A Appendix

A.1 Provider Interview Protocol

Below are the questions which serve as a basis for our interviews with providers of circumvention tools, as discussed in §4.2.

Q1. What is your expertise around circumvention tools? What is your job? Are you a developer, distributor, or operator of a tool? *Self-describe your role in the Internet freedom community.*

Q2. What type of tools do you recommend to users? Here, users are persons with average computer skills who come to you for advice on using circumvention tools. *Here, users are persons with average computer skills who come to you for advice on using circumvention tools.*

Q3. If you develop your own tools or operate proxies that you provide access to others, what are the different ways you reach users experiencing censorship? What are usually the different channels used to share and tell others about circumvention tools?

Q4. Say a tool malfunctions/goes down in a particular region, what steps do you take to first understand the censor's actions and What steps do you take to debug it and fix it?

Q5. What are the different ways you gain trust with your community and what role does trust play in your community? *For example, does trust matter? Or users are generally OK with even "free VPNs"*

Q6. Following previous question, what are some of your red flags and concerns when it comes to circumvention tools? What would make you NOT want to use/recommend a particular tool?

Q7. What are some usability issues you have seen users struggle with?

Q8. In your words, what are the main problems circumvention tool developers and distributors face? What are the main issues in this ecosystem?

Q9. What types of questions would you ask users experiencing censorship to understand the main issues that users have?

Q10. Is there anything else you want to emphasize or add?

A.2 User Interview Protocol

Below are the questions which serve as a basis for our interviews with users of circumvention tools, as discussed in §4.2.

Q1. What comes to mind when you think about your experience with censorship?

Q2. Walk us through what the process of finding and using a circumvention tool looks like for you?
- Was it free or paid?
- What features made you want to use them?

Q3. What does your journey of using the tool look like? Similarly, do you only use it for a certain category of sites? *Is it turned on all the time on your computer? Or on the family computer etc...?*

Q4. At any point, did the tool become unavailable/unusable and when that happens what steps do you take to debug it and fix it?

Q5. Typically how do people in your circles find a CT? What are usually the different channels used? *Examples include sharing via encrypted messaging services, local methods such as USB sharing, etc...*

Q6. How much trust do you have in the developers of these CTs, what are some ways or signals you use to put trust in them?

Q7. What are some of your red flags and concerns? What would make you not want to use these CTs? *Examples include, worry about government honeypots, fake tools that want to scam, etc...*

Q8. Do you notice the Internet behaving differently near sensitive events? *How do you prepare for these events?*

Q9. Have you helped friends/family use CTs?

- What are the technical issues you have seen yourself or have seen friends and family struggle with?
- What are some usability issues you struggled with?
- How accessible are these tools to non-technical people?

Q10. Lets say we have direct connections to people that develop these tools, what are a few problems that you can enumerate and say, if we solved these problems, that would make it easier? Ideally what issues would you like to see solved? What issues make tools unusable for you?

Q11. How should operators of CT typically try to advertise their tool?

Q12. What types of questions would you ask users experiencing censorship to understand how these tools are used and identify the main issues users have?

Q13. Before we leave, can we get some demographic information – can you confirm for us your gender identities, and age range?

A.3 Consent Form

Consent Form. Below is the consent form shown to participants before the start of the interview. We receive verbal confirmation that they understand before proceeding with the questions, as discussed in §4.3.

- I, _____, voluntarily agree to participate in this research study.
- I understand that even if I agree to participate now, I can withdraw at any time or refuse to answer any question without any consequences of any kind.
- I understand that I can withdraw permission to use data from my interview within two weeks after the interview, in which case the material will be deleted.
- I have had the purpose and nature of the study explained to me in writing and I have had the opportunity to ask questions about the study.
- I understand that participation involves understanding and answering questions about my experience with internet censorship and circumvention tools.
- I understand that I will not benefit directly by participating in this research.
- I agree to note taking occurring during my interview.
- I understand that all information I provide for this study will be treated confidentially.
- I understand that insights gained from my interview may be quoted in a published research paper, conference presentations, and research reports.
- I understand that if I inform the researcher that myself or someone else is at risk of harm they may have to report this to the relevant authorities — they will discuss this with me first but may be required to report with or without my permission.
- I understand that under freedom of information legalization I am entitled to access the information I have provided at any time while it is in storage as specified above.
- I understand that I am free to contact any of the people involved in the research to seek further clarification and information.

Fingerprinting Obfuscated Proxy Traffic with Encapsulated TLS Handshakes

Diwen Xue* Michalis Kallitsis† Amir Houmansadr ‡ Roya Ensafi*
*University of Michigan †Merit Network, Inc. ‡ University of Massachusetts Amherst

Abstract

The global escalation of Internet censorship by nation-state actors has led to an ongoing arms race between censors and obfuscated circumvention proxies. Research over the past decade has extensively examined various fingerprinting attacks against individual proxy protocols and their respective countermeasures. In this paper, however, we demonstrate the feasibility of a protocol-agnostic approach to proxy detection, enabled by the shared characteristic of nested protocol stacks inherent to all forms of proxying and tunneling activities. We showcase the practicality of such an approach by identifying one specific fingerprint–encapsulated TLS handshakes–that results from nested protocol stacks, and building similarity-based classifiers to isolate this unique fingerprint within encrypted traffic streams.

Assuming the role of a censor, we build a detection framework and deploy it within a mid-size ISP serving upwards of one million users. Our evaluation demonstrates that the traffic of obfuscated proxies, even with random padding and multiple layers of encapsulations, can be reliably detected with minimal collateral damage by fingerprinting encapsulated TLS handshakes. While stream multiplexing shows promise as a viable countermeasure, we caution that existing obfuscations based on multiplexing and random padding *alone* are inherently limited, due to their inability to reduce the size of traffic bursts or the number of round trips within a connection. Proxy developers should be aware of these limitations, anticipate the potential exploitation of encapsulated TLS handshakes by the censors, and equip their tools with proactive countermeasures.

1 Introduction

The recent decades have witnessed a global escalation in censorship and surveillance by various nation-state actors [76]. Among the most notorious examples is China, where the Great Firewall (GFW) has been blocking foreign websites, filtering search results, and interfering with private communications [14,28,58,74]. In Iran, the government blocks social media and throttles targeted protocols during periods of political unrest [12,34,35]. In Russia, "Sovereign Internet" prevents access to news and media during the Ukraine war, demonstrating how easily censors can create information bubbles and isolate specific regions from the broader Internet [75,90].

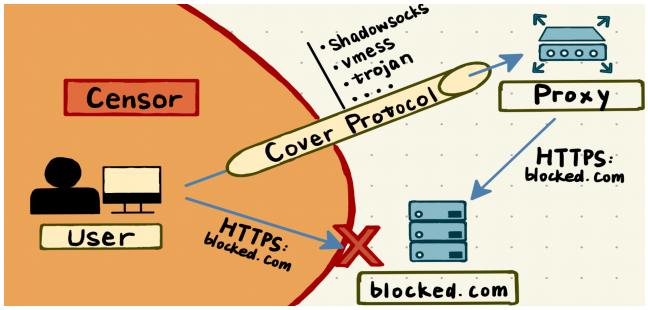

Figure 1: **Channel-based Circumvention.** Users' traffic is encapsulated within a cover protocol in order to pass through censors without being directly exposed. Figure inspired by [49].◇

In reaction to such escalating censorship measures, users have resorted to proxying and tunneling tools. As shown in Figure 1, users in censored regions encapsulate their application traffic within a *cover* (i.e., proxy) protocol and transmit it to a proxy server outside the censor's jurisdiction, which then forwards the traffic to its destination. The cover protocol encrypts its payload, so that application traffic containing censored keywords does not trigger blocking. This strategy, referred to as "channel-based circumvention" by previous work [78], necessitates obfuscation over the cover protocol – otherwise, the channel itself could be fingerprinted and blocked. Over the past decade, the circumvention community has developed numerous obfuscation approaches, either making the channels look like protocols that are allowed [4,39,45,66], or disguising the channels to ensure they do not resemble protocols that are prohibited [19,27,30].

On the other hand, advancements like carrier-grade deep packet inspection (DPI) have enabled censors to evolve from basic IP or keyword filtering to more sophisticated modes of detection. This has led to an ongoing arms race between circumvention proxies, who implement obfuscation mechanisms to avoid detection, and censors, who aim to see through such obfuscation: censors use active probing to identify proxy servers, driving proxies to implement probe-resistance mechanisms [46, 52, 86]. Censors block circumvention proxies by their unique TLS ciphersuites [2, 51, 86], in response to which proxies change their ciphersuites to mimic mainstream browsers [53]. Censors block fully encrypted proxies based

on high entropy [89]. Proxy developers then modify the byte patterns to show less entropy [11, 20]. Such back-and-forth interactions represent the current state of the circumvention arms race, with censors exploiting the design and implementation flaws of individual cover protocols, and developers patching the flaws and experimenting with new protocols. A common assumption shared in the community is that each new cover protocol requires its own unique set of features and separate analysis by the censor to block [20].

What we demonstrate in this paper, however, is the feasibility of a *protocol-agnostic* approach to proxy detection. We observe that, despite the varying designs and implementations of cover protocols, the fundamental concept underpinning all forms of proxying and tunneling is that of nested protocol stacks, where one protocol stack is encapsulated within the payload of another. For example, users' web browsing traffic (HTTPS) can be encapsulated within another TLS or application-layer protocol, which serves both as a cover and transport for the former, in order to pass through censors without being directly exposed. The near-universal presence of nested protocol stacks in proxied connections, contrasted with the rarity of finding such behavior in direct client-server communications, establishes them as a fingerprinting vulnerability that is shared across various proxy protocols and is orthogonal to existing attacks and countermeasures.

In this paper, we focus on one specific fingerprint of this kind, termed as *encapsulated TLS handshakes*, and the practicality of exploiting it in detecting obfuscated proxy traffic. Encapsulated TLS handshakes refer to TLS handshakes that take place within an encrypted or obfuscated cover protocol. As shown in Figure 2 (red), these handshakes are generated by user applications (e.g., browsers), and the proxy protocol then encrypts and transports them to the proxy server, which in turn forwards them to the final destination (e.g., web servers). This differentiates them from standard TLS that has plaintext structures and is visible to network intermediaries. We explain how the presence of encapsulated TLS handshakes indicates nested or redundant protocol stacking, which in turn signals that the connection carries proxied traffic. While encapsulated TLS handshakes cannot be easily identified by protocol parsers, we show that the packets exchanged during an (encapsulated) TLS handshake exhibit distinct patterns in their size, timing, and direction. These patterns remain visible even after encryption, enabling a censor to reliably identify encapsulated handshakes without breaking the encryption of the cover protocol.

We evaluate the practicality of fingerprinting obfuscated proxy traffic with encapsulated TLS handshakes, from the perspective of a censor or an adversarial ISP. We aim to answer: *How practical is this fingerprinting attack? Can censors deploy it at scale without significant collateral damage?* Addressing these questions requires not only identifying a vulnerability but also demonstrating feasible exploits, all while considering the real-world operating constraints of the censors, such as their sensitivity to false positives. To this

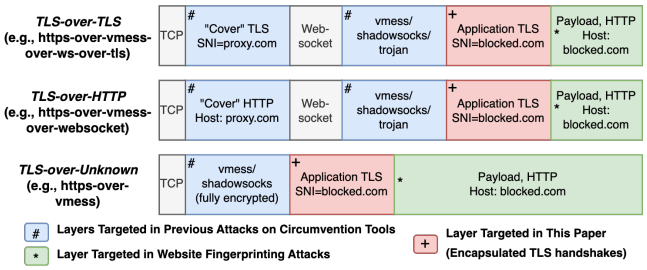

Figure 2: **Comparison with previous attacks on circumvention tools.** Prior work targeted cover or proxy protocol's failure to achieve indistinguishability, while this paper exploits fingerprints of the encapsulated layers within, which are agnostic to proxy protocols.◇

end, we develop a detection framework using similarity-based classifiers, following a *conservative* censor capability model informed by empirical studies on real-world censorship events. Next, in collaboration with *Merit*, we deploy our framework within the ISP's network, adopting the position of a censor to evaluate the potential impact and collateral damage if the fingerprinting attack were to be widely deployed.

We test 23 obfuscated proxy configurations, including major circumvention protocols used by millions around the world like *shadowsocks*, *vmess*, *trojan*, and *vless*, and protocols proposed in previous research like *httpt* [19, 25, 27, 54]. We find that *all* tested obfuscated proxy protocols, in their standard configurations, are vulnerable to fingerprinting based on encapsulated TLS handshakes, with true positive rates (TPRs) all exceeding 70%. Such TPRs carry significant implications (§ 3), especially as a single detection can result in a censor blocking all subsequent connections to the corresponding proxy server. Even advanced configurations that encapsulate proxy traffic within additional cover layers, such as *shadowsocks* within websocket within TLS, provide limited defense and only marginally lower the detection rates. Contrary to common belief, we find that random padding slightly increases the fingerprinting difficulty, but not to a degree sufficient to prevent the exploit. Even for more aggressive padding schemes like *XTLS-vision* and *obfs4*, we demonstrate that censors could easily adapt their statistical models and rely only on packet order and direction, rather than size, for detection.

During a 30-day evaluation, our deployment within *Merit* processed over 110 million flows, maintaining an upper-bound false positive rate as low as 0.0544%. Such precision positions our fingerprinting attack on par with approaches previously deployed by real censors [89]. Notably, our technique remains fully passive, agnostic to unpadded obfuscated protocols, and can be adapted to identify padded variants.

Obfuscated proxies are essential tools for facilitating unrestricted access to information and resources on the Internet. However, our findings suggest that traffic of obfuscated proxies, even with padding and layers of encapsulation, can be effectively detected by fingerprinting encapsulated TLS handshakes. Our approach shifts the focus from the cover layer to the encapsulated layers within, introducing a new threat di-

mension that is orthogonal and potentially complementary to existing attacks against circumvention tools. While we show that stream multiplexing could be a viable mitigation, we caution that obfuscations relying solely on padding and multiplexing are inherently limited. Proxy developers should be aware of the limitations of current obfuscation strategies, anticipate the potential exploitation of encapsulated TLS handshakes by censors, and equip their tools with proactive countermeasures.

2 Background & Related Work

2.1 Internet Censorship and Circumvention

News, anecdotes, and measurement studies collectively suggest that governments have been increasingly censoring the Internet on a global scale [68, 73, 76]. These studies document how governments practice censorship and, in particular, censors' technical capabilities, ranging from blanket IP-based blocking [24,47,69], content-based blocking [40,58,70,74], to blocking of protocols and circumvention tools [32, 46, 86, 89, 90]. In addition to exposing otherwise covert practices of Internet censorship, these measurement studies contribute to the understanding of real-world censors and assist in approximating a realistic threat model [78]. Developers and researchers rely on this knowledge when building circumvention tools and evaluating the practicality of potential attacks against them.

Users from regions with restrictive censorship policies have been seeking ways to circumvent the censorship using various approaches, which can be roughly classified into strategy-based and channel-based circumvention. Strategy-based circumvention [38, 43, 63, 83] involves the client or server implementing custom packet manipulation rules, such as dropping or injecting specially crafted packets, in order to confuse middleboxes into not recognizing censorship triggers. On the other hand, channel-based circumvention [78] involves users establishing *channels* to *forwarders* located outside the censored region, which then route the users' traffic to its final destination. Obfuscated proxies fall into the latter category.

Channel-based circumvention necessitates obfuscation mechanisms. Most obfuscation mechanisms either make channels look like protocols that are allowed (i.e., mimicry), or disguise channels so they don't look like protocols that are forbidden (e.g., randomization). Mimicry-based obfuscation simulates traffic characteristics of popular, permitted protocols (e.g., HTTP, Skype [45, 66, 85]). Some even take the mimicry approach to the extreme by tunneling circumvention traffic through actual, legitimate network services like cloud storage, email, VoIP, and DNS [4, 39, 60, 93], resulting in more plausible protocol fingerprints [59]. On the other hand, randomization-based obfuscation approaches aim to eliminate all fingerprints by encrypting traffic into bits indistinguishable from random. Examples of these include *shadowsocks*, *vmess*, and *obfs4* [19, 27, 30], which defeat protocol parsers with the absence of a fixed protocol structure.

2.2 Attacks on Obfuscated Circumvention Tools

Previous research has documented several active and passive attacks by real-world censors against obfuscated circumvention tools. Active attacks involve censors sending specially-crafted probes to suspected endpoints and analyzing their responses. The GFW was able to identify Tor, VPN, and shadowsocks servers by sending connection requests of a targeted protocol and monitoring if the responses conform to the expected protocol behaviors [32, 46, 86]. In response, "probe-resistant" proxies were developed, which remain silent when probed by an unauthenticated client [52]. However, recent work shows that it is still possible to identify a server even without explicit server responses, due to application-specific features at the network level, such as how and when a server closes a connection [22, 80, 91].

Passive attacks have been used to detect both mimicry and randomization-based obfuscations. Houmansadr et al. argue that obfuscation by imitation is "fundamentally flawed" as seamlessly simulating all implementation-specific behaviors is too difficult and suggest tunneling as an alternative [59]. However, even when circumvention traffic is tunneled, detection remains possible through fingerprinting implementation discrepancies of the cover protocol. Past examples include the blocking of Tor due to the unique fingerprints in its custom TLS implementation, such as uncommon ciphersuites [23, 53, 86]. Snowflake [21], a Tor obfuscation based on WebRTC, was similarly fingerprinted by its unusual DTLS behaviors [41,51]. Non-content features can also be exploited, such as excessive TCP ACK packets [81] or abnormal packet size distribution [36, 56]. While randomization-based approaches eliminate many of these potential fingerprints, looking like random could itself become a feature. Wang et al. demonstrate that packet length and entropy could identify fully encrypted proxies like obfs4 [81], and more recently, the GFW was found to block fully encrypted traffic using entropy as one of the features [89]. In response, developers have implemented several countermeasures, such as allowing users more fine-grained control over the fingerprints and entropy of the cover protocol [11, 20, 53].

2.2.1 Contextualizing Our Fingerprinting Approach

The fingerprinting attack discussed in this paper is orthogonal to all aforementioned attacks that target circumvention protocols. Both active and passive attacks found in previous work exploit implementation flaws in the cover/proxy protocols (depicted in blue in Figure 2). In contrast, this work focuses on the fingerprints generated by encapsulated application traffic (user-generated traffic inside the tunnel, e.g., from browsers), illustrated in red in Figure 2. This means that 1) our attack can potentially complement existing active or passive fingerprinting strategies targeting the cover protocols to further improve accuracy; and 2) existing countermeasures such as *utls* [53] are not effective against our approach, as

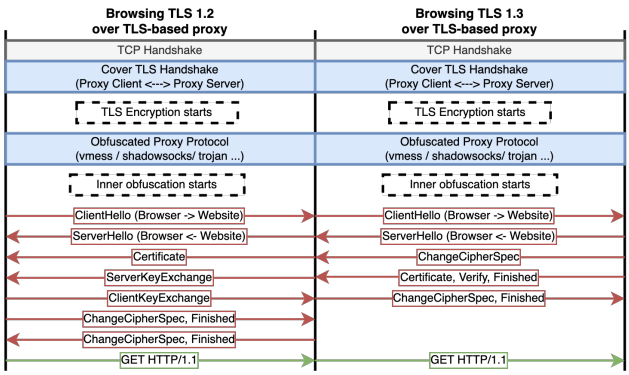

Figure 3: **TLS handshakes inside TLS-based proxy.** Messages transmitted during the handshake stage are well-specified and exhibit characteristics in their size, timing, and direction.◇

they act on the cover protocol rather than the encapsulated layers within. A particular point of emphasis is to distinguish our approach from "TLS fingerprinting" as characterized in previous work [31, 53, 61]. These previous efforts aim to identify TLS implementations by looking at fields within ClientHellos of the cover/surface layer (e.g., distinguishing between TLS flows generated by Tor browsers versus those by Chrome). In contrast, our work looks for patterns that indicate the presence of TLS handshakes that are encapsulated within encrypted/obfuscated protocols.

The works most closely related to ours are those that infer the underlying protocol and protocol semantics from encrypted streams [33,57,72,87], using features that remain visible after encryption, such as packet size, timing, and direction.

3 Threat Model

We outline a realistic threat model for the fingerprinting attack evaluated in this paper. Although real-world censorship practices are often covert, we approximate a *conservative* censor capability model informed by previous work on the arms race between censors and circumvention tools [32, 46, 59, 78, 89]. We assume an *on-path* censor performing passive traffic fingerprinting attacks on all connections passing through its network. The censor cannot inject, drop, or modify any passing packets, nor actively probe suspected servers. While the censor is stateful, it is bounded by memory and computational resources. This means the censor can maintain only a limited number of states per connection within a limited observation window. The censor is familiar with the targeted obfuscated proxy protocols and can adapt its detection methods as needed. However, it cannot break the encryption or obfuscation of the targeted protocol if standard cryptographic primitives are used. We note that these assumptions align with a *weak* adversary as defined in previous work [59].

The censor's reactions to false positives and false negatives are asymmetric. The censor is highly sensitive to collateral damage – the economic costs associated with falsely blocking legitimate traffic during censorship efforts. The censor's reluctance to cause collateral damage is essentially what enables circumvention to be possible [49]. Furthermore, due to the low base rate of circumvention traffic, even a seemingly low false positive rate (1%) can still be economically impractical [81, 91]. On the other hand, a moderate false negative rate can be considered acceptable. This is because circumvention tools users are likely to use them on a daily basis, generating hundreds of flows for each browsing session, and the censor only needs to detect a single flow to block the proxy server.

4 Encapsulated TLS Handshakes

We begin by providing the intuition of how we fingerprint obfuscated proxy traffic. Fundamental to all proxying and tunneling activities is the concept of nested protocol stacks, where one protocol stack is encapsulated within the payload of another, in order to pass through network intermediaries without being directly exposed. This observation forms the basis of the fingerprinting attack we evaluate in this paper and renders the approach agnostic to the choice of proxy protocols. Nested protocol stacks are rare in regular, direct client-server connections. In proxied connections, however, a cover protocol serves as a transport between the client and proxy, while an encapsulated application protocol facilitates end-to-end communication between the client and the final destination server. Nested protocol stacks can result in violations of the layering of the OSI model, such as when the same protocol is encapsulated within itself, as in the case of a TLS-based proxy encapsulating HTTPS traffic (i.e., *TLS-over-TLS*).

The presence of nested protocol stacks is indicative of proxying. Identifying this behavior, however, can be challenging, as the cover protocol encrypts or obfuscates its payloads. Previous work has approached this problem by modeling non-proxied connections and detecting anomalies by comparing their behaviors to the model [44]. Nevertheless, precisely characterizing "legitimate" traffic can be challenging due to the diversity of traffic and protocols on the Internet. For example, while HTTPS constitutes a significant fraction of TLS traffic, TLS payloads deviating from the expected HTTP behaviors do not always imply a second protocol stack, since there are other protocols that use TLS for encryption.

Instead, our approach focuses on fingerprinting a unique behavior that results from nested protocol stacks, termed *Encapsulated TLS Handshakes*. Encapsulated TLS handshakes refer to the TLS handshakes of user traffic transmitted within an encrypted or obfuscated cover protocol (including an outer layer of TLS). This contrasts with standard TLS with plaintext headers and structures that are identifiable by protocol parsers, as shown in Figure 2. The rationale for using encapsulated TLS handshakes as indicators of proxying is intuitive: since TLS is designed to provide end-to-end security over an unsecured network, an encapsulated TLS session within an already-encrypted cover channel suggests redundant protocol

stacking and implies that the outer encryption is not carried through to the final destination but is instead terminated earlier, e.g., at the forwarding proxy server.

Several aspects of encapsulated TLS handshakes make them an ideal fingerprint for proxy traffic. **Distinct:** Similar to standard TLS handshakes, encapsulated TLS handshakes are also well-defined, and the packets transmitted during the handshake stage exhibit distinct size, timing, and directional characteristics, as shown in Figure 3. For example, most *ClientHello* messages typically range from 200 to 550 bytes depending on the TLS version, whereas *ServerHello* messages with certificates can span several thousand bytes and exhibit a higher degree of variation across flows. Moreover, as each handshake message logically depends on the preceding message transmitted, an on-path adversary can exploit the order in which packets carrying these messages are observed on the wire. These characteristics remain visible even after encryption and thus allow us to identify encapsulated TLS handshakes without breaking the cover protocol. **Reliable:** TLS is ubiquitous on the Internet, providing a foundation for secure communication across a variety of applications. As such, encapsulated TLS handshakes serve as a reliable fingerprint, as it would be impractical for proxy users to avoid generating such fingerprints by not using TLS. **Precise:** As described earlier, encapsulated TLS handshakes are indicative of proxied connections. In § 7, we provide empirical evidence to demonstrate that this behavior is fairly unique to the use of proxies. Consequently, using encapsulated TLS handshakes as a fingerprint results in minimal collateral damage for censors.

```
if is_obfuscated_or_encrypted(flow) :
    extract: size, timing, direction from flow[payload]
    if matches_TLS_handshake(size, timing, direction) :
        log_as_proxy_traffic(flow)
```

The pseudo-method above conceptualizes how censors could exploit encapsulated TLS handshakes for proxy detection. In the following sections, we demonstrate the practicality of this approach by building a detection framework using similarity-based classifiers and evaluating it in a real network.

5 Ethical Considerations

Research on censorship and circumvention is inherently sensitive, especially when it involves raw network traffic containing real users' data. For this, we sought approval from our university's IRB for our research plan. Although the IRB determined that the work is "Not Regulated", we take extensive procedural and technical measures to minimize potential risks.

A primary ethical concern relates to the handling of raw network traffic. We access live ISP traffic via our *Monitor* within *Merit* to train classifiers and evaluate the proposed fingerprinting attack. Our *Monitor* deployment is overseen by *Merit*, who has extensive collaboration experience and well-established ethics and privacy guidelines for such projects. The *Monitor* receives only a mirrored copy of traffic without handling the actual routing, ensuring that *Merit*'s service remains unaffected. The raw traffic is processed by a Zeek [92] cluster that carries out protocol parsing and feature extraction (§ 6.2). Instead of recording raw traffic, we log only extracted features, consisting of sequences of packet sizes and timing, without including any packet payloads. These logs are stored and processed on a *Merit*-maintained server, accessible only to select members of the team on a least-privilege basis. We emphasize that *at no point during the project's duration are packet payloads recorded to disk or inspected by humans*.

As with all research on attack methodologies, there is a risk that the fingerprinting attack evaluated in this paper could be deployed by real-world adversaries. We are currently disclosing relevant information to the developers of the proxy protocols examined in our study. It is worth noting, however, that there have already been speculations in the community regarding the potential exploitation of TLS handshakes by GFW in its recent attempts to block circumvention tools [13, 37]. As these obfuscated proxies are used by millions of people to circumvent censorship, we believe it is crucial to bring these vulnerabilities to light, especially considering the realistic threat they pose, as evidenced in this paper. Our work intends to provide users with accurate information about the proxy tools they depend on and encourage proxy developers to implement principled countermeasures.

6 Similarity-Based Classification

Our objective is to distinguish traffic generated by obfuscated proxies from non-proxied user traffic. At the same time, it's equally important to identify the specific features that contribute to detection, as this knowledge will inform future developments in obfuscated proxy protocols. For example, although deep learning–based classifiers have been used in previous research to evaluate the distinguishability of proxy/VPN traffic [3, 26, 55, 65, 82], the limited explainability of deep learning models makes them less suitable for investigating specific fingerprinting vulnerabilities, such as the encapsulated TLS handshakes in our study.

We approach our problem as a binary classification problem – determining whether (obfuscated) network traffic flows contain TLS handshake sequences. We explored several options for classification, such as clustering or supervised learning techniques. We found that classifiers constructed with similarity-based metrics achieve a precision level (in terms of false positive rates) that we consider practical for a censor to deploy, while being computationally efficient. In similarity-based classification, similarity scores are derived for each class by applying selected distance metrics to the test sample and training datasets. Next, a class label is estimated for the test sample based on its similarity scores to each class [42].

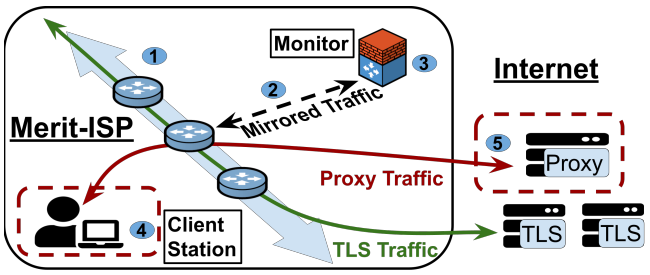

Figure 4: ***Merit* Setup** for collecting plain TLS/non-TLS traffic (1–3:§ 6.1) as well as obfuscated proxy flows (4–5:§ 7.1.2).◇

In this section, we collect a large training dataset comprising TLS/non-TLS flow records by applying a protocol parser to traffic passing through a major *Merit* point-of-presence. Next, we build two classifiers using the training datasets and task them with identifying TLS handshakes *using only features visible post-encryption*, i.e., packet size, direction, and inter-arrival time. We evaluate our classifiers first on *plain* TLS/non-TLS traffic for both TLS version 1.2 and 1.3. In the following section, we adapt our classifiers to detect *encapsulated* TLS handshakes from obfuscated proxy traffic.

6.1 Data Collection

To compile a training dataset with TLS and non-TLS traffic, we set up our monitoring station within *Merit*, as shown in Figure 4, which oversees 50 Gbps of ingress and egress traffic mirrored from a backbone router. First, a user inside *Merit* initiates a TLS connection to an external TLS server (1). As the traffic passes through the monitored router, a copy of the traffic is sent to our *Monitor* (2). The *Monitor* operates a cluster of 23 Zeek [92] instances running our custom script (3). Due to the large traffic volume, we optimize our setup with PF_Ring to enhance packet processing speed [71]. We apply the following filtering rules when creating datasets for training and testing: For both TLS and non-TLS flows, we filter only TCP and require the observation of both a SYN packet and a SYN-ACK packet in the reverse direction. This ensures symmetric routing and that we see the beginning of the connection, where protocol handshakes are expected to occur. We record the first W_o data-carrying TCP packets transmitted in either direction for analysis. We discard short-lived flows with fewer packets than the observation window W_o. For TLS flows, we differentiate between version 1.2 and 1.3 based on the *Supported Version* extension within *ServerHello* records [17]. We filter out flows with an empty *Server Name Indication* field and flows where no TLS records with *Application Data* type are observed (e.g., failed handshake).

Despite the optimizations implemented to improve packet processing speed, handling traffic at 50Gbps on a single server still results in non-negligible packet loss due to CPU bottlenecks. Therefore, we sample only 1/8 of all TCP flows arriving at the *Monitor*. This sampling is based on IP pairs. A detailed breakdown of the collected datasets is shown in Table 1.

TLS flows	All flows	26,500,694
	TLS 1.2	10,851,340 (40.95%)
	TLS 1.3	15,649,354 (59.05%)
Non-TLS flows	All flows	7,020,287
	Unknown Protocols	479,982 (6.84%)

Table 1: **TLS/non-TLS dataset for training and testing classifiers.**

6.2 Feature Extraction

Each flow is represented as a sequence of integers, where the absolute value of each integer corresponds to the size of the TCP payload, and the sign indicates the packet's direction. We use SEQ/ACK analysis to establish a total ordering in which the packets should be processed. An example of such a sequence is $(+517, -1400, -1400, +80)$. Additionally, we record the inter-arrival times between packets.

We extract n-grams from these sequences of packet sizes. n-grams have been used in previous work to analyze encrypted DNS and VoIP traffic [64, 77, 88]. In our case, the intuition is that, compared to 1-grams, n-gram representations can better differentiate between bulk transfer and interactive communications, such as protocol handshakes. Moreover, for protocols with well-defined handshake processes like TLS, we anticipate that n-grams can capture patterns in size tuples during state transitions. For example, the first 3-gram extracted from the previous packet sequence is $(+517, -1400, -1400)$, which often signals an outgoing *ClientHello* followed by a segmented *ServerHello*. Such patterns would be obscured in a 1-gram representation. We experimented with 2-gram, 3-gram, and 4-gram, and found that 3-gram provides the best balance between performance and memory requirements.

We augment the n-gram representation with "burst" features, which consider packet directions and inter-arrival times. Bursts refer to sequences of consecutive packets traveling in the same direction, often occurring when TCP splits large application layer *write()* into smaller pieces for transport. Burst sequences are more robust to minor changes at the packet level, as they consider only the aggregated traffic volume and the direction in which it travels. Specifically, given an original TCP flow record and the corresponding inter-arrival times, we first estimate the connection's RTT as the time elapsed between the observation of the SYN packet and the arrival of the first ACK packet sent from the client at the *Monitor*. To construct burst sequences, we aggregate the sizes of consecutive packets that 1) travel in the same direction and 2) have an inter-arrival time less than three times the estimated RTT.

6.3 Classifiers

To make a classification, we deploy two tests – a Chi-squared (χ^2) test over the 3-gram representation, and a Mahalanobis distance metric over the burst sequence. We classify a flow as TLS only when both tests are satisfied. The intuition behind this approach is that the former test captures local orders of

Algorithm 1 Chi-squared Test over 3-grams.
T_0, T_1:training sets; G:set of all 3-grams; δ:decision threshold
s:test sample; M:size mapping; f:dimensionality parameter

Input: $T_0, T_1, G, \delta, s, M, f$
Training:
$T_c = [M(x) \text{ for } x \text{ in } T_c], c \in \{0,1\}$
$Pr(c,g) = \frac{1}{(\sum_{t \in T_c} N_t)} \sum_{t \in T_c} (N_t \times Pr(t,g)), c \in \{0,1\}, g \in G$
$Distinc(g) = (\sum_{c \in \{0,1\}} \frac{1}{|T_c|} \sum_{t \in T_c} (Pr(t,g) - Pr(c,g))^2)$ /
$(\frac{1}{\sum_{c \in \{0,1\}} |T_c|} \sum_{c \in \{0,1\}} \sum_{t \in T_c} (Pr(t,g) - Pr(\bar{c},g))^2 + \varepsilon), g \in G$
$F = Sorted(G, key = Distinc(g), reverse = 1, g \in G)[0:f]$
Testing:
$s = M(s)$
$D(s,c) = \sum_{g \in F} \frac{1}{Pr(c,g)} (Pr(s,g) - Pr(c,g))^2, c \in \{0,1\}$
Return $D(s,1)/(D(s,0) + \varepsilon) \geq \delta$

packet sequences and state-transition patterns, whereas the latter offers a more aggregated view of a flow's dynamics.

6.3.1 Chi-squared Test

Chi-squared test is a statistical method for determining whether the distributions of categorical variables significantly differ from one another, by comparing the observed frequencies with the expectation for each category. Specifically, the expected number of occurrences of each 3-gram can be found given training sets T_0 and T_1 for non-TLS and TLS, respectively, as well as a set of all 3-grams G. Next, given a test sample s, Chi-squared distances for each class are derived, and we classify the sample by comparing the ratio of the two distances with a decision threshold δ.

However, using raw packet sizes to generate all possible 3-grams leads to an extremely high-dimensional feature space. For a standard MTU of 1500 bytes, the number of unique 3-gram features would be 3000^3. We implement two measures to reduce dimensionality. First, raw packet sizes are discretized into groups $\in L$ before generating 3-grams. We experimented with different grouping strategies (e.g., equal-width, equal-frequency) and found that the strongest results are obtained when packets carrying the same semantic meanings (i.e., TLS Record Type) are grouped together. Using Zeek [92], we label handshake packets from the training set according to their TLS handshake types. Next, given group size $|L|$, we derive a custom mapping that attempts to map sizes associated with the same TLS handshake type into the same group. The mapping function preserves directionality; that is, same packet types in different directions are grouped together, distinguished by their respective polarities. For our analysis, we set $|L| = 4$ to differentiate *ClientHello*, *ServerHello*, *ChangeCipherSpec*, which exhibit the most distinct size patterns, from other packets. We then search for a mapping that separates each of the three handshake types while minimizing the packets deviating from their respective groups. We use the mapping $M = [L_1 : 1-160, L_2 : 161-600, L_3 : 601-1210, L_4 : 1211^+]$. For example, 99.26% of *ClientHellos* in our training dataset are mapped into L_2. This step reduces the dimensionality to $(4*2)^3$. Furthermore, inspired by [88], we only use 3-grams that provide the best distinguishability by selecting those that exhibit low variance among samples from the same class but high variance among samples from different classes.

The overall training and testing process is outlined in Algorithm 1, where N_t and $Pr(t,g)$ correspond to the number of all 3-grams and the probability of the specific 3-gram g in flow t, respectively. The variables f and δ control the number of 3-gram features considered in the model and the decision threshold. $\bar{c}$ denotes the opposite class of c. As an example, Table 2 lists the top five 3-gram features ranked by the distinguishability they provide. As expected, we observe that 3-grams most likely representing state-transition patterns are among the top features that offer the best distinguishability.

6.3.2 Mahalanobis Distance

The Mahalanobis distance provides a method to measure the multivariate distance between a point and a distribution, incorporating both the variances of each variable and the inter-variable correlations. In our use case, we apply the Mahalanobis distance to the burst representation of a given flow, where each burst is considered as a separate dimension. Our rationale for this approach stems from the observation that each phase of the TLS handshake typically forms its own burst, as successive stages transmit packets in alternating directions. Additionally, while individual packets within different TLS handshakes can exhibit wider variability, the aggregated dynamics of a flow – characterized by traffic volume and direction – are likely more consistent across samples. In contrast to distance metrics like the Euclidean distance, the Mahalanobis distance effectively normalizes for the variance within each dimension by considering the covariance matrix. In other words, it takes into account the relative importance of changes in each dimension based on their expected variability. For example, the Mahalanobis distance computation will inherently recognize and accommodate the fact that the sizes of *ServerHello* bursts might vary more across samples than the sizes of *ClientHello* bursts.

Algorithm 2 outlines the process of measuring the Mahalanobis distance, given a TLS training set T_1, a test sample s, a burst window W_b, and a detection threshold γ. We set W_b to be $2 \times RT + 1$, where RT is the minimum number of round trips required for a *full* TLS handshake. Therefore, for TLS 1.2 and 1.3, W_b is set to 5 and 3, respectively.

6.4 Evaluation on plain TLS/non-TLS traffic

We train and test our classifiers using the TLS/non-TLS dataset, which is fully labeled with protocol parsers as de-

3-gram	Most frequently occurring labels	Distinc.
$(L_2,-L_4,L_1)$	(*C-H*, *S-H+S-EX*, *C-EX+C-CCS*)	7.226
$(-L_4,-L_4,-L_4)$	(*S-H*, *S-H (cont.)*, *S-H (cont.)*)	5.886
$(-L_4,L_1,-L_1)$	(*S-H*, *C-EX+C-CCS*, *S-CCS+S-FIN*)	2.879
$(-L_4,-L_4,-L_3)$	(*S-H*, *S-H (cont.)*, *S-EX*)	2.780
$(L_2,-L_4,-L_4)$	(*C-H*, *S-H*, *S-H (cont.)*)	2.416

Table 2: **Example top 3-grams with TLS labels.** *C*-:Client Sent, *S*-:Server Sent, *H*:Hello, *EX*:KeyExchange, *CCS*:ChangeCipherSpec.◇

scribed in § 6.1. We partition the TLS class flows based on their respective TLS versions and train a separate classifier for each version. The negative class consists of non-TLS flows, shared between both classifiers. We set the observation window as $W_o = 25$, a length that we found to be sufficient for over 99.95% of TLS handshakes in our dataset. Additionally, we set the number of 3-gram features under consideration as $f = 100$. Upon completing the initial round of training, we compute the Chi-squared distance and Mahalanobis distance for each sample within the training set. Then, we remove outliers exhibiting abnormally large distances from the models and re-derive the models with the remaining samples.

We evaluate the classifiers under varying Chi-squared and Mahalanobis distance thresholds. Figure 9 shows the performance of both classifiers using the parameter sets that yield the highest TPRs under specific FPR constraints. As expected, the TLS 1.2 classifier outperforms the 1.3 classifier across a range of threshold configurations, especially in terms of minimizing the false positive rate (FPR). This can be intuitively explained by the fact that a full handshake in TLS 1.2 requires one additional round trip compared to version 1.3, which manages to exchange all necessary information in the initial round trip, resulting in shorter handshake sequences. As our Mahalanobis classifier uses a moving window to identify potential handshake sequences, this means that in TLS 1.3, fewer elements need to match consecutively in the stream, increasing the likelihood of coincidental matches. We emphasize that the low FPR of classifying TLS 1.2 traffic makes it a more attractive target for censors, who tend to prioritize minimizing collateral damage. Regarding the source of false negatives, while we couldn't manually inspect raw traffic due to ethical concerns (§ 5), based on packet labels and sizes, we conjecture that irregular handshakes resulting from optimizations such as TLS Session Resumption and False Start [15,16] may contribute to the majority of false negative instances.

7 Detecting Obfuscated Proxy Traffic

In this section, we evaluate the practicality of exploiting encapsulated TLS handshakes to detect traffic belonging to obfuscated proxies. In line with previous studies on censorship and fingerprintability [91], our goal is to conduct our evaluation in a realistic setting while incorporating perspectives on how censors operate in practice. To this end, we adopt

Algorithm 2 Mahalanobis Distance over Bursts
T_1:TLS training set; s:test sample; γ: detection threshold
$W_b = 5$ for TLS 1.2 and $W_b = 3$ for TLS 1.3

Input: T_1, s, W_b, γ
Training:
  $T_1 = [x[0:W_b]$ for x in $T_1]$
  $\vec{M} = GetMeanOfBurst(T_1)$
  $C = GetCovarianceMatrix(T_1)$
Testing:
  $Dis \leftarrow \{\}$
  for i in $(0...|s| - W_b)$ **do**
    Dis.add$(\sqrt{(s[i:i+W_b] - \vec{M})^T C^{-1} (s[i:i+W_b] - \vec{M})})$
  end for
  Return $min(Dis) \leq \gamma$

the viewpoint of a potential censor by deploying our detection framework within *Merit*. As illustrated in Figure 4, our framework processes two types of traffic: obfuscated proxy traffic generated from a control machine (4) to a proxy server (5), with our *Monitor* positioned on-path, as well as legitimate, passing network traffic produced by *real* users served by *Merit*. Throughout this section, we aim to address three research questions: *(1) How effective is the proposed fingerprinting attack? (2) Can current countermeasures, such as random padding and stream multiplexing, effectively defend against the attack? (3) How practical is it for censors to deploy at scale without causing significant collateral damage?*

7.1 Experiment Setup

7.1.1 Selection of Proxy Configurations

We compile a list of obfuscated proxy configurations based on previous research [32, 46, 78, 89], online censorship discussion forums [1, 9], and our experience with circumvention tools used in regions with strict information control. We do not include configurations that lack obfuscation, such as plain HTTP/SOCKS proxy or VPN protocols, as they are trivially detectable. We also exclude "stealth VPNs" as marketed by commercial VPN providers, since previous work has shown that most of them do not deploy standard obfuscation mechanisms and can be easily probed and detected [91]. The proxy configurations we examined are shown in Table 3.

