Prolific (www.prolific.co), defining 50 target sub-samples for U.S. residents as a result of the cross combination with sex, age, and ethnicity, utilizing the Prolific pre-screening functionality. Replicating Prolific's in-house representative sampling solution determined the simplification of ethnicity groups in the U.S. census [64, 66]. Prolific allows a relatively cost-effective and fast way to collect data that has been shown to be representative of the U.S. population, at least with respect to some assessed items [64]. As such it might be considered a more feasible approach for non-commercial research purposes as compared to other face-to-face omnibus representative sampling procedures (e.g., ipsos.com). Nevertheless, we have to assume a general bias in our sample, potentially relevant to our research questions, in the sense that it only contains people who have internet access via a computer or mobile device to answer Prolific surveys. Accordingly, we treat our estimation of the prevalence of self-hosting behavior in the U.S. population as an upper bound. The total targeted sample size was $n = 1500$, based on the availability in the Prolific participants pool. Data collection took place between August and September 2022.

4.3 Data Cleaning and Preparation

We only included participants in the sample who had completed the entire survey and passed both attention checks. Due to our aim to achieve a representative sample, we excluded participants who did not meet these criteria, and we re-sampled in line with the requirements of our target sub-samples. Due to technical issues, some participants were observed twice. For these participants, we kept only the first complete data set. Once data collection was complete, three researchers coded participants' final survey comments (codes: "issue", "no issue") to see whether any comments raised doubts about data quality, e.g., the participant mentioned having accidentally indicated to self-host a tool. In case of disagreement, they discussed their ratings and came to a consensus. Four participants were excluded from the sample.

4.4 Survey Weighting

The sampling procedure closely aligned the distribution of sex, age, and ethnicity in our sample to the distribution in the population (see Table 7). Still, slight deviations occurred due to integer sample size limitations and data cleaning (see section 4.3). To resolve these small discrepancies and accurately estimate self-hosting prevalence, we applied the Generalized Regression (GREG) Estimator [14] to obtain calibration weights for our survey, as is best practice in other research areas and official statistics [11,39,50,54]. The weights were determined such that the estimated weighted proportions exactly meet the census proportions in Table 7. The weights are $w_h = N_h \Big/ n_h^{(1)}$ for each element in the h-th socio-demographic group defined by sex, age, and ethnicity. N_h and $n_h^{(1)}$ denote the group sizes in the census and our first survey, respectively. This ensures that our results accurately reflect the diversity of socio-demographic groups in the population, mirroring their exact

proportions in the U.S. population. For example, this counterbalances variations among different groups in participant exclusions based on attention checks.

4.5 Operational Classification of Self-Hosters

We identified participants as self-hosters when they selected or added at least one self-hostable tool in one of the use case categories as privately used, indicated that they had set it up themselves on a server, and confirmed that they had come into contact with self-hosting before taking part in our survey. Alternatively, they were identified as self-hosters when they described in the open response format (i.e., Are there any other tools that you self-host and that have not been mentioned above?) that they use self-hosted tools or network services, set up and maintain services themselves, and are in control of the infrastructure. In addition, they had to confirm that they had come into contact with self-hosting before taking part in our survey. As the latter strategy relied on open responses, four raters coded the open responses independently, checking for the criteria described above. In case of disagreement, they discussed their ratings and came to a consensus. A final sanity check was applied to all self-hoster classifications. Open responses of all identified self-hosters were coded by four coders for any indications raising doubts about the classification (e.g., a non-self-hostable tool was mentioned by the participant as being self-hosted). In case of disagreement, they discussed their ratings and came to a consensus. The classification process produced three outcomes. Participants were either classified as self-hosters, as non-self hosters, or as having an unclear self-hosting status (i.e., due to conflicting information about their self-hosting behavior). This procedure does not necessitate inter-rater-reliability calculation, as conflicts are resolved.

5 Prevalence Survey 1 - Results

We achieved a representative sample ($n = 1505$) of the United States, with respect to age, sex, and ethnicity, in line with the U.S. Decennial Census of Population and Housing Census [67] and the corresponding demographic data available on Prolific. A comparison of the respective shares of age, sex, and ethnicity for our survey and the population can be found in Table 7 in the Appendix.

We rely on confidence intervals (CIs) for assessing statistical significance because, unlike p-values, they quantify (im)precision of reported quantities. For statistically independent groups, non-overlapping CIs imply significance [58]. Where groups are not independent, we additionally used tests for dependent samples (Wald- for binary and t-Tests for continuous variables) to ensure the correctness of reported significances. CIs alone yielded identical conclusions to tests for dependent observations.

Table 1: Estimated self-hosting prevalence and group comparison by age, ethnicity, sex and gender (in %)

		Distribution in subgroups	
	Prevalence	Self-Hosters	Non-Self-Hosters
Age			
18 – 28	8.3 ± 3.2	18.4 ± 6.3	18.6 ± 0.6
28 – 38	10.9 ± 3.7	22.3 ± 6.6	16.5 ± 0.6
38 – 48	7.9 ± 3.2	17.1 ± 6.3	18.2 ± 0.6

5.1 RQ 1: Prevalence of Private Self-Hosting

One of the main goals of Survey 1 was the determination of self-hosting prevalence among the U.S. population. In total, we identified $n = 124$ self-hosters in our sample, indicating an upper-bound prevalence of 8.4 %, CI [7, 9.6] of self-hosting behavior in the US. We also identified $n = 1355$ non-self-hosters and $n = 26$ received an unclear self-hoster status. Table 1 shows the self-hosting prevalence (i.e., estimated occurrence of self-hosters in the population) broken down by age, ethnicity, sex and gender in column 2. For example, we estimated a self-hosting prevalence of 11.6 % in the age group 48-58. We compared the share of age, ethnicity, sex and gender characteristics between the group of self-hosters (column 3) and non-self-hosters (column 4) to determine any significant differences between the two groups with regard to these characteristics (e.g., are self-hosters more likely than non-self-hosters to fall in age group 48-58?). Compared to non-self-hosters, the age group of 48-58 is significantly more frequent, while people older than 58 years are less frequent in the self-hosters sample. Moreover, men are more while women and non-binary people are less frequent among iden-

tified self-hosters. All other assessed demographic characteristics did not differ significantly between self-hosters and non-self-hosters.

5.2 RQ 2: Tool Usage Patterns

To better understand self-hosting behavior, we looked at the distribution of the different use cases and tools selected from the range of presented tools by participants identified as self-hosters. Tools additionally listed by these participants under a respective use case were, due to relatively small numbers, summarized as 'Other'. Participants who we identified as self-hosters solely based on their responses in other open response formats (i.e., Are there any other tools that you self-host and that have not been mentioned above?) are not included in the table due to inconsistent information about use cases, tool names, and server types. Table 2 shows that from our predefined use cases, websites are most frequent among self-hosters. Communication, file storage, synchronized password managing, and smart home are less frequent use cases and do not differ significantly from each other in their frequency. For websites, the most frequently used tool is WordPress, which in the majority of cases is hosted on a home server. For the smart home use case, Home Assistant is most frequently used and in the majority of cases not accessible from the

internet. All tools that were indicated as being privately used by self-hosters from our pre-selection of tools can be found in Table 2.

In addition, we not only looked at the tools that are self-hosted by participants but also at the usage of non-self-hosted tools (i.e., self-hostable and non-self-hostable) for the same use cases in self-hosters and non-self-hosters. Interestingly, Table 3 shows that, across all use cases, self-hosters seem to use more tools in general. That is, they not only use more self-hostbale tools but also more of the non-self-hostable tools (e.g., Microsoft Teams, Google Drive and Home, LastPass) as compared to non-self-hosters.

6 Prevalence Survey 1 - Discussion

The goal of Survey 1 was to determine the prevalence of self-hosting in the U.S. to get a better understanding of how widespread the phenomenon is. To this end, we used a representative sampling method (additionally corrected by weighting), which in turn allows us to gauge the upper bound of the occurrence of self-hosting in the U.S. population. Based on the results of Survey 1 we estimate the occurrence of self-hosting with an upper bound of 8.4 %, CI [7, 9.6]. As such, self-hosting should not be considered a niche phenomenon.

The results of Survey 1 also indicated that self-hosters are more likely to be male and in the 48-58 age group, and less likely to be older than 58. Speculatively, a possible connection between the age of the participants and self-hosting could be the time of the emergence of relevant technologies and the life phases in which the people were at that time. People in the 48-58 age group were born between 1964 and 1974. This means that they were in the late adolescent phase of their lives at the time of the advent of the Internet and might have been open to innovations. At that time, however, the Internet was more technically demanding. More technical knowledge was required, and cloud computing in the current sense did not exist back then. If you wanted a certain service or functionality, "self-hosting" was the default. This is one attempt to reason about this finding, but the present research approach does not allow us to verify such claims. Still, our finding serves as a basis for future research to explore causal demographic variables to explain self-hosting behavior.

Our results also revealed that a large proportion of self-hosting behavior is hosting WordPress websites on a home server. This is a potential high-risk use case, as people are running internet-connected services from their homes. Further research might look into this use case to investigate security configurations and assist people in making secure decisions. Notably, our analyses also showed that being a self-hoster does not necessarily mean solely turning to self-hostable tools and avoiding commercial alternatives. Quite the contrary, across all use cases, self-hosters seem to use more self-hostable and commercial tools in general as compared to non-self-hosters. An avenue for future research is to explore

usage dependencies between tools and across use cases when people self-host.

7 Characteristics Survey 2 - Methods

To be able to better describe the group of self-hosters and understand individual characteristics that correlate with self-hosting behavior, we invited all self-hosters identified with the help of Survey 1 to take part in Survey 2 and matched them with an invited control group of non-self-hosters identified in Survey 1.

7.1 Measurements

The median response time was 614.5 seconds, and participants were compensated with an hourly wage of 14.01 GBP. This section presents details of the survey instrument as well as the hypothesis construction based on qualitative insights from focus groups.

7.1.1 Focus Groups to Identify Predictors

To identify candidate characteristics relevant to self-hosting behavior we conducted two focus groups with self-hosters (three participants) and non-self-hosters (ten participants), respectively. We provide an overview of the procedure, analysis, and results below.

One researcher moderated both sessions, which took about 90 mins each. The researcher followed a protocol (detailed in the replication package) but allowed and encouraged participants to discuss topics freely. To provide a common ground for everyone, the sessions started with an introduction to self-hosting which was especially vital for the non-self-hoster group. As an ice-breaker question, we asked participants about their prior experiences with self-hosting. Only the self-hoster group was then asked about their personal definition of self-hosting, contrasting it with the definition we offered. Afterward, the researcher opened the main discussion which was structured into six key questions: We explored reasons that would discourage individuals from using cloud services (Q1) and why they might be inclined to engage in self-hosting (Q2). Then, participants reflected on situations that might have influenced their decision to self-host (Q3). Moreover, we discussed other possible aspects and domains of life that could be relevant to self-hosting, such as personality traits and individual characteristics (Q4). Last, participants reflected on possible reasons for not self-hosting even though one would want to (Q5) and why some individuals would reject to self-host altogether (Q6). Afterward, we asked only the self-hoster group to identify technical skills they consider essential for self-hosting.

Thematic Analysis. Two researchers (computer scientist and psychologist) first grouped the audio data by questions, then listened repeatedly while applying open coding [9,13,59] independent from each other. The researchers discussed their coding, resolving all mismatches by revisiting the audio data and updating the codes. During this iterative process, it became evident that coding across questions yielded a better fit with the data compared to strictly adhering to the question structures. For instance, the theme "privacy" was observed both as a lack of privacy, which acted as a deterrent from using cloud services, and as a desire to attain privacy, which served as a motivation for self-hosting. Consequently, the coders developed the codebook to capture such overarching concepts. Once the coders reached an agreement, they organized the resulting codes in a mindmap, grouping them into topics and illustrating connections between them. Finally, they used the mindmap as the basis for a discussion to identify themes. In doing so, the coders listened to audio data again, this time identifying and transcribing relevant quotes. They identified ten core themes, for which they found supporting data in both focus groups: *work effort* (the amount of work, time and resources it requires to self-host), *security* (security advantages and disadvantages of self-hosting), *technology interest and skills* (aptitude for and ability to acquire know-how to self-host), *tinkering and DIY* (aptitude for self-hosting and ability to acquire the respective know-how), *interpersonal aspects* (different personal factors influencing the motivation to self-host), *money* (financial aspects involved in self-hosting, required spendings and saving money), *privacy* (privacy concerns and needs that can be addressed by self-hosting), *usefulness of self-hosting* (fulfilling unique needs that are not fulfilled by other services), *control* (self-hosting as a means to gain control over one's own life), *openness to new things* (trying out things and setting trends). Many of these core themes concur with recent research findings, identifying privacy, security, and autonomy needs, saving costs, usefulness, and enjoying learning something new as motivational factors for self-hosting [26]. The authors also showed that a specific skill set and expertise is needed (or needs to be brought in) for self-hosting.

7.1.2 Scale Measurements and Hypotheses

We mapped scale measurements of individual characteristics to all core themes that could be captured by such measures and for which we found validated and reliable scales in the literature (i.e., *security, privacy, technology interest and skills, openness to new things, tinkering and DIY, money, work effort, control*). This allowed us to empirically test if the characteristics that emerged from the qualitative analysis of the focus groups can predict self-hosting behavior. In the survey, scale order was randomized. Similar to Survey 1, to ensure data quality, we used two attention checks in the survey to identify inattentive participants [47]. Below we provide details on the hypotheses and scales we selected to measure the corresponding concepts. Refer to the replication package for further information on the scales.

Security. To assess participants' security concerns with respect to the protection of their personal information, we used the 4-item security concern scale (i.e., "I worry about wrong information being linked to my identity due to security breaches") [1]. Responses were given on a 5-point answering scale ranging from strongly disagree (1) to strongly agree (5). Because results from the focus groups revealed two possible directions for the relationship between security concerns and self-hosting (i.e., providing more security and increasing security risks), we predicted a non-directional relationship between security concerns and self-hosting behavior.

Privacy. Participants' concerns regarding the availability of private information on the Internet were assessed with the 4-item privacy concern scale (i.e., "I am concerned that a person can find private information about me on the Internet") [16]. Responses were given on a 5-point answering scale ranging from strongly disagree (1) to strongly agree (5). Based on the results of the focus groups, we predicted a positive relation between privacy concerns and self-hosting behavior. This would indicate that self-hosting is accompanied by a higher concern for information privacy.

Technology interest and skills: Affinity for technology interaction (ATI). To measure participants' aptitude for interacting with technical systems, we used the 9-item ATI scale (i.e., "I try to understand how a technical system exactly works") [24]. Responses were given on a 6-point answering scale ranging from completely disagree (1) to completely agree (6). Based on the results of the focus groups, we predicted a positive relation between ATI and self-hosting behavior because self-hosters might show a higher interest in technical systems.

Openness to new things: Personal innovativeness in the domain of information technology (PIIT). We assessed participants' interest in trying out and experimenting with new technologies with the 4-item PIIT scale (i.e., "If I heard about a new information technology, I would look for ways to experiment with it") [2]. Responses were given on a 6-point answering scale ranging from strongly disagree (1) to strongly agree (6). Based on the results of the focus groups, we predicted a positive relation between PIIT and self-hosting behavior because self-hosters might be more open to trying out and experimenting with technologies.

Technology interest and skills: Computer self-efficacy. To assess participants' confidence in performing computer-related activities, we used the advanced (i.e., "Using a computer's task manager"; BITS-Ad) and expert ("Analyzing computer error log files"; BITS-Ex) subscales of the Brief Inventory of Technology Self-efficacy (BITS) [68], asking people to indicate their level of confidence performing each activity. Responses were given on a 6-point answering scale ranging from not at all confident (1) to completely confident (6). Based on the results of the focus groups, we predicted a positive relation between BITS-Ad and BITS-Ex and self-hosting behavior because self-hosters might show more advanced and expert technology skills.

Technology interest and skills: Self-hosting skills. Self-reported skills to set up and administrate a server were assessed with a self-developed 6-item scale. We first presented participants with a job description of a system administrator. Subsequently, we asked them to rate their abilities in different domains (computer networks, operating systems, servers [virtual or physical], software, system security, and system administration). Responses were given on a 6-point answering scale ranging from poor (1) to excellent (6). Based on the results of the focus groups, we predicted a positive relation between self-hosting skills and self-hosting behavior. This should be the case if self-hosting requires a certain basic skill set.

Technology interest and skills: IT background. To assess IT background, we used an item (i.e., "Are you studying or have you been working in any of the following areas: information, technology, computer science, electronic data processing, electrical engineering, communications technology, or similar?") introduced by Elbitar and colleagues [21]. Responses were given on a dichotomous answering scale (yes/no). Based on the results of the focus groups, we predicted a positive relation between IT background and self-hosting behavior. An IT background might provide people with the necessary skill set.

Tinkering and DIY: "Maker" activities. To measure how much time participants typically spend with domestic activities (e.g., baking), DIY activities (e.g., woodworking) and arts and crafts (e.g., ceramics), we adapted 18 different activities from Collier and Wayment [12] and asked participants to indicate their time spent with each activity on a scale from "none" (1) to "I spend large amount of time doing activity" (5). Based on the results of the focus groups, we predicted a positive relation between "maker" activities and self-hosting behavior. This should be the case if self-hosting goes along with other tinkering and DIY activities.

Tinkering and DIY: "Maker" self-identity. Participants' self-identity as a "maker" or DIY person was assessed by presenting them with a short description of what is meant by do-it-yourself (i.e., "sometimes this can be called crafting, sometimes it refers to hobbies. Typically it leads to making something tangible. That is, what you can create with your own two hands.") and asking them to indicate on a scale from not at all (1) to extremely so (5) how much they identify as a "maker" or DIY person. This procedure was adapted from Collier and Wayment [12]. Based on the results of the focus groups, we predicted a positive relation between "maker" self-identity and self-hosting behavior. This should be the case if self-hosters perceive themselves as DIY persons.

Money: Frugality. Participants' economical consumer lifestyle was assessed with the 9-item frugality scale (e.g., "I believe in being careful how I spend my money") [38]. Responses were given on a 6-point answering scale ranging from definitely disagree (1) to definitely agree (6). Based

Table 4: Consistency between operational and self-classification as self-hoster

	Self-classification		
	Non-Self-Hoster	Self-Hoster	Overall
Operational classification			
Non-Self-Hoster	355 (60.3%)	122 (20.7%)	477 (81.0%)
Self-Hoster	32 (5.4%)	80 (13.6%)	112 (19.0%)
Overall	387 (65.7%)	202 (34.3%)	589 (100.0%)

on the results of the focus groups, we predicted a positive relation between frugality and self-hosting behavior because self-hosters might ponder more about what to spend their money on.

Work effort: Grit. The extent of participants' consistency of interest (GRIT-Co) and perseverance of effort (GRIT-Pe) was assessed with the 8-item GRIT-S scale (e.g., "I often set a goal but later choose to pursue a different one"; "I am diligent.") [19]. Responses were given on a 5-point answering scale ranging from strongly disagree (1) to strongly agree (5). Based on the results of the focus groups, we predicted a positive relation between GRIT-Co and GRIT-Pe and self-hosting behavior. This might be the case if self-hosting behavior goes along with being consistent in an area of interest and putting effort into reaching a goal.

Control: Autonomy. To assess participants' valuation of self-direction and freedom of choice in their daily activities and undertakings, we adapted eight autonomy items (e.g., "I feel I'm doing what really interests me") from the Basic Psychological Need Satisfaction and Need Frustration Scale (BPNSNF) [10]. Responses were given on a 5-point answering scale ranging from not important to me at all (1) to very important to me (5). Based on the results of the focus groups, we predicted a positive relation between Autonomy and self-hosting behavior because self-hosting behavior might go along with the importance that is ascribed to having control over one's life.

7.1.3 Self-Report Identification

Because the identification of (non-)self-hosters in Survey 1 was based on operational criteria (i.e., participants' response behavior in closed and open questions), we employed a self-report identification procedure in Survey 2 to complement the measurement from the previous survey. To this end, we presented participants with a definition and examples of self-hosting and then asked them whether they would describe themselves as a self-hoster (i.e., whether they currently self-host or have recently self-hosted at least one tool/service in their personal life). We emphasized that their answer would not affect survey length or compensation to minimize externally motivated answering behavior.

7.2 Sample Selection Process

To allow for a meaningful comparison between self-hosters and non-self-hosters with reliable group estimates, self-hosters were matched with non-self-hosters in an approximate (influenced by the availability and responsiveness of participants in the pool) ratio of 1:3 [60] with respect to age, ethnicity, and sex, keeping the influence of these demographics as constant as possible in both groups. Choosing 3 non-self-hosters per 1 self-hoster, rather than 1:1, reduces error and confidence interval width when comparing the two groups [58]. To ensure estimates generalize to the broader U.S. population, our weighting scheme (Section 7.4) adjusts for non-proportional group sizes. For data collection, we again used Prolific. Data collection took place between September 2022 and November 2023. 98.68% of the sample was completed in December 2022. However, to increase the chances of including the maximum number of self-hosters, the survey was opened up to November 2023.

7.3 Data Cleaning and Preparation

We only included participants in the sample who had completed the entire survey and passed both attention checks. Participants who did not meet these criteria were excluded, and we re-sampled in line with the requirements of our sample selection process. Once data collection was completed, three researchers coded participants' final survey comments to see whether any comments raised doubts about data quality (e.g., participant indicated having trouble with filling out the scale items). In case of disagreement, they discussed their ratings and reached a consensus. Following this approach, one participant was excluded.

7.4 Survey Weighting

To be able to make valid claims about the population for our findings in Survey 2, we adjusted for deviations between our sample and the population with respect to the distribution of sex, age, and ethnicity as well as for the over-representation of self-hosters, both resulting from our sampling design (see section 7.2). The calibration weights are determined such that the

estimated weighted proportions across all socio-demographic groups containing self-hosters are the same in Survey 2 as they were in the representative Survey 1 and that the estimated share of self-hosters within each of these groups also corresponds to the prevalence estimated in Survey 1 (see tables 7 and 8). As in section 4.4, we used the Generalized Regression estimator [14] for this purpose. The weights for Survey 2 are therefore $w_h = \widehat{N}_h^{(1)} \Big/ n_h^{(2)}$ for each element in the h-th group defined by sex, age, ethnicity, and self-hoster status. $\widehat{N}_h^{(1)}$ denotes the *weighted* size of this group in Survey 1 and $n_h^{(2)}$ the sample size in Survey 2.

8 Characteristics Survey 2 - Results

Our initial sample in Survey 2 consisted of $n = 112$ self-hosters (i.e., a retention rate of 90.32%) and $n = 477$ non-self-hosters (self-selected from a pool of $n = 1355$), identified in Survey 1. Appendix B contains details on sample demographics.

Because we asked participants in Survey 2 to indicate whether they described themselves as self-hoster, we used this indication to compare it with the classification based on operational criteria from Survey 1. Table 4 shows the consistency between classifications of Survey 1 and Survey 2. The results reported hereafter follow a conservative approach and are thus solely based on participants whose classification concurred.

8.1 RQ3: Individual Characteristics

We inspected all scales and, if applicable, subscales, with respect to their internal consistencies [33]. We calculated Cronbach's alpha (α) for all scales requiring simple mean scores [1, 2, 12, 21, 24, 38, 68] and McDonald's omega (ω) for all scales requiring mean scores weighted with factor loadings [10, 16, 19]. Internal consistency ranged from $\alpha = .82$ to .95 and $\omega = .77$ to .92, indicating an overall acceptable to good reliability for the scales. To investigate which of our selected predictors best explain self-hosting behavior, we entered all predictors into a backward stepwise regression analysis (see Table 5). The model that best fits our data, as indicated by the lowest Akaike information criterion (AIC) [3], contains affinity for technology interaction (ATI), "maker" self-identity (DIY-self), perseverance of effort (GRIT-Pe), IT background and self-reported self-hosting skills as significant predictors. ATI, DIY-self, IT background, and skills showed significant positive relations to self-hosting behavior, indicating that participants who belong to the group of self-hosters show a higher aptitude for interacting with technical systems, identify themselves stronger as makers, report more frequently having an IT background and report better self-hosting skills than participants who belong to the group of non-self-hosters. GRIT-Pe showed significant negative relations with self-hosting behavior, indicating that self-hosters report less perseverance in their efforts as compared to non-self-hosters.

9 Characteristics Survey 2 - Discussion

The goal of Survey 2 was to get a better understanding of self-hosters with respect to their individual characteristics. Our results showed, in line with our predictions that self-hosters (as compared to non-self-hosters) show greater interest in technical systems, more often have a skill set that allows them to perform the behavior, and more frequently have an IT background. In Survey 1, we learned that self-hosters in general use more tools, including SaaS solutions. Both findings suggest that self-hosting goes hand in hand with a strong technical background. Speculatively, technical people who use a broad set of tools also adopt self-hostable solutions. Our observations may also point to major roadblocks in the self-hosting ecosystem, allowing only skilled people to stay in it.

Moreover, we found that self-hosters perceive themselves more often as DIY persons, although we did not find evidence that self-hosters' DIY activities differ from those of non-self-hosters. Contrary to our prediction, self-hosters seem to show less perseverance in their efforts as compared to non-self-hosters. What might appear as a counter-intuitive finding at first glance could be explained by research showing that having grit not only helps people to achieve difficult goals [18] but can also have a flip side, making it hard for people to let go [4], therefore making them persist when moving on might be the better choice [42]. Accordingly, the fact that self-hosters show less perseverance of effort also indicates that they might have an easier time letting go of goals that are not worth pursuing. Further research should explore whether and how being more flexible in goal pursuit might aid or result from self-hosting behavior.

Unexpectedly, we did not find any evidence that self-hosters differ from non-self-hosters with respect to their security or privacy concerns, their computer self-efficacy, their openness to new technologies, their economical consumer lifestyle, or their valuation of autonomy. This is especially surprising because self-hosters named privacy, autonomy, and security as motivational factors [26]. However, our results do not imply that security or privacy concerns play no role when it comes to self-hosting. Rather, these factors do not explain the behavior beyond the predictors discussed above.

At present, we can only speculate that, although carefully considered, selected scale measures might not exactly represent the core themes identified in the focus groups (e.g., did the frugality scale capture all financial aspects involved in self-hosting?) or identified core themes might not apply to all self-hosters but potentially only to a specific subgroup (i.e., concurring themes in Gröber et al.'s research are based on a specific community, that is Nextcloud users [26]). It is

Table 5: Logistic regression model for self-hoster status: stepwise selection

also possible that identified core themes are at least partly influenced by focus group participants' ideas and conceptions about self-hosters and that these conceptions do not perfectly match the actual characteristics of self-hosters.

10 Discussion and Future Research Directions

In this section, we discuss future research directions and highlight opportunities and challenges.

Security and Usability of Infrastructure. This work focuses on people who are currently self-hosting. Thus, we must assume survivorship bias with regard to the perspective of people who would like to become self-hosters or people who tried and failed. Based on our findings, having technical skills (or believing to have technical skills) and IT background are indicators for self-hosting. This possession of technical skills could lead to people "surviving" when self-hosting. However, it may actually indicate severe technical roadblocks or usability challenges. Thus, future research should investigate what is currently preventing people from self-hosting. In doing so, studies should maximize external validity to provide a realistic view of entry burdens such as set-up procedures, infrastructure decisions, and secure configurations. We argue further that research may focus on usability and security challenges of hosting infrastructure in the long run. In general, conducting research tailored to assist private hosters, who may have fewer resources and background knowledge, will benefit the greater population of IT administrators if security and usability challenges are streamlined.

Investigate Socio-Technical Influences. Infrastructure does not exist in a vacuum but is directly impacted by the people administrating it and the social environment they are embedded in [26]. We identified different individual characteristics that (may) predict self-hosting behavior. Future research should investigate the interplay of individual characteristics enabling or constraining different stages of the hosting process. The social embeddedness may actually be a determining factor of self-hosting success. Long-term studies could help to link infrastructure configurations with socio-technical parameters, such as individual characteristics of administrators, and relate those to observable security outcomes. This way we obtain valid assessments of the security of self-hosted systems. Moreover, this work identifies demographic data that describes the self-hosting community. This data identifies prominent populations of self-hosters and highlights underrepresented groups. For example, we found that gender minorities are less likely to self-host. Future research might investigate this beyond organizational embedded administrators [34].

Community-Driven Design. While we cannot directly offer implications for design based on our findings, the demographic data we collected provide valuable perspectives for future design efforts. Specifically, it is useful for building personas representative of the self-hosting population, while being mindful of underrepresented groups. We suggest community-driven and participatory methodologies when designing solutions or tooling for self-hosters. That is because of the various use cases and diverse demographical traits, which makes one-fits-all solutions unlikely.

11 Ethical Considerations

Both studies received approval by Saarland University's ethical review board. Before collecting any data, we obtained informed consent of the participants for both studies. We told the participants that the survey was anonymous and that all data will be treated confidentially. Moreover, we clarified that their participation was voluntary and that they had the right to withdraw at any point. We disclosed our identity and offered a contact email address for any questions. We were transparent about the overall study process including an optional follow-up survey. The collected data was stored on CISPA Helmholtz Center for Information Security private servers. To protect the participants' privacy, we anonymized the study data we made available to the public.

12 Limitations

Generalizability. With our sampling and weighting method, we recruited a representative sample of the United States with respect to age, sex, and ethnicity. Our sample might still be biased by our approach to recruiting participants only via Prolific. However, recent research showed that sampling on Prolific does allow to generalize results at least with respect to certain topics [64] and outperforms other means of online data collection [17,49]. Accordingly, in terms of overall feasibility, our approach maximizes the currently available resources and instruments.

Self-selection Bias. Our sampling method and, thus, our results are not immune against self-selection bias [29]. However, we took utmost care when announcing the survey and creating the instructions to conceal the actual purpose of our research. Accordingly, we cannot entirely rule out self-selection bias due to the general topic (e.g., software and application usage), but we minimized self-selection based on the topic of self-hosting.

Framing of Self-Hosting. The results of our research largely rest on our definition of self-hosting, which also determined the selection of use cases and tools. Accordingly, our research might underestimate other instances in which people administrate their own infrastructure and services but did not see their behavior reflected in our definition of self-hosting. We paid close attention while coding the open responses in Survey 1 to include all possible cases that went beyond our pre-selection of use cases (e.g., gaming, media server) and are confident to have included these in our classification. Yet, the self-report identification in Survey 2 (i.e., whether people would describe themselves as self-hoster, taking our definition into account) might have led to an exclusion of actual self-hosters who do not agree with our definition. Because it is not possible to conduct the present research without at least a working definition of self-hosting, future research should explore other use cases and potentially more inclusive or more narrow sub-definitions of self-hosting. For example, we included smart home devices as an edge-case if people administrated a home automation service in a server-client model. Future work could look into sub-aspects of self-hosting that only satisfy parts of our definition like "responsibility", "available over a network", and "software control", e.g., for open-source IoT devices.

Causality. As our results rest on correlations, we cannot make any claims about causal relationships between self-hosting behavior and individual characteristics [41]. More specifically, we do not know whether interest in technical systems, self-hosting skills, and having an IT background is a precondition for self-hosting or follows from self-hosting behavior. Likewise, perceiving oneself as a DIY person might be a necessary prerequisite or might simply result from the experience of self-hosting. Similarly, having an easier time letting go of goals might be beneficial for self-hosting in a fast-moving technology ecosystem or might be a result of having experienced the need to adapt and shift goals quickly when practicing self-hosting.

13 Conclusion

We find that self-hosting is not a niche phenomenon, with an upper-bound estimate of 8.4% of the U.S. population. Results identify prevalent potential high-risk use cases such as Wordpress instances running on home servers and home automation accessible from the Internet. Our work lays the foundations for further research about a population previously assumed to be strongly motivated by security and privacy concerns [26]. However, we find that people who have higher privacy or security concerns are just as likely to be self-hosting as those who do not have such concerns. In other words: neither privacy nor security concerns are predictors of self-hosting behavior. Instead, we find that characteristics related to technology interest, hosting skills, and "maker" self-identity are positively correlated with self-hosting. Since we only consider present self-hosters, these characteristics might be subject to survivorship bias. Our findings may actually indicate severe technical roadblocks or usability challenges in the hosting ecosystem. Thus, our findings can inform the design of new solutions that benefit both expert and novice administrators.

Acknowledgments

We thank the reviewers and the shepherd of this paper for their time, valuable feedback, and guidance, which helped to improve our work. We also thank the participants of the focus groups and surveys for their important contributions and insights. Additionally, we thank our colleagues Matthias Fassl, Sebastian Roth, and Marius Steffens for their helpful feedback and support throughout this project. Your efforts and encouragement have been greatly appreciated.

A Large-Scale Studies on Technical Topics

Identifying a Sub-Population Based on Operational Criteria and Self-Report. One of the main goals of our research was to identify a group of people based on their specific behavior (i.e., private self-hosting). We spent time and effort to (1) define the behavior of interest as exactly as possible, and (2) derive measurable indicators of usage from this definition. This allowed us to use operational criteria for identification without the necessity for participants to self-identify. Using operational criteria can be advantageous to avoid answering behavior based on demand characteristics [5] and to ensure that the behavior intended to be captured is represented entirely in what is actually measured. However, this method is not immune to participants' misconceptions influencing their response behavior. To illustrate, without relevant background knowledge, downloading and installing an application might be misconceived as administrating it on their own hardware. Accordingly, the right wording of items and questions is paramount in minimizing the number of false positives for identification. Yet, exact wording cannot entirely rule out misconceptions.

A remedy against misconceptions is educating participants about the behavior of interest. Under the premise that participants read the information attentively, understand the definition, and can apply it to their own behavior, false positives in identification might be reduced. Yet, such an approach is more susceptible to demand characteristics. In our research, we combined both methods to keep participants' misconceptions and demand characteristics at a minimum. We suggest that this might be good practice for investigating certain behaviors with surveys to balance out trade-offs.

Representative Sampling and Data Processing. In order to assess how commonly individuals host their own services and understand how this behavior relates to personal traits, an important task was to facilitate drawing conclusions from volunteer web surveys (i.e., Prolific) that are reasonably generalizable to the population. As part of our two web surveys, we put a lot of effort into increasing the precision of our results by (1) carefully selecting a sample that reflects the overall population in terms of age, gender, and ethnicity, and (2) mitigating potential biases and selectivity in responses through thorough data cleaning and the application of calibration weighting.

We are convinced that such efforts to capture the population's full diversity in the sample and minimize the impact of potential selectivity and bias (e.g., due to low-quality responses) contribute significantly to advancing human subjects research in the area of security and privacy.

Abstract

This work considers the threat model of wireless signal injection attacks on Very Small Aperture Terminals (VSAT) satellite modems. In particular, we investigate the feasibility to inject malicious wireless signals from a transmitter on the ground in order to compromise and manipulate the control of close-by satellite terminals. Based on a case study with a widely used commercial modem device, we find that VSATs are not designed to withstand simple signal injection attacks. The modems assume that any received signal comes from a legitimate satellite. We show that an attacker equipped with a low-cost software-defined radio (SDR) can inject arbitrary IP traffic into the internal network of the terminal. We explore different attacks that aim to deny service, manipulate the modem's firmware, or gain a remote admin shell. Further, we quantify their probability of success depending on the wireless channel conditions and the placement of the attacker versus the angle of arrival of the signal at the antenna dish of the receiver.

1 Introduction

VSAT satellite communication systems are used for two-way data transfer, including internet connectivity, voice communication, and video transmission. They are commonly deployed to remote areas, maritime environments, crisis regions, and other locations where terrestrial communication infrastructure is limited or unavailable.

Despite the vital importance of VSAT communication for connecting critical infrastructure, it has not received the same attention in security research as other wireless communication systems. Historically, high equipment costs of satellite communication have acted as a barrier to entry for both researchers and attackers. Recently, however, researchers have demonstrated the feasibility to eavesdrop on such communication with less than $300 of widely-available television equipment [2, 24]. Furthermore, the security vulnerabilities of this infrastructure have not gone unnoticed by cyber threat actors. In February 2022, at the beginning of the Russian attack on Ukraine, a major operator of satellite communication services, Viasat, experienced a disruption that resulted in a significant portion of its network becoming inoperable across Europe. According to the company's official statement [39], the attacker used a misconfigured VPN to gain access to the central hub. From there, they issued legitimate commands to the remote endpoints and rendered thousands of them inoperable. SentinelLabs identified a malicious binary called AcidRain that was uploaded to the affected modems and wiped the file system [14]. Recently, in June 2023, another attack on the satellite communication system of the Russian company Dozor-Teleport was reported [27]. This event coincided with the uprising of the mercenary group Wagner in Russia and resulted in the failure of their system. However, little is known about how the attackers proceeded in this case and in general the security dimensions of satellite Internet services remain not well understood. What is becoming clear, though, is the strategic importance such systems have gained in this day and age.

In this work, we aim to better understand the threat of wireless signal injection attacks on VSAT communication. In particular, the main research question we tackle in this paper is how an attacker may compromise the operation of VSAT modems by injecting malicious signals from a close-by transmitter. Signal injection attacks have been considered in various wireless communication systems including the Global Positioning System (GPS) [11, 15, 33, 34], aviation [37, 38] or phone networks [10, 40], but VSAT communications are quite different to these systems in terms of antenna and modem software stack, and the results thus do not generalize to this type of communication. Salkield et al. [29] provide a theoretical, application-independent security analysis of overshadowing attacks on satellite communication, but their analysis remains theoretical in nature and does not address the impact that the signal injection attacks may have on real antennas, modem's software and networking stack.

With the emergence of software-defined radios and readily available, low-cost radio equipment, enabling an attacker to

generate and emit arbitrary electromagnetic signals, signal injection attacks have become more viable. Of particular interest to our study is how modems implement conventional defenses like firewalls or authentication and how an attacker on the ground may successfully inject a spoofed signal in a receiver given the high directionality and gain of VSAT satellite antenna dishes, and their orientation towards the sky.

This work makes the following contributions to the current state of research on satellite communication system security:

- We conduct a comprehensive analysis of a VSAT satellite modem, exploring its communication functionality, hardware architecture, and firmware components.
- We introduce a SDR-based attacker implementation capable of executing arbitrary spoofing attacks.
- We demonstrate proof-of-concept signal injection attacks against a satellite modem. We show how to disrupt the modem's operation and gain privileged access.
- We provide an empirical analysis of the conditions that facilitate the successful execution of such attacks.

2 Background

This section introduces several concepts underlying this work. On the one hand, we describe the topology of satellite communication systems and VSATs. On the other hand, we also present the protocol stack used in the evaluated satellite communication system.

2.1 Satellite Communication Systems

Satellite communication systems transmit and receive signals for various types of communication, such as television broadcasts, phone calls, and internet connectivity. On a high level, they consist of three components:

Central Hub: The central hubs or ground stations which are located on Earth serve as communication hubs. They are equipped with large dish antennas that transmit and receive signals to and from the satellites. Central hubs act as a relay between the satellites and terrestrial communication systems, such as the internet, or between several VSAT modems in a mesh network.