Basic Configurations include raw protocols such as *vmess*, *Shadowsocks*, *Trojan* (*trojan-go*), and *vless* [19,25,27]. These protocols are specifically designed for censorship circumvention, and as such, obfuscation is among their top priorities. *Shadowsocks* and *vmess* are random-looking proxies that use encryption to make their traffic indistinguishable from random bytes. *Trojan* and *vless* are TLS-based protocols, encapsulating traffic inside TLS tunnels to avoid detection.

Advanced Configurations build upon raw protocols, adding additional "cover" layers to encapsulate proxy traf-

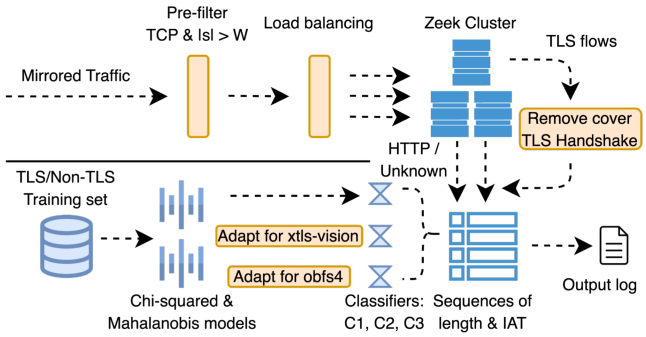

Figure 5: **Detection Framework in *Merit*.** For TLS flows, we remove the handshake of the cover TLS layer before feature extraction in order to only identify handshakes that are encapsulated.◇

fic inside popular, legitimate protocols. Examples include vmess-over-tls, vmess-over-websocket, shadowsocks-over-websocket-over-tls, *etc.*. This category also includes dedicated pluggable transports like Cloak and shadowTLS [5, 7], which improve the censorship-resistance of *Shadowsocks*, and httpt and gost [6, 54], which are probe-resistant proxy systems that hide proxy traffic inside TLS tunnels.

MUX Configurations combine multiple application streams within a single TCP connection. Without multiplexing, each TCP stream from local applications arriving at the proxy client would result in a new outgoing TCP connection to the proxy server. With multiplexing enabled, a small number of long-lived connections are maintained between the proxy client and server, with all application streams being multiplexed inside these connections. Although multiplexing is often discussed as a performance optimization, previous work has found that multiplexing can mitigate the effect of traffic analysis attacks [62, 67]. Table 4 in Appendix lists the implementations examined and their multiplexing support.

Random Padding Configurations involve appending dummy data to payloads in order to obscure patterns in packet sizes. For obfuscated proxies, padding is implemented as part of the traffic obfuscation mechanism. The method for choosing a padding length varies across protocols: some select a padding length uniformly at random from a range and append to each packet [8, 27], while other proxies pad all packets to a target range [29] or according to a specific distribution [30].

7.1.2 Proxy Traffic Generation

To generate and test on obfuscated proxy traffic, we use the *Client Station* inside *Merit* to connect to a server running proxy protocols. As shown in Figure 4, all traffic to/from the *Client Station* passes through a *Merit* backbone router, which is configured to send mirrored traffic to the *Monitor*.

On the *Client Station*, we run an automated script to generate proxy traffic. For each obfuscated proxy configuration, we connect to the proxy server and use Selenium [18] Firefox to visit the top 1K domains as ranked by Cloudflare [10] while collecting packet captures for reference. We note that the goal of browsing 1K domains is to generate a diverse set of TLS traces on proxy. However, the exploit is not dependent on web browsing – any proxied application using TLS will generate encapsulated TLS handshakes. We configure the Selenium browser to use 1.2 only when negotiating TLS versions. In § 7.4, we extend the experiment to include TLS 1.3 and show that, at the moment, it is in censors' interest to focus on TLS 1.2, due to the higher precision that TLS 1.2 handshake fingerprints offer. For configurations with stream multiplexing, we restart the proxy client between consecutive domain visits. On average, this process generates over 15,000 flows exceeding the observation window $W_o = 25$ for non-multiplexed configurations. We note that some of these proxied flows might not be TLS and therefore do not contain an encapsulated TLS handshake, resulting in an underestimated True Positive Rate in our evaluation. However, as shown in § 7.4, we estimate that only 0.39% of flows are non-TLS connections when conducting experiments on Cloudflare's 1K list; thus, we ignore them when reporting TPRs.

7.2 Detection Framework

Our *Monitor* inside *Merit* receives up to 50 Gbps of mirrored traffic, which necessitates sampling due to CPU bottleneck in our single-server setup. We use a sampling rate of 1/8 to minimize the effect of packet loss, and we sample traffic based on 4-tuples so that both directions of a flow are either selected for analysis or dropped together. Traffic to/from the *Client Station* is not subject to sampling. We note that while nation-state censors could potentially scale up their deployment to avoid sampling, a recent work shows that GFW operates under an approximate sampling rate of 1/4, presumably to conserve resources and limit collateral damage [89].

As shown in Figure 5, once mirrored traffic arrives, it is first processed by a cluster of Zeek [92] instances running our custom script. We then use protocol parsers to extract the application-layer protocol for each flow. For flows that parsers cannot identify (e.g., fully encrypted protocols like *shadowsocks*), we label them as *Unknown*. Since all our proxy configurations have either *Unknown*, *TLS*, or *HTTP* as their (application-layer) cover protocols, we filter out flows with any other labels, which account for 0.89% of all flows exceeding the observation window W_o. [1] Next, we extract features including TCP payload sizes and inter-arrival times (IAT) of the first W_o TCP data-carrying packets and pass them into our classifiers. Importantly, *for TLS flows, we remove packets forming the (cover) TLS handshakes prior to feature extraction* so that the classifiers disregard the "cover" TLS and instead only focus on identifying potential TLS handshakes that are encapsulated in the payload of the cover TLS (i.e., TLS-over-TLS).

[1] Note that non-obfuscated protocols that use TLS for encryption, e.g., SMTP/SSL, POP3/SSL, IMAP/SSL, *etc.*, are filtered out at this stage.

We follow the process outlined in § 6.3 to derive the statistical models. Notably, the training datasets used here are the same as in § 6.1. This highlights an advantage of the proposed exploit over previous work: censors do not need to generate a synthetic training dataset of proxy traffic. Instead, they can model encapsulated TLS handshakes by observing real TLS traffic in their network. It's important to clarify that all evaluations in this section are conducted on live and proxy traffic, entirely separate from the training traces. To adapt the classifiers for detecting proxy traffic, we modify the mapping of packet sizes M to reflect the framing overheads introduced by the proxy protocols. Although this overhead varies between proxy protocols, they tend to be small in size (typically ranging between 20 to 60 bytes) due to performance considerations. While adjusting specific framing overheads for each proxy protocol might lead to marginally improved results, for the purpose of evaluation, we choose the median overhead size for all proxy protocols that have fixed framing overheads.

However, for protocols with complex random padding schemes, framing overheads vary across packets, making it challenging to separate packets with different semantic meanings based on sizes. For example, *XTLS-vision* [29] pads *all* packets at the beginning of a flow to a range of 900-1400 bytes, effectively nullifying individual packet sizes as a feature. Yet, packet directions can still serve as a feature, although less informative, because proxies we examine only pad payloads from upstream applications and don't send "dummy" packets when there is nothing to transmit. Thus, for *XTLS-vision* and *obfs4* [29, 30], we use a mapping that groups packets by their directions, regardless of their sizes ($|L| = 1$). Furthermore, we adapt the Mahalanobis model as these padding schemes lead to increased burst sizes and higher variances across flows, which needs to be accounted for when computing distances. Specifically, we apply the padding procedures as implemented by *XTLS-vision* and *obfs4* to each flow in the training dataset, as detailed in Appendix A.1. Then, we derive the new means and covariance matrices based on the padded flow sequences.

7.3 Results and Findings

Beginning March 16, 2023, we deploy our detection framework on the *Monitor* for 30 days to evaluate it on both proxy and ISP traffic. Despite the sampling, the *Monitor* still processes over 36 terabytes of traffic daily, consisting of 34 billion packets from over 3.9 million flows exceeding the observation window $W_o = 25$. As *Merit* is located in a country with minimal censorship on network traffic, we expect that the vast majority of traffic seen on *Merit* does not contain traffic from *obfuscated* proxies designed for censorship circumvention. For this reason, we consider all ISP flows that our framework labels as proxy traffic to be false positives to derive a conservative upper-bound False Positive Rate (FPR).

We extract distances for each proxy and ISP flow, labeling a flow as "proxy" if both distances fell below specific thresholds. We identify the "optimal" thresholds and their corresponding True Positive Rates (TPRs), contingent upon the network operator's tolerance to false positives (how aggressive the censor is). Figure 6 presents the results, broken down by configuration groups, under varying FPR constraints. To provide context on the framework's practicality, we highlight the region where $FPR < 0.6\%$, aligning with the estimated FPR of the inferred algorithm used by the GFW to block fully encrypted proxies [89]. We highlight that our approach not only captures the majority of non-multiplexed proxy flows but also retains precision comparable to attacks that employ protocol-specific active probing [91], while being applicable to a broader range of circumvention proxies. Table 3 details evaluation results using one set of detection thresholds, grouped by configurations. Note that for C_3 (obfs4), we used a more permissive FPR constraint, as it applies only to traffic whose application-layer protocol is *Unknown*, a category that censors have historically approached more aggressively.

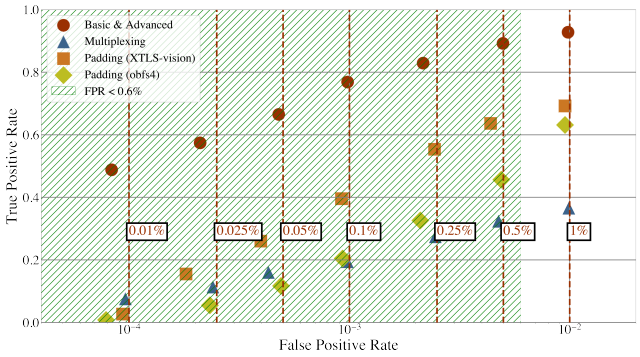

Figure 6: **Results by configurations.** Data points are obtained using the parameter set of Chi-squared threshold δ and Mahalanobis threshold γ that yield the highest TPRs under a specific FPR constraint. ◇

Major obfuscated proxies, in their standard configurations, are vulnerable to fingerprinting based on encapsulated TLS handshakes. We are able to detect over 70% of flows generated by any of the four most widely used obfuscated proxy protocols, specifically *vmess*, *shadowsocks*, *vless*, and *trojan*. The implication of such detection rates is amplified when considering that a censor only needs to identify a single flow to block the corresponding proxy server. Although *vmess* features a built-in payload padding scheme, the padding size is drawn from a limited range of 0-63 bytes [27]. While such a scheme may be effective in obscuring values within request header fields, such as the destination URL, our findings has demonstrated that it falls short in obfuscating the size and directional traffic characteristics of (encapsulated) TLS handshakes from even simple statistical models.

Wrapping proxy traffic inside additional cover protocols does not provide an effective defense against traffic analysis. Encapsulating proxy connections within another protocol is a popular strategy to provide extra security that comes with the cover protocol, such as the probe-resistance of

Table 3: **Evaluation Results.** Top: performance of the detection framework, broken down by proxy configurations. Bottom: False Positive Rates estimated on ISP traffic. We do not include *vmess* in the Random Padding group, as its padding scheme is limited (0-63 bytes).◇

TLS. However, such connections can still be accurately distinguished from legitimate sessions running the cover protocols (HTTP, TLS), since TLS handshakes are not expected to occur *on top of* these cover protocols in their typical use cases. We note that our exploit does not assume implementation flaws and discrepancies in the cover protocols, which could become additional fingerprintable features orthogonal to our attack [52,53,80]. For example, Cloak [5] encapsulates proxy traffic in a cover TLS tunnel, which preserves the syntactic validity of TLS but not its semantics [59] (e.g., the absence of server certificate). A censor could complement the exploit of encapsulated TLS handshakes with discrepancies at the cover protocol layer to further improve detection accuracy.

Random padding is not the final word when it comes to obfuscating patterns within packet size sequences. Implementing a random padding scheme is often the first step taken by developers of obfuscated proxies to hide patterns in packet sizes. Yet, we show that simple random padding schemes drawing padding sizes from limited ranges (e.g., *vmess*: [0, 63]), while increasing the challenge, doesn't render detection infeasible (TPR: 0.859 $\rightarrow$ 0.687 for vmess-ws-tls after padding). For more aggressive padding schemes e.g., *XTLS-vision* and *obfs4*, censors could adapt their statistical models by mirroring the padding schemes, training on padded ver-

sions of datasets, and leveraging packet directions over sizes for classification. Although doing so substantially increases FPR (0.0544% → 0.6127%), empirical evidence suggests that a motivated censor may be able to tolerate this level of collateral damage during politically sensitive times [89].[2]

It's worth emphasizing that the need for dedicated classifiers for protocols like *XTLS-vision* and *obfs4* inherently demands more from censors in terms of resources, efforts, and potential costs from collateral damage. This additional complexity contrasts with configurations from the *Basic* and *Advanced* category, which can be fingerprinted in an effectively protocol-agnostic manner.

Multiplexing proves to be a more effective mechanism for masking the fingerprint of encapsulated TLS handshakes. On a positive note, introducing connection multiplexing significantly reduces the detection rate, regardless of the underlying proxy protocol used. Even the most basic form of multiplexing – combining every two application streams in one proxy connection – lowers the TPR by over 70%. Intuitively, when a TLS handshake takes place concurrently with data transmission from another stream sharing the multiplexed connection, individual TLS handshake packets are likely to interleave with other data packets, thus disrupting the size and timing patterns typically expected from a non-multiplexed TLS handshake. We note that the actual impact of multiplexing may be more substantial than the differences in TPR suggest, as there will be significantly fewer proxy connections crossing the censor's firewall. One caveat to consider is that the effectiveness of multiplexing is limited when there is only one application stream. Without packets from co-existing streams to interleave, patterns in packet sizes remain exposed to fingerprinting in the same way as non-multiplexed flows.

False Positives: It is possible that some of the flows labeled as obfuscated proxies are actually true positives. To investigate this possibility, we look for circumstantial evidence, independent of the encapsulated TLS fingerprint we exploit, to corroborate our detection results. Specifically, we extract 7,100 unique server endpoints from the 63,887 connections labeled by C_1 over the 30-day evaluation period. For each endpoint, we then examine the number of unique client IPs (and SNIs, if applicable). Intuitively, we expect endpoints running proxy protocols to have fewer unique client IPs and SNI values. As illustrated in Figure 10, while labeled endpoints indeed connect fewer unique clients, they also tend to have more unique SNIs than average. A closer look at WHOIS and SNIs of the labeled endpoints reveals that streaming, gaming, and CDN services are among the top heavy hitters, suggesting that the majority of labeled endpoints are unlikely to be obfuscated proxies.

[2]The FPRs in Table 3 are broken down by application-layer protocols. That is, the FPR for C_3 (0.6127%) applies to *Unknown* flows only – FPR:0.0038% when all traffic is considered.

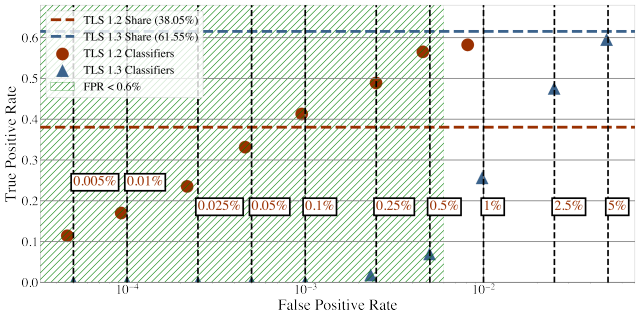

Figure 7: **Performance of classifiers on mixed TLS 1.2/1.3 traffic.** TPR is averaged from *vmess*, *shadowsocks*, *vless*, and *trojan*.◇

7.4 TLS 1.2 vs TLS 1.3

To investigate the effect of the increasing adoption of TLS 1.3 on the proposed fingerprinting attack, we repeat the experiment described in § 7.1.2 using Cloudflare's 1K domains [10]. This time, instead of forcing the browser to negotiate TLS 1.2, we allow the browser and server to decide on their preferred protocol version. We tested on two classifiers, each trained specifically for a particular version of TLS. For each version, we conducted the experiment five times, using the *Basic* configurations, and reported the average results in Figure 7.

We find that although most top domains themselves support TLS 1.3, resources loaded on the page (e.g., images, ad trackers) may lag in TLS 1.3 adoption. As a result, on average, when visiting the top 1K domains, TLS 1.2, 1.3, and HTTP represent 38.05%, 61.55%, and 0.39% of all TCP flows, respectively. These figures align with what we observed in *Merit* traffic (Table 1) and a recent TLS Telemetry Report [84]. Regarding classifier performance, we observe that although the TLS 1.3 classifier offers a relatively higher detection rate, it comes at the expense of a significantly elevated FPR, which can be attributed to its shorter (and thus less specific) handshakes. In contrast, the TLS 1.2 classifier effectively detects the majority of proxied TLS 1.2 flows, despite being limited by the version share, while maintaining a lower FPR which makes it more practical for deployment. As discussed in § 3, a moderate TPR is unlikely to be a major concern for a censor, as a non-multiplexed proxy would generate hundreds of flows during a typical browsing session, and the censor only needs to detect one of them. Considering that TLS 1.2 still represents a significant share of Internet traffic, we believe that, at this moment, the optimal strategy for a perspective censor implementing the proposed exploit would be to exclusively target encapsulated handshakes of TLS 1.2.

8 Discussion and Mitigation

Obfuscated proxies play a crucial role in facilitating unrestricted access to information and resources on the Internet, particularly in regions where censorship is prevalent. However, we demonstrate that detecting obfuscated proxy traf-

fic, even with random padding and layers of encapsulation added, is highly effective by exploiting encapsulated TLS handshakes. The ability of censors to identify proxy connections could pose significant risks to users, especially in countries where circumventing censorship is deemed illegal.

Would censors deploy the fingerprinting attack based on encapsulated TLS handshakes? Our evaluation on *Merit* shows that, with conservative detection thresholds, the proposed fingerprinting attack yields an exceptionally low FPR, while only requiring passive monitoring and remaining largely agnostic to the choice of circumvention protocol. [3] Furthermore, this exploit targets layers encapsulated *within* the proxy protocol, thereby making it orthogonal and potentially complementary to attacks targeting the proxy protocols themselves [53,56,81] as well as host-based network analysis [79]. For this reason, we believe that proxies featuring fully encrypted cover layers, e.g., raw *shadowsocks* and *vmess*, are especially vulnerable: given that censors have already demonstrated a willingness to block them based on entropy [89], the additional use of encapsulated TLS handshakes as a complementary feature could further reduce the collateral damage.

However, we note that even with a false positive rate of 1 in 2000 (§ 7.3), due to the sheer volume of traffic passing through a national firewall and the low base rate of circumvention traffic in the wild, our fingerprinting attack would likely still label more legitimate connections as proxied than actual proxied connections [81]. Furthermore, a nation-state censor is not just a traffic classifier, and deploying a new censorship technique involves considerations beyond false positive rates, such as public sentiment and operational costs. As such, we caution against prematurely declaring any of the tested proxies as "broken" based on our findings alone. Rather, proxy developers should anticipate the potential exploitation of encapsulated TLS handshakes as a shared fingerprint of proxy traffic, and proactively equip their tools with mitigation mechanisms.

Mitigation Encapsulated TLS handshakes cannot be easily eliminated from proxy traffic without compromising end-to-end security. Hence, the responsibility falls on proxies to implement effective obfuscation mechanisms to hide them from traffic analysis. Our evaluation suggests that multiplexing could be a more viable strategy compared to random padding alone. Intuitively, multiplexing interleaves packets from multiple streams, disrupting traffic patterns not only in packet size but also timing and direction. Different co-existing streams introduce additional unpredictability. However, the effectiveness of multiplexing as an obfuscation mechanism depends on the presence of co-existing flows. In situations where there is only a single flow, or where the co-existing flows are inactive, patterns in packet sequences will remain as exposed as they are with non-multiplexed proxies. One direction for future work could be exploring methods for generating synthetic co-existing flows when they are not naturally present.

[3] The approach to fingerprint proxy flows with encapsulated TLS handshakes is generally protocol-agnostic. However, classifiers may need adjustments for protocols using random padding (§ 7.2).

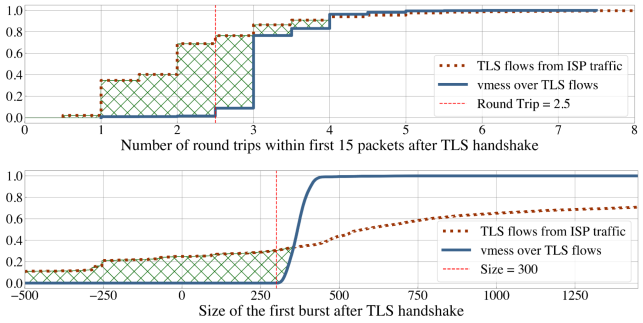

Figure 8: **Round trip count and size of first burst after TLS handshakes.** *TLS-over-TLS* requires more round trips and a larger initial burst due to a second (encapsulated) handshake. Shaded areas highlight dissimilarities that padding and multiplexing cannot obfuscate.

However, obfuscation mechanisms based on padding and multiplexing alone are subject to fundamental limitations. Specifically, *padding can only increase the size of a packet or a burst, not decrease it. Stream multiplexing can only increase the number of round trips in a connection, not decrease them.* These limitations become significant when the pattern requiring obfuscation is inherently characterized by larger sizes and more round trips than what might be considered "normal" within the context.

Consider normal HTTPS versus TLS-based proxies. In a typical HTTPS connection, the packets that immediately follow the TLS handshake usually consist of just one round trip: an outgoing GET and an incoming response segmented into multiple packets. In contrast, when accessing HTTPS over a TLS-based proxy (i.e., *TLS-over-TLS*), what immediately follows the initial TLS handshake is a second (encapsulated) TLS handshake, thereby requiring more round trips and resulting in larger packet sizes due to multiple framing overheads. Figure 8 shows the number of round trips and the size of the first burst following the initial handshake for normal TLS and *TLS-over-TLS*. Importantly, the shaded areas represent *dissimilarities that padding and multiplexing cannot obfuscate*. In theory, a censor could combine two simple filtering rules ($RT < 2.5, Size < 300$) to effectively filter out 82.5% of legitimate and 1.5% of proxied connections. More sophisticated analysis could then be applied to the remaining connections. This example illustrates that, if obfuscated only with padding and multiplexing, traffic of TLS-based proxies can always be distinguished from the majority of genuine HTTPS traffic.

A dedicated obfuscation layer An effective obfuscation mechanism should transform patterns in packet size, timing, and direction such that traffic observable on the wire does not reflect any dynamics of the traffic encapsulated within, thereby hiding fingerprintable features such as encapsulated TLS handshakes. Existing padding and multiplexing schemes, unfortunately, do not meet this criterion. We believe that to achieve this, proxies need to decouple obfuscation from

encapsulated application streams, in order to allow maximum flexibility to simulate any given traffic shape [48, 50]. For example, one approach is to implement a traffic scheduler at the obfuscation layer that dictates when, how, and how much traffic should be sent at any given time. Such scheduler goes beyond existing padding schemes as it would require proxies to send dummy packets when there is no application data to send, or buffer application data when the scheduler demands quiet time. Abstracting an obfuscation layer would also allow proxies not only to multiplex but also de-multiplex application streams. For example, the obfuscation layer could use two separate network connections to transmit upstream and downstream application traffic. For each connection, half of the traffic is dummy data that could be arbitrarily interleaved with the uni-directional application streams.

A dedicated obfuscation layer would ensure a more principled and sustainable defense against traffic analysis. However, defining a "legitimate" traffic shape for proxies' obfuscation to simulate, and balancing obfuscation and performance, remain open questions for future research.

Generalizing to UDP-based Proxies and VPNs While our work primarily focuses on TCP-based proxies, the principles behind our approach are transferable to UDP-based proxies such as MASQUE or vmess/shadowsocks over QUIC. This is because the patterns for fingerprinting are generated by encapsulated layers inside a proxy's payload, rather than the characteristics of the proxy layer itself. Adapting the classifiers to these contexts would need to consider factors such as the unreliability of UDP and the potential frame padding of QUIC.

Our fingerprinting attack is predicated on the presence of nested protocol stacks – the rarity of finding a TLS layer inside another TLS or application layer in direct connections makes this behavior an ideal fingerprint for proxy flows. While this paper explores one specific attack, it points to broader risks across all proxying and tunneling tools that rely on nested protocol stacks. For example, a layer-3 analogy would be detecting obfuscated VPN flows by considering encapsulated *TCP* handshakes (and the rarity of finding TCP handshakes inside another transport layer protocol).

9 Conclusion

We explore the practicality of exploiting encapsulated TLS handshakes as a fingerprint to detect obfuscated proxy traffic. Our evaluation within an ISP demonstrates that, even with random padding and layers of encapsulation, traffic of obfuscated proxies can still be reliably detected with minimal collateral damage. Considering that users in censored regions depend on obfuscated proxies for access to information, it is critical for proxy developers to anticipate this emerging threat and to design and deploy proactive countermeasures.

A Appendix

A.1 *XTLS-vision* and *obfs4* Padding Schemes

Algorithm 3 and 4 outlines the padding schemes as implemented by *XTLS-vision* and *obfs4* (iat-mode=0/1). For *XTLS-vision*, TLS handshake packets are padded to a range of 900-1400 bytes, and the first 7 packets transmitted in either direction are padded with a random size of 0-255 bytes. For *obfs4*, both the client and server maintain a padding distribution. For each burst in a flow sequence, a padding size is determined by sampling from the sender's distribution.

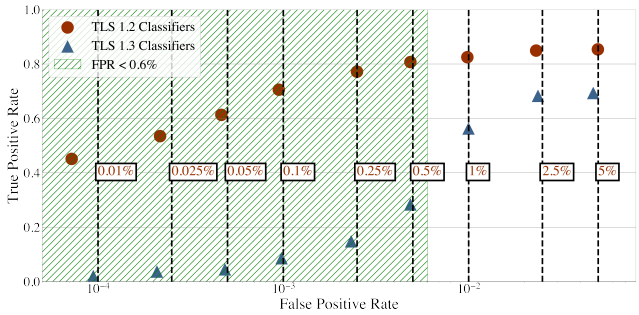

Figure 9: **Performance of classifiers on plain TLS traffic** TPR and FPR for classifiers with varying detection thresholds $\delta \in [0.1, 0.15, ...1.0], \gamma \in [1, 1.25, ...5]$. For each given FPR constraint, we select the parameter set that yield the highest TPR.◇

Abstract

Augmented reality (AR) experiences place users inside the user interface (UI), where they can see and interact with three-dimensional virtual content. This paper explores UI security for AR platforms, for which we identify three UI security-related properties: Same Space (how does the platform handle virtual content placed at the same coordinates?), Invisibility (how does the platform handle invisible virtual content?), and Synthetic Input (how does the platform handle simulated user input?). We demonstrate the security implications of different instantiations of these properties through five proof-of-concept attacks between distrusting AR application components (i.e., a main app and an included library) — including a clickjacking attack and an object erasure attack. We then empirically investigate these UI security properties on five current AR platforms: ARCore (Google), ARKit (Apple), Hololens (Microsoft), Oculus (Meta), and WebXR (browser). We find that all platforms enable at least three of our proof-of-concept attacks to succeed. We discuss potential future defenses, including applying lessons from 2D UI security and identifying new directions for AR UI security.

1 Introduction

Extensive past research and practice have considered user interface (UI) security for two-dimensional screens (desktop, browser, and mobile), e.g., clickjacking attacks that trick the user into interacting with UI elements [33,37,44,54,67,82], information leakage via the user interface [27,42], and isolating UI components from other entities [13,74,92]. In this paper, we explore UI security in emerging augmented reality (AR) platforms.[1] AR immerses the user *inside* a three-dimensional user interface — including, in some contexts, the real world itself — in contrast to the user merely observing it from the outside.

Scope and Threat Model. UI-level security for AR includes potential attacks on: (1) the user's *perception of the physical world*, (2) the virtual world or other *virtual content*, and (3) the user's *interactions with virtual content*. Regarding the first threat model, recent work has begun to study security and privacy for emerging AR platforms more generally, including some UI-related issues related to attacks on physical world perception. For example, it has discussed or demonstrated attacks in which malicious AR content is used to obscure important real-world (or virtual) content [43, 61] and side-channel attacks that allow malicious applications to infer information about the user's physical surroundings [70, 99, 101]. In this work, we consider a threat model where multiple entities might be interacting within the AR UI, such as third-party embedded code (e.g., a library) running inside an AR application in which the embedded code (e.g., the library) seeks to compromise a property of the AR application or vice versa. As the ecosystem continues to develop, we envision our threat model extending to future multi-user/multiple AR applications simultaneously augmenting the user's view of the world.

Given our focus on multiple principals, we thus particularly consider threat models (2) and (3), i.e., from one principal on another principal's virtual content and on the user's interaction with another principal.

AR UI Security Attacks and Properties. Given this problem scope, we prototype several multi-principal UI security attacks on currently available AR platforms. These include:

1. A *clickjacking attack* on ARKit (Apple), where a malicious AR application component tricks the user into interacting with another component's virtual object. This attack is achieved by placing both objects at the same 3D coordinates and taking advantage of ARKit's inconsistency about which object is visible and which receives user input.
2. A *user input denial-of-service attack* on Hololens (Mi-

[1] We use the term "augmented reality (AR)" to refer to technologies that place virtual content in a user's view of a real-world environment, whether embedded in it or overlaid on it. Other works may use other terms to refer to the same or related concepts, including mixed reality (MR) and extended reality (XR). We focus on AR and while we believe some findings might be possible in VR too, we are not in a position to fully clarify all differences between AR and VR.

crosoft), where a malicious AR application component blocks the user from interacting with another or *any* virtual object. This attack is achieved by surrounding the target AR object in an invisible 3D box and/or entirely surrounding the user with an invisible 3D virtual box that captures all user input. This attack is possible on platforms that support invisible objects that are allowed to receive inputs.

3. An *input forgery* attack in ARCore (Google), where a malicious AR application component impersonates the user's interaction with virtual objects, even when they are not within the user's field of view. This attack is achieved by programmatically generating synthetic user interactions, taking advantage of the absence of input provenance, i.e., the ability to verify the origin of input.
4. A *object-in-the-middle attack* on Oculus (Meta), where a malicious AR application component snoops on the user's interactions with another component's virtual object. This attack is achieved by a combination of (a) an invisible object that intercepts the user's intended input, and (b) synthetic user input that is then dispatched to the original target object.
5. An *object erasure* attack in WebXR (browser), where a malicious AR application component uses an invisible virtual object to cause an underlying victim virtual object to disappear completely. This attack is possible due to WebXR's method for rendering invisible objects.

These proof-of-concept attacks are possible because of the way each platform implements three *specific UI-related properties* that we identified: What happens when multiple virtual objects are placed at the same 3D physical coordinates (*"Same Space"* property)? (2) How do "invisible" virtual objects work (*"Invisibility"* property)? (3) Do platforms allow synthetic user input (*"Synthetic User Input"* property)?

Empirical Evaluation of Current AR Platforms and SDKs. After identifying these properties and demonstrating their security and privacy implications through the proof-of-concept attacks, we conduct a *systematic empirical investigation* of how current AR platforms and SDKs handle them. Specifically, we conduct experiments with ARCore (Google), ARKit (Apple), Hololens (Microsoft), Oculus (Meta), and WebXR (browser). We find inconsistencies in how current platforms handle the AR UI security properties that we identify and observe that many current implementations of these platforms enable attacks such as those we describe above.

Towards Future Defenses. Our results highlight the necessity for emerging AR platforms to implement UI-level security precautions in their designs and implementations. However, defenses are not necessarily straightforward. In some cases, we recommend that platforms adopt known approaches from 2D UI security (e.g., adding user input provenance information [11]), though we found that no current platform has implemented this feature. In other cases, AR-specific approaches may need to be devised [63] or AR-specific tradeoffs considered (e.g., aligning the physics and rendering engines around UI security properties and handling UI isolation in a 3D, interleaved context [60]) when 2D mitigation fails to work.

Contributions. We contribute the following:

1. We identify **three AR UI properties that have security and/or privacy implications** and provide criteria for evaluating them (Section 3).
2. Based on these properties, we demonstrate **five proof-of-concept AR UI security attacks** that are possible on today's AR platforms (Section 4).
3. We present **results of an empirical analysis** of these AR UI security properties in five commercially available AR platforms and associated SDKs: ARCore, ARKit, Hololens, Oculus, and WebXR (Section 5).

Finally, we reflect on **foundations for future defenses**, including known defenses that have not to date been applied to AR platforms and SDKs, as well as potential novel defensive directions (Section 6).

Disclosure. We have reported all of our findings to Apple, Google, Meta, Microsoft, WebXR, and Unity.

2 Background and Motivation

We begin with background on AR technologies, AR UI, and prior work on AR security and privacy to motivate our work.

Augmented Reality. AR technologies — technologies that seamlessly blend the physical and the digital worlds — are receiving increasing attention from both academia and industry. Once considered niche yet expensive research prototypes, AR devices are becoming more available and affordable, and mainstream smartphones and browsers are now supporting AR functionalities. Technologies like Microsoft's Hololens 2 [16], Meta's Oculus Quest 3 [15], Nreal's AR smartglass [17], Snapchat's Spectacles [22], and Apple's newly announced Vision Pro headset [3] are transforming previous visions for AR into market-ready products. In addition to the hardware advancements, the platforms and application development ecosystems surrounding these technologies are growing, as well. In this paper, we study five leading AR platforms: Apple's ARKit [9], Google's ARCore [5], Meta's Oculus Integration [20], Microsoft's MRTK [30] for Hololens, and WebXR [28] for the web. These platforms cover all three AR hardware form factors currently available: handheld mobile devices, video passthrough AR headsets, and optical see-through AR headsets.

UI in Augmented Reality. Unlike traditional 2D contexts where users interact with UI content on flat screens, the AR UI is a conjunction of visual elements from the physical world, the AR virtual world, and the user's interactions within the immersive 3D world. The AR context requires that the system

process and understand the physical world surrounding the user [7,8,14,18,47], and virtual content is often "anchored" to physical-world surfaces, requiring rapid updates in response to change's in the user's physical surroundings or position.

Figure 1 shows how these elements are combined by platform-specific SDKs that process sensory data from the physical world as well as user input, and then pass this data to the platform's rendering engine to generate the final UI that is perceived by the user. Some SDKs include their own rendering engine; for example, both ARCore and ARKit handle rendering using the platform-specific built-in engine. Other SDKs offload rendering to external engines or libraries; e.g., while both Hololens 2 and Meta Quest provide their own platform SDKs, rendering is managed by existing game engines like Unity [25] or Unreal [26], while WebXR uses existing 3D rendering JavaScript libraries, such as Three.js [23] or Babylon.js [10]. The breadth and complexity of this ecosystem mean that different AR platforms may make different design or implementation choices in building the AR UI experience, and platform developers may fail to realize the security, privacy, and safety implications of these decisions or their integrations of different components.

Security and Privacy for AR. We add to a growing body of work from the computer security and privacy community, which has been addressing security, privacy, and safety risks in AR for over a decade [78]. The initial security threat modeling taxonomies for AR were proposed by Roesner et al., identifying input, data access, and output as key areas of concern [79]. Guzman et al. then built on these categories, incorporating user interaction and device protection [46]. Much prior AR security work falls into these taxonomies, including studies focusing on sensor data input privacy in AR/VR platforms [50,55,56,86,93,95,101], on device and network safety [52,87,90], on user input [63,88] and work identifying and addressing malicious AR output [32,43,61]. Prior works also proposed mitigation strategies via AR platform design [56,59,61,80,81,96]. Though some of these prior works touched on topics related to AR UI security (e.g., virtual content "output attacks" by malicious AR apps [43,59]), to our knowledge no prior work has systematically studied AR UI security — including both application output and user input — as we do in this paper.

3 Selected Properties and Evaluation Metrics

In Section 1, we described five proof-of-concept attacks on AR UI security. Before we return to these attacks in Section 4, we first identify and introduce three key AR UI security related properties that underpin these types of attacks.

Properties. Our team, which included eight researchers, conducted multiple rounds of interactive threat modeling, structured brainstorming, and preliminary experiments to generate

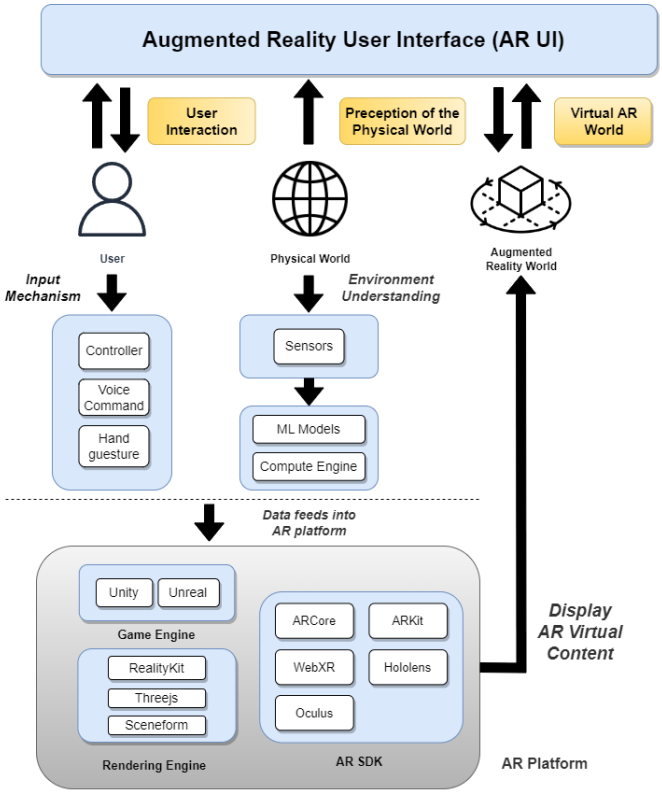

Figure 1: Overview of Augmented Reality User Interface. The yellow box represents the three main components: perception of the physical world, virtual AR world, and user interaction.

and refine ideas for design choices, properties, and/or test cases for AR platforms. Six (of eight) authors participated in the brainstorming process. This process involved: (1) each author independently generating security or privacy related questions and associated testable properties about AR platform designs (using sticky notes and a spreadsheet), (2) multiple authors reviewing and refining each row of the spreadsheet, and (3) clustering the properties according to themes (e.g., user input, multiple applications or components, hardware, sensors). From there, we chose to focus on AR UI security issues because we found them particularly interesting given the relationship between the UI, the environment, and the user and underexplored in current platforms.

1. **Same Space.** How do AR systems manage objects that share the same physical world mapping? For instance, when two AR objects with identical shapes and sizes are anchored at the same 3D coordinates, which object(s) become visible to the user? Which receive (s) the user's input? We leverage this property in the clickjacking attack (Section 4.2).
2. **Invisibility.** How do AR systems handle virtual objects in the AR world that are transparent? To what extent, if any, does an object's visibility influence its functionality?

For example, are transparent objects capable of receiving user input? What happens when a transparent object renders over another virtual object? We leverage this property in the user input denial-of-service (Section 4.3), object-in-the-middle (Section 4.5), and object erasure (Section 4.6) attacks.

3. **Synthetic User Input.** How do AR systems handle synthetic user input? For example, can adversarial code generate synthetic input to mimic human interaction, such as via a programmatically generated raycast? We leverage this property in the input forgery (Section 4.4) and the object-in-the-middle (Section 4.5) attacks.

Evaluation Metrics. Moving from these properties and questions to *specific evaluation metrics* that we can use in our empirical investigation of platforms in Section 5:

For **Same-Space,** if two virtual objects from different application components are created with the same size and placed at the same 3D coordinates, we evaluate:

- *Rendering Order:* Is the object placed first or the object placed second visible?
- *Interaction Order:* Does the object placed first or the object placed second receive user input?
- *Rendering Flicker-Free:* Is rendering order consistent within a single trial, or does it flicker?
- *Rendering Consistency:* Is rendering order consistent across trials?
- *Interaction Consistency:* Is interaction order consistent across trials?
- *Rendering-Interaction Consistency:* Are the object that is visible and the object that receive user input the same object?

For **Invisibility**, if objects are transparent, we evaluate:

- *Create Invisible Object:* Using each of the following possible invisibility mechanisms, can an invisible object be created? Mechanisms include: (1) setting a zero alpha value, (2) disabling the object's renderer, (3) using a null material for the object, and (4) using a custom transparent material for the object?
- *Invisible User Interaction:* Can invisible objects based on the preceding mechanism take user input?
- *Composes as Expected with Virtual Objects:* If an invisible object is rendered overlapping another virtual object, what is the resulting visible rendering? Is the other virtual object visible? [2]

For **Synthetic Input**, if input is not created by real AR users, we evaluate:

- *Create Synthetic Input:* Does the platform support synthetic user input, such as through a simulated raycast?
- *Invisible Synthetic Input:* When synthetic input is dispatched, has any visible indication to the user occurred (e.g., via a visible raycast)?
- *Input Provenance:* When a virtual object receives user input, is there a way for it to distinguish real user input from synthetic input?

We stress that completeness, in properties or metrics, is not our goal. Instead, we focus on metrics derived from our brainstorming activity that we considered important, challenging, and interesting in the AR context.

Valid Use Cases for Properties. While we focus on the security implication of these properties, we emphasize that they can also enable necessary features in many AR applications. Thus, seemingly simple solutions such as disallowing objects from occupying the same space, disabling invisible objects, or disallowing synthetic input will not be tenable.