Satellite: Satellites are positioned either in geostationary, medium Earth, or low Earth orbit. Geostationary (GEO) satellites remain fixed with respect to a specific location on Earth, while medium (MEO) and low (LEO) Earth orbit satellites move along orbits closer to the Earth's surface. Most satellites only forward the signals from the central hubs to the endpoint or vice versa. They can be compared to a bent pipe, as they do not perform any data processing, routing, or authentication.

Endpoint: The remotely deployed endpoints communicate with the satellites. The received data at the endpoints is then delivered to the intended recipient, which could be a television, a phone, a computer, or any other device capable of decoding and utilizing the information. Depending on the type of satellite, endpoints may also be able to transmit data back to the central hub via the satellite.

These three components communicate with each other over radio signals. The signals are usually transmitted within the Ku band between 12 GHz and 18 GHz as well as within the Ka band between 27 GHz to 40 GHz. Depending on the system, the communication is separated into two channels: a *forward channel* and a *return channel*. The forward channel is the transmission link from a central hub to an endpoint. The return channel is the transmission link from an endpoint to the central hub. Typically, only the central hub transmits on the forward channel, so channel access method is a consideration only on the return channel. Non-interactive systems, such as television broadcasts, have only a forward channel.

Each channel in turn consists of an *uplink* and a *downlink*: The uplink is the communication path from the central hub or user terminal back to the satellite. The downlink is the reverse communication path, namely from the satellite to the central hub or endpoint. These concepts are illustrated in Figure 1. Once the satellite receives the uplink signal, it amplifies and retransmits the signal on another frequency back to Earth using a transponder. It is important to note that this is a simplified explanation of satellite communication systems. There are variations in the technology and protocols used depending on the specific application and satellite network architecture. Additionally, satellite systems may employ multiple satellites in a constellation or employ complex beamforming and frequency reuse techniques to optimize coverage and capacity.

2.2 Very Small Aperture Terminals

VSAT systems are used for two-way data transfer, including internet connectivity, voice communication, and video transmission. They are commonly deployed to remote areas, maritime environments, crisis regions, and other locations where terrestrial communication infrastructure is limited or unavailable. The topology is identical to a generic satellite communication system shown in Figure 1. The endpoints consist of an *outdoor unit* (ODU) and an *indoor unit* (IDU).

The ODU comprises a high-gain dish antenna, typically ranging from 0.75 m to 1 m in diameter that has a directionality, and a transceiver. The dish is used to transmit and receive signals to and from a geostationary satellite. It is installed outdoors to establish a line-of-sight connection with the satellite. Once the dish points at the satellite, it does not need to be readjusted as the satellite does not move relative to Earth.

The indoor unit serves as the interface between the outdoor unit and the user's network. It typically includes a modem, network interface, and other control and monitoring functions. The IDU allows users to configure and manage the VSAT settings. The modem is used to modulate outgoing data signals

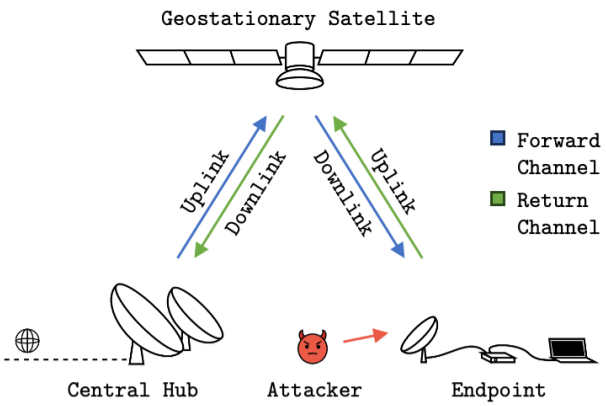

Figure 1: VSAT satellite communication system.

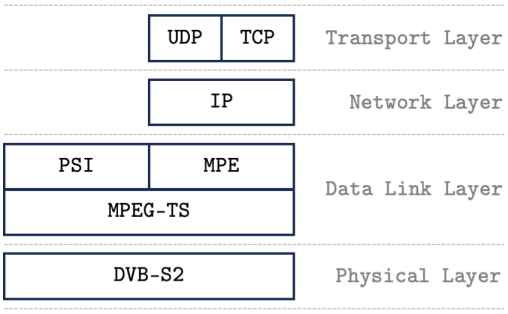

Figure 2: Protocol stack of the DVB-RCS forward channel.

for transmission and demodulate incoming signals for reception. Moreover, it performs functions such as encoding and error correction to ensure accurate and reliable data transfer. The indoor unit is also equipped with a network interface to connect to the user's local network. It may include Ethernet ports, WiFi capabilities, or other networking options to enable connectivity with computers, routers, and other devices within the user's premises.

VSAT operators are typically responsible for maintaining the remotely deployed endpoints. To this end, they maintain a service connection between the central hub and the endpoints, to issue firmware and configuration updates.

2.3 DVB-RCS Protocol Stack

Digital Video Broadcasting - Return Channel via Satellite or short DVB-RCS [18] is a standard for two-way satellite communication systems published by the European Telecommunications Standards Institute (ETSI) in 2000 and at the heart of the wireless injections shown in this paper. It defines a protocol stack for both the forward and return channel that enables communication between a central hub and endpoints. On the forward channel, a signal is broadcast from a central hub to all endpoints. In this way, each endpoint receives the same signal, demodulates and demultiplexes it, but only processes data addressed to it. The return channel, on the other hand, uses Multiple Frequency Time Division Multiple Access (MF-TDMA) to coordinate access to the shared medium and prevent the endpoints from interfering with each other. This requires synchronization among endpoints.

This work focuses solely on the forward channel because injecting a signal into this channel suffices to attack an endpoint. The forward channel protocol layers in DVB-RCS, shown in Figure 2, closely align with layers in the OSI model. Since DVB-RCS supports classical IP-based communication for higher layers, we only describe here the satellite-specific physical and data link layers.

Physical Layer: The physical layer is responsible for transmitting and receiving raw bits over the satellite link. In DVB-RCS, it is specified by the DVB-S2 standard. It supports multiple modulation schemes and adds error correction codes. The standard specifies packetized and continuous data streams.

Data Link Layer: In DVB-RCS, the data link layer uses MPEG-TS, which multiplexes multiple data streams intended for different recipients into one transmission. In addition, DVB-RCS supports Multiprotocol Encapsulation (MPE) for encapsulating different types of data packets, such as IP packets. MPEG-TS specifies two types of communication: unaddressed and addressed communication. In unaddressed communication, the data is transmitted to any receiver that receives the signal. In addressed communication, the transmitted data is intended only for reception and processing by a subset of receivers, namely those specified as receivers.

3 Threat Model

The threat model we consider in this work is an attacker that injects wireless signals on the downlink of the forward channel in order to deceive or disrupt the satellite-based communication at the VSAT endpoint. Similar to recent work [29], we define 'signal injection' in this paper as an attacker sending signals from the Earth's surface to the receiver's dish, which otherwise receives its signals only from the intended satellite beam.

This can be considered a significant change from normal operating procedures, whereby the satellite dish and receiver are pointed at a satellite in the sky and receive signals coming exclusively from this direction. In this work, we show that this inherent physical security assumption is not effective in defending against ground-based attackers, also on higher layers of the network stack.

If the legitimate satellite signal is being sent at the same time as the attacker's, this additionally constitutes so-called overshadowing of the legitimate signal by the attacker signal [29].[1]

For example, a spoofing attacker might be able to trick an endpoint into accepting forged configuration updates or com-

[1] For legal and ethics reasons, we did not test this option.

mands. To do this, we assume that the attacker has intimate knowledge of all the protocols in order to forge legitimate communication, and that they have radio equipment to send arbitrary signal waveforms on the frequency of the downlink channel. For example, they may use a software-defined radio such as a USRP or a HackRF together with an upconverter and an antenna to send in the Ku or Ka bands. With this knowledge and equipment, they are able to create arbitrary packets and transmit them to an endpoint.

The attacker must not necessarily be in the direct line between the endpoint's antenna dish and the satellite, but they must have a line-of-sight connection to the antenna of the endpoint and be able to transmit with such power that its signals are stronger than the signals of the legitimate satellite. This is not difficult to achieve since the attacker is on Earth and thus much closer to the endpoint than the satellite in orbit, but high power and close proximity may aid potential detection.

The attacker's goal is to exploit any protocol or software vulnerabilities on the endpoint's side in order to deny service, compromise the integrity of the device, or gain privileged access.

Here, we assume that the attacker knows the modem of a victim (or opportunistically targets any vulnerable device) and can acquire similar hard- and software in order to create a laboratory setup for the initial reverse engineering and vulnerability research similar to what we did in this work. This is a straightforward assumption as satellite modems are generally commercial-off-the-shelf hardware with standard Linux systems (we exclude proprietary military or governmental hardware from our analysis). They can be sourced either directly from a satellite provider/reseller together with a working connection or be bought off second-hand platforms such as eBay.

4 Case Study: Newtec MDM2200

In order to better understand the security of real-world VSAT satellite communication, we analyze the software and hardware architecture of the popular Newtec MDM2200 satellite modem [22] as a typical VSAT endpoint device in the non-governmental/military market. The information in this section is based on knowledge we extracted from publicly available product briefs and technical sheets [22] as well as our own reverse engineering efforts of the modem software's version *2.2.6.19* from *Oct 2014*, which corresponded to the most current version provided to us from the service provider in *March 2021*. The MDM2200 device was introduced by Newtec in 2012 as part of its Dialog modem series. The company was acquired by iDirect in 2019. iDirect as well as Newtec are mainly active in the business-to-business sector. They sell their modems and central hubs to resellers who in turn sell satellite communication services to their customers.

A diverse mix of iDirect systems are in use worldwide. By their own account, in 2022 they held the greatest market share

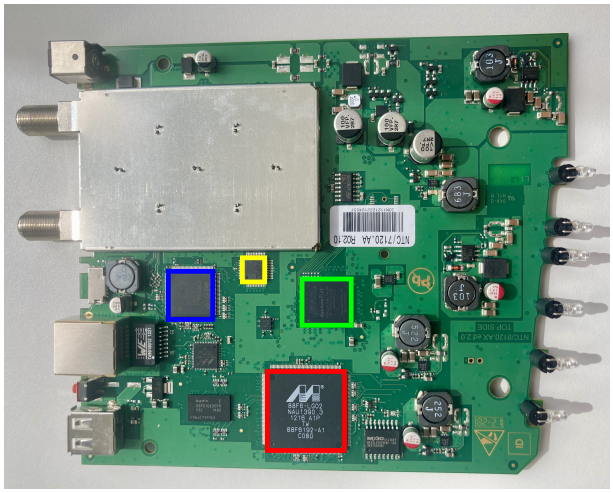

Figure 3: The modem incorporates dedicated hardware components for signal processing, including a microcontroller (red), FPGA (green), demodulator (blue), and DAC (yellow).

in the maritime, commercial airspace, as well as media and broadcast market [16]. Moreover, they claim to be relied on by 19 NATO member states. The MDM2200 is aimed particularly at consumers, enterprises, and government agencies [22]. Considering the widespread use as well as the criticality of communication systems, it needs to be considered critical infrastructure that require increased protection.

Examining the security of this modem not only provides insight into this device, but into an entire product line of one of the largest satellite communication system vendors. The company continues to develop the same product line, possibly drawing on earlier generations and adopting the same vulnerabilities. Therefore, our findings conceptually apply beyond this modem.

In the following section, we rely extensively on the modem control messages and log analysis. This was necessary to reverse engineer the system. However, once the attacker knows how the general system works from their own laboratory setup, it is not necessary to access the logs of a victim setup to perform the attacks against the modem.

4.1 Signal Processing Pipeline

The Newtec MDM2200 IP satellite modem receives and transmits radio signals via two separate coaxial F connectors. These are connected to an ODU consisting of a frequency converter which in turn is connected to a feed horn pointing at the satellite dish. The incoming analog signal is demodulated and decoded by several dedicated hardware components in the modem, shown in Figure 3. These convert the signal into IP packets that are output to the LAN or forwarded to internal processes running on the microcontroller. In detail, this is done as depicted in Figure 4.

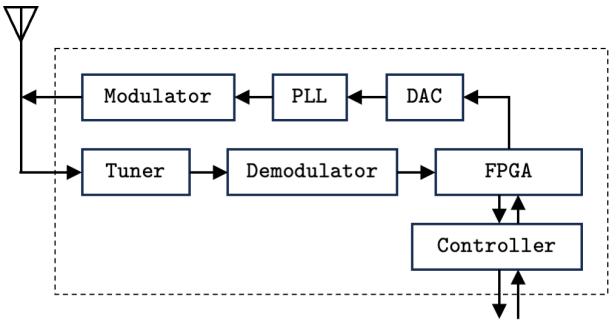

Figure 4: Signal processing pipeline of the Newtec MDM2200 IP satellite modem.

A satellite tuner IC, an STV6111, is used to tune to the correct frequency. It supports an L band frequency input in the range 950 MHz to 2150 MHz. The frequency of the first carrier is configured statically in the web interface, which is usually done by the vendor before sending the modem out to its customers. The parameters of the subsequent carriers are signaled via program-specific information and service information.

The signal is then passed to a demodulator IC, an STV0900A. This chip contains an analog-to-digital converter and supports both the DVB-S and DVB-S2 standards with all their modulation and coding schemes.

The demodulated byte stream is passed to a Field-programmable Gate Array (FPGA), an Altera Cyclone IV EP4CGX30BF14C8N. From reverse engineering the driver, we concluded that the FPGA decodes and demultiplexes the MPEG transport stream. It supports several filters that specify which elementary streams are to be demultiplexed. This allows filtering out all those elementary streams that are not destined for that modem. More specifically, MPEG packets can be filtered by packet identifier and by MAC address. It is also possible to specify whether only the MPEG-TS packet header should be removed or also the transport section header.

Finally, the decoded MPEG-TS section is forwarded to the microcontroller, a Marvell 88F6-LG02, running an embedded Linux operating system. It configures the entire modem with all its components. For this, it parses the received program-specific information (PSI) and service information (SI) sections of the MPEG-TS and applies their changes. The signal pipeline is abstracted behind a network interface: the received IP packets are fed into the IP network stack. Depending on their destination, they are either output to the LAN via the RJ-45 Ethernet port or routed to an internal process.

4.2 Control Software and Networking

A microcontroller acts as a link between the DVB-RCS-based communication and the IP-based communication. It runs an embedded Linux operating system based on BusyBox, which contains user-defined drivers for interaction with the various hardware components. In addition, it listens for configuration updates and applies them accordingly.

The Linux kernel running on the microcontroller contains four kernel modules that configure and communicate with the hardware-based signal processing pipeline: `modem.ko`, `fpga.ko`, `stv0900-demod.ko`, and `s3p.ko`. As the names suggest, the first three initialize the various hardware components, whereas the last one, `s3p.ko`, initializes the overall communication system Sat3Play (S3P), Newtec's proprietary implementation of the DVB-RCS protocol.

Several processes are further running in user space of the operating system. Two of them are of particular interest: `modem_controller` and `swdownload`. `modem_controller` listens for configuration updates on UDP ports 49153 and 49154 as well as on TCP port 49157. It supports multiple configuration message types, both in the form of protocol buffers and in other formats, such as ACM messages. Messages are generally neither authenticated nor encrypted. However, there is optional support for the encryption of some message types. `swdownload` listens for firmware updates on UDP port 49152. These are neither encrypted nor authenticated.

The modem also contains other software that can modify local configurations specific to the satellite communication system, such as `modem_controller_client` and `s3p`. These are CLI tools for interacting with other firmware components, in this case `modem_controller` and `s3p.ko`, respectively. They can be used to apply configuration changes directly from a shell on the modem.

Apart from the PSI and SI, data is transmitted in IP packets. This also applies to configuration updates processed by user space processes. The IP packets are encapsulated within MPE packets, which are addressed with a destination MAC address. For the modem to demultiplex such a stream, the filters on the FPGA must be initialized accordingly. After successful forward channel initialization, the modem sets up three additional filters for receiving elementary data streams: one unicast and two multicast filters. The unicast filter requires that the MPE packets be addressed with the modem's MAC address. On the other hand, the multicast filters necessitate the addressing of packets with one of the standardized multicast MAC addresses. These consist of a multicast IPv4 address with the standardised prefix `01:00:5E`. The 24 bits following this prefix must be in the range from `00:00:00` to `7F:FF:FF` and set to the low 23 bits of the multicast IPv4 address [1, 8].[2] Thus, if the packets are addressed with the MAC addresses `01:00:5e:00:00:01` or `01:00:5e:01:00:01`, they are accepted by all modems receiving the signal.

After being demultiplexed by the FPGA and forwarded to the microcontroller, the encapsulated IP packets are ingested into the network stack and routed according to their destination IP address. For example, if it is set to `192.168.1.1`, they are routed internally within the modem.

[2] See [21] for a detailed explanation.

5 SDR-based Signal Injection Transmitter

In this section, we introduce our SDR-based signal injection transmitter. It was developed with the purpose of demonstrating the practicability and assessing the impact of signal injection attacks on VSAT modems.

5.1 Software and Hardware

For a signal injection attack to work, an attacker needs to replicate authentic central hub transmissions. Signals must be generated in such a way that they deceive the modem into performing demodulation, decoding, and subsequent signal processing. In the case of the MDM2200 modem, this necessitates the development of an S3P-compatible transmitter. Operators of central hubs have specialized equipment for signal generation, including the S3P protocol. However, such devices are both expensive and have limited availability. In addition, dedicated radio equipment typically offers little flexibility, which limits its adaptability to different use cases. To address these cost, availability, and flexibility constraints, we chose to implement our transmitter entirely in software. SDRs provide an ideal platform due to their relatively low cost and ease of reconfiguration.

Our SDR platforms are the Ettus Research USRP B200 and USRP B200mini radios, which cost about $1300 each. We chose them primarily because of their availability and because they meet our frequency requirements: They are capable of transmitting in the range 70 MHz to 6 GHz, which includes the receive frequency range 950 MHz to 2150 MHz supported by the modem. This is beneficial when connecting the SDR directly to the modem via a coaxial cable, which is useful during development and testing of the transmitter. In principle, however, all SDRs that meet these requirements are suitable. For example, our implementation is also compatible with the HackRF One, which is available at a lower price of about $350.

The generation of valid S3P signals is implemented in software on a general purpose computer. In doing so, we focus on a minimal version that fulfills the requirements of initializing the modem and transmitting arbitrary data packets, rather than implementing the entire protocol. To accomplish this, we leverage GNU Radio [28], an open source framework for building SDR systems and signal processing applications.

For our transmitter pipeline, we use a combination of existing and self-developed blocks. The UDP, IP, DVB-RCS, MPE, and MPEG-TS layers are implemented in a new C++ OOT module called `gr-dvbrcs`. This module adds a single source block to GNU Radio, which generates the bitstream for initializing the modem and also sending attack packets. Its architecture is depicted in Figure 5. The bitstream is then modulated by the DVB-S2 layer, which is implemented using existing GNU Radio blocks from the `gr-dtv` module. The resulting IQ samples are forwarded through a sink block to the SDR, from where they are transmitted.

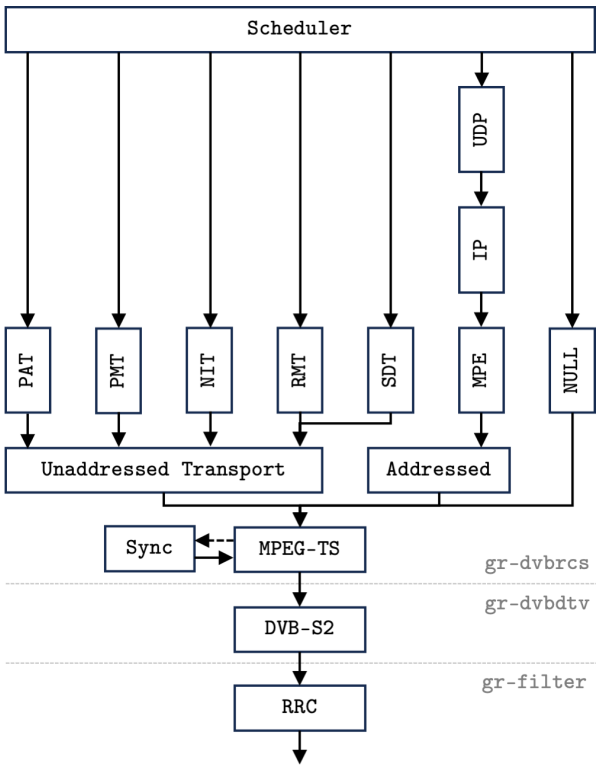

Figure 5: Proof-of-concept transmitter software architecture.

5.2 Forward Channel Establishement

When the modem is started, only the parameters related to the initial carrier are preconfigured, such as its frequency and symbol rate. These settings can be adjusted via the modem's web interface, although they are usually preset by the vendor. We experimentally verified that data transmission on this carrier is not possible. The modem simply ignores it. Therefore, the main challenge of the transmitter is to put the modem in a state where it accepts and processes data packets.

Since S3P is an implementation of the DVB-RCS protocol, the initialization procedure can be derived from the public specification [18]. However, it should be noted that S3P uses a specific configuration of DVB-RCS that does not support all options and subprotocols, and in some cases even deviates from this standard. Through the collection of information from the standard, the reverse engineering of the parsing logic in the kernel modules, and the analysis of log messages, we iteratively reconstructed the required initialization procedure.

5.2.1 Carrier Lookup

To give network operators flexibility in assigning forward channels, especially because the first carrier must be manually configured on the modem, the modem uses a multi-stage

carrier lookup process. Consequently, this first carrier is used exclusively to transmit information pointing to the subsequent carrier. The discovery is then performed in several steps: The modem must tune to three different carriers, one after another, on each of which a transport stream is transmitted. After parsing the packets from the first carrier, the receiver learns the parameters to tune into the second carrier, from which it learns about the third carrier. Only on the third and final carrier, it finds the elementary data stream.

This setup presents a challenge for our transmitter. If it does not switch the transmitted carriers at the same time as the modem, the modem tunes to an empty carrier and thus aborts the initialization process. Since we receive no feedback from the modem about such an event, it is impossible for our transmitter to determine the exact time. Consequently, we are forced to transmit on all three carriers simultaneously, which increases the requirements of our attacker.

To bypass this carrier lookup procedure and prevent unnecessary restrictions on our attacker, we leverage the versatility of MPEG transport streams, particularly their ability to accommodate multiple programs and elementary streams. Specifically, we initiate the communication so that each carrier points to itself, albeit with a distinct program number. This is achieved through the proper configuration of the NIT and RMT, communicating the frequency and symbol rate of the initial carrier. This effectively results in a single transport stream containing all the necessary information from the beginning. Consequently, the modem consistently tunes to the same carrier during initialization but demultiplexes a different program from the transport stream each time. It processes only the elementary streams it is expected to receive, disregarding the rest. This approach greatly simplifies the implementation of the transmitter.

5.2.2 Forward Channel Initialization

The DVB-RCS standard defines the syntax of the various PSI and SI sections used for modem initialization, each of which may contain multiple descriptors. However, it often does not specify which descriptors are required for particular sections and their required repetition rates, but only provides a list of compatible descriptors. This may increase flexibility for vendors, but makes it difficult to develop an attacker implementation. As a result, we often had to rely on information provided by the modem and guessing to identify what information it was expecting at what times. In this regard, several resources proved valuable, such as the log errors of firmware components, decompiling `s3p.ko`, and the CLIs `s3p` and `modem_controller_client`, from which the internal modem driver state, including the received section values, could be retrieved.

Our analysis revealed multiple inconsistencies. In two cases, we found that the implementation of the modem's initialization protocol deviates from the standard. In another case, the modem uses a private byte to signal a proprietary feature. In total, the transmitter must support three adjustments, otherwise the forward channel cannot be initialized. Firstly, on the final carrier, the modem expects the Service Description Table (SDT) before the Program Association Table (PAT) and Program Map Table (PMT). As long as it does not receive the SDT, it does not attempt to parse other tables. This order differs from the standard [19]. Secondly, instead of using a Stream Identifier Descriptor within the PMT to identify the data elementary stream configured in the SDT using its component tag, the modem expects an RCS Content Descriptor to identify it by its table ID `0x3E`. The use of this descriptor also differs from the standard [19]. Finally, the private bytes field in the Satellite Return Link Descriptor of the RCS map table [18] is used to configure a proprietary and undocumented transmission mode, also referred to as Mode of Operation (MoO), a designation used by the developers of the modem. A value of `0x00` configures the modem to use ATM/GMSK on the return channel, whereas a value of `0x01` configures it to use GSE/4CPM. Since the Newtec MDM2200 satellite modem only supports GSE/4CPM, the RMT private byte must always be set to `0x01`.

5.3 Data Transmission

After the initialization is completed, the modem is configured to receive and process IP packets. IP packets must be encapsulated within MPE sections, which can be addressed using either unicast or multicast MAC addresses. Besides their increased efficiency for the provider, multicast destination addresses are also more efficient for attacks, as an attacker does not need to enumerate all possible addresses to find the correct one. Instead, the packets are processed by any modem receiving the transmission.

By default, the MDM2200 demultiplexes both unicast and multicast packets. Consequently, it becomes possible to target a modem regardless of whether the attacker knows its MAC address.

In implementing the data transmission logic, we encountered two main challenges. Firstly, we required a method to send payloads that exceeded the maximum length of lower protocol layers, as some of our malicious packets surpassed this limit. Some of the data packets we intended to spoof exceed the fixed MPEG-TS packet length of 188 bytes. To transmit them nonetheless, a mechanism for fragmenting the packets into multiple segments is necessary. DVB-RCS supports fragmentation in various protocol layers to accommodate payloads that surpass the maximum payload length. In our transmitter, we implemented fragmentation exclusively for MPEG-TS packets, as they present the most stringent limitation in terms of packet length. With fragmentation implemented at this layer, the payload can be of any size, provided there are no other constraints imposed by the payload itself. Taking into account the restrictions of the other layers, our

implementation is therefore able to transmit arbitrary UDP packets with a length of up to 4073 bytes which is sufficient for our use case.

Secondly, we faced an issue where the modem lost connection after 200 milliseconds due to a lack of synchronization information. The reason for this is that it expects adaptation information containing a program clock reference (PCR) as defined in the MPEG-TS standard [13]. The PCR value must be taken from a 27 MHz clock, which is measured when the fifth byte of the PCR value is transmitted. The maximum allowed jitter is 500 ns. Theoretically, the protocol also supports the transmission of programs without PCR information. However, this does not seem to be supported by the modem, since its clock loses synchronization when signaled that no PCR is present. When it loses synchronization, the modem resets itself to the initial carrier and starts the initialization process over again. Therefore, we implemented synchronization with the goal of performing and evaluating more persistent attacks. Due to the structure of our signal processing pipeline, it is not possible to derive the clock reference from the system clock. In particular, batch processing and recurrent buffers cause irregular delays in the transmission of packets. Therefore, we precompute the PCR based on the number of generated bytes. We count the bytes between two PCRs and derive the value using the byte rate. With this approach, sufficiently accurate PCR values can be generated and transmitted. This suffices to synchronize the clock of the modem.

6 Implemented Attacks

With the signal transmitter from the previous section, we can now perform spoofing attacks and send arbitrary packets wirelessly to any modem in range. This section describes four attacks that target different parts of the modem and vary in terms of goals and sophistication.

It is crucial to reiterate that once the attacker comprehends the fundamental workings of the general system, no access to sensitive information is required for executing attacks against victim modems. The sole prerequisite is knowledge of the parameters of the forward channel.

Scanning the entire RF spectrum is impractical due to its vast size. However, this is unnecessary. Given that the forward channel is a broadcast channel used to transmit data to many modems, commercially acquiring a modem provides the attacker not only with their own parameters but also those of all other modems tuned to the same broadcast channel. Consequently, an attacker is potentially able to target thousands of modems without spectrum scanning at all.

Moreover, the RF spectrum is subject to regulation, with services allocated by the FCC and similar regulatory bodies in other countries. These allocations are publicly accessible. Leveraging open-source intelligence (OSINT), it becomes therefore possible to significantly reduce the search space, rendering spectrum scanning feasible even in the absence of prior information.

6.1 Modem Reset

The first and simplest attack vector aims to reset the modem. For this purpose, we emit a jamming signal consisting of random noise or arbitrary packets at the same frequency as the forward channel. As our objective is to only interfere with the signal rather than overpower it, we establish a jamming-to-signal ratio of $J/S = 1$, where J represents the received jamming signal strength, and S stands for the received legitimate signal power. Because the modem is no longer able to receive the necessary configuration signals to keep the channel active, the modem restarts the channel initialization process, corresponding to an effective reset of the modem. By keeping the jamming signal on, the modem is not able to reinitialize the forward channel. As soon as the jammer is off, the modem reestablishes the link with the central hub again.

6.2 Permanent Channel Disconnect

This second attack aims to permanently disconnect the forward channel from the central hub to the modem. We identified Adaptive Coding and Modulation Messages (ACM) messages as appropriate for this purpose. These messages serve the purpose of signaling the supported modulation and coding schemes (MODCOD), depending on current weather conditions.

By intentionally misconfiguring these values, an attacker can put the modem in a state where it no longer supports the same modulations as communicated by the central hub. This capability can be used to create a discrepancy between the modem and the central hub that affects the availability of the system even after the attack is switched off.

The discovery of this functionality was made through an examination of the modem's data sheet [22]. By eavesdropping on the local communication of an operational modem, we were able to identify the ACM messages. Despite the existence of a standardized ACM protocol [17], our investigation revealed significant differences between the implemented protocol and the established standard. Therefore, we reverse-engineered the parsing logic of the ACM messages to understand their structure and application. Note that this attack is not limited to RCS but effectively applies to the widely-used forward-link of DVB-S2/S2X systems.

We have integrated the generation of such ACM packets into our transmitter. Employing the encapsulation mechanisms described earlier, these UDP packets are encapsulated in IP packets, addressed to all modems, and injected into the MPE elementary stream.

6.3 Malicious Firmware Update

Similar to how network operators provide modems with configuration updates, they also apply firmware updates over the satellite link. On the MDM2200 modem, the update process involves the transmission of an update signalization UDP packet addressed to the internal update management application `swdownload`. Among other information, it contains the version requirements, the size of the update, and instructions on how to get the update. Upon receipt of such a message, the application joins the respective multicast group and starts listening for firmware update blocks on a distinct UDP port, as communicated by the signalization packet. Once the transmission is completed, it checks the CRC checksum of the firmware update and installs it. Crucially, neither the signalization packet nor the update are encrypted or authenticated. Consequently, our attacker transmits a malicious firmware by sending both a signalization packet and a firmware update to the corresponding port. Thus, this represents an attack on the availability, integrity and confidentiality of the system.

6.4 Remote Admin Shell

Finally, the last and most powerful attack vector aims to obtain a remote admin shell in order to execute arbitrary commands on the modem with root privileges. As it is not possible to send shell commands over standard modem features, this requires us to inject a signal that contains an exploit of a vulnerability on the software of the modem. To do so, we rely on a buffer overflow vulnerability in `swdownload` that was previously known and reported but is still unpublished.[3] This vulnerability enables us to execute arbitrary commands with root privileges by sending a malicious UDP packet to the corresponding port.

Specifically, the exploit makes use of a vulnerability in the parsing logic of update signalization messages. There, the `sscanf` function is used to parse and copy a string from the received message into a buffer. Because there is no width specified in the format string of `sscanf`, namely the format string is simply defined as `"%s"`, the function can be misused to overflow the buffer. In this instance, the buffer is allocated with a length of 80 bytes. Thus, by supplying a string longer than 80 bytes, we can overwrite the call stack.

The exploit takes advantage of this vulnerability to alter program execution through return-oriented programming by overwriting the return address of function calls on the stack. The injected sequence of gadgets finally points to the libc function `system`, which executes a shell command passed as an argument. Thus, by transmitting such a crafted update signalization message, an attacker can modify the `swdownload` process to execute an arbitrary shell command. Since `swdownload` is executed with root privileges, the provided shell command is also executed as root.

We inject the exploit by encapsulating the malicious payload within UDP and IP packets, which are then inserted into the MPE elementary stream. These packets are addressed to all modems, which route them internally to the targeted application upon receipt. We establish the reverse shell towards the LAN, although this attack could potentially be extended to connect with any host on the internet, provided that the modem is fully initialized and connected to the internet via satellite.

[3] We note explicitly that this exploit is not specific to this attack vector. Any similar exploit could be used over the wireless interface via the same signal injection method (e.g. CVE-2016-9494 to 9497). As such the exploit is just a means of illustration, not a contribution of this work.

7 Evaluation

In this section, we evaluate the presented attacks using our SDR-based transmitter. We evaluate not only their impact, but also their feasibility by examining the conditions under which a successful execution is possible depending on the location of the attacker relative to the victim modem.

7.1 Experimental Setup

Our evaluation is based on three configurations: a transmission over coaxial cables, a transmission over the wireless channel on satellite frequencies in a reflection-free anechoic chamber and a transmission over a wireless multipath channel.

The setup over coaxial cables is used to avoid transmitting electromagnetic signals that could potentially interfere with real systems. The modem receives the signals from the SDR directly over a RF cable without any intermediate antennas and up-/downconverters.

The setup over the wireless channel is used to evaluate our attacks under realistic conditions. For this purpose, we configure the VSAT as if it were in regular operation. Ku band signals are transmitted to the satellite dish where they are downconverted by a low-noise block (LNB) before reaching the modem. Consequently, our transmitter needs to be able to generate and transmit signals on the upconverted satellite frequency. Conventional SDRs are usually limited to a frequency range of up to 6 GHz. This is also true for the Ettus Research USRP B200. However, the endpoint can only receive frequencies in the range of 10.7 GHz to 12.75 GHz, a range allocated to direct broadcast satellite services. Therefore, the SDR signal must be upconverted to this range. To do this, we used a block upconverter (BUC), a UMT-TV BUC-Ku002-10.6 v2.0. This BUC upconverts a signal from the L band (950 to 1950 MHz) to the Ku band (11.55 to 12.55 GHz). Specifically, the SDR is connected to a power injector, a UMT-TV DC Injector IDCI with IP Ctrl, which in turn is connected to the BUC. The power injector provides the necessary power to operate the BUC, enabling us to set the transmission power to a value in the range 9.5 dBm to 19 dBm. Finally, the upconverted signal is passed from the BUC to a directional feed horn, a UMT-TV Offset Feed, that emits it. The feed horn has a gain of 13.9 dB.

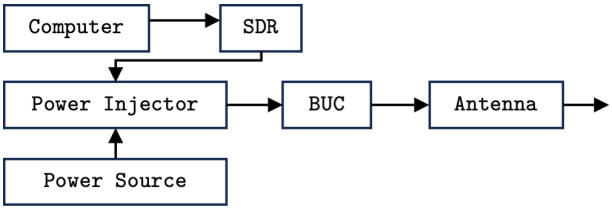

Figure 6: Hardware components for signal transmitter.

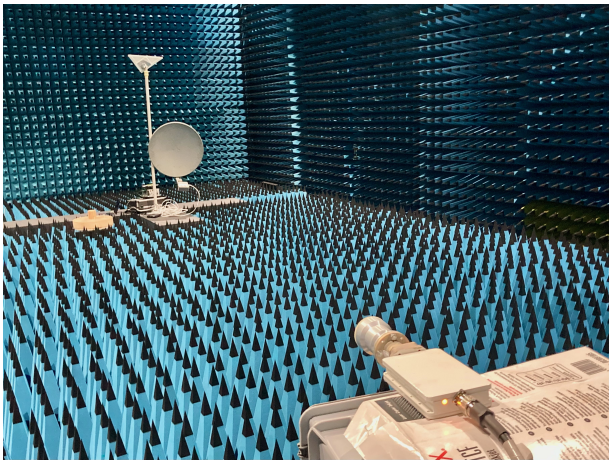

Figure 7: Setup for evaluating signal injection attacks in anechoic chamber.

Overall, the cost of this setup is about $1000, not including the software-defined radios.

On the receiver side, we use the default configuration of the Newtec MDM2200 modem as provided by the vendor. It comprises an iLNB, a Newtec Interactive LNB NTC/2530.AA, and a 75 cm parabolic antenna. The iLNB is connected to the modem and points at the antenna. It downconverts received Ku band signals (10.7 to 12.75 GHz) to the L band (950 to 2150 MHz), a frequency band that is supported by the modem. In addition, it upconverts the transmission signal emitted by the modem to the Ku band (14 to 14.5 GHz). According to the data sheet [22], the gain of the iLNB is 57 to 70 dB.

The experiments over the wireless channel are conducted in two environments: a multipath environment and an anechoic chamber that mitigates multipath reflections. In both environments we set up the receiver and transmitter in a distance of 10 meters with direct line of sight. The multipath environment comprises a corridor that is 3 meters high, 1 meter wide, and 60 meters long, with rooms on both the left and right sides. The transmitter is positioned within the corridor and is oriented towards the transmitter located in one of the room bulges. The walls are constructed of concrete. The anechoic chamber is a rectangular room that is roughly 5 meters high, 10 meters wide, and 15 meters long. The walls, floor, and ceiling are damped with anechoic material.

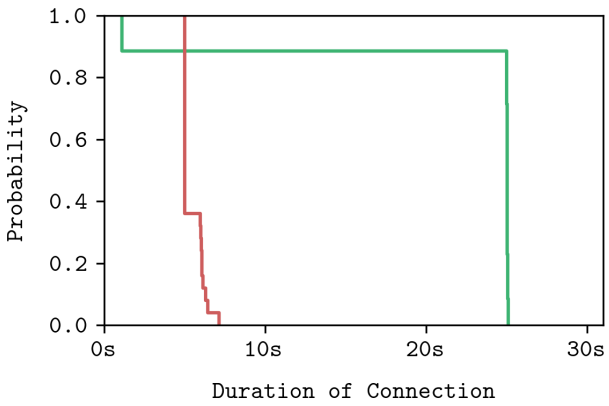

Figure 8: The cumulative distribution of connection duration under jamming (red) and under normal conditions (green).

7.2 Impact of Attacks

7.2.1 Modem Reset

First, we evaluate the effects of interference attacks on the modem, in particular the feasibility of the modem reset attack. For this purpose, two SDRs are connected to the modem via coaxial cable with a T-shaped adapter. One SDR is configured to emulate a legitimate central hub, transmitting the forward channel initialization stream. The other emits a jamming signal consisting of random noise at the same frequency. Given that the SDRs are not calibrated, we adjusted the output to ensure that both emitted signals were received with equal strength at the modem, specifically at -53.4 dBm.

We conduct a comparative analysis between the scenario in which the jammer is present and without the jammer. Specifically, we compare the connection duration, defined as the time interval from when the modem confirmed acquisition of the final carrier signal and commenced synchronization, to when the connection was subsequently lost. The results of the two scenarios are shown in Figure 8. In the absence of a jammer, it can be seen that most connections persisted for about 25 seconds. This corresponds to the time when the modem drops the connection because it does not receive the necessary configuration sections to initialize the return channel. This is intentional, since our transmitter does not send this data. In the scenario with the jammer active, the connections have a much shorter duration, about 5 seconds. The exact reason for the connection losses occurring only after 5 seconds is not entirely clear but most likely related to the time the modem needs to report a loss of connection in the logs. Nevertheless, this evaluation clearly shows the effectiveness of jamming signals to disrupt a connection and reset the modem.

7.2.2 Permanent Channel Disconnect

In evaluating a permanent channel disconnect, we instructed our transmitter to first initialize the modem. We then transmit-

ted the ACM *Client Configuration Message*, *Polling Request Message*, and *PID Mapping Message* either together or individually. We generated these messages with both false and real values.

While we were able to confirm that the spoofed ACM messages are correctly interpreted and applied by examining the modem state, we did not observe any exploitable behavior, such as the ability to change the signal processing configuration, which could be misused to disrupt communication. Despite the modem appropriately configuring the transmitted parameters for switching schemes, and making attempts to adapt coding and modulation schemes based on the received SNR, no other effects were detected.

The use of a proprietary ACM protocol by the modem, deviating from the standard, complicates the determination of the attack's failure cause. It is plausible that the demodulator chip is exceptionally robust, capable of demodulating any signal regardless of the configured settings. However, it is also possible that a different encoding is necessary to indicate ACM usage. Unfortunately, this hypothesis could not be tested, as the modem proved incapable of demodulating and decoding the standardized DVB-S2 ACM format.

7.2.3 Malicious Firmware Update

Due to the risk of rendering the modem inoperable by applying a bogus firmware update, we only examined the wireless reception of an update, not its installation. To this end, we sent an update signalization packet to `swdownload` that instructs the modem to listen for update fragments on the specified port if the version is at least 1 and no greater than 9999999. These requirements apply to effectively all modems. We then transmitted an update fragment to the specified port, with an invalid checksum to make sure that the update is not intalled. In our experiments, the modem received it correctly and acknowledged its reception with `SW download completed` while reporting that the checksum was incorrect as intended. This demonstration confirms the feasibility of injecting malicious firmwares of the satellite downlink channel. Since no cryptographic primitives are implemented, the CRC checksum can be easily calculated correctly and trick the modem to apply the firmware update.

7.2.4 Remote Admin Shell

To evaluate the remote admin shell attack, we first initialized the forward channel on the modem. Subsequently, we transmitted the malicious update signalization message containing commands opening a reverse shell to a command and control host. We directly obtained a remote admin shell. The established shell is shown in Figure 9. Thus, this represents an exploitable vulnerability that allows arbitrary commands with root privileges to be executed remotely through wireless transmissions. Given the nature of the vulnerability, which leverages a buffer overflow and subsequently manipulates the call stack, it leaves it in a corrupted state, allowing the attack to be executed only once.

7.3 Evaluation of Channel Conditions

In the following, we evaluate the conditions that facilitate successful signal injection attacks by measuring the received signal characteristics when attacking the complete receiver setup including the low-noise block (LNB) which points at the satellite dish. We performed these experiments at different angles between transmitter and receiver in both the horizontal and vertical planes as it is not clear under which angle a signal injection attack may work. In the horizontal plane, we conducted measurements on one side only, given the antenna's symmetrical construction. The results are thus identical regardless of the side from which the signal is transmitted. Therefore, we mirrored them to the other half accordingly.

In this analysis, we mainly focus on three metrics as they were reported by the modem:

- The *Signal-to-Noise Ratio* (SNR) provides a measure of the signal strength relative to the noise floor.
- In addition, the *Signal Strength* offers an absolute value of the received signal at the specific frequency, encompassing the sum of noise and signal.
- The *Success Rate* quantifies the likelihood that signal injections can be effectively performed from a given angle. In this context, we define a successful signal injection as a transmission where the demodulator successfully locks on and reports a positive signal-to-noise ratio.

Figures 10 and 13 show the results in the anechoic chamber for the signal characteristics of the horizontal and vertical planes, respectively, with a 9.5 dBm signal transmitter. The signal characteristics of the horizontal plane reveal a peak of approx. 40 degrees in width at the center, signifying that this beam is the most suitable for mounting an attack. Additionally, we observe a slight increase in both SNR and signal strength with increasing angles. We attribute this phenomenon to the fact that above a certain angle, the signals can be received directly by the feed horn, bypassing the indirection through

the satellite dish. In the vertical plane, we observe comparable outcomes. A peak with an approximate width of 30 degrees, centered around 25 degrees, exhibits optimal reception characteristics. As in the horizontal plane, we observe an elevation in both SNR and signal strength with increasing angle. Beyond an angle of roughly 100 degrees, the transmitter maintains an unobstructed line of sight to the feed horn, facilitating direct transmission before encountering obstruction at higher angles by the satellite dish. Lastly, the success rate shows that signal injection attacks have the highest chance of success across a range of angles, especially when transmitted from frontal positions or directly at the feed horn.

In the multipath environment, we conducted measurements using two distinct transmission powers. Given that the BUC can only be configured to transmit at a minimum of 9.5 dBm, we employed damping materials to attenuate the emitted signal strength. As a result, we conducted experiments utilizing both this lower, damped transmission power and the undamped transmission power of 9.5 dBm. When employing the lower power setting, we observe a pattern similar to that seen in the anechoic environment. The signal characteristics shown in Figures 11 and 14 exhibit a peak when transmitted from frontal positions. Furthermore, we note a marginal increase in both SNR and signal strength with increasing angles. This can be attributed to the phenomenon where, beyond a certain angle, signals are received directly by the feed horn, circumventing the indirect path through the satellite dish. The success rate measurements, depicted in Figure 11c and 14c, support these observations. However, if we look at the measurements performed at a transmission power of 9.5 dBm, we observe a different phenomenon. Instead of individual angles showing favorable reception, we can measure high reception values over the entire range. Remarkably, both the signal characteristics as well as the success rate shown in Figure 12 and 15 exhibit high values for each angle. This result shows that attacks can be carried out successfully from any angle given sufficient transmission power.

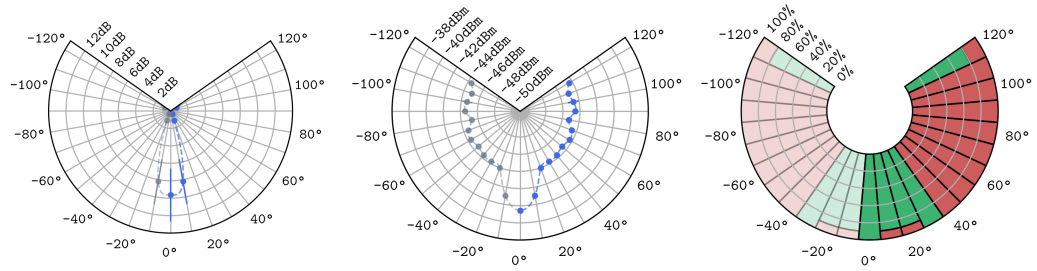
8 Discussion

On a first glance, the attacks discussed in this work may appear specific to one device. However, we argue that the underlying problem is systemic and arises from a neglect of security measures in both standards and security lifecycle management. While any specific software vulnerability can be addressed with a software patch, the fact that it is possible to inject arbitrary packets into the network stack, specifically the control plane, exposes a wide attack surface that is hard to control in the present architecture of VSAT systems.

Many traditional and professional users of satellite communication (i.e, military and government) use their own proprietary solutions to secure their systems. While these may work, it is clear that this leaves any other less sophisticated user of the same underlying VSAT architecture vulnerable.

8.1 Impact

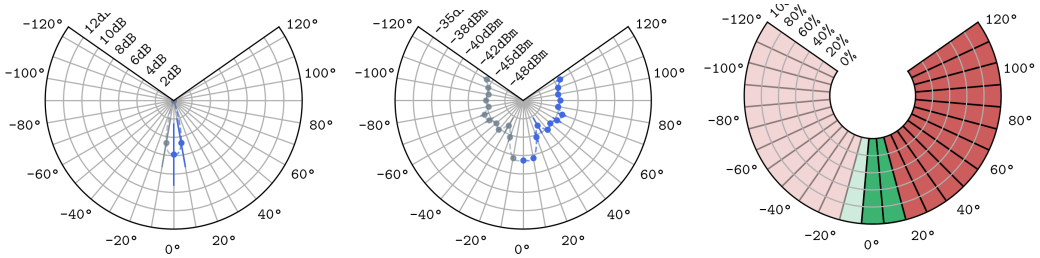
The underlying DVB-RCS standard has been developed in the 1990s by, among others, Newtec and the European Space Agency [3]. Importantly, many VSAT modems support and have been using the DVB-RCS standard and are thus fundamentally vulnerable to receiving wireless signal injections. Examples include the entire product line of Newtec that operates on their Sat3Play technology (e.g. NTC2210 and NTC2215). Attacks against these modems are highly likely to succeed without requiring any adaption, given their shared implementation. Some of these modems have subsequently been incorporated into iDirect's brand following the acquisition.



In addition, other vendors have established satellite networks based on DVB-RCS, with prominent examples being Viasat's Linkstar product line (e.g., Linkstar S2 and Linkstar S2A) and Hughes' HN series (e.g., HN7000S and HN9000). Since all devices implement the same standard, we believe that the results of this study can be transferred to these devices with only minimal adjustments. While current numbers on the VSAT market are difficult to find, the Comsys VSAT report [5] lists further standards-based DVB-RCS system vendors (for example Advantech and Satlink). Together with a study by the European Union Agency for Railways [12], both reports put the market share of such solutions around 10-20% out of millions of deployed VSAT terminals.

A designated successor, RCS2, was developed with improved security features [4] but so far has found limited publicly visible adoption. Its concepts have found their way into proprietary solutions used e.g. by providers for government and military and recently the standard has been extended to high capacity beam hopping.

As is known from recent research into vulnerabilities in critical infrastructures and embedded systems, the focus on stability, uptime and verified safety combined with difficulty of access leads to many obsolete software versions with known and unknown vulnerabilities being in use for many years. [6,7] In summary, we believe our approach and our case study transfer to many other satellite modems in current usage with only relatively small modifications, specifically any which do not implement data link layer protection measures, e.g. DVB-RCS or DVB-RCS2 without optional protection or proprietary signaling protocols without link layer security. This attack vector was simply ignored at the time of development of DVB-RCS, likely because it predated the rise of SDRs, and there has been no (public) awareness about it since.



8.2 Mitigations

To mitigate the discussed vulnerabilities, mechanisms to authenticate and encrypt the communication are needed. Such protections can be put in place on multiple layers.

8.2.1 Physical Layer

Several strategies have been proposed to detect spoofed signals at the physical layer. For instance, Jedermann et al. [20] advocate for the utilization of time difference of arrival measurements obtained from multiple receivers to compute the satellite's position and compare it with the satellite's actual position. In cases where these do not align, it can be concluded that the signal is spoofed.

In addition, Smailes et al. [36] advocate for employing fingerprints, which are derived from distinctive signal characteristics exhibited by the transmitter. To implement this, they propose an architecture for transforming satellite signals into unique fingerprints. If these deviate significantly from pre-recorded reference fingerprints, the system categorizes the signal as spoofed and rejects it.

While these approaches provide robust results, their implementation requires additional hardware, either in the form of multiple receivers for multilateration or integrated circuits that provide the necessary signal characteristics for fingerprint computation.

8.2.2 Data Link Layer

The DVB-RCS [18] standard outlines encryption and authentication mechanisms that cryptographically scramble the transmission. However, the adoption of these measures is optional and contingent upon the specific implementation. The data necessary for the modem to discern if a packet is intended for it is retained in unauthenticated plaintext. Furthermore, these protective measures are only activated following the exchange of keying material. Consequently, they do not provide protection against spoofing during modem initialization, unless they keying material has previously been exchanged offline.

8.2.3 Network Layer

To provide supplementary protection, the DVB-RCS standard advocates for the implementation of network layer security mechanisms. For instance, IPsec [9] could be leveraged to encrypt and authenticate the communication between the endpoint and central hub. Consequently, user communication is encrypted and authenticated, regardless of the implementation of lower layers. However, protection measures at this layer do not protect against spoofing attacks that use lower-layer protocols. Attacks that exploit vulnerabilities in the data link layer therefore remain a potential threat against all modems not implementing a proprietary layer 2 encryption authentication scheme.

9 Related Work

Although the security of satellite communication systems has so far received little attention by the research community, there is a small but growing body of work in this domain. Pavur and Martinovic [23] have compiled a comprehensive list of incidents from the past six decades, underscoring the critical importance of satellite security and its vulnerability to potential attacks.

9.1 Security of VSAT Systems

After decades dominated by closed and proprietary satellite systems, the European Telecommunication Standards Institute (ETSI) published the DVB-RCS protocol in 2000, nowadays still an important protocol in VSAT systems. Skinnemoen et al. [35] present a comprehensive study of this protocol, with their main focus on performance evaluation. The lack of security adoption in DVB-RCS is evident in a number of papers dealing with forward channel communication security. For example, Adelsbach and Greveler [2] and Pavur et al. [24] analyzed DVB-S broadcast communication. They found that a significant portion is unencrypted, allowing an attacker with a budget of $300 or less to intercept confidential communication. In following work, Pavur et al. [25] come to a similar conclusion when analyzing DVB-S2 traffic. They find that much of the communication is unencrypted, revealing confidential information, and should be secured with new countermeasures such as secure proxies [26]. Although these papers do not analyze DVB-RCS specifically, their results show that many protocols supported by RCS — and their users — do not adopt any security measures.

While these papers targeted vendor-independent communication, others have analyzed the security of specific hardware implementations. For example, Santamarta [30] performed an analysis of several satellite communication modems. In

each of them, he uncovered exploitable vulnerabilities, such as backdoors, hardcoded credentials, and insecure protocols. In subsequent work [31], Santamarta analyzed the impact of accessing such systems in the aerospace, maritime, military and space industries, ranging from attacking onboard communication to disrupting it altogether.

This field of research has gained practical relevance in light of the ViaSat incident [39], the largest publicly known attack on satellite communication systems, which disrupted a significant portion of its network. Following the incident, Guerrero-Saade and Amerongen [14] identified the wiper malware uploaded to the affected modems. Subsequently, Santamarta [32] confirmed these findings and identified the mechanism used to upload the malware to the modems. In contrast, to our work, this attack was performed by infiltrating the central hub, while we study the threat model of a wireless signal injection from a device in the neighborhood of a VSAT receiver.

9.2 RF Signal Injection Attacks

Salkield et al. [29] provide an general security analysis of satellite downlink spoofing. Their study addresses the factors that influence the success of such attacks, including modulation scheme, antenna directionality, and signal strength.

A particular topic that has attracted a lot of attention is the security of Global Navigation Satellite Systems (GNSS). Several studies addressed the characterization and mitigation of GPS jamming [34]. For example, Ferreira et al. [11] assessed the utilization of low-cost SDRs for implementing a jammer capable of generating an effective interfering signal targeting an unmanned aerial vehicle. Horton and Ranganathan [15] introduced a low-cost implementation of a GPS spoofer.

Finally, there are many demonstrated RF attacks on terrestrial systems, particularly within mobile communication. Both Yang et al. [40] and Erni et al. [10] implemented overshadowing attacks against LTE, showing that it is possible to inject arbitrary messages and achieve a denial of service.

To the best of our knowledge, no previous study considered an active wireless attacker model on the communication stack of VSAT endpoints. This study fills this gap by analyzing signal injection attacks on a real-world VSAT system.

10 Conclusions

Satellite communication systems serve as a crucial link often connecting critical infrastructure to the internet. Consequently, many of these satellite systems may qualify as critical infrastructure themselves, a fact not lost on threat actors, as evidenced by recent attacks targeting such networks. However, these systems have received only limited attention from the research community so far.

This study is a first step towards examining satellite endpoint security against signal injection attacks. We focused on the Newtec MDM2200, a modem of a leading VSAT vendor. To assess the feasibility of these novel attacks, we constructed a proof-of-concept transmitter that can wirelessly initialize the modem and transmit arbitrary data packets to it. This enables the remote exploitation of protocol and software vulnerabilities in the modem. To understand the conditions required for successful execution, we evaluated our attacker implementation in both an anechoic chamber and a multipath environment. This enabled us to determine the positions from which signal injection attacks have the highest probability of success. We find that if the transmission power is high enough, an attack can be carried out from any angle.

Signal injection attacks are possible, because the modem supports communication without encryption and authentication, thus neglecting protection against unauthorized eavesdropping, manipulation, or injection of packets in the lower communication layers. This likely stems from a time when security considerations were not as prevalent. However, in the age of software-defined radios, it is imperative to reevaluate these assumptions. Protection against such attacks must be considered a primary systems requirement.

Ethics / Disclosure

All experiments involving malicious signals injections have been performed against our own modem. Signals that could potentially compromise neighboring modems have been transmitted in a shielded environment or over shielded RF cables to avoid collateral damage.

The attack and all vulnerabilities used in this paper have been reported responsibly to the vendor of the modem. iDirect has not reacted to multiple inquiries over one year. After submission of the paper, we have further disclosed the paper and all used vulnerabilities with the Swiss National Cyber Security Center (National CERT). They are working to obtain a response from the vendor and are preparing CVE numbers where applicable. Further discussions are being conducted regarding other manufacturers using potentially unsecured DVB-RCS systems.

Acknowledgments

We thank Knut Eckstein from the European Space Agency for his helpful feedback.

Abstract

The dynamic evolution of the space sector, often referred to as "New Space," has led to increased commercialization and innovation. This transformation is characterized by a surge in satellite numbers, the emergence of small, cost-effective satellites like CubeSats, and the development of space networks. As satellite networks play an increasingly vital role in providing essential services and supporting various activities, ensuring their security is crucial, especially concerning trust relationships among satellites and the protection of satellite service users.

Satellite networks possess unique characteristics, such as orbital dynamics, delays, and limited bandwidth, posing challenges to trust and privacy. While prior research has explored various aspects of space network security, this paper systematically investigates two crucial yet unexplored dimensions: (i) The integrity of PKI components directly impacts the security and privacy of satellite communications and data transmission, with orbital delays and disruptions potentially hindering timely certificate revocation checks. (ii) Conversely, transmitting user signals to satellites requires careful consideration to prevent location tracking and unauthorized surveillance. By drawing on insights from terrestrial studies, we aim to provide a comprehensive understanding of these intertwined security aspects, identify research gaps, and stimulate further exploration to tackle these research challenges in the evolving domain of space network security.

1 Introduction

The space sector has witnessed a remarkable surge in commercialization and innovation over the past decade. The number of operational satellites has quintupled to almost 5,500 since 2013[1], which is projected to quadruple again in the next decade[2]. Further, the total value of the global space economy reached $464 billion in 2022[3], up from the $290 billion in 2012[4]. The space sector is rapidly changing, often called the *New Space*.

Several key trends have disrupted the development of the space sector. While only large, mostly governmental players could access space in the past due to the tremendous costs and complexities of operating satellites, many private players now have access to the final frontier. Small, light, and inexpensive satellites are replacing the prevalence of the traditional large, heavy, and costly satellites. A key development in this trend is the *CubeSats*, standardized microsatellites of scalable 10 cm³ units. CubeSats often use commercial off-the-shelf (COTS) hardware and can be launched as secondary payloads on the launch vehicles, thus minimizing the costs. Some companies offer an all-inclusive package to build and launch a CubeSat for as little as $44,000[5]. Accessibility to space is further increased by services that simplify the operation of satellites. These services range from Amazon's AWS ground-station-as-a-service offer[6], which eliminates the need to deploy satellite dishes to operate a satellite, up to rentable in-orbit satellites[7] and projects that allow researchers to deploy and run their experiments directly on a deployed satellite[8]. Further, satellites are incorporating more powerful processors and onboard computing capabilities[9]. This allows for real-time data processing, reducing the need for large ground-based computing infrastructure. Advances in communication technology have led to more efficient and higher bandwidth communication systems.

Another trend is the move towards *space networks*. A space

network refers to a system of *interconnected satellites*, ground stations, and other space-based assets designed to facilitate communication, data transmission, navigation, and other functions in space and between space and Earth. These networked satellites enhance global coverage, reduce latency, and support various applications, including broadband internet services. *External users* can tap into satellite-based communication services to access long-distance voice calls, data transmission, and internet connectivity.

A recent popular space network architecture is the mega-constellation, such as SpaceX's Starlink satellite Internet project, aiming to deploy a total of 42,000 satellites[10]. The traditional space agency aims to exploit this development by designing communication protocols that support multi-hop communications for the sparsely connected space network. Namely, IETF's Bundle Protocol[11] [10] aims to enable Delay/Disruption Tolerant Networking (DTN)[12] for satellite networks. NASA and their partners plan to use this technology for the Artemis program to establish an outpost on the Moon[13].

However, the unique characteristics of satellite networks, including orbital dynamics and limited bandwidth, give rise to various security and privacy challenges, exacerbated by the diversity among satellite owners. Moreover, the interconnected nature of satellite systems means that an attack on one satellite can potentially impact others within the same network or constellation, amplifying the consequences of successful attacks. In the worst cases, satellite collisions may occur if satellites deviate from their orbits, generating dangerous space debris that poses risks to other satellites and spacecraft.

The existing literature on satellite security has focused on various aspects, such as satellite platform (e.g., potential attacks, design issues, access control) [23, 31, 46, 79, 96], communication (e.g., cryptographic schemes, authentication protocols) [53, 65, 87, 93, 97] and satellite networks (e.g., Global Navigation Satellite Systems (GNSS), key management, secure routing, network attacks) [17, 28, 38, 54, 55, 60, 62, 66, 73, 85, 91, 101, 105, 107].

Our literature investigation identified two critical security and privacy dimensions within satellite networks that have not yet received sufficient attention. The first dimension revolves around Public Key Infrastructure (PKI) complexity. PKI has been proposed for use in terminal to satellite encryption [16, 29] as a trust framework that provides the necessary key management, cryptographic protocols, and infrastructure to establish and maintain secure communication channels. In the case of Public Key protected Satellite-to-Satellite (SS) connections, there exist few works considering this scenario explicitly in the first place, whereas Ground-to-Satellite (GS) [35, 70, 99] link security works exist in plathora. Unfortunately, works on SS security only rely on symmetric key cryptography [34] or do not address revocation [75], maintaining an open gap in the literature.

The usage of PKI in space or Delay Tolerant Network (DTN) scenarios was proposed for key distribution [5, 6, 39, 82] establishment [6] or agreement [69].

However, deploying PKI in satellite networks faces unique challenges. Orbital dynamics, limited bandwidth, and computational resources impose constraints on certificate management, with satellite mobility and intermittent connectivity complicating certificate revocation procedures.[14]

The second aspect pertains to the security implications of satellite networks for users. As satellite networks become increasingly popular, ensuring user location privacy is crucial, especially with the rising adoption of satellite-based services like satellite internet for terrestrial applications. Signals transmitted from ground users to satellites can be intercepted by other satellites, enabling user location triangulation.

The interconnection between PKI complexity and location privacy within satellite networks is multifaceted, underscoring the intricate balance needed to uphold security and user autonomy. Compromised PKI elements, such as certificates, can lead to unauthorized access and data breaches, including location-related data. Conversely, robust mechanisms for preserving user location privacy are essential for strengthening trust in satellite networks. Advanced privacy-enhancing techniques, like location obfuscation, can be integrated into PKI frameworks to mitigate privacy risks while maintaining security assurances. Moreover, orbital delays and disruptions may impede timely certificate revocation checks, while transmitting user signals to satellites requires careful consideration to prevent location tracking and unauthorized surveillance.

We examine these challenges and explore research conducted in these areas, assessing their applicability and adaptability to the space domain. Given the limited research in space network security, we also incorporate insights from terrestrial studies as they can offer valuable perspectives for addressing security concerns in space networks.

This paper is structured as follows. Section 2 presents the background on space networks. Section 3 describes the challenges in space networks. Sections 4 and 5 presents a comprehensive literature overview on revocation checks and user location privacy, respectively. We also provide insights into the prior works and highlight the open research challenges.

2 Background on Space Networks

Space-based communications architectures are historically quite simple. In the past, satellite communication required

[12] https://www.nasa.gov/directorates/heo/scan/engineering/technology/disruption_tolerant_networking_overview

[13] https://www.nasa.gov/gateway/overview

[14] Other space-related aspects concern the exposure of satellites to harsh environmental conditions such as radiation, temperature fluctuations, and mechanical stress, which can affect the reliability and integrity of PKI components onboard.

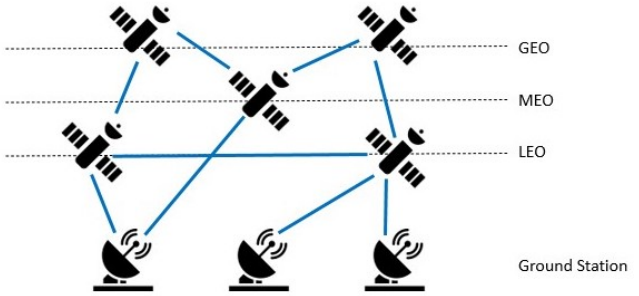

Figure 1: Exemplary overview of a simple space network architecture.

a direct connection from the satellite dish to the satellite. However, the future paradigm for space communications involves leveraging multi-hop communications among many satellites. i.e., *space networks*. Space networks refer to the interconnected system of satellites and other spacecraft that communicate with each other and with ground-based control stations. These networks play an important role in various applications, including telecommunications, Earth observation, navigation, and scientific research. Concrete examples can already be seen, such as the already-deployed European Data Relay Satellite System (EDRS)[15], which enables other Earth observation satellites to transmit data continuously instead of waiting to orbit over a satellite dish. Another example is the concept of creating an *Interplanetary Internet*[16] in the solar system using Delay-/Disruption Tolerant Networking (DTN) [**?**]. This concept is currently being standardized by both the IETF [10] and CCSDS [**?**]. As technology advances, space networks are expected to play an increasingly vital role in our interconnected world.

Figure 1 shows an example of how a space network may be structured. The initial layer of the architecture consists of the ground station, which includes a network of satellite dishes to establish the connection between Earth and space. At the next level, satellites are in different orbits[17]. A distinction is made between three types of orbits: Geostationary orbit (GEO), Low Earth orbit (LEO), and Medium Earth orbit (MEO). The geostationary orbit (GEO) is positioned above the equator, allowing satellites to remain stationary over a fixed point on Earth. This orbit is primarily used for telecommunication and weather monitoring satellites. In contrast, low Earth orbit (LEO) is relatively close to Earth, and LEO satellites can be placed in different orbital planes as they do not have fixed orbital paths. An example of this is Starlink LEO[18]. Satellites in LEO are interconnected, allowing them to downlink data via multi-hop connections, even if they are not in the line of sight to a satellite dish. Medium Earth Orbit (MEO) covers a wide range of orbits between LEO and GEO. Satellites in MEO do not require fixed orbital paths and are used for constellations such as GPS. It is important to note that satellites are in constant motion, resulting in a highly dynamic network topology. However, it is possible to predict the topology based on their regular orbits.

Satellite networks encounter various challenges that affect their efficiency, reliability, security, and privacy. One of the primary concerns is *latency*, as signals traveling between Earth and satellites experience delays due to the distances involved. Interference from atmospheric conditions, electromagnetic signals, and physical obstacles can degrade signal quality and disrupt communication. Adverse weather conditions such as rain, snow, and fog can further attenuate signals, affecting network performance. Further, satellite networks exhibit a highly *dynamic topology* due to the constant movement of satellites orbiting Earth. Consequently, any communication scheme should be able to tolerate potentially long delays. This may also lead to entire disruptions of some nodes, as they may lose line of sight to the rest of the network. Dealing with such delays is challenging, especially for security approaches that rely on reliable connections to other nodes. Limited *bandwidth* is another significant issue, as satellite communication links have finite capacity that can become congested in high-demand areas. *Security threats*, including unauthorized access and cyberattacks, also jeopardize the integrity of satellite communication systems. Hence, space networks require careful planning, coordination, and advanced technology to ensure reliable, efficient, and secure communication and data transfer in the challenging environment of outer space.

3 New Challenges in Space Network

Satellites progressively play an important role in numerous areas of modern life, underscoring the imperative of prioritizing the security of satellites and their users. Our investigations dive into two primary concerns within satellite networks: PKI integrity concerning handling certificate revocation and user location privacy. We concentrate on these security dimensions, which are emerging as indispensable yet remain largely unexplored in the existing literature. The former pertains to the security and trust relations among satellites, while the latter focuses on the security and privacy dynamics between the satellite network and its users. Subsequent subsections offer a comprehensive elucidation of these issues.

Revocation checks are fundamental to the integrity of PKI for space networks. They involve verifying and enforcing access control policies, ensuring that only authorized entities can interact with the satellite network. Revocation checks help mitigate the risks posed by compromised or unauthorized access attempts by regularly evaluating and updating the credentials of users and devices.

On the other hand, user location privacy is concerned with safeguarding the confidentiality and anonymity of users' geographic location in a network. In the space scenario, this involves mechanisms to prevent malicious actors from track-

[18] https://www.comsoc.org/node/19101

ing or deducing users' whereabouts, thereby preserving the users' privacy and safety.

The interconnection between revocation checks and user location privacy in the context of satellite networks lies in their complementary roles in ensuring the overall security and privacy of the system and provided services. Compromising either aspect can have cascading effects on the overall security posture of the satellite network.

For instance, if user location privacy is compromised, it could potentially aid malicious actors in circumventing access controls or targeting specific users. Similarly, weaknesses in PKI integrity caused by failing revocation checks could lead to unauthorized access and exposure of sensitive user location information.

3.1 Revocation Checks

In recent years, the utilization of public key cryptography within Space Delay Tolerant Networks (DTNs) [68] and specifically Satellite Networks [93] has been on the rise. This trend emphasizes the growing importance of PKI in guaranteeing the security and integrity of communication within space networks [29]. Hence, a well-defined and practical PKI for satellite networks is becoming increasingly desirable. PKI is a comprehensive system managing cryptographic keys and certificates, which is crucial for securing communication, ensuring data integrity, and facilitating secure access to online services. The European Space Agency (ESA) recently organized an open competition to develop a scalable PKI concept tailored for large constellation networks[19].

While many studies propose the integration of public key cryptography in space or between ground stations and satellites, a functional PKI is often lacking [16, 29, 36, 61]. Others suggest PKI utilization in space or DTN scenarios for purposes such as key distribution [5, 6, 39, 82], establishment [6], or agreement [69]. However, the critical and challenging issue of key revocation in a space environment has not been adequately addressed without imposing impractical resource requirements, such as the unmanageable memory usage associated with Certificate Revocation Lists (CRLs) [4, 20]. Ensuring revocation checks for keys and certificates is crucial when employing PKI. Failing to revoke compromised keys promptly poses severe security risks, enabling adversaries to exploit compromised keys to deceive other network nodes or take control of affected satellites.

As we detail in Section 4.2, traditional and popular revocation check approaches, like the Online Certificate Status Protocol (OCSP) [8], are unsuitable for space networks due to their reliance on uninterrupted connectivity and the potential for large communication overheads. OCSP requires direct contact with issuing certificate authorities (CAs), which is infeasible in space networks because of the inherent delays and disruptions. Similarly, CRLs pre-cache revocation information and depend on regular updates, which creates vulnerability windows and adds communication overhead, particularly in partially disconnected space networks.

In conclusion, revocation checks in space networks necessitate innovative methods and strategies. Addressing this challenge is a focal point of ongoing research efforts.

3.2 User Location Privacy

Satellite-based services encompass a diverse range of applications utilizing satellites orbiting Earth to provide essential functions such as communication, navigation, Earth observation, and scientific research. These services, facilitated by constellations like GPS and GLONASS, offer precise positioning, navigation, and timing data, serving applications from personal navigation devices to aviation and maritime navigation.

Preserving location privacy in space networks is evident due to the potential implications for individual privacy, security, and safety. The revelation of users' geolocations can facilitate targeted surveillance, tracking, or even physical harm in sensitive or hostile environments. Furthermore, compromised location privacy may undermine users' trust and confidence in satellite-based services, hindering their adoption and utilization.

While existing literature has extensively discussed threats such as eavesdropping, jamming, and spoofing on communication channels between ground users and satellites [43, 93], another critical but less explored class of attacks concerns compromising the location privacy of satellite-based service users. Signals transmitted from ground to satellite can be triangulated by neighboring satellites, enabling adversaries to estimate users' geolocations. For instance, if a satellite internet user uploads a large file, adversarial satellites nearby can track the signal, measure its strength at multiple points, and estimate the user's location. With the increasing access to satellites, this issue poses significant concerns for user privacy and security.

Addressing the challenges of realizing location privacy in space networks requires novel solutions tailored to satellite-based communication systems' unique characteristics and constraints. Location privacy in space networks is usually achieved by spanning a mesh network over the already deployed base stations. Unfortunately, solutions to mitigate users' geolocation in other types of networks (e.g., the internet) do not apply to partially connected networks, such as mesh networks, e.g., terrestrial ground-based satellite network users. We will discuss different approaches in Section 5.2. Solutions like TOR [19] are overlay networks and require a well-connected network (c.f., [49]) and, therefore, will be omitted from the following comparison and analysis.

4 Revocation Checks

This section dives into the literature on revocation checks applicable to the space networks, focusing on several core selec-

[19] https://esastar-publication-ext.sso.esa.int/ESATenderActions/details/60478

tion criteria. Firstly, many works in this domain assume that replacing an old key with a new one inherently results in revocation. However, this assumption proves insufficient when keys are re-issued before expiration, leaving both old and new keys considered benign despite potential compromises. Therefore, our focus lies on literature explicitly addressing revocation, aiming to address this limitation.

Secondly, a noteworthy aspect of our paper is the inclusion of literature addressing revocation within Delay/Disruption Tolerant Networking (DTN), as the system model in these environments applies to space networks. Given that space networks are among the primary use cases for DTN, incorporating this literature enriches our understanding of revocation mechanisms in relevant contexts.

Additionally, our selection criteria emphasize works that address mutual authentication scenarios. We exclude prior works assuming a client-server architecture (e.g., traditional Certificate Revocation Lists (CRLs)), where only one party needs to assure authentication and the validating party maintains a reliable connection to the issuing certificate authority (CA). Such scenarios differ significantly from those applicable to space networks. We opt not to include the cases where a simple on-demand revocation check mechanism suffices.

4.1 Literature Overview

This section offers details on revocation approaches applicable to the space network, which are presented in Table 1. The *Authentication Method* column treats both Public Key Cryptography (PKC) and PKI as distinct methods. PKI implies a chain of certificate authorities that issue certificates. PKC only means that the public cryptography algorithms (e.g., elliptic curves) are used without certificates and sometimes without a certificate authority.

We also distinguish between *broadcast* and *gossip*. Numerous papers generally leverage an implicitly reliable broadcast channel. However, often, there are no details on how the broadcast works practically. Other papers specifically mention that the nodes spread information by sending data to their neighbors, who, in turn, send it to their neighbors, and so on. While a varying degree of detail describes how this process works, we classify such methods as gossip.

Further, we analyze the mutual trust between the parties, as shown in the *Mutual Trust* column. The $\sim$ symbol indicates a trust imbalance between the parties, and their mutual authentication methods may differ. One party may require a timely revocation check while the other may merely rely on certificate expiration *without* a revocation check. The ✓ symbol indicates that both parties check each other's revocation status.

Finally, the last column shows the evaluation approaches. *Theoretic* evaluation indicates that the work presents mathematical calculations for the evaluation. For example, equations to calculate expected storage overheads when using certain data structures. *Experimental* evaluation indicates a deployment on a real device to measure the run-time overheads in a representative environment. *Simulation* refers to large-scale evaluation using a network simulator to measure network overheads. We categorize the works based on revocation methods for the following discussion.

Short-lived credentials Short-lived credentials implicitly revoke credentials if they are not renewed within a specified timeframe. Seth and Keshav [88] propose an authentication scheme for Delay-Tolerant Networks (DTNs) based on hierarchical identity-based cryptography (IBC) [27]. IBC [9] uses the identity of a node (e.g., an email address) as its public key. The certificate authority (CA) typically combines a node's general public parameter with its identity. The hierarchical IBC approach in this work is based on regions, with an overarching root certificate authority (CA) and each region having its sub-certificate authority (CA). On registration, nodes authenticate via a PKI-based certificate towards the IBC-based CA. The CA then generates the respective private key for the node's identity. Users may register region-specific keys with region CAs or get general keys with the root CA. Each IBC-based certificate is only valid for a defined time frame. Thus, it is argued that revocation is implicit as the certificate will eventually become invalid if not renewed. This also addresses the typical problem of re-issuing all nodes' keys in IBC if one key is compromised.

Chen et al. [14] propose that each node generates its private key. It then sends a challenge signature to the CA, which uses the signature to calculate the user's master key. The master key is used to derive symmetric session keys for the node. These session keys have a short lifetime; thus, each node must request a new one regularly. If the node is revoked, the CA does not issue a new session key and deletes the node's identity material.

Meng et al. [70] target mutual authentication between a user and a satellite service. The CA on the ground delegates partial trust for authentication checks to the satellites to reduce delays. The satellites can use proxy signatures based on elliptic curves to provide proxy authentication for the CA. This proxy authority is temporary. Users first register with the CA directly and get temporary anonymous credentials and information on the proxy authorities. The revocation is thus implicit with the expiry of either side's certificate. On certificate expiration, an online direct check is triggered with CA to get up-to-date validation information. The paper proposes a scheme to handle handovers, as long user sessions involve multiple satellites and thus proxy authorities.

Broadcast or gossip-based revocation dissemination Another class of works distributes revocations in the network via broadcast or gossip. Roy-Chowdhury et al. propose to use both PKI and TESLA [86]. Timed Efficient Stream Loss-tolerant Authentication (TESLA) [80] is a symmetric broadcast authentication protocol. It uses a hash chain in which each hash represents a time slice, with a secret key at the end

Table 1: Overview of revocation literature applicable to space networks. In the mutual trust column, the ∼ symbol denotes varying mutual authentication methods between parties and ✓ symbol indicates that both parties verify each other's revocation status. The ✗ symbol indicates lack of security analysis and evaluation.