The **Same Space** property allows designers and developers greater flexibility when creating AR experiences, enabling them to design complex scenes and arrangements where objects can interact, stack, or blend with each other in creative ways. In architectural or interior design AR applications, the ability for virtual objects to overlap becomes particularly useful as they can represent multiple layers or illustrate the relationships between different elements, providing a rich visual representation of the design. Moreover, the Same Space property facilitates intuitive user interaction and manipulation. Users can freely move around in the physical space, effortlessly viewing, moving, rotating, or scaling individual objects. The dynamic updating of visuals in response to changes in the user's physical surroundings or interaction occurs smoothly without rigid collision constraints, ensuring a seamless and natural experience.

The **Invisibility** property also contributes to a broad range of practical functionalities. For example, Pokemon Go, one of the most popular AR games, uses invisible objects as a placeholder for Pokemon that are still under development [31]. Moreover, existing research corroborates the value of this functionality in medical training scenarios [39]. Here, the AR objects are designed to be context-sensitive and can transition to an invisible state, allowing surgeons to look through overlaid content without obstruction. In addition, invisibility is also widely used for handling occlusion between virtual objects and real-world objects to ensure that virtual objects are realistically occluded by real-world objects, improving overall immersiveness [6].

The **Synthetic User Input** property, commonly implemented via raycasting, is integral to the functioning of AR features. Its primary function is to indicate user interaction and selection in the real world by returning information about the selection, such as the distance, position, or a reference to a real-world object (plane, surface) or virtual AR object. The many legitimate use cases of synthetic user input include, for example, an AR shooting game that generates synthetic input

[2] We were motivated to add this evaluation metric after discovering the object erasure attack for WebXR, described in Section 4.6.

as a shooting ray to intersect with the designated object.

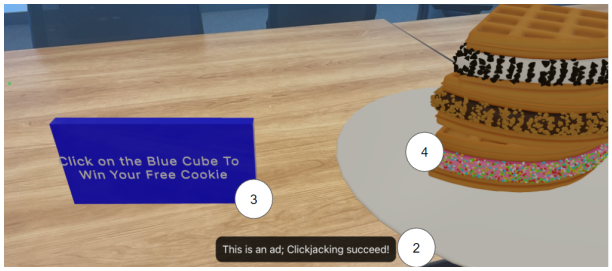
Hence, it is crucial not to simply disable the features associated with these properties solely due to their potential security implications. Rather, we advocate that AR platform and application designers carefully consider the potential security implications in addition to the desirable use cases.

4 Threat Model and Proof-of-Concept Attacks

We now return to the proof-of-concept AR UI security attacks that we previewed in Section 1. First, we detail our threat model. Then, we describe in detail our proof-of-concept attacks on five AR platforms (ARCore, ARKit, Hololens, Oculus, and WebXR). Though we choose one platform on which to implement each attack, our empirical investigation in Section 5 will reveal that multiple platforms provide the preconditions for implementing most attacks.

4.1 Threat Model And Attack Preconditions

We assume adversarial behavior might extend from one entity (e.g., an included ad library) to another entity (e.g., the main app), or vice versa. Attackers could directly call the API from the SDK to either gather sensitive information from the AR application (e.g., location of a target AR object) or place content within the AR virtual world. Our threat model resembles those used in other platforms, e.g., malicious third-party iframes [36, 98] or included third-party libraries in the mobile ecosystem [97, 100]. However, the current AR environment is arguably more vulnerable given there are no iframe-like primitives that isolate the execution of third-party code; instead, it shares a portion of the displayed AR scene.



All proof-of-concept attacks rely on at most these three preconditions (in addition to the individual attack-specific metrics we test): (1) the location of the targeted object, (2) the ability to generate virtual content interleaved with the victim's content, and (3) the execution of synthetic input. These preconditions are straightforwardly met in today's systems, where third-party libraries are included in applications as either the attacker or victim components.

4.2 Clickjacking: Leveraging Inconsistency between Rendering and Interaction Orders

Attack Motivation: Bait User Interaction. Clickjacking is an attack that fools users into thinking they are clicking on one thing when they are actually clicking on another. As they can on web and mobile platforms today, app developers will be able to use third-party ad libraries on AR to display ads and generate revenue. AR advertising has attracted huge interest, and revenue in this market is projected to reach US $1.05 billion in 2023 [4]. Attackers are well-incentivized to mount clickjacking attacks on ads it includes, tricking users into clicking on them and thereby increasing ad revenues. Prior work has hypothesized and demonstrated clickjacking attacks through hijacking the cursor in the context of VR [63]. Here, we demonstrate one type of clickjacking attack in AR without modifying the user's interaction.

(a) User's view of an AR advertisement object.

(b) Demonstration of the clickjacking attack

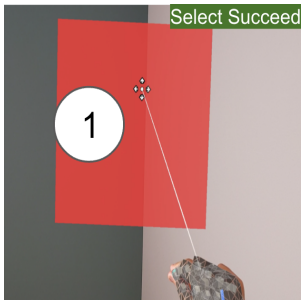


Figure 2: **Clickjacking attack on ARKit.** ① The advertisement object displayed in the AR world. ② A prompt after the advertisement is clicked. ③ A bait AR object rendered on top of the advertisement object exploiting the Same Space property. ④ An accompanying bait AR object. After the user clicks on the bait object ③, the interaction goes into the advertisement object ① and generates the prompt ②.

Attack Design. We implement this attack in iPhone 13 using the ARKit SDK. Our intuition is that the AR platform will handle the rendering sequence and interaction sequence differently when two objects are placed in the same 3D coordinates. For example, when we place two AR objects in ARKit using the same anchor (`(object.setParent(AnchorEntity))`), the object placed second will always render over the first object, but the user's interaction will always trigger the functionality of the first, now hidden object. The attacker here is a revenue-hungry developer. The ad revenue will go to the developer as the user's interaction with the bait object goes into the ad object. The preconditions for this attack are (1) the location of the targeted object, and (2) the ability to generate virtual content interleaved with the victim's content.

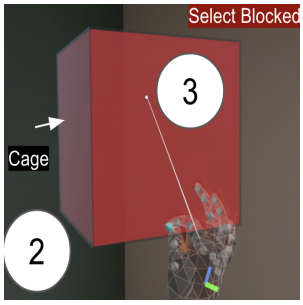

Figure 2 illustrates the attack. When the victim/user launches the application, an advertising platform places a third-party ad ① in a certain bounded region of the main app, and a revenue-hungry developer/attacker then places a new interactive bait object ③ in the same space as the advertisement. This component displays the message "click here to win your

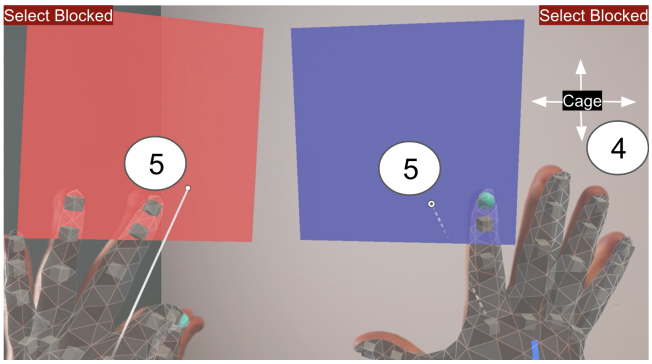
free cookie" to bait user clicks. However, the user's interaction with the bait object actually triggers the underlying ad ① even as the attacker 'steals' revenue from the click.



4.3 Denial-of-Service Proof-of-Concept: Leverage Invisibility

(a) User's view of the victim object. User is able to interact with the object.

(b) Demonstration of the first denial of service attack. "Cage" covers the object.

(c) Demonstration of the second denial of service attack. "Cage" covers the entire space.

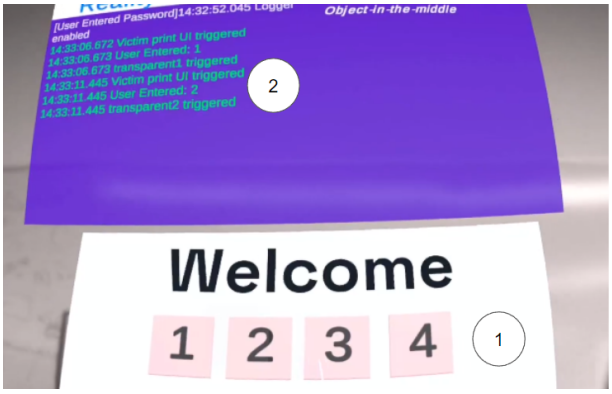
Figure 3: **Denial-of-user-input attack on Hololens.** ① The user can select and interact with the victim object (red). ② The attacker overlays a fully transparent object over the victim object (red). For demonstration, we make the transparent object ("cage") slightly visible. ③ The invisible "cage" blocks user interaction with the victim object (red). ④ In addition, the attacker can surround the user in a fully transparent "cage". ⑤ The invisible "cage" blocks the user from interacting with *any* AR objects , in this case, the red and blue AR objects.

Attack Motivation: Block User Interaction. A denial-of-service attack refers to an explicit attempt by a malicious entity to deny legitimate users access to an object/service. In this context, the attacker's goal is to stealthily prevent the user from interacting with the target AR object, e.g., preventing the user from engaging with a competitor's content or disrupting the user from properly engaging with *any* AR object.

Attack Design. We implement two variant of the denial-of-service attacks in Hololens 2 using the MRTK. The attack insight is that the Hololens default raycast implementation, i.e., `private static RaycastResult PrioritizeRaycastResult`, would return the closest hit object. Based on our findings in Section 5, we find that an attacker can construct a completely invisible object that captures the user's input. Furthermore, the 3D nature of the AR virtual world lets the attacker envelop the user within this invisible 'object cage,' causing the invisible object to intercept, initially and always, the user's interactions. The preconditions for this attack are (1) the location of the targeted object, and (2) the ability to generate virtual content interleaved with the victim's content.

Figure 3 illustrates this attack. The victim/user launches the application and intends to select an AR object ① using a hand ray as the input mechanism. However, the attacker can either overlay an invisible object ② on the targetted AR object to block user from interacting with it ③. Furthermore, the attacker can overlay a large invisible object ④ that encapsulates the user such that the user is always physically inside of the object. The user's interaction towards *any* AR object is thus blocked ⑤ regardless of their movements within the physical space.

(a) User's view of the victim app.



(b) Demonstration of the input forgery attack

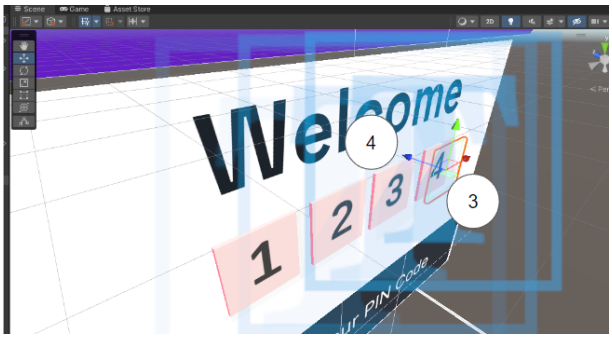


Figure 4: **Input forgery attack on ARCore.** ① The advertisement object displayed in the AR world. ② When the advertisement object is outside of the user's view, ③ the attacker launches a synthetic input to interact with the object. The prompt demonstrates the attack is successful.

4.4 Input Forgery: Leveraging Synthetic User Input

Attack Motivation: Impersonate User Interaction. Similar to the motivation in the clickjacking attack, here the adversary's goal is to maximize advertisement engagement. The attacker places an advertisement object outside of the user's

(a) User's view of the victim app.

(b) Demonstration of the object-in-the-middle attack.

Figure 5: **Object-in-the-middle attack on Oculus.** ① The interface for authentication. ② The logger for the execution result. ③ The invisible object the attacker places over the pin pad object. ④ The blue arrow suggests the direction of the synthetic input to trigger the pin pad object.

view and generates synthetic user input to increase the number of ad interactions. Placing it outside of the user's peripheral is not a requirement though it will make the attack more stealthy.

Attack Design. We implement this attack in Pixel 5 using the ARCore SDK. The attack insight here is that a programmable click can interact with objects outside of user's view by exploring the limited display of field-of-view. The precondition for this attack is the execution of synthetic input.

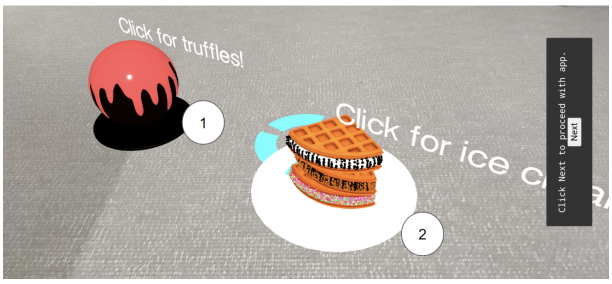
Figure 4 illustrates the attack. When the victim/user launches the application, the malicious application developer will place the third-party ad ① in the user's view. When the ads' location is outside of the user's view ②, the attacker will then generate synthetic input ③ to trigger interactions on the ads, increasing its interaction count, and later charging the respective advertisers for this inflated number of ad views.

4.5 Intercepting User Inputs: Combining Invisible Objects and Synthetic User Input

Attack Motivation: Hijack User's Interaction. Object-in-the-middle is an attack in which a third party object gains access to (or "intercepts") the communication between two other objects. As AR applications continue to grow in domains beyond entertainment, users may enter sensitive information—such as PIN codes, passwords, or private messages—by interacting with a virtual keyboard rendered in the AR space. Each virtual key is a `collider` that provides collision detection. When the user either presses a key or casts a ray, the collider detects the intersection and outputs the corresponding value.

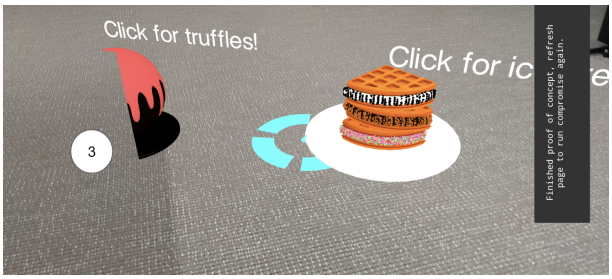
Prior work has shown the possibility to sniff user text input through various side-channels [69, 86]. Here, we demonstrate in AR that not only can an attacker surreptitiously steal the user's input, but it can also impersonate the user or even modify the original input, similar to a man-in-the-middle attack.

Attack Design. We implement this attack in the passthrough mode of Oculus Quest 2. Our attack intuitions here are twofold. First, similar to the denial-of-service attack, it is possible to block the user's original input by overlaying a transparent object on top of the keyboard. Second, we can cast a synthetic ray to impersonate the user's interaction since the current platform does not provide input provenance.



Given our observations, we implemented an object-in-the-middle attack on Oculus. The preconditions for this attack are (1) the location of the targeted object, (2) the ability to generate virtual content interleaved with the victim's content, and (3) the execution of synthetic input.

Figure 5 illustrates the attack. When the victim/user launches the application, it shows a mock authentication interface ①, part of the main app that consists of a pin pad for the user to enter their password. We present a logger ② to illustrate the efficacy of the attack. A malicious third-party component places several transparent meshes in front of the pin pad entity to intercept the user's input ③. Once the transparent meshes detect the user's interaction, the malicious component casts a synthetic input ④ to the pin pad, passing the user's input on to its intended destination.



The result is that the attacker has intercepted the password, but the user has not noticed anything amiss. Following the same attack logic, the attacker could also modify the user's input if needed since they can arbitrarily define the synthetic input destination.

4.6 Object Erasure: Leveraging Invisible Meshes

Attack Motivation: Erase Other AR Objects. Echoing our attack focus, here we consider a scenario where the attacker aims to interfere with another party's virtual content by ma-

(a) User's view of victim app.

(b) Demonstration of the object erasure attack.

Figure 6: **Object erasure attack on WebXR.** (①,② Two competing advertisements. ③ Attempt to erase the competitor advertisement using transparent mesh. (We partially offset the invisible object for attack visibility.

nipulating targeted objects. Motivations for such actions can vary greatly. For instance, one potential objective could be to erase a competitor's AR content, such as advertisements or promotional material. Another might be the desire to manipulate the user's perception: by altering or erasing certain AR objects, e.g., vital information or safety warnings, an attacker could significantly distort the user's view of reality [43, 61]. Such manipulation of AR content could also be deployed as a form of digital vandalism [57], comparable to defacing a physical sign or billboard.

Attack Design. We implement this attack in the Chrome browser using the WebXR SDK and Three.js library. When we assign a fully transparent mesh (png format) as the material of an AR object using `new THREE.MeshBasicMaterial( map: THREE.TextureLoader().load('transparent.png' ))`, we find that not only does the AR object become fully invisible, but it also "erases" the rendering of other AR objects positioned behind it. The preconditions for this attack are (1) the location of the targeted object and (2) the ability to generate virtual content interleaved with the victim's content.

Figure 6 illustrates the attack. When the user launches the application, it presents two competing third-party ad libraries ① and ②. Code from one mock ad library then places a transparent mesh in the same space as the competing advertisement to erase it ③.

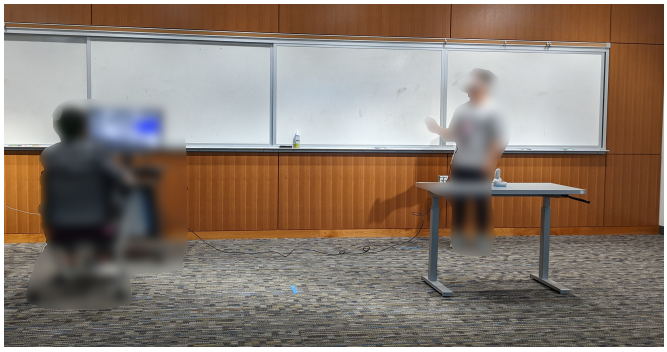


Figure 7: Researchers conducting the experiments.

5 Empirical Investigation

Stepping back from individual proof-of-concept attacks, we now turn to a more systematic investigation of current AR platforms. We evaluate how five leading AR platforms — ARCore (Google), ARKit (Apple), Oculus (Meta), Hololens (Microsoft), and WebXR (browser) — implement the AR UI properties identified in Section 3. In this section, we first describe the infrastructure for our experiments, detail the platforms and configurations we used, and then present results of experiments. Finally, we discuss the security implications of our results (Section 5.4).

5.1 Overall Experiment Infrastructure

We systematically developed a repeatable set of experiments for each property that we identified in the previous section (i.e., Same Space, Invisibility, and Synthetic Input) . The experiments we conducted varied depending on the evaluation metrics for that property.

A human experimenter ran each experiment and another researcher recorded the experiment results, as demonstrated in Figure 7. Each experiment follows the procedure described in Figure 8. The central component of each experiment is a harness launched at the procedure's beginning. Corresponding to our threat model, each experiment further involves two AR application components, ComponentA and ComponentB, representing two pieces of code from different entities (e.g., a main app and an embedded third-party library).

With the experimenter's input, the harness (1) launches ComponentA, then (after the experimenter made necessary observations) (2) launches ComponentB, and finally (3) steps through the experiment in four different locations, which we annotated as Location N, S, E, W, interacting with the AR object in different spatial locations and providing input to the harness to proceed.

To account for potential non-determinism, we conducted each test case experiment $M = 5$ times. Further, each test can have up to $N = 5$ sub-experiments. Details about ComponentA and ComponentB depend on the nature of each test case.

```
Experimenter's Procedure(M,N)
    For j = 1 to M do
        Launch Harness(N)
        Launch and provided any user input to start experiment
        Launch and provided any user input to start
            ComponentA.launch()
        Launch and provided any user input to start
            ComponentB.launch()
        For k = 1 to N do
            click "Next" button
            Start ComponentA.next()
            Start ComponentB.next()
            Perform sub-experiment observations and interactions
        Exit Harness(N)
```

Figure 8: The parameter M denotes the number of experiments that the experimenter (a person) should run. Throughout the procedure's pseudocode is the assumption that the experimenter records detailed notes of observations during each experiment.

5.2 Experiment Platforms and Configurations

We describe here the specific experimental configurations and versions we used for each platform. An experimental setup requires not only a choice of platform (e.g., ARKit) but also additional choices for the entire tech stack (e.g., which SDK to use). Different choices for the full tech stack might have led to different experimental results, and we will release our experiment code to allow future work to adapt it for other contexts — including future technologies, like Apple's recently announced Vision Pro headset [3].

ARCore. ARCore [5] is Google's Android core SDK for augmented reality. We built our test cases using ARCore v1.32.0 [5] for AR functionalities and Sceneform SDK [12] for 3D content rendering (version 1.20.5). The test cases were implemented in Java and tested on the Pixel 5a.

ARKit. ARKit [9] is Apple's main AR SDK and includes multiple iOS AR frameworks, such as RealityKit [1] and RoomPlan [2]. We built our test cases using ARKit and RealityKit for necessary AR functionalities. The three test cases were implemented mainly in Swift and tested on the iPhone 13 Pro.

Oculus. We use Quest 2 with the experimental Passthrough API [40] and spatial anchors to enable an AR experience. We built our test cases using Oculus Integration SDK v44.0 [19]. They were implemented mainly in C# (Unity) and tested on the Oculus Quest 2.

WebXR. The WebXR Device API [28], led by the W3C Immersive Web Community Group, provides a uniform abstraction layer to host immersive web content. We built our test cases using the WebXR API-20220601 [29] for necessary AR functionalities and Three.js [23] for 3D content rendering. The three test cases were implemented mainly in JavaScript and tested on the Chrome Browser.

Hololens. We deployed a Hololens 2 application using the Mixed Reality Toolkit (MRTK) 2.0 [30] and Unity 2021.3.16f1 [24]. MRTK is an authorized Microsoft project that provides components to facilitate MR development in Unity. We employed numerous features of MRTK in our test cases, including spatial anchors, gesture recognition, and object manipulation.

5.3 Experiments and Results

We now examine our experiments and results, per property, based on the evaluation metrics presented in Section 3. Table 1 highlights all our results.

5.3.1 Same Space Experiments and Results

Experiment Design. In the SameSpace experiment, ComponentA creates a virtual Cube1 object at one coordinate in the physical world, and ComponentB creates a second Cube2 placed in the same physical location. Both Cubes use the same spatial anchor, which is a specific 6-degree-of-freedom pose (position and orientation) of the physical world, as the physical location reference and are registered with a user input handler. The experimenter moves to four different locations (noted as North (N), South (S), East (E), and West (W)). At each location, the experimenter observes the rendering sequence of the overlapping cubes and interacts with the Cubes by sending a virtual ray or tapping on the overlapping region to register the returning result. To verify our code is operating correctly, each Component displays additional cubes that the experimenter observes and verifies as part of the procedure. We omit further details about such checks because in all cases the checks were made and passed.

From these activities, the experimenter evaluates the metrics specified in Section 3. Specifically, the experimenter observes: which cube is visible (based on which color is visible), which cube takes user input (based on log output from the cube's input handler), and whether these observations are consistent across multiple conditions and trials.

Experiment Results. The top section of Table 1 presents the results. We find that platforms are inconsistent about which object is visible, which object receives input, and whether the visible object is the one receiving input. Significantly, these inconsistencies appear between platforms, across multiple trials of a single platform, and even within a single trial (i.e., flickering cubes). For example, for ARKit, Cube2 is always rendered, but Cube1 receives the user input; the opposite is true for HoloLens. For WebXR, there was significant inconsistency across multiple experiments as the overlapping Cube flickers and either cube could register the user's input. ARCore flickers in a slower way, but all of the user's input goes

Property	Condition	Metrics	ARCore	ARKit	Hololens	Oculus	WebXR

Table 1: Overview of experiment results. Filled circles indicate the metric is satisfied, and empty circles indicate they are not. For the Same Space experiment, circled 1 indicates that the object is created by the first (victim) principal; circled 2 indicates that the object is created by the second (adversarial) principal. "Unstable" means that the results are inconsistent during a single trial. "Unstable*" means that the results are inconsistent between multiple trials.

into Cube2.

We find that Oculus is the only platform that handles rendering-interaction consistently, with a caveat that 15% (15 out of 100) of the trials fail to maintain this consistency. While Oculus prevents flickering from the overlapping Cube, we find that the rendering sequence and the corresponding interaction sequence flip as the user moves to the next testing location. In addition, we also notice an inconsistency across multiple trails in terms of which Cube appears on top.

These findings suggest that current AR platforms have not systematically considered the Same Space property or these types of corner cases.

5.3.2 Invisibility Experiments and Results

Experiment Design. In the Invisibilityexperiment, ComponentA creates a visible Cube1 object at one coordinate, and ComponentB creates a visible Cube2 in front of Cube1. Cube2 is significantly larger than Cube1. The harness asks the experimenter to confirm if Cube2 completely occludes Cube1 and, upon confirmation, ComponentB deletes Cube2 and creates a new invisible Cube2' at the same location and with the same geometry; it does this by attempting four different mechanisms: (1) setting the alpha value to zero, (2) providing a null material, (3) disabling rendering, and (4) uploading a transparent texture as the object's material. Both Cubes are registered with a user input handler. The process with Cube2 size and placement verification and then Cube2' instantiation ensures that input makes sure any interaction will go into Cube2' first. The experimenter then evaluates the metrics from Section 3, observing whether the invisible cube is fully invisible and dispatching user input to the invisible cube to observe if its input handler is triggered.

Experiment Results. The middle section of Table 1 presents the results. We find that all five AR platforms can create invisible objects that take the user's input. However, the detailed implementation condition for each platform differs slightly. For example, by setting Cube2's alpha value to zero, ARKit and Oculus both generate a completely transparent cube while registering the user's input. When disabling the rendering, ARCore and ARKit completely occlude Cube2', meaning that the cube can neither be seen nor receive input; Cube2' in WebXR, Hololens, and Oculus instead take input while being fully invisible. For Hololens and Oculus, this occurs because the rendering and collision engines are separate, which means objects can still possess physical characteristics without being rendered.

When uploading the customized transparent texture, we find that ARCore and WebXR produce a fully invisible Cube2 that takes input, while the other three platforms generate a slightly visible Cube2. All platforms except WebXR handle the null material edge cases by generating a solid color Cube2. Surprisingly, we found that the AR object generated by one principal in WebXR can affect the appearance of *other* AR objects. Specifically, whenCube2' is created with an uploaded transparent texture, we observe that the visible object located behind the invisible object (based on the user's viewing position) seems to disappear.

5.3.3 Synthetic Input Experiments and Results

Experiment Design. In the Synthetic Input experiment, ComponentA creates a virtual Cube1 object at one coordinate with an input handler. When the experimenter presses a button, ComponentB creates synthetic user input — in the form of a simulated raycast — to interact in the direction of Cube1. The direction of the simulated raycast is calculated by retrieving the location of Cube1 and generating the corresponding direction vector. In addition, we test if input visualization is required to generate synthetic input. The experimenter observes whether the input handler of Cube1 was triggered. This experiment is repeated with the target object (Cube1) inside the user's field of view and outside the user's field of view (e.g., behind the user).

Experiment Results. The bottom section of Table 1 presents the results. We find that all platforms allow synthetic user input, which is moreover invisible *and* can interact with the target AR object (Cube1). One consistent observation across all platforms is the absence of effective input provenance verification. This is a significant shortfall as the raycast API does not supply sufficient information to distinguish between genuine and synthetic user input. In addition, we discovered that for synthetic user input to be functional, the target objects need not be within the user's field of view. This leverages users' limited visual awareness when they are physically present within the 360-degree immersive AR user interface when the AR objects themselves remain rendered within the scene, exploiting this gap in user perception.

5.4 Security Implications

Returning to our proof-of-concept attacks from Section 4, we can now directly connect our empirical evaluation results with those attacks. In Table 2, we connect each attack to its preconditions — that is, to the necessary experiment result(s) that would enable the attack. For example, our denial-of-service attack requires that a platform be able to create invisible cubes and that those cubes be able to receive user input (i.e., "Invisible Cube Input Registration: ●"). Based on our experiment results in Table 1 and each of the attack preconditions, we can thus summarize in Table 2 which of our tested SDKs are vulnerable to which attack. We demonstrate all five proof-of-concept attacks in current AR platforms in Section 4.

Proposed Attack	Property	Attack Precondition	ARCore	ARKit	Hololens	Oculus	WebXR
Denial-of-service	Invisibility Invisibility	Create Invisible Object: ● Invisible User Interaction: ●	★	★	★	★	★
Object Erasure	Invisibility	Composes as Expected w/ Virtual Obj.: ○					★
Input Forgery	Synthetic Input	Input Provenance: ○	★	★	★	★	★
Clickjacking	Same Space Same Space	Interaction Consistency: ● Rendering-Interaction Consistency: ○		★	★	★*	
Object-in-the- Middle	Invisibility Synthetic Input Synthetic Input	Invisible Interaction: ● Input Provenance: ○ Invisible Synthetic Input: ●	★	★	★	★	★

Table 2: Analysis of which attacks each platform (in our testing configuration) enables. ★ indicates this attack is possible to implement based on our experimental results; * indicates the attack might fail due to the AR platform's inconsistent behavior.

6 Discussion

As with all emerging technologies — from smartphones (in the early 2000s) to computerized automobiles (also in the early 2000s) — many defensive strategies can be adopted from earlier technologies and new challenges must be overcome. We view this paper as one component in the evolution of computer security and privacy for AR systems. While it is impossible to predict the future, we reflect on our work's possible place in this evolution here.

6.1 Problem Formulation

There are often vulnerabilities in emerging technologies that, from a purely abstract technical perspective, are unsurprising. Consider, for example, the discovery of `strcpy` vulnerabilities in automobiles in 2011 [41], over two decades after Aleph One's classic "Smashing the Stack for Fun and Profit" [72]. The contribution of such results is not in finding yet another vulnerability but in assessing *how* an emerging technology — one that has not yet seen significant security analysis — *might* be vulnerable. We consider our work — our identification of properties to assess as well as our exploration of case study attacks — to be of this lineage. Moreover, we consider not only how AR systems might be vulnerable, but we empirically find that the designs of *all* five instantiations of the AR technologies that we study *do* expose themselves to attacks.

Today's AR systems may not need to be secure against the types of attacks we study. They are still emerging and predominantly single-principal. But, under the assumptions that future systems might be multi-principal, more widely used, and make design decisions that often persist in future technologies even as the threat landscape changes, we believe that it is imperative for AR platform designers to consider mitigation strategies now.

6.2 Knowledge of Defenses for 2D UIs Will Help

Applying existing (known) defensive strategies from other domains is a natural and appropriate first line of defense when considering newly discovered vulnerabilities in emerging technologies. For example, in the automotive domain, early research suggested the use of (even then) standard defenses, such as application-level authentication and encryption and the avoidance of unsafe code like `strcpy` [41]. Likewise, there is already an existing wealth of knowledge on UI security for 2D interfaces (desktop, mobile, web), and we encourage the adoption (or extension) of those defensive techniques to AR systems.

For example, an invariant that can provide resilience to clickjacking on the web is the following: a user can interact with a web object if and only if the web object is visible and has been visible for at least a minimum amount of time [54]. That defensive strategy, if implemented and fully instantiated, would serve to strengthen AR systems. However, is it possible to fully instantiate that defensive strategy? We elaborate on this question below.

Other known techniques that could be adapted for AR UI security — once the need to adapt them has been identified, as through our work — include: (1) input provenance to help the application distinguish real user input from synthetic input, as well as synthetic input from different sources [11, 49]; (2) "Z-fighting" (same space) mitigations for same space conflicts (such as slightly offsetting multiple objects [21] or higher resolution buffers [58]); and (3) the isolation of different application components (i.e., a "same origin policy" for AR applications).

However, applying these techniques for AR may not always be straightforward or sufficient, as we elaborate in the next subsection.

6.3 Knowledge of Defenses for 2D UIs Is Not Sufficient

Though it is impossible to fully predict all the challenges with future 3D interfaces, we observe several potential differences here.

For example, consider known defenses for clickjacking. From our assessment of 3D gaming environments, there *are* reasons for which developers might intentionally create invisible yet interactable objects. Thus, the anti-clickjacking invariant mentioned above may not be directly applicable in all immersive 3D environments and use cases. Further, unlike desktop and web environments, where one object is clearly "on top," the visibility of an object might be impacted by the position of the viewer, who could be moving around the objects, or the objects could be moving around the viewer. This "on top" nature becomes even more complicated if the same set of objects are being viewed by multiple people (different viewers of the same scene might see different objects on top). Certainly, computational methods could be used to determine which object is on top of each user, though platform designers must account for the different architecture of AR systems and the different roles of the physics and rendering engines. Even then, some invariants, such as minimum time of visibility before being clickable, may be incompatible with some use cases, like playing a game with fast-moving objects while simultaneously using another leisure application.

As another example, consider that our attacks depend on a threat model in which multiple application components — or multiple applications — are mutually distrusting. While current AR platforms do not (yet) support rich multi-application interactions (except with applications confined to 2D windows), we can anticipate that future platforms will evolve to fully support two (or more) immersive augmented reality applications at the same time: for example, walking directions interspersed with game content from another application. Securely managing the integration of content from multiple applications in the AR context, or even isolating content from different sources within the same application (like Site Isolation for iframes on the web [75]), will be a large technical and research challenge [60].

6.4 Potential Defensive Techniques

Work has already begun to emerge within the security research community that provides potential defensive directions against the issues we raise in this paper. For example, Lee et al. [63] introduced AdCube, a defensive system to counter several WebXR attacks. The attacks they consider have some similarity (and some differences) with the ones we discuss here. The blind spot tracking attack from AdCube places the ad entity outside of the user's peripheral to increase the number of ad appearances, while the input forgery attack in this paper maximizes the number of ad clicks through synthetic input. The cursor-jacking attacks from AdCube exploit the user's perception to hijack authentic clicks whereas our clickjacking attack utilizes the rendering-interaction inconsistency of virtual objects placed in the same space. Despite these differences, the AdCube idea of confining untrustworthy third-party libraries and preventing them from placing virtual objects could mitigate attacks like those we explore as well: specifically, attacks that rely on the ability to generate virtual content interleaved with the victim's content. Future researchers could build upon AdCube and our findings to develop a cross-platform AR defensive toolkit. More generally, future work should also explore other possible approaches that isolate UI components from multiple principals in future AR platforms.

Another line of work that may contribute to defensive directions focused on automated evaluation in AR/VR. Wang et al. [94] defined and used interactable properties of virtual objects to perform automatic testing in the VR environment. Lehman et al. [65] provided automated feedback to help with UX issues debugging. Our methodology is inspired by property-based testing (PBT), a testing technique that leverages the specification of generic properties as the driving force behind the testing process, ensuring that the system under test satisfies these properties [51]. There is rich literature on applying PBT in programming languages [45, 53] and 2D rendering engines [68]. Building on top of our findings, future work could automatically generate test cases analyzing specific metrics — for example, rendering-interaction consistency across multiple conditions, since our results show that the platform may have inconsistent behavior in different scenarios.

6.5 Stepping Back

The preceding observations do not imply that the types of attacks we describe here are insurmountable. Rather, this discussion reflects our view of how this work might fit into the broader evolution of security and privacy for AR systems. At the highest level, and returning to Section 6.1, we believe that our first and most important contribution is the knowledge of *what* vulnerabilities might exist and how they presently manifest in different systems. With that knowledge, it is possible to defend systems by leveraging existing knowledge from 2D contexts (Section 6.2), by creating new knowledge (Section 6.3), and by extending existing defensive directions from AR contexts (Section 6.4). Toward the creation of new knowledge and new defenses, a critical step will be the assessment of what types of applications and use cases the designers intend to support and the management of tensions that arise when the exact feature exploited by an adversarial UI application is also needed by a desirable application.

7 Additional Related Work

Finally, we connect to additional related work in the broader context of AR platform analysis and 2D UI security that was not previously discussed.

Empirical Analysis of AR Platforms. As AR platforms continue to emerge and develop, recent work has compared and evaluated AR platforms according to other criteria as well. Scargill et al. [83] investigate AR object placement stability in mobile AR platforms. Slocum et al. [85] measure the spatial inconsistency when placing virtual objects in the real world on ARCore, while Lee et al. [62, 76] analyze the AR object placement deviation on WebXR. Other works have proposed functionality metrics, such as general performance (CPU/memory use) [71] body movement and marker-based tracking [34, 91], accessibility and ease-of-use [89], lighting estimation [73], and plane and feature point detection [73] that allow direct comparison across multiple AR platforms.

2D UI Security. UI security in 2D has been well-studied. For example, early work in this space included secure windowing systems like Trusted X [48] and EROS [84]. More recently, a line of work considered UI security requirements and threats on Android and iOS [35, 38, 42, 64, 77]. Luo et al. [66] provide a thorough analysis of UI vulnerabilities in mobile browsers. As mentioned, there is also significant prior work mitigating clickjacking attacks on the web and in other contexts (e.g., [54]). Our work takes the next step in the broader space of UI-level security, studying emerging AR platforms.

8 Conclusion

We presented an empirical analysis of five current AR platforms, systematically investigating how they handle three UI security related properties: Same Space, Invisibility, and Synthetic Input. We demonstrated five proof-of-concept attacks — one implemented for each of our test platforms — that leverage different design choices in the context of these AR UI security properties. We found that these current AR platforms, including Apple's ARKit, Google's ARCore, Meta's Oculus, Microsoft's Hololens, and WebXR, are all designed and implemented in ways that enable our AR UI attacks to succeed. Our findings lay the groundwork for future research and design work to consider and address AR UI security to mitigate the risks of such attacks, either through directly applying past lessons from 2D UI security or by grappling with new, AR-specific challenges and tradeoffs.

Along with this paper, all code for our experiments and the video demonstrations are available online at https://ar-sec.cs.washington.edu/ar_ui/ to support future researchers in extending our analyses to other and future AR platforms, including the Apple Vision Pro headset that was announced on the day before this paper's submission.

Acknowledgments

We would like to thank our shepherd and the anonymous reviewers for their valuable feedback. We would also like to thank the following people for their feedback: Michael Flanders, Alex Gantman, Gregor Haas, Rachel Hong, Sandy Kaplan, Inna Wanyin Lin, Rachel McAmis, Kentrell Owens, and Yuan Tian. This work was supported in part by the National Science Foundation under Award #1651230, as well as by awards from Cisco, Google, and Qualcomm.

Can Virtual Reality Protect Users from Keystroke Inference Attacks?

Abstract

Virtual Reality (VR) has gained popularity by providing immersive and interactive experiences without geographical limitations. It also provides a sense of personal privacy through physical separation. In this paper, we show that despite assumptions of enhanced privacy, VR is unable to shield its users from side-channel attacks that steal private information. Ironically, this vulnerability arises from VR's greatest strength, its immersive and interactive nature. We demonstrate this by designing and implementing a new set of keystroke inference attacks in shared virtual environments, where an attacker (VR user) can recover the content typed by another VR user by observing their avatar. While the avatar displays noisy telemetry of the user's hand motion, an intelligent attacker can use that data to recognize typed keys and reconstruct typed content, without knowing the keyboard layout or gathering labeled data. We evaluate the proposed attacks using IRB-approved user studies across multiple VR scenarios. For 13 out of 15 tested users, our attacks accurately recognize 86%-98% of typed keys, and the recovered content retains up to 98% of the meaning of the original typed content. We also discuss potential defenses.

1 Introduction

Virtual Reality (VR) offers a whole new dimension of online interaction significantly more immersive and lifelike than those offered by existing services. By eliminating the need for physical proximity and formal attire, VR cultivates a more convenient, comfortable, and efficient environment for work, play, and social interaction. Thus, VR is increasingly adopted for both personal and professional purposes [40, 42]. In particular, remote work through VR has witnessed remarkable growth. Numerous companies actively promote its adoption with their remote work platforms, including Meta's Horizon Workrooms [41] and VR applications and startups such as Valve [2] and vSpatial [54]. Apple's recent launch of Vision Pro [4] serves as further validation of the substantial interest and investment being made in VR-based remote work.

Because users interact with others using their digital representations or avatars, VR also provides them with a unique sense of privacy and added security. Representation through their digital selves can be particularly attractive for sensitive professional/work activities [26]. In general, VR users can customize how they present themselves and choose what they want to show of their physical environments. This "natural filter" can help prevent the unwanted leakage of private information without the user's knowledge. For example, it might block traditional side-channel attacks, where an attacker can use physical observations of a user or their devices to steal information, e.g., screen peeking, shoulder surfing, and keystroke inference [58, 59, 62].

In this paper, we challenge this assumption by investigating the feasibility of keystroke inference attacks in shared VR environments, where one VR user may attempt to recover the content typed by another user by recording and analyzing their avatar's actions. Since typing is the primary input method for sensitive information to computing systems [57], successful keystroke inference attacks can cause significant damage, such as unauthorized disclosure of confidential or classified data that may lead to breaches of personal privacy or even financial losses. Compared to physical attacks, keystroke inference attacks over VR can be much more powerful, because a single attacker can target numerous remote victims without physical proximity constraints.

Ironically, we show that VR's most appealing properties, its immersive and interactive nature, are the source of VR users' vulnerability to keystroke inference attacks. Specifically, immersive experiences in VR rely on each individual's *expressive* avatars [16, 28], which display the user's body movements, hand gestures, and facial expressions. When an individual performs physical actions such as grasping objects, clapping hands, or typing on a keyboard, their avatar demonstrates an approximate, digital version of those hand movements, which are visible to other users in the same virtual space. Thus, VR actually "facilitates" side-channel attacks by eliminating the need and costs of physical sensing.

Our work shows that, while the accuracy, resolution, and

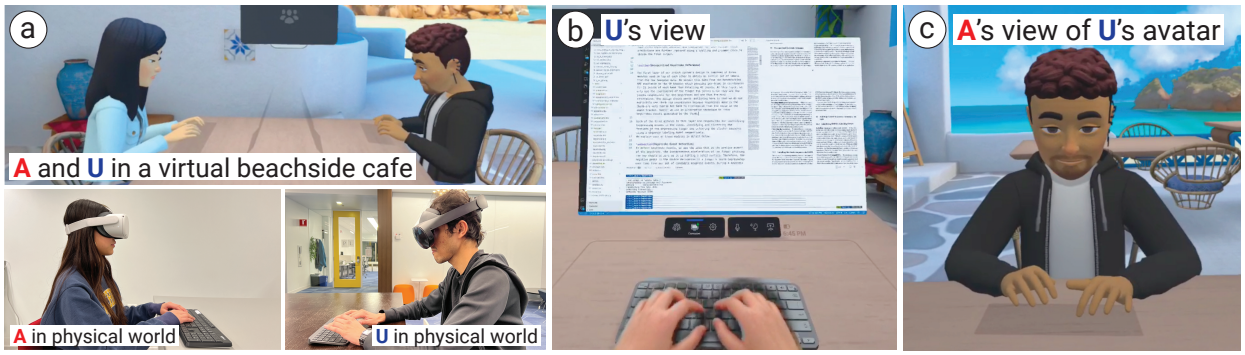

Figure 1: An illustrative example of keystroke inference attacks in the shared VR space. (a) In this scenario, U is replying to emails while enjoying the immersive experience of a virtual beachside cafe. U types comfortably and swiftly on a physical keyboard that is wirelessly connected to the VR headset. This is a typical setup of a VR office. Adversary A is another VR user in the same virtual beachside cafe. (b) From their VR headset, U sees the typed content on a virtual screen and a rendered view of their own hands. (c) A's view of U's avatar, displayed by A's VR headset. Using this information, A seeks to recover the content that U is typing. Credit: The VR scenes are screenshots taken when running the Horizon Workroom application from Meta [41].

granularity of these VR movements are far from those of physical observations (e.g., a physical video recording of the hands), intelligent attackers can still use them to extract detailed information "carried" by the movements, e.g., keys being typed. Therefore, the same feature of VR that drives growing usage and adoption is also enabling a real-world threat against user privacy and information security.

In this paper, we describe the design, implementation, and evaluation of keystroke inference attacks in shared VR spaces. Figure 1 plots an illustrative scenario of the attack. This attack occurs entirely in the virtual space between avatars, without any sensing or data from the physical world. An attacker in the same virtual space as the target gathers the noisy digital representation of hand movements displayed by the target's avatar, and uses it to reconstruct the typed data. We hereby refer to these digital movements as **telemetry** of the VR user.

An effective attack faces two unique challenges: (i) the excessive amount of noise and inconsistency in the telemetry data, and (ii) the lack of knowledge and labeled data on the target user and their physical devices, as they are physically isolated from the adversary. These factors, combined with the inherent complexity and variability of human typing, make it challenging to extract meaningful information from the available data. Commonly used transferability-based attacks (i.e., training a model on known users and applying it to others) are ineffective because an individual's typing behaviors are unique [9, 14, 23] and do not transfer to others [58].

We address these challenges by developing a componentized, self-supervised learning pipeline. We decompose the difficult task of keystroke inference into three sequential components, responsible for detecting keystroking events, identifying finger used, and recognizing the key, respectively. For each component, we first run statistical analysis on simplified telemetry data to produce initial inference results, leveraging general understandings of human typing. Then in the second component, we use these results to curate labeled training data and train a DNN classifier (i.e., a transformer), one that learns the intricate relationship between keystrokes and the full telemetry data. The output of this DNN classifier is then fed to the final component. Using this componentized design, our attack can progressively extract, filter, and learn important keystroke information from the noisy telemetry data, while minimizing the spread of error in the pipeline.

Our attack also supports flexible placement of the adversary in the virtual space, whether it is sitting at the same table (Figure 1), across the room, or floating in the air on a balloon. This is achieved by applying a coordinate transformation to normalize telemetry data seen by *arbitrary* VR users onto a unified coordinate system so that a wide variety of attacks can be executed using a single attack pipeline.

Our work makes four key contributions.

- We identify three forms of keystroke inference attacks that can be executed by a VR adversary in the same virtual space as the target user. These attacks consider different levels of information access available to the adversary, including the original 3D telemetry collected by the target's headset, the transformed 3D telemetry sent to the adversary to render the target's avatar, and its 2D version extracted directly from the adversary's screenshots of the avatar (i.e., Figure 1(c)).
- We design an effective attack pipeline to infer keystroke content from noisy attack data, using a componentized self-supervised learning approach.
- We perform IRB-approved user studies to evaluate the proposed attacks under a variety of VR scenarios and settings, varying avatar distance and placement, keyboard device, and typing content. Moreover, we test the attacks on 15 users. On average, our attacks accurately recognize 91.3% of the typed keys, and the recovered content retains 71.5% of the meaning of the typed content (see Table 5).
- We explore potential defenses and find that adding zero-mean Gaussian noise to the telemetry data can reduce attack effectiveness while preserving the immersive experience to some degree.

To the best of our knowledge, our work is the first to explore and demonstrate the feasibility of keystroke inference attacks in shared VR environments. Our work identifies the crucial challenge of designing VR systems that can provide immersive and engaging experiences while ensuring personal and information security. Also, our attack methodology represents a substantial departure from the conventional understanding of transformers. We hope our results can inspire more self-supervised, transformer-based attack/defense designs.

2 Background and Related Work

In this section, we first describe existing keystroke inference attacks in both physical and VR environments. We then discuss the key features adopted by VR to create immersive experiences (which are the base of our proposed attack) and the general landscape of privacy threats in VR.

2.1 Existing Keystroke Inference Attacks

In a keystroke inference attack, an attacker can reconstruct a target's typed content without control over their input devices. We divide existing attacks into three categories: (i) physical attacks that place sensors near the target to capture their typing actions, (ii) remote attacks analyzing the target's network traffic, and (iii) attacks where the target is a VR user.

Physical attacks. By physically placing sensors (e.g., cameras, microphones, inertial measurement units (IMU), electromagnetic (EM), and radio frequency (RF) devices) near a target, attackers can record data related to the target's typing actions. The recorded sensor data includes audio [62] and video [8, 34, 43, 47, 56, 59], as well as vibration, EM [31], WiFi and LTE measurements [15,33,35]. As pressing different keys causes changes in signals recorded by sensors, attackers can use statistical or machine learning analysis to determine keystroke content. For example, a well-known audio-based attack [62] placed a microphone next to the target to capture key-specific sounds generated by typing on a mechanical keyboard, and trained a machine learning model to identify key entries from the recording. Follow-up works replace microphones with other sensors like IMUs, WiFi/LTE radios, or EM sniffers. Other examples use cameras to capture the screen and the pressing fingertip reflected by the target's eyes or eyeglasses [43, 56], or to record the reflections around the pressing fingertip produced by a reflective typing surface, such as a tablet [59].

Physical attacks are mostly ineffective in the VR attack settings where the adversary, a VR user, cannot place or access sensors or side channels (e.g., eye reflection or surface reflection) in the target's physical space. Moreover, many physical attacks require knowledge of the keyboard and its layout, which are inaccessible to the VR attacker.

Remote attacks by traffic analysis. Song et al. [49] show that by analyzing encrypted SSH traffic, attackers can detect when a user is typing a password, and estimate the password length and content. This is possible because SSH pads data for encryption using an 8-byte boundary and sends packets upon each keystroke in interactive mode. Thus, attackers can infer password length by counting packets and estimate its content using packet inter-arrival times. On the other hand, this attack is only applicable to SSH sessions.

Attacks against VR users. Recent works have examined keystroke inference attacks against VR users [5, 36, 37, 50]. They all target VR users who use a virtual keyboard to input text. To enter a key, the user may either rotate their head to move the cursor on the virtual keyboard and make a specific hand gesture to select the key [36], or type by moving two fingers (one per hand) in the air [50] or by pointing handheld controllers [5]. These virtual keystrokes result in simple and slow typing movements that can be monitored by attackers using methods such as deploying a stereo camera [36] or a pair of WiFi devices [5] near the target, or by installing malware directly on the target's VR headset [36,50]. These attacks also assume perfect knowledge of the "virtual keyboard" layout and screen location, and often labeled data from the target.

2.2 Creating Immersive Experiences in VR

Expressive avatars. The most compelling aspect of VR is its capacity to generate immersive experiences through expressive avatars. Expressive avatars foster a heightened sense of presence and connection by closely emulating users' real-life movements and expressions. To build such avatars, modern VR systems (e.g., Meta Quest 2/3/Pro, HTC VIVE XR Elite) deploy real-time hand tracking and isomorphic rendering, so users can see and manipulate virtual objects with their own hands. The rendering of hand movements and gestures in their avatars adds an additional layer of immersion, allowing users to communicate, gesture, and interact with others naturally in the VR environment. This level of realism and expressiveness provides a true sense of presence and social interaction [52].

Hand tracking. Hand tracking in VR tracks the position and orientation of a user's physical hands. Today, it is achieved using multiple cameras and IMUs deployed on the user's VR headset [53]. The accuracy of hand tracking is influenced by various factors such as the relative position of the hands and headset, the number and placement of IMUs and cameras, lighting conditions in the environment, and the type and speed of hand movements. Even with advanced VR systems, some level of error, latency, or jitter in tracking may still occur, particularly when the user's hands are moving rapidly.

Currently, the accuracy of hand tracking falls short of the level required for precise keystroke recognition [20]. This is due to the fast and intricate finger movements that are specific to each user and constantly changing, along with the natural obstruction of the headset-mounted cameras by the user's hands. To overcome this challenge, commercial VR systems utilize a physical keyboard as the input device, while researchers suggest incorporating additional sensors, such as

IMUs on the user's wrists [39], to improve the capture of finger-tapping movements.

2.3 Privacy Threats and Defenses in VR

As VR systems can gather large amounts of data, including user activity, location, and behavior, they are inherently susceptible to privacy attacks that steal or misuse personal information or sensitive data. A recent study [25] summarizes the landscape of VR privacy threats and defenses by reviewing 68 publications, which lists 30 VR attacks, including the two keystroke inference attacks [5, 36] discussed in §2.1. The other 28 attacks focus on revealing the user's demographics (e.g., age, gender, ethnicity) or sensitive attributes (e.g., emotion, physical and mental health, and wealth).

3 Keystroke Inference Attacks in a Shared Virtual Environment

We study a new, VR-based scenario for keystroke inference attacks where both the target and the adversary are VR users in the same virtual environment (see Figure 1). While the target types, the adversary seeks to recover the typed content using information displayed by the target's avatar. Without the constraints of physical proximity to the target, a single adversary can attack many remote victims, increasing the potential reach and impact of the attack. Next, we discuss the motivation behind the attack and the threat model.

3.1 Motivation and Real-World Implications

Our attack is driven by two important trends in VR. *First*, productive typing on a full physical keyboard is becoming a common mode of input in VR systems. Compared to virtual keyboards, physical keyboards offer precision, comfort, familiar use, and haptic feedback [12]. Popular VR platforms like Oculus Quest 2/3/Pro and HTC VIVE and VR apps like vSpatial and Immersed already support physical keyboards through Bluetooth connection [1, 2, 29, 54]. Many VR users also prefer to use them to input text, especially when working for extended period of time [12]. As users can now type efficiently and professionally in their VR workspace, text input in VR will quickly grow to encompass emails, documents, and other text-based materials that may contain sensitive information and personal data.

Second, VR enables immersive interaction among people in shared virtual environments where each VR user is represented by their own avatar rather than their physical self. This contrasts with the well-known privacy issue in physical spaces where people are directly visible to each other.

These two developments prompt the following question, which motivated our study: ***"Is it safe to type sensitive information in a shared virtual environment, since VR users can only see each other's avatars?"***

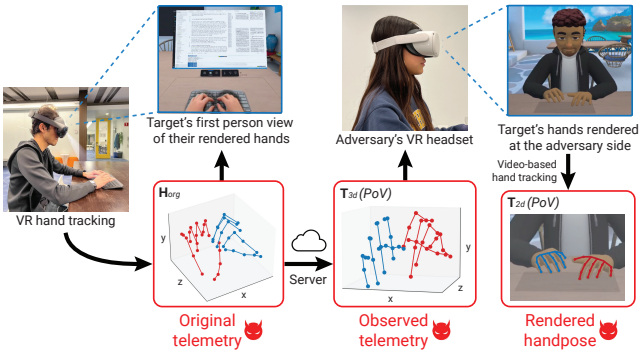

Figure 2: The three keystroke inference attacks considered by our work, operating on the original telemetry, the observed telemetry (used to render the target's avatar), or the video of the target's avatar displayed on the adversary's VR screen.

3.2 Threat Model

We consider a VR user $\mathcal{U}$, who is doing work in VR by typing on a physical keyboard wirelessly connected to their VR headset. We consider an adversary $\mathcal{A}$ who is another VR user sharing the virtual environment with $\mathcal{U}$. To enable seamless interaction, the VR platform uses an expressive *avatar* to represent each user in the virtual environment, which displays their nonverbal behaviors such as body movements and hand gestures [16, 28].

We assume that $\mathcal{A}$ can *only gather data related to* $\mathcal{U}$*'s avatar*. To render $\mathcal{U}$'s avatar to be seen by $\mathcal{A}$, the headset of $\mathcal{A}$ will receive a continuous stream of $\mathcal{U}$'s telemetry data, i.e., $\mathcal{U}$'s handposes. We note that although hand tracking is a built-in feature of modern VR headsets, the regulations governing the access and sharing of its data are still in development. Upon user consent, VR apps can access, store, and stream this information to render avatars on other devices. Therefore, we investigate various attack scenarios by varying the adversary's level of information access and the design of the VR app. Following this process, we identify three versions of the attack, defined by the telemetry data gathered by the adversary (see Figure 2).

- **Attack I: Original telemetry attack operating on $\mathbf{H}_{org}$.** This represents the strongest adversary, one who has access to either the target's headset or the VR rendering server [25]. Here $\mathbf{H}_{org}$ is the 3D telemetry data on $\mathcal{U}$'s hands collected by $\mathcal{U}$'s headset, which is extracted from a top-down (or bird's-eye) view of the hands.
- **Attack II: Observed telemetry attack operating on $\mathbf{T}_{3d}(PoV)$.** Here the adversary obtains $\mathcal{U}$'s avatar data by setting up a virtual camera. To render the virtual hands of $\mathcal{U}$'s avatar to be seen by $\mathcal{A}$, the VR system needs to transform the original telemetry data $\mathbf{H}_{org}$ to screen coordinates of $\mathcal{A}$'s virtual camera. The latter is defined by PoV, $\mathcal{A}$'s camera point-of-view (PoV) with respect to $\mathcal{U}$. For example, when $\mathcal{A}$'s avatar (thus the camera) directly faces $\mathcal{U}$, i.e., $PoV = (0,0)$, the observed telemetry $\mathbf{T}_{3d}(0,0)$ captures a

frontal-view of $\mathcal{U}$'s hands. Depending on the VR system/app design, $\mathbf{T}_{3d}(PoV)$ can be calculated by the VR server and sent to $\mathcal{A}$'s headset, or by $\mathcal{A}$'s headset after receiving $\mathbf{H}_{org}$. Here we note that the latter makes it possible for $\mathcal{A}$ to gather $\mathbf{H}_{org}$ directly from $\mathcal{A}$'s VR device and launch the Attack I mentioned above.

- **Attack III: Rendered handpose attack using $\mathbf{T}_{2d}(PoV)$.** The attack operates on a 2D projection of $\mathbf{T}_{3d}(PoV)$ used by Attack II such that the depth-to-camera data is removed. This represents a limited adversary who has no access to any telemetry data, but instead records $\mathcal{U}$'s avatar shown on $\mathcal{A}$'s VR screen and applies a hand tracking tool to extract the 2D handpose per video frame.

In our attack design, the only assumption is that the attacker is aware of the language used by the target (English in this study). More importantly, the attacker has **no** other information about the target. This means the attacker lacks knowledge of the target's keyboard layout and position, does not have access to labeled data or prior observations of the target, and does not have any additional side-channel information besides the avatar telemetry/handpose data previously discussed.

Extension to virtual keyboards. Note that our proposed attack naturally extends to future VR systems allowing controller-free virtual typing on a surface. The attack works because it requires only handpose data and no knowledge of a "keyboard." While such virtual typing is infeasible today due to insufficient accuracy in hand tracking, it may become a reality in the near future as VR hardware/technology advances. Ironically, improvements in the accuracy of VR hand tracking systems will only increase the potency of our attack.

4 Design Challenges and Baseline Solutions

The proposed attack scenario is unique because the adversary only utilizes telemetry/handpose data of the target's avatar. However, this also presents significant difficulties in constructing a successful attack due to the high levels of noise present in the data. In this section, we address this challenge through a thorough analysis of the attack data and an examination of potential attack designs. Our discussion focuses on the original telemetry attack ($\mathbf{H}_{org}$) because $\mathbf{T}_{3d}$ and $\mathbf{T}_{2d}$ are lossy transformations of $\mathbf{H}_{org}$.

4.1 A Closer Look at the Telemetry Data

We examine the 3D telemetry data $\mathbf{H}_{org}$ produced by the Oculus Quest Pro headset, using bird's-eye views of the wearer's hands captured by the headset's four cameras. At a sampling time t, the 3D telemetry is represented by (x,y,z) for each of the 46 joints on both hands (23 joints per hand). This 3D coordinate system is arranged by p, the physical position of the headset measured at the start of the VR session, and remains unchanged throughout the session even as the user's head moves around. Therefore, given the (x,y,z) coordinate of a joint, y is the depth of the joint to p, while the (x,z) are the deviation from p in the horizontal plane. Figure 4 (a) shows a sample instance of $\mathbf{H}_{org}$, where the left pinky is pressing a key. Since the physical keyboard is placed on a horizontal plane, the y value captures the relative *height* to the keyboard while the xz values indicate the *positions within* the keyboard.

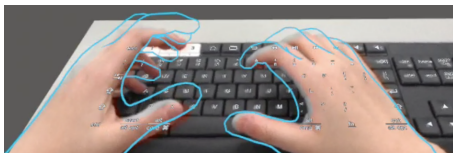

Figure 3: The virtual hands rendered by VR headset, overlaid on top of their corresponding physical hands.

Virtual vs. physical hands. Figure 3 plots a sample observation seen by $\mathcal{U}$, where the *virtual* hands (rendered by $\mathcal{U}$'s headset from $\mathbf{H}_{org}$) are overlaid on top of the physical hands. The virtual hands do not align with the physical hands, especially at the fingertips, demonstrating that the telemetry data is noisy. This is expected as hands can often obstruct fingertips from the view of the headset cameras and typing on a physical keyboard is rapid and delicate.

Error analysis. We present an in-depth analysis of the noise in the telemetry data. As it is challenging to obtain ground truth positions of hand joints, we choose to analyze the fingertip coordinates when the user is pressing a key. Accurate recording of timing and keystrokes is ensured by the physical keyboard. For each keystroking event, we determine the corresponding pressing fingertip by manually reviewing an external video of the typing hands.

Noise in (x,z)**:** Figure 4 (b) shows, for two users, the spread of (x,z) values of pressing fingertips (reported by $\mathbf{H}_{org}$) on top of the actual physical keyboard. Each press point is marked by the color of the key being pressed. For clarity, we only show the top 15 frequently used letters. Both users exhibit clear deviations, with variations among keys and users. The physical size and spacing of keys do result in some level of separation in the xz-plane of pressing points.

Noise in y**:** The noise effect on the depth y value is greater due to the tendency of users to rest their hands on the physical keyboard and only slightly lift their fingers to press keys. This results in a small depth difference between pressing and non-pressing fingertips. Figure 4 (c) plots, for two users, the error of depth measurements for pressing the letter 'e', normalized by the key height (4.4mm). These results come from 300 instances of typing 'e', extracted from a random typing session. For each instance, we find the pressing fingertip's y value, subtract from it the ground truth depth of the keyboard, and divide the residual by the key height. Ideally, the values should be very close to 0 (i.e., the blue line marking the ground truth depth of the keyboard). The actual results demonstrate significant deviations and display a user-specific bias. For both users, over 50% of the typing instances have depth errors higher than 2×key height.

The same depth noise affects non-pressing fingers, making

Figure 4: (a) A sample instance of $\mathbf{H}_{org}$ where the left pinky is pressing a key. (b) VR collected (x,z) touchpoints from 2 participants. The corresponding ground truth key positions are marked with the same color. Top-15 frequent letter samples are shown. (c) Depth of sequential keystrokes when 'e' is typed by Participants 1 and 2. Normalized depth error puts the ground truth at zero and scales by the height of an individual key. Standard Deviation for Participant 1: 1.639. Standard Deviation for Participant 2: 1.853.

it challenging to identify both keystroking events and their corresponding pressing fingertips. To study the impact on identifying the pressing fingertip, we compute, for each keystroking event, the deviation from the "lowest" non-pressing fingertip's y to the pressing fingertip's y. Ideally, the deviation should be positive and $\geq 1\times$ key height, since the pressing fingertip is the lowest across all fingers. Yet we find that, for both users, **more than 30%** of the instances have negative values, i.e., at least one non-pressing fingertip is wrongly reported as pressing lower than the pressing fingertip.

Summary. These findings collectively demonstrate the presence and impact of excessive noise in the 3D telemetry data $\mathbf{H}_{org}$, particularly for the y values. We also note that, for the other two forms of handpose data ($\mathbf{T}_{3d}$ and $\mathbf{T}_{2d}$), the errors are exacerbated by the lossy transformations from $\mathbf{H}_{org}$.

4.2 Exploring Attack Design Options

In our quest to find an effective attack, we attempted the following methods, but none proved to be successful. We present them below and summarize key limitations of each.

Denoising telemetry data. An important question is whether techniques such as data pre-processing and denoising can enhance the quality of the telemetry data. Unfortunately, this is challenging as the noise in the telemetry data follows a Gaussian distribution. For instance, noise in the depth y value of the pressing fingertip is confirmed to be Gaussian through KS goodness-of-fit tests, with a p-value greater than 0.5.

Manual inspection. A curious attacker can manually inspect each telemetry frame to identify keystroke events and the corresponding pressed key. However, we attempted this and found that the random noise in the telemetry data makes it challenging for the human eye to accurately identify keystrokes and the finger responsible.

Attack by transferability. Another option is to leverage transferability across users [50], i.e., collecting accurately labeled keystroke/telemetry data from a set of users, training a DNN inference model, and applying it to infer keystroke content of other target users. We examined this attack among 7 users, applying leave-one-out cross validation. In each round, we selected 6 users, trained a supervised DNN keystroke classification model using labeled telemetry data from them, and tested the trained model on the one new user. We evaluated the attack by comparing the typed and recovered content (after apply spell correction). The results were consistent: the attack on a new user unseen during training produced a large character error rate (56% $\pm$11%) and could not recover any meaningful content. But on trained users, the models can correctly detect and recognize more than 90% of keystrokes (i.e., $<$10% character error rate). This aligns with other keystroke studies, which show that human typing behaviors are user-specific and transferability-based attacks are ineffective [50, 58].

Statistical analysis of fingertip motion. With no labeled data from the target to train an ML model, one can apply unsupervised inference by studying the target's fingertip movements. Specifically, one can extract fingertip positions from the telemetry data, and apply statistical analysis to detect the keystroking events and identify the corresponding pressing fingertip. However, given the abundant noise in the telemetry data, the attack is ineffective (see our experiments in §7.5).

Our finding aligns with existing studies on VR keystroke recognition [39]: the depth y of the VR hand tracking lacks the required accuracy to identify keystroking events and the pressing finger. To compensate for these errors, researchers propose placing extra IMUs on the user's wrists and collecting labeled data to train a DNN model for finger identification [39]. Yet both are infeasible under our attack scenario.

5 Our Proposed Attack

In this section, we present the proposed attack design. We begin with the key insights behind our design and a summary of the attack pipeline. Later in §6 we delve into the individual components and the implementation of the attack.

5.1 Design Insights

Our exploration of the transferability-based attacks (in §4.2) revealed that, with accurately labeled training data from the target user, a sophisticated DNN model can be trained to learn the intricate connections between keystrokes and noisy 3D

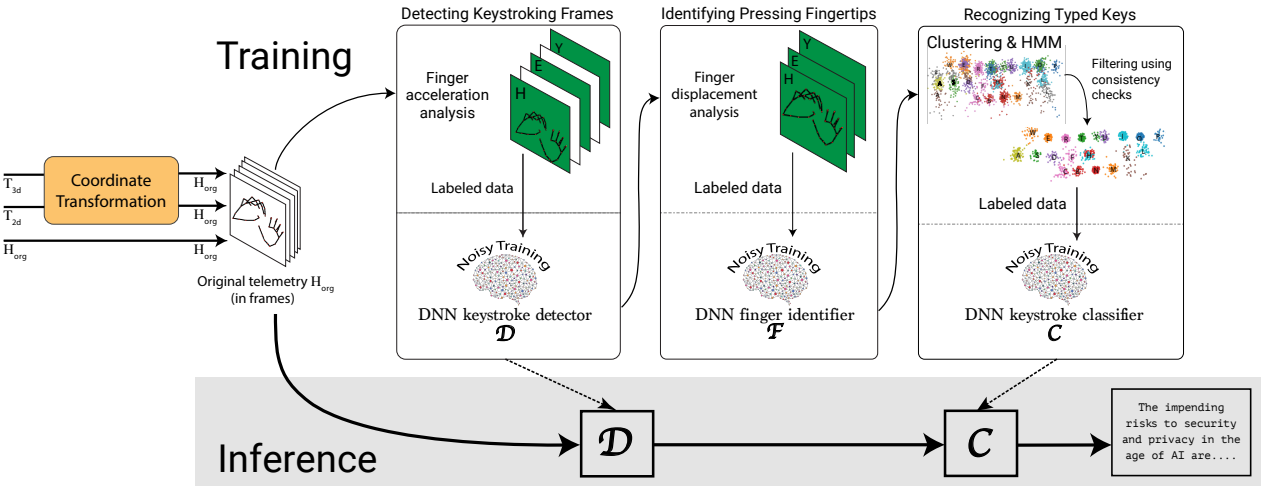

Figure 5: The end-to-end attack design, using a componentized self-supervised learning pipeline

telemetry data, allowing it to correctly recognize over 90% of keystrokes. This suggests that an effective attack is possible if we can self-label some of the target's 3D telemetry data and use them for model training. Such labeling is done on the target's data since transferability-based attacks are ineffective.

The concept of self-curating labeled training data from the target data is an established technique in self-supervised learning [3, 61]. A recent work [58] applies this concept to recognize keystrokes from a video recording of the target's physical hands. This is done by first applying hand tracking to locate the target's fingertips in each video frame, followed by a HMM-based statistical analysis to estimate labels for a small subset of the video frames. These labeled data are then used to train CNN models to recognize the keystrokes captured by all video frames.

But when applying the method of [58] to our attack scenario, we observe significant failures (see Table 5). This is because the amount of noise included in our attack data is higher than that of [58], i.e., our attack data is the noisy hand tracking results estimated by the VR headset, while [58] uses the raw video capturing the target's physical fingers as the input to their CNNs. This qualitative change renders the method of [58] ineffective and requires a new approach.

Self-supervised learning of noisy handposes using task-specific transformers. To handle the extremely noisy telemetry data, we design our attack based on two key insights. First, different from CNN models, the self-attention mechanism of transformers enables the model to learn dependencies between hand joints and give more importance to the joints responsible for performing a specific task, e.g., pressing a key on the keyboard. As such, transformers can be highly effective in extracting key patterns from noisy handpose data and greatly boost attack robustness in noisy data settings.

Second, despite the common belief that transformers require vast amounts of training data, our work demonstrates their suitability for our attack, even with limited data. This is attributed to two design decisions. The first is that we exclusively train transformers on the current attack data, "forcing" them to concentrate solely on learning crucial features from this specific dataset. Next, we break down the main task into three sub-tasks or components, and train transformers separately for each component. This empowers each transformer to focus on its designated learning task. By adopting these design choices, we effectively leverage transformers to execute our attack, even when faced with limited training data.

5.2 Attack Overview

Based on the above insights, we propose a new attack design, which applies a set of three sequential components to infer typed characters from noisy telemetry data. Our design tackles the challenging issue of noisy telemetry data through a two-step self-supervised learning approach, which is applied to each of the three components separately. By applying this self-learning method to each individual component, we design the attack to progressively extract and learn important keystroke information from the noisy input, while effectively reducing the spread of error in the end-to-end attack pipeline.

The three components. We break down the main task into three components: detecting keystroking telemetry frames, identifying pressing fingertips, and recognizing typed keys. The first component focuses on detecting telemetry frames[1] that represent keystroking events. The next component takes as input the detected keystroking frames and identifies the specific finger that touches the keyboard. The third component leverages the detected finger information to locate the pressing location on the keyboard and analyzes the pressing locations of all the keystroking frames to estimate the sequence of keys that the target user has entered.

Training per-component transformers. For each component, we first self-curate labels for its input telemetry data by performing statistical and motion analysis on the data.

[1] Here each telemetry frame refers to the telemetry data collected on the target user at a specific time t.

Here the statistical analysis focuses on a subset of hand joints closer to the keyboard and leverages general understandings of human typing behavior. After creating the initial labels for the telemetry data, we use them to train a deep neural network (DNN) model dedicated for this component. Note that this DNN model learns the detailed relationship between keystrokes and telemetry data from 3D coordinates of *all* hand joints (i.e., the full telemetry). To minimize the impact of the noise present in both the self-generated labels and the telemetry data, we employ multiple noise-aware training strategies during DNN model training.

Here we choose transformers as the DNN architecture for the first two components, but CNN for the last component due to the issue of class imbalance (details in §6).

End-to-end attack pipeline. Figure 5 plots the attack pipeline, which takes as input a sequence of 3D telemetry frames ($\mathbf{H}_{org}$) captured during the target's typing session, and applies the three sequential components to analyze the data and train DNN models. This pipeline produces three DNN models, one per component: (i) a transformer based keystroke detector $\mathcal{D}$, which identifies the set of telemetry frames where the target enters a key, (ii) a transformer based finger identification $\mathcal{F}$, which determines the finger used to press the key, and (iii) a CNN-based keystroke classifier $\mathcal{C}$, which predicts the key entered for each keystroking telemetry frame. The final inference process only employs $\mathcal{D}$ and $\mathcal{C}$, since $\mathcal{F}$ is only used to produce cleaner labels for the last component and train a more effective $\mathcal{C}$.

Supporting observed telemetry and rendered handpose attacks. To enable these attacks (i.e., using $\mathbf{T}_{3d}$ or $\mathbf{T}_{2d}$), we deploy a pre-processing module that transforms $\mathbf{T}_{3d}$ or $\mathbf{T}_{2d}$ into a coordinate system equivalent to that of $\mathbf{H}_{org}$. This is the "coordinate transformation" module in Figure 5.

6 Detailed Attack Design

We now present in detail each of the three sequential components of the attack pipeline, the pre-processing module, followed by the end-to-end attack implementation.

6.1 Detecting Keystroking Frames

The first component studies the input sequence of 3D telemetry frames to identify keystroking events and their associated telemetry frames. This is done in two steps, first applying statistical and motion analysis to self-label the frames, then using these labeled data to train a transformer-based DNN model, leveraging noise-aware model training techniques. Note that our discussion assumes the telemetry frame is from $\mathbf{H}_{org}$.

Step 1: Self-curating labels via motion analysis. When typing on a keyboard, each keystroking action is a characteristic movement of the finger, which starts from reaching the key, then a brief moment of zero acceleration as the finger hits the key, followed by a return to the starting position. This movement creates a distinctive pattern, represented as a positive peak in the plot of the second derivative of the keystroking finger's depth coordinate (or the y value of the fingertip in the telemetry data).

This general pattern only stands when the fingertip depth (y) values are measured at a very high accuracy (i.e., sub-mm precision). Today's VR hand tracking is far from that. The noise in the telemetry data, in combination with hesitant typing behavior, produces many "fake" positive peaks. On the other hand, these fake peaks often display a smaller amplitude than the real ones. Thus, we model the overall peak series as a mixture of two Gaussian distributions [58] and compute a decision threshold to produce an equal error rate between admitting a fake keystroke and missing an actual keystroke.

Step 2: Training a transformer-based keystroke detector. In Step 1, we analyze the unique feature of fingertip acceleration in the y axis to identify keystroke events, resulting in a set of "rough" labels for all telemetry frames. Using these labeled data, we train a *transformer*-based [51] keystroke detection model in Step 2. The choice of the transformer architecture deserves some explanation. The telemetry data consists of 3D positions of 42 hand joints in each frame, which have natural correlations in their movements and configurations across time and space. Furthermore, these joint configurations have spatial constraints due to the hinge nature of hand joints. To effectively learn and accurately predict finger activity, it is essential to have a model that understands these correlations and constraints. Along this line, the self-attention mechanism used by transformers [7] is well-suited for our learning task as it allows the model to learn dependencies between hand joints and give more importance to the joints relevant for performing a particular task (i.e., keystroke).

To model the spatial-temporal relationship among hand joints, we choose the DSTA-Net architecture proposed by Shi et al. [46] for skeleton-based gesture recognition. This architecture calculates spatial attention to create a combined spatial representation of joints and then utilizes it to compute the temporal attention of joints across time. The pre-trained model provided by [46] and its training data only cover a single hand. Thus, we adapt the model architecture to support both hands and train the detection model from scratch to run a binary classification task (keystroke or non-keystroke). The input to the transformer-based classifier is a collection of 16 telemetry frames to capture the spatial-temporal movement of the hands. Specifically, we first identify each telemetry frame labeled as "keystroke" in Step 1, then take 7 telemetry frames before it and 8 telemetry frames after it to form a telemetry segment of 16 frames, and label it as "keystroke." We also build non-keystroke segments by grouping 16 non-keystroke telemetry frames between two detected keystroke events.

Noise-aware model training. Since both the telemetry data and the labels we self-curate (during Step 1) contain errors, we apply two noise-aware training techniques when training the transformer model. First, we apply mixup data augmentation [60] to prevent the model from overfitting into

the training data and label. This is done by generating new training samples via blending two existing training samples using convex combinations, teaching the model to make linear predictions on those new data. The presence of noise in both the data and labels impedes the model's ability to learn these linear relationships and naturally prevents overfitting.

Second, we use bootstrapping for refurbishing labels which relies on the idea that as training progresses, the model learns to predict the correct class with higher confidence. Therefore, for a sample with a noisy label, the model's own prediction is a better source of the ground truth label and should be used as such during training whereas correctly labeled samples should be trained in the regular way. To identify the noisy labels, Arazo et al. [6] leverage the idea that noisy labels are learned in the later stages of training. Therefore, the difference in the loss can be used to identify the noisy labels which can then be trained using the model's predictions. In practice, convex combinations of the noisy and model-predicted labels are used. For samples that are noisy with high probability, the model-predicted labels are weighted higher in the refurbished label and vice versa.

6.2 Detecting the Pressing Fingertip

Self-curating labels using finger displacement. After detecting keystroke events, it is important to identify the finger used to generate each keystroke in order to estimate the location of the keystroke. For this, we adopt the idea from [58] that given any position of the hand, the finger used to press the key needs to move the most in comparison to the non-pressing fingers. Therefore, we compute the displacement of each fingertip, at the moment of a keystroke, from its mean position across the entire typing session. We label the fingertip with the maximum displacement as the pressing finger. However, due to subtle typing behaviors and sensor noise, finger identification with this method is prone to errors thus some pressing fingertips are often incorrectly labeled.

Training a transformer for fingertip identification. Using the labeled fingertips, we train another transformer model to leverage features in the raw telemetry data. Again, this model is trained in a noise-aware manner from scratch on a set of 16 raw frames for each detected keystroke and predicts which finger was used to press a key. After training, this model is evaluated on the same data used for training in order to correctly predict the noisy labels. However, noisy training has its limits. If the proportion of noisy labels in the training set is beyond a certain threshold, noisy training techniques are unable to produce a reliable model due to overfitting. We identify these cases by observing the clustering output (§6.3) and avoid using the transformer in this component if it produces a worse clustering result.

6.3 Recognizing Typed Keys

Self-curating labels using clustering & HMM. After obtaining fingertip labels (from the fingertip transformer), we use the 3D coordinates of each identified fingertip, at the precise moment of the keystroke, to estimate a touchpoint map which corresponds to the layout of the keyboard. Since keys are separated and have fixed locations on a keyboard, this form factor naturally clusters keystrokes generated from the same key and allows us to run unsupervised inference to reconstruct the typed content. We use K-Means clustering with K=38 to cluster the keystrokes and label these clusters arbitrarily. This labeling gives us a sequence of cluster IDs where each element in the sequence corresponds to a keystroke in the order that it occurred. The final task is to map each of these elements to one of 29 keys (period, comma, space key, and the 26 letters of the English alphabet). This is the kind of task Hidden Markov Models are well-suited to solve. We explain the detailed HMM implementation in Appendix 9.2. The output of the HMM gives us another set of labels which we use to train a DNN model for keystroke classification.

Due to the accumulated errors in our pipeline, there are errors in the HMM's prediction of the typed content. Therefore, we use the consistency checks between the clustering and the HMM's output introduced by [58] to identify the incorrectly recognized typed keys. As a result, instead of solely relying on noisy training, we can remove noisy labels from the self-curated labels to create a cleaner training dataset for the DNN-based keystroke classifier. The details of these consistency checks along with the explanation of other clustering related components are explained in Appendix 9.1.

Training a CNN for recognizing keys. The natural choice for training the keystroke classifier would be the transformer architecture used previously. However, after filtering, the training dataset (of 29 classes) is much smaller compared to those used to train the previous transformer models. This dataset is also severely class imbalanced due to the uneven distribution of the alphabet frequency in the English language. Due to these factors, a transformer-based keystroke classifier does not perform well.

Thus, we opt for a 3D-CNN model (ResNext-101 [55]) for keystroke classification. This model is pretrained on the Jester [38] dataset which contains videos of humans performing different gestures and can therefore be fine-tuned with limited data. However, our data is in the form of 3D hand coordinates whereas the 3D-CNN is trained on images. Following common practice [21, 45], we convert our hand joint data to images by using the (x,z) coordinates as the pixel locations and the (x,y,z) coordinate as the pixel value. Like before, such a sample in the training dataset consists of 16 consecutive raw telemetry frames corresponding to a detected keystroke and its label obtained from the HMM.

6.4 Coordinate Transformation

The adversary with access to original telemetry data ($\mathbf{H}_{org}$) poses the strongest threat, as they have the "cleanest" data among all three attacks. For the other two attacks, $\mathbf{T}_{3d}(PoV)$ is a lossy, transformed version of $\mathbf{H}_{org}$, while $\mathbf{T}_{2d}(PoV)$ is

a projected version of $\mathbf{T}_{3d}(PoV)$ with the depth dimension removed. Since the above described pipeline is designed using the 3D coordinate system of $\mathbf{H}_{org}$, we execute the other two attacks by first applying a coordinate transformation, which converts their attack data into an equivalent version of $\mathbf{H}_{org}$.

Converting $\mathbf{T}_{3d}(PoV)$ to $\mathbf{H}_{org}$. $\mathbf{T}_{3d}(PoV)$ is the telemetry observed from $\mathcal{A}$'s point of view. It is generated from $\mathbf{H}_{org}$ by first applying 3D transformation defined by PoV, including translation, scaling, and rotation [32]. This is followed by perspective projection [13, 32] where the telemetry joints are projected onto a 2D viewing window (like a camera frame) based on $\mathcal{A}$'s PoV. Together, this transformation and projection create misalignments and distortions that interfere with the motion analysis used by our attack pipeline.

To execute the observed telemetry attack, we apply a 3D rotation to $\mathbf{T}_{3d}(PoV)$ by calculating the dot product of each telemetry joint's coordinates[2] with standard rotation matrices [32]. This allows us to convert $\mathbf{T}_{3d}(PoV)$ into an $\mathbf{H}_{org}$ approximation, which can be input to our pipeline.

Multi-camera rendered handpose attack. $\mathbf{T}_{2d}(PoV)$ is a 2D version of $\mathbf{T}_{3d}(PoV)$ without the z (i.e., the depth information). Given the hefty information loss, the attack becomes ineffective if the adversary $\mathcal{A}$ has only a single $\mathbf{T}_{2d}(PoV_1)$. However, $\mathcal{A}$ can easily compensate for the information loss by adding another *hidden* camera at a different PoV_2 and collect $\mathbf{T}_{2d}(PoV_2)$, and use them to recover the lost depth values based on stereo epipolar geometry [24]. Setting up multiple, simultaneous, *hidden* cameras by a single VR user is a functionality supported by VR systems and developments. For instance, $\mathcal{A}$ could register multiple sybil accounts and place their avatars in the same VR environment with $\mathcal{U}$ to capture $\mathbf{T}_{2d}$ from different angles.

6.5 Putting It All Together

Once the DNN models are trained, we run inference using the DNN-based keystroke detector $\mathcal{D}$ and classifier $\mathcal{C}$. The keystroke detector identifies the telemetry frames which contain keystrokes and these are passed to the classifier to infer the key used for that keystroke. The finger identifying DNN becomes redundant in the inference stage as its purpose is to obtain a cleaner clustering that improves the labels in the training set of the keystroke classifier. The keystroke classifier sidesteps the issue of finger identification by directly inferring the keystroke labels using patterns in raw telemetry frames.

After reconstructing the typed content, we further improve it using spell check. We find that conventional spell checking tools operate at a word level whereas spell checking can benefit from context. Thus, we use the spelling and grammar checking tool available in Google Docs, which makes use of the context using machine learning techniques [27], to improve the recovered text. We build an automated version of the Google checker using the Selenium [44] library.

[2] Since z is in a different unit than x and y, normalizing them into the same scale is needed before applying the 3D rotation.

7 Evaluation

We assess the effectiveness of the proposed attack through user studies approved by our Institutional Review Board (IRB21-1396). We evaluate five key aspects of the attack:

- **Effectiveness of original telemetry, observed telemetry, and rendered handpose attacks (§7.2)**, which utilize three types of telemetry data;
- **Performance under different VR configurations (§7.3)**, where we vary the distance between the avatars, the keyboard device, and the content type;
- **Attack effectiveness on 15 users** of varying typing styles (§7.4);
- **Comparison to other solutions (§7.5)**, including the baseline solutions (attack by transferability and unsupervised inference) discussed in §4.2 and the attack design of [58];
- **Attack complexity (§7.6)** in terms of computation time on a standard server and a breakdown across components.

7.1 Experimental Setup

User (or target) configuration. By default, each of our study participants wears a Meta Quest Pro VR headset and sits in front of a table (on a wheeled chair). A physical keyboard (Logitech K375s) is placed on top of the table and connects to the headset via Bluetooth. Before each typing experiment, we leave sufficient time so that our participants can freely adjust their headset, the chair, and the keyboard. On average, each typing session lasts about 25 minutes.

While wearing the VR headset, each participant types on the keyboard. Through the headset, the participant can see a rendered (virtual) display showing the text they have entered and those to be typed. They can also see their virtual hands, rendered locally using the tracked telemetry $\mathbf{H}_{org}$. By default, we ask each participant to type, on average, 26 email sentences randomly selected from a popular corporate email dataset [17], and to correct their typing mistakes using the backspace key. To simulate actual working conditions, each participant is allowed (and encouraged) to take breaks during the typing session, including pausing, leaving, and returning to their seat. Both the table and the keyboard remain stationary during a typing session.