Authentication Method	Revocation Method	Trust Assumptions	Key Assumptions	Mutual Trust	Security Analysis	Evaluation
[88] IBC	Short-lived keys	CAs know node secrets, CAs are always trusted,	Secure PKI in place	∼	✗	✗
[14] PKC for registration, rest SKC	Short-lived session keys	CA can derive all secrets	—	∼	Informal	✗
[70] PKC	Short-lived trust, online check on expiry	CA can derive all secrets	—	✓	Formal	Experiment, theoretic
[86] PKI for registration, rest TESLA	Individual broadcast, short-lived certificates	CA can derive all secrets	CA has reliable broadcast	✓	Informal	Experiment
[81] PKI	Hierarchical Bloom filter, individual gossip	Majority benign nodes	Reputation-based adversary detection system	✓	Informal	Theoretic, simulation
[37] PKC	Individual gossip	Inherently secure second channel (confirms identity)	Revocation spreads faster than re-issued keys	✓	Informal	Simulation
[26] Distributed PKI	Implicit, individual broadcast	Group of reputable nodes as distributed CA	Reputation-based adversary detection system, reliable broadcast	✓	Informal	Theoretic, simulation
[16] PKC	CRL	—	—	✓	✗	✗
[35] PKC	Only CA can check for revocation	CA can reveal anonymous nodes	Satellites are not revoked	∼	Informal	Theoretic, experiment
[103] PKC	CRL contains parameters to compute new group key	CA can derive all secrets	Nodes sign as a group	∼	Informal	Experiment, theoretic
[30] IBC	CRL stored on blockchain	Registration authority group (blockchain consensus)	Reliable access to blockchain	∼	✗	Simulation
[4] NOVOMODO	Time slice hashes for CA, hash table for nodes	—	Efficiency / vulnerability window tradeoff	✓	Informal	Experiment, simulation
[47] Distributed PKI	Terrestrial schemes	Multiple CAs via consensus	—	✓	✗	In-orbit experiment
[48] PKI	Sparse Merkle Tree	—	Subset of nodes use more storage space	✓	Informal	In-orbit experiment, simulation
[20] PGP	Neighbors vouch for node's revocation (and new key)	Neighbors with direct connection establish trust	Only protects against impersonating adversary	✓	Simulation	Simulation
[59] PKC	Time-specific certificates and CRL	CA can derive all secrets	Users know the satellites along the route	∼	Informal	Experiment, theoretic

of the chain. The hashes, concerning the current time, are used to calculate MACs over the sent messages. The hashes—and finally, the secret key— are gradually disclosed, which allows the receiving parties to confirm the authenticity of the message, given the arrival time of the message is before the hashe disclosure. First, a node registers with the CA by providing a PKI-based certificate for identification. Then, the CA sends the node a TESLA certificate back, allowing the node to start its own authenticated TESLA chain. As nodes are assumed to be sufficiently time-synchronized, two nodes can use the current hash in the TESLA chain to authenticate each other. The nodes can confirm each other's certificate with the respective hash disclosure in the next time slice. When a certificate needs to be revoked, the CA broadcasts this information to all nodes. The paper further argues that the TESLA certificates have a short lifetime, and thus, an eventual implicit revocation exists.

In Qian et al.'s revocation scheme for space networks [81], the revocation information is stored in a hierarchical set of Bloom filters [7]. This structure improves the false positive rate inherent in Bloom filters. To justify revocations in the first place, the paper assumes an adversary detection scheme is in place, which allows nodes to check each other for misbehavior. Each misbehavior is reported, and a reputation system tracks each node. In case the reputation of a node falls below a defined threshold, the CA revokes the node and issues a new bloom filter.

Jia et al. propose a public key distribution scheme for DTNs based on *two-channel* cryptography [37]. Aside from the normal broadband communication channel, these systems assume an inherently secure second low bandwidth channel and an established identity. Nodes exchange public keys and other identifying information on the normal channel, while a hash of the transferred data is sent via the second channel. Due to the inherent security of the channel, it is sufficient to authenticate the received credentials. In some cases, the two carriers (with many nodes) exchange credentials of an entire group of nodes, meaning an entire set of keys is exchanged.

For revocation, the affected node or carrier starts the epidemic routing and spreads the revocation. As this requires indirect forwarding by other nodes to reach the entire network, each node checks if there is a direct chain of trusted nodes to the receiver. Further, as revocation implies a re-issued public key and DTNs expect a dynamic topology, the paper assumes a quality of service mechanism to ensure the revocation spreads faster than the new key.

Fang et al. propose a distributed approach to PKI [26], in which a distributed certificate authority (CA) is established, i.e., a subset of nodes are chosen to operate as the CA cooperatively. The nodes are chosen based on a reputation system, and the most reputable nodes become part of the CA group. The paper assumes that an intrusion detection scheme is deployed, which allows the nodes to measure each others' trustworthiness. If a node detects suspicious activities, it broadcasts the information to the network, and each node individually tracks the reputation of all the nodes in the network. A node can be revoked in three cases: (1) if a node's reputation is low, (2) if a node's certificate is expired, or (3) if a node revokes its certificate. The revocation is implicit in the first two cases. The paper does not address how a node proves its identity to others in the latter case.

Certificate Revocation List (CRL) Some works use straightforward revocation techniques, such as traditional CRLs in space networks. Cruickshank [16] is one of the first works to address revocation for space networks. The approach is essentially a standard hybrid for channel security between the ground users and the satellites. Public keys are exchanged via signed certificates, and a symmetric key is exchanged to establish a secure channel through symmetric encryption. They propose CRLs for revocation. However, the paper does not address the distribution of the CRL in the space environment.

Ibrahim et al. [35] propose a method where ground-based users and satellite networks authenticate each other while keeping user identity hidden. The user's authentication data needs to be anonymous and untraceable. A Certification Authority (CA) uses elliptic curves to generate and share a set of blinded secrets to achieve this. When users register, they pick a random blinded secret from this set, compute a session key, and use it for communication protection. By changing the blinded secret regularly, the user stays anonymous. Only the original generator of the secrets can calculate the mutual session key so that the user can authenticate the service provider. The scheme resists jamming as authentication isn't interactive, so the jamming adversary doesn't know when the user communicates. For revocation, the service provider can determine the user's identity and delete their registration, preventing them from establishing a valid session key. However, it's unclear how this revocation information is sent to the satellites.

Yang et al. propose another approach for the same setting as above which leverages group signatures for roaming users [103]. A set of users sharing the same *domain* are grouped. The CA provides the necessary information to the users to calculate group signatures, and the satellites use traditional certificates. For user authentication, the satellites check if the group signature used by any of the group users is valid. They use a special type of CRL for revocation, which contains the necessary parameters to update the group certificate information. When a user is revoked, the satellites and the users update their certificates.

Guan et al. propose another approach based on IBC which leverages blockchain technology [30]. In this scheme, nodes register with one of the registration authorities, the registration authorities are blockchain nodes. The authorities come together to establish a permissioned blockchain. A permissioned blockchain contains a limited set of consensus nodes, as opposed to a permissionless blockchain, which anyone can join, and consensus happens amongst all the network's participants. Upon registration, the registration authorities generate and encrypt their key shares, which the registering node uses to retrieve its private key. As the scheme uses IBC, the node's identity acts as its public key, which is stored on the blockchain, along with the encrypted private key. Satellites act as proxy authorities, storing their identities on the blockchain. The blockchain is also used to store and distribute a CRL for revocation. The key assumption is that the nodes keep an up-to-date version of the chain and thus have reliable access to the blockchain.

Efficient data structures Bhutta et al. [4] and Silvio Micali [71] propose NOVOMODO scheme, which involves splitting the time until certificate expiration into discrete time slices, each represented as a hash in a hash chain spanning the entire validity period. When a node wants to authenticate itself before others, the Certificate Authority (CA) provides the current hash to append to the certificate, enabling a single hash instead of a complete proof akin to OCSP. Moreover, the validity of these time slices can be adjusted, allowing for handling delays with granularity. For instance, if each time slice is an hour—including a new validity hash per hour—nodes also accept hashes that are five hours old. This approach allows for handling delays with a selected granularity.

Multiple CAs within the network are responsible for their nodes, and the NOVOMODO scheme is employed explicitly for these CAs. The respective CA issues a hash table of revoked nodes alongside the current NOVOMODO hash for node revocation, facilitating validation even with delayed arrival. However, this efficiency-security trade-off entails more considerable periods, increasing vulnerability windows while reducing overhead.

Koisser et al. propose to use multiple CAs to form a distributed CA [47]. They explore various revocation schemes based on terrestrial methods. Since space networks involve many distrustful parties, agreeing on a single CA is challenging. To address this, the paper proposes a consensus protocol among CAs using a signature aggregation scheme, keeping communication overhead low. Revocation schemes are di-

vided into two categories: burden shifting to the prover and data structures containing all revocations. The first category includes OCSP Stapling, where the prover regularly fetches short-lived OCSP responses, and Merkle hash trees, providing a Proof-of-Inclusion (PoI). The second category proposes CRLite, using cascading Bloom filters, and Let's Revoke, using incremental numbers and compressed bitvectors. The paper evaluates the runtime overhead of both signature aggregation and revocation schemes on an in-orbit satellite.

Koisser et al. [48] build on using a Merkle hash tree to aggregate certificate validation information as a revocation scheme for space networks. Specifically, the paper proposes to use the Sparse Merkle Tree (SMT) [50] to store all certificates' validation information. The SMT builds a complete hash tree over the entire search space, i.e., all possible outputs of the used hash function. In the beginning, all leaves of the SMT are empty and are consequently populated by the hashes of all active certificates in the network. As the tree mostly contains empty leaves and branches, large parts of the tree can be omitted to make it calculable. Since the position of any certificate (or rather its hash) is deterministic in the tree, leaves can be deleted without recalculating the entire hash tree. This results in properties that allow up-to-date nodes to share their valid PoI to repair outdated nodes' PoIs on any changes (e.g., a revocation that deletes a leaf in the SMT). This allows nodes to spread revocation information epidemically throughout the network without directly contacting the CA or inducing large communication overheads. The paper argues that the scheme enforces fast revocations due to the inherently epidemic spread and is independent of the network topology. This work also evaluated the proposed scheme on an in-orbit satellite.

Other approaches Djamaludin et al. [20] propose an approach to leverage a PGP-style trust network for revocation. In Pretty Good Privacy (PGP) [108], each node self-signs its certificate and trusts the certificates of only certain nodes (e.g., nodes it already met). If a new node, and thus an unknown certificate, is encountered, the node checks if anyone knows the new node of its trusted nodes. Thus, a chain of trust is established such that the node can indirectly establish trust in the new node. In the presented work, neighboring nodes (i.e., nodes that have a direct connection to each other) can inherently establish trust in each other's identity. The PGP approach is then used to communicate with nodes that do *not* have a direct connection. If a node needs to revoke its certificate, it collects signatures from its neighbors. Thus, these neighbors essentially vouch for the revoked node without a certificate. The number of signatures required is defined as a fraction of the total number of nodes in the network. If the revoking node has collected enough signatures, it broadcasts its revocation. This typically also includes a new certificate, which is then vouched for in the usual PGP way. As trust is established by direct contact, the approach only protects against an adversary who tries to impersonate another node.

In the work of Liu et al. [59], satellite service users move and encounter different access points, i.e., satellites. The proposed scheme establishes a mutual authentication scheme between the users and the encountered access points. First, both users and access points register with the CA. Users anticipate the times they will encounter the various access points before they start their trip and send a list of this information to the CA. The CA generates anonymous credentials for the user based on group signatures, which are only valid for a specific period for each access point (according to the user's trip plan). A list of the respective public keys is also retrieved to authenticate the access points. These credentials (per access point) are short-lived for revocation. Additionally, if a user is found malicious, the CA reveals the user's identity and distributes a special CRL to the satellites, which contains parameters to subtract the user's key from the group's credentials. For the revocation of access points, only short-lived certificates are implied.

4.2 Analysis

In this section, we analyze the literature on revocation schemes in the light of their applicability to the space scenario and give intuitions about their shortcomings. The *short-lived credential* method implicitly revokes the certificate if it is not renewed in time [14, 70, 88]. Even though the assumptions required for these approaches are not impractical (c.f., Table 1), these straightforward approaches have a clear downside. To enforce a quick revocation in case of a compromise, the lifetime of the credentials needs to be kept short. However, the shorter the lifetime, the more network overhead is implied, as the credentials need to be renewed often. Further, some satellites may be disconnected at the time of renewal, leading to issues regarding either missed updates or how these credentials are distributed. For example, DTN uses a store-and-forward approach, and network disruptions imply that the forwarding nodes spend resources to store the message until they can successfully forward it. This strains the network and may even lead to situations in which a node may miss several renewals.

The next approach simply informs the network nodes of revocations directly via *broadcasts or gossip-based dissemination* [26, 37, 81, 86]. While this is a valid strategy in principle, we highlight two issues with this approach. First, these works do not consider how the respective dissemination is affected by the topology of satellites. In works that use broadcast [26, 86], there is no discussion on how to broadcast in a space network. As shown in Table 1 column *Key Assumptions* a reliable broadcast technique is assumed. However, the effectiveness and swiftness of the revocation directly depend on the implicit properties of the used dissemination. While the broadcasting technique itself is an orthogonal issue, it needs to be considered to hint at the guarantees of the revocation. Another issue is that the broadcast/gossip messages may not arrive at all the nodes in the space networks, e.g., when

parts of the network are temporarily disconnected. One of the works assumes that a share of the network is malicious [81], and it can also affect the gossip protocol. This has crucial implications on the effectiveness of the revocation.

The straightforward revocation techniques [16, 30, 35, 103], such as *traditional CRLs* [8], pre-cache revocation information on virtually all certificates in the network, and the absence of a revocation indicates the certificate's validity. Usually, a CA distributes such a CRL to all nodes in the network and regularly updates it. Note that even if there are no revocations since the previous update, it is important for the CA to distribute still an update such that nodes can be sure that they have the newest CRL. However, there are two intertwined problems with this approach. Updating the CRL in a defined interval also implies an inherent vulnerability window. For example, if a certificate is revoked just after a CRL update, nodes in the network will not know about the revocation until the next CRL update. While a revocation could also trigger an exceptional update to be distributed earlier, nodes in a space network may experience disruptions and not receive the exceptional update. Due to a recently received regular update, they will assume a compromised certificate to be benign. This problem can be avoided by shortening the time interval between expected CRL updates, yet such a strategy ties into the second problem. A CRL may grow to large sizes, and regularly sending out updates may induce large communication overheads. Combined with a partially disconnected space network due to delays and disruptions, this results in a non-trivial challenge when using CRLs. Further, so far, we assumed that the updates reach all nodes in the network, which may not be the case in an actual deployment. They also do not discuss the implications of how the data is disseminated. Further, there is a lack of discussion and analysis on updating this data, such as delta CRLs. Delta CRLs may significantly reduce the overhead of revocation information dissemination but may also cause problems if nodes are disconnected.

Other works use *efficient data structures* to reduce the network overhead [4, 47, 48]. These approaches alleviate the dissemination problem by removing the need to send distinct messages for revocation. However, these works also do not consider how to disseminate the revocation information by relying on terrestrial schemes (c.f., Table 1) column *Revocation Method*; thus, there can be issues in real-world deployment of these approaches. One exception is the work by Koisser et al. [48], whose revocation approach is topology-independent. They define exchange protocols relying on small amounts of data that allow nodes to ascertain if they're outdated. If nodes notice that they are not up-to-date, they can reject credentials and try to update their revocation information without contacting the authorities. Djamaludin et al. [20] relies on a *PGP-style revocation system* in which neighbors vouch for each other. It assumes that the involved parties are willing to establish an entirely self-organized trust network, which may be difficult in a real-world scenario. Moreover, the neighbor-based trust and dissemination approach is prone to scalability issues, especially in the highly dynamic environment of a space network. Liu et al. [59] rely on credentials only valid for a specific time frame. This work assumes that the nodes know in advance exactly which other nodes they will encounter and interact with. This assumption may be impractical in many scenarios, especially for a large-scale space network. There is a trade-off between either using a pre-computed long list of encounters or regularly acquiring a new list. Both cases imply a significant communication overhead, with irregular large amounts of data or regular updates of small lists.

4.3 Open Research Challenges

In this section, we outline the identified research challenges based on our analysis of the prior works.

Multiple CAs In a practical deployment, PKI can include multiple stakeholders such as governmental space agencies and commercial players; relying on a single CA is unfeasible, as the parties mutually distrust and may not agree to trust a single authority. The use of multiple CAs may cause additional challenges in terms of scalability, which needs to be considered explicitly.

Some existing works *do* consider multiple CAs. In Fang et al. [26], a reputable group of nodes inside the network is elected to do the decision-making as a CA for the entire network. However, it assumes all parties agree to place their trust in a distributed approach. The work of Bhutta et al. [4] also considers multiple CAs, which work independently. If a node belonging to one CA wants to check the validity of another CA, the leveraged NOVOMODO approach supports efficient checks. Guan et al. [30] leverages a blockchain to let a group of authorities create a consensus-based repository, which stores all agreements among the group, e.g., issuance or revocation of certificates. However, this approach, therefore, assumes a reliable blockchain in place. Similarly, Koisser et al. [47] proposes a consensus protocol for secure agreement among CAs. However, this solution works only if the involved parties accept quorum-based decision-making, i.e., the others may override a single authority. Multiple CAs in the unique topology of space networks constitute a challenging research problem.

Topology Optimizations Network topology is another aspect that has received much attention. Unlike other dynamic networks, the periodic nature of orbits creates a predictable topology in space networks, which can be exploited to build solutions that efficiently spread revocation information. Yet, in our investigation of the prior works, we did not encounter any work that explicitly considered the network topology.

Practical Evaluation

To thoroughly evaluate schemes designed for space networks, deploying and testing them on in-orbit satellites is essential. To our knowledge, only Koisser et al. [47, 48] have

conducted such tests for their proof-of-concept software on real-world satellites. Evaluations on actual space networks provide representative results that can lead to new insights and reveal opportunities for optimization.

5 Location Privacy for Space Networks

This section presents approaches for achieving location privacy for users of ground-based satellite services. Only one paper directly addresses the issue of location privacy for space networks [49]. However, the issue of location privacy arises in the security of the physical layer in satellite communications. Furthermore, we found that the issue of location privacy has been extensively researched in Wireless Sensor Networks (WSNs). Although originally designed for terrestrial networks, the system model applies to space networks. In WSNs it is assumed that nodes form a mesh network and use multi-hop routing to reach a *sink*, which is connected to the WAN. If we apply this to, e.g., a satellite-based Internet scenario, the sink would be the satellite terminal and the service user needs location privacy. Unlike WSNs, it is assumed that there are many sinks, which may form the mesh network instead of the users themselves.

5.1 Literature Overview

The section analyzes the approaches applicable to location privacy for ground-based satellite network users.

Table 2 depicts various location privacy approaches and their corresponding attributes. The *Adversary Model* concerns one of three adversary models - local, global, or hunter - related to them. The *Global* adversary passively eavesdrops on the entire network, representing the strongest adversary model. The *Local* adversary has a limited view, observing only specific network traffic. A *Hunter* adversary has a localized view, seeing traffic from nearby nodes, and can trace a user's connection back to the root, assuming the adversary can move. In the section *Phantom Routing*, we offer a detailed definition of this adversary model as introduced in the paper [77]. Furthermore, Table 2 provides a general indication of each approach's overhead, including latency, computational, and communication overheads. It is important to note that these schemes were chosen optimistically, as the overheads vary. The *Latency* overhead indicates the average delay of messages with each approach; e.g., taking a slightly longer route may induce less latency than storing messages before forwarding them at each hop. The *Computational* overhead refers to the additional computing resources or effort required to perform specific tasks or processes, e.g., apply complex cryptographic primitives on each node along the route. Finally, the *Communication* overhead considers the entire network rather than just the sending node, referring to the additional payload data.

Anonymous Satellite Internet A recent work that specifically addresses location privacy for satellite service users, such as satellite Internet, is AnonSat introucded by Koisser et al. [49]. Their scheme aims to protect location of satellite Internet users from triangulation by other satellites The objective is to utilize cost-effective, off-the-shelf devices to facilitate the implementation of this system. This will enable the system to be used directly from consumer devices, such as common smartphones, without needing a bespoke device or application. AnonSat employs long-range wireless communication to establish a local mesh network among dispersed base stations in a designated area. It redirects users' communication through distant base stations to prevent geolocation of the satellite Internet base station and nearby users. Consequently, an adversary monitoring base stations to find the user's traffic and geolocate the user cannot assume that the up-linking station is closest to the user.

Physical Security for Satellite Communication While physical security approaches aim to enable satellite communication resilience against eavesdropping, they also facilitate location privacy properties. Various approaches propose the utilization of wireless communication characteristics to achieve communication confidentiality, which will be introduced below.

The goal is, therefore, to achieve a signal-to-noise ratio (SNR) above a specified threshold at the location of the authorized receiver, while maintaining the SNR below the threshold in all other areas. The low SNR of the transmission ensures that the message cannot be decoded by an unauthorized listener [2, 52, 100]. Lei et al. [52] use beamforming and power modulation to negate the SNR of the eavesdropper thereby preventing proper reception of the signal. This technique also safeguards location privacy by preventing geolocation when signals aren't received. It necessitates the use of specialized satellite hardware and the acquisition of channel state information, which includes details about communication link properties such as scattering, fading, and power decay with distance. Additionally, some approaches use artificial or natural noise to disrupt eavesdroppings, like those by Yan et al [100] or An et al. [2]. Importantly, these approaches may potentially result in unintended consequences about location privacy. An attacker could potentially estimate the location by continuously testing the SNR and observing the direction of increase or decrease.

Below we describe additional approaches, not utilizing physical security but relying on software- or network-based approaches, developed for WSNs to address location privacy, in addition to those previously discussed.

Phantom Routing The first paper to propose the Phantom-Routing approach was by Ozturk et al. [77], which also introduced the *hunter*-adversary model. In this model, it is assumed that the adversary knows the sink's location. If the target node routes messages to the sink, the adversary can trace the node used as the last hop of the route. This process could potentially be repeated until the adversary reaches the target node. In the context of a satellite Internet connection,

Table 2: Overview of approaches for user location privacy. The latency, computational and communication overhead are approximated.

Approach	Adversary Model	Key Assumption	Latency Overhead	Computational Overhead	Communication Overhead
Anonymous Satellite Internet [49]	Local	No compromises of nodes	Low	Low	Low
Physical Security [52]	Global	Channel state information must be known	Low	Low	High
Phantom Routing [42, 57, 58, 77, 92, 95, 98, 106]	Hunter	Single hunter	Medium	Low	Medium
Fake Traffic [1, 11, 63, 64, 67, 89]	Global	—	Medium	Low	High
Ring Routing [13, 21, 44, 56, 83, 104]	Hunter	High capacity node form ring	Medium	Low	Medium
Multi-Path Routing [15, 33, 45, 94]	Hunter	Single hunter	Low	Medium	High
Network Coding [24, 25]	Global	Feasible overhead for homomorphic encryption	Low	High	Medium
Avoid Adversary [22, 84]	Local	Adversary can be detected	High	Medium	Low
Artificial Delay [32, 40, 41]	Hunter	Messages may arrive out-of-order	High	Low	Low
Pseudonymity [18, 72, 76, 90]	Global	Pre-shared secret in place	Low	High	Low

the term 'sink' refers to the satellite dish that is connected to the WAN. The hunter can trace the terrestrial route until they locate the actual user. To counter this, the scheme operates in two phases. In the initial phase, the target node employs a random walk scheme to regularly route to various nodes, with the final node designated as the phantom node. Subsequently, in the second phase, messages are transmitted towards the sink, which may result in a flood of messages in that direction. This way, the adversary will be misled to different directions, never reaching the target node. Another work by Yan et al. [42] modifies this scheme to use a direct route to the sink instead of flooding. Xi et al. [98] propose an adaptation of the hunter-adversary model to consider several malicious nodes monitoring the network. Their approach involves the target node routing to multiple phantom nodes simultaneously, while the sink regularly transmits discovery messages. When a phantom node receives such a message, it forwards it to the sink, thereby utilizing multiple concurrent routes, which presents a challenge for any potential adversaries attempting to track them. Another proposal by Wang et al. [95] assumes that the adversary has a limited and known visibility range. The presented scheme incorporates this consideration to perform a directed random walk in a manner that ensures phantom nodes are dispersed sufficiently to prevent potential adversaries from gaining an advantage. To guarantee that the phantom nodes are always a minimum distance away from the target node, Lightfoot et al. [58] propose the selection of phantom nodes within an annular area surrounding the target node. This ensures that phantom nodes are sufficiently far away from the target, without including significant delays due to their proximity. To implement this successfully, it is necessary to have an understanding of the network topology. Similarly, in the RRIN scheme proposed by Li et al. [57], nodes only require knowledge about their neighbors. Note that this scheme is primarily designed for small networks and may not be suitable for larger networks. An alternative approach proposed by Zhou et al. [106] is to utilize an ant colony optimization instead. Here, reasonably direct routes are selected from target to sink, yet the algorithm is modified to select sufficiently different routes each time. The PEM scheme proposed by Tan et al. [92] starts by identifying the shortest route between the target and sink. Then, phantom nodes are selected from nodes that are near this shortest path.

Fake Traffic This context addresses works that consider *global* attackers, i.e. attackers who can monitor the entire network. While some works use fake traffic to address a local or hunter adversary [12, 42], this is not the primary focus of this consideration. Mehta et al. [67] proposed a *periodic collection* scheme to address a *Global* adversary. In this scheme,

nodes collect messages that have been received, and then forward a fixed number of these messages during a given period, regardless of whether they have collected any messages. This also applies to the forwarding of artificially generated messages. A similar approach entails nodes regularly transmitting fake messages, as proposed by Shao et al. [89]. The target node can take the transmission interval into account to cover its message. To reduce communication overhead and delays, the scheme further proposes to use variable and probabilistic transmission times. Similar to the previous approach, Majeed et al. [64] propose a scheme that lets nodes regularly send messages. The method has been extended to use multiple paths from source to sink, which increases privacy and dynamically adjusts the rate of fake news in the network to account for the load of real news. The idea of using a probabilistic distribution for the fake message rate is extended by Alomair et al. [1]. Instead of only using the distribution for the fake messages, the scheme considers the real messages as well and fits them into the distribution. The proposal by Mahmoud et al. [63] combines phantom routing with fake traffic generation. In order to enhance efficiency, the generation of fake traffic is only activated when genuine traffic is in operation. According to Bushnag et al. [11], it is recommended to use a low average rate for transmitting both fake and real messages. For implementation, the transmission rate for all messages is constant. Alternatively, real messages can be transmitted at a high rate while subsequent fake messages are transmitted at a low rate to maintain an unchanged overall average.

Ring Routing The ring routing scheme [44] establishes topological rings for each cluster, with nodes clustered together and forwarding in one direction. Messages are efficiently routed through multiple clusters, each with a designated head node that reliably transfers messages to other ring clusters. As messages go along similar routes and form cyclic paths, it becomes harder for a hunter adversary to trace messages back to the actual target node. According to Li and Ren [56] the ring routing approach can be effectively combined with the fake traffic approach. Here, a single ring is used with relay nodes breaking cycles and forwarding messages to a sink, supplemented by fake messages. A similar approach uses multiple rings, layered around the sink Yao et al. [104]. The target node then chooses an adjacent ring as its next hop. Afterward, the message is forwarded towards the sink, with a chance to be routed along any ring on its way. Another approach similar to the initial ring routing methodology [44] involves generating fake traffic within each cluster Ren et al. [83]. Dong et al. [21] also suggest implementing random walking within the ring cluster before performing the forwarding along the ring. Another proposal is to use flooding inside the ring cluster Chen et al. [13].

Multi-Path Routing Wang et al. [94] propose a multi-path scheme to protect against a hunter adversary. Multiple paths from the target to the sink are selected with different general angles towards the sink. Each node randomly chooses a new angle to establish diverse routes such that the adversary cannot trace the route back to the target. The work proposes another scheme that includes message aggregation and fake traffic generation to provide additional protection against a global adversary. Koh et al. [45] optimize the previous approach by leveraging a Bayesian strategy for route selection. The approach by Huang et al. [33] tries to optimize multiple paths globally for the network and merges redundant paths to significantly reduce network overhead. Chen et al. [15] optimize path selection by selecting next-hop nodes through an annular area around the target, combined with the general angle towards the sink. This approach establishes routes that are not only short but also sufficiently diverse.

Network Coding To protect against a global adversary, messages are divided into smaller segments and transmitted through multiple routes to the sink, ensuring a highly effective method Fan et al. [25]. Nodes combine parts from different messages and forward them collectively. The division of messages provides clear instructions on how to reassemble the message at the sink. The adversary's ability to trace the message back through traffic analysis is directly linked to their ability to obtain this information. To avoid this problem, simply encrypting the aggregation information is the recommended solution. It should be noted that intermediate nodes will need to modify this information during transmission. The proposed scheme leverages homomorphic encryption to prevent intermediary nodes from accessing and adding their own aggregation information. This ensures that only the sink can decrypt the information. Another work by the same authors extends this approach with fake traffic to further exacerbate the adversary's efforts [24]. In this case, the artificially generated message components are absorbed to increase efficiency. If any intermediary node processes the fake message, the homomorphic function will filter out any non-real parts. This approach effectively reduces the induced network overhead, without requiring the knowledge of any intermediary node.

Avoid Adversary To ensure network security, it is crucial to guard against *internal* adversaries. These adversaries may control specific nodes in the network, often by compromising them. The approach proposed by Dutta et al. [22] assumes that the adversary can be detected and geolocated by the network, thus enabling the protection of the network against this adversary. The network is divided into a grid. When any node detects an adversary within a grid, all benign nodes in the grid will immediately stop communicating until the adversary has left. To detect an arriving or leaving compromised node in a grid, the special grid nodes will detect the adversary's movement and immediately inform the respective grid to deactivate or activate. Rios et al. [84] replaces the grid with a hop-based distance measurement. Benign nodes can detect adversarial nodes as they cannot authenticate themselves. The detecting node broadcasts a message to inform the rest of the

network, incrementing a counter for each hop of the message. This gives an estimate of the adversary's location and allows the other benign nodes to circumvent the adversary when choosing a route for their packets. Nodes near to the adversary will buffer messages until the adversary has departed.

Artificial Delay According to Hong et al. [32], encrypting and padding all messages can make them indistinguishable from one another. In addition, they suggest the addition of a random delay before the forwarding of messages. This prevents a local adversary to trace messages back over multiple hops, even if they arrive out of order. The same work also suggests an extension to handle networks with low traffic. In this case, if a node receives only one message for a while, it re-triggers the random delay for the message until a set maximum of delay periods or another message arrives. The work by Kamat et al. [40] focuses on analyzing the effects of different distributions and how the intermediary nodes handle the buffering of messages. To avoid analyzing the chosen distribution of the delays, message delays can be mixed Kamat et al. [41]. For this, intermediary nodes can adopt strategies in which they skip waiting for the delay, e.g., just sending the message with the longest delay contained in the node's buffer.

Pseudonymity One of the first works that protect against a global adversary via pseudonyms is by Misra et al. [72]. In this approach, all nodes have a shared secret key pair with their neighbors. Additionally, nodes form clusters, which select individual nodes as cluster heads. Each cluster establishes a cluster key and all traffic is forwarded via the cluster head. To protect against the adversary, the paper proposes two solutions. One leverages a global pseudonym space, in which every node gets its sub-space. Nodes then randomly select a pseudonym and the sink has an attribution table to know which node belongs to the used pseudonym. Forwarding nodes also keep a table that indicates the direction of nodes for certain pseudonym ranges. The other solution aims to reduce the storage overhead of using large pseudonym attribution tables. Instead of doing a lookup in a table, nodes use a keyed hash function that directly generates the pseudonym. The key for this hash function is a shared seed among the nodes. The work by Ouyang et al. [76] proposes two similar strategies to the previous ones. One strategy extends the keyed hashing for resolving pseudonyms to protect against an internal attacker. Briefly, any node will create two hashes, one for communicating with the sink and one for communicating with its next neighbor. The alternative strategy generates a complete hash chain to transmit to the sink, which effectively reverses the order of the other strategy. Another work leverages three mechanisms to achieve anonymous routing Sheu et al. [90]. One mechanism is an anonymous one-hop communication based on encryption keys established with the node's neighbors. The second mechanism enables multi-hop routing, by using a pseudonym next hop routing table. Lastly, the last two mechanisms are combined to get a per-hop encryption along the entire route. The work of Di Pietro et al. [18] organizes the network in a tree-like structure with a sink as the root. First, the sink and all nodes will send random values down the tree for i rounds to create shared key values of i bits, which are used for per-hop encryption. We omitted the works specifically focusing on protecting the sink, as the location of the sink will be revealed through triangulation anyway.

5.2 Analysis

This section compares the individual approaches, highlighting their drawbacks and applicability to location privacy for ground-based satellite network users. The analysis is predominantly conducted under the key factors of latency, computational, and communication overheads as displayed in Table 2. This is because location privacy in network approaches is often a trade-off between throughput and privacy guarantees. Due to missing implementation, open-source code, or even evaluation of the specific works, the overheads were approximated. The work on *Anonymous Satellite Internet* [49] directly addresses the issue of location data protection in the specific context of satellite services and provides.

However, at the same time, a customized approach may offer several advantages over the presented scheme. Therefore, in the following, we provide an analysis on proposed mechanisms.

Physical Security may be able to inherently provide location privacy. However, they are designed for confidentiality and not for location privacy of high bandwidth services. Manipulating the SNR in this way will impair the data rates. Additionally, they assume the knowledge of all Channel State Information (CSI), which may be impractical.

Due to the random (and flooding) nature of *Phantom Routing* approaches, they incur large communication overheads. The random walk may also direct the message unfavorably, causing further delays. In contrast, other works rely on complete knowledge of the network topology to avoid this issue. In the highly dynamic environment of a space network, this is non-trivial to achieve and to consider for routing.

Fake Traffic approaches provide strong location privacy guarantees against an adversary with a global view. However, generating fake traffic across the entire network results in insignificant communication overheads. Additionally, these approaches also employ a form of aggregation with regular release, which also implies delays. Some of the works propose an efficient method for generating traffic that does not require knowledge of when a benign node is sending, ensuring correct timing of the generation (e.g., [89]). This is quite impractical and if this information leaks to an adversary, it could be abused to defeat the entire approach by exactly knowing the timing of the benign transmissions.

Ring Routing assumes a set of powerful nodes that establish the ring, which implies large bottleneck overheads in terms of communication and might not be achievable in many scenarios. Also, the one-way routing along the ring may imply

significantly longer routes, leading to delays.

Multi-Path Routing implies communication overhead proportional to the number of distinct routes. This approach also requires in-depth knowledge about the topology of the network to properly and efficiently set up the multiple routes.

Network Coding is a powerful approach against a global adversary. The scheme's computational intensity results from homomorphic encryption at every hop. This is especially pronounced when numerous parties are communicating, as the holistic overhead is significant. Also, the setup of pre-shared secrets is inadequately addressed.

Avoid Adversary is effective if the network knows which nodes are compromised and their locations. One effective approach is to assume the presence of an adversary detection scheme that enables all nodes to validate each other and accurately identify any malicious nodes. This assumption is based on the fact that without such schemes, it is not feasible to ensure the security of the network.

Artificial Delays cause significant latency, detrimental in many use-cases like satellite Internet. Incorrectly received messages can cause further complications.

Pseudonymity While this approach protects against a global adversary, there are two caveats to accomplish this. Firstly, these approaches rely on a bootstrapping phase to set up shared secrets, which in some cases requires numerous all-to-all communication rounds. This may be impractical, especially for large networks. Secondly, the pseudonymity of an individual node depends on how many other nodes use the mechanism and if they are close to the node. Otherwise, it will be easy for an adversary to identify the node despite the pseudonym, if there are no other messages in the network.

Tor network As stated earlier, the Tor network [19] is not an applicable location privacy approach in satellite internet networks. In addition, satellite communications can be monitored by any satellite and, more concerningly, can be triangulated to pinpoint the user's location. For instance, many attacks on Tor rely on an adversary conducting *entry-point* monitoring [74, 102]. While this is usually a challenging position for the adversary, it becomes much simpler with satellite-based Internet since the connection first goes to the satellite before reaching the Tor network. Additionally, some attacks on Tor assume the adversary can monitor both the *entry* and *exit points* [3, 51, 78]. However, as described in Section 5.3 onion routing could be utilized in future research.

5.3 Open Research Challenges

This section will outline some open research challenges we identified. As space networks are not commonly addressed in most works, numerous research questions remain unanswered in this unique environment.

Physical Security While we covered physical security as a potential way to achieve location privacy, the respective works were not designed with this goal in mind. Thus, we think there is an opportunity to optimize the general idea of this approach to either conceal the ground-based user's location or maybe even prevent the triangulation entirely.

Compromised Nodes *Internal* adversaries are often overlooked in many works, despite their significant impact on network security. These attackers have control over a node within the network, usually as a result of a compromise. Thus, we think this problem can be addressed more explicitly and in combination with other approaches. Moreover, it is imperative to analyze the aspect of adversary detection schemes more practically, including scenarios of imperfect detection or dissemination of information about a detected compromise.

Optimized Fake Traffic There are opportunities to optimize fake traffic methods for ensuring location privacy by distributing generated traffic. The predictable and regular orbits of typical space networks can be leveraged to design an effective fake traffic generation strategy tailored for space networks.

Onion Routing One of the practical ways to achieve anonymity on the Internet is onion routing, e.g., as used by the Tor network [19]. As an overlay network, it can be utilized to provide better location privacy guarantees for satellite service users. Particularly, is can prevent an internal attacker from accessing the routes of specific messages, thereby ensuring location privacy protection.

6 Conclusion

In this SoK, we look into two important security areas that are crucial for robust and secure space networks, yet haven't been explored enough in satellite network literature. Firstly, as collaborative efforts among satellites from diverse and distrusting entities gain popularity, setting up PKI becomes important for secure communication. However, we find that checking certificate revocations in space networks is hard due to long delays and disruptions. Secondly, with more people using satellite internet and other services, there's concern about potential disclosure of users' locations. This is a noteworthy consideration in safeguarding user privacy and security. Throughout this paper, we analyze existing research in these fields and point out the challenges that need more attention. Our examination revealed numerous open research challenges, emphasizing the need for further investigation and innovation in these domains.

Abstract

Low Earth orbit (LEO) satellite communication has recently experienced a dramatic increase of usage in diverse application sectors. Naturally, the aspect of location privacy is becoming crucial, most notably in security or military applications. In this paper, we present a novel passive attack called RECORD, which is solely based on the reception of messages to LEO satellite users on the ground, threatening their location privacy. In particular, we show that by observing only the downlink of 'wandering' communication satellites over wide beams can be exploited at scale from passive attackers situated on Earth to estimate the region in which users are located. We build our own distributed satellite reception platform to implement the RECORD attack. We analyze the accuracy and limiting factors of this new attack using real-world measurements from our own Iridium satellite communication. Our experimental results reveal that by observing only 2.3 hours of traffic, it is possible to narrow down the position of an Iridium user to an area below 11 km of radius (compared to the satellite beam size of 4700 km diameter). We conduct additional extensive simulative evaluations, which suggest that it is feasible to narrow down the unknown location of a user even further, for instance, to below 4 km radius when the observation period is increased to more than 16 hours. We finally discuss the transferability of RECORD to different LEO constellations and highlight possible countermeasures.

1 Introduction

Low Earth orbit satellite constellations such as Starlink, Kuiper and Oneweb are gaining momentum in the market of Internet access providers, promising worldwide, fast, and cheap Internet. This is not a new phenomenon, the Iridium constellation has been providing global telephone and data services to millions of users for 25 years.