Attacker configuration. We consider an attacker who is able to acquire the telemetry data of the target. The telemetry data is in one of the three forms: original telemetry $\mathbf{H}_{org}$, observed telemetry $\mathbf{T}_{3d}(PoV)$, and rendered handpose $\mathbf{T}_{2d}(PoV)$. The sampling rate of telemetry is around 60Hz, a standard setting used by both Quest 2 and Pro VR headsets. The latter two attacks depend on the attacker parameter PoV, i.e., the virtual camera placement configured by the attacker. Figure 6 illustrates the PoV configuration. $PoV = (0,0)$ means the attacker places a frontal virtual camera at the same height

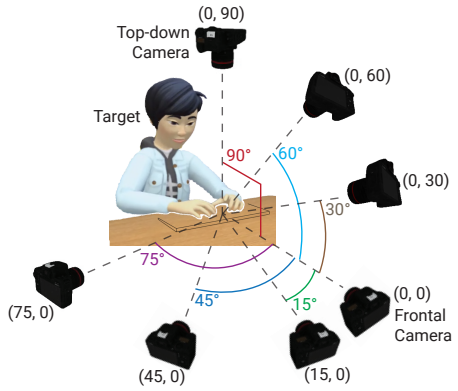

Figure 6: A graphical illustration of virtual camera *PoV*s. $(0,0)$ means a frontal camera at the same height as the keyboard pointing towards the target's typing hands. (x,y) means the camera is horizontally, vertically deviates by x,y degrees from $(0,0)$, e.g., $(0,90)$ represents a top-down camera. Credit: The target avatar is created using the built-in avatar tool on a Meta Quest Pro headset.

as the keyboard, which points toward the target's typing hands. $PoV = (x,y)$ means the virtual camera deviates vertically and horizontally from $(0,0)$ by x,y degrees, respectively. For all *PoV* configurations, the virtual camera always points toward the target's typing hands.

Dataset. We build a Unity program to collect telemetry data used by our attack and ground truth typing input for our evaluation. For each user, we collect their telemetry data over a typing session (≈500 words). Each session's data, i.e., a set of telemetry frames, is used to implement the attack for the current user and the current session. Specifically, we first self-curate binary labels (i.e., keystroking or non-keystroking) for a subset of the telemetry frames, and use them to train a keystroke detector $\mathcal{D}$. We feed the entire session's data to $\mathcal{D}$ to identify the set of keystroking frames. Next, for all keystroking frames, we curate finger-specific labels to train a finger identifier $\mathcal{F}$ and apply $\mathcal{F}$ on all keystroking frames to help curate the key-specific labels, followed by a consistency check filter to construct the labels for a subset of keystroking frames. The resulting labeled data is used to train the keystroke classifier $\mathcal{C}$, which is then applied to all keystroking frames to produce the attack output.

Here we note that the quantity of training data used to train the three DNNs ($\mathcal{D}$, $\mathcal{F}$, $\mathcal{C}$) differs across users and sessions. As reference, Table 8 in the Appendix displays, for each of the 15 users, the quantity of telemetry frames used to train these DNNs and the quantity of inference data being fed into the trained DNNs.

Evaluation metrics. Following an existing work [58], we evaluate each attack attempt by comparing the typed and inferred content at the character, word, and semantic levels.

- Character error rate (CER): It measures errors at the character level by computing the ratio of the number of errors and the length of the actual typed content. The number of errors is measured by the minimum edit distance, comprising insertions, deletions, and substitutions, required to convert the inferred content to the typed content. The lower the CER, the higher the accuracy of the inferred content.
- Word error rate (WER): The WER is computed using the same ratio as the CER with the difference that the edit distance is computed at the word level. It is worth mentioning that while WER penalizes words that are not exact matches, they may be comprehendible by a human reader. We use the WER function available within the Hugging Face [22] library as it uses dynamic string alignment to best match word indices for comparison.
- Content similarity using plagiarism detection: Plagiarism detectors are used to compute similarity between documents and are thus a natural fit for evaluating the recovered content. We use the plagiarism detector offered by CopyLeaks [18] which provides a similarity score in the range of 0-100% for the actual and inferred content. With moderate errors in the inferred content, the similarity score operates as a hybrid between character and word level similarity. However, with higher levels of errors, the similarity score usually collapses and is much lower than the word recovery rate (1 - WER). We refer to the obtained similarity score as the **similarity**.

7.2 Attack Effectiveness vs. Telemetry Data

We begin by examining the attack performance on original telemetry, observed telemetry, and rendered handpose data. It is intuitive to assume that the original telemetry attack is the strongest as the adversary has access to $\mathbf{H}_{org}$, the "cleanest" data among the three. As explained earlier in §6.5, the observed telemetry data ($\mathbf{T}_{3d}(PoV)$) is produced from $\mathbf{H}_{org}$ using a lossy, non-linear perspective projection, while the rendered handpose data ($\mathbf{T}_{2d}(PoV)$) suffers even more information loss from the 3D-to-2D projection.

In Table 1, we compare the performance of the three attacks, by varying the attacker's virtual camera *PoV*. For consistency, we invited a single participant as the attack target for all the experiments. We also include the result for the **two-camera rendered handpose attack**, where the attacker sets up two virtual cameras to collect two $\mathbf{T}_{2d}$ at different *PoV*s.

Effectiveness of original telemetry attack. Our results show that the Original telemetry attack (using $\mathbf{H}_{org}$) is highly successful – the attacker effectively recovers 85.8% of the words in the typed text. The recovered text has a semantic similarity of 87.4% to the original.

Observed telemetry attack with different *PoV*s. In the observed telemetry attack using $\mathbf{T}_{3d}(PoV)$, the attacker needs to set up a virtual camera at an observation point *PoV* to collect $\mathbf{T}_{3d}(PoV)$. We experiment with 7 different *PoV* values and find that the attack is consistently effective – the attackers can recover around 78% of the typed words. The performance is slightly less than that of the original telemetry attack because

Attack Type	Attack Data	Attacker's PoV	CER (%)	WER (%)	Sim. (%)
Original Telemetry	$\mathbf{H}_{org}$	–	4.7	14.2	87.4
Observed Telemetry	$\mathbf{T}_{3d}(PoV)$	(0,0)	6.6	21.6	80.4
		(0,30)	6.2	21.4	83.7
		(0,60)	6.5	21.4	81.5
		(0,90)	7.2	23.8	74.6
		(15,0)	5.8	18.0	86.1
		(45,0)	6.2	19.4	84.2
		(75,0)	7.6	21.0	77.6
Single camera Rendered Handpose	$\mathbf{T}_{2d}(PoV)$	(0,0)	29.3	78.0	0.0
		(0,45)	23.7	58.6	2.9
		(15,0)	28.5	66.8	0.0
Two-camera Rendered Handpose	$\mathbf{T}_{2d}(0,0)$ & $\mathbf{T}_{2d}(PoV)$	(0,15)	6.9	20.8	85.3
		(0,45)	6.3	20.6	81.7
		(0,75)	6.5	20.0	80.5
		(15,0)	7.6	21.2	79.0
		(30,0)	5.0	17.4	84.1

Table 1: Performance of original telemetry, observed telemetry and rendered handpose attacks, using $\mathbf{H}_{org}$, $\mathbf{T}_{3d}$, and $\mathbf{T}_{2d}$ handposes, respectively. We also include an extended rendered handpose attack using two $\mathbf{T}_{2d}$ at different camera *PoV*s.

the inverse transformation of $\mathbf{T}_{3d}(PoV)$ produces a noisy version of $\mathbf{H}_{org}$. We observe the same performance trend from other participants (see Table 7 in Appendix).

Two-camera rendered handpose attack. Using a single virtual camera, the rendered handpose attack (using $\mathbf{T}_{2d}(PoV)$) is ineffective because $\mathbf{T}_{2d}(PoV)$ is a noisy 2D projection of $\mathbf{H}_{org}$, making it hard to estimate the 3D telemetry. Yet we can overcome this challenge by setting up another virtual camera at a sufficiently different *PoV*. With two different $\mathbf{T}_{2d}$ observations, we can estimate the 3D telemetry $\mathbf{H}_{org}$ based on the stereo epipolar geometry [24]. In our experiments, we complement a frontal-view camera $\mathbf{T}_{2d}(0,0)$ with either a side-view or a vertical-view camera. Results in Table 1 show that the two-camera rendered handpose attack performs comparably to the observed telemetry attack. Again, these observations are confirmed across other users (see Table 7 in Appendix).

Real-world implications. The above results demonstrate the effectiveness of the three attacks. The success of the two-camera rendered handpose attack is particularly alarming due to two reasons. First, the attack is simple and stealthy. To collect $\mathbf{T}_{2d}(PoV)$, the attacker $\mathcal{A}$ does not need to hack any server or VR headset, but just acts as a benign user in the same VR environment with $\mathcal{U}$ and performs screen recordings of their VR screen on the headset. After applying video-based hand tracking[3] on the recorded video of the VR view, $\mathcal{U}$ obtains $\mathbf{T}_{2d}(PoV)$. Second, $\mathcal{A}$ can register multiple sybil accounts in VR and record $\mathcal{U}$'s typing from many *PoV*s. With more versions of $\mathbf{T}_{2d}$, $\mathcal{A}$ can potentially obtain better estimates of the original telemetry $\mathbf{H}_{org}$ and improve attack effectiveness.

[3]Open source hand tracking tools are commonly available online, e.g., MediaPipe [11] and OpenPose [48].

7.3 Effectiveness under Different VR Settings

To test the generalizability of our attack, we conduct multiple experiments by varying factors involved in our end-to-end attack pipeline. These include changing the (virtual) distance between the adversary's virtual camera to the target's avatar, the physical keyboard type, the typed content, and the amount of data available to launch the attack. To maintain consistency, a single participant in our user study was the target in all these attack scenarios.

Varying avatar distance. To assess the impact of avatar distance in the virtual world, we conducted an experiment in which four adversaries were positioned at increasing distances (0.6m, 1.2m, 1.8m, and 2.4m) from the target avatar during a single typing session. The adversaries recorded four separate sequences of transformed 3D telemetry ($\mathbf{T}_{3d}(0,0)$) using their virtual cameras. The results are summarized in Table 2, where we consider 0.6m attack as the baseline with CER $= 3.8\%$ and report the CER difference between the 1.2m/1.8m/2.4m attack and the baseline. The results confirm that the virtual distance between the target and the adversary avatars does not impact the attack performance.

Avatar distance (m)	1.2	1.8	2.4
CER $-$ CER$_{0.6}$ (%)	-0.17	-0.06	$+0.03$

Table 2: Attack performance when the virtual distance between the target and the adversary avatars varies. The default attack is conducted with the avatar distance = 0.6m. We report the CER difference from that of the default attack (CER = 3.8%).

Varying keyboard type and size. People can use different keyboards of various sizes. To evaluate our attack under such conditions, we ask our participant to type on three different keyboards: Logitech K375s, Logitech MX Keys Mini, and Apple Magic keyboard. The results for these experiments, displayed in Table 3, show that our attack is successful against all three physical keyboards.

Keyboard	Dimension (cm)	CER (%)	WER (%)	Similarity (%)
Logitech K375	42.7 × 13.0	4.7	14.2	87.4
Logitech MX	29.3 × 12.8	6.2	19.6	86.4
Apple Magic	28.0 × 11.5	6.6	17.9	82.4

Table 3: Attack performance when the target types on three different physical keyboards.

Varying content type and length. We investigated the performance of our attack with different types and lengths of text content. In addition to corporate emails, a participant typed approximately 500 words of text from scientific papers and medical patents, which contain technical terms and uncommon words. To evaluate the effect of limited typing data, we also conducted the attack when the participant typed only around 250 words. The results, presented in Table 4, indicate that our attack is effective with various content types and lengths tested.

Impact of numbers in text. The Enron [17] dataset includes sentences that contain numbers, which account for

	Word Count	CER (%)	WER (%)	Similarity (%)
Abstract	509	5.2	18.1	83.3
Patent	501	4.6	20.8	80.6
Emails	501	4.7	14.2	87.4
	262	5.4	17.6	84.5
w. numbers	488	5.5	18.7	81.9

Table 4: Attack performance when the target types content of different kinds and lengths.

1.2% of keystrokes. Using these sentences, we evaluate our attack to study the impact of number keys. Intuitively, the presence of numbers in the typed content would affect the HMM-based labeling process because HMM (trained on text) is unable to recognize numbers and will label them as letter keys. However, because these number keys are physically separated from letter keys on the keyboard, they will be filtered out by our consistency checks and will not appear in the training data for the keystroke classifier. As such, the moderate presence of numbers has minimum impact on our attack. Our results in Table 4 (last row) also confirm this hypothesis.

7.4 Performance across Users

To assess the effect of individual typing styles on the proposed attack, we recruited 15 participants to our user study (age: 21-53, 7 males and 8 females). In Table 5, we report the performance of our original telemetry ($\mathbf{H}_{org}$) attack against each participant. Overall, the attack is highly effective – for 13 out of 15 participants, our attack accurately recognizes 86%-98% of typed keys, and the recovered text retains 50%-98% of the original content's meaning.

The successful cases (P1-P13). After closely observing these users, we identified two distinct typing patterns that increase users' vulnerability to our attack. First, they type with prominent motion, so the hand tracking sensors on the VR headset can capture sufficient amounts of finger movements. The hand tracking accuracy is hardware dependent and does vary across users. Second, their body posture and hand orientation minimize self-occlusion across their fingers, meaning the joints are not blocking each other from the view of the hand tracker (located on their VR headset). When a joint is obscured, the joint's coordinates are often inaccurately estimated, leading to random tracking noise.

The unsuccessful case (P14 and P15). Our attack is less effective on P14 and P15, due to high hand tracking noise. For P14, the VR hand tracker is unable to track the pressing fingertip location (i.e., the x and z values) accurately. To illustrate this, Figure 7 compares P14's keystroke pressing locations reported by the VR tracker to those of P1. We see that P14 has many more overlapping keystrokes than P1, making it hard to create reliable labels.

For P15, the major issue is the height data (y) collected by the VR hand tracker. This is because, rather than having the keystroking finger much closer to the keyboard than the other fingers, P15's fingers stay at roughly the same height level when pressing keys. As a result, the tracking data is particularly noisy on the y axis, making it hard to reliably detect keystroke events and the pressing finger.

7.5 Comparison to Other Solutions

We compare our attack design to baseline solutions discussed in §4.2 and related work [58] discussed in §5.1. Overall, our attack design significantly outperforms these solutions.

Our attack design vs. baselines. We compare our approach with two baseline approaches discussed in §4.2. The first baseline is *unsupervised inference via statistical analysis*, which takes three sequential steps of detecting keystrokes, identifying pressing fingertips, and recognizing keys. These are the same three steps used by our attack design to generate initial labels but this baseline does not involve any DNN models. The second baseline is *attack by transferability*, where for each target, we use ground truth labels on all 14, non-target participants to train a DNN keystroke classifier, and hope it can also recognize the target's keystrokes. Note that in this implementation of transferability-based attacks, we assume perfect keystroke detection on the target user. Thus, the result represents the best case of transferability-based attacks.

The results in Table 5 show that our attack design significantly outperforms the two baselines. Compared to the *unsupervised inference via statistical analysis*, our approach curates labeled training data for training transformer-based DNN models, which can better capture the intrinsic features of the noisy training samples. The second baseline *attack by transferability* failed largely because human typing behaviors are highly user-specific and do not transfer to others [58]. Our approach overcomes this challenge by utilizing the target's own data to learn their specific typing behaviors.

Our attack design vs. [58]. We obtain the source code from the authors of [58] and follow the training method described in [58]. To train and test the CNN classifiers used in [58], we convert the telemetry frames to images. For a fair comparison, we apply the same conversion method used by our approach (see §6.3).

The results in Table 5 show that our attack design significantly outperforms that of [58]. As discussed in §5.1, the amount of noise in our attack data is significantly higher than that of [58], rendering the method of [58] ineffective. Our design addresses this challenge by deploying multiple task-specific transformers where the self-attention mechanism allows these models to extract key patterns from noisy data.

7.6 Attack Complexity

We measure attack complexity by the amount of time required to produce the recovered text after the typing session stops. We run our end-to-end attack pipeline on a standard server with an AMD EPYC 7313P 16-Core processor, and train all the models on a single NVIDIA A40 GPU. The overall runtime of our attack is 423 minutes for a 500-word, 19-minute typing session. The majority of time was spent on the training

of transformer-based keystroke detector (79 mins), the finger identifier (64 mins), and the CNN-based keystroke classifier (259 mins). The other components only take 21 minutes in total. Specifically, clustering & HMM take 3 minutes and spell checking takes 11 minutes.

8 Defenses

Our study shows that by either intercepting the telemetry data used to render a target's avatar or simply observing rendered hand movements of their avatar, an attacker in the same virtual environment can successfully recover the text physically typed by the VR user. Untreated, these attacks can cause significant damage to users. Given this threat, it is important for VR platform and app developers to exercise caution and implement adequate safeguards during the development process. We discuss several defense options below and their impact on the attacks and the VR experience.

Defense 1: limiting access to telemetry (hand tracking) data. The first type of defense seeks to minimize the chance of leaking sensitive handpose data ($\mathbf{H}_{org}$ and $\mathbf{T}_{3d}$) to attackers. After detecting the user is typing, the VR system can either ban access to its hand tracking API by any application, put a significant limit on the query frequency, or largely reduce the sampling rate of the hand tracking module. For example, by reducing the sampling rate from the default 60fps to 15fps, the defense can increase attack WER from 14.2% to 38%. When further reduced to 6fps, the attack becomes ineffective.

Defense 2: adding noise to telemetry data. Another type of defense is to add noise to the 3D hand tracking data captured by the wearer's headset (i.e., $\mathbf{H}_{org}$). In particular, by perturbing the depth (y) value of $\mathbf{H}_{org}$, one can effectively confuse the attacker at the stages of keystroke detection and finger identification, preventing them from identifying the keystroke events and/or the pressing finger. In our design, we choose to add zero-mean Gaussian noise to the y value. This is because our empirical measurements show that the noise naturally present in the hand tracking data follows a Gaussian distribution. Adding zero-mean Gaussian noise on top makes it hard for the attacker to denoise the data.

Table 6 summarizes the attack performance on the original telemetry data ($\mathbf{H}_{org}$) before and after applying this defense. We consider two noise levels: *moderate*, where we add zero-mean Gaussian noise with an STD of 0.3 × key width, and *high*, where the STD rises to 0.5 × key width. We see that adding a moderate level of noise can already disrupt the attack, raising CER from 4.7% to 20.1%, WER from 14.2% to 55.4%, and dropping semantic similarity to 14%. Under a high level of noise, WER further rises to 71.4% and semantic similarity drops to 0%. We also visually inspect the target's avatar under both noise levels. The avatar still displays normal typing behavior under moderate noise, while the typing speed appears to be considerably accelerated under high noise.

Noise Level (STD)	CER (%)	WER (%)	Similarity (%)
No noise	4.7	14.2	87.4
Moderate noise: 0.3 × Key Width	20.1	55.4	14.1
High noise: 0.5 × Key Width	26.6	71.4	0.0

Table 6: Attack performance after perturbing the depth axis of $\mathbf{H}_{org}$ using zero-mean Gaussian noise.

Impact on VR immersiveness. As expected, both defenses could impact the VR experience, because the user's physical hand motion is no longer synchronized with their avatar. Here the user can choose to run the defense directly on telemetry data collected by the VR headset, or only when the collected telemetry data leaves the VR headset. The first option provides a more thorough protection but affects how the target interacts with the VR environment. In particular, the target user may not see their correct typing movements inside the VR. The second option only affects the avatar observed by other VR users, but cannot resist attacks that can access the headset's telemetry data. Clearly, this represents an inherent tradeoff between usability and security.

9 Conclusion

Our study is the first to explore the possibility of keystroke inference attacks in a shared virtual reality environment. In this scenario, an adversary VR user can reconstruct text typed by another user by observing their avatar. Unlike prior work, our attack does not require physical observation of the target, only

a noisy VR representation of their avatar's hand movements. This avatar-based attack highlights the tension between immersive experiences and personal/information security in VR. While adding noise or reducing tracking frequency can reduce the attack's effectiveness, it also impacts the immersive experience to varying degrees. This raises the important question of how to design VR systems that balance the user's desire for immersive and engaging experiences with the need to protect their personal and information security.

Limitations and Future Work. The major limitation of our attack pipeline is that we ultimately choose a 3D-CNN model for our keystroke recognizer because the self-labeled training data for this component is very limited and imbalanced. The 3D-CNN works adequately with limited training data as it has already been pretrained on a large gesture recognition dataset [38]. We were not able to find pretrained transformer models or large datasets with telemetry data for both hands. Nevertheless, as transformers are being successfully applied to non-NLP domains, it is reasonable to expect that pretrained models in the future would make our attack more effective.

Appendix

9.1 Clustering

Detecting and clustering thumb generated keystrokes. We observe that most users have very subtle motions with regards to typing keys with their thumbs (usually the space key). Therefore, our motion and displacement based techniques do not work well for thumb tip data. However, we are still able to detect thumb-based keystrokes via the movement of the other four fingers, because they have a distinct movement pattern when the thumb is used to press a key. Specifically, the four fingers move in tandem much more as compared to when a non-thumb finger is used for a keystroke. So if the fingers move together, the variance in their relative displacement is low and we use this signal to mark detected keystrokes as being thumb-generated.

However, this process is not very accurate and we follow the approach laid out by [58] to deal with thumb generated keystrokes. Despite having some confidence that a keystroke was thumb-generated, we treat it as if it was a non-thumb keystroke i.e., we proceed by including it in the clustering process by using the coordinates of the non-thumb key identified as having generated that keystroke. The only difference is that we do not let these keystrokes be clustered in the regular non-thumb key clusters. Rather, we let these keys form their own clusters and let the HMM decide which of these clusters correspond to thumb keystrokes, i.e., space keys and which are non-thumb keystrokes.

Labeling consistency within each cluster. If the clustering was perfectly clean, we would expect each cluster to contain touchpoints of the same key and the HMM would most often label the clusters as such. However, given the errors in our clustering, the HMM often assigns different labels to keystrokes within the same cluster as it is not bound to assign a one-to-one mapping between a cluster's ID and its associated label. Rather, it relies on its learned parameters to decide the most likely labels at each time step. While the HMM can often assign the correct label to an incorrectly clustered keystroke, we find that minority labels within a cluster are unreliable. Therefore, we only select labels from the most dominant class in each cluster.

Cross-cluster label compatibility. By inspecting the majority label assigned by the HMM to the keystrokes in each cluster, we are further able to identify errors by previous modules in our pipeline. Specifically, we can identify errors in finger identification and the presence of non-keystroke events in our pipeline by doing a cross-cluster label consistency check. Intuitively, if two clusters have the same majority label, they should be close together in the clustering space since the clustering is spatial and each key has a fixed location on

the keyboard. Therefore, if two clusters are far apart and have been assigned the same majority label, one of them cannot be legitimate. Following this observation, we sort such clusters by size and remove all but the largest one from our training set for the keystroke classifier.

Detecting backspaces For accurate keystroke inference, it is imperative that we detect backspaces with high precision as failure to do so leads to high rates of error accumulation. We use two heuristics to identify backspaces among the set of detected keystrokes. We assume that the backspace is one of the edge keys on the keyboard and secondly, it is often pressed multiple times together to fix typos. As a result, we label the corner cluster on our touchpoint map with the highest ratio of consecutive keystrokes associated with it. For every keystroke in the backspace cluster, we remove the previous non-backspace detected keystroke for it. After this step, the backspace cluster is not used anymore in the attack pipeline.

9.2 Hidden Markov Models (HMM)

The output of the clustering module gives us a sequence of cluster IDs where each element in the sequence corresponds to a keystroke in the order that it occurred. We want to map each element in the sequence to 29 keys (period, comma, space key, and the 26 letters of the English alphabet) and a sequence tagging algorithm such as the HMM can perform this mapping. We are interested in obtaining the actual keys being typed by the victim but are unable to directly observe them. However, we have obtained a sequence of cluster IDs that are causally related to the actual keys being typed. HMMs can model this causal relationship between the observed and unobserved events and then infer the unobserved events.

Formally, HMMs are characterized by two sets of parameters **A** and called the Transition and Emission matrices respectively. Matrix **A** models the probability of moving from one hidden state to another whereas the matrix **B** models the probabilities of hidden states producing the observed states. In our case, **A** models the actual $N{=}29$ keys and is a $N\,X\,N$ matrix whereas **B** models the $M < 50$ cluster IDs being produced by the alphabets and is therefore a $N\,X\,M$ matrix. Probabilities in both matrices satisfy the Markov assumption. Inspired by [58], we compute **A** by empirically estimating the transition probabilities in the English language by using 40,000 sentences from the CNN/DailyMail dataset [19]. Matrix **B** is learned using a variant of the Expectation-Maximization (E-M) [10] algorithm given **A** and the cluster sequence. Given **A, B**, and the cluster sequence, the HMM infers the most probable hidden state sequence, i.e., the typed keys.

However, since the E-M algorithm performs local optimization [30] it often converges to local minimas. To deal with this, we run multiple iterations of the HMM and select the model that produces the most number of high-confidence predicted labels using the consistency checks explained in Appendix 9.1.

Abstract

As Virtual Reality (VR) applications grow in popularity, they have bridged distances and brought users closer together. However, with this growth, there have been increasing concerns about security and privacy, especially related to the motion data used to create immersive experiences. In this study, we highlight a significant security threat in multi-user VR applications, which are applications that allow multiple users to interact with each other in the same virtual space. Specifically, we propose a remote attack that utilizes the avatar rendering information collected from an adversary's game clients to extract user-typed secrets like credit card information, passwords, or private conversations. We do this by (1) extracting motion data from network packets, and (2) mapping motion data to keystroke entries. We conducted a user study to verify the attack's effectiveness, in which our attack successfully inferred 97.62% of the keystrokes. Besides, we performed an additional experiment to underline that our attack is practical, confirming its effectiveness even when (1) there are multiple users in a room, and (2) the attacker cannot see the victims. Moreover, we replicated our proposed attack on four applications to demonstrate the generalizability of the attack. These results underscore the severity of the vulnerability and its potential impact on millions of VR social platform users.

1 Introduction

[1] As technology advances, Virtual Reality (VR) has gained significant attention and has become an easily accessible technology in people's lives. Experts estimated that over 171 million people use VR globally in 2024 [16]. An emerging trend in VR is its use in multi-user applications [48]. These applications are becoming popular as they provide virtual spaces for users to interact, especially in situations in which environments dramatically improve the user experience.VR applications are unique in their ability to translate users' movements in the real world into corresponding movements of their virtual avatars, thereby making users less cognizant of the gap between real and virtual worlds. Multi-user VR applications further extend the immersive experience of VR applications by accommodating various forms of communication and by rendering avatars for users across all application clients.

Although using real-life motion data to render avatars across different clients can create a better immersive experience for users, it requires the transmission of motion data over the Internet. As mentioned by Nair et al. [47], user motion data is very sensitive and can be used to derive personal information such as the identity, anthropometric measurements (e.g., height and wingspan), as well as demographic details (e.g., age and gender) of users. Unfortunately, current multi-user VR applications do not offer adequate protection for motion data. As a result, the beneficial functionality of this data in VR environments becomes a side channel that leaks users' private information.

Recent research has demonstrated the feasibility of performing keylogging attacks (attacks that attempt to infer a user's keystrokes) against VR by leveraging side-channel motion information tied to typing behavior. For instance, VR-Spy [17] performs this attack by utilizing the side channel from channel state information of WiFi signals in the victim's local environment. HoloLogger [41] and TyPose [55] employ malware to harvest hand or head tracking data from the victim's device to predict the victim's keystrokes. Another approach by Zhang et al. [71] capitalizes on the side channel sourced from rendering performance counters in VR devices to infer user-typed numbers. A key assumption made by all these attacks is the ability to install malware or a dedicated surveillance implant in a user's *local* environment in order to obtain local motion-related data.

In our work, we propose a keylogging attack that also leverages motion data, but it operates under a significantly less stringent assumption. That is, adversaries are able to execute our keylogging attack remotely. The only requirement is that

* Both authors contributed equally to this research.

[1]The full version can be found at https://arxiv.org/abs/2405.14036.

they need to be in the same virtual room as the victim. This assumption makes our attack more practical and makes all users of multi-user VR applications potential victims.

Adapting keylogging attacks to remote contexts while achieving high performance can be challenging. Unlike local keylogging attacks that leverage local sensors, we choose to recover typing-related motion directly from network packets received by the adversary's client. Although this motion data is sent to all users in the virtual room via network packets, the applications themselves operate as black boxes. This creates difficulties in understanding how this information is transmitted to each remote application client and in which format. Furthermore, reversing the packet encoding or semantics can be difficult due to the lack of tools to debug the applications at runtime, given that these apps are frequently protected by anti-cheating engines and DRM (digital rights management) components. These difficulties collectively make recovering motion data from network packets a challenging task. Moreover, even if we manage to successfully recover motion data from the packets, it is uncertain whether the motion data in the packets is high-quality-enough for an accurate keylogging attack. This is because applications often use methods such as compression and under-sampling to ensure stable and efficient network transmission. Consequently, the remote motion data has lower fidelity compared to the original sensor data. In this paper, we have overcome these challenges with our proposed attack, which can accurately reconstruct the motion data required to infer the keystrokes.

Our attack consists of four steps, each extracting more fine-grained information about the typing activity from the previous step. In these four steps, we aim to understand and accurately leverage the data in network packets, converting the data to recover keystrokes and thereby executing the remote keylogging attack. We evaluated our attack through a user study conducted on Rec Room [8], one of the most widely used multi-user VR applications with more than 15 million users [42]. We successfully reconstructed the typed secrets at top-1 accuracy of **97.62%**. Our attack results demonstrate that we can infer almost all user-typed information correctly, even though remote settings offer lower-fidelity information compared to local settings. Furthermore, we performed an additional experiment in which (1) there are multiple users in the room, and (2) the attacker does not see any other user (from their application client's point of view). Our attack achieves comparable performance under this setting (top-1 accuracy of **97.53%**), demonstrating the practicality of our attack. Lastly, we replicated our attack on three additional applications and performed user studies on them, in which we achieved comparable performance across all applications (top-1 accuracy of 98.24%, 98.27%, and 99.07% respectively from the additional applications). This result further demonstrates that our attack is generalizable across applications. We reported our attack to Rec Room, the three additional applications, SteamVR, and Unity. The developers of Rec Room, Sing Together: VR Karaoke [14] and SteamVR [15] acknowledged the issue and Rec Room also awarded us a bounty for the vulnerability.

Contributions:

(1) To the best of our knowledge, we are the first to demonstrate the feasibility of remote keylogging attacks in the context of multi-user VR applications. Our approach enables more practical attacks under a remote setting, significantly enhancing the practicability and stealthiness compared to existing methods.

(2) We introduce a novel attack approach to overcome the challenge of recovering typing-related motion from a remote application client. Additionally, we provided new tools for VR motion data processing, such as precise motion input control and precise cursor/keyboard measurement.

(3) We also introduce an alternative attack strategy effective on network packets that have been partially reverse-engineered, by applying machine learning techniques to the raw bytes we extracted from the packets. Our result demonstrates that a remote keylogging attack with only minimal manual reverse engineering effort is also possible, with trade-offs in additional attack setup and accuracy.

(4) We conducted user studies to assess the efficacy, practicality, and generalizability of our attack. In Rec Room, we analyzed typing data from 22,092 clicks (involving letters, numbers, and special characters) provided by 20 participants, as well as typing data from additional 2,431 clicks by two participants typing concurrently, while the attacker cannot see them (in the VR space). We further analyzed typing data from 7,656 clicks provided by 9 participants for three additional applications (three participants for each application). From our analysis, we provide insights into which real-world keystrokes are vulnerable to our attack. Also, from the feedback of the participants, we studied users' awareness and concerns about our attack to understand its implications.

(5) We propose countermeasures for multi-user VR applications to mitigate our remote keylogging attacks and avoid privacy leakage associated with transmitting motion data across the Internet.

2 Background

Multi-user VR Applications. As the name suggests, a multi-user VR application provides interaction opportunities for users, allowing them to communicate with other players across the Internet. Typically, users can communicate by both typing and speaking. The typing functions are usually achieved using a virtual keyboard, either in-application or through overlay applications such as Steam Chat or Messenger. These newly emerging services allow users to interact in realistic digital worlds, and distinguish themselves from traditional social networking services by capturing and translating real-world user motions into their virtual landscapes [65].

Motion Update in Multi-user VR Applications. Motion,

which has six degrees of freedom (6DOF) as shown in Figure 1, is normally described by position (x, y, z) and rotation (roll, pitch, yaw). In this paper, we define TRANSFORM to be the composition of position and rotation.

Popular game engines describe motion with their own data structures that encapsulate TRANSFORM. For example, Unity, the most popular game engine for multi-user VR applications [22], has a standard data structure to represent TRANSFORM using a Quaternion (for rotation) and a Vector3 (for position) [61]. In Unity-based applications, this standard data structure is transmitted over the network to synchronize user motions.

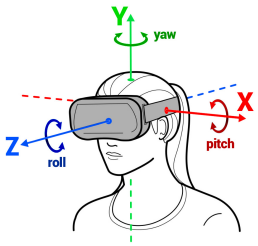

Figure 1: Example of user head motion in 6DOF [27].

For multi-user VR applications, the server continuously receives motion data updates from clients and broadcasts them to all clients [4], as seen in Figure 2. Typically, the synchronization process employs UDP packets with established libraries such as Photon PUN/Fusion [4], Unity Netcode [10], and Mirror [3] to ensure stable and accurate motion transmission. However, the motion data may not be fully identical after the transmission, as sometimes, applications (e.g., Rec Room) may use lossy compression on the motion data update, trading off a slight loss of fidelity of motion data in exchange for a lower burden on the transmission process.

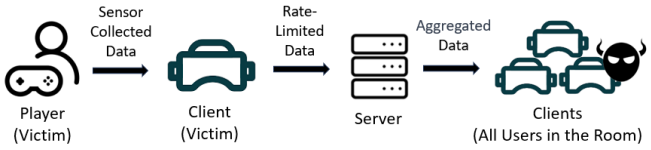

Figure 2: Motion data flow in multi-user VR applications.

Moreover, the transmitted motion data is also undersampled from the original motion data. In current multi-user applications, the server usually sends updates to the clients at a rate of 20-30 packets per second. This rate takes into account the network bandwidth limitation on both the server and client sides, ensuring efficient communication without overloading either end [5]. But applications usually run at 60-120 frames per second (FPS) [62], so they have adapted mechanisms like interpolation [31] to compensate for performance loss.

VR Typing Mechanism. In VR, there are multiple options for text input. The most commonly deployed methods include using voice or typing on a virtual keyboard [28]. In this paper, our primary focus is on the typing method that utilizes a virtual keyboard. Typing on a virtual keyboard involves two major steps: (1) moving the cursor, which can be a controller cursor or a virtual hand, to the target key on the virtual keyboard, and (2) selecting the key by performing a click, either by pressing a button on the controller or by poking at the key with a hand gesture. Since both of these steps involve the movement of the user's hand, multi-user VR applications map the corresponding motion to the avatar. This ensures the avatar feels realistic and accurately represents the details of the user's hand motion.

Figure 3: Example of a participant typing in Rec Room using a virtual keyboard.

For the click mechanism, we focus on clicks represented by button presses on a controller, which is a widely adopted method for both interaction between users and typing on virtual keyboards. Considering the importance of click functionality, Unity offers standardized APIs, such as OVR [2] and Input system [59], to help applications detect these clicks. These APIs use the trigger value (i.e., how deep the trigger button is pressed down, from 0.0 to 1.0) to detect clicks. Typically, the API registers a click when the trigger value is higher than a specific threshold. Since the trigger button is typically held for more than one frame per click, to avoid repeated firing, the first frame where the trigger is pressed is recognized as the click moment [1].

3 Threat Model

Adversary Objective. Our attack aims to extract user-typed secrets inside multi-user VR applications. By extracting these secrets, an attacker may gain access to the following types of sensitive information:

(1) *Credit Card Information:* Modern VR applications often incorporate payment gateways to facilitate transactions, requiring users to input sensitive financial details, such as credit card numbers. Such information represents a profitable target for adversaries aiming for unauthorized financial access. Conventionally, credit card numbers are sequences of digits.

(2) *User Authentication Data:* Within the context of multi-user VR applications, authentication mechanisms, such as password inputs, are employed when users attempt to access their accounts, private virtual rooms, or private virtual assets. Adversaries can actively seek these credentials to gain unauthorized access to user accounts. These credentials typically consist of alphanumeric characters, and may sometimes include special characters.

(3) *Private Conversation:* Multi-user VR applications incorporate social elements that include both professional and social activities. Users often engage in private chats within these applications to communicate with business partners or friends, which could include the exchange of sensitive information, such as business-related data or personal matters. The private conversation is usually composed of strings of alphabetical characters.

Given that recent applications offer functionalities such as in-app purchases of virtual items and private user chats, the entry of private information, as explained above, has become common in multi-user VR applications.

Adversary Knowledge. For the scope of the attacks discussed in this paper, we operate under the assumption that the adversary operates a remote client (an unmodified client located on the adversary's side that can receive updates about other players sent by the server) of a multi-user VR application and does not have access to the victim's devices or local environment. The target multi-user VR application should have both typing capabilities and the functionality to synchronize user motion across a network infrastructure. To the best of our knowledge, these features are ubiquitously supported across current multi-user VR applications.

Also, we assume that an adversary is a legitimate user (by downloading the application and registering an account in the application) who can enter a virtual room with other users. This presence makes the other users in the room potential victims (i.e., the attacker does not necessarily follow and target a specific user). This assumption is reasonable because, in multi-user VR applications like Rec Room, most rooms are public to facilitate the applications' purposes of socializing and meeting strangers. Being in the same virtual room allows the adversary's application client to receive motion updates from all other users in the room, including their typing-related motion data, even if their avatars are not visually seen by the adversary in the application. Moreover, the attacker can differentiate and group motion updates from different victim users. This is because current network protocols for multi-user VR applications require a unique user identifier to associate user avatars with their network updates. Therefore, by grouping motion updates using this user identifier, the attacker can analyze motion updates from different user entities, and perform the attack independently on each of them, thereby stealing keystrokes from all users in the room. Note that this user identifier only allows the attacker to group the inferred keystrokes and associate these keystrokes to any network updates linked to the user identifier (e.g., in-game username); further linking such information back to each user's identity in the real world is out of scope.

Additionally, given that the adversaries control their own clients, we assume they have the ability to access the binary files of the application client and capture the network traffic that their client sends and receives. Furthermore, we assume that the adversary can prepare for the attack by studying the application behavior. For example, the attacker can create multiple accounts, perform typing-related experiments on their own clients using these accounts, and observe the visual outputs of the application (e.g., how the keyboard looks).

4 Approach

The basic insight behind our approach is that multi-user VR applications transmit a user's VR motion data over the network and make it available to all other users who are in the same virtual room. This includes the motions that occur when a user is typing. Thus, typing-related motions are received by everyone in the same room. Consequently, anyone can analyze the network traffic and reconstruct the user's typing motion to infer the user's keystrokes.

As mentioned previously, it is challenging to extract motion data from packets and perform accurate keylogging attacks using low-fidelity motion data. We solve these challenges with a four-step approach, which is outlined in Figure 4. The first step takes the network packets and filters for those including motion data. It is followed by a step that parses the packets and identifies the data fields within each packet. The third step recovers the semantics of these fields and extracts the motion data. In the last step, the extracted motion data is mapped to key positions, which provides us with the prediction of the user's keystrokes. Our approach differs from existing keylogging approaches as it only requires network packets collected from an attacker's own application client as inputs.

In this section, we present how we implemented each of these steps for a specific target. In particular, we choose Rec Room, one of the most popular multi-user VR applications that has more than 15 million users [42], as an example to demonstrate our attack.

4.1 Step 1: Packet Extraction

The first step of the approach is to capture the raw network traffic and filter out the packets irrelevant to motion data. To recover motion data, we use Wireshark [11] and locate the incoming network traffic of our Rec Room client by its application port. Note that a single VR application is typically communicating with different servers (IP addresses) that handle different channels (such as voice data, messages, motion updates, etc.), but each server uses a fixed IP address while we stay in the room. In order to find the server that sends traffic specifically related to motion data, we group the network

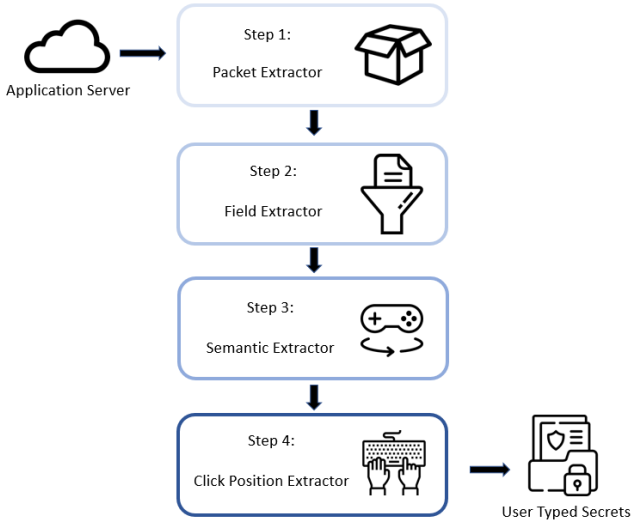

Figure 4: Our approach consists of four extraction steps to extract keystrokes from network traffic.

traffic from the VR application by source IP address, and take the packets from the IP address with the highest transmission frequency. These packets will most likely contain the motion data sent from Rec Room's server, as it updates motion data with clients at a high frequency (a fixed rate of 15 packets per second). Therefore, by performing this filtering step, we can exclude the majority of network traffic irrelevant to motion data, and limit the scope of analysis for the next step.

For other multi-user VR applications, this strategy can be similarly applied, as they need to update users' motion data at a high frequency to ensure smooth motion (see Section 2 for details about motion updates for multi-user VR applications), which makes it easy to isolate the motion update traffic. In addition, we can also use other common characteristics of motion updates to further eliminate irrelevant packets (e.g., motion updates are usually sent as UDP packets).

4.2 Step 2: Field Extraction

Once we obtain the packets that contain the user's motion data, we need to parse the packets and extract data fields serialized within the packets, so that we can extract the semantics from the fields later. In Rec Room, we implemented this step by first using a parser for Photon Engine [4], a networking library that Rec Room uses and whose network protocol parser can be found in an open-sourced project [19]. With this parser, we are able to parse the packet into data fields, and extract the types (e.g., integer, float, etc.) and values of the data fields. However, Photon allows developers to define and transmit their own custom objects (i.e., objects of custom data type, which may include multiple fields defined by the developers), and Rec Room uses this feature. Without knowing the fields serialized inside of these objects, we only see them as blobs of raw bytes. To parse these objects, we decompile Rec Room and find how it defines and deserializes the relevant objects, which allows us to build a parser that breaks down these objects into individual fields.