In certain application scenarios and for some users of LEO satellite communication, location privacy is of utmost importance for operational security, such as for instance in the military domain. In the current Ukraine conflict, the Starlink constellation plays a crucial role for Internet access, even in critical infrastructure. Obviously, there is a high interest to not reveal even an approximate location of the Starlink receivers on the ground as they may be targeted by hostile physical means when discovered. Similar thoughts apply to activists, dissidents and other actors in areas without reliable ground infrastructure as illustrated in a case in Syria in 2012 [8].

Hence, in this paper, we investigate to what extent location privacy is threatened in LEO satellite communications. At first, one may conjecture that an attacker who wants to find the location of a satellite receiver would have an impossible task if the only thing they know is that the receiver is located in a satellite beam. Despite being only in an orbit between 200 and 2000 km, LEO satellite beams can be quite expansive and easily cover areas of the size of a big country such as Ukraine (an area of $603,700\ \text{km}^2$) sometimes even a whole continent such as Europe (an area of $10,523,000\ \text{km}^2$). In addition, classical wireless localization techniques such as multilateration with distributed ground receivers are not applicable at scale to satellite users as the uplink signals emitted by the terminals are typically oriented towards the sky, and can only be received at most a few kilometers from the users.

However, as we show in this paper this is not the end of the story. We present a new attack called RECORD (RECeption-Only Region Determination), which based on recording the *downlink* communication from a satellite reduces the *region* in which a targeted satellite user is located to an extent that is several orders of magnitude below the beam size of the satellites. In fact, equipped with the knowledge of this region, an attacker can subsequently perform an accurate positioning of a satellite user employing standard localization methods such as multilateration of messages being *sent* by the user. Hence, the RECORD attack can be seen as an enabling threat for a complete loss of location privacy. Crucially, even if the targeted satellite user never sends anything but solely receives (possibly unwanted) traffic, the RECORD attack results in a considerable loss of location privacy as we will demonstrate.

The key idea of the RECORD attack is to estimate the

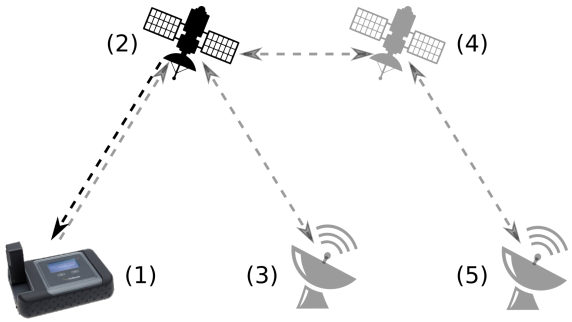

Figure 1: Satellite system schematic: A terrestrial user terminal (1) communicates with a satellite (2). The satellite either has a bent-pipe structure and forwards the signals directly to a ground station (3) or it can process the data and route messages to further satellites (4), which are sending the signals to their terrestrial target, a ground station or user terminal (5).

location of a satellite user based on the reception transition events of the different satellite beams as the satellites move towards and away from the user. We investigate the feasibility of this attack on our own Iridium communication and perform extensive additional simulations. Our experimental results reveal that by observing 2.3 hours of traffic, it is possible to narrow down the position of an Iridium user to a region with a radius below 11 km (compared to the satellite beam size of 4700 km diameter). Our simulations show that the region can be narrowed down further over time, for instance to below 5 km when the observation period is increased to 16 hours.

Note that the attack does not require access to the payload of the communication and thus works even on encrypted communication. This is in contrast to recent work that detected ships' locations in the unencrypted payload of LEO satellites [22]. Our attack is agnostic and works on all users communicating with a typical LEO system — as our experimental and simulative evaluation shows it depends mainly on the observation duration invested by the attacker.

Contributions This paper describes a novel attack to calculate the location region of a stationary terrestrial satellite user. It is based exclusively on observations of downlink receptions and the predictability of the footprints of a communication satellite system. We implement the RECORD attack on a purpose-built distributed satellite reception platform and conduct a measurement campaign using our own real-world data. To fully understand the effect of different parameters of the attack, we further provide a comprehensive simulative evaluation again based on real-world measurements. We observe that the attack is highly effective if sufficient observation time of the downlink satellite communication is invested; and that it can be boosted by an attacker with access to the packet contents in order to gain more knowledge that enables to restrict the area of the targets location even further.

Outline The paper is organised as follows: Section 2 provides the necessary background on the satellite system model and the properties to understand the RECORD attack, which is then described in detail in Section 3. In Section 4, we describe and measure our real-world implementation of the attack including our antenna beam model. With a simulative evaluation in Section 5 we provide further insights. To evaluate the potential location privacy leakage, Section 6 analyses the impact and limitations of the RECORD attack, potential countermeasures and ethical implications, before Section 7 discusses the related work. Finally, Section 8 concludes.

2 Background

2.1 Satellite System Model

In this work, we focus on LEO satellite communication systems with *packet-based communication*. A generic satellite communication system is pictured in Figure 1, where one terrestrial user device (1) is communicating directly with a satellite (2). This satellite is typically of a simple bent-pipe structure and directly forwards the signals from the user device to a ground station (3). But it is also possible for the satellite to process the messages and/or send the messages to other satellites (4) which forward them further (5). Both of these common satellite communication setups are vulnerable to our attack scheme. However, most of the actors and connections in the Figure 1 are greyed out, since they are not directly included in the attack, which will be described in Section 3. Only the target user device (1), the directly connected satellite (2) and the downlink from satellite to target device are required in the remainder of the paper.

One special property of LEO satellites is their high relative angular velocity while orbiting Earth. This causes them to quickly 'wander' across the sky, when seen from a terrestrial observer. As we are working with communication satellites, the receivable area of a satellite is thus also moving, as visualized in Figure 2. First, the satellite is moving over time from left to right. The antenna beams (1) are directed from the satellite towards the Earth and create a footprint (2) on the Earth's surface. Only receivers inside this moving footprint are able to receive signals from this satellite. This reliable and predictable property is crucial for the following work.

It is common that a communication satellite has multiple antennas on board, each of which create a so-called spot beam. This has several advantages: the satellite can focus and increase the signal strength in a certain area and also re-use frequencies across neighbouring beams. This approach is also taken by the satellite systems considered in this work, illustrated in Figure 3. Without loss of generality, the satellites pictured in all figures are shown with one major beam and no separate spot beams. This does not change the concept of the introduced attack but simplifies the explanations and improves the clarity of the graphics.

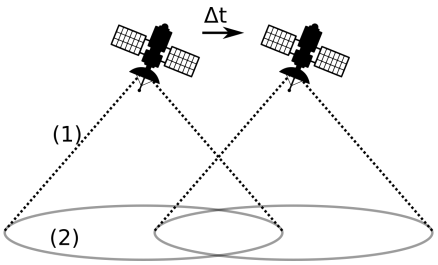

Figure 2: As a LEO satellite moves across the sky, antenna beams (1) and footprints (2) move across the Earth surface.

By design, a terrestrial user terminal is always covered by at least one spot beam during ongoing communication. The messages that are sent on the downlink from the satellite to the terrestrial user terminal are receivable in the whole beam, due to the broadcast nature of such a beam antenna. This is the second fundamental property that we exploit in this work.

2.2 Location Privacy Metric

In order to quantify the impact of our attack on the location privacy of terrestrial satellite users, we require a suitable metric. Wagner and Eckhoff [30] analyzed more than 80 different privacy metrics from the literature for different application fields. They describe different measures to classify adversary capabilities, usable data sources, and output measures.

Based on their work, we choose the size of the *uncertainty region* as a our natural target metric. Defined as the area where the transmitter must be located, it is an intuitive approach to understand the basic location privacy leakage. Throughout the paper we call it the region of interest (*RoI*). To calculate this region, Lamberts equal area map projection is used, as described in the Appendix 9.1. Obviously, the lower the *RoI*, the more accurately the position of the transmitter can be retrieved, and the bigger the privacy leakage of the user.

2.3 Communication Properties

As we are exploiting exclusively the received downlink communication, we define the properties and requirements regarding the reception of such communication.

First, we require one or more hardware receivers to observe the frequency band(s) of the downlink. To not miss any communication, either the whole frequency band must be observed or sufficient knowledge of the underlying communications protocol must be available to ensure a correct and complete recording. For labeling the observations reliably, a synchronized clock and the position of the observer is required. The observer may move during the observation, as long as the location is precisely known at any given time of message reception. In the extreme, this could even be a large distributed sensor network such as SatNOGS [18].

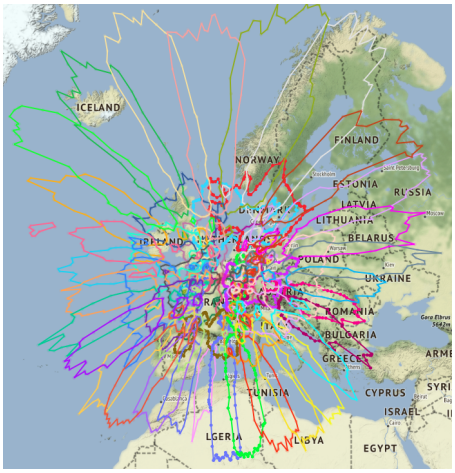

Figure 3: Footprint of a single randomly chosen Iridium satellite, comprising 48 antennas and their respective spot beams.

As we deal with packet-based communication, each packet is assumed to have a property to identify its intended receiver. This can be a device/target address in the packet header, a dedicated frequency channel, or an explicit time slot. It is crucial to note that it is not necessary to understand the payload of the packet, which is often encrypted as in the case of Internet traffic. The question how an adversary selects a specific target or victim is out of the scope of our work and we do not touch other user traffic in our measurements for reasons of ethics and privacy. However, in real-world systems it does not pose a hard problem, as there are typically less than a dozen satellite users in a typical spot beam. Traffic identifiers such as device/IP addresses, statistic traffic analysis or known communication patterns can be obtained through other means as shown in the literature even for encrypted traffic.

2.4 The Iridium Constellation

In this work, we use the Iridium satellite communication system to perform measurements and conduct a real-world implementation of RECORD. The Iridium system consists of 66 LEO satellites covering the globe at an altitude of 780 km. Iridium is the longest-running LEO constellation used by 1.9 million users globally, across military, government and corporate domains as well as by private individuals [10].

The Iridium satellite orbits are in north-south orientation with an orbital period of 100 minutes. In each revolution a satellite performs a uniform rotation, precisely aligned with its orbit period and trajectory. This rotation ensures the consistent alignment of the satellite's downlink antennas with the Earth's surface. A single satellite creates 48 spot beams and covers the size of Europe, as illustrated in Figure 3. A footprint of a single spot beam typically measures 400 km or more in diameter in its smallest dimension. All spot beams combined create a satellite footprint with a diameter of 4700 km.

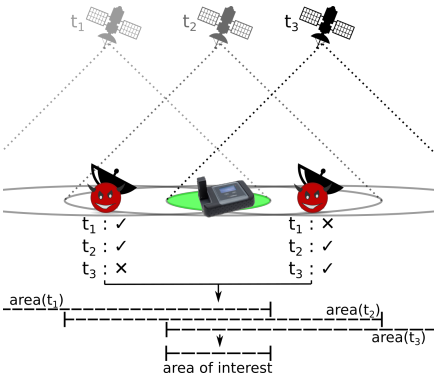

Figure 4: Schematic of the attack. Two observers receive downlink messages over time and combine their observations to estimate the location area of the terminal.

The spot beams alignment is fixed on the satellite. Over the span of a year we observed Iridium satellites and their beam alignments without detecting deviations in the resulting footprint patterns. This makes the Iridium system predictable and susceptible to the proposed attack.

3 Principle of the RECORD Attack

RECORD's goal is to gather information about the position of a terrestrial target device that communicates via a generalized LEO satellite system. Intuitively, the adversary records the freely available downlink communication (inside the spot beam) towards a victim's satellite device and extracts knowledge from the received messages to calculate the *RoI* where the target device is located. Since the attacker is only receiving signals, the attack is entirely passive and does not require any interaction with the target device or the communication satellite. The reason to use the downlink of the satellite communication is that the satellite antenna spreads its signal over the full footprint of the spot beam (see Section 2.1). This enables the attacker to receive messages intended for a specific device, over a large distance of hundreds of kilometers.

Figure 4 visualizes the simplified attack principle. The adversary controls two observers, which are recording the downlink traffic of the target device. At time t_1, the satellite is at the leftmost position and only the left observer can receive. As time progresses and the satellite moves, both observers are able to receive messages at t_2. At t_3 only the right observer can do so. These observed reception events are shown at the bottom for each observer, containing the recording time and location. In the next step, the attacker calculates the area that is covered by the antenna footprint for each observation time. Finally, the intersected area must contain the target.

The attack itself consists of three different phases, a modeling phase, a collection phase and finally the estimation phase.

3.1 Modeling Phase

In the *modeling phase*, the adversary employs one or multiple observers to gather data about the satellite antenna patterns, with the objective of constructing a so-called *satellite model* to enable precise antenna footprint calculations. This is achieved through the creation of a set of empirical antenna models using beam-specific status messages, as demonstrated in Sec. 4.2. By calculating satellite positions relative to the receiver, we derive an antenna model, describing the directional characteristics, i.e. the opening angles, for each satellite antenna. This set of antenna models is combined to the satellite model, modelling the full satellite footprint. Importantly, this phase is a one-time calculation for each satellite constellation.

3.2 Collection Phase

In the *collection phase* the attacker eavesdrops on the downlink communication to the target device. Therefore, it is necessary to identify the packets that belong to the user communication reliably over the whole observation period. The recorded messages are labeled with their time of receiving and the position of the recording. One important aspect is that the modeling phase and the collection phase are independent of each other. They can be conducted in an arbitrary order or even overlapping, using the same measurements.

3.3 Estimation Phase

The goal of the *estimation phase* phase is to combine the antenna model with the recorded messages to get an area of interest in which the target is located. To extract information about the target's position, the recorded messages are transformed into *observation events*, which provide knowledge of the antenna beam used by the target at the observation time and its respective footprint. By intersecting all antenna footprints of the observation period, we then decrease the uncertainty about the target's position.

We have six observation events: The *general reception* (e_{gr}) and *non-reception during communication* event (e_{ndc}) are two fundamental events that appear when the traffic of the target device is received or not. *Reception after handover* (e_{rh}) and *non-reception after handover* events (e_{nh}) occur when the attacker is able to detect beam-handover messages in the observed target traffic. *Sudden reception* (e_{sr}) and *sudden non-reception* events (e_{sn}) are extracted when an observer unexpectedly finds or loses the target traffic, which are likely to be caused by beam switches of the observer or undetected beam switches of the target device.

For each individual event the attacker calculates the *RoI* ($region(e)$) by the rules described in Appendix 9.3. In case of the e_{ndc} event, a negative *RoI* ($not\_region(e)$) is calculated. The resulting region ($region(E)$) is the intersection of all

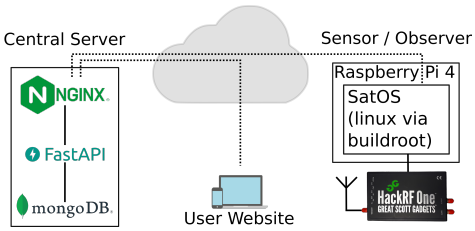

Figure 5: Architecture overview of the observer system.

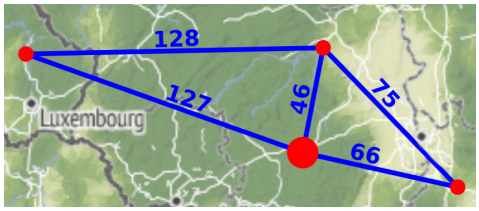

Figure 6: Geographical distribution of the three attackers (small dots) and the Iridium target device.

single regions from all observation events:

$$region(E) = \bigcap_{e \in \{E \setminus e_{ndc}\}} region(e) - \bigcup_{e_{ndc}} not\_region(e_{ndc})$$

For each observed event, the attacker calculates the positions of all satellites using public databases such as CelesTrak [14] or space-track [13]. The satellite positions are combined with the antenna model to calculate the footprint of each satellite antenna. Since the observation events are independent, we can combine multiple separate observation periods.

With the RECORD attack it is possible to gain knowledge from the recorded messages over a large distance and identify an area where the target device has to be located in. This may already provide the desired accuracy for the adversary (see Section 5.2). In case it does not, knowledge of this small area should be sufficient to launch more expensive localized follow-up attacks, such as traditional radio-frequency scanning or multilateration of the uplink communication which have much lower range but better resolution. We illustrate such an end-to-end attack combining RECORD with known methods in the next section.

4 Real-World Attack Implementation

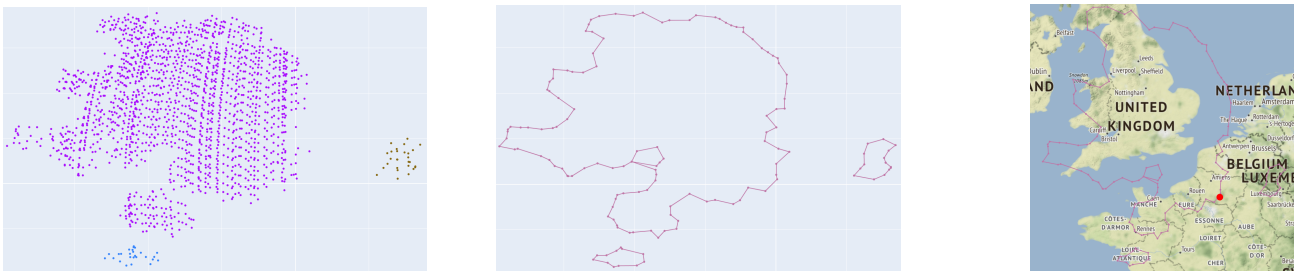
To demonstrate that the RECORD attack is practical and works end-to-end in the real world, we collect traffic using our purpose-built Iridium sniffer and a distributed receiver network. We exclusively target our own Iridium device, which we subsequently attempt to locate. In the following, we explain our experimental setup and discuss the three attack phases.

4.1 Experimental Setup

In Figure 5 an overview of the observer system is given. A central server runs NginX, FastAPI and a monolithic database. The server provides a website to control and manage the system, enabling the creation of new observation tasks.

The heart of each observer is a Raspberry Pi 4 that is connected to a HackRF One with an Iridium antenna and a GPS- & LTE-shield. GPS reception is required to know the precise position of the sensor and to obtain a reliable time-synchronization. The LTE connectivity is an alternative to the WiFi and Ethernet connections of the Raspberry Pi to make the sensor easy to deploy in different environments. The electronics, besides the Iridium antenna and a power connection, are protected by a weather resistant box.

The Raspberry Pi is running a minimal Linux system created with buildroot, which we named 'Satellite data Acquisition Tool Operating System' (SatOS). Inside SatOS, a service automatically sends status reports to the central server and pulls for new tasks. Currently the major task is the collection of Iridium packets via gr-iridium. However, it is planned to enable the connection of different antennas to the sensor, enabling also the recording of other satellite constellations.



The reason we decided not to use the already available SatNOGS system [18] for our data collection is the different scope and capabilities. SatNOGS mainly targets open radio amateur frequency bands and the tracking/receiving of single satellites. For this work we required a tool to gather data from the complete satellite communication network, that may contain sensitive information.

For our measurements in the following, we used three observers distributed 127 km to the West, 46 km to the North and 66 km to the East of our research institution, represented by the smaller red dots in Figure 6. The large red dot in the center of the map is the location of the Iridium GO! device.

4.2 Phase 1: Modeling the Antenna Beam

For calculating the footprints of the satellite beams a model of each spot beam antenna is required. As previously mentioned, we conduct this modeling phase by collecting Iridium status messages, the so-called Iridium Ring Alerts. They are sent periodically every five seconds. Each message contains the number of the satellite and the beam antenna that was sending the message. By knowing the positions of the satellite and the observer at the receiving time, it is possible to calculate the sending angle of the satellite antenna. Over time a model emerges, revealing the opening angles of all satellite antennas. More details are in Appendix 9.2.

In the first phase of the RECORD attack, we used the observers to collect data of the Iridium system for two weeks and collected 328,000 ring alert messages. For each antenna-specific model, we combined the data from all observed Iridium satellites, since we did not find significant differences between the satellites' antenna patterns.

(a) Clustered measurements. (b) Optimized borders. (c) Projection onto Earth surface.

Figure 7: Example of the modeling phase showing measurements, calculated borders, and surface projection of Iridium beam 32.

Figure 7a shows the combined measurements for beam 32 of the Iridium satellite system. Each data point represents a beam 32 ring alert message, the position of the point represents the sending angle. Thereby the points represent the opening angles of the beam 32 antenna. We kept the full opening angles of every beam, even if they overlapped with neighbouring beams. In this way, the maximum receivable footprint of each antenna beam was extracted. The different point colors represent the different lobes. For many antennas we detected sidelobes, we kept them to obtain the maximum possible antenna footprint. Using the density-based spatial clustering for applications with noise (DB-SCAN) algorithm of the scikit-learn library, the measurements of each antenna were divided into clusters for each lobe of the antenna. We further processed each cluster to keep only the outer data points to represent the footprint. In this way, an efficient and lightweight model for calculating the maximum antenna footprint was created. Figure 7b shows the optimized antenna model of Iridium beam 32.

With a given satellite position, the resulting footprint of the optimized antenna model can be projected onto the Earth surface, covering the complete area where signals of the specific antenna can be received. For our example of beam 32 in Figure 7, we assumed a satellite position in the North of Paris with a North-directed orientation. This results in a complete empirical footprint, covering the whole of England and much of the surrounding area, as shown in Figure 7c. The combination of all 48 antenna models, each for one of the 48 spot beams of an iridium satellite, forms the satellite model. The result is visible in Figure 3, showing all beams superpositioned across the surface of Europe.

4.3 Phase 2: Recording the Victim Traffic

For phase 2, we placed our Iridium GO! device on top of a university building, with free view towards the horizon, as shown in Figure 18. The battery-powered device provides WiFi connectivity and with smartphone apps supplied by the manufacturer, it can be configured to provide an Internet connection via the Iridium satellite network. The device's legacy bandwidth of 2.4 kbps is too slow to comfortably browse modern websites but it still enables the sending and receiving of emails and text messages anywhere on the globe. For the RECORD attack, the bandwidth is irrelevant as we target the fact that there is any communication in the first place, rather than how much communication can be collected. Using this connection, we manually accessed several websites and created the required traffic for our attack. It is important to note that the type of the website and the precise traffic pattern are not relevant as long as any downlink traffic is generated.

Over the course of nine sessions spanning over eight days, we gathered a total of 5 hours of traffic data. Some measurement sessions were done on one day with 1-hour between sessions, while others featured a 5-day pause between measurements. This does not have a significant effect on the combination of the measurements, as detailed in section 5.4. The three observers in the West, North and East recorded the downlink and further processed the recordings locally to compile a list of received Iridium messages. For recording and demodulation, we used gr-iridium [4] and for parsing the packets the iridium-toolkit [5].

To first identify the downlink messages of a target device, one can exploit the connection setup, where a static TMSI is transmitted unencrypted in the downlink. The authentication in Iridium is a restricted version of the GSM authentication process. One of the restrictions is a static TMSI, which allows an attacker to identify devices during connection setup. To get the static TMSI of the target device the attacker can eavesdrop on traffic over a longer time and search for the targets name in unencrypted email or voice transmissions, which are standard in Iridium. Once an interesting transmission is found, one can backtrack the connection to the connection setup, where the TMSI was transmitted. We avoided this for ethical reasons by also recording the uplink and using the uplink channel frequency as a hint, since the downlink channel is always a neighbour of the uplink.

Once the target connection is found, it is easy to follow: A device that enters a spot beam is assigned a dedicated frequency channel. The Iridium network uses clear-text handover messages. Hence, when a device switches from one spot beam to another, the information which frequency channel will be used in the new beam is broadcast. This made it straightfor-

ward to follow a connection and resulted in a list of messages for our (own) target device to give to the estimation algorithm in the third phase of the attack.

There are other practical possibilities for an adversary to identify the traffic of the target device as already discussed in Section 2.3. For Iridium, creating a phone connection offers an additional possibility. Alternatively, it is also realistic to brute-force the locations of all devices in the targeted spot beams, which we also avoided for ethical reasons.

4.4 Phase 3: Estimating the Target Location

(a) Single antenna footprints. (b) Union of the footprints.

Figure 8: The observer (red dot) is able to receive both antennas. For e_{gr} events, the footprints of both are united.

The list of messages of our Iridium target device is transformed into a list of events, as introduced in Section 3.3. We used all our knowledge about the Iridium protocol and the available clear-text status messages to extract as much information from the messages as possible.

With the extracted events, it is possible to calculate the *RoI* for each event. To do so, we identified the satellite antennas with the help of our antenna model, created in phase 1 of the attack. For each antenna we calculated the footprint and depending on the type of event, the footprints are combined. As an example how this process can be visualized, in Figure 8a two antennas are receivable at the observer, the red dot in the middle. The footprints of those two antennas are calculated and in Figure 8b the union of both footprints is created. This represents the *RoI* for one single e_{gr} event.

Via the combination of many events and calculating the region that is shared by all events, the *RoI* is reduced further and further over time. Intuitively, if some seconds later the footprints are shifted several dozen kilometers to the North, the *RoI* is reduced to the overlapping part of both events.

4.5 Results

In total, we conducted 9 independent measurements, at the same locations, with a total uplink time of 5 hours. Table 1 shows the complete data of all 9 measurements. The measurements are ordered by their uplink duration. We also calculated the aggregate of all measurements. The four observations marked with $*$ added valuable information to the combined result, in the form of one edge of the final *RoI*.

measurement	duration	area estimation	event count			
			e_{gr}	e_{ndc}	e_{sr}+e_{sn}	e_{rh}+e_{nh}
1	288 sec	102534 km^2	665	0	0	9
2*	683 sec	81437 km^2	1269	51	5	4
3	1028 sec	81337 km^2	1404	19	1	13
4*	1463 sec	17118 km^2	3371	211	4	23
5	1715 sec	88292 km^2	2463	12	2	13
6*	2085 sec	3240 km^2	5337	93	7	27
7	2318 sec	47704 km^2	4422	14	1	33
8*	4044 sec	8654 km^2	8050	123	21	68
9	4237 sec	43152 km^2	7596	125	17	54
Effective Aggregate	8275 sec	383 km^2				

Table 1: Measurements ordered by the uplink time with their area estimations and their observed events. Event notations are described in Section 9.3.

In the end, these measurements 2, 4, 6 and 8, resulted in a combined length of roughly 2.3 hours, creating a target region of 383 km^2, which is equivalent to a circle with the radius of 11 km. This successfully illustrates the principle of this attack. Starting from an initial guess with more than 100,000 km^2, this is an improvement by a factor of 260 in a relatively short time. Reducing the estimation to an area of this size enables complementary attacks with a more limited range but higher precision, such as triangulation of the uplink signal, depending on the local conditions (see Section 4.6).

The relationship between observation time and size of the estimated area in Table 1 is blurred by the high variance of the estimation. This becomes especially visible when comparing measurements 5, 6, and 7: Measurement 5 with roughly 29 minutes has an area of 88,000 km^2, measurement 6 with 35 minutes only 3,240 km^2 — a fraction of the previous estimation. The following measurement 7 achieves an RoI of 48,000 km^2 with 39 minutes. This illustrates that the recording duration is not the most dominant factor influencing the *RoI*.

Instead, the number of events collected during each measurement is relevant. In particular, the high fluctuation among *ndc* events is striking. Consequently, we calculate the time per e_{ndc} rate by dividing the measurement duration by e_{ndc}, which reveals an interesting property that is illustrated in Table 6.

From this, we note two interesting observations: the measurements that successfully contribute to the combined evaluation are all in the upper half of the table. They contribute by having some of the borders of their individual *RoI* closer to the true position of the target device than all other observations. Thereby, the combination of only these four measurements recreates the result of the combination of all measurements. All four also have a good time-to-area ratio when compared with the other measurements. Therefore, this ratio is a promising property for future applications, in order to provide a solid basis for reliably performing setups. Finally, the positioning of the observers can play an important role in generating useful events. We analyse this in Section 5.3.

Distance (km)	Noise Level (dB)	Signal Level (dBm)
0.226	-109.43	-17.27
2.243	-109.26	-21.01
2.692	-109.89	-24.2
5.184	-109.84	-26.08
31.056	-109.63	-39.92

Table 2: Median signal strength of the Iridium GO! uplink recordings at known distances.

4.6 The Last Mile

4.6.1 Basic Signal Strength Modelling

The RECORD attack can be used to passively determine a small *RoI* in a first step over a large, continent-sized area. In a second step, more expensive and locally-restricted techniques from the literature can be applied within the *RoI* to localize the target more precisely — if it is transmitting uplink data to the satellite system. One possibility to localize a device is to use true-range multilateration techniques based on the received signal strength (RSS) as introduced by Bulusu et al. [2]. To assess the effective range of traditional RSS sensing and range finding techniques in ground-to-LEO communication, we conducted several signal strength measurements targeting our Iridium GO!. The line-of-sight range between the Iridium GO! and our receiver varied between 200 m and 31 km. For recording and processing the signals the *gr-iridium* and *iridium-toolkit* libraries were used. During each measurement we exchanged several emails via the Iridium email portal to generate the necessary traffic. The source identity of the captured traffic could be verified by observing the plaintext login credentials of the used Iridium email account in our recordings. In Table 2, the observed background noise and the signal level during each measurement campaign are given. Each measurement lasted roughly 15 minutes.

The measurements show that Iridium GO! signals can be received at a distance of more than 30 km. The signal levels in Table 2 suggest that in theory also larger distances could be received. However, in reality, larger distances on the ground with line of sight are rare. Therefore, this is a reasonable upper bound, when considering the distance where a Iridium GO! can be precisely located by uplink measurements.

4.6.2 Receiver Localization

To perform uplink measurements to localize an unknown receiver position, we consider the hilly and wooded landscape surrounding our experimental setting. We conduct several measurements at elevated locations with good view of the surrounding area. We start with four measurements well distributed near the boundaries of the *RoI* created previously. Only at measurement point two, we successfully received uplink traffic of our target device, indicating that it is in range. Consequently, we conducted a fifth measurement close to that location. All measurements are listed in Table 3. Using Friis' transmission formula and the measurements from Table 2 as a reference model, we calculate an assumed distance between the target and the measurement locations.

Location	Noise Level (dB)	Signal Level (dBm)	Distance* (km)
1	-109.17	—	—
2	-111.07	-37.37	4.180
3	-110.91	—	—
4	-109.63	—	—
5	-110.46	-34.08	2.862

Table 3: Median signal strength of the Iridium GO! uplink recordings at unknown distances in last mile attack.

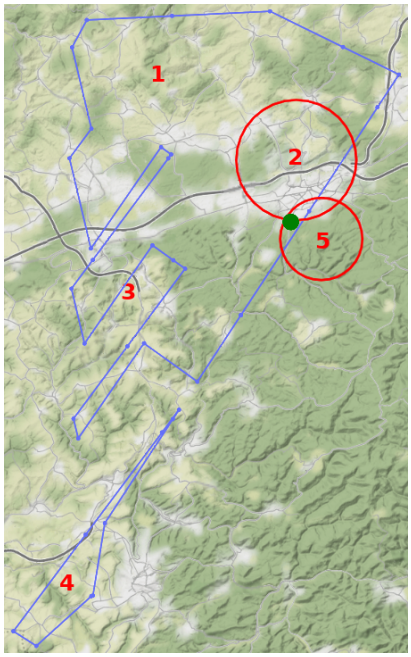


Figure 9: Last mile example: The calculated *RoI* (blue polygon), with the positions of five uplink measurements (red numbers) and the target device (green dot) close to the estimated location.

In Figure 9 the *RoI* is shown in blue, while the five signal strength measurement locations are numbered in red. The locations two and five are surrounded by circles that indicate the modelled distance of the Iridium GO! sender. Only the Western intersection of the two distance circles is inside the *RoI* — and is thereby our final position estimation. The real location of the device is shown as a green dot, which is 457 meters away from the estimation. Further measurements from additional positions can be taken to reduce this estimate even more.

A much simpler but less precise alternative to local uplink measurements is to apply a point estimator to the already calculated *RoI*. Calculating the centroid of the region is a straightforward baseline approach for this. The precision of

this estimator naturally depends on the size of the *RoI*: our simulations indicate that the centroid estimator has an average distance error to the target location of 30% of a circle's radius, assuming a circle with the area equivalent to the *RoI*.

Using the aggregate *RoI* of 383 km^2 from the measurements, this indicates a circle radius of 11 km. In contrast, the centroid has a distance of 8 km to the device location.

5 Simulative Evaluation

Besides the real-world measurement campaign, which illustrated the feasibility of the RECORD attack in principle, we also conducted comprehensive simulations in order to gauge the parameters of the different attack dimensions. This helps evaluating more precisely which characteristics of the system leak the most location privacy information. We focus in particular on the duration of the measurement period, the knowledge of the attackers about the system, and the number of observation devices.

The code of the simulation is published on GitHub: https://github.com/ErJedermann/RECORD.git.

5.1 Simulation Setup

For the simulations we generate artificial observations to evaluate the performance of different attack scenarios. We implemented the simulation in Python with intense usage of numpy vectorization. The simulation is designed to run at least 100 iterations with a fixed parameter set, introduced in this section. In the first part of each iteration, the artificial observations are generated. The second part provides them to the estimation algorithm and evaluates the computed *RoI*. Depending on the selected parameters, the computation time for one iteration matches the simulated observation duration, thus simulating one hour can also take up to one hour.

For generating the artificial observations, we used real satellite position data from the non-profit organisation Celestrak to ensure realistic behaviour and placement of the satellites. The starting time of the simulations was randomly chosen in a 24h interval around the creation time of the satellite data, to ensure their validity. The starting location of each simulation was randomly chosen up to a latitude of 65 degree north/south. To avoid unrealistic behavior, we decided to limit the placement of scenarios, since the simulated Iridium constellation turns off outer spot beams as the satellites approach the poles to reduce overlaps. The attacker's observers were equally distributed on a Fibonacci grid[27], placed around the starting location with a distance d_{obs} between the observers. The target device was placed randomly around the starting location, up to a distance of d_{obs}. More details about the observer placement are available in appendix 9.5. In Section 5.2, we used $d_{obs} = 100$ km, inspired by the closest neighbour distances in the real-world setup, shown in Figure 6. After this, in Section 5.3 the distance was varied.

Attacker	Observers	Beam Model	Event Types
1	1	noisy	weak
2	3	noisy	weak
3	3	strong	weak
4	3	strong	strong

Table 4: Properties of the simulated attackers.

We used four attacker models with different capabilities to evaluate the impact of distinct properties on RECORD. Available capabilities may vary between LEO constellations and based on the attacker's resources. In the following, we discuss three properties, a summary is provided in Table 4.

Observers: Increasing the number of observers enables the attacker to gain information about the signal reception at multiple locations at the same time. In the evaluation in Section 5.2, it will vary between 1 and 3 receivers. In Section 5.3, we also simulated up to 12 observers.

Beam Model: The precision of the beam model used for the evaluation. As a strong beam model we used the same model during the evaluation as for the generation. To weaken the beam model, we added white noise to it that increased the footprint, with a mean of 6.7 km. This is the distance an Iridium footprint moves in one second.

Event Types: The usable event types represent the accessibility of the satellite system to internal information. Weak event types are observations from the outside — a message is received or not. Strong event types allow the usage of internal information (e.g., handover messages).

Knowing the locations of the target, of the observers, and the start time of the simulation, we calculated the positions of all satellites of the Iridium constellation. Every second, the closest satellite and its best aligned antenna towards the target device were determined. To achieve realistic behaviour, we used the satellite antenna beam model from the real-world attack in Section 4.1. The selected antenna was the communication endpoint of the target device. For each observer we checked if it is located in the same footprint as the target device. Depending on the result a message receiving event for the receiver was created. All events discussed in Section 9.3 were generated at this point.

The simulation provides the generated event lists and observer positions to the attack algorithm to determine the final smallest *RoI*. To evaluate the quality of the *RoI* calculation, the resulting area of the returned estimation is used.

5.2 Observation Duration

We first vary the observation duration between 1 minute and 4 hours, shown in Figure 10 for the four different attacker types.

To obtain a better feeling for the areas in Figure 10 we

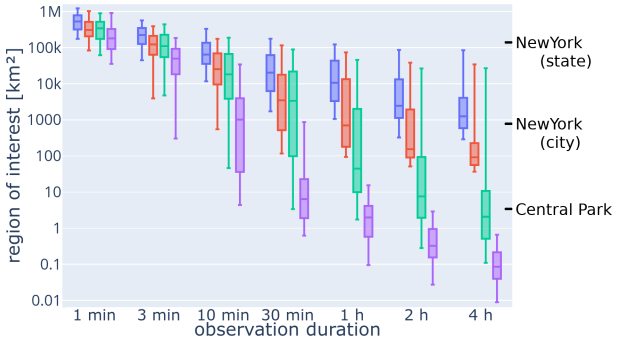

Figure 10: Simulated area estimations of different attackers (attacker 1 - 4: blue, red, green, purple) over different observation periods from 1 minute to 4 hours. Log scale.

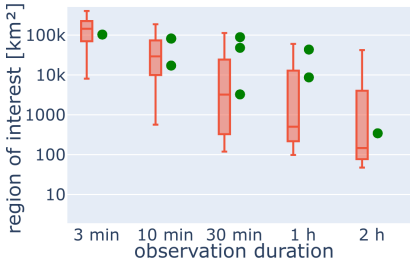

Figure 11: Attacker 2 vs. real world (green dots).

added the areas New York State (141300 km^2), New York City (784 km^2) and the Central Park in New York (3.41 km^2) as reference points.

According to the expectations, a longer observation time results in a better location estimation of the target. All attacker variants start with areas between 100,000 and 1 million km^2 at one minute. It is clearly visible that more advanced attacker types are reducing faster their area estimations than more limited attackers. While attacker 1 reaches 10,000 km^2 after 1 hour of observation, attacker 4 is already at 2 km^2.

At four hours, attacker 4 has reached a median area of 0.086 km^2, which corresponds to a circle with a radius of 166 meters. A more realistic scenario in most cases is attacker 2 with limited information but a few distributed observers. After 1 hour, this limited attacker attains an area of 700 km^2, which reduces to 92 km^2 after four hours.

To compare the simulations with the performed real-world attack, Figure 11 shows the simulations of attacker 2 next to the *RoI* of each measurement from Table 1. The results of attacker 2 are best-fitting to our measured results and also its properties from Table 4 are matching our expectations. Thus, we can expect that improvements on our real-world results are realistic with further measurements.

To analyze the improvements for longer observation periods of up to 16 hours, we simulated a realistic attacker for an increased observation duration (Figure 12). The median size of the *RoI* decreased down to 48 km^2, which corresponds to a

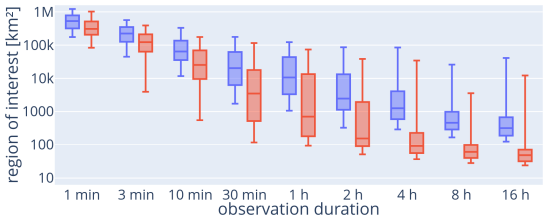

Figure 12: Long-term simulation of attacker 1 and 2.

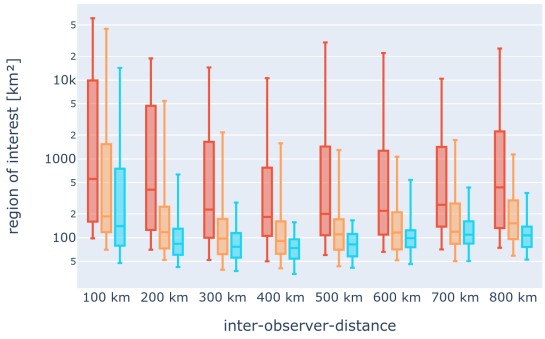

Figure 13: Observer number and spacing. Attacker type 2 with 3, 6 and 12 observers, respectively (red, yellow, blue).

circle with a radius of 3.9 km.

We note that the results of attacker 4 have to be interpreted with care. We expect them to be the upper bound of the RECORD attack. As already mentioned, the antenna beam model used in the evaluation for this attacker was a perfect representation of the ground truth, used for creating the measurement events. To approach this performance in reality is a challenge. This is discussed further in Section 6.2.

5.3 Observer Placement

Placement and number of the utilized observers are the main factors that the attacker can influence. To evaluate the impact of these two parameters, we conducted additional simulations.

First, we examine the observer placement by varying the space between them from 100 to 800 km while fixing the observation duration to 1h. Additionally, we simulated attackers with 3 (red), 6 (yellow) and 12 (light blue) observers, respectively. The evaluation results are available in Figure 13.

All attacker variants, independent of the number of observers, are most effective with a spacing of around 400 km between observers. This is roughly the size of the diameter of a single spot beam in the Iridium constellation (see Section 2.4). This finding supports our assumption that the optimal observer placement depends on the spot beam size of the satellite system.

By increasing the number of receiving observers from 3 over 6 to 12, the median *RoI* reduces from 183 to 91 and 74 km^2, for the optimal 400 km spacing setup. Notably, the variance in size of the resulting *RoI* is much reduced. Besides

the increased performance, it is obvious that the covered area of the attacker scales with the number of observers. For a spacing of 400 km, 3 observers cover 418 and 12 observers cover 836 km^2. However, we can also see that even large inter-observer distances of 800 km remain effective, with 107 km^2 for 12 observers, making RECORD a viable attack across countries and continents.

5.4 Robustness of Fragmented Observations

To support our statement from Section 4.3 that multiple, separate, observations can be combined over time in a robust and stable fashion, we conduct simulations with fragmented observations. We simulate an attacker type 2 with 6 observers and 400 km spacing between them. The attacker recorded traffic for 120 observation intervals of each 30 seconds. Between two intervals, a break of 10 minutes was taken to ensure their independence. The 120 independent intervals were appended to create one combined observation with a total duration of 1 hour, which was used to perform the *RoI* estimation.

The resulting *RoI*s of the fragmented observations had a size of 42, 64, 97, 162 and 557 km^2 (5th, 25th 50th, 75th and 95th percentile). The comparable *RoI* of a continuous 1 hour observation are has a size of 41, 62, 91, 161 and 1579 km^2. Both results are close together and are in the normal variance for this setup. So no significant difference in the resulting *RoI* between those two scenarios was found. This supports the statement that multiple observations can be combined without causing significant drawbacks or advantages.

5.5 Moving Targets

We now extend RECORD to simulations with a moving target. We simulate attackers of type 2 with 6 observers, 400 km observer spacing and 1 hour observation duration. The random way point model by Johnson & Maltz [12] is used for the victim movement. The movement area is placed inside the area covered by the observers, similar to the target location described in Section 5.1. The victim moves in a straight line from a random start to a random destination inside this movement area with a velocity between 3.6 km/h and 50 km/h, somewhere between a walking human and a car driving in a city. At the destination, the victim pauses randomly up to 3 minutes before moving to the next random location.

The diameter of this movement area is our target variable, which is varied between 1 and 8 km. Crucially, we consider an estimation *invalid* if a single of the random way points is outside the final *RoI*.

The results of this simulation are shown in Figure 14. The four histograms reflect the four simulated movement area diameters of 1, 2, 4, and 8 km. Immediately, there is a visible difference in validity: for diameters of 1 and 2 km, there are no invalid estimations found. As the movement diameter of

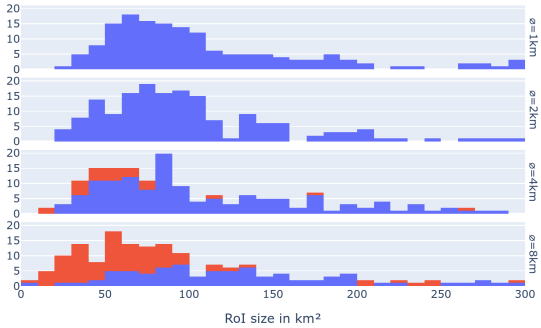

Figure 14: Histograms of valid (blue) and invalid (red) *RoI* estimations at different victim movement diameters.

the victim increases to 4 and 8 km, invalid estimations happen 13% and 49% of the time, respectively, meaning that the victim has left the *RoI* at least partially during observation.

Naturally, as the estimated *RoI* gets smaller, the rate of invalid estimations increases. For 8 km, at a *RoI* size around 50 km^2, 75% of the estimations are invalid, while at 100 km^2 only 30% of the estimations are. This is an expected effect since the probability for way points to move outside the *RoI* increases as the *RoI* gets closer in size to the movement area.

6 Discussion

6.1 Deployment Example

To illustrate the practicality of RECORD over large surveillance areas, we calculate the number of observers needed to cover Europe and compare it to a conventional localization approach against an actively communicating target.

A typical localization hybrid using angle of arrival and RSS [3] can localize a sender within the full reception area of a single observer. Thus, it is more efficient when compared to other approaches such as multilateration, multiangulation or pure RSS, which need additional infrastructure. Using the maximal range measured in Section 4.6, a radius of 31 km, equalling an area of 3019 km^2 per observer can be monitored. Monitoring an area of the size of Europe, 10.523 million km^2, would require 3486 observers, ignoring the fact that achieving line of sight for the whole area is unrealistic.

Using the placement strategy of Section 5.3 and a spacing of 400 km, RECORD requires only 58 observers to cover an area the size of Europe, a reduction by a factor of 60. A more aggressive approach with a spacing of 800 km has a slightly decreased performance but requires only 15 observers, a hardware reduction of factor 230.

6.2 Limitations

A fundamental assumption of RECORD is that the target device does not move too far during the observation period. The

intersection calculation always removes positions from the *RoI* that are not possible at that point in time. If the target device moves too far to an area that was removed previously, its new position will never be added again to the *RoI*. The generated observation events from the new position can reduce the area of interest to zero after some time, indicating that the device has moved, and the localization has failed.

A second challenge that remains open is the reliable identification of other events besides the 'general receiving event' in practice. In the simulation the assumption was made that all observers have a perfect view of the sky and do not drop any packets. In reality, obstacles and noise prevent a perfect reception of satellite signals. Then the challenge is to distinguish between messages that cannot be received due to such obstacles/noise or due to being outside the antenna beam. One possible approach to this challenge is to build an empirical visibility map for each sensor, thus taking into account when satellites are in non-visible areas.

6.3 Countermeasures

The assumption of a static target device shows one of the most effective countermeasures: A moving target device is much harder to detect, as already explained. This is related to the fact that a certain number of observation events is required to estimate the position. So limiting the number of usable observation events is an effective way to preserve some location privacy. This is either possible by limiting the communication time directly or by moving the device to a different location and thereby preventing the combination of observation events before and after the relocation. The frequency of relocations and the distances between the locations affect the preserved location privacy. But all this requires potentially inconvenient actions from the satellite user.

A second type of countermeasures aims at preventing the observer from identifying the traffic of the target device. Without the ability to reliable identify the target traffic, not many communication events can be extracted. This makes the location estimation much harder for an adversary. Techniques as generating artificial traffic, rolling identities or unpredictable channel hopping of multiple devices are just two possibilities to hide the real traffic of the target device. Such countermeasures have to be implemented by the operator of the satellite communication system.

6.4 Applicability to Starlink

The RECORD attack principle is also applicable to other LEO constellations, including Starlink with its millions of users. Starlink, as a highly-publicised and fairly recent operational newcomer, shares the same fundamental network characteristics that make it vulnerable to attacks on users' location privacy. As of May 2023, there were over 4,000 Starlink satellites in orbit and operational, with plans for 12,000 or even 42,000 satellites forthcoming. While not much is publicly known, some technical information about the antenna beams can be derived from official FCC documents [21, 31] and be used to model the antennas. According to the documents, the antenna coverage area should be inside the -3 dB zone which, according to the antenna beam contours is at roughly 2.2^o from the beam center. At an altitude of 550 km this means a spot beam footprint diameter of 42 km at nadir.

Attacker	Observers	Beam Model	Event Types	d_{obs}
3a	1	strong	weak	40 km
3b	3	strong	weak	40 km

Table 5: Properties of the simulated Starlink attackers.

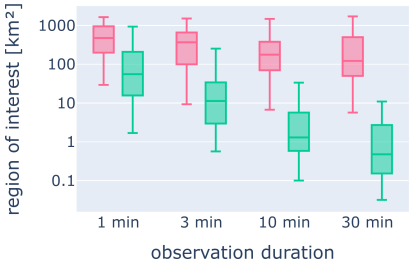

Figure 15: Simulating Starlink attackers 3a (red) and 3b.

Table 5 gives the parameters of simulated Starlink attackers. Both are analogous to attacker 3 in our Iridium setup, with a single observer for attacker 3a and three observers for attacker 3b. Due to the much smaller size of the spot beams, the distance d_{obs} was set to 40 km.

The smaller spot beam also reduces the starting size of the *RoI*: For attacker 3b in the Starlink simulation the median is 56 km^2, compared to 342k km^2 for attacker 3 in the Iridium simulation. Beyond this starting difference, the Starlink attacker 3b converges faster with 2.3% (10 minutes) and 0.85% (30 minutes) of their original starting size, compared to the Iridium attacker 3 with 5.3% (10 minutes) and 1% (30 minutes) of the starting size. This faster convergence is likely caused by the higher frequency of handovers for the Starlink constellation. Overall, the RECORD principle tends to become more accurate with more satellites and handovers but requires more receivers on the ground due to smaller beams.

6.5 Attack Impact

The impact of the RECORD attack on LEO-constellations is manifold: currently Iridium has 1.9 million users around the world and growing. Other LEO constellations such as Starlink (1 million terminals released in Q3 2022), OneWeb and Kuiper will multiply the number of satellite users globally as their ease of access and bandwidth is attractive for many user-bases, in particular in areas without sufficient, reliable or trustworthy ground infrastructure.

We believe this inherent characteristic of many satellite user

groups is what makes the attack impactful. Satellite ground-stations are used by groups of interest such as investigative journalists, activists, government employees and the military, in particular in potentially hostile areas. While it is possible to scan locally for satellite phones' radio emissions, and the satellite service provider naturally also knows the exact position, our attack enables this knowledge for many other groups. Tracking the home base of a target person thus becomes possible for anybody as long as they can place an Iridium sniffer within the reach of a satellite beam, which may easily be in a different country. As time is the main ingredient for accurate localization, privacy-conscious groups should thus strongly consider using their LEO-based communication devices for periods of time at the same position.

This is consistent with advice given by the Committee for Protecting Journalists, which recommended already a decade ago to limit phone use to 10 minutes at a time [8]. However, this advice was aimed mainly at local radio frequency tracking or against the sniffing of weakly encrypted or unencrypted content that might give away the position. With the presented approach even many short transmissions over a long period of time could be dangerous for such vulnerable groups. On the other hand, fairly mobile units for example in the Ukraine war with a Starlink terminal are less likely to be impacted, as their general presence is known and the time/accuracy trade-off is unlikely to be problematic for them.

6.6 Ethical Considerations

As with any potentially network- and privacy-infringing attacks, we took careful considerations to minimize any negative impact on real users. As such, we only passively captured our own communication, which was generated with very low bandwidth as not to impact the service quality of the Iridium system. In order to not make it too trivial to exploit our approach, we also do not release the antenna model, which after (extensive) one-time generation is highly transferable between all Iridium satellites.

Overall, we believe that it is more important for satellite users to know about potential location privacy leakage of their setups, even when they only use it to receive data. This knowledge enables users to protect themselves, and satellite providers to consider this in future system designs.

We publish the code for the simulation and analysis. We do not publish the conducted measurements and the resulting antenna beam models, as they can be used to perform the proposed attack in reality, as we demonstrated.

7 Related Work

Wireless physical-layer security is a longstanding research area, from small sensors to satellites. Canonical overviews are provided for example in [6, 24]. We briefly cover the related work in the areas of wireless localization and privacy in general and in satellite networks in particular.

7.1 Wireless Localization

The localization of wireless transmitters is a popular research discipline and has many applications touching on security (verifying the true location of transmitters) and privacy (leaking transmitter location to eavesdroppers). We discuss the prevalent approaches and how they differ from RECORD.

Opportunistic localization of wireless transmissions These approaches require the target to actively transmit data, which is received opportunistically by the localizer in one or more locations (i.e., the receiver does not transmit itself). Many wireless signal characteristics have been exploited in the literature to estimate or verify positions of such transmitting objects, including time of flight, time difference of arrival, angle of arrival, Doppler shift and RSS [1].

Opportunistic localization and positioning is crucial to many applications. Time difference of arrival for example is applied at scale in the Global Positioning System (GPS) and multilateration of aircraft. Indoor localization has seen use in contact tracing [29], asset tracking and process automation. [17] provides an overview of localization methods.

All of these localization methods fundamentally require the target to be actively transmitting data, and often a line of sight. In case of exploitation by an attacker, victim transmissions must happen while the attacker is present and in range. In contrast, RECORD only needs the target to be receiving data during the attacker's presence in the same satellite beam.

Radar Radar systems transmit electromagnetic waves and exploit the reflection of a target object to detect and localize it. This class of approaches does not require the target to transmit data but is not stealthy as, often very strong, transmission sweeps are conducted by the localizing entity [25].

Here, passive radar [28] is an interesting extension, whereby the localizer opportunistically exploits existing radio signals, such as from television stations, and their reflections in order to stealthily locate the target. However, like all radar detection, it is generally not applicable to ground targets.

Cellular Networks In cellular networks, mobile users are positioned within a static radio environment established by network base stations. Typical localization approaches are proximity, multiangulation, multilateration or fingerprinting based algorithms, that rely on RSSI, TOA or TDOA [7, 16]. There are crucial differences to our approach. The RECORD attack is based on the covered area of the network cell (spot beam) rather than on RSSI, TOA or TDOA. We exploit the continuous and predictable change of the network access nodes (satellites) rather than relying on it static environment.

Also the party, gaining the location information is neither the network operator, nor the user of the network but an outside third party. And the large scale, our attack can be deployed is unmatched compared with other approaches.

7.2 Location Privacy in Mobile Networks

By and large, the focus on mobile location privacy has been on smartphones and their users, including many relevant attacks exploiting privacy leakage on the physical layer.

During the wake of the Covid-19 pandemic, privacy-preserving digital contract tracing using Bluetooth Low Energy (BLE) has gained significant prominence as the DP3T proposal [29] was implemented in billions of smartphones worldwide. DP3T relies on identifying proximity of other users through radio frequency ranging.

Givehchian et al [9] evaluated location tracking attacks on BLE. By fingerprinting beacons on the physical layer, an attacker can effectively bypass cryptographic privacy protections built into applications such as digital contact tracing.

In the work perhaps closest to ours, LTRack [15] allows adversaries to extract both device locations and identifiers by passively sniffing the up- and downlink of LTE phone networks. LTRack illustrates the power of passive localization attacks indoors, reaching an accuracy of several meters.

7.3 Satellite Security

Security and privacy in satellite networks have recently enjoyed a renaissance in the academic community.

In 2020, Pavur et al. outlined the ease of eavesdropping on the downlink contents of unencrypted legacy geo-stationary satellite systems [22]. It illustrated that it is feasible to identify the traffic of a specific user in the same satellite beam.

Oligeri et. al. [20] used Iridium Ring Alert messages to verify their own position and detect spoofed GPS signals.

Recently, Sabbagh et al. [23] show how a receiver can determine its own position using pseudo-ranges from a single known LEO satellite. While achieving location errors below 1 km, this approach requires direct timing measurements at the receiver and is not applicable to a third-party attacker.

In [11, 19, 26], the authors propose several alternative systems in order to authenticate communication satellites based on physical properties. They authenticate the satellite by using a fingerprint of the satellite sender hardware or the time difference of signal arrivals at multiple receivers, respectively.

8 Conclusion

We have described a novel attack on LEO satellite systems that leads to significant leakage of location privacy for their users. The RECORD attack exploits the fact that for such systems the target satellite in LEO frequently changes for the communicating ground user. As they overfly the horizon, satellites and their specific antenna beams leak positional information, which, over time, can give away a user's position.

Using an empirical model for Iridium, we passively exploited the observed downlink communication of a target device in order to estimate its location. The RECORD attack is impervious to encryption and only requires the identification of a device in the downlink. We implemented it in the real world with commercial off-the-shelf hardware to show its feasibility. Through further theoretical and practical evaluation, we showed that with only four hours of observation, the uncertainty region can be reduced to less than a few km^2 after which conventional localization methods may be deployed.

9 Appendix

9.1 Used coordinate systems

During all observations and measurements in the real world we used up-to-date Two Line Elements (TLEs) from Celestrack in combination with the SGP4 library[1] for calculating the positions of the satellites.

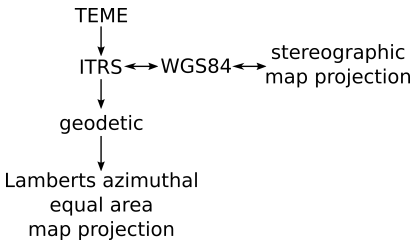

Figure 16: Overview of the used coordinate systems.

The positions of the satellite are given in the 'True Equator Mean Equinox' (TEME) coordinate system, the left upper coordinate system in Figure 16. It is used by the SGP4 library since the movements of the satellites are more precise when described in an inertial coordinate system. We convert the satellite coordinates to the 'International Terrestrial Reference System' (ITRS), which has its z-plane in the equatorial plane of the Earth and is rotating with the Earth. This allows us to combine the antenna model with the satellite position and calculate the antenna footprints at the surface of the Earth. The Earth surface is modelled by the WGS84 model, which follows the ITRS specification. Thereby the antenna footprints are projected on the surface of an Earth ellipsoid, which models the general Earth shape but does not take into account elevations such as mountains.

From the Cartesian 3D ITRS coordinate system the footprints are calculated via the WGS84 model and converted to a stereographic 2D map representation. The map is centered at the observers position and is used to calculate the intersections of the footprints with the shapely library[2]. The resulting *RoI* is converted back to the 3D ITRS. For visualizing the footprints and regions are translated from ITRS to a geodetic coordinate system. We implemented the evaluation of the *RoI* in Lamberts azimuthal equal area map projection, which allows a simple calculation of the covered Earth surface and has a stable transformation from the geodetic coordinate system.

Here it is noteworthy that the majority of the calculations during the algorithm execution are performed in the stereographic map projection. The number of coordinate system and projection translations was kept to a minimum to avoid the accumulation of transformation errors.

9.2 Model Creation

With RECORD, the attacker has to calculate the footprint of the satellites antennas at all times. To make this possible, the attacker needs to have models of all the antenna footprints of a satellite. This is realized by the procedure, described in sections 3.1 and 4.2. Here we provide additional insights to the generation and usage of the satellite model. The satellite model is a set of antenna models, each modelling one of the satellites downlink antennas. Each of this antenna models holds a list of polygons, representing the lobes of the antenna.

During the model creation, we indirectly use the satellites rotational adjustment, that enables a fixed orientation of the satellite towards the Earth. This ensures that the antennas point to the earth at the same angle during the whole orbit period. At the initial stage of an attack the antenna's exact orientation and the corresponding footprint is not known. The description of the antenna's orientation and the resulting footprint contour, are addressed by the antenna model. During the model creation, the attacker receives status messages, the "Iridium Ring Alerts", containing the satellite ID and the antenna/beam ID. An actual Iridium satellite comprises a constellation of 48 antennas, which are distinguished by the beam ID. Since we know the 3D position and 3D velocity of the satellite and the location of the receiver, we calculate the angle at the satellite, pointing to the receiver, the sending angle. The angle is calculated relative to the velocity vector and nadir of the satellite. This makes the measurement independent of the satellite and observers location and enables the combination of many data points over time. These two-dimensional data points are illustrated in Figure 7a. Through a labeling based on the received antenna/beam identifier, it is possible to combine many data points that belong to a specific antenna. Over time, a profile emerges, revealing many sending angles for each satellite antenna. This aggregation of data points forms the core of the antenna model, revealing the opening angles (the outer hull of the sending angles) of each respective antenna. To reduce the size of the antenna model, we optimize the model by keeping only the outer data points of each antenna. These outer points, which are delineating the footprint, are stored in a polygonal format to streamline computations during upcoming footprint calculations. Such polygons are shown in Figure 7b. This storage format also allows efficient checks if an observer's placement is within the footprint, by verifying the polygonal inclusion of the directional angle pointing to the observer. Since we are working with real systems, the antennas often have side lobes. During the data processing, each antenna lobe is identified (each color in Figure 7a represents a distinct lobe of beam 36) and subsequently encapsulated within a separate polygon. Importantly, the side lobes are preserved within the model, since it is possible that satellite devices also use this side lobes, if no other signal is available. In the end, the satellite model is a set of antenna models. Each antenna model is a set of polygons

(a) Maximum footprint. (b) Minimum footprint.

Figure 17: Max. and min. observer footprints (red dots). The max. consists of the visible antenna beams. The min. subtracts all beams outside the observer's view from the max.

representing an individual antenna lobe.

9.3 Observation Events

We now formalize the relation between the received messages, observation events, and antenna footprints. First, some basics for working with the antenna footprint areas are defined followed by the calculation of the areas of interest, i.e. the location knowledge added by different event types.

Basic Definitions E defines the set of all observation events that are made during an observation.

$e_{l,t}$ is one observation event from the set of events E ($e_{l,t} \in E$), that was detected at location l at time t. In each event, the information about location and time is always included, also in the simplified form e (without the indices) which we use to increase readability.

$region(e)$ describes a function that computes the *RoI* of an event e. Accordingly, $region(E)$ defines the region that is covered by the whole set of observation events.

B_e defines the set of all visible antenna beams during one event e. Since every event includes the location l and time t, it is possible to determine the visible beams. The simplified form is B. In some cases, the visible beams one time step before t are required, they are denoted as B_{t-1}.

b is a single antenna beam in set B ($b \in B$). The full description is $b_{s,n,t}$, which uniquely identifies the beam number n of satellite s at time t.

f_b refers to the footprint of a beam b. All required information for calculating the footprint is given by b.

$max(B)$ is a helper function that describes the maximum footprint of a set of beams B. It is defined as:

$$max(B) = \bigcup_{b \in B} f_b$$

Where $\cup$ is the union of all individual footprints f_b. Figure 17a shows the maximum (highlighted in green) of two antenna footprints for one observer (the red dot in the middle).

$min(B)$ is a second helper function that describes the minimal footprint of a set of beams B. This includes only the area that is covered by the given beams, overlapping areas with other beams are excluded. Following this, it is defined as:

$$min(B) = max(B) - max(B^*)$$

where B^* denotes the negative of B, so the set of all beams that are not visible for an observer at location l and time t. Figure 17b illustrates the minimum footprint of an observer.

Observation Events Definitions During the communication of a target device with the satellite, the attacker observes a sequence of messages. In the following explanation, the translation from observed messages to observation events and the calculation of the resulting *RoI* is provided. The term 'target beam' refers to the satellite antenna beam that is currently used to communicate with the target device. The term 'observer beam' refers to the antenna beam that currently can be received by the observers. Based on LEO satellite geometry and system behavior, we can define six different observation events:

General reception (e_{gr}): An observer that is in the same footprint as a target device is able to receive target messages on the downlink. The target device is in the maximum footprint of all receivable beams (see Fig. 17a):

$$region(e_{gr}) = max(B) = \bigcup_{b \in B} f_b$$

Non-reception during communication (e_{ndc}): Multiple observers cooperate and not everyone is receiving target traffic. The non-receiving observers gain the knowledge that the target is not in their minimal footprint. Hence, a 'negative region' is calculated that is ensured not to hold the target position:

$$not\_region(e_{ndc}) = min(B) = \bigcup_{b \in B} f_b - \bigcup_{b^* \in B^*} f_{b^*}$$

Reception after handover (e_{rh}): When the target device switches from one spot beam at $t-1$ to another, it exchanges messages with the satellite to perform a handover. An observer who receives those messages and is still able to receive downlink messages afterwards at t gains the knowledge that the target device is in an overlapping area of two observable beams:

$$region(e_{rh}) = \bigcup_{b_1, b_2 \in B_{t-1}, b_1 \neq b_2} (f_{b_1} \cap f_{b_2})$$

Non-reception after handover (e_{nh}): An observer who receives handover messages at $t-1$ and is not able to receive downlink messages at t. The observer has to cooperate with other observers to guarantee an ongoing communication. He gains the knowledge that the target device was switching from an observable beam at $t-1$ to a non-observable beam at time t:

$$region(e_{nh}) = max(B_{t-1}) - min(B)$$

$$= \bigcup_{b_{t-1} \in B_{t-1}} f_{b_{t-1}} \cap \bigcup_{b^* \in B^*} f_{b^*}$$

Sudden reception (e_{sr}): This is the case when an observer did not receive target traffic at $t-1$ but suddenly receives messages at time t. This either happens because (a) the target device switched to an attacker beam or (b) the attacker switched to the target beam. In case (a), the target is in the maximum footprint at time t, while not being in the minimal footprint at time $t-1$. For case (b), the target device is in a beam that was observable at time t but not at time $t-1$:

$$region_a(e_{sr}) = max(B) - min(B_{t-1})$$

$$region_b(e_{sr}) = max(B_t \setminus B_{t-1})$$

$$region(e_{sr}) = region_a(e_{sr}) + region_b(e_{sr})$$

$$= \bigcup_{b \in B} f_b \cap \bigcup_{b^*_{t-1} \in B^*_{t-1}} f_{b^*_{t-1}} \cup \bigcup_{b \in \{B_t \setminus B_{t-1}\}} f_b$$

Sudden non-reception (e_{sn}): The observer was able to receive target messages at $t-1$ but not at time t. The causes are either (a) the target device switched from an attacker beam to a new beam or (b) the observer left the target beam:

$$region(e_{sn}) = max(B_{t-1} \setminus B_t) = \bigcup_{b \in \{B_{t-1} \setminus B_t\}} f_b$$

The resulting region is the intersection of all single region from all observation events:

$$region(E) = \bigcap_{e \in \{E \setminus e_{nr}\}} region(e) - \bigcup_{e_{nr}} not\_region(e_{nr})$$

9.4 Real-World Downlink Measurements

9.5 Observer Placement Strategy

To distribute the attacker's observers, we use the Fibonacci grid methodology [27] that facilitates a uniform spatial point distribution on the Earth's surface. By manipulating the overall number of points, we influence the inter-point spacing, in a first step. By generating the last 'n' points of this world-spanning grid, we generate the 'n' points in closest proximity to the North Pole. In a second step, we rotate the North Pole-centered points by a random angle, to avoid generating exactly the same pattern. In a third step, the North Pole-centered points are rotated to our designated starting location on the earth surface. Each of these resulting 'n' points becomes one location of the 'n' observers. To assess the quality of the point distribution, we analyzed the distance separating a point from its nearest neighbor. We conduct evaluations across inter-point distances spanning 50 to 1000 km, incremented in intervals of 10 km, coupled with numbers of points ranging from 3 to 100. The mean proximity to the nearest neighbor is 1.15% off from the desired inter-point distance, with a standard deviation of 2.5%. The largest deviation observed attains 9.29%. The distance between an observer location and the target device depends on the number of attackers and the inter-observer distance. For the optimal distance of 400 km, a 12 observer setup covers a circular area with 836 km in radius. The target device is placed randomly around the starting location, up to a distance of the given inter-observer distance. This means the device can be placed on the opposite side of the outer observer, up to 400 km away from the starting location. Thus, the maximum distance of the outer observer to the target device is 1236 km, for this setup.

measurement	duration	area estimation	$\frac{\text{duration}}{e_{ndc}}$
4*	1463 sec	17118 km^2	6.9
2*	683 sec	81437 km^2	13.4
6*	2085 sec	3240 km^2	22.4
8*	4044 sec	8654 km^2	32.9
9	4237 sec	43152 km^2	33.9
3	1028 sec	81337 km^2	54.1
5	1715 sec	88292 km^2	142.9
7	2318 sec	47704 km^2	165.6
1	288 sec	102534 km^2	-

Table 6: Measurements ordered by duration over e_{ndc}.

Table 7 shows the covered area of the observer setups generated in Section 5. It includes covered areas of 24 observer setups to clarify the emerging pattern: when doubling the distance between observers, one can reduce the amount of observers by a factor of 4 and still cover the same area.

inter-observer distance	number of observers			
	3	6	12	24
100 km	34,271	68,542	137,078	247,138
200 km	137,078	274,139	548,203	1,096,112
300 km	308,401	616,708	1,233,043	2,464,594
400 km	548,203	1,096,112	2,191,045	4,377,374
500 km	856,438	1,712,157	3,421,435	6,831,356
600 km	1,233,043	2,464,594	4,923,218	9,822,653
700 km	1,677,942	3,353,119	6,695,180	13,346,129
800 km	2,191,045	4,377,374	8,735,883	17,396,308

Abstract

Collision avoidance systems have been a safety net of last resort in aviation since their introduction in the 1980s. Through constantly refined safety procedures and hard lessons learned from mid-air collisions, the Traffic Collision Avoidance System (TCAS) II Version 7.1 has become the global standard, significantly improving safety in a fast-growing field.

Despite this safety record, TCAS was not designed with security in mind, even in its newest versions. With the rise of software-defined radios, security researchers have shown many wireless technologies in aviation and critical infrastructures to be insecure against radio frequency (RF) attacks. However, while similar attacks have been postulated for TCAS with its built-in distance measurement, all attempts to execute them have failed so far.

In this paper, we introduce the first working RF attacks on TCAS. We demonstrate how to take full control over the collision avoidance displays and create so-called Resolution Advisories (RAs) of arbitrary aircraft on a collision course. We build the necessary tooling using commercial off-the-shelf hardware, creating sufficient conditions for the attacker to spoof colliding aircraft from a distance of up to 4.2 km.

We evaluate this and further attacks extensively on a live, real-world, certified aircraft test system and discuss potential countermeasures and mitigations that should be considered by aircraft and system manufacturers in the future.

1 Introduction

In aviation, collision avoidance is a critical safety measure, with the TCAS standing out as the last line of defense against mid-air disasters. As advancements in aviation technology have contributed to an exponential surge in air traffic globally, there is a critical need for robust, reliable, and secure systems capable of serving the ever-growing number of passengers and flights. TCAS, operational since the 1980s, has demonstrated its effectiveness through continuous safety enhancements and now has an impressive safety record, preventing many mid-air collisions every year [44, 50].

On the most basic level, TCAS operates by detecting and tracking nearby aircraft, displaying them in the cockpit and providing pilots with visual and aural advisories and resolutions to avoid potential conflicts in time. Crucially, the system is independent of Air Traffic Control (ATC) and can thus catch human errors made by pilots or controllers as a last resort. Consequently, when TCAS malfunctions or is accidentally deactivated, the repercussions can be significant. Such incidents have been ranging from very close calls [33] to tragic mid-air collisions [8]. Pilots erroneously disregarding the advisories of TCAS has previously led to fatal incidents, too [14].

Beyond such traditional safety issues, glaring novel security vulnerabilities have been exposed in many avionics and communication systems in the academic literature of the last decade. The evidence has shown most of the employed wireless technologies in aviation to be exploitable in controlled laboratory environments using accessible Software-Defined Radios (SDRs) and software tools [10,41–43,45,46]. Notwithstanding their potentially major impact, these vulnerabilities seem straightforward in hindsight: as there are few to no cryptographic security measures, and encoding and modulation are known, full control over the channel is dependent only on an attacker's sending power.

However, while TCAS is using some of the same underlying vulnerable wireless channels, it has so far resisted any proof-of-concept attack even in the laboratory. This is due two main reasons: first, TCAS has a strong physical-layer component, whereby dynamic, fast-moving, targets use interrogations and responses for speed-of-light distance measurements. Second, the complexity of TCAS-specific communication and its associated state machines, along with the need for more advanced SDR setups than those used for analyzing other protocols, results in a lack of existing tooling for this purpose.

Indeed, many researchers have postulated the possible existence of vulnerabilities in TCAS [5, 17, 18, 48] and even examined their potential impact on aircraft and pilots in flight simulators [47]. However, unlike attacks on systems such as ADS-B, actually executing an attack on TCAS has proven hard, with all previous attempts coming up short.

The present research thus marks a significant breakthrough, employing commercial off-the-shelf hardware to delve into the theoretical and practical aspects of a real-world TCAS attack. We explore the challenges and complexities that have made successful exploitation impossible so far and construct the necessary tools, models and laboratory setups for comprehensive, yet safe and ethical, attack execution and evaluation.

Given the significance of TCAS and its presence on most commercial jetliners [1, 23], the goal of this research is to understand the attack requirements against this crucial system. In combination with existing literature on the impact of such attacks on collision avoidance systems, we hope that our work will lead to increased awareness within the aviation community and the development of adequate technical or procedural countermeasures and mitigations.

In summary, our contributions are as follows:

- We present the first working RF attacks on TCAS. Most notably, we take arbitrary control over the collision avoidance displays and create resolution advisories of aircraft on collision course at will.
- We build novel tooling, modeling, and a certified testbed needed in order to truly understand and conduct live attacks on physical-layer collision avoidance systems.
- We experimentally, yet safely, evaluate the feasibility and working parameters of three different attacks on TCAS with our testbed setup.

2 Background

2.1 Mode S Communication

Mode S, short for "Mode Select", is a communication protocol used in air traffic control and aviation. It enables aircraft to exchange information with ground-based radar systems and other aircraft through on-board radio transponders. Its *select* feature sets it apart from previous communication methods. This feature is the inclusion of a globally unique 24-bit address in each message, assigned by the International Civil Aviation Organization (ICAO) according to a regional delegation scheme [20]. Such an address identifies the sender or recipient of each message.

Physical layer. Mode S specifies two distinct packet-based communication channels over radio links. The first, the *uplink*, uses Differential Binary Phase Shift Keying (D-BPSK) over the 1030 MHz frequency, running at a data rate of 4 Mbit/s. The second, namely *downlink*, uses pulse position modulation over the 1090 MHz frequency, with a data rate of 1 MBit/s. Each packet consists of a fixed amplitude modulated preamble followed by either 56 or 112 bits of modulated payload [39].

Data format. Each message is distinguished based on the channel used and the initial five bits, known as the *format*. Uplink channel messages are denoted as UF=x, with "x" representing the format. Similarly, downlink channel messages are designated as DF=x. For any given DF=x or UF=x, the interpretation of its subsequent bits remains consistent, with the standard [39, 2.2.14.1] determining the position, length, and names for multiple fields. However, it is essential to note that while a particular field may appear in multiple messages, it does not necessarily mean that the same type of information will consistently be present within it. As an example, the four-bit *Reply Information* (RI) field in *Short air-air surveillance* (DF=0) responses can either signify the maximum velocity range of the queried aircraft (if $RI < 8$) or describe the type of installed TCAS (if $RI \geq 8$).

Additionally, every packet ends with a 24-bit CRC-based parity. Depending on the message's channel and format, this parity can either be XORed with 24 ones or undergo a channel-specific mathematical transformation, encoding a 24-bit ICAO address (uniquely identifiying the aircraft transponder) in conjunction with the parity. This method conserves bits that would otherwise be used for adding the address to each message. However, it requires recipients of the mathematically adjusted parity field to possess prior knowledge of the address, acquired from earlier messages that included the parity XORed with 24 ones.

Protocols. Mode S integrates two primitives that its upper-layer protocols use: *broadcasts* and *interrogations*. Broadcasts do not require a response. Interrogations are sent over uplink and are associated with a response on downlink 128μs after reception. In the case of interrogations, a message with format specifier UF=x is often associated with its DF=x counterpart.

These primitives are leveraged to implement multiple functionalities such as *Air Traffic Control Radar Beacon System/Mode Select (ATCRBS/Mode S)* [11], *Automatic Dependent Surveillance - Broadcast* (ADS-B) [21], and Traffic Collision Avoidance System (TCAS) [37], the subject of this study.

2.2 The Traffic Collision Avoidance System

TCAS is a standard aircraft collision avoidance system that plays a crucial role in modern aviation safety. Originally introduced as TCAS I by the Radio Technical Commission for Aeronautics (RTCA), this system was created to offer pilots proximity alerts regarding nearby aircraft using radio communication [36]. Subsequently, an upgraded version known as TCAS II was introduced, adding the capability of suggesting evasive maneuvers to actively avoid potential mid-air collisions [37]. Both iterations of the standard are internationally ratified by ICAO under the names Airborne Collision Avoidance System (ACAS) I and ACAS II [22]. These ACAS standards are equivalent to their TCAS counterparts

in terms of functionality and purpose [19]. TCAS is a widely adopted standard, not just due to its effectiveness in enhancing flight safety but also because of legal mandates requiring its installation in almost every commercial aircraft [1, 13, 23]. Interoperable TCAS II equipment is sold by four US-based vendors. TCAS is set to be superseded by ACAS X, which is currently still in the standardization phase and not yet operational. Even after the eventual introduction of ACAS X in the 2030s, downwards compatibility with TCAS will ensure that the latter will remain in use for decades to come.

Surveillance. A primary feature of TCAS is *surveillance*. This function allows pilots to see on their instruments the relative positions and altitudes of other aircraft equipped with Mode S transponders. To find traffic in the vicinity, TCAS listens for spontaneous broadcasts, namely *squitters*, keeping track of the ICAO addresses contained in them. TCAS periodically interrogates the found aircraft to track their altitude, bearing, and range. In particular, it extracts altitude from the message content replied by the interrogated aircraft. Bearing and range are instead measured independently using signal processing techniques. For bearing, the TCAS equipment must incorporate a radio direction finding device capable of estimating the angle of arrival of the interrogation response. In contrast, the range calculation relies on the fixed delay of $128\mu s$ between the reception and the initiation of each Mode S interrogation response.

$$R = \frac{c}{2}(\Delta T - 128 \cdot 10^{-6}) \tag{1}$$

Equation 1 details the method for determining range. It involves multiplying the speed of light, denoted as c, with subtraction between round trip time ΔT and the expected delay. This result is then halved to account for the round-trip journey of the radio wave to the interrogated aircraft and back.