For other multi-user VR applications, we can replicate this implementation with mostly automated steps, and some reversing effort. It is likely that we can reuse the network protocol parser. Many applications use well-established networking libraries (e.g., Photon Engine and Unity Netcode [10]) instead of implementing networking functionalities from scratch. For example, among the **34** multi-user VR applications that we investigated, **21** of them use Photon Engine, including Rec Room and VRChat [63], two of the most popular multi-user VR applications on the market. Therefore, we can spend a one-time effort to find or implement the protocol parser and reuse it on other multi-user VR applications, and only spend reversing effort to recover the custom objects if the applications define them (as Rec Room does). However, if it is a rare case that the application does not use any networking library, we will need to reverse how the application deserializes the entire packet, which requires more manual effort.

One possible extra obstacle in this step is that the network traffic may be encrypted. While it is rare that VR applications encrypt the packets that include motion data (only **1** out of the **34** multi-user VR applications that we investigated encrypts their packets that include motion data), this obstacle can still be overcome. The key exchange process and decryption happen on the attacker's own client. Therefore, the attacker can decrypt the network traffic with a user CA certificate to conduct a Man-in-the-Middle attack on their own client, and previous work [60] has successfully performed this step and decrypted network traffic for 140 VR applications.

4.3 Step 3: Semantics Extraction

After parsing all the fields, it remains unknown which fields correspond to the typing-related information, and hence, we need to associate the fields with their semantics. Specifically, we aim to find the fields with the following semantics, which are needed for the next step:

(1) *Body motion data*, which includes TRANSFORM (i.e., the position and rotation) of the left hand, right hand, and head. They are used to track a user's typing motion. Such data is widely used in multi-user VR applications to update a user's body position.

(2) *Click data*, which includes the trigger values of the left controller and right controller. They are used to determine when a user is performing a click. This data is typically included in multi-user VR applications to update users' hand gestures.

(3) *Keyboard-opening event data*, which is signaled through the menu-opening event, is used to determine the keyboard position and when the user may start typing. This event data is specific to certain applications, but it is optional, as previous

work [32] demonstrates that the keyboard location can also be accurately approximated using the bounds of hand motion data. Also, the starting point of user typing can be inferred using click patterns as discussed in [66].

(4) *User identifier*, which associates the motion update with the user (avatar) who that update belongs to. This field allows us to extract a separate motion data stream for each user when there are multiple users in the room.

To identify fields (1) to (3), we perform an experiment in which we (a) programmatically provide controlled motion data by running simulated VR hardware inputs, (b) compute the changes in packet fields, and (c) manually observe how changes to the inputs correspond to changes in the packet fields (details in Section 4.5.1). Identifying field (4) is trivial since each motion update is annotated with a user identifier (a built-in field of the Photon protocol).

This step can also be replicated in other multi-user VR applications. Since most multi-user VR applications use Unity, which uses a standard data structure to represent motion data (see Section 2 for more details), we observed similar associations between the motion data inputs and the packet fields across applications. Furthermore, this experiment can be performed on any other multi-user VR application, since it only relies on manipulating the VR hardware inputs and observing packet data. Moreover, even if the mapping is not obvious (e.g., if an application applies obfuscation in the packets), we can resort to reversing the semantics from the application's binary by tracing how the packet fields are being used, which would require some more manual effort.

4.4 Step 4: Click Position Extraction

Once we extract the motion data, the last step is to infer keystrokes by (1) finding the TRANSFORM (i.e., the position and rotation) of all keys, (2) detecting the timing of the clicks, (3) calculating the cursor's TRANSFORM (the cursor refers to a point that projects a line to select keys) at click time, and (4) finding the intersection of the cursor's projection and keys. Essentially, these steps are reversing and emulating how multi-user VR applications compute keystrokes.

Firstly, we need to calculate the keys' TRANSFORM. To do this, we first need to know (a) how the keyboard is positioned relative to a user (see **Keyboard Measurement** in Section 4.5.2 for how this is measured), and (b) how the keys are positioned on the keyboard (see **Key Measurement** in Section 4.5.2), both of which only need to be measured once for an application in the attack preparation stage, as they are fixed. Then, we can find the packet that contains the *keyboard-opening event*, and use the *body motion data* in the packet to find the user's TRANSFORM at the time of keyboard opening. With this information, we can use the pre-measured values in (a) to calculate the absolute position of the keyboard, and use the pre-measured values in (b) to calculate the positions of each key.

Secondly, we need to determine the timing of the clicks. That is, we find in which packet each click happens, matching one packet to a click, so that we can later analyze the motion data in each of these packets to understand where the cursor is at the time of the click. This can be done by analyzing the *click data* and performing click detection (see Section 2 for details about how clicks are performed and detected in VR).

Thirdly, we need to calculate the cursor's TRANSFORM. To do this, we first need to know how the cursor is positioned relative to the hand, which is a fixed relation (e.g., the hand position is at the palm of the hand, whereas the cursor is at the tip of the index finger). Similar to the pre-measured values of the keyboard, this also needs to be measured only once for an application (see **Cursor Measurement** in Section 4.5.2). Then, for each packet matched to a click, we find the hand's TRANSFORM from the *body motion data* and use this pre-measured value to obtain the cursor's TRANSFORM.

In the fourth phase, knowing the cursor's and the keys' TRANSFORM during a click, we can detect the actual key clicked. Specifically, as illustrated in Figure 5, we project a line (the blue arrow lines in the figure) following the cursor, and when this line intersects with any of the keys on the keyboard, we log this information (the blue dots on the keys in the figure). Intuitively, one can visualize a line through the fingertip of the avatar's hand and see where this line points to and intersects the virtual keyboard. Note that this process is the same as how applications would calculate user keystrokes on local clients, and we are essentially "replaying" the keystroke entries extracted from the network packages in this step.

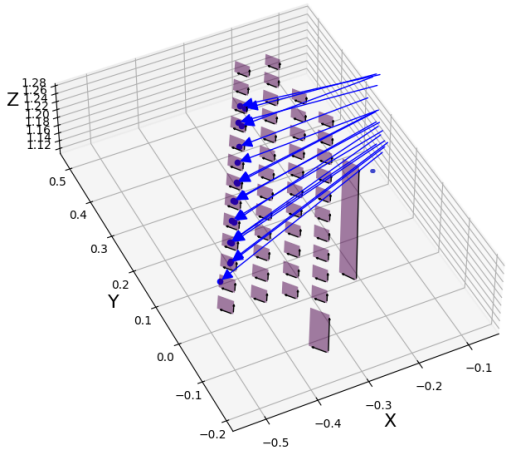

Figure 5: By visualizing the extension of the cursor with blue arrow lines, we calculate its intersection with the keyboard, as indicated by the blue dots on the keys, to log the key selections.

In other multi-user VR applications, the pre-measured values of the cursor and keyboard may be different from Rec Room, and we need to repeat this one-time measurement process. Note that this process can be performed on any other multi-user VR applications, as it operates by manipulating

the VR hardware data and observing visual outputs.

4.5 Reverse Engineering Challenges

In our approach, there is information that needs to be extracted once per application in the attack preparation stage: the semantics of key fields in network packets (Step 3) and the pre-measured values of the cursor and keyboard (Step 4). One of the most effective ways to obtain such information is to debug an application by accessing the application's memory while manipulating the inputs and observing the outputs at runtime. However, due to protections from anti-cheat engines [6,21,29], attaching a debugger to multi-user VR applications is difficult. In this section, we introduce two methods to overcome these challenges without the need to bypass the anti-cheat engines. They employ only the readily available channels: VR hardware input, network packet output, and visual output (as mentioned in our threat model in Section 3). These methods enable us to (1) understand the associations between hardware inputs and packet fields by providing controlled inputs and (2) precisely measure the cursor and keyboard TRANSFORM (i.e., position and rotation) using geometric manipulations of the hardware inputs and visual validation.

4.5.1 Precise Input Control

In Step 3, we aim to recover the semantics of packet fields. To do that, we want to provide precisely controlled inputs to the application and observe how changes are reflected in the fields of observed packets. VR device inputs are highly dimensional (e.g., a controller has 6DOF inputs to represent its position and rotation), and we need to isolate and control each input dimension to understand the effect of their changes. Moreover, such inputs cannot be easily controlled manually because of the sensitive sensors built into the VR hardware. For example, if we want to determine the effect of only changing the x coordinate of the left controller position, we need to (1) fix the right controller and head-mounted display (i.e., the VR headset) and avoid even the slightest movements, (2) move the left controller along the x-axis without any movement in the y-axis and z-axis, and (3) prevent any rotation in any directions. Using the actual controller, performing such a task "by hand" is essentially impossible.

To solve this challenge, we leverage Nvidia's VR Capture and Replay (VCR) tool [49], which allows developers to record tracking data from VR devices and replay them. Specifically, we utilize the "replay" component of VCR to serve as a VR hardware simulator and use it to run programmatic inputs. With this feature, we can (1) locate the fields affected by each input by isolating changes in the input, and (2) uncover conversions from inputs to fields.

First, we associate inputs and fields by observing their correspondence. For example, if we want to locate the x coordinate of the left hand, we can (1) fix all other input components in our replay script and only change the x coordinate, then (2) only fix the x coordinate and change every other input component. If there is a field in the network packets that changes if and only if x changes, it is highly likely that this field corresponds to x.

Second, after we locate an input component's corresponding field, we can reason how they are converted by observing how the field value changes with the input. For example, we can vary the x coordinate from -1.0 to 1.0 and see how the field for x changes accordingly.

4.5.2 Precise Measurement

In Step 4, we can parse the TRANSFORM (i.e., position and rotation) of hands and head from packets, but the cursor and the keyboard information are not directly (explicitly) included in the motion data, even though they have certain fixed relations with the motion data (hands or head). We could attempt to leverage the visual outputs to observe these hidden attributes. However, this presents a challenge due to the difficulty in obtaining precise direct observations. For example, just by looking at the visual outputs, it is hard to gauge the distance between two virtual objects, and an error of just 10 cm can shift a key prediction by three keys (a key has a side length of about 3cm) and render the attack ineffective.

We present a method to solve this challenge and measure the "hidden attributes" with visually verifiable tests. Specifically, we design geometric tests, which move virtual objects in specific ways to visualize geometric properties, so that we can verify our measurements visually. We perform the measurements in two steps: (1) Cursor Measurement: we measure the relations between cursor and hand, and uncover how we can convert the hand's TRANSFORM that is present in packets to the cursor's TRANSFORM. (2) Key Measurement: we use the cursor as a reference point to measure the keys.

Cursor Measurement. Cursor measurement is a problem of finding the fixed *offset* (i.e., a constant transformation in position and rotation) between the hand's TRANSFORM in packets (referred to as TRANSFORM_{hand}) to the cursor's TRANSFORM (referred to as $\text{TRANSFORM}_{cursor}$). From inputs, we can only manipulate the controller's TRANSFORM (referred to as $\text{TRANSFORM}_{controller}$), which has a fixed *offset* to both the hand and the cursor. These three TRANSFORM values can be all different (in position and rotation), as seen in Figure 6. At a high level, we solve this problem by first finding the *offset* between the hand and the controller, then finding the *offset* between the controller and cursor, and combining these two *offsets* to get the *offset* between the hand (which appears in the packet data) and cursor. The detailed steps are as follows:

(1) Find the *offset* between TRANSFORM_{hand} and $\text{TRANSFORM}_{controller}$. Since we can read out TRANSFORM_{hand} from packets, it is straightforward to find this *offset* by inputting one sample value of $\text{TRANSFORM}_{controller}$ and observing the corresponding

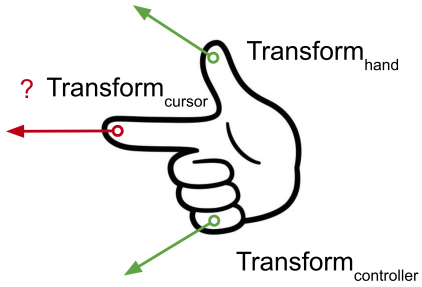

Figure 6: We need to uncover conversion from hand's TRANSFORM in packets to cursor's TRANSFORM by manipulating controller's TRANSFORM.

TRANSFORM$_{hand}$, then calculate the constant *offset* in position and rotation between them.

(2) Find the offset between TRANSFORM$_{cursor}$ and TRANSFORM$_{controller}$. This can be broken into three steps: (a) We start with a guess for one part (i.e., position or rotation) of this *offset*. For example, if we want to measure the rotational offset, we can start with the guess that the controller and cursor have the same orientation (offset is zero). (b) Next, we perform a spatial binary search of the real offset. That is, we plug in the guessed offset as a part of controller inputs and run geometric tests to visually inform us whether our guess is off from the real offset, and in which direction the real offset is. For instance, we can perform the geometric test as seen in Figure 7 and move the hand along the initial guessed direction. If the offset is non-zero, we are not moving the cursor along its pointed direction, and the reticle (cursor's projection on a screen) will move. (c) Then, we iteratively adjust our guess until the geometric test shows that the guessed offset aligns with the real offset. Continuing from the example in (b), we can keep adjusting the guess based on which direction the reticle deviates, until the reticle does not move, which is easy to verify visually. At this point, we know that the hand is moving along the cursor's orientation, and thus our guess is correct. To learn more about other geometric tests we use, see Appendix B.

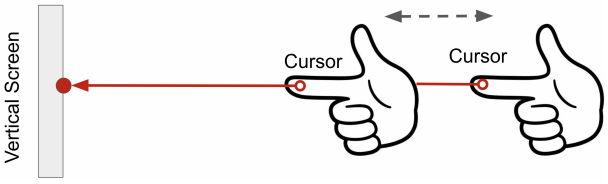

Figure 7: Geometric Test 1: test if the guessed cursor orientation is correct by moving the hand along the guess.

(3) Calculate our target *offset* by combining the two obtained *offsets*. The *offset* in (1) takes us from TRANSFORM$_{hand}$ to TRANSFORM$_{controller}$, and the *offset* in (2) then takes us from TRANSFORM$_{controller}$ to TRANSFORM$_{cursor}$, so combining them takes us from TRANSFORM$_{hand}$ to TRANSFORM$_{cursor}$, which is our goal.

Key Measurement. Key measurement is the problem of finding the positions of the four corners of a key at a fixed player location. The four corners of a key determine the key's location, as they define a bounded plane region as the key's region. For this problem, we need to know the cursor's TRANSFORM, and use it as a reference. To measure a corner of a key, we (1) position the cursor at an arbitrary position and find a way to point the cursor at the corner (again through a spatial binary search procedure), then (2) find the distance between the cursor and the key corner, which can be done by using a spatial binary search with another geometric test (see Appendix B), and lastly (3) calculate the key's position by adding a vector that is along the cursor's pointing direction and of the length equal to the distance to the cursor's position.

Keyboard Measurement. Keyboard Measurement is the problem of finding each key's position when the player is in an arbitrary position and orientation. This problem is straightforward to solve once we are able to perform **Key Measurement**. We can use the originally measured keys as a baseline, and repeat measuring all keys' positions at multiple player positions and rotations. This allows us to calculate how the changes in player positions and rotations transform into changes in the keys' positions. Therefore, for a new player's position and rotation, we simply calculate the changes in position and rotation from the baseline, and apply this transformation.

5 Data Collection

We performed data collection experiments to assess the effectiveness of our attack in real-world scenarios. Specifically, we conducted a user study involving 20 participants to collect real-world typing activity data from Rec Room, one of the most popular multi-user VR applications, as the main experiment (see Appendix A for more details on the experiment setup and recruitment). Additionally, participants were asked to fill out a survey to understand their perceptions of our attack after the debrief. We have also conducted further experiments to demonstrate that our attack works well in three additional applications of various genres and in realistic scenarios.

User Study Typing Trials. For each experiment, a participant started by opening the Rec Room chats to perform typing trials. In each trial, the participant was presented with a prompt and was asked to type all the characters in the prompt into the chat. In total, each participant completed 65 trials, of which 30 trials were with number prompts, 20 were with password prompts, and 15 were with sentence prompts. To simplify the setup, all prompts were shown to the participants in the same chat in which they performed the trials, so they could see the prompt while typing. We had a researcher continuously observing the participants' inputs and asking the participants to retype a prompt if they mistyped it (e.g., they typed "124" when the prompt was "123"). By doing this correcting step,

the prompts could conveniently serve as the ground truth without modifications during the evaluation of the attack accuracy later. As previously mentioned, the participants engaged in trials with **three** types of prompts: (1) *Numbers*, (2) *Passwords*, and (3) *Sentences*, each representing a common typing behavior (see detailed in Appendix A–Typing trails). After the study concluded, we asked the participants if they wished to exclude their data and address any questions they might had. At the time of submitting this paper, we have not received any requests for excluding data.

Data Labeling. During the study, we utilized a timing application to mark the beginning and end of each trial. This ensured only data from the trials was considered for labeling. Then, we check the recording of tracking data during the trials to verify that the number of clicks corresponds to the expected number of clicks from the prompts. For example, if the prompt asks the user to type "123," then we should expect three clicks in the recording of tracking data. If the number of clicks matches, we then label each click using the characters in the prompts along with its timestamp in the tracking data recording, so that we can later compare the clicks detected in the network traffic with the ground truth clicks. However, if the number of clicks does not match, it signals that the prompt was mistyped, which may happen when the prompts are long, and the researchers did not spot the errors in what the participants typed during the study. The data for such trials is discarded and not considered for evaluation. However, these cases are rare. In total, we dropped a combined 638 clicks out of 22,730 clicks (29 out of 1,300 trials) collected from the 20 participants in our study. This leaves 22,092 keystrokes (from 1,271 trials) for the evaluation.

Other Practical Scenarios. We also conducted an experiment to demonstrate the practicality of our attack in scenarios where (1) there are multiple users in a virtual room, and (2) the attacker does not see the victim users. We created the same experiment setup as the **User Study Typing Trials** experiment but with two modifications: (1) we placed another four different victim users in the room instead of one; (2) the attacker faces a wall, thus they are unable to see any other users. We then conducted a user study with the same procedure as the main experiment but with two participants typing concurrently (the other two users in the room were dummy users). Since the attack worked exactly the same in this setting, we ran this experiment only once. In total, we collected 2,431 clicks from the participants.

Other Multi-user VR Applications. To show that our attack generalizes beyond Rec Room, we tested it on three additional popular applications from diverse genres: Galaxity [12] (social app), Sing Together: VR Karaoke [14] (music app), and oVRshot [13] (shooter app). Specifically, we conducted an end-to-end attack on each of these applications following the same attack procedure (Section 4) and setup of the experiment on Rec Room (the **User Study Typing Trials** experiment). Among these applications, we targeted keystrokes on the full keyboards of two (Galaxity and Sing Together: VR Karaoke), whereas in oVRshot, attention was directed to the numeric keyboard, given that it is the only type available. During the typing experiment, which was conducted with three participants for each application, we collected a total of 3,423 clicks for Galaxity, 3,473 clicks for Sing Together: VR Karaoke, and 760 clicks for oVRshot (numbers trials only). Note that for passwords and sentences trials, we selected random words that can have slightly different lengths, which leads to a slight variance in total keystrokes for different applications.

6 Evaluation

In this section, we evaluate our attack and analyze various factors that may affect the attack accuracy. We have analyzed whether the attack accuracy is affected by packet drop rates, key position on the keyboard, and typing speed.

To evaluate the attack accuracy, we use top-k accuracy, which assesses how many of the user-typed keys are correctly predicted within our attack's top-k predicted keys, sorted by distance from the position of the cursor's projection on the keyboard. In other words, the top-k accuracy is calculated as (number of successfully inferred keys) / (number of total keys). If the click is not identified by the keylogging attack, we automatically mark the prediction as wrong.

	Top 1	Top 3	Top 5
Numbers	96.78%	97.98%	98.23%
Passwords	97.42%	97.88%	98.17%
Sentences	98.16%	98.41%	98.52%
Total	97.62%	98.15%	98.34%

Table 1: Keylogging attack accuracy from 20 participants across three different typing tasks.

Table 1 presents the overall accuracy of our attack based on 22,092 keystrokes collected from all 20 participants in the user study. The evaluation setup is consistent with the character-level evaluation in prior research on VR keylogging attacks [32, 41, 56, 66].

Across all three types of prompts, our keylogging attack consistently exhibited a very high accuracy, inferring 97.62% (21,567 out of 22,092 keystrokes) of all keystrokes correctly with top-1 prediction, 98.15% (21,683 out of 22,092 keystrokes) with top-3 prediction, and 98.34% (21,726 out of 22,092 keystrokes) with top-5 prediction. Against a 2.13% random guess baseline for one-key inference, our attack's effectiveness increases over 45 times.

Although our attack is nearly perfect in accuracy, there are a few incorrect predictions. This can happen for one of the following two reasons: (1) Loss of motion data precision due to lossy compression of the data: To ensure stable

network performance, multi-user VR applications such as Rec Room compress motion data items before transmitting them over the Internet. When this data is decompressed by the adversary client, it will be slightly off compared to the ground truth motion. This slight imprecision in motions and cursor positions might cause inaccurate predictions. (2) Stale hand motion update: From our experiment, we observed that some hand motions are not updated (propagated) immediately. This might happened because of the lag on the victim client or the interpolation mechanism applied on the previous motion update. Consequently, when this happens, the hand's TRANSFORM associated with a click tends to be closer to the previous click rather than the intended target click and leads to incorrect keystroke predictions by our attack.

It should be noted that the loss of motion data precision due to the compressed data is not significant. Additionally, the cases of stale hand motion occur with a low probability. This explains why only 2.38% of the keystrokes in our experiment are predicted incorrectly.

These findings from our attack highlight the significant risk of privacy breaches due to motions detected in the network packets, emphasizing the urgent need for protection against such vulnerabilities.

6.1 Our Attack is Robust Under Traffic Loss

Since the attack is conducted remotely, it is crucial for us to study the packet loss during the transport of motion data and how it affects the accuracy of our attack. According to a recent article by Obkio [36], apps with a packet loss rate of more than 10% are considered unusable [36]. To stress-test our attack, we conduct an analysis by dropping random packets at an even higher rate of up to 20% from the participants' network captures. The corresponding attack accuracy is illustrated in Figure 8. From the result, we observe that the attack accuracy after 20% of random packet drops rate still remains very high (94.97% top-1 accuracy), showing that our attack is robust even under significant packet loss.

In total, we lost 2.65% of the keystroke recovery accuracy due to the following two reasons: (1) Loss of brief keystroke data due to packet loss: In instances where the click duration is extremely short, the motion data corresponding to this key might only be present in a few packets. If there is packet loss, these packets might be dropped. As these packets are never received, they cannot be used for key recovery; (2) Packets after a click motion are considered as the actual click: By definition, a click occurs the moment the victim presses the key beyond the click threshold, as mentioned in Section 2. However, a packet loss might occur at the moment of a click. As a result, the initial packet representing the click might be missing. In this case, our attack identifies a subsequent packet during the click period as the click packet (i.e., the attack thinks this later packet is the first frame of a click). However, the subsequent packet might show a minor difference in the hand's TRANSFORM from the original click packet, resulting in a variation in the click motions and causing a wrong keystroke identification.

It should also be noted that we observed only an additional 0.42% of clicks undetected when a 20% packet loss is introduced. Also, the situation where selecting later packets results in a decrease in attack accuracy only arises in specific cases. It happens only when the click motion changes rapidly and the initial few packets are lost. This is why our attack accuracy is only slightly affected by the significant packet drop rate.

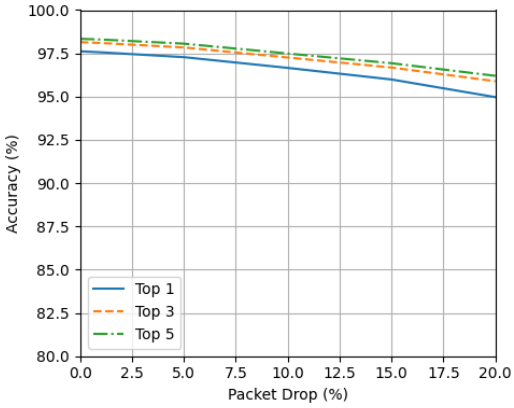

Figure 8: Our attack is robust against random packet drop, achieving a top-1 accuracy of 94.97 percent even when 20 percent of the packets are dropped.

6.2 Our Attack Remains Robust Under Varying Typing Speed

We also studied how the typing speed impacts the accuracy of our attack. Intuitively, predicting faster clicks might be more challenging since the cursor moves more quickly. Even a slight lag could significantly affect the position of the cursor's projection on the keyboard. We present accuracy data grouped by click duration percentiles (e.g., the 0-20 percentile group comprises the fastest 20% of clicks). Contrary to our initial expectations, we did not observe a significant effect of typing speed on the attack accuracy. This finding could be attributed to the fact that even the fastest click (with a duration between 0.255 and 0.721 seconds for the 0-20 percentile group) is captured in multiple motion updates, given that motion updates occur frequently (15-20 updates per second, or 0.05 to 0.067 seconds between updates).

6.3 Our Attack Can Be Stealthy Under Practical Scenarios

For the experiment setting in which (1) there are multiple users typing concurrently in the same room and (2) the attacker is facing the wall, the attack has comparable performance to the **User Study Typing Trials** experiment. Our

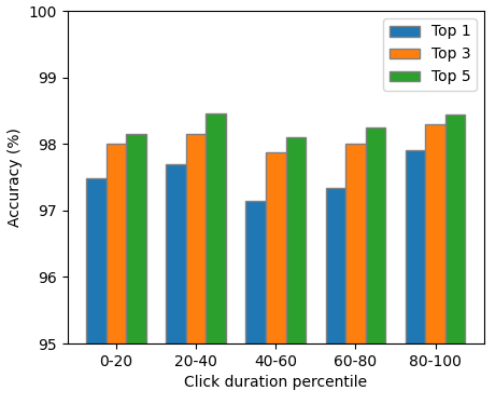

Figure 9: Our attack is unaffected by typing speed, with similar accuracy across different click duration percentiles.

attack correctly inferred 97.53% (2,371 out of 2,431) of all keystrokes with top-1 prediction, 99.51% (2,419 out of 2,431) with top-3 prediction, and 99.59% (2,421 out of 2,431) with top-5 prediction. This result shows that (1) our attack is not affected by the number of participants in the room, and (2) even when the attacker cannot see the victim, the motion data is still received and can be used to recover the keystrokes. Thus, we conclude that our attack is applicable in a multi-user environment, and the attack is stealthy since the attacker can hide anywhere in the room while performing the attack.

6.4 Our Attack Generalizes Across Applications

	Top 1	Top 3	Top 5
Galaxity	98.25%	99.71%	99.73%
Sing Together: VR Karaoke	98.27%	99.97%	99.97%
oVRshot	99.07%	99.61%	99.61%

Table 2: Keylogging attack accuracy from three participants typing in the selected three additional applications.

By performing our proposed attack on Galaxity [12], Sing Together: VR Karaoke [14], and oVRshot [13], we have successfully recovered the motion data from the collected traffic and infer the key participants typed.

The performance of our attack is as detailed in Table 2. The slightly varied attack accuracy across applications may be attributed to differences in keyboard layouts and participant typing habits. Nevertheless, all attack results demonstrated performance comparable to our main experiment on Rec Room, underscoring the generalizability of our attack across different applications.

7 Keylogging is Possible Even with Partial Reverse Engineered Packets

In the previous sections, we demonstrated the effectiveness of performing a keylogging attack by fully reconstructing the typing process. However, the involved steps require some manual effort and can be time-consuming. If an adversary aims to execute our remote keylogging attack rapidly, with minimal manual reversing effort, the keylogging attack can still be performed with the help of machine learning. This approach operates under an additional assumption compared to the threat model introduced in Section 3. In particular, we allow the adversary to obtain some motion data from a victim's typing that is paired with the actual text being typed, serving as labeled (ground truth) data. This assumption is commonly accepted and used in previous VR keylogging work [17, 56, 71]. In the case of multi-user VR applications, adversaries can collect the necessary data by chatting with the victim (via the application chat) and capturing any messages with the corresponding motion data. Since the victim can perform multiple tasks without closing the menus, and the keyboard position is fixed once they open the menu, this collection step allows the adversary to use the labeled data to predict other keystrokes on the same keyboard location.

Attack Setup. To show that our attack works with limited reversing, we use the example of Rec Room to further demonstrate this attack. Figure 10 outlines the process.

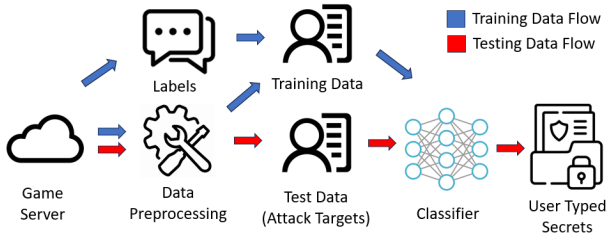

Figure 10: Machine Learning Attack Overview: The blue arrows illustrate the model training process, while the red arrows describe how an adversary might utilize the trained model to infer user keystrokes.

To build the training dataset for the machine learning model, we first collect raw packets and their corresponding labels (the typed text) using the aforementioned phishing approach. To preprocess the raw packets, we follow the steps from Section 4 that do not require significant manual effort and can be consistently applied across applications: (1) Filter for the packets that contain motion data, as explained in Section 4.1. (2) Use the protocol parser for Photon, as referenced in Section 4.2, to parse the packets, given that Rec Room employs the Photon library for motion updates. This step parses the packets into different fields of readable formats (e.g., integers, floats), except for the custom object fields, which are left as raw bytes. This step is easy because the Photon protocol

parser is a readily available tool that can be applied to all applications that use the Photon libraries. (3) Run the **Precise Input Control** experiment (see Section 4.5.1) to identify the fields that correspond to the click data (which are stored in floats), and the custom object fields that contain the motion data. This step is easy because the experiment can be run automatically, and we only need to manually observe the associations between the input data and the fields. (4) Determine the timing of clicks by performing click detection, which is done in the same way as in Section 4.4. We can use this information to find the packets that correspond to clicks and select the custom object field that contains the hand motion in these click packets (e.g., select the custom object field that contains the right-hand motion if the participant uses the right hand to click). Recall that click identification is straightforward via standard Unity APIs (see Section 2).

Compared to the attack described in Section 4, the resulting data will no longer have the following information: (a) The parsed motion data in a readable format. This requires reversing the parsing of custom objects, and this process needs to be redone for each application, as mentioned in Section 4.2; (b) The TRANSFORM of the cursor and key. This is because we do not have motion data in a "meaningful" format, so we cannot perform calculations on top of it (e.g., measure cursor and keyboard offsets).

After these data preprocessing steps, for each click, the resulting data provides only a custom object field in raw byte format that contains the motion data associated with typing. The resulting data is paired with the corresponding labels to create a dataset to train a machine learning classifier. Subsequently, we gather more traffic as the victim types. These attack targets (traffic with keystrokes) can be processed in the same manner as the training data and fed into the trained machine learning classifiers to infer corresponding keystrokes.

Attack Evaluation and Results. For evaluation purposes, we utilize the traffic traces collected from the user study and divide them into an 8:1:1 ratio for training, testing, and validation. Then, we follow the attack steps above to carry out the attack and evaluate the attack result using the top-k accuracy of the testing data.

To identify the best machine learning model for the task, we compare the attack results from various models, including SVM [26], GBM [34], MLP [52], and CNN [37], to the Random Guess baseline. These models are trained with a learning rate of 10^{-4} for 500 epochs, from which we chose the checkpoint with the highest validation accuracy as the best attack model.

From the results in Table 3, we observe that all ML models extract the victim-typed keystrokes significantly better than the random guess baseline. Additionally, we observe that the CNN model performs the best, with a 68.07% top-1 accuracy, 85.96% top-3 accuracy, and 90.28% top-5 accuracy in predicting keystrokes. This result highlights that machine learning models like CNN can effectively learn about mapping the bits in packets to corresponding motions and click positions, so the model can predict keystrokes with reasonable accuracy.

Our CNN model structure consists of three convolutional layers. Each layer has a one-dimensional kernel size of three, with 32, 64, and 128 neurons in each layer. Subsequent to these convolutional layers, the architecture includes two fully-connected layers and a softmax layer. The output space of this CNN model corresponds to the number of classes, equivalent to the distinct keys on the keyboard (47 in total).

The success of CNN might be attributed to its ability to learn from small datasets with generalizability [20]. Also, the CNN model might be able to learn from the features with significant effects on the key presses (e.g., those bits directly related to the TRANSFORM of the typing hand) [20], which can be effective in capturing relevant parts from the partially reversed data items that contain non-parsed custom fields used in this task.

	Top 1	Top 3	Top 5
Random Guess	2.13%	6.38%	10.64%
SVM	44.87%	64.47%	71.57%
LightGBM	46.49%	66.24%	71.61%
MLP	61.99%	79.81%	85.34%
CNN	68.07%	85.96%	90.28%

Table 3: Comparison of machine learning models on inferring the keystrokes with partially reversed data in raw bytes.

The accuracy is still lower compared to the full extraction keylogging attack we proposed earlier, which uses high-fidelity typing-related motion data. This is due to two reasons: (1) From the prior experiment, we find that a slight deviation in the motion data received by the adversary can cause an incorrect prediction since the motion data of typing nearby keys is similar due to the relatively small space of keys. As the model is trained on partially reversed data, the data might have less learning signal to predict the key and might introduce errors. (2) As the model is trained on data items collected through chatting with a victim, the quantity of the data is also limited. This can potentially lead to the overfitting of the model and cause a deviation when inferring the motion data that the model has never seen, leading to a decrease in prediction accuracy. However, even with the drop in accuracy, the attack can still very effectively infer the victim's keystroke.

8 Discussion

User Awareness and Concerns. From the results of the participant feedback from our data collection,none of the participants had ever imagined that their input in multi-user VR applications could be stolen by adversaries. However, after disclosure, 12 out of 20 participants expressed concerns regarding this type of attack. These findings suggest that VR

users do recognize the potential harm from such attacks. The user study results highlight the importance of educating VR users about potential security and privacy threats, such as our keylogging attacks in multi-user VR applications. This education can serve as a warning, encouraging users to exercise caution and prevent privacy leakage.

Privacy policies of VR applications play a crucial role in educating users about their data privacy. However, to the best of our knowledge, major VR applications often fail to clearly explain sensitive data like motion data in their privacy policy. Furthermore, Trimananda et al. [60] find that approximately 70 percent of PII data sent in traffic of VR applications are not properly disclosed. This highlights the need for better disclosure and compliance efforts from VR developers.

Impacts of Our Attack. We have reported our attack findings to all of the applications we evaluated, as well as SteamVR and Unity. Rec Room, Sing Together: VR Karaoke and SteamVR responded, acknowledging the vulnerability. Furthermore, Rec Room classified it as *P3 severity (Medium: Vulnerabilities that affect multiple users and require little or no user interaction to trigger)*. This underscores the fact that our attack is feasible and poses a privacy risk to numerous users. At the time of writing, we still have ongoing discussions with SteamVR and Unity.

It should also be noted that our reverse engineering approach is not limited to recovering typing-related motion; it can also recover other types of sensor data shared over the internet, such as voice data. Our tool can serve as a baseline for future studies aiming to further reveal the potential threats posed by the misuse of sensor data in VR.

Moreover, our attack poses a threat not only to users in applications in which we have performed our attack. For multi-user VR applications, the function of correctly synchronizing avatar movements and displaying them to other users is foundational, serving as the cornerstone of real-time interaction within the application. To accurately render user avatars and their movements, it's important to note that even if motion data is encrypted when sent over the network, it will eventually be decrypted on every client. Therefore, attackers can recover motion data (of other users) received by their own client, which allows them to fully track how a victim's avatar moves when selecting a key. Since our attack targets and exploits the foundational design of transmission of motion data, the threat posed by the attack is not limited to the applications we have evaluated. In addition to them, we have analyzed the functionality of **30** multi-user VR applications from various platforms, including Oculus and Steam. Of the applications we studied, **18** offer virtual keyboard typing functionality and transmit motion data online, making their users potential victims of our attack. Additionally, the wide support of overlay system messaging apps like Steam Chat or Messenger on VR devices makes all multi-user VR applications potentially susceptible to our attacks, since the applications may transmit motion data when these overlays are activated.

Our Attack is Applicable Regardless of Physical Setup. It is important to note that the transmitted motion data represents the movements of in-game objects (e.g., avatar hands), rather than the physical movements of devices (e.g., controllers). As such, the motion data remains consistent irrespective of the attacker's or victim's physical setup (e.g., VR device, WiFi router), with the setup only affecting the data's quality (e.g., refresh rate). In Section 6.1, we have shown that our attack is robust against degraded motion data quality.

Defenses. To the best of our knowledge, no current defense mechanism directly addresses our attack, and common data protection defenses struggle to mitigate our attack for the following reasons:

(1) Encrypting network traffic is not enough: as discussed by Trimananda et al. [60], if an adversary controls the client application, they can intercept packets during the key exchange, thereby obtaining the encryption key. This enables the adversary to decrypt subsequent traffic to their client and access motion data, facilitating the described attack. Interestingly, among the applications we examined, only VRChat encrypts the user's motion data in the packets. This highlights a general oversight by multi-user VR applications with respect to the potential privacy breaches related to motion data.

(2) Differential privacy comes with utility trade-offs: by introducing noise to all motions, differential privacy can decrease attack accuracy and mitigate potential motion-related privacy breaches. However, as highlighted by Nair et al. [45], incorporating differential privacy to protect the motion data can lead to utility drops. That is, it can lead to altered and inaccurate avatar movements, and can potentially reduce the quality of the immersive experience in VR applications.

We propose a defense to mitigate this attack: full blockage of motion updates during typing activities. That is, a user's motion data should not be sent to remote clients when the user is typing, and perhaps an idle or random animation can be sent instead. While this solution may sound trivial, it requires efforts from developers, game engines, and VR systems alike.

For typing activities using an application's built-in typing functionalities, the burden of defense is now put on every developer to identify scenarios in which typing happens and fix them, which can be error-prone. Therefore, it may also be necessary for game engines to provide a standard API and defense mechanism for the typing functionality.

However, as previously mentioned, just protecting motion data for an application's built-in typing functionalities is insufficient because of the wide support of system overlays like Steam Overlay [9]. As the application is still active, motion data is still updated when the overlay is launched, and typing activities inside the overlay are also vulnerable to our attack. In this case, the application can not know whether the users are typing and when to block motion updates. Consequently, a standardized system-level API for typing detection also needs to enable communication between the system and applications.

Limitation and Future Work. At this stage, our method predominantly targets a common input approach: using controllers to select inputs from virtual keyboards, which highlights vulnerabilities in motion data transmission. While alternative input methods exist, such as using one's hand to tap keys on a virtual keyboard, these mechanisms still rely on motion data for input. Therefore, the foundational concept of our attack remains valid. Thus, our technique should also be effective in extracting typed secrets from these variations.

Also, our work primarily showcases that keylogging attacks can be performed with motion data extracted from network traffic. However, the use of motion data is not limited to updating remote avatars; it also plays a role in various stages of a VR system, such as rendering, haptic feedback, and video recording. We will leave this as future work to further explore other remote channels available for keylogging attacks.

As highlighted by Nair et al. [47], motion data can lead to other forms of privacy breaches, such as user identification, anthropometric measurements (e.g., height and wingspan), and even demographic details (e,g., age and gender). It would be valuable to conduct a separate study in the future, exploring how to remotely exploit these vulnerabilities to deduce such information from VR players.

Ethics Statement. Our paper demonstrates a practical keylogging attack that utilizes an inherent issue of VR multiplayer applications. We have followed a responsible disclosure process to notify affected parties and to mitigate potential harm. Also, we believe that our work serves as an important warning to developers and we hope that it will inspire the design of better defenses and secure future applications.

9 Related Work

Keylogging and Side-channel Attacks on VR/AR Devices. Given that typing in VR and AR applications is dependent on hand or controller movements, recent studies have identified potential side channels for keylogging on VR devices, such as using malware running in the background on the victim headset to collect a user's hand or head movement for keylogging [41, 56, 66] or using system-side channels, like rendering performance counters [71] or channel states [17] to infer user keystokes.

It is also worth noting that methods of keylogging through video capture of user typing have been extensively researched in previous studies [32, 39, 44]. However, previous studies operate under the assumption that adversaries can access a user's local information during typing. This may not be applicable in many VR usage scenarios. In contrast, our keylogging attack is executed remotely without necessitating any modifications that could alert or impact the victim, rendering our method both practical and discreet. Although our attack is performed under a more challenging threat model, it still achieves comparable performance to the state-of-the-art keylogging attack on VR motion data [66].

Keylogging and Side-channel Attacks on Other Devices. Keylogging has also been well-studied on smart devices, including smartwatches, mobile phones, and tablets. The techniques for keylogging on these devices also focus on exploiting side channels, such as sensor leakages [23, 40, 43, 64, 67], video recordings of human typing [58, 68], voice [33, 53], Wi-fi signals [18, 54], CPU-related side channels [51, 70] and GPU-related side channels [35, 69]. Again, these prior efforts are also based on the assumption that adversaries can access and exploit side channels on user local devices. This is primarily because the motion data associated with typing does not necessarily need to be exported or shared with another person or client over the Internet. In contrast, our attack exploits the unique property of immersive VR environments, which requires broad sharing of motion data for rendering. The effect of remote motion data leakage proposed in our work is understudied and unique to multi-user VR applications.

Other VR/AR Security or Privacy Issue. Other than keylogging attacks, security and privacy problems in VR have also received attention recently. Regarding privacy in VR/AR applications, Nair et al. [45–47] have demonstrated different kinds of privacy threats related to the data-collecting process in VR/AR systems and proposed utilizing differential privacy tools for protection. Trimananda et al. [60] investigated VR app network flows for privacy breaches, while Farrukh et al. [30] utilized VR/AR spatial maps to identify sensitive environmental details. Regarding security, studies have centered on Perceptual Manipulation Attacks (PMA) [24, 25], clickjacking [57], and ad fraud [38]. Similar to these prior efforts, our keylogging attack utilized unique designs in VR/AR systems. However, our method is specifically designed to execute a remote keylogging attack in multi-user VR applications to extract user typing information.

10 Conclusion

In this work, we present the first VR remote keylogging attack that targets multi-user VR applications. Specifically, our attack can accurately infer user keystrokes by recovering motion data from the attacker's client, *without* the need to compromise the victim's device or physically approach the victim. In a user study with 20 participants, our attack showcases that, even with rate limitations and the potential for packet loss under a remote attack setting, we can still infer the victim's keystrokes with a nearly perfect top-1 accuracy of 97.62% and top-5 accuracy of 98.34%. Furthermore, our results indicate that even with minimal manual reversing efforts, an adversary can swiftly deploy this keylogging attack across various applications with an added phishing step using machine learning, still achieving a reasonable top-1 accuracy of 68.07% and top-5 accuracy of 90.28%. We hope this work can assist the VR research community and industry by highlighting potential threats from motion leakage in VR and encouraging the development of more effective defense mechanisms.

A Data Collection Details

Data Collection Setup. During the user study, we installed and ran Rec Room in VR mode through SteamVR on a Windows PC, with an Oculus Quest 2 connected via Quest Link (we will refer to this as the *Victim PC* later). We installed and ran Rec Room in non-VR mode on another Windows PC to simulate the attacker behavior (we refer to this as the *Attacker PC*). The two PCs then join one private virtual room, as mentioned in our threat model. After we begin capturing network traffic with Wireshark on the *Attacker PC*, the participant, wearing the Quest 2 headset, starts entering the prepared text into Rec Room's chat functionality using the virtual keyboard. Lastly, to serve as a reference during the data labeling process, on the *Victim PC*, we use VCR to record the VR tracking data during each session.

User Study Recruitment. We conducted a user study to collect VR typing data from volunteers using the *Victim PC*. This study has been approved by our university's Institutional Review Board (IRB). Through email advertisements via our institution's email list, we recruited 20 participants of varying ages, heights, genders, and experience with VR from our institution's campus. Prior to the experiment, participants were provided with instructions on how to operate the Quest 2 headset and controllers. Additionally, they were guided on the typing functionalities and practiced typing within Rec Room. Before the start of the experiment, the participants were also informed that their typing-related information would be recorded and that they could stop the study at any time. To minimize bias and more closely mirror real-world typing scenarios, participants were not initially informed of the study's exact purpose. Instead, they were simply told that the goal of the study was to examine VR typing behavior. After the participants completed all the typing experiments, we debriefed them about the real purposes of the study and asked them to fill out a survey to understand their perceptions of our attack.

Typing trails.

(1) *Numbers*: The prompts are random numbers with lengths of 3 (e.g., "823"), 9 (e.g., "804458083"), and 12 (e.g., "595397360820") digits, with 10 prompts per length. This simulates entering credit card information.

(2) *Passwords*: The prompts are passwords with characters, numbers, and punctuation marks. To emulate real-world password typing activity, we generated 10-17 characters long combinations of English words with numbers and punctuation marks, using the Memorable Password Generator [7].

(3) *Sentences*: The prompts are English sentences that consist of 3 words (e.g., "Clouds are drifting"), 6 words (e.g., "The sunset today looked absolutely stunning"), and 9 words (e.g., "My cat just did the funniest thing this morning"), with 5 prompts for each length. These sentences are generated by ChatGPT [50]. This experiment is to simulate the scenario of typing in private chats.

B Geometric Tests for Cursor and Key Measurement

Cursor Measurement. If all the measurements of the cursor are correct, we can verify them with these geometric tests:

(1) If we point the cursor at a vertical screen and move the hand along the measured forward direction of the cursor (i.e., which direction the cursor is pointing at), the cursor's reticle (projection of the cursor on the screen) should not move. Passing this test shows that the movement axis aligns with the cursor's real forward direction, and we have measured the cursor's orientation correctly. This test is illustrated in Figure 7.

(2) Once we measure the cursor's forward direction correctly, if we rotate the hand around the forward direction axis along the measured cursor's center point, the cursor's reticle should not move. Passing this test shows that the rotation axis crosses the measured cursor's center point and that we have measured the cursor's position correctly. This test is illustrated in Figure 11.

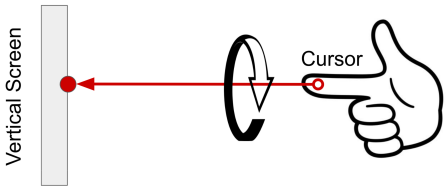

Figure 11: Geometric test 2: test if the cursor position is correct by rotating the hand around the cursor's forward direction.

Key Measurement. If the measurement of a key's corner position is correct, we can verify it with the following geometric test: Once we measure the cursor's TRANSFORM, if we can find an axis that crosses a key's corner, then move the cursor around this axis while pointing at the key's corner, the reticle should not move. Passing this test shows that we are able to triangulate the key's corner and that we have measured the position of the key's corner correctly. This test is illustrated in Figure 12.

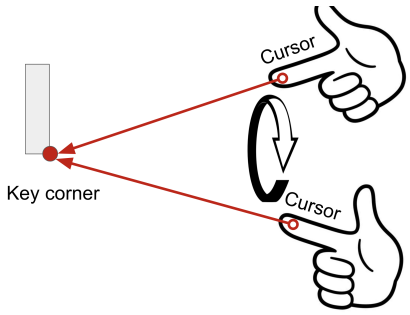

Figure 12: Geometric test 3: test if the key corner measurement is correct by drawing a cone shape around the key corner with the cursor.

That Doesn't Go There: Attacks on Shared State in Multi-User Augmented Reality Applications

Carter Slocum[*1], Yicheng Zhang[*1], Erfan Shayegani[1], Pedram Zaree[1], Nael Abu-Ghazaleh[1], Jiasi Chen[2]
[1]*University of California, Riverside*
[2]*University of Michigan*

Abstract

Augmented Reality (AR) can enable shared virtual experiences between multiple users. In order to do so, it is crucial for multi-user AR applications to establish a consensus on the "shared state" of the virtual world and its augmentations through which users interact. Current methods to create and access shared state collect sensor data from devices (*e.g.*, camera images), process them, and integrate them into the shared state. However, this process introduces new vulnerabilities and opportunities for attacks. Maliciously *writing* false data to "poison" the shared state is a major concern for the security of the downstream victims that depend on it. Another type of vulnerability arises when *reading* the shared state: by providing false inputs, an attacker can view hologram augmentations at locations they are not allowed to access. In this work, we demonstrate a series of novel attacks on multiple AR frameworks with shared states, focusing on three publicly accessible frameworks. We show that these frameworks, while using different underlying implementations, scopes, and mechanisms to read from and write to the shared state, have shared vulnerability to a unified threat model. Our evaluations of these state-of-the-art AR frameworks demonstrate reliable attacks both on updating and accessing the shared state across different systems. To defend against such threats, we discuss a number of potential mitigation strategies that can help enhance the security of multi-user AR applications and implement an initial prototype.

1 Introduction

AR technologies have enabled a large variety of applications that use real-world data to create environments enriched with overlaid virtual holograms. These virtual holograms can take many forms, from face filters to virtual characters, and they are typically placed relative to some point in the real world, such as a table, face, or recognizable landmark. Although AR has been around for several decades [4], the recent ubiquity of mobile devices and the availability of commercial AR headsets have made it possible for AR applications to reach the mass market [59]. Recent AR applications even allow multiple users to interact with the same AR holograms. For example, in 2019, Pokémon Go enabled users to view the same virtual creatures at the same time in some shared space using a "Buddy Adventure" system [40]. In order for these multi-user interactions to take place, some information about the state of the real world (*e.g.*, nearby flat planes, landmarks, and virtual objects) must be sensed, processed, and shared between users to provide a common frame of reference. We call this information, together with the hologram information, as the "shared state" of the AR application. Several multi-user AR systems with cloud-based AR shared states exist and are in use, including those by Google [12] and Meta [32]. Thus, a natural question emerges after the rise of such systems: **What security threats can exist for AR frameworks involving this shared state?**

In this work, the attacks that we focus on relate to one of the fundamental problems in AR: how to place a hologram accurately in the real world and have it persist over time, space, and across users. Successful manipulations of hologram locations could have serious impacts on both owners and users of the system. As the number of users and businesses relying on AR continues to increase, the incentives for attackers to manipulate the shared state to their advantage also increase. For example, suppose a construction company is using AR to place and visualize markings in the environment. Construction workers wearing AR glasses might visit the site and visualize where a water pipe should be built or where to dig a hole. A vulnerable AR construction application could cause confusion, destruction of property, or danger to workers if an attacker's efforts result in a construction worker viewing virtual demolition markers in unsafe real-world areas and bulldozing those areas.

Our first goal is to identify the threat models that affect the shared state. At a high level, interactions between users and shared state in AR can be thought of as *read* and *write* operations, which are provided by AR frameworks through

[*]Equal contributors.

an API. One can write a new virtual hologram to the shared state and read others' virtual holograms in order to render them on the device. Direct manipulation of the shared state is impossible since it's typically stored on cloud/edge servers controlled by the AR service and is well-secured, requiring physical or software exploitation not unique to AR. Instead, we investigate exploits that allow attackers to remotely manipulate the shared state using only the basic read/write API calls available to users. Calls to the API typically involve associated location data consisting of one or more of the following: Global Positioning System (GPS) coordinates, camera images, and/or Inertial Measurement Unit (IMU) sensor data. This information allows the attacker to map the read or write operation to a location within the AR space.

We seek to understand these threats and develop end-to-end attacks on commercial systems, in order to demonstrate how they work and inform designers and develop mitigations. We develop a range of attacks targeting write or read operations on the Google's Cloud Anchor API [12], Google's ARCore Geospatial API [15], and Meta's Mapillary system [32]. We focus on these because they are major commercial players, and their multi-user APIs work on many common AR devices. We show that malicious reads and writes are possible on the three systems despite the substantial differences in how they perform these operations. We are able to write information to different, potentially inaccessible, locations on the map, as well as falsify our own location to access information at potentially private or inaccessible locations. These end-to-end attacks rely on known image and GPS spoofing methods; our contribution lies in combining these methods with multi-user AR, which brings unique challenges in that the interactions between the real world, virtual world, and downstream victims must be accounted for in a successful attack.

In summary, we make the following contributions:

- We create a taxonomy of existing commercial AR frameworks with shared state and identify their common vulnerabilities regarding the read and write operations. We form a unified threat model that covers these current and prospective AR applications.
- We demonstrate attacks on shared state in the novel AR domain on three frameworks using real devices (smartphones), and quantify their success. To the best of our knowledge, this is the first documented demonstration of such attacks on AR using these frameworks.
- We repeat the attacks of these three scenarios in various environments (*e.g.*, different locations, lighting, clutter) to demonstrate the attack's robustness.
- We propose and evaluate a defense strategy that uses multimodal sensors (depth and visible light cameras) available on some AR devices. The source code and dataset are available online.[1]

[1] https://sites.google.com/view/multi-ar-defense/

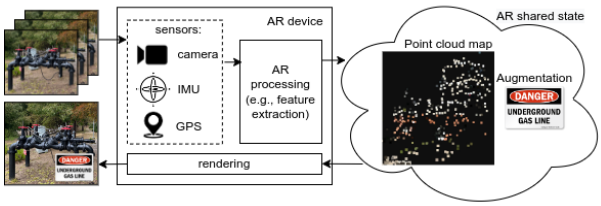

Figure 1: AR processing pipeline. An AR device senses the environment, processes the sensed data, and uploads information to the shared state. The shared state returns an augmentation overlaid onto the user's display.

Disclosures and ethics. We disclosed our findings to Google and Meta. We performed all experiments either in sandboxes or in our own local sessions, so no external public users were affected by our experiments.

2 Background

In this section, we first introduce the background of shared state in AR (Section 2.1). We then describe the current landscape of shared state in commercial AR systems (Section 2.2). Finally, we define the general threat model (Section 2.3).

2.1 Shared State in Augmented Reality

To facilitate interactions between multiple users in AR, a mutually agreed-upon model of the reality to augment, and the augmentations within it, is needed between users [44, 57]. Ideally, this model should be consistent across devices and thus is typically stored in the cloud, providing a central access point. In such a model, multiple users interact with the shared augmentations (*e.g.*, other participants in a remote meeting app). They also fuse spatial information about the real environment using the collected sensor data. We call this shared model of reality the *shared state*.

The shared state commonly contains a "map" of 3D points (an example is shown on the right side of Fig. 1). The points in this map are features extracted from images (*e.g.*, [29, 48]). Each feature contains an estimate of its 3D position and a descriptor of its visual neighborhood for use in finding and correlating the same feature in other images. To give augmentations the appearance of blending in with the real world, they are described by their 3D coordinates. Thus, the AR shared state consists of the map of visual features combined with the augmentations placed on the map. Fig. 1 shows the processing pipeline of an AR device accessing the shared state in the cloud, including communicating with the shared state to receive augmentations and render them onto the display.

Communication with the shared state. For a user to view or place shared holograms/augmentations, communication

	Non-curated	Curated
Local	**Scenario A: Cloud Anchor** *Keys*: camera, IMU *Attacks*: read, write	**Commercial scenario not found.** *Keys*: camera, IMU *Attacks*: read
Global	**Scenario C: Mapillary** *Keys*: camera, IMU, GPS *Attacks*: write	**Scenario B: Geospatial Anchor** *Keys*: camera, IMU, GPS *Attacks*: read

Table 1: Taxonomy of AR shared states.

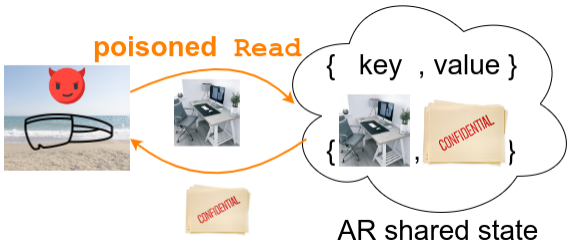
with the shared state is needed. Abstractly, we can think of viewing or placing the shared holograms as read and write operations against the shared state, respectively, using key-value pairs. The *key* is some piece of information relating to the user's physical location, which a user provides (details later), and the *value* is the associated hologram's coordinates (and optionally its visual appearance). The cloud processes these key-value pairs and updates (or retrieves information from) the shared state accordingly. There are two operations for users to communicate with the shared state: *read* and *write*, as follows.

- **Read:** A user may read the shared state to determine where she is on the map and render the appropriate holograms. For instance, a user may go to a park where virtual art is displayed and upload an image *key* of the park to the cloud, captured by the phone's camera, and receive back the *value* of the hologram's coordinates, and then render the virtual art on her display.

- **Write:** Users may write holograms at specific locations in the map in the shared state. For instance, a user may place their own virtual art for other users to view by uploading a *key* consisting of a short image sequence near the art and the associated GPS coordinates alongside a *value* of the virtual art's coordinates.

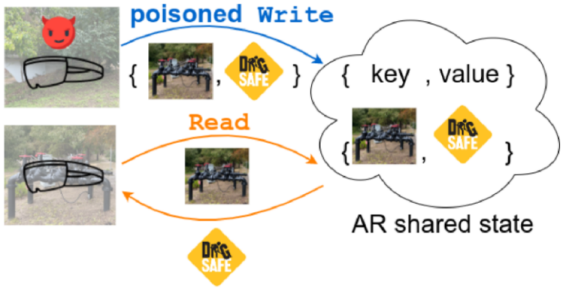
Keys consist of information used to identify locations within the shared state. Keys are usually derived from three main types of sensors commonly used in AR applications: GPS, camera, and IMU. GPS data provides information about the user's geographical location and typically consists of latitude, longitude, altitude, and time. Camera data in AR applications can take the form of video or a sequence of timestamped images. IMU data refers to the measurements collected by sensors such as accelerometers, gyroscopes, and magnetometers. This data provides information about the device's orientation, acceleration, and rotation. The IMU may not be strictly necessary for these applications to work but is often included to assist in speed and accuracy [24].

2.2 AR Shared State Taxonomy



We studied the current landscape of multi-user AR and found three major examples of shared state: Cloud Anchor [12], Geospatial Anchor [15], and Mapillary [32], which we primarily focus on in this work. Cloud Anchor and Geospatial Anchor are part of Google ARCore, which is Google's AR Software Development Kit (SDK) for Android devices. Mapillary is a crowd-sourced mapping service acquired by Meta in 2020. These frameworks abstract away low-level details so that developers can more easily build AR applications on top, so vulnerabilities in the underlying frameworks will affect many AR applications. The design of these frameworks can be dissected along two dimensions: global/local and curated/non-curated, as summarized in Table 1. Next, we describe each of these dimensions.

Global vs. local shared state. AR applications can run in local or global geographic areas; for example, a treasure hunt may take place locally within a building, while Pokémon Go takes place globally. Consequently, they can have larger or smaller maps in their shared state, which we categorize as a global or local shared state. AR frameworks with the global shared state tend to utilize GPS coordinates plus camera images as the key to writing into the shared state. Specifically, each writer uploads local images tagged with GPS coordinates to the shared state, where the cloud merges all data to create a global shared state. Users seeking to read from the shared state may use a combination of GPS, camera, and, optionally, IMU data as a key into the database. Global shared states tend to be persistent without a clear expiry time, typically persisting for years.



AR frameworks with local shared states are typically smaller in geographic scope and lack global positioning (GPS). The key typically consists of just camera images and optional IMU data, without GPS. Local shared states tend to be ephemeral in that they have a configurable lifetime, typically of less than one year [12].

Curated vs. non-curated shared state. The maps contained in the shared state can be either curated or non-curated. Curated maps are constructed by "high trust" users or "curators". These curators have elevated write permissions to the shared state and usually have the incentive to avoid malicious behavior. Most commonly, these curators are paid employees, contract workers, or trusted research groups. An example is the Street View Car [17], where company employees drive a car around and capture camera images to upload to the cloud, which processes them and inserts them into the shared state's map. Non-curators can still read the curated shared state but cannot otherwise manipulate it.

AR frameworks with non-curated (*i.e.*, crowd-sourced) shared states allow all users to read and write to the map in the shared state. These users are low trust but come with

(a) Read attack.

(b) Write attack.

Figure 2: Attacks on AR shared state. Read attack: A private hologram is read outside the area it was written to (beach instead of office). Write attack: A hologram is written to an area where the attacker is not present (pipes instead of field).

the advantage of increased numbers, allowing rapid construction and updating of the shared state compared to curators. An example is Mapillary's crowd-sourced street mapping model, where public users can upload camera images to the cloud, which processes them and inserts them into the map.

The write permissions for the shared state maps and the shared state holograms may be separate. For our purposes, a curator has permission to write both shared state map and hologram data to the shared state, while a non-curator can only read map data from the shared state but may be able to both read and write holograms. In the future, applications with more granular permissions may become more common [8].

2.3 Threat Model

We assume an attacker engages in AR experiences with shared states using an unmodified AR application. The attacker only possesses the same read/write permissions as normal users. The primary objective of the attacker is to compromise the integrity or confidentiality of the multi-AR shared state. We identify two classes of attacks in this context (see Fig. 2): *(a) read attack* and *(b) write attack*.

Read attack. Such an attack focuses on extracting sensitive information stored within the shared state created by other users. For example, suppose a victim user has created a hologram of a whiteboard and written sensitive company secrets onto it. The whiteboard is uploaded to the shared state and is only supposed to be viewable from the private office. Thus, in Fig. 2a, the shared state contains the {key=office image, value=confidential whiteboard document} entry. The objective of the attacker is to retrieve and access this private document, thereby breaching confidentiality, by providing a forged {key=office image} to retrieve the associated value (the private hologram). The attacker benefits from retrieving confidential information, which is a serious concern in multi-user AR [49]. It is assumed that the attacker can gain temporary physical access to the office in order to obtain images to use later during the attack, or is able to find publicly available images of the office.

Write attack. The attacker seeks to manipulate the shared state in order to deceive subsequent victim AR users. Specifically, the attacker creates and uploads manipulated images or falsified sensor readings as keys in the shared state, and uses them to add to the shared state at that location without being there. It is assumed that the attacker possesses images and GPS coordinates of the target location needed for manipulation. Thus, in Fig. 2b, the shared state contains the {key=pipe image, value="dig safe" sign} entry created by the attacker. Subsequently, when victims attempt to read from the shared state, they may encounter misleading or false information, leading to inaccurate perceptions or actions within the AR environment. For example, in Fig. 2b, the victim uses a legitimate {key=pipe image} and retrieves a hologram telling her it is safe to dig there. The attacker benefits by causing disruption of legitimate AR use cases. Moreover, with companies now making efforts to combine their maps (*e.g.*, Overture Maps Foundation [42] includes Amazon, Meta, and Microsoft as contributors), poisoned writes to one shared state could potentially propagate to other shared states.

Key issues. The fundamental issue with the shared state that enables these attacks is that the ingest pipelines of these AR frameworks accept most keys as inputs. They do not have a way of verifying that users are uploading legitimate information consistent with the key they provide. Furthermore, even if the attacker fails to generate perfect keys identical to legitimate inputs, the shared state still accepts them because it attributes their imperfections to noise. We speculate that these weaknesses are due to the nascent nature of multi-user AR frameworks; because AR frameworks want to encourage user participation, they favor functionality and lowering barriers to participation over security. The collaborative nature of these applications necessitates opening a shared state for read and possibly write access among large groups of users that are not necessarily mutually trusting.

Attacker's goal in each scenario. As various multi-AR platforms rely on different combinations of sensor inputs to

generate these keys, our investigation focuses on three attack scenarios outlined in Table 1.

In Scenario A, the attacker's goal is to perform both read and write attacks on the shared state. It aims to read or write holograms to locations where they are not physically present. By doing so, it deceives other users by providing false or manipulated information. Since AR applications in such a scenario run in local areas only, the attacker only needs camera and IMU data as keys to read or write from the shared state, and not any global information (GPS), making this attack easier to realize. We assume that the attacker can participate as a regular user in the AR session, which can be protected by API credentials and a room code. API credentials are commonly hard coded into the app, so the attacker does not need to learn it, and the room code is an integer that by default starts at 1 and increments every session, making it feasible for the attacker to find through brute force [12].

In Scenario B, the attacker's goal is to perform a read attack only. It attempts to read a hologram from a location where the hologram does not exist, effectively lying about her location and reaping the benefits. In addition to the camera and IMU data needed as keys in Scenario A, the global nature of this scenario requires the attacker to understand the global position of the hologram she wishes to read, necessitating GPS data in the key. We do not investigate write attacks in Scenario B due to the curated nature of the shared state. In other words, since the threat model assumes the attacker is an ordinary user, only read attacks can be performed on a curated shared state with the appropriate key. These keys are used by all users freely with no need for special permissions. We assume that the attacker has the API credentials hardcoded in the app, as in Scenario A, but it does not require a local room code because the shared state is global.

Finally, the Scenario C attacker writes holograms to false locations. This would allow an attacker to manipulate holograms that other users view, potentially leading to sabotage and safety issues. The attacker's writes are uniquely enabled by the non-curated nature of the shared state in this scenario. Again, special attention must be paid to the global positions of the holograms and map data for successful attacks due to this scenario's global scale. We do not investigate read attacks in Scenario C because this API does not yet exist in the commercial framework we studied. The attacker does not require any special credentials or room codes because the shared state is global and crowd-sourced.

We did not find any current examples of an AR framework that provides a local and curated shared state (upper right box in Table 1). We speculate that such a shared state could be created by a local administrator who curates the map and holograms in small areas, such as a university campus. Related frameworks also exist in the research domain [5].

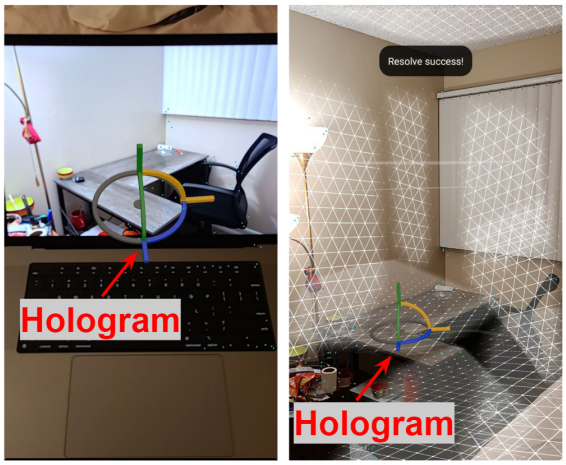
3 Scenario A: Local, Non-Curated Shared State

In this section, we focus on attacks on AR frameworks with local and non-curated shared states. In particular, we focus on the Cloud Anchor API [12], which allows multiple users to share experiences within a single app. It is the underlying mechanism enabling multi-user AR apps on Android devices. Using an app that integrates this API, a user (User A) can write a hologram to a specific location within their environment, such as the surface of a desk. Another user (User B), who has access credentials to the app (see §2.3), can then read the hologram from the shared state and view and interact with it in the same physical space. We identified an attack vector related to this multi-user functionality, described in the following subsection. The experiments were performed with our own test devices in a private local session only, so no external users were affected by our experiments.

3.1 Methodology

The normal process of writing a hologram to the shared state involves User A pointing her AR device at the desired location of the hologram (*e.g.*, a desk) and moving around it to capture the required keys (camera images and IMU readings), which are uploaded to the shared state along with the hologram. If User B wants to read the hologram uploaded by the previous user, she points her device at the same location, captures a key, and sends it to the shared state. If the key matches an entry in the shared state, the corresponding value (hologram uploaded by User A) is retrieved from the cloud, and User B can view it. If there is no matching key, the API rejects User B's read request.

Normally, successful reads and writes require the user to be physically present in the environment where the hologram was placed in order to generate the correct corresponding key. However, our attack disrupts this workflow and demonstrates that attackers can remotely launch read and write attacks. Specifically, we show that the attacker can perform these actions using only an image of the environment (*e.g.*, printed on a photograph or displayed on a computer monitor). By pointing the camera at the image, the attacker deceives the API into believing that it is physically located in the environment, even though it is not actually present. Next, we describe three sub-types of this general attack: read, write, and triggered write. We focused on read and write because they are fundamental primitives, and triggered write is an advanced version with more targeted attack timing. Further technical details on the methodology of this attack and others are provided in Appendix B.



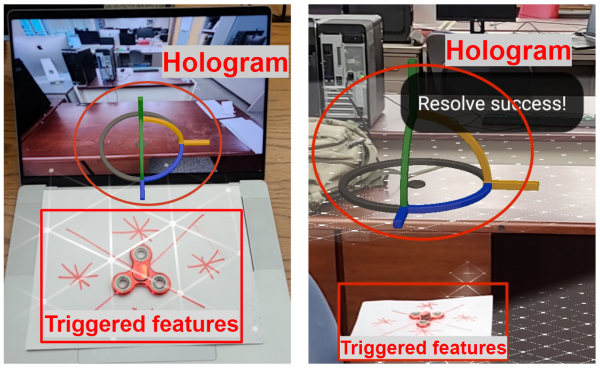
Remote read attack. In this attack, an attacker can remotely read a hologram, different from where a victim originally placed the hologram. The attacker benefits because it

Write hologram at physical location

Read hologram at remote location

Figure 3: Remote read attack in Scenario A. *Left:* A victim places a hologram in front of a yellow sign. *Right:* An attacker is able to view the hologram from a photograph without being physically near the yellow sign.

Write hologram at remote location



Read hologram at physical location

Figure 4: Remote write attack in scenario A. *Left:* An attacker is able to write a hologram at a real-world location (a desk) without being physically present. *Right:* A victim views the unexpected hologram on the desk.

can read private notes, passwords, or even sound files that belong to the victim. We assume the attacker has the pre-knowledge of the victim's physical location. For instance, the attacker may have a chance to view an image of the victim's office. The attacker's methodology is simple yet effective: it prints physical photographs or displays virtual images of the location where a hologram is placed and moves the AR device around to view the photograph/display from slightly different angles. This generates the necessary key (camera images and IMU readings) to retrieve the hologram from the shared state. Both the camera images and IMU readings (orientation of the device) must reasonably match the key previously stored in the shared state by the victim. The attacker's read request may fail if the camera image differs significantly (*e.g.*, zoomed out) from where the victim originally wrote the holograms or if the IMU readings differ (*e.g.*, the victim wrote the hologram while the device was in landscape mode but the attacker tried to read the holograms from portrait mode). Fig. 3 shows an example of such an attack ("Resolve success!" means attack succeeds). The hologram (a colorful 3D axis) is initially placed in front of the yellow sign by a victim. Later, an attacker with a photograph of the yellow sign can view the hologram, despite being at a different location and nowhere near the yellow sign.

Remote write attack. In this type of attack, an attacker can write AR holograms in places where it is not authorized to access or contribute, such as holy sites, museums, private spaces, kindergartens, and more. This situation becomes even more concerning if the written AR holograms contain inappropriate material, such as racist, extremist, pornographic, or disturbing content, causing psychological harm to victims. The attacker's methodology is similar to the remote read attack, with the additional step that after viewing the photograph/display, the attacker also indicates (by interacting with the AR device) where within the photograph/display the hologram should be placed. However, a significant challenge was that the key the attacker needs to generate a write request is more detailed than that needed for a read request; more camera images of the scene need to be captured from different angles to generate a successful write request (while looking at a single image on the display). We successfully tackled this challenge by carefully maneuvering the camera and prioritizing the capture of the image displayed on the monitor while minimizing the inclusion of the surrounding environment.

In Fig. 4, we show an example of this attack. The attacker displays an image of a desk on a computer monitor and places (writes) the hologram onto the desk in the shared state. When the victim later visits the location and views the desk through her AR device, it retrieves the hologram maliciously written by the attacker. Note that the key of the attacker's write request did not have to exactly match the key of the victim's read request, as illustrated by the differences in the camera images of the attacker and victim (compare the left and right sides of Fig. 4); for example, the attacker had extra features such as the keyboard and the monitor's border in view. The attack was still successful because the shared state matches keys that are not perfectly identical to allow for legitimate scenarios, such as two users viewing the same scene from slightly different angles.

Write hologram at remote location with **triggered** features

Read hologram at physical location with **triggered** features

Figure 5: Triggered remote write attack in scenario A. *Left:* An attacker employs triggered features to remotely write a hologram at a real-world location without being physically present. *Right:* A victim encounters an unexpected hologram on their desk, triggered by features injected by the attacker.

Triggered remote write attack. This attack can be treated as an advanced type of write attack, but it is more stealthy. We assume that an attacker not only has the ability to execute a successful remote write attack and poison the shared state, but it also has the ability to manipulate the victim's environment with pre-determined triggered features. This allows the attacker to exert control over the timing and extent of the attack, targeting specific individuals or groups. For instance, consider a scenario where a TV is present in the environment. Suppose the attacker could strategically turn on the TV and display the trigger on the screen when a specific person enters. This greatly increases the probability of the victim's successful reading and display of the attacker's hologram, leading to potentially severe consequences as desired by the attacker.

Figure 5 illustrates this, where the attacker initially writes a hologram remotely with the triggered features (left side of Fig. 5). Subsequently, if the attacker places the same triggered features at the victim's physical location (right side of Fig. 5), the victim will read the hologram placed by the attacker from the shared state. Ideally, if the triggered features are not added by the adversary, the attack remains benign in most cases, and the victim will be unaware that their private location has been manipulated by the attacker.

3.2 Evaluation

Next, we evaluate the attacker's success rate in both the remote write, remote read, and triggered remote write attacks in different environments, including investigating the impact of clutter, lighting, and indoor vs. outdoor environments.

Environment	Attack success rate	
	Static scene	Add clutter
Office desk	13/16	10/16
Bedroom desk	12/16	7/16
Bedroom bed	14/16	7/16
Outdoor garden	5/16	2/16
Outdoor BBQ	16/16	15/16
Outdoor pool	16/16	15/16

Table 2: Success rates of remote read attacks in *Static scene* and *Add clutter* conditions. Attacks succeed often and perform better in a *Static scene* compared to *Add clutter*.

3.2.1 Remote Read Evaluation

Experiment setup. We execute the remote read attack in six different environments, as shown in Table 2. These environments include a range of backgrounds, including an office, personal home, and pool, with about half being indoor environments and the other half outdoor (see Fig. 14 in the Appendix). All of the experiments were been done with a Samsung Galaxy S20 Android phone, and an Apple MacBook Pro served as the monitor to display the environment images. The success rate was used as the evaluation metric. It was defined as the number of trials in which we were able to successfully read the written hologram remotely. We also evaluated a benign baseline where the user reads the hologram from the real environment.

Furthermore, we evaluated the success rate under two conditions: *Static scene* and *Add clutter*. The motivation for studying these two conditions is to simulate the case where the attacker does not have perfect information about the victim's environment or the environment has changed in the interim. In the *Static scene* condition, the victim's true environment closely resembles the attacker's image of the environment. The *Add clutter* condition involves environments that have new objects or alterations in the attacker's image compared to the victim's original environment. It is a more challenging condition because there are additional features during the attacker's read process which were not been present during the victim's write, *i.e.*, the read key may not exactly match the write key, so the attacker's read may fail. The results of these evaluations provide insights into the effectiveness of the remote read attack under different conditions.

Results. As Table 2 shows, the success rate of the attack is generally good, with the attack succeeding about half the time, on average, across all of the environments we experimented in. This makes sense because, according to our observations, the critical phase of shared state communications is usually the writing process. The better the quality of the key uploaded by the victim during her write request, the easier it is for subsequent users (including the attacker) to read successfully. In other words, because the writing was performed in the real

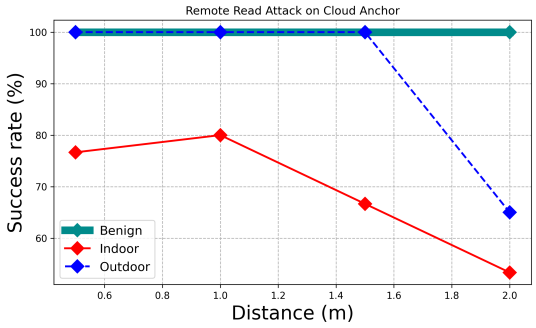


Figure 6: Remote read attacks in Scenario A.

Environment	Attack success rate	
	Static scene	Add clutter
Office desk	8/16	7/16
Bedroom desk	6/16	4/16
Bedroom bed	10/16	8/16
Outdoor garden	1/16	0/16
Outdoor BBQ	16/16	15/16
Outdoor pool	15/16	14/16

Table 3: Success rates of remote write attacks in *Static scene* and *Add clutter* conditions. The overall success rate of remote write attacks is slightly lower than that of remote read attacks. The success rates decrease in the *Add clutter* condition.

environment (not from a photograph) by the victim, there are many 3D features extracted from the victim's camera images and inserted into the map in the shared state. This creates a larger attack surface because there are many possible matching keys (*e.g.*, different angles of the scene) that an attacker could use to successfully launch a remote read.

We conducted additional experiments at different distances between the AR device's camera and the attacker's image of the environment. The results in Fig. 6 show that the attack success decreases as the attacker moves further away and the image becomes smaller in the camera's field of view. On the other hand, if the distance is less than 0.5 meters, it becomes challenging for the camera to focus on the visual features of the image, and the attack tends to be less successful. The benign baseline can read the hologram the vast majority of the time, while the attacker is only moderately less successful.

3.2.2 Remote Write Evaluation

Experiment setup. The setup is similar to the remote read attack (§3.2.1). A minor difference is that the *Add clutter* condition refers to environments where there are additional objects or changes in the victim's real environment (during the read) compared to the attacker's image (used to do the poisoned write). We also informally experimented with different environment lighting, conducting experiments in both brightly lit and dimmer versions of the same environment (*e.g.*, by turning on/off a lamp or daytime/sunset).

Results. Table 3 shows the success rates of the remote write attack in different environments. As can be seen, the attack reaches a high degree of success in both indoor and outdoor environments. The success rate is generally lower than the remote read attack because, as discussed earlier in Section 3.1, a write request generally requires more camera images in its key, and for an attacker to capture these multiple camera images from different angles of a single photograph is challenging. The "Outdoor garden" scene has a particularly low success rate. This can be attributed to the limited number of planes present in the scene compared to other environments, as the API typically relies on an adequate number of planes to create a map in the shared state and enable writing. However, it is important to emphasize that the low success in this environment affects both the remote write attack and a legitimate write process equally. We also evaluated the impact of distance on the attack, and the results follow those of the indoor scenario (presented in Fig. 15 in Appendix B.1).

Our attack demonstrates strong robustness against environmental factors like lighting changes, clutter, and distance, which barely affect its success rate. Based on our experiments, we have observed that when the actual environment that the victim is in is significantly darker than what is shown in the attacker's image, such as during nighttime or when the lights are almost turned off, the success rate of the attack degrades by approximately 15-25%. The robustness of our attack, which doesn't require precise knowledge of the victim's environment, makes it particularly dangerous. Notably, clutter impacts the success rate of remote read attacks more than remote write attacks. This occurs because remote reads face two layers of noise (photographic noise and clutter) simultaneously, reducing success rates. However, for remote write attacks, the layers of noise are separated (the photograph adds noise during the attacker's write, and the added clutter adds noise during the victim's read), and thus the impact on the success rate is less.

3.2.3 Triggered Remote Write Evaluation

Experiment setup. The setup is similar to the remote write experiment in the previous attack (Section 3.2.2), except that the attacker adds additional trigger features during remote write as depicted in Fig. 5. For our experiments specifically, we have used a simple piece of paper with some marks on it and a spinner on the paper placed near the image on the monitor. During the attacker's remote write, we do our best to move the attacker's camera to capture features both from the image on the monitor and the additional trigger features. In addition to having the victim read from the same environment as the attacker's write, we also examined the false positive rate in two cases: (case 1A) whether the victim can view the

Environment	Attack success rate	
	Static scene	Add clutter
Office desk	15/16	15/16
Bedroom desk	13/16	12/16
Bedroom bed	15/16	13/16
Outdoor garden	3/16	1/16
Outdoor BBQ	16/16	16/16
Outdoor pool	16/16	16/16

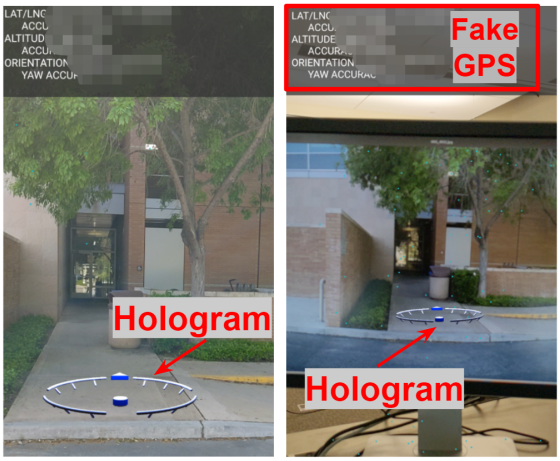

Table 4: Success rates of triggered remote write attacks in *Static scene* and *Add clutter* conditions **with triggered features**. The success rates are nearly identical in the *Static scene* and *Add clutter* conditions.

hologram in a different environment containing the trigger and (case 1B), whether the victim can view the hologram in the correct environment without the trigger present. Ideally, the false positive rate should be low in both cases.

Results. Table 4 shows the results derived from the experiments. As the results suggest, there is a large boost in the success rate compared to the vanilla remote read attack results in Table 3. We examined two critical aspects of the triggered remote write attack: the false positive rate in cases 1A and 1B. Fortunately, in case 1A, false positives never happen in our experiments; we believe this is probably because the trigger features that we used are very simple and constitute a relatively small fraction of features from the entire environment. In other words, they act as auxiliary features and are not sufficient alone for the victim to use them as a key to read the hologram. In case 1B, the victim can sometimes (around 50% of the time) still read the hologram even if the trigger used by the attacker during the remote write is absent from the scene. This aligns with our hypothesis that the trigger features serve as auxiliary features in the scene. These results are comparable to the those achieved by Ji et al. [23] without adversarial patch triggers, in a non-AR domain. However, we find that if an adversary adds the triggered features to the victim's environment, the victim will read the attacker's hologram from the shared state with a much higher success rate of over 90%, so the triggers are effective.

4 Scenario B: Global, Curated Shared State

Built on Google's extensive database of public street images, the Geospatial API [15] allows users to attach AR holograms to any location within Google Street View, creating an AR experience on a global scale. This is an example of a global, curated, shared state. In this section, we demonstrate a practical attack in which the attacker can remotely read to steal a private hologram written by the victim. For example, in a city-wide scavenger hunt, an attacker could cheat to collect the virtual treasure simply by trying images of the possible

Write hologram at physical location

Read hologram at remote location

Figure 7: Remote read attack in Scenario B. *Left:* A legitimate user places a hologram in front of a building. *Right:* The attacker can view the hologram on an image of the building.

treasure locations. The attacker benefits by eliminating the physical labor needed to visit all the locations, gaining a competitive advantage over other users. The attack technique is similar to those on the local, curated shared state discussed in Section 3, but the main difference is the addition of GPS as a key (along with camera images), which requires changes to the attack methodology. Also, the Geospatial API, being built on Google Street View, limits the read and write of holograms to outdoor environments. However, we have discovered that by manipulating GPS, camera, and IMU readings, we are able to deploy remote read attacks indoors as well. All experiments were performed on local applications and devices only accessible by us, without malicious writes to the shared state, so they did not harm external users.

4.1 Methodology

The Geospatial API gives users the capability to place holograms in their physical surroundings by leveraging spatial data obtained from Google's Visual Positioning System (VPS) [16], based on Street View images. Using computer vision algorithms on the camera images, the API facilitates the accurate determination of the device's location and orientation to locate and display the correct holograms, surpassing the localization capabilities of GPS alone. However, this technology also introduces potential security vulnerabilities that can be exploited by malicious actors.

Remote read attack. By employing GPS spoofing applications, an attacker can remotely read holograms by altering the GPS location of her device. Along with utilizing a GPS emulator, the attacker points her device's camera toward printed

photographs or virtual images displayed on a monitor in order to generate a poisoned read request to the shared state and view the hologram at the target location. We assume the attacker has sourced these photographs/images from public online platforms, such as Google Street View, Mapillary [39], or even real estate websites. Fig. 7 demonstrates the process, illustrating how the attacker successfully manipulates the device's GPS location using a GPS emulator combined with image spoofing to achieve the remote reading of holograms onto her AR display.

4.2 Evaluation

Experiment setup. To begin with, we place 23 holograms at various campus locations using the Geospatial API. We selected these locations to encompass a range of environmental differences and varying light conditions, shown in Fig. 16 in the Appendix. Subsequently, we capture photographs of the areas where the holograms were placed. We employ a GPS emulator application [47] to generate fake GPS locations on the Android phones utilized for testing. By manipulating the GPS coordinates and displaying an image of the target location, we aim to deceive the shared state into returning the associated holograms at those locations.