Traffic Advisory (TA). The collision avoidance capability of TCAS extends beyond simply displaying nearby aircraft. In fact, it continuously monitors each tracked aircraft to alert the crew of potentially dangerous encounters preemptively. Whenever it detects an intruding aircraft as a threat, TCAS issues a Traffic Advisory (TA), an urgent alarm highlighting an elevated risk of in-flight collision. Triggering a TA requires a potential threat to satisfy specific conditions on altitude and range:

$$ADOT = \dot{A} \cdot \mathrm{sgn}(\Delta A)$$
$$(\Delta A < THR_{TA}) \bigvee \tag{2a}$$
$$\left(ADOT \geq -1\text{ft/s} \bigwedge -\frac{\Delta A}{ADOT} < TAU_{TA}\right) \tag{2b}$$

Equation 2 reports the condition on altitude in Disjunctive Normal Form (DNF). There, ΔA is the difference in altitude between the TCAS-equipped aircraft and the intruder, with $\dot{A}$ being its derivative w.r.t. time. The first term (2a) merely checks whenever the altitude difference is less than THR_{TA}. Instead, the second term (2b) applies whenever the altitudes of the aircraft are converging, comparing the time to the closest vertical point of approach with a threshold TAU_{TA}.

$$\left(R\dot{R} \leq H1_{TA} \bigwedge \dot{R} > 10\text{ft/s} \bigwedge R \leq DMOD_{TA}\right) \bigvee \tag{3a}$$

$$\left(\dot{R} \leq 10\text{ft/s} \bigwedge \frac{\frac{DMOD_{TA}^2}{R} - R}{\min(-10\text{ft/s}, \dot{R})} \leq TAU_{TA} \bigwedge R > DMOD_{TA}\right) \bigvee \tag{3b}$$

$$\left(\dot{R} \leq 10\text{ft/s} \bigwedge R \leq DMOD_{TA}\right) \tag{3c}$$

Equation 3 reports the condition on range in DNF. It contains the currently measured range R and its time derivative, i.e., closure rate, $\dot{R}$. The first term (in 3a) applies whenever the aircraft are approaching each other, the tracked range is less than $DMOD_{TA}$, and the product between range and closure rate is less than $H1_{TA}$. The second (3b) and third (3c) terms apply to the case of diverging or non-rapidly approaching intruders. Similar to the previous case, those last two terms trigger a TA either when the horizontal time to the closest point of approach is less than TAU_{TA} or when a range measurement is closer than the $DMOD_{TA}$ threshold value.

Table 1 details the coefficients and thresholds associated with triggering a TA, as they appear in the standard. It is worth noting that the values vary according to the current Sensitivity Level (SL). We discuss SL in the following.

Resolution Advisory (RA). RAs are one of the main innovations introduced with the second version of TCAS. They extend TAs with facilities for automatically resolving conflicts by issuing commands, called RAs, to the cockpit. These commands direct the pilots to either adopt a specific vertical attitude (for example by climbing or descending) or to modify the ongoing collision avoidance action, such as leveling off or adjusting the ascent/descent rate. TCAS will continue to issue and update those commands until resolution of the conflict.

The decision of issuing a RA is taken by TCAS once an ongoing TA risk increases to an even more critical level. As such, RAs are triggered by repeating the checks found in Equations 2 and 3 but replacing each coefficient value with the one from its non-TA counterpart. For example, $H1_{TA}$ in Equation 3a gets replaced by $H1$. In addition, RAs can only be issued whenever the intruder vertical separation at the closest point of approach V_{CPA} is less than the value $ALIM$.

$$V_{CPA} \approx \begin{cases} \Delta A + (\dot{A} - \dot{A_O})\frac{R}{\dot{R}} & \text{if } \dot{R} \gg 0 \\ \Delta A & otherwise \end{cases} \tag{4}$$

For brevity, we approximate the procedure for calculating V_{CPA} [38, 3.96] with Equation 4 where $\dot{A_O}$ is the intruder altitude time derivative.

The choice of which action to issue as RA can be performed either autonomously or collaboratively, depending on the intruder equipment. TCAS II systems announce their presence by periodically emitting an additional dedicated TCAS squitter. An intruder is considered capable of coordination after reception of such squitter and when DF=0 responses to the surveillance function indicate an "On-board TCAS with vertical-only resolution capability" in their RI field.

If TCAS is unsure about the availability of coordination, it unilaterally chooses RA contents according to the intruder-tracked position and attitude. For instance, TCAS issues *climb* RAs against lower altitude targets.

Instead, intruders capable of coordinating encounters negotiate by choosing their action as per the uncoordinated case and exchanging *Long Special Surveillance interrogation* (UF=16) messages instructing the other aircraft to not pick a conflicting resolution, e.g., a descending aircraft will instruct the other to not do so. In a disagreement, the TCAS associated with the aircraft with the highest ICAO address will pick an action opposite to the one chosen by the other system.

Sensitivity Level (SL). TCAS relies on standardized thresholds to classify the status of intruders. The values of these thresholds depend on the currently set Sensitivity Level (SL), a value ranging from 1 to 7. SL=1 is a special level corresponding to a disablement of all TCAS functions, including surveillance. SL=2 corresponds to the *TA Only* mode of operation in which TCAS does not issue any RAs. SL values of 3 to 7 are instead associated with the full functionality, with higher sensitivities corresponding to larger areas (so-called *protected volumes*) being considered dangerous by the system.

On most TCAS units, pilots can only choose between three settings: STBY (standby), TA, and TA/RA. STBY and TA correspond to fixed SLs of 1 and 2, respectively. TA/RA mode automatically selects a SL from 2 to 7 depending on the current altitude and the standardized values in Table 1. During flight, standard procedures suggest that pilots should always set the TCAS mode selector to "TA/RA" [12].

3 Related work

Past literature has discussed the possibility of vulnerabilities in TCAS, as outlined in several surveys on aviation cybersecurity [16,30,31,49]. Overall, the findings agree that there are potential issues originating from the unauthenticated nature of TCAS compounded by the absence of encryption.

Hannah et al. [18] described the threat landscape within TCAS, including the capabilities of malicious actors and the potential range of attacks. Among the threat taxonomy, they classify the ability of adversaries to inject aircraft into a target's traffic display as *False Injection* and the capacity of denying, degrading, or destroying communications as *Denial-of-Service (DoS)*. Importantly, the authors emphasize the complexity of executing such attacks by linking them to individuals possessing extensive skill sets, such as Advanced Persistent Threats (APTs) or criminal organizations.

Previous literature has explored proof of concept for false injection attacks, mostly within simulated environments. Here, we discuss these representative studies.

Graziano [15] presents an instance of an attack using SDRs aimed at an operational TCAS device. The implementation highlights the challenge of managing response times. The best latency achieved is around 606*ms*, far exceeding the threshold for an effective attack by over three orders of magnitude. Indeed, the author mentions that this latency corresponds to an *intruder positioned approximately* 908*km away*.

Berges et al. [4, 5] design an attack using SDRs, targeting a model that emulates functionalities of the TCAS system's state machine. This approach utilized SDR technology to create a partially simulated environment, distinct from direct engagement with an actual TCAS. Notably, their model does not consider the response time constraint for range estimation.

Table 1: TCAS thresholds [37,38][1].

Sensitivity Level		2	3	4	5	6	7
Altitude	[ft]·10^3	<1	<2.35	<5	<10	<20	>42
$H1$	[nm^2/s]	n/a	.002	.00278			.004

Table 2: Summary of quantities found in Section 2.2.

Quantity	Description
A	OA altitude
$\dot{A}$	OA altitude derivative
A_o	IA altitude
$\dot{A_o}$	IA altitude derivative
ΔA	Altitude difference $= A - A_o$
$ADOT$	Direction-weighted IA altitude derivative [38, 3.60]
R	IA range
$\dot{R}$	IA range derivative
V_{CPA}	Vertical separation at Closest Point of Approach

OA = Own Aircraft, IA = Intruding Aircraft.

[1] SI units: 1 nautical mile (nm) is 1852 m, 1 foot (ft) is 0.3048 m.

Lomas et al. [28] presented at DEFCON 28 the effects of radio frequency spoofing attacks against TCAS by adding multiple traffic aircraft to an Airbus flight deck simulator scenario. They emphasize that in a realistic environment, TCAS is *difficult to spoof* due to its reliance on time of flight information to determine the distance between aircraft.

Hannah et al. [17] examine attacks in simulated environments to identify what ranges, altitudes, and relative bearings are most vulnerable to false injections.

Smith et al. [47] demonstrate the significant impact of wireless attacks on pilots, including TCAS false injections, by implementing and analyzing malicious flight simulator scenarios. They also simulate collision avoidance attacks against ACAS X [48], and identify a theoretical success rate ranging from 44% to 79%, with an average deviation of 590 feet.

Regarding DoS attacks, past work [16, 17] hypothesizes about potential implementations to leverage electronic warfare tactics, specifically spot jamming techniques.

To the best of our knowledge, no prior research has successfully proven and executed any practical attacks against an airworthiness certified [24] TCAS. Going further, we are also the first to show how to arbitrarily position an intruder ghost aircraft in a controlled manner by effectively managing the complexity of range estimation. Moreover, this is the first work introducing a DoS attack that uniquely exploits features of the TCAS without depending on electronic warfare tactics.

4 Threat Model and Challenges

4.1 Threat Model

In this paper, we consider an attacker whose goal is to increase the probability of a safety incident significantly.

We assume that the aircraft under attack is equipped with a standard-compliant ACAS/TCAS II device operating in TA/RA mode, supporting a flight crew that has been trained to operate it correctly and follow its advisories. In addition, we assume that the attacker has access to a (fixed) location from which they can receive/transmit radio signals targeted at the victim aircraft.

We consider an adversary who is a professional actor capable of gathering solid knowledge for generating or testing a novel attack. Resource-wise, they can access moderately-priced ($\approx 10,000$\$) Commercial Off-The-Shelf (COTS) hardware components such as SDRs, signal amplifiers, antennas, and powerful computers. Based on these capabilities and potential motivations, we identify three main threat actors: terrorists, activists, and nation states. Terrorists primarily aim to instill fear and broadcast their extremist ideologies. Their interest in aviation can be attributed to the potential for causing significant economic disruption, impeding international travel, or even loss of life, and leveraging the visibility of such attacks to convey their extremist ideology to the general public. Activists, sometimes known as "hacktivists" in the digital realm, are driven by a burning desire to spotlight perceived injustices and agitate for societal change. Activists have previously targeted the private aviation sector to demand political action against highly polluting short flights and the usage of private jets. Finally, nation states might be interested in compromising another country's economic stability from a commercial aviation perspective and obtaining a logistic or direct advantage in military theaters as TCAS is standard in governmental and even military aircraft.

4.2 Challenges

TCAS is a public and well-specified standard with theoretically known vulnerabilities. Graziano [15] and Berges et al. [4] illustrate a comprehensive understanding of transmitting and receiving the TCAS protocol via SDRs. However, despite this theoretical knowledge, there is no proof that an attacker, even with the capabilities of a professional actor, can develop a practical, SDR-based, COTS solution capable of interacting with and exploiting an actual TCAS to fulfill malicious intentions as outlined in our threat model.

According to the literature the primary reason for this absence are the complex requirements of an attack implementation that effectively manages the range estimation of TCAS, which serves as a de facto physical-layer security feature.

To meet this timing constraint, attackers face several challenging requirements. Firstly, they must develop a high-performance application capable of receiving signals on the uplink frequency, demodulating, decoding, computing a response, modulating that response, and then transmitting it on the downlink frequency — all within a stringent timeframe of less than *128 microseconds* (Equation 1).

To solve the range spoofing problem (Equation 5) and ensure the practicality of the attack, the actual response time must be even shorter than this challengingly short period. This duration is significantly shorter than the typical response times of programs running on general-purpose operating systems.

Secondly, the precision of these timings is paramount. They must be accurate within hundreds of nanoseconds and maintain coherence across uplink and downlink frequencies. In addition, the continuity of this process is critical: it must operate uninterrupted over a long period for the intended effects of the attack to become apparent.

Achieving such precise timing is possible with specialized and purpose-built hardware solutions but poses significant difficulties for SDRs that rely on general-purpose processors. However, a custom hardware solution created by expert engineers would necessitate resources and time that surpass those available to even relatively resourceful entities. For this reason, an additional challenge is to identify the COTS hardware that can meet the requirements of these attacks and to take full advantage of optimizations in the software layer.

5 Attacks on TCAS

In the following, we present three different attacks on TCAS: traffic advisory injection, resolution advisory injection, and a simple, but effective denial-of-service attack.

5.1 Traffic Advisory Injection

This first attack involves deceiving the TCAS device about the existence of an intruder that is endangering the victim aircraft, prompting it to issue an alarm to alert the crew.

Recalling the functionality of TCAS, malicious actors can accomplish this goal by (i) getting tracked by the victim TCAS, and (ii) ensuring that the injected intruder position satisfies the conditions for a TA.

We detail these two phases below, denoted as *tracking* and *positioning*. Finally, we demonstrate the consequences of an attacker-initiated TA on the traffic display.

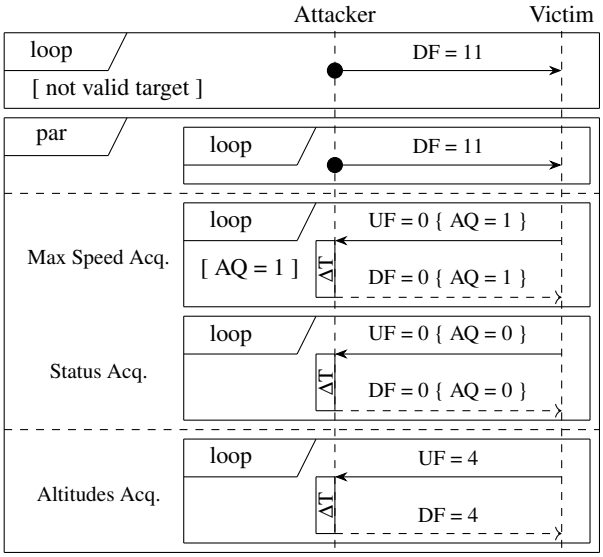

Figure 1: Minimal TCAS surveillance tasks.

Tracking. We consider an attacker implementing a protocol subset roughly corresponding to the air-to-air protocols found in a Level 1 Mode-S transponder [39, 2.2.18]. We also assume the attackers choose an identity for the spoofed aircraft, i.e., an ICAO address. The address is required to initiate interactions with the victim and remains fixed during the attack.

Figure 1 shows the sequence of interactions and messages attackers need to exchange with the victim to enable tracking of a spoofed aircraft.

Operations begin with the attackers emitting *All-call reply* (DF=11) squitters, which broadcast the identity of the spoofed aircraft. This phase loops until the victim adds the spoofed aircraft to its surveillance routines. The standard does not prescribe a specific quantity of squitters but hints at two emissions within its implementation suggestions [37, A.8].

After the victim's TCAS is aware of the spoofed aircraft, operations proceed with three parallel interactions. The first consists of periodically broadcasting DF=11 squitters to keep the surveillance routines active on the victim.

The rest of the interactions are interrogations from the victim to the attacker. In detail, the second interaction comprises two phases. In the first phase, the victim uses *Short air-air surveillance* (UF=0) interrogations to acquire the maximum speed of the spoofed aircraft. This phase concludes when the *Acquisition* (AQ) field of the interrogations is set to 1. In the second phase, throughout the entire attack, the victim monitors the status of the spoofed aircraft. It uses UF=0 interrogations to assess if the spoofed aircraft is airborne.

Finally, the third interaction responds to *Surveillance altitude request* (UF=4) interrogations, continuously updating the injected aircraft altitude on the victim's TCAS.

After completing one round of status and altitude acquisition, the victim initiates tracking of the spoofed aircraft. The victim continues displaying the track on the screen as long as the attacker responds correctly to the victim's interrogations.

With each interrogation, the range of the spoofed aircraft gets updated based on the round-trip time, as previously described (see Section 2.2).

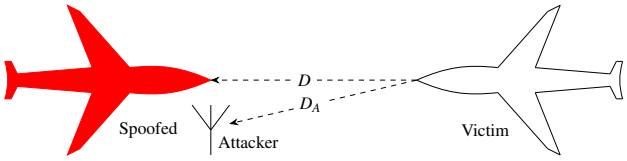

Figure 2: Range spoofing problem.

Positioning. Triggering a TA requires placing the spoofed aircraft such that its measured altitude and range satisfy the conditions described in Section 2.2.

Recalling Equation 2a, responding with any altitude closer than THR_{TA} w.r.t. the victim's altitude suffices in satisfying the altitude condition. The condition on the range instead distinguishes two cases, depending on the spoofed aircraft's closure rate. Placing an aircraft at an almost fixed and less than $DMOD_{TA}$ range suffices in triggering a TA (Equation 3c). Otherwise, the range must evolve over time to satisfy either Equation 3a or Equation 3b.

As higher sensitivity levels are associated with higher likelihoods of generating TAs, attackers can actively ascertain the current SL to gauge which values to use in the formulas. This is performed by sending out a UF=0 interrogation and retrieving the victim's currently configured value in the SL field found in the associated DF=0 response. Otherwise, they can assume the worst-case scenario of SL=2.

For satisfying the altitude condition, attackers modify the *Altitude Code* (AC) field contained within *Surveillance altitude reply* (DF=4) responses. This gives them complete and precise control over its value.

Manipulation of the range is instead performed by altering the interrogations' round trip time ΔT (see Equation 1). Figure 2 depicts the range spoofing problem. There, attackers are positioned at a distance D_A w.r.t. the victim aircraft and aim to inject an aircraft perceived to be at a *different* range D. Under the assumptions from Section 4.1, attackers cannot alter their position throughout the attack execution.

Recalling Equation 1, the detected range is calculated by dividing ΔT by the speed of light after a fixed processing delay of $128\,\mu s$. This delay allows attackers to appear closer than their actual distance by replying to interrogations before a legitimate TCAS system would. Similarly, artificially delaying responses will increase the measured range.

$$T = 128 \cdot 10^{-6} + \frac{c}{2} \cdot (D - D_A) - T_p \tag{5}$$

Equation 5 shows which response time T the attackers should use to make the spoofed aircraft appear at a desired distance D, considering a processing time of T_p.

This equation approximates D_A as a constant. Such simplification is acceptable, as an aircraft approaching at the maximum closure rate accepted in the standard of $1200\,kn$ would move by just $0.08\,m$ during the $128\,\mu s$ round-trip time.

Finally, the assumptions from Section 4.1 state that attackers receive and transmit from a fixed position. Consequently, they cannot alter the injected aircraft bearing. It is worth noting that such a limitation does not influence the attack success rate for TCAS II systems, which do not consider horizontal movements for their corrective maneuvers.

In summary, as long as Equation 5 is non-negative, attackers can control the altitude, speed, and range of the spoofed aircraft, but not its bearing.

Attack effects. In this example, a spoofed intruder is tracked by the victim. The attack assumes SL=2 and uses a fixed range of 0.25 nm. For the altitude, the attack performs an altitude acquisition and simply replays the victim's AC as their own.

Figure 3 shows the effects of the resulting TA on the victim's display. This notification, accompanied by an aural "*TRAFFIC, TRAFFIC*" annunciation, is displayed as a popup over the instrument screen. It contains a flashing yellow banner and a traffic Plan Position Indicator (PPI). This PPI shows the spoofed aircraft bearing and range (yellow circle), augmented with its relative altitude (`00`, i.e., the intruder is at the same altitude).

Figure 3: Avionics displaying a Traffic Advisory.

5.2 Resolution Advisory Injection

A RA injection is a more dangerous variant of the previous attack. In addition to sending the crew an even more urgent alert, a RA effectively allows attackers to impose commands on the victim as pilots are mandated to follow any RA and do so automatically (up to a limit) [47]. This issue becomes more urgent in modern airliners equipped for autonomous RA execution [3], as they allow attackers to manipulate the flight path directly, bypassing human intervention.

Recalling Section 2.2, RAs can be either negotiated between aircraft or fall back to unilateral decisions. In this section, we consider both cases, even though the simpler non-negotiated alternative already allows the attackers to fulfill their goals.

Non-collaborative encounter. This case requires attackers to escalate a TA into a RA by further reducing the separation w.r.t. the previous attack and meeting the additional condition on *ALIM* (see Section 2.2). As such, this attack requires following the same procedure detailed in Section 5.1 with the restriction that altitude should be chosen within *ALIM* of the victim's altitude.

Furthermore, in some situations, attackers can choose which advisory will be issued by reproducing particular encounter geometries. For instance, whenever the victim is climbing or descending, attackers can induce a "*LEVEL OFF*" advisory. To that end, they place the spoofed aircraft at a fixed altitude above/below the victim, forcing the victim's TCAS to abort the current maneuver in order to avoid crossing in front of the intruder stationed around the climb/descent path.

Climbs and descents can be forced whenever the victim is staying at a fixed altitude. Placing a rogue aircraft above will induce a descent, with the opposite inducing a climb.

Other geometries will still trigger a RA, although their outcome might be undefined in real-world scenarios and less useful to attackers aiming to associate a specific action with

their induced RA.

Collaborative encounter. Collaborative encounters are more complex as they require the attackers to perform all of the steps needed by their non-collaborative counterparts and then to take part in the negotiation in order to influence the victim's chosen RA towards their preferred outcome.

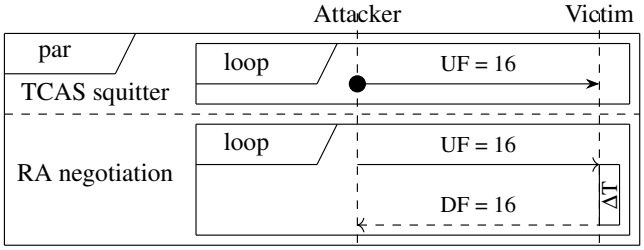

Figure 4: TCAS collaborative encounter tasks.

Figure 4 shows the sequence of additional interactions and messages attackers must exchange to negotiate a RA successfully. These two parallel tasks allow the spoofed aircraft to participate in the RA negotiation. The first operation consists of periodically broadcasting UF=16 TCAS broadcast interrogation squitters, allowing the victim to register the spoofed aircraft as equipped with TCAS. The second operation consists of periodic interrogations with UF=16 TCAS resolution messages with the *Vertical RA Complement* (VRC) field set to the opposite of what maneuver they want to impose, e.g., *don't descend* to order a climb. The victim responds to these interrogations with its currently selected RA sense. Finally, once the RA negotiation is started, attackers need to respond to UF=16 interrogations with *Long air-air surveillance* (DF=16) TCAS coordination replies. Such replies indicate to the victim that the spoofed aircraft's chosen maneuver in the *Active RA* (ARA) field is the opposite w.r.t. the attackers' desired outcome, e.g., an ARA field mentioning *currently descending* will make the victim's TCAS issue a climb.

As mentioned previously, there's a basic arbitration mechanism. By choosing an ICAO address lower than the victim's one, attackers can ensure that their resolution advisory will always prevail over the victim's initial decision.

Attack effects. In this example, attackers are tracked by the victim. Following observation of the victim's squitters, they choose the victim's ICAO address-1 as their spoofed aircraft identity. Attackers assume SL=3 and chose a fixed range of 0.15 nm. Similar to the previous example, they replicate the victim's AC as their own. In addition, they are sending UF=16 coordination messages instructing *don't descend* to the victim's TCAS and indicating a descent as its chosen action in DF=16 responses.

Figure 5 shows the resulting RA on the victim's display. Similar to the previous case, an RA is presented as a popup

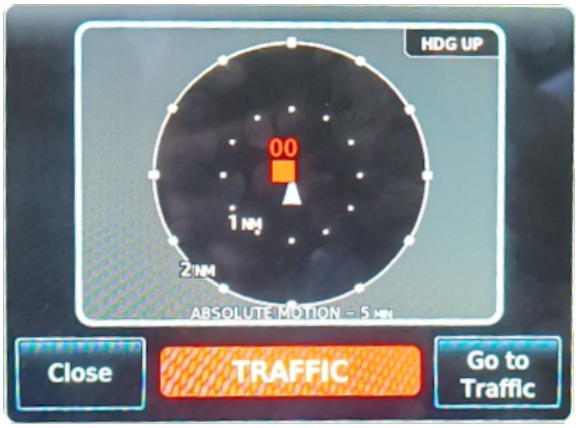

Figure 5: Avionics displaying a Resolution Advisory.

over the instrument screen and is accompanied by an aural indication of its associated action ("*CLIMB CLIMB*"). With respect to the TA case, RAs associate a square symbol to the intruder, and color their indications in red to better convey the urgency of the situation.

5.3 Resolution Advisory Denial-of-Service

According to the protocol, there is an ability to supersede the automatic altitude-based sensitivity level selection with ground-originated Mode S commands.

Specifically, a ground station can issue a *Comm-A Identity Request* (UF=21) directed Sensitivity Level Control (SLC) message containing a candidate sensitivity level. The aircraft, in turn, adjusts its sensitivity settings to the lowest one received from ground stations. This feature was conceived to enable airspace controllers to reduce spurious RAs during procedures with problematic geometries, e.g., parallel approaches. Since SLC messages do not authenticate the issuing ground station, adversaries can manipulate the system into TA-only mode, thereby completely disabling the RA functionality.

(a) Before SLC (b) SLC receipt (c) After SLC

Figure 6: Avionics display during RA DoS.

Figure 6 illustrates the state announcements of the TCAS and the corresponding information displayed on the avionics screen during the attack.

As its initial setup, it is configured to operate normally, i.e., in TA/RA mode (Figure 6a). Attackers identify the victim by listening to its squitters and extracting the corresponding ICAO address. Then, they can impersonate a ground station and send a SLC command directed at the found address. The display shows that the victim has correctly received the com-

mand, as indicated by the *R* in Figure 6b. Once processed by the system, the operating mode is automatically switched to TA-Only mode (Figure 6c), disabling the RA functionality.

If not renewed by a further transmission, standards state that this command should be reset after 240 seconds from its reception to TA/RA mode [37, 2.2.3.10.4]. The above requirement provides adversaries with a significant opportunity, as an attack can be executed and persisted over an extended period with a small number of messages at a very low rate, making detection unlikely.

Moreover, being a *low-and-slow* attack, adversaries can simultaneously engage with multiple aircraft. This capability potentially enables them to further enhance the impact of the attack by easily disabling the RA functionality over a substantial portion of the airspace.

6 TCAS Security Testbed

We design and develop our testbed adhering to the following properties and requirements. A TCAS cybersecurity testbed must be able to facilitate analysis in a *secure* setting, ensuring it does not interfere with the external environment. Additionally, it should be *cost-effective*, eliminating the need to fly an aircraft, and should provide facilities for a consistent and *reproducible* test execution. Finally, its components should be *instrumented* to enable the execution of the experiments and ex-post analysis of the system outputs.

We identify three main components, each composed of multiple constituent elements. The two primary components are the *System Under Test (SUT)* and the entity simulating the TCAS of another aircraft, i.e., the *traffic simulator*. The traffic simulator can also assume the role of the attacker. An additional component, namely the *orchestrator and recorder*, manages the execution of the experiments and records the system outputs. Figure 7 depicts the testbed architecture and its elements. Below, we detail each component.

System Under Test. The core element is a TCAS unit with a radio transponder (XPDR) and processor (PROC). Making this unit operational and testable requires connecting with other elements using avionic data buses. Briefly, the control panel enables its configuration by providing the mode selector switch access. The communication radio, equipped with a headset, and the traffic display provide the outputs from the unit. The former permits the reception of aural warnings, while the latter displays nearby aircraft and related advisories. The execution of the surveillance, TA, and RA functions relies on consistent sensor readings as if the system were in flight. To this aim, an avionic bus simulator provides coherent data, such as the present altitude and velocity. Finally, positioning antennas connected to the radio transceiver inside a Faraday cage prevents unintended transmission of disruptive signals to external sources and complies with the security requirement.

Traffic simulator. This element simulates the presence of other aircraft interacting via radio waves. It contains a workstation (*traffic simulator workstation*) and a linked SDR. On the workstation, an application utilizes the SDR for receiving and transmitting Mode S messages, thereby interacting with the SUT. This application must reliably decode messages, process them, and generate responses coherent with the current condition and desired test scenario. These tasks must be reliably carried out within the $128\,\mu s$ time constraint.

The connected SDR has to feature two independently tunable full-duplex channels, enabling simultaneous downlink and uplink communication. Moreover, it should support highly precise coherent timestamping between reception and transmission and between the two channels. Finally, its sampling rate for each channel has to be higher than its Nyquist rate, i.e. 2 MS/s[2] for the downlink and 4 MS/s for the uplink.

Orchestrator and recorder. The orchestrator and recorder component is responsible for managing the execution of the experiment and capturing measurements from the outputs of the SUT. The *experiment instrumentation workstation* represents the core element.

On the coordination front, it continuously instructs the traffic simulator regarding the specific conditions to simulate. At the same time, it configures the avionic bus simulator to provide data to the avionics buses.

It also captures output data from the TCAS. It records the traffic simulator's current state, representing the desired traffic conditions, and captures the traffic display unit via a camera. Subsequently, image recognition software automatically extracts quantitative data from the raw video feed. This function allows the testbed to align inputs from the traffic simulator with their respective outputs.

7 Implementation

In the following, we will explore the software architecture, adjustments to the operating system, and hardware setup required to overcome the challenges detailed in Section 4.2.

System Under Test. It consists of the elements indicated as "SUT" in Figure 7, with a commercial ARINC 429 bus tester, specifically an Astronics UA2000, as our avionic bus simulator. The TCAS unit consists of a Garmin XPDR model GTX 3000 with GAE 43 and a PROC model GTS 8000. The control panel and traffic display unit, model GTN 750, communication radio, model GMA 342, and antennas, model GA 58, are also from Garmin. Antennas are positioned in a Faraday cage model Ramsey STE3000F2. This setup includes only certified avionic components, all of which, along with their installation, hold a valid airworthiness certificate.

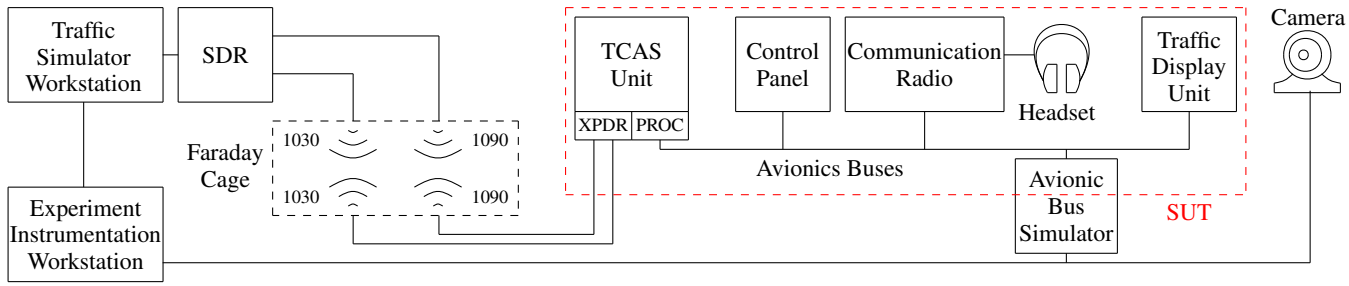

Figure 7: Testbed architecture.

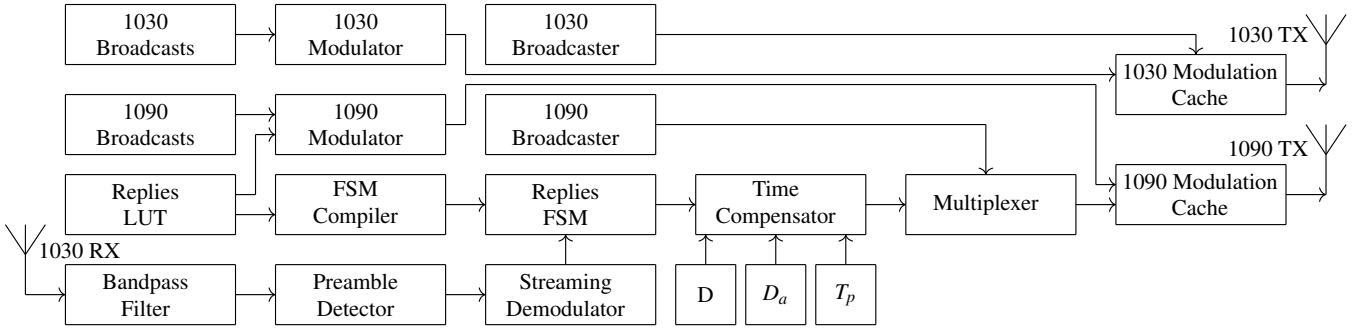

Figure 8: Schematic of the implemented attack software.

Software. A software application was developed to carry out the attacks from this article. Its design aims at handling the interactions described in Section 5, minimizing the reply latency. Its source code consists of 2557 lines of C++ and 15.2K lines of Rust, compiled with GCC 13 and rustc 1.69.

Figure 8 illustrates the architecture of the implemented attack software. Its configuration, continuously updatable from an outside coordinator, is comprised of five parameters:

1. A Replies Lookup Table (LUT) holding UF=x requests and their corresponding DF=x responses, with payload sizes of either 56 or 112 bits.

2. A set of payloads designated for broadcast over the downlink (1090 MHz) frequency (1090 broadcasts), along with their minimum (T_{min}) and maximum (T_{max}) emission intervals.

3. A similar set of payloads for the uplink (1030 MHz) frequency (1030 broadcasts), also governed by T_{min} and T_{max} intervals.

4. The distance D_a between the attacker and the target, as well as the desired distance D of the spoofed aircraft.

5. The estimated processing time T_p.

The system continuously acquires baseband complex quadrature samples at a rate of 20 MS/s from the SDR channel tuned on the uplink frequency. These samples are processed through a Digital Signal Processing (DSP) chain, starting with a bandpass filter and then a fast preamble detector. Given that amplitude modulated pulses identify Mode-S preambles, the detector starts by computing the magnitude of each sample using Single Instruction Multiple Data (SIMD) instructions [25]. It then identifies potential preambles within the received signal by calculating its spectrum using Fast Fourier Transform (FFT) and applying the convolution theorem to calculate its cross-correlation with those characteristic pulses. Candidate preambles are then selected by thresholding their correlation value. The spectrum associated with the pulses is pre-calculated at program startup, halving the number of required FFT calculations.

A streaming demodulator processes each identified preamble and its subsequent samples. This involves frequency and time synchronization, followed by D-BPSK decoding. The resulting bits are then used to navigate the replies Finite State Machine (FSM), looking for prefixes found in the LUT.

Whenever decoded data is unequivocally associated with a LUT entry, the FSM outputs the payload bits to be sent on the downlink frequency. This payload is then timed for transmission based on an interval T relative to the preamble's starting timestamp. T is calculated as given in Equation 5, while T_p is measured by calibrating the system beforehand with self-interrogations.

The system includes two broadcasting elements (1030 and 1090) periodically transmitting payloads (squitters) at random intervals between T_{min} and T_{max}. The broadcasts are managed using a delay queue data structure. A software multiplexer

[2] 1 MS/s = 10^6 samples per second.

handles potential transmission conflicts between the downlink broadcaster and reply transmissions, prioritizing the FSM.

Both the FSM and the broadcasters output bits. These bits are converted into samples using a modulation cache (1030 and 1090 modulation caches) to avoid performing modulation in the attack time-sensitive path. Unique payloads from both the LUT and broadcast lists are pre-modulated by background tasks (1030 and 1090 modulators), which keeps the modulation caches populated and in sync with the configuration. These updates occur without stalling the critical path by leveraging atomic compare and swap operations. Similarly, any update to the LUT prompts a recompilation of the FSM states, which is then introduced into the program's receive path through atomic intrinsics. Finally, the produced samples are sent to the SDR transmission channels.

System configuration and tooling. Our approach involved the strategic implementation of available operating system configurations and the utilization of specialized software tools. We employed a Linux operating system with real-time capabilities (Ubuntu 22.04 with kernel 5.15.0-1032-realtime). Its scheduler was configured to ensure the application was never preempted. We compiled the program with profile-guided optimization and aggressive optimization levels. We pinned the latency-sensitive threads of the application on specific physical cores. Conversely, the kernel threads were moved out of such cores. The application memory was configured to be allocated from huge pages and locked in to prevent swapping. We disabled hardware failure detection interrupts.

Hardware. The attack software ran on an Intel i9-12900k workstation (16 cores running at 5.20GHz). We used an Ettus USRP X300 as our SDR, as it possesses two independently tunable duplex channels with precision timestamping capability, satisfying the requirements outlined in Section 6. Some further tweaks improved the performance: The workstation firmware had all its power-saving features turned off. Unnecessary peripherals and buses in the workstation were removed or disabled to decrease interrupt numbers. The SDR was directly connected to the PCIe bus. We disabled the CPU simultaneous multithreading feature.

8 Evaluation

In this section, we present different experimental evaluations against our TCAS system. We start by assessing the achieved response time and its precision. We also examine whether our implemented optimizations improved these metrics w.r.t. the standalone software. Then, we verify the capability to simulate scenarios with moving aircraft and the accuracy of these simulations. Additionally, we investigated whether stationary injected aircraft scenarios would trigger TAs or RAs and measured the time needed for triggering these alerts. Lastly, we tested the feasibility of the RA DoS attack.

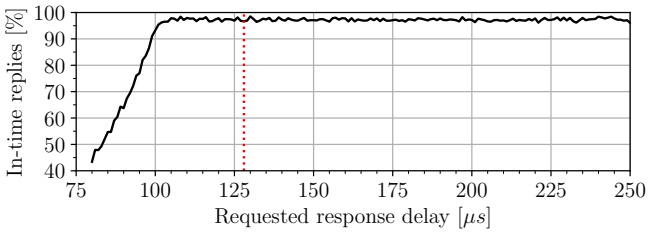

Figure 9: In-time replies as a function of requested delay.

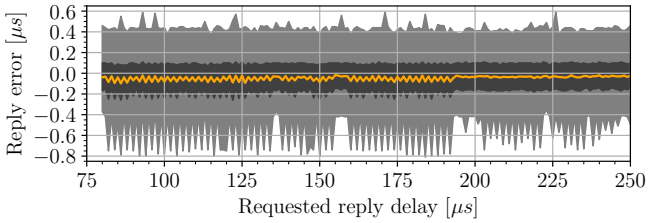

Figure 10: Reply timing precision as requested delay varies.

Reply performance testing. The initial test focused on evaluating timing performance by transmitting a Mode S interrogation, responding to it, and concurrently monitoring the timings using a separate SDR connected to the instrumentation workstation. Response time targets ranging from 80 to 250 μs were tested, with 10,000 samples collected for each target setting. Figure 9 illustrates the percentage of responses received within the desired timeframe. Notably, the success rate begins at approximately 45% around the 80 μs mark and steadily increases to nearly 100% at 100 μs.

Figure 10 illustrates the error envelope, encompassing the min, max, 25th percentile, 75th percentile, and an orange line for the average. These errors consistently stay within a 1.0 μs range, maintaining a stable average around zero. Similarly, Figure 11 displays the Cumulative Distribution Function (CDF) of these errors, demonstrating that the majority remains within a 0.2 μs margin in relation to the desired value.

Figure 12 presents the CDF for jitter, which illustrates the range of delay variations between these responses. The data indicates that the majority of jitter remains below 300 ns.

Effect of optimizations. Figure 13 shows a comparative analysis of response times over 10,000 trials, between the software in its original state and the software after implementing all operating system and hardware modifications. These response times were collected by configuring a target reply time of zero. The analysis reveals that while both distributions exhibit similar patterns, the optimized software's mean response time is reduced by around 45 μs.

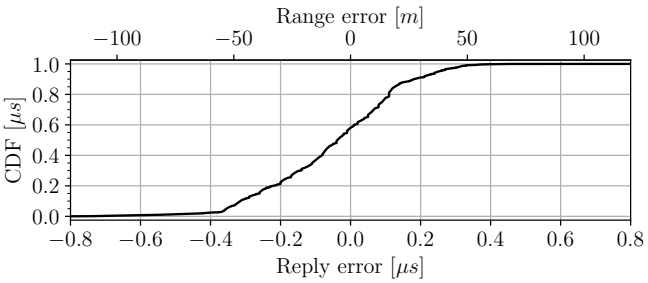

Figure 11: Distribution of reply timing errors.

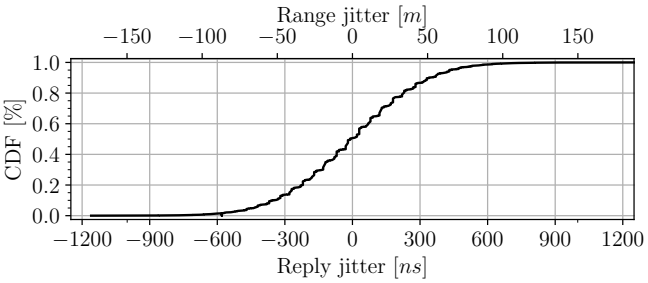

Figure 12: Distribution of reply jitter times.

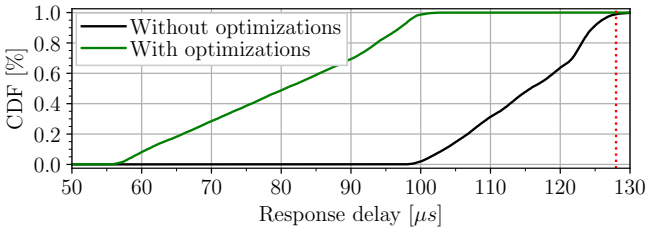

Figure 13: Effects of optimization on reply delay.

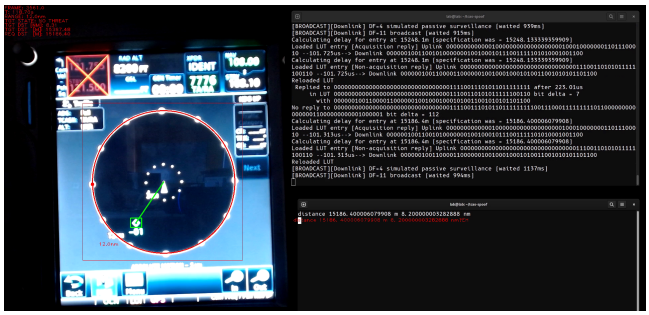

Figure 14: Image recognition applied to the TCAS display.

Moving target scenario. In this test, we simulated an intruder aircraft, commencing the simulation at a distance of 12 nautical miles and advancing towards our location at a steady speed of 100 knots. The data for this experiment was collected by utilizing image recognition techniques on a composite video stream captured from the attack workstation and traffic display. Figure 14 illustrates the computer vision algorithm in action, clearly marking the detected intruder on the avionic display. This procedure was carried out 25 times, resulting in a total of 222,936 data points over a recording duration of 217 minutes. Figure 15 presents a comparison between the desired and observed distance of the moving intruder. The median distance error, depicted in orange, was approx. 125 meters. In Figure 16, we illustrate the distances at which our intruder triggers a TA or an RA. As observed, TAs occur first at approximately 1500 meters, followed by RAs, which occur around the 800-meter mark.

Time delay. For this scenario, we position a static aircraft extremely close, just within the required threshold to initiate a RA. We then monitor the elapsed time of the attack until a TA or RA notification occurs. Figure 17 illustrates the CDF based on 200 repetitions of this scenario. Similar to previous instances, RAs occur after TAs in terms of timing, with TAs taking a maximum of 10 seconds and RAs taking up to 20 seconds to trigger.

RA denial of service. In this test, we transmit the payload detailed in Section 5.3 and interrogate with a separate radio to collect information on the reported sensitivity level. Similar to the display in Figure 18, every sensitivity alteration succeeds immediately upon the TCAS unit receiving the message.

9 Discussion

9.1 Capability Considerations

In relation to the challenges outlined in Section 4.2, our experimental results demonstrate that our implementation consistently and accurately meets the response time requirements using COTS hardware. Furthermore, the applied adjustments and optimizations have effectively and demonstrably decreased this latency. The moving target experiments demonstrated that the precision of reply timing was also maintained over attacks spanning extended periods and distance ranges.

With current hardware and software, attackers can leverage their 28 μs time advantage to fake an aircraft's presence at a distance zero, provided they are within approximately 4.2 km of their victim (Equation 5). With a typical cruise speed of 950 km/h, an aircraft can cover this distance in around 16 seconds, giving attackers a probability of around 80% to successfully execute a RA (Figure 17). As computational power increases, attackers' capabilities will also increase, up to a theoretical limit of 19.186 km, associated with a reply time of zero. Therefore, current cutting-edge COTS hardware has made such attacks feasible, and the attackers' capabilities are expected to continue to grow over time.

As per the RA DoS attack, it can be executed directly and straightforwardly. This simplicity implies that an attacker can initiate this attack even with limited expertise or resources.

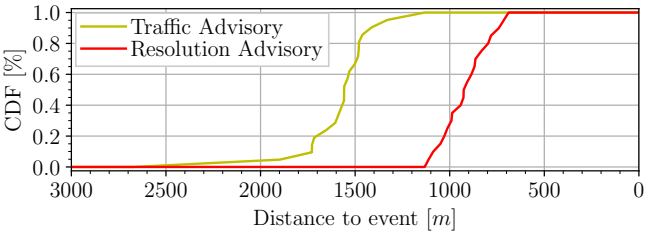

Figure 16: Distance to induce a TA or RA.

9.2 Enabling Factors

In the following, we discuss the enabling factors of the attack based on our experience in its implementation. Briefly, we examine a combination of hardware and software components, and their configurations.

Given that previous attempts used COTS radios attached to workstations similar to ours, we can argue that our success did not stem from any peculiarities in the hardware configuration. In fact, excluding the general requirements set forth in Section 6, our architecture does not rely on any specific radio transceiver.

Instead, the critical difference lies in the software element and our effort to analyze and overcome the limitations of the general-purpose SDR frameworks and standard operating system configurations used in past attempts. Unlike other approaches that utilized multipurpose COTS SDR frameworks like GNURadio [6], which prioritize generality and throughput, our bespoke implementation was designed specifically for low latency and precise timing. For instance, general-purpose frameworks often have buffers built into their processing pipelines, which can improve their throughput, but at the cost of negatively impacting latency — a design choice contrasting with the peculiarities of TCAS communication. Additionally, we made specific changes to the operating system configurations and workstation settings aimed at minimizing delay and jitter. These customizations were crucial in fully exploiting the hardware capabilities to overcome the challenges from Section 4.2, even at the cost of increased energy consumption.

9.3 Limitations

The primary limitations of the attacks detailed in this article are due to their dependency on radio wave transmission. In our controlled experiments, the attacks were conducted without any other device sharing the frequency. However, in actual operational environments, an attacker would face the challenge of developing a more sophisticated receiver system capable of filtering out signals unrelated to the target aircraft.

Transmission-wise, our tests indicated that the attacker's signals must be high enough to be received correctly. This is known as Minimum Trigger Level (MTL) in the standards. In practical terms, the attacker needs a powerful radio transmitter to ensure adequate signal strength and coverage.

Finally, for attacks like the RA injection, it is critical to precisely determine the victim's position and attitude. This task becomes especially challenging due to the high movement speeds associated with aircraft. The complexity escalates if the attacker uses a moving platform, such as a drone, introducing more variables that must be accurately controlled for the attack to succeed.

9.4 Mitigations

Although no practical attacks have been demonstrated in the literature to prove the exploitability of TCAS, general awareness of its possible vulnerabilities has prompted the involved community to evaluate and propose mitigations. These include solutions such as distributed voting algorithms, where aircraft share detected traffic conditions for mutual verification [17], and the integration of encryption to authenticate messages and prevent false aircraft reports [40]. In [17], the authors mention using the radio vertical angle of arrival to verify altitude, providing an additional check before issuing RAs.

Other fields may also inspire viable mitigations. In particular, distance bounding protocols [7, 35] have been used to protect from range spoofing attacks, while Doppler effects have been leveraged to estimate the closure rate of moving transmitters [2, 9, 26, 27, 34].

However, any proposed solution must be evaluated for its

viability. The TCAS specification mandates the acceptance of any correctly addressed message, posing a challenge for the backward-compatible integration of any authorization scheme. As such, enhancements involving protocol changes, while robust, would require widespread adoption and significant changes to existing systems, likely making them infeasible for rapid deployment. Moreover, these changes involve a safety-critical component where false positives are preferred over missed advisories, making them susceptible to downgrade attacks [32], where attackers pose as legacy endpoints unequipped with the security enhancements.

In contrast, modifications that can be implemented per aircraft are progressively deployable and inherently backward compatible. Such solutions involve the integration of physical layer fingerprinting measures on top of the already existing transponder logic. For instance, the proposed vertical angle of arrival calculation is one such method. This enhancement enables cross-checking the declared altitude against the detected angle, quickly identifying discrepancies. Similarly, the analysis of Doppler effects provides an estimated closing rate between aircraft. We deem those two solutions as the most viable as they can significantly increase the difficulty for attackers to spoof aircraft positions effectively. For example, attackers attempting to induce a "DESCEND" RA would be constrained to position their antenna above the victim, inhibiting almost every attack carried out from the ground. Similarly, fooling the Doppler-based solution would require emulating the frequency shift as perceived by the victim, requiring solving the positioning problem also for the derivative of range, i.e., closure rate.

Given our findings, authorities must avoid relying solely on self-reported information in future collision avoidance standards, including ACAS X, until robust security measures are in place. As such, we urge standards bodies to explore incorporating modern wireless security technologies into future collision avoidance systems before they become commonplace. Therefore, an ongoing discussion [51] is contemplating a backward-compatible modification to allow additional data to be transmitted in each Mode-S downlink message, possibly enabling the inclusion of dedicated cryptographic authentication fields.

Interestingly, the ACAS X draft standards inadvertently address the vulnerability to RA DoS attacks by not depending on the SL parameter for their calculations.

Finally, it is worth considering procedural approaches such as awareness for pilots and controllers for the (highly unusual) case of an attack as discussed in [47].

9.5 Ethical Considerations

We disclosed our work and this associated article on submission, and the process is still ongoing. The manufacturers we contacted acknowledged the attack and understood that the vulnerabilities presented in the article are not specific to their devices. They deemed no action necessary on their end, as the attack affected any standards-compliant system. Specifically, Garmin recognized it as a vendor-independent vulnerability. Airbus had prior knowledge of one of the attacks (RA DoS) and had already notified their contacts. The division of Leonardo that manufactures TCAS equipment organized a dedicated meeting to discuss the details of the attack. We are working on a formal collaboration involving our institutions to further test their systems with our tools. Several European national and supra-national authorities and pilot organizations were informed of the results and are in contact with the authors. A dedicated meeting was held with EASA, and they will incorporate our feedback as part of their future decisions on this topic. The Aviation ISAC has forwarded our paper to relevant stakeholders in their disclosure process.

Additionally, we have disclosed our findings to the FAA, Boeing, Pilatus Aircraft, and Thales, although we have yet to receive an acknowledgment from them. We have asked the United States CISA CVD to facilitate further communication.

TCAS will be in use for a long time and no changes are expected. We hope that our work will lead to improvements for ACAS X and future collision avoidance standards.

Attacks on TCAS have been hypothesized before, but by proving their existence and defining the practical parameters and requirements, we hope to improve awareness in aviation. Military actors are likely to have access to toolsets able to attack TCAS, so we need to think about processes and procedures now to not be surprised when an attack happens.

We created our experimental setup such that we followed all local laws regarding radio frequency communication, taking care that no signals leaked outside the setup and the building.

We have chosen not to include the source code for executing the attack in our artifact release, as the potential negative impacts of enabling such capabilities outweigh its value to the research community.

10 Conclusions

This paper presents three wireless attacks against the TCAS. The first two attacks aim at disrupting pilots' situational awareness by inducing a traffic alert. Our study presents the first successful implementation overcoming the well-documented challenges in the realm of TCAS range estimation, which has long served as a de facto physical-layer security feature. Our experimental evaluations demonstrate that we can surpass the required performance metrics, leaving a margin of $28\,\mu s$. We can arbitrarily position the spoofed aircraft in both dynamic and stationary scenarios, consistently inducing the intended effects. The third novel attack causes a DoS simply by using features found in the TCAS protocol. We also discussed potential mitigations but the practical implementation of a countermeasure is still an open problem. We hope that demonstrating the feasibility of the attack will enhance aviation awareness and drive advancements for ACAS X.

Availability

The primary data sets used in this study, including all raw measurements, as well as the scripts used for analysis, are openly available for review and further research. Additionally, supplementary videos providing visual evidence and additional context are also provided.

All these materials can be accessed at [29].

We encourage readers to explore these resources for a more comprehensive understanding of our research and findings.

Acknowledgments

We are grateful for the support of Q.C.M. quality control management AG, who assisted in assembling the testbed. This work was partially funded by the NextGenerationEU project "Security and Rights in CyberSpace" (SERICS). It was carried out while Giacomo Longo was enrolled in the Italian National Doctorate on Artificial Intelligence run by the Sapienza University of Rome in collaboration with the University of Genoa. Giacomo would like to extend his sincere thanks to Daniel, Giorgio, Ivo, Michiel, and his co-authors for their emotional support throughout the project execution.

Abstract

Data race is one of the most common concurrency issues in OS kernels, and it can cause severe problems like system crashes and privilege escalation. Therefore, detecting kernel races is important and necessary. A critical step of kernel race detection is to identify locking rules that which variable should be protected by which lock. However, due to insufficient documents of kernel concurrency, it is challenging to identify accurate locking rules, causing existing approaches to produce many false results in kernel race detection.

In this paper, we design a new static analysis approach named LR-Miner, to effectively detect data races in OS kernels by mining locking rules from kernel code. LR-Miner consists of three key techniques: (1) a field-aware mining method that constructs and statistically analyzes the structure field relation between locks and accessed variables, to mine accurate locking rules from kernel code; (2) an alias-aware checking method to detect data races that violate the mined locking rules; (3) a pattern-based estimation strategy to estimate the security impact of the found races and identify harmful ones. We have evaluated LR-Miner on two popular OS kernels including Linux and FreeBSD, and it finds 306 real races with a false positive rate of 19.9%. Among these found races, 200 are estimated to be harmful, and 61 of them have been confirmed by kernel developers. 10 harmful races have been assigned with CVE IDs.

1 Introduction

To utilize multiple CPU cores in modern computer systems, OS kernel code is often concurrently executed for high performance, but inevitably introducing the risk of concurrency issues. Data race is one of the most common concurrency issues in OS kernels, and it can cause severe problems like system crashes and privilege escalation. Many well-known kernel vulnerabilities [22–25] are caused by data races. For example, Dirty COW [24] is a dangerous vulnerability caused by a data race in memory-management subsystem of Linux kernel. By exploiting Dirty COW, the attacker can maliciously corrupt critical memory and even obtain root privilege. Thus, for security and reliability, detecting data races in OS kernels is important and necessary.

Static analysis is a high-coverage and effective technique of bug detection, without actual execution of the tested program. Many existing approaches [1,2,10,31,32,43,52,61,70] focus on static analysis of user-level applications for race detection. Indeed, different from applications actively executing code, kernel code is often passively executed via system calls invoked by upper-level applications [9,67]. Thus, kernel concurrency is actually caused by application concurrency in many cases, without having explicit operations of thread creation and termination like applications do. However, these existing approaches require such thread operations to perform concurrency analysis, and thus they cannot effectively check kernel code to perform static race detection.

To detect kernel races, a few existing approaches [3, 14, 29, 64, 73, 74] perform static lockset analysis according to kernel concurrency. They assume all the functions can be concurrently executed or require the user to provide guidance about code concurrency, and then use static lockset analysis on concurrent functions to detect races. However, these approaches report many false races, and most of the found real races are benign and thus have no harmfulness. Indeed, their unsatisfactory results are caused by three main limitations:

(L1) They fail to identify accurate locking rules, namely which variable should be protected by which lock. In fact, a data race is often caused by missing necessary lock protection, and thus identifying locking rules is a critical step of race detection. If locking rules are unavailable or inaccurate, static lockset analysis will blindly search code paths and thus produce many false results in race detection. However, due to insufficient documents of kernel concurrency and complicated logics of kernel code [6,54,60], it is difficult for these existing approaches to statically identify accurate locking rules.

(L2) They fail to consider accurate alias relationships in static lockset analysis. Such alias relationships involve both locks and accessed variables, which are main objects handled

by static lockset analysis. If such alias relationships are neglected or inaccurately identified, static lockset analysis will make mistakes in checking the accessed variables protected by the related locks, and thus produce many false results in race detection. However, due to complex data structure usages and complicated control flows in kernel code, it is difficult for these existing approaches to identify and consider accurate alias relationships during lockset analysis.

(L3) They never estimate the security impact of the found races. A data race can be benign or harmful [44, 62]. Benign races are deliberately introduced by developers to improve the efficiency of concurrent execution, and they are expected to cause no security problem when being triggered. Only harmful races have security impact and can cause security problems, and thus identifying such races is valuable for concurrency bug detection. However, these existing approaches fail to check the influence of racy variables on possible code execution, and thus they cannot automatically identify harmful races from the produced results.

To solve the above limitations and improve static analysis of kernel race detection, we propose three key techniques:

(1) Field-aware mining method. To solve *L1*, our method automatically mines accurate locking rules from kernel code, by constructing and statistically analyzing the structure field relation between locks and accessed variables. In OS kernels, data structures are commonly used to share data between concurrent functions [54, 63]. In this case, *a shared variable and its protection lock are often represented as different fields but in the same data structure*. Based on this concurrency feature, our method analyzes each lock usage and variable access involving data structure field, to identify *locking relation*, namely which variable is actually protected by which lock in the code. To improve analysis accuracy of data structure fields, our method identifies locking relations based on *field graphs* that represent access paths [17, 45]. Then, for each variable in locking relations, this method statistically calculates the proportion of the accesses to this variable protected by each involved lock among all the accesses to this variable. If the proportion is large enough, indicating it is very likely that this variable should be protected by the involved lock, which is the *locking rule* mined by our method. Such locking rules are used for subsequent kernel race detection, and they can also help improve the documents of kernel concurrency.

(2) Alias-aware checking method. To solve *L2*, our method performs static lockset analysis to detect data races that violate the mined locking rules. To improve accuracy, our method performs flow/context/field-sensitive and inter-procedural alias analysis, to identify and utilize accurate alias relationships involving both locks and accessed variables. To improve efficiency, our method creates and uses function summaries containing alias relationships to perform inter-procedural checking. Moreover, our method performs SMT-based validation of code-path feasibility for each reported race, to reduce false positives in race detection.

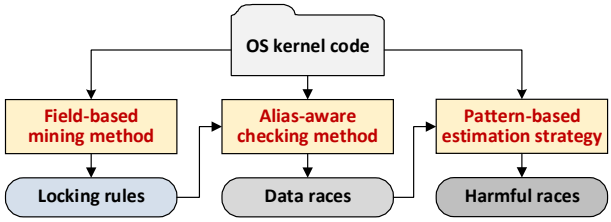

Figure 1: LR-Miner workflow.

(3) Pattern-based estimation strategy. To solve *L3*, our strategy checks the racy-variable usage of each reported race, based on some representative patterns that can cause security bugs like null-pointer dereferences, double fetch issues, etc. Our strategy can automatically estimate the security impact of the reported races and identify harmful ones.

Based on the above three techniques, we design LR-Miner (Locking Rule Miner), a new static analysis approach, to effectively detect data races in OS kernels by mining locking rules from kernel code. LR-Miner has three stages shown in Figure 1. LR-Miner first uses our field-aware mining method to mine accurate locking rules from the kernel code; then uses our alias-aware checking method to detect races according to the mined locking rules; and finally uses our pattern-based estimation strategy to identify harmful races from the found races. We have implemented LR-Miner with LLVM [53], and it performs automated analysis on the LLVM bytecode. Overall, we make three technical contributions in the paper:

- To improve static analysis of kernel race detection, we propose three key techniques: (1) a field-aware mining method that constructs and statistically analyzes the structure field relation between locks and accessed variables, to mine accurate locking rules from kernel code; (2) an alias-aware checking method to detect data races that violate the mined locking rules; (3) a pattern-based estimation strategy to estimate the security impact of the found races and identify harmful ones.
- Based on these key techniques, we design a novel static analysis approach named LR-Miner, to effectively detect kernel races by mining locking rules from kernel code. To our knowledge, *LR-Miner is the first systematic static analysis approach that detects kernel races by mining accurate locking rules and identifies harmful races*.
- We have evaluated LR-Miner on two popular OS kernels including Linux and FreeBSD. It in total mines 2.7K locking rules from kernel code, and finds 306 real races with a false positive rate of 19.9%. Among the found races, 200 are estimated to be harmful as they can cause security problems, and 61 of them have been confirmed by kernel developers. 10 harmful races have been assigned with CVE IDs. We also perform experimental comparison to multiple existing static approaches of kernel race detection (including Relay [74], RacerX [29] and CPALockator [3]). The results indicate that LR-Miner finds many real races missed by these approaches, with fewer false positives.

2 Background and Motivation

In this section, we first introduce kernel race and its static detection, then study data structure usages for kernel concurrency, and finally introduce how to use locking rules in static analysis for kernel race detection.

2.1 Kernel Race and Static Detection

Kernel race. To guarantee the correctness and security of kernel concurrency, a shared variable accessed by concurrently-executed threads should be protected by necessary synchronization primitives like locks. Otherwise, when at least one thread writes the shared variable during concurrent accesses, a data race can occur, causing the value of this shared variable to be uncertain.

In fact, a data race can be benign or harmful [44, 62]. Benign races are deliberately introduced by developers to improve the efficiency of concurrent execution, and they are expected to cause no security problem when being triggered. In comparison, harmful races are dangerous and can cause security problems. These harmful races may corrupt critical kernel data and affect important execution paths, and thus can lead to system crashes, privilege escalation, etc. Many well-known kernel vulnerabilities [22–25] are actually caused by data races. Thus, for security and reliability, detecting data races in OS kernels is important and necessary.

Static detection of kernel races. Static analysis is a popular and effective technique of bug detection, and it can conveniently analyze all the possible code paths of the tested program without actual execution. For this reason, static analysis can achieve higher detection coverage and find many bugs missed by runtime testing. In fact, many existing approaches of static analysis have produced promising results of kernel bug detection, but most of them [8, 34, 51, 57, 59, 71, 76, 85] focus on detecting bugs in sequential code, and thus cannot detect kernel races in concurrent code.

A few existing approaches [3, 14, 29, 64, 73, 74] use static lockset analysis to detect kernel races, but they report many false races, and most of the found real races are benign and thus have no harmfulness. Indeed, their unsatisfactory results are caused by three main limitations: *(L1)* lacking the identification of accurate *locking rules* (namely which variable should be protected by which lock), *(L2)* neglecting accurate alias relationships in static lockset analysis, and *(L3)* lacking the estimation about the security impact of the found races.

Among the three limitations, we believe *L1* is the most important one, because locking rules directly reflect kernel concurrency and thus determine basic analysis process of race detection. However, there are lots of variables and locks in kernel code, and thus it is error-prone and time-consuming to consider all these variables and locks when identifying locking rules. *L2* heavily affects the accuracy of race detection, and *L3* is related to the importance of the found races.

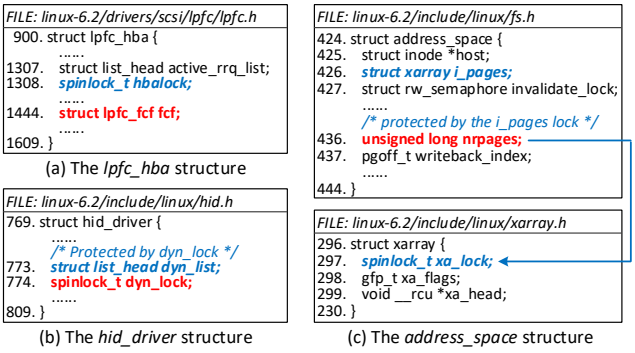

Figure 2: Example structures about kernel concurrency.

2.2 Structure Usages for Kernel Concurrency

In OS kernels, data structures are commonly used to share data between concurrent functions [54, 63]. In this case, *a shared variable and its protection lock are often represented as different fields but in the same data structure*. Figure 2 shows three examples of this concurrency feature in Linux:

In Figure 2(a), the structure `lpfc_hba` is used by Linux *lpfc* SCSI drivers. In this structure, the lock field `hbalock` actually protects some other fields, including `fcf`, according to code implementation and our discussion with kernel developers.

In Figure 2(b), the structure `hid_driver` is used by the human interface drivers in the Linux kernel. In this structure, the lock field `dyn_lock` protects the list field `dyn_list`, as described in its definition comment.

In Figure 2(c), the structure `address_space` is used by the filesystems in the Linux kernel. In this structure, the integer field `nrpages` is protected by the lower-layer nested field `i_pages->xa_lock`, as described in its definition comment.

We believe this feature can help to describe locking rules in a simpler way, without considering all the accessed variables and locks in kernel code. Specifically, when a lock and a variable are different fields in the same data structure, they may have protection relation. In this way, ***a locking rule is specifically described as: which data field should be protected by which lock field***. As for the accessed variable and locks in unrelated data structures, we consider that they have no protection relation and thus neglect them when identifying locking rules. Though using this simpler way, identifying locking rules from kernel code still has two main difficulties:

(D1) As shown in Figure 2(b) and Figure 2(c), the code comments clearly describe the locking rules of some structure fields. However, many parts of kernel code are not sufficiently commented or documented [6, 54, 60] (Figure 2(a) is such an example that has no code comment about locking protection), and thus just analyzing code comments and kernel documents is insufficient and infeasible to identify locking rules.

(D2) As shown in Figure 2(a) and Figure 2(b), the lock field and its protected data field are in the same layer of data structure. However, this phenomenon is not always correct. For example, as shown in Figure 2(c), the protection lock

```
FILE: linux-6.2/drivers/scsi/lpfc/lpfc_hbadisc.c
1230. int lpfc_linkdown(struct lpfc_hba *phba)
      ......
1251.   spin_lock_irq(&phba->hbalock);
1252.   phba->fcf.fcf_flag &= ...;
1253.   spin_unlock_irq(&phba->hbalock);
      ......
1323. }
```

```
FILE: linux-6.2/drivers/scsi/lpfc/lpfc_hbadisc.c
1597. void lpfc_mbx_cmpl_reg_fcfi(struct lpfc_hba *phba, ...)
      ......
1612.   spin_lock_irq(&phba->hbalock);
1613.   phba->fcf.fcf_flag |= ...;
1614.   spin_unlock_irq(&phba->hbalock);
      ......
1640. }
```

```
FILE: linux-6.2/drivers/scsi/lpfc/lpfc_hbadisc.c
1858. void lpfc_register_fcf(struct lpfc_hba *phba)
      ......
1864.   spin_lock_irq(&phba->hbalock);
1865.   if (!(phba->fcf.fcf_flag & ...)) {...}
1886.   spin_unlock_irq(&phba->hbalock);
      ......
1908. }
```

```
FILE: linux-6.2/drivers/scsi/lpfc/lpfc_hbadisc.c
6961. void lpfc_unregister_fcf_rescan(struct lpfc_hba *phba)
      ......
        // No protection of phba->hbalock!
6979.   phba->fcf.fcf_flag = 0; // Race!
      ......
7009. }
```

Figure 3: Example of locking rule usage.

field `i_pages->xa_lock` is a lower-layer nested field of the data field `nrpages`, but they are both in the same structure `address_space`. Thus, it is necessary to consider different layers of nested structures when identifying locking rules.

2.3 Race Detection Using Locking Rules

We illustrate how to utilize locking rules for kernel race detection, by using the *lpfc* SCSI driver in Linux 6.2. From Figure 2(a), we have a locking rule that the data field `fcf` should be protected by the lock field `hbalock` in the structure `lpfc_hba`. In Figure 3, the three functions `lpfc_linkdown`, `lpfc_mbx_cmpl_reg_fcfi` and `lpfc_register_fcf` all protect the variable `phba->fcf.fcf_flag` using the lock `phba->hbalock`, and thus they conform to the locking rule. However, in the function `lpfc_unregister_fcf_rescan`, the variable `hba->fcf.fcf_flag` is not protected by the lock `phba->hbalock` in any calling context of this function, which violates the locking rule, and thus a data race occurs. This race is found by our approach LR-Miner, and has been confirmed and fixed by the related kernel developers.

Inspired by the example, we can detect kernel races by checking the lock usages and variable accesses according to locking rules; if there is a violation of the rules, a possible data race will be reported. However, achieving this idea still faces three main challenges:

(C1) How to identify accurate locking rules? As described in Section 2.2, identifying locking rules is difficult, due to insufficient kernel documents/comments and complex structure layers. LockDoc [54] is the sole existing systematic approach of identifying locking rules in OS kernels for race detection, and it is based on dynamic analysis. It analyzes the execution traces of the provided workloads, to identify locking rules. However, due to the limited code coverage of the provided workloads, LockDoc misses many execution situations for the analyzed traces, which affects the accuracy of the mined locking rules. In our opinions, static analysis can conveniently analyze all the possible execution situations without actual kernel execution, so it can be used to identify accurate locking rules. RacerX [29] is the sole static approach that can identify simple locking rules from kernel code, but its used techniques (like field-insensitive and non-alias analysis) are imprecise and non-systematic for locking-rule mining, and thus it has a high false positive rate of over 40% in its race-detection experiments. As a result, it is important but challenging to systematically mine *accurate* locking rules in OS kernels.

(C2) How to effectively check locking rules? In kernel code, due to heavy use of pointers and data structures, the alias relationships between variables can be very complex. On the one hand, if such alias relationships are neglected or inaccurately identified when checking locking rules, many false results would be produced in race detection. On the other hand, the OS kernel is large-size and has lots of functions, and thus checking locking rules by identifying and considering accurate alias relationships can be quite time-consuming. For these reasons, improving both the accuracy and efficiency of locking-rule checking with alias relationships is challenging for kernel race detection.

(C3) How to identify harmful races from the results? As described in Section 2.1, a data race can be benign or harmful, and only harmful races can cause security problems. Several approaches [44, 56, 62, 77] control thread scheduling and analyze execution traces of the tested programs, to reproduce the given races and estimate their security impact. However, because thread scheduling of concurrent programs has much non-determinism, these approaches cannot always stably reproduce and effectively analyze all the given races. In our opinions, static analysis is a feasible way of identifying harmful races, because it does not require race reproduction and can achieve high analysis coverage. However, we find that this way has not been well explored so far.

3 Key Techniques

To address the three main challenges mentioned in Section 2.3, we propose three key techniques. For *C1*, we propose a *field-aware mining method* that constructs and statistically analyzes the structure field relation between locks and accessed variables, to mine accurate locking rules from kernel code. For *C2*, we propose an *alias-aware checking method* to detect data races by checking whether a variable access violates the mined locking rules. For *C3*, we propose a *pattern-based estimation strategy* to estimate the security impact of the found races and identify harmful ones. We will introduce these three techniques as follows:

3.1 Field-Aware Locking-Rule Mining

Method design. We design our method inspired by an existing dynamic analysis approach LockDoc [54], which analyzes the execution traces to identify locking rules about structure fields. Similar to LockDoc, our method has two basic steps: *(S1)* It first analyzes each lock usage and variable access involving data structure field, to identify *locking relation*, namely which data field is actually protected by which lock field in the code. *(S2)* For each data field in locking relations, it statistically calculates the proportion of the accesses to this data field protected by each involved lock field among all the accesses to this data field; if the proportion is large enough, it considers that this data field should be protected by the involved lock field, which is a mined locking rule.

However, our method is based on static analysis, and has two significant differences compared to LockDoc:

(1) LockDoc requires the user to provide various workloads for trace analysis; but due to limited code coverage of these workloads, LockDoc misses many execution situations for the analyzed traces, which affects the accuracy of the mined locking rules. To solve this problem, our method should statically mine locking rules from kernel code, without the requirement of workloads or execution traces.

(2) LockDoc never considers nested structures, so it cannot identify the locking rules involving the fields in different layers of nested structures. However, such locking rules are common in kernel code, like the example in Figure 2(c). To mine such locking rules, our method should accurately analyze the fields in different layers of nested structures. For this purpose, we use a new description form named *field graph* to describe the relation between each data field and lock field in structures (including nested ones).

Field graph. This form is based on access path [17, 45], to represent the relations between different structure fields (including nested ones). We introduce it as follows.

A field graph is defined as $FG =< N, E >$, where N is a set of nodes, and each node represents a field. Note that a field can be in the lower-layer structure. E is a set of edges, and each edge is labeled with a field and represents how a lower-layer field is accessed from a higher-layer structure. For convenience, a basic data type like *char*, *int* or *float* is regarded as a special structure that only contains a single field. For a nested structure with multiple layers, accessing a lower-layer field from a higher-layer structure can be expressed as an access path from the node representing the higher-layer structure to the node representing the lower-layer field. Fields in different functions with the same access path are regarded as identical fields. In a field graph, two fields in different layers are in the same structure if the nodes representing them have a common ancestor.

Field graph is updated by handling each arrow operator (->) and dot operator (.). For example, for each instruction like $v_2 = v_1$->f, our method inserts an edge labeled with f from

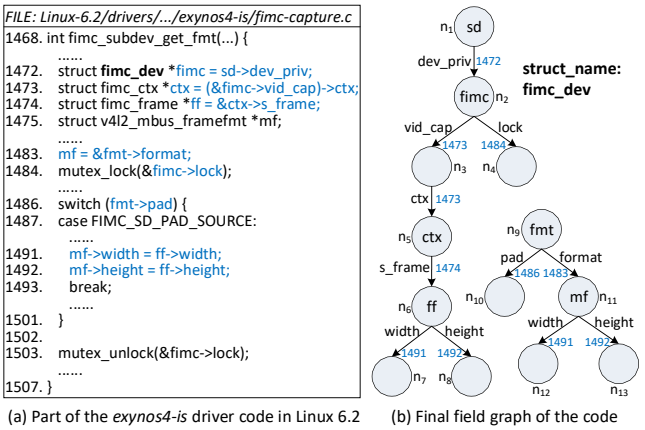

Figure 4: Example of field graph.

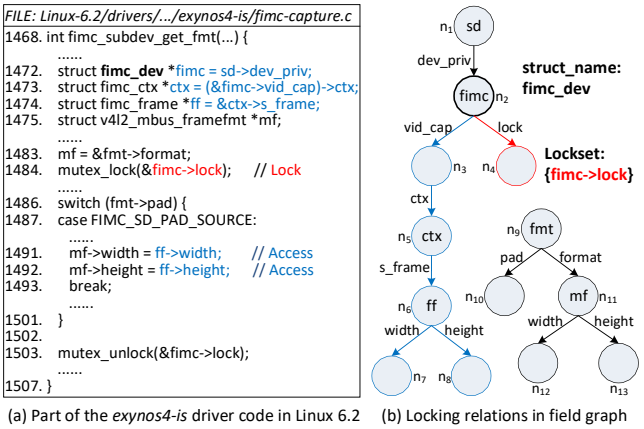

the node representing v_1 to the node representing v_2. After this operation, v_2 can be expressed as an access path $v_1.f$

Example. Figure 4(a) shows a part of the *exynos4-is* driver code in Linux 6.2. We use this example to illustrate how to build a field graph and how to check whether two fields in different layers are actually in the same structure with the built field graph. Take the instruction `fimc = sd->dev_priv` at Line 1472 as an example, it gets the field `dev_priv` of `sd` (represented by n_1), and then assigns this field to `fimc` (represented by n_2), so our method inserts an edge labeled with `dev_priv` from n_1 to n_2, indicating that the lower-layer field `fimc` can be accessed through the access path `sd.dev_priv` from the higher-layer structure `sd`. After handling all arrow operators in the code, our method figures out the final field graph shown in Figure 4(b). Take the fields `ff->width` and `fimc->lock` as an example, they are represented by n_7 and n_4 separately, and these two nodes have a common ancestor n_2 which represents the higher-layer structure named `fimc_dev`. Therefore, the two fields are identified to be in this common structure. To indicate the relation between the two fields, we use access paths to them from their common ancestor (namely `fimc_dev.vid_cap.ctx.s_frame.width` and `fimc_dev.lock`) to represent these fields. For convenience, in the remaining examples of this paper, the inner access path `vid_cap.ctx.s_frame` is omitted, and the structure fields such as `fimc_dev.vid_cap.ctx.s_frame.width` will be represented as `fimc_dev...width`.

S1: Locking relation construction. Based on field graph, locking relations can be identified by checking whether the accessed variable of each variable-access instruction is in the same data structure with the held locks. To get the held locks at each variable-access instruction, our method performs a static lockset analysis. Typically, lockset analysis maintains a set of locks held at each program site, and updates the set according to lock-acquire/release function calls. Specifically, when encountering a lock-acquire function call, our method adds the acquired lock of this call into the lockset; and when encountering a lock-release function call, our method drops

```
CollectLockingRelation(func)
Input: func – Analyzed function in the kernel code
Output: LR_set – Set of the collected locking relations
 1:  field_graph := ∅;
 2:  lock_set := ∅;
 3:  LR_set := ∅;
 4:  foreach code path cp in func do
 5:    foreach instruction inst in cp do
 6:      if inst is a lock-acquire/release function call then
 7:        lock_set := LockSetAnalysis(inst);
 8:      else if inst is an arrow operation then
 9:        field_graph := UpdateFieldGraph(inst);
10:      else if inst is a variable-access instruction then:
11:        var := GetAccessedVariable(inst);
12:        access_type := GetAccessType(inst);
13:        foreach lock in lock_set do
14:          anc := FindCommonAncestor(var, lock, field_graph);
15:          if anc is not NULL then
16:            AP_var := GetAccessPath(var, anc, field_graph);
17:            AP_lock := GetAccessPath(lock, anc, field_graph);
18:            insert [<AP_var, AP_lock>, access_type, cp] into LR_set;
19:          end if
20:        end foreach
21:      end if
22:    end foreach
23:  end foreach
24:  return LR_set;
```