We conducted the remote read attack with the attacker's device located from [0.25, 0.5, 0.75, 1, 1.5, 2] meters away from the monitor. To assess the effectiveness of these attacks, we utilize the attack success rate as the primary metric. We define a successful attack when each read operation can succeed in less than three trials. Our testing involved two Android phones, namely the Samsung Galaxy S8 and the Samsung Galaxy S21. The former was used by the victim to place the holograms, while the latter was used by the attacker to capture the images (size 3024 x 4032 pixels) and conduct the attacks.

Results. Fig. 8 shows our findings in terms of the attack success rate as a function of the attacker's distance. When the distance between the attacker's device and the monitor is too close, such as at 0.25 meters, the camera on the device may struggle to focus properly. This can result in blurred images, making conducting successful remote read attacks challenging. Notably, we achieved a 100% success rate for remote read attacks conducted at a distance of 0.5 meters. This distance proves to be optimal for the camera on the device to focus properly, resulting in clear and discernible images. However, as the distance between the attacker's device and the monitor increases, the success rate of the remote read attacks declines significantly. We speculate that several factors may influence this decline in success rate. Firstly, as the distance increases, the images displayed on the monitor become smaller, making the attacker's read key significantly different from the victim's initial write key. Similarly, when the device is positioned at a greater distance from the monitor, there is an increased likelihood of capturing unrelated objects

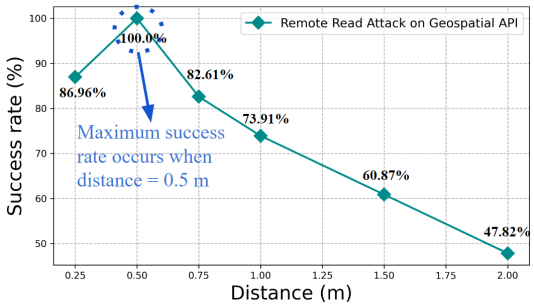

Figure 8: Remote read attacks in scenario B.

in the field of view. This can significantly impact the success rate of the attack. In contrast, the benign baseline, without any attack in the real environment, succeeds 100% of the time as expected, but our attack still succeeds most of the time.

5 Scenario C: Global, Crowd-Sourced Shared State

While the imagery needed for global AR exists in Geospatial Anchor, as discussed in the previous section, such services' shared states are curated, meaning that only trusted individuals (paid contractors) are able to gather and upload data to write to the map. However, more recent services like Mapillary [32] allow users to both read from the map and write new data to expand and update it. Mapillary is a non-curated service, which means that all users have the ability to read and write in the shared state. This includes the raw map data as well as holograms that are virtual representations of real objects (*e.g.*, traffic signs, fire hydrants, and light poles).

Non-curated applications that rely on GPS and camera images as keys, such as Mapillary, introduce new attack vectors, as attackers with minimal permissions gain more capabilities. Although allowing users to read or write to the shared state is the desired behavior of a crowd-sourced platform, carefully poisoning the read or write updates can cause adverse downstream effects that are unique to AR. Towards this, in this section, we investigate attacks on global, crowd-sourced AR shared states, using Mapillary as an example. We investigate two types of attacks: a poisoned write to the map in the shared state (Section 5.1), and a poisoned write that creates false holograms in the shared state (Section 5.2). For the former, we will demonstrate the construction site example from §1, where the attacker causes a victim worker to see the wrong construction signs and dig in unsafe real-world areas.

All experiments conducted in this section were carried out with permission from Mapillary. The experiments were conducted within a designated geo-fenced area, which was specifically created for the purpose of these experiments. This, in addition to Mapillary-provided test accounts, ensured that data uploaded for the experiments only appeared on the test accounts and devices, and had no impact on external users.

Figure 9: Two image sequences with their GPS coordinates swapped are shown in a screenshot of the Mapillary shared state map.

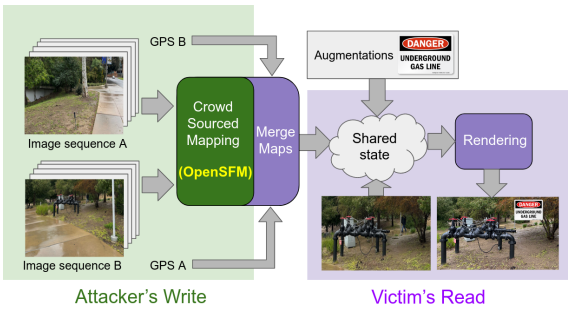

Figure 10: Details of poisoned write to the shared state's map mechanics. We used Mapillary's open-source OpenSFM [34] library to demonstrate the attack with swapped GPS keys.

5.1 Poisoned Write to the Shared State's Map

5.1.1 Methodology

The high-level idea is for the attacker to poison the GPS part of the key associated with the write request while keeping the hologram part of the key legitimate. Specifically, the attacker obtains image sequence A and image sequence B from two locations, A and B. Normally, these locations should be associated with holograms A and B, respectively. It swaps their GPS coordinates and makes two write requests: one with {key=image sequence A + GPS B, value=hologram B}, and another with {key=image sequence B + GPS A, value=hologram A}. Thus the hologram at location B becomes associated with image sequence A, and vice versa. Because of this, a victim who later reads with {key=image sequence A} will receive a response from the shared state with {value=hologram B}, and view the wrong hologram at location A.

Note that while the mechanics of this attack are similar to the global, non-curated attack (Section 4) in that the GPS part of the key is modified, here we focus on write attacks rather than read attacks, which means that we need to carefully craft the spoofed GPS (by swapping) during the write request, in order to cause adverse effects to downstream victims who read the poisoned shared state. Next, we describe the detailed attack mechanics in terms of writes and reads.

Attacker's write mechanics. To upload images to the shared state, a sequence of images, each with associated metadata (latitude, longitude, altitude, and time), is needed. The sequence can range from a minimum of three images to several hundred. All of the image metadata is in Exchangeable Image File (EXIF) format, whose data is freely manipulable using scripts. An attacker can modify the metadata so that the image seems to have been captured at any arbitrary location and time (within reason; for example, timestamps from the future will be rejected by the shared state). An illustration of image sequences with modified metadata being successfully ingested by the shared state is shown in Fig. 9. In this particular example, two sequences of five images each, captured using an iPhone 12, were uploaded with swapped latitude, longitude, altitude, and time. The images were successfully uploaded using Mapillary's desktop uploader utility [35]. Mapillary allows these sequences to be uploaded, processed, and displayed at the swapped locations for viewing by other users.

Victim's read mechanics. After the attacker's poisoned write on Mapillary, we next turn our attention to visualizing the results on the victim's side. One challenge that we faced is that Mapillary is a closed source and does not currently have a public AR interface to experiment with, which is needed in our study to read the shared state and demonstrate the impact on AR victims. To overcome this, we utilize Mapillary's underlying computer vision library, OpenSFM [34], plus our own additional Python scripts to construct a simple AR viewer that replicates, to the best of our ability, how a legitimate user's read request would be visualized. Fig. 10 shows the data flow of the AR application from an image sequence to the hologram. First, the initial maps in the shared state are generated using OpenSFM [34] from the data in the attacker's write request. Next, the spoofed GPS from the write request is used to facilitate the processing of the maps that are then stored in the shared state alongside the augmentations. Finally, a victim captures new images and uploads them to the shared state in a read request, which is processed by the OpenSFM to return nearby holograms for rendering on the victim's display. This step is similar to how a commercial AR service would handle read requests [44, 51]. We do not use GPS as a key during the read because OpenSFM does not support it, and frameworks that support image and GPS keys are research prototypes only [3].

5.1.2 Evaluation

We repeated the write attack a total of 8 times on Mapillary's shared state for 15 total image sequences with false GPS data (one sequence was a duplicate, not a swap). These swaps occurred using imagery captured outdoors within 1 km^2 of

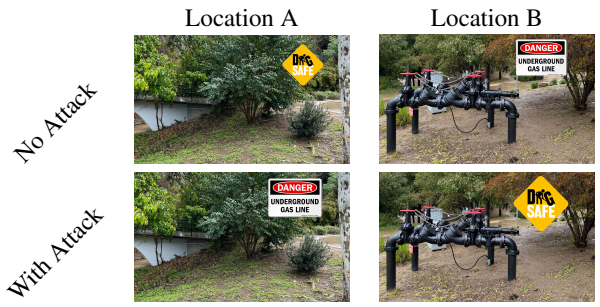

Figure 11: Effect of poisoned write to the shared state's map. Holograms are read at the wrong locations; in this example, a "safe to dig" sign is placed next to an underground pipe.

the geo-fenced area. The images were taken at different times of day, ranging from early morning to early evening, facing different directions, and at different locations (*e.g.*, streets, and grass fields without roads). These images were captured on iPhone 12 at 1080p and uploaded in PNG format. We verified through the Mapillary web interface that all the attacker's write requests with spoofed GPS data were successfully ingested by the Mapillary pipeline, uploading, processing, and displaying the spoofed imagery. This shows that the fundamental write attack mechanic works. The main reason this works is that while Mapillary does check for basic undesirable content, it does not check whether crowd-sourced images indeed correspond to the claimed GPS locations.

With the write attack mechanics validated on Mapillary, we next sought to show the impact on a victim AR user. To showcase this, we had the attacker write two image sequences (a grass scene and a pipe scene), containing five images each, to the shared state. We reserved one additional image per sequence for use by the victim. The holograms (a "dig safe" sign and a "danger: underground gas line" sign) included in the write request were associated with locations 5 meters in front of the first image in each sequence. After running through the pipeline in Fig. 10, the final display to the victim is shown in Fig. 11. The first row shows the AR display seen by a victim without our attack. The "dig safe" hologram is displayed in the grass field, and the "danger" hologram is displayed near the pipes, as intended. The bottom row shows that with our attack, the wrong hologram ("dig safe") is shown near an underground gas line, leading to serious safety issues.

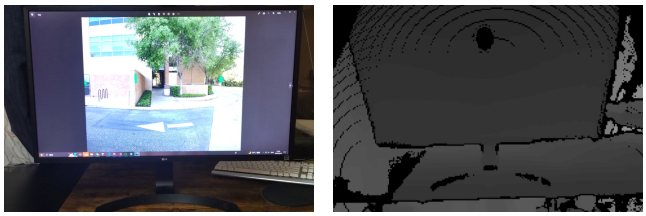
5.2 Poisoned Write of Shared Holograms

In this subsection, we discuss another vulnerability through modifications to the image sequence part of the key. Some AR shared states (*e.g.*, Mapillary) perform object detection on the images uploaded by users to their service [33]. When an image sequence is uploaded, these detected objects are added to the shared state map at the positions they were detected. This presents attackers with the opportunity to tamper with

(a) Real-world ground truth. (b) Tampered image.

Figure 12: Poisoned write to the shared state's holograms. A fake stop sign has been inserted into a sequence of images in order to fool the shared state's object detector, resulting in a fake stop sign hologram being added to the shared state.

the images and introduce fake holograms into the shared state. For example, the attacker could create a fake stop sign hologram overlaid onto an otherwise empty street, causing an AR navigation app to provide wrong directions to the user.



Methodology. We used Photoshop to edit a sequence of images to add a stop sign and write them to the shared state. For the attack to be successful, the stop sign's size had to be proportional to the user's distance from it, and the octagonal shape preserved using transparency layers. Mapillary required photo-realistic stop signs in order for the fakes to be successfully ingested and recognized. The fake object also had to be present in at least 3 images in order for Mapillary to place it accurately, which requires multiple photographs of the stop sign with appropriate scaling. Without these changes, the Mapillary pipeline rejected the write request.

Evaluation. Fig. 12 shows an example of a successful attack. Fig. 12a shows the real-world ground truth. Fig. 12b shows the tampered image, with a photograph of a stop sign taken from public sources cropped and overlaid on top of it. The small subfigure in the bottom left of Fig. 12b shows a screenshot of Mapillary's web interface where the stop sign hologram is accepted into Mapillary's shared state. We expect that attackers could also write other false holograms into the shared state; any of Mapillary's pre-defined object detection classes (*e.g.*, traffic signs, lamp posts) could work.

6 Shared State Attack Mitigations

The fundamental question at issue for these attacks is how to accurately establish the true location of an AR device. All of these attacks involve deceiving the shared state about the attacker's location to read or write data maliciously. We discuss multiple potential mitigation strategies related to this and our defense prototype utilizing additional sensor modalities.

Additional sensor modalities. The risk of shared state attacks on AR devices can be reduced by leveraging multiple

(a) Hololens 2 RGB camera. (b) Hololens 2 depth camera.

Figure 13: Mitigation via depth sensors on Microsoft Hololens 2. Depth sensors show the screen as flat and lacking details of an image captured of the real location.

sensor modalities to verify the consistency between the shared state and other accessible sensor data. For instance, the Microsoft Hololens 2 incorporates Red-Green-Blue (RGB) and depth cameras. As shown in Fig. 13, the depth camera can help identify a computer monitor or photograph, which was key to launching the attacks in Scenarios A and B. Thus, an automated comparison between the outputs of the depth and RGB cameras can be conducted to detect whether the user is physically present in the actual scene.

To demonstrate this, we designed the following experiment. We trained a convolutional neural network (CNN) to take color and depth images as input and classify whether the scene is being viewed at the actual physical location or not. We collected data using the Hololens 2 Sensor Streaming (HL2SS) system [10], which consists of color images saved as 640x480 24-bit RGB images and depth images stored as 640x480 16-bit monochrome images. Since the two cameras have different fields of view, we pre-processed the images using the camera's intrinsic parameters to ensure a 1:1 correspondence between pixels in the color and depth images. The data was collected from 15 real scenes, with 300 pairs of color and depth images gathered from each scene. To simulate an attack, we then collected images taken in front of computer monitors displaying photographs of the same 15 scenes. These monitors varied in size, with diagonals of 11, 32, and 55 inches.

Subsequently, the dataset was partitioned into 12 scenes for training and 3 new unknown scenes for testing (80/20 training/test split). The CNN was a customized ResNet-18 network [62] modified to incorporate four input channels (three RGB channels plus depth), followed by a fully connected layer for scene classification of whether the user is physically present in the scene or not. The results for the multi-model defense are promising, achieving 79.35%, 79.99%, and 84.22% for the F1 score, recall, and precision, respectively. However, note that not all AR devices, such as iPhones or Android phones, come equipped with depth sensors. This absence of hardware features could potentially restrict the applicability and effectiveness of this defense methodology and further investigation is needed.

Clean slate design. Alternatively, the core design of these applications could use traditional security measures to prevent tampering. Non-curated shared states (Scenario A and C) could be changed to curated with a permissions system where only trusted users may perform write [8]. Still, for those applications where crowd-sourcing (non-curation) is desirable, a compromise involving a user reputation system based on past good behavior may prove sufficient, although this requires oversight by AR providers. Additional checks in non-curated applications could be added, such as only accepting appropriately watermarked images with embedded GPS as keys [30], to prevent false hologram attacks in Scenario C.

Real space security. QR codes printed and placed into the real location can offer a form of locality assurance, particularly if those codes are changed regularly [25]. This method ensures that attackers who lack regular physical access to the locations will be unable to read holograms remotely. Additionally, as we found in §4.2, read attacks are less successful at greater distances. Thus, we can request that users collect more images at different distances and angles, although this places an additional burden on users.

Local moderators. AR frameworks with crowd-sourced shared state (Scenario C) may be considered as a form of content hosting (where the content is image keys and hologram values being uploaded). Hence, human moderators may be used to great effect, as in other successful applications like Facebook [43]. However, moderator teams are expensive and must be located close to locations of the uploaded image keys to verify them.

7 Related Work

AR/VR security and privacy overviews. Recent overviews [9, 45] broadly cover existing issues. Literature covering human factors of multi-user AR also exists [25], which our work aligns with. Work on securing AR output in multi-user AR [49] is orthogonal in that it focuses on content sharing for holograms given their locations, whereas we study how these locations are determined. The global shared state scenarios also intersect with geospatial information services security covered in [2].

AR leakage vectors. Prior research [7, 31, 46] has highlighted the issue of unauthorized acquisition of sensitive information from AR/VR devices. Several studies [37, 56] demonstrate the feasibility of inferring the user's location by analyzing network traffic information. Other works [53, 55] establish the ability to deduce keystrokes based on the user's head motions or other user interactions based on performance counters [63]. Several studies [18, 38] shows that attackers can exploit sensor-based side-channel leakages to exfiltrate

sensitive information. However, none of these investigate attacks on the shared state in multi-user AR as we do.

Computer vision attacks. AR uses computer vision techniques as part of its foundation, and thus such attacks could apply. Such work includes software [6,19,20,26,58] and hardware [61,64,66] based attacks on machine learning models. While our work uses photographs, screens, manipulated images, and GPS to trick computer vision systems, attacks using additional hardware like lasers have also been explored [60]. SLAM attacks also exist [21,41,52] and could impact AR systems. Our work takes inspiration from these to show computer vision attacks can cascade into interesting behaviors in the AR domain rather than general object detectors or autonomous vehicles.

Sensor spoofing and confusion. Our work uses GPS spoofing by simply altering the metadata stored in plain text. While not necessary for our attacks, more sophisticated GPS spoofing has reached widespread use [54]. Tricking IMU sensors was not done in this work but is possible with acoustic waves [23,50] and is an interesting future direction.

AR/VR threat mitigation. Defenses against user-manipulated input data, such as image manipulation [1, 27, 28, 65], have become sophisticated in recent years. GPS spoofing mitigation [22] focuses on real-time mitigation, but frameworks like Mapillary provide the ability to upload batched imagery at later times for user convenience, and thus such mitigations may not be directly applicable. The most effective mitigation is likely to come in the form of permissions systems like in [8], but these will require non-curated shared states to become curated.

8 Conclusions

As AR become ubiquitous, there is growing need for research into security and privacy risks unique to AR, especially multi-user AR. This paper introduced and explored attacks on multiple shared state AR applications and frameworks. Specifically, we show that the basic use of GPS and camera images is insufficient to accurately establish the location of an AR device and hence what holograms should be writeable/readable by a user. We proposed a threat model that applies to several different scenarios and demonstrated them on off-the-shelf AR systems in a variety of environments. Simple defenses such as image manipulation detection or the use of multi-modal sensors can help, but further investigation of other defenses, such as defining map update policies by trusted users or fraud detection, is needed.

Appendix

A Additional Scenario A results

Fig. 14 shows examples of the environments where we conducted our experiments in Scenario A. Fig. 15 shows the remote write attack as a function of the distance between the AR device's camera and the attacker's image. It also includes a benign baseline where the attacker writes the hologram while actually being present in the real environment. Similar to the results in indoor environments (Fig. 6), the attack success rate is lower than the benign baseline, as expected, but is still above 60% in the worst case.

B Details on experimental procedure

In this section, we provide additional technical details on the experimental procedure for each scenario. We mention the specific APIs called by the applications, although our attack methodologies apply broadly to AR devices that read and write from shared state.

(a) Office desk. (b) Bedroom desk. (c) Bedroom bed. (d) Outdoor garden. (e) Outdoor BBQ. (f) Outdoor pool.

Figure 14: Examples of scenes where we conducted our attacks in scenario A.

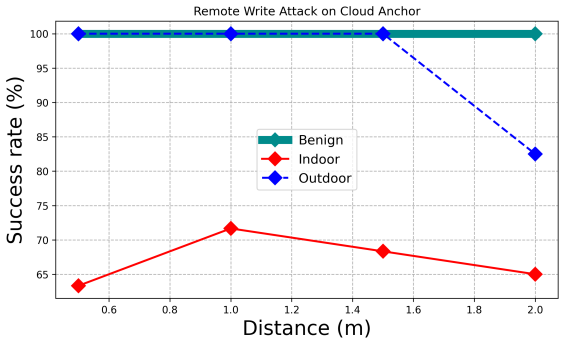

Figure 15: Results of remote write attacks at varying distances for scenario A.

B.1 Scenario A

The hardware and software dependencies for this attack are: an ARCore supported device (*e.g.*, Android phone) and access to the ARCore CloudAnchor API. The attack application was developed using Android Studio version 2022.2.1.

Attacker reads hologram from the remote location. First, a regular user writes a hologram at a physical location using the ARCore CloudAnchor API, for example using the Persistent CloudAnchor demo app [13]. This involves opening the app, setting a room code, moving the camera around until the app has scanned the scene sufficiently (following the onscreen prompts), and then tapping on the screen to place the hologram. Under the hood [11], the app sends a `hostCloudAnchor` request containing an `Anchor` object to the Firebase server. The details of the function call are closed source (it calls some underlying NDK C/C++ code), but the documentation indicates that the anchor contains the location and orientation of the hologram and a summary of visual features in the scene near the hologram. If the call is successful, the server returns the ID of the hologram (*i.e.*, the room code) [12].

After this, an attacker opens the same app and enters the same room code. The attacker points the device's camera at a picture of the previous environment on a screen (*e.g.*, a laptop monitor or a TV) and waits for the hologram to appear. Under the hood, the app sends a `resolveCloudAnchor` request containing the hologram ID to the Firebase server. Again, the details of the function call are closed source, but if the call is successful, the server returns the `Anchor` object corresponding to the ID number and uses this to render the hologram. To make the attempt successful, the attacker should have a high-quality picture of the environment and also try various distances and slightly different angles when pointing the camera at the picture.

Attacker writes hologram to the remote location. The attacker opens the app (*e.g.*, the CloudAnchor demo app), sets a room code, and points the camera at a picture of the target environment. In our experiments, we used an Apple monitor to display the picture. The attacker moves the camera around until the app has scanned the environment sufficiently and taps to place the hologram. This involves the `hostCloudAnchor` API call as described previously. A high-quality picture of the environment is necessary to enhance the success rate of the attack. Following the attacker's successful remote write of the hologram, we verified it by having a regular user view the hologram in the physical environment from the picture. This involves opening the same demo app, entering the room code to call `resolveCloudAnchor`, and moving the camera around until the hologram appears.

B.2 Scenario B

The hardware and software dependencies for this attack are: an ARCore-supported device (*e.g.*, Android phone), access to the ARCore Geospatial API, and a GPS emulator [47].

(1) Regular user writes hologram to the physical location. Before the attacker can launch the remote read attack, a regular user should first write a hologram at a physical location as follows. The user first aims the device's camera towards the intended outdoor environment. Fig. 16 shows three outdoor environments we evaluated in this work. Once the Geospatial API identifies sufficient features within the scene (this step may take tens of seconds) to localize the device, the user can establish a Geospatial anchor at the precise location by tapping on the screen by following the on-screen prompts [14]. Under the hood [11], this involves a call to the `createAnchorWithGeospatialPose` API function, which saves the latitude, longitude, altitude, and orientation of the

(a) (b) (c)

Figure 16: Examples of three outdoor scenes where we conducted our attacks in scenario B.

hologram (all automatically determined by the location of the user's tap) into an `Anchor` object. Subsequently, the GPS coordinates in the `Anchor` can be recorded and preserved in the shared state.

(2) Attacker reads hologram from the remote location. The attacker first employs a GPS emulator [47] to fabricate GPS locations on the mobile device corresponding to the locations in step (1) above. At the same time, the attacker utilizes a monitor to display an image of the desired location from step (1) and directs the mobile device's camera towards it. To ensure optimal focus, the attacker may need to adjust the device's position, moving forward or backward as necessary. (In our attack, we find that when the distance between the monitor and the phone is 50 centimeters, our attack succeeds 100% of the time.) Together, the GPS and the camera frames help mislead the shared state into believing the attacker is physically present at the target location. This is done by the Geospatial API's `Earth` object, which makes calls to the shared state to determine and track the device's location on Earth. After the device localization is successful (*i.e.*, the `Earth`'s tracking state is not null), the hologram corresponding to the target location will be rendered on the monitor in the device's display, effectively deceiving the shared state into supplying holograms to be read remotely.

B.3 Scenario C

(1) Image capture. The attacker uses a smartphone (iPhone 12 at 2532 × 1170 pixels in our experiments) to capture photos of a location that is desired to appear somewhere else. These photos are automatically geo-tagged with latitude, longitude, time and elevation by the mobile device's operating system. The user then transfers the photos from the mobile device onto a computer with the ability to run Mapillary's desktop client [35] as well as simple scripts written by the attacker.

(2) GPS spoofing. There are two convenient ways to determine the desired GPS data to spoof. The simplest for the attacker is to physically go to the target location that she wishes to write the fake data to, and take real images in a manner similar to the image capture step above. Then, the attacker can swap the EXIF metadata between the two image sets (from the image capture step and from the GPS spoofing step) to perform the spoof. This can done using a Python script or through manual edits to the image metadata. For the second set of images, It is important to take the same number of images while moving or walking in the same direction as the first set. This helps the GPS coordinates match up between the two sets of images.

The second method to determine the desired GPS data is to overwrite the EXIF image metadata manually, using a program like Windows Photo Viewer or a custom script. This is tedious as it requires the attacker to guess the change in GPS coordinates for each image in the set.

(3) Upload. Finally, the attacker uploads the altered image set to the shared state servers using a desktop client (*e.g.*, [35]). Under the hood [36], This follows a standard upload procedure including the image file, metadata, and account information. In our experiments, we did this using special accounts that uploaded data to a private sandbox, thus avoiding any impact on regular public users. Care must be taken that no other EXIF data was removed during any of the previous image capture or GPS spoofing steps, as otherwise the upload may fail. For example, we found that during the image transfer process between mobile devices and desktops, the timestamps did not transfer and had to be re-added manually. Each step in this process also keeps the images as PNG to avoid lossy compression.

Penetration Vision through Virtual Reality Headsets: Identifying 360-degree Videos from Head Movements

Anh Nguyen
George Mason University

Xiaokuan Zhang
George Mason University

Zhisheng Yan
George Mason University

Abstract

In this paper, we present the *first* contactless side-channel attack for identifying 360° videos being viewed in a Virtual Reality (VR) Head Mounted Display (HMD). Although the video content is displayed inside the HMD without any external exposure, we observe that user head movements are driven by the video content, which creates a unique side channel that does not exist in traditional 2D videos. By recording the user whose vision is blocked by the HMD via a malicious camera, an attacker can analyze the correlation between the user's head movements and the victim video to infer the video title.

To exploit this new vulnerability, we present INTRUDE, a system for identifying 360° videos from recordings of user head movements. INTRUDE is empowered by an HMD-based head movement estimation scheme to extract a head movement trace from the recording and a video saliency-based trace-fingerprint matching framework to infer the video title. Evaluation results show that INTRUDE achieves over 96% of accuracy for video identification and is robust under different recording environments. Moreover, INTRUDE maintains its effectiveness in the open-world identification scenario.

1 Introduction

Virtual Reality (VR) is a rapidly growing technology with a projected market value of $22 billion in 2025 [80]. Meta, one of the industry's leaders, has sold approximately 20 million Oculus VR headsets as of March 2023 [70, 83] and invested billions in its VR venture. Beyond the popularity in gaming and entertainment, VR head-mounted displays (HMDs) are transforming a wide range of industries, including military training, medical operation, and virtual conferencing [34, 64].

The immersive nature of VR HMDs has given rise to various prevalent applications, one of which is the 360° video. 360° videos are widely used in areas such as virtual tours, live concerts, and immersive storytelling [10, 58]. Unlike traditional 2D videos with limited viewing perspective on a 2D frame, 360° videos enable viewers wearing an HMD to freely explore the video content in all directions by simply moving their heads, as if they were physically present in the scene.

VR technology presents unique privacy challenges due to its collection and storage of extensive personal data [25, 37, 82, 92]. Researchers have identified several attacks aimed at inferring VR keystrokes [9, 45, 51, 56, 77, 91, 101]. In this paper, we unveil a new threat that identifies the titles of 360° videos being viewed inside the HMD. The leakage of video titles reveals significant information about users' personal interests, opinions, and even religions [93], which unintended third parties have exploited for pushing political agendas [2] or conducting blackmail [3]. Note that video identification is not necessarily related to user identification. For example, video identification attacks can target a group of users and reveal the political or religious interests of certain organizations or regions, without performing user identification. While side-channel attacks identifying 2D videos displayed on smartphones, PCs, and TVs have been previously studied [26, 30, 68, 74, 93], no research has demonstrated the feasibility of side-channel attacks on 360° videos displayed on a VR HMD.

INTRUDE. We present INTRUDE, a v**I**deo ide**N**tification a**T**tack towa**R**d virt**U**al reality HM**D**s on 360° vid**E**os by leveraging a new *contactless* side channel – user head movements. While the VR content displayed inside the HMD remains inaccessible to external attackers, we discover that the head-movement-based interaction between the user and the HMD creates a side channel that is completely exposed to the public. As video content drives the user to move or fix his/her head [6], there is a subtle relationship between the user's head movement and the displayed 360° video, which can be exploited to infer video titles without direct access to the HMD. By taking advantage of the fact that the victim cannot see the physical world when using the HMD, the attacker can freely record the victim's head movements. After extracting the head movement from the camera recording and matching it with fingerprints of videos of interest, INTRUDE can infer the title of the playing 360° video.

Compared to prior camera-recording-based attacks on smartphones and PCs [20,81,99], INTRUDE is easier to launch and harder to detect as VR users are oblivious to their physical surroundings when wearing the HMD. The attackers have more flexibility in choosing when, where, and how to record the victim's head movement. Furthermore, since INTRUDE utilizes a new side-channel that does not exist in 2D video viewing, conventional countermeasures designed for 2D video identification, such as varying video encoding configuration for traffic analysis attacks and adjusting screen brightness for screen reflection attacks [74, 93], become ineffective.

Challenges and Approaches. Realizing INTRUDE requires addressing two new challenges in the context of 360° video identification on VR HMDs. *First*, it is non-trivial to extract the victim's head movement trace from the image pixels of the recording. Given that HMDs cover the majority of users' faces and users may look around in all directions during 360° video viewing, existing head pose estimators [16, 63, 71, 102] harnessing facial features for limited front-facing positions cannot be directly used. To overcome this challenge, we propose an HMD-based *head movement estimation* scheme to extract the full-spectrum head movement trace from the image pixels of the camera recording via a deep convolutional neural network (DCNN).

Second, the correlation between the video title and the head movement is implicit and subtle, making it challenging to fingerprint and identify the video. Fingerprinting a video directly by head movement traces is ineffective due to the fluctuation of these traces in response to changes in human conditions or environments. Consequently, treating the head movement trace as the fingerprint may lead to poor matching with the victim's actual trace, even if they embed similar head movement patterns. Hence, we propose to fingerprint a video by saliency maps as they can capture the stable features embedded within the fluctuating head movement traces across different trials with the same video. We design a *trace-fingerprint matching* framework to match the extracted head movement trace with the video saliency fingerprints via a multi-modality model, enabling video identification.

Evaluations. We validate INTRUDE through extensive evaluations that involve 31 users, 635 videos, and two HMDs. In the default indoor attack scenario, INTRUDE achieves the top-1,2,3 accuracy of 96%, 99%, 99% for 360° video identification. The robustness analysis under various recording environments shows that the attack maintains a stable video identification accuracy across different recording distances, lighting, backgrounds, and angles. Moreover, the risk of INTRUDE is validated in the *open-world* identification scenario.

Ethical Consideration. All experiments involving human subjects in this study have been approved by the IRB. We have only used INTRUDE to perform attacks on the datasets described in this paper. INTRUDE has never been used in other ways or released to other parties.

Contributions. The contributions of this paper include:

- We present the first 360° video identification attack on VR HMDs through a new *contactless* side channel – user head movements (§2 and §3). This threat has not been identified and is fundamentally different from previous attacks.
- We build new techniques to realize the attack, i.e., a head movement estimation scheme to obtain the victim's trace (§4) and a trace-fingerprint matching framework for video identification (§5). The cores of these two system components are two novel neural networks, one that can extract head orientations from recordings of 360° HMD viewing and the other one that can match different input modalities for video inference.
- We perform an extensive evaluation (§6 and §7) of the proposed attack system INTRUDE, including validation of system components and parameters, baseline comparison, robustness analysis, and open-world identification attacks.

2 Background and Motivation

2.1 360° Videos and Head Movement

360° video viewing is an important application in VR. To view a 360° video using an HMD, a user must first select the video of interest via the VR hand controller. Once the video playback starts, the VR engine of the video player decodes the video into a spherical scene wrapping around the user's head. A subset of the sphere to which the head is oriented, i.e., the viewport, is rendered and displayed on the HMD screen. This way, the user can simply move his/her head around to explore the 360° video in an immersive hands-free way.

It is well-known that the displayed 360° video drives the head movement of the user [27, 60]. This is because the human vision system tends to selectively pay attention to some salient objects or events in a visual scene instead of processing every single pixel. As a result, the user follows his/her visual attention and moves his/her head around when viewing the 360° video. The user may explore and glance through the content or fixate on a region of interest. Low-level content features of 360° videos, such as color, contrast, and textures, can affect visual attention and head movement. High-level content features such as human faces and notable objects are also critical to the head movement.

More importantly, such a correlation between the 360° video and the head movement are similar across users [17, 22, 48, 59]. In other words, different users would present similar head movement patterns when viewing the same video. Therefore, even though we have no knowledge about the victim, we can collect fingerprints for videos of interest and utilize this correlation to match the victim's head movement trace with all the fingerprints. By finding the most similar fingerprint, we can infer the video being viewed.

Figure 1: The head movement traces of different users (right figure, 4 colors) on the same video may be different in the time domain, but they do present a similar head movement pattern on regions of interest (right figure, brighter areas).

Figure 2: The saliency maps (bottom) uniquely identifies 360° videos (top) through regions of interest.

2.2 Video Fingerprint and Saliency Maps

Despite the intuitive principle, matching head movements with videos is challenging. Our study discovers that even though similar patterns exist in different head movement traces of the same video, it does not mean that these head movement time series are exactly the same. In fact, these head movement traces of the same video may differ from each other significantly in the time domain due to the time-varying physical and emotional states of the viewer and external factors of the viewing environment [6, 38]. For example, two viewers may look at the same object at different moments or view different parts of the same object at the same time. Figure 1 illustrates this fact via one-second head movement traces of four users (right) viewing a sample 360° video (left). We can see that different users' head movement traces (marked by four different colors) deviate from each other. Therefore, because of the randomness of head movement in the time domain, even if we can obtain the head movement trace for a video, it is infeasible to use it as the video fingerprint and directly match it with the victim's head movement.

Fortunately, we also observe that different users' head movements tend to focus on the same region, e.g., the bright area in Figure 1 (right). This is attributed to the fact that this region contains attentive content, i.e., the blueish upper body of the human, and thus drives all users' heads to move here. This phenomenon is consistent with previous findings in viewing behavior of 360° videos [17, 27, 60]. In essence, these salient regions of a 360° video are highly correlated to different users' head movement traces. They actually represent the similar head movement pattern across different users' traces. Hence, we propose to fingerprint 360° videos by their salient regions and then match the victim's head movement trace with the fingerprint (salient regions).

Figure 3: Sample attack scenarios – recording with a smartphone rear camera (left) and front camera (right).

The saliency of a video can be quantified by *saliency maps*. A saliency map is a 2D heat map that indicates the salient regions in a video frame. More salient regions where users stay for a long time are assigned higher saliency values and represented by brighter pixels in the saliency map, and vice versa for less salient regions that users glance through. The saliency map of an image can be generated by saliency detection, an established technology that has been widely used in surveillance [98], advertising [42], and content generation [35, 87]. As shown in Figure 2, the saliency maps in the bottom row signify salient regions in the frames of four 360° videos in the top row. These saliency maps contain distinctive information about a visual scene that uniquely identifies the 360° videos. For instance, the man on the stage in the left-most image is the most conspicuous. Note that saliency maps remain effective in fingerprinting video frames even when they contain multiple salient regions. For example, the second-from-the-left saliency map in Figure 2 has two salient regions. It is possible for different users to attend to either the left or right region, with the likelihood being proportional to the brightness of the salient region. However, regardless of which region the users focus on, their head movement traces would still be correlated with this double-region saliency map rather than a saliency map of another video frame that has no overlap with their head movements. Essentially, the saliency map essentially captures the collection of regions with frequent head movements.

As for a video, the saliency map changes over time for each frame, following the progress of the content. The saliency fingerprint of a video, i.e., a sequence of saliency maps, becomes even more distinct. Therefore, we can conclude that it is *feasible* to utilize saliency maps to fingerprint a 360° video.

3 Overview of INTRUDE

3.1 Threat Model

We consider an adversary with a library of target 360° videos whose viewers can be exploited for malicious purposes, e.g., pushing agendas or conducting blackmail. The attacker wants to know if a victim is viewing one of these videos and, if so, infer the specific video title. Existing studies [30,54,68,74,93] have confirmed the sensitivity and privacy associated with such video title information. In our attack scenario, the victim

is viewing a 360° video using an HMD in a public space (e.g., a library [4] or an airport [1]). Watching 360° videos publicly with VR headsets has become popular due to the low purchasing cost [97]. For example, 100% libraries from the Association of Research Libraries provided VR headsets for in-library usage [24]. There is also an increasing number of users watching 360° videos during a flight [67, 84]. At the same time, the attacker is recording videos of the victim's head movement using a filming device, such as a smartphone or a digital camera (examples shown in Figure 3). The captured videos are referred to as *recordings* and used to infer the 360° video viewed by the victim. This scenario is inspired by prior works where the attacker captures shoulder surfing recordings to infer the victim's unlock patterns on Android [41, 86, 95]. However, our case is more plausible because the victim's eyes are fully covered by the HMD and thus the victim is less vigilant about the proximity. The attacker may choose to place a hidden camera to record the victim's head movement to further reduce suspicion.

We assume the attacker has physical access to the location where the victim is viewing 360° videos and can capture the recording. Also, we assume that the attacker knows the type of HMD the victim is using, which is trivial to obtain since the attacker can visually recognize it. The HMD type information will be used to tune the system components of INTRUDE. We do *not* assume any other capabilities for the attacker. For example, the attacker cannot lure the victim into downloading and installing a malicious App [77], and the attacker cannot sniff the network traffic coming from the victim's device.

3.2 Challenges and Key Components

To identify 360° videos from recordings of victim head movement, we need to tackle the following challenges.

- **Extracting Head Movement Traces in VR**. Head movement tracking in VR presents a distinct challenge compared to traditional head pose estimation in 2D scenarios [57]. VR head movement encompasses omnidirectional viewing directions and the user's face is covered by the HMD. As a result, prior head pose estimators [16, 40, 71] assuming that head poses and facial features are explicitly displayed in front of the camera in a limited range of orientations would be ineffective.
- **Identifying Videos by Trace-Fingerprint Matching**. Another challenge is that the video title is hidden inside the spatial-temporal correlation between two different data sources – the head movement trace and the video fingerprint. Unlike previous video identification attacks that utilize a univariate time series, e.g., network traffic [30] or light effusions [93], to fingerprint a video and match it to the victim's corresponding time series, fingerprinting a video by fluctuating head movement traces is ineffective for trace-fingerprint matching and video identification.

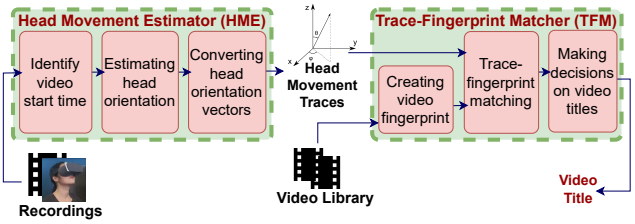

Figure 4: Overview of the proposed INTRUDE system.

INTRUDE overcomes these challenges through its two components as shown in Figure 4. First, the head movement recording of the victim while viewing an unknown video is passed to the HMD-based head movement estimation scheme (HME). This scheme accurately identifies and extracts visual head movements during the omnidirectional viewing. The extracted movements are then converted into a head movement trace, a time series of coordinates tracking the head orientations relative to the VR coordinate system throughout the viewing session. Second, the head movement traces are fed to the video saliency based trace-fingerprint matching framework (TFM). The trace-fingerprint matching model matches the victim's trace with each video fingerprint in the library of target videos and produces a video identification decision.

4 HMD-based Head Movement Estimation (HME)

This section presents INTRUDE's head movement estimation scheme. INTRUDE identifies the start of video playback from the recording, extracts head orientations using the proposed DCNN, and generates the head movement trace after representing the head orientations in the VR coordinate system.

4.1 Identifying the Start of Video Playback

A prerequisite to launching INTRUDE is determining if the victim is viewing a 360° video or engaging in other VR activities. Filtering the recording to obtain the 360° video viewing session is necessary because the recording may contain redundant information generated when the victim is using other VR Apps. If the victim is viewing a 360° video, it is also critical to identify the moment when the 360° video starts playing on the HMD screen. After this moment, the victims will only move their heads based on the video content. Hence, this moment should be identified as the start of the head movement trace for launching the attack.

This challenge can be overcome by directly inspecting the recording due to the unique interaction pattern in 360° video viewing sessions. Initiating the playback requires the user to navigate to the desired video and "click" it for playback. Despite the differences in user interfaces in different HMDs, the navigation and selection of the video are always executed by a set of head and hand actions, ending with a press on

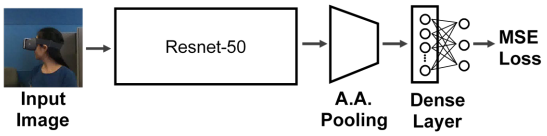

Figure 5: The head orientation estimation model.

the hand controller for starting the playback. After this final clicking, the viewing session starts and the victim only moves his/her head to explore the 360° video without further operation on the controller. This head-only, hand-free interaction design ensures immersive user experience [55, 85], differing from other VR Apps that always require both hand controller and head movement. By recognizing this unique sequence of user actions through visuals and sounds in the camera recording, we can infer that the victim is viewing a 360° video and pinpoint the moment of the final controller clicking as the playback start time. INTRUDE extracts all frames from this starting moment for a recording length of T seconds.

We then locate and crop the regions that are relevant to the attack in the filtered recording. This can be easily performed by off-the-shelf video editing software because victims interact with 360° videos only through head movement and their body positions remain stable during the viewing. Consequently, the recording becomes a smaller version only containing the victim's head, shoulders, and HMD. This preprocessing reduces the input size and thus the computation cost. It also eliminates noise in the background pixels, boosting the head movement estimation performance. After cropping, the recording is split into individual video frames before being sent to the head orientation estimation model.

4.2 Estimating Head Orientation

This section details our head orientation estimation model's design, which analyzes the processed frames in the recording. The core of the head movement estimation (HME) component, the head orientation estimation model, transforms visual data from the *recording* into numerical head orientation data. Previous estimation methods [16, 63, 71, 102] extracted head orientations from general non-HMD head pose images. By assuming that users mostly look straight ahead into the camera, they relied on facial landmarks to derive head orientations. However, these models fail when users' faces are obscured by HMDs and users turn their heads away from the camera's filming direction during 360° video viewing. In INTRUDE, our head orientation estimation model is specifically designed to estimate HMD users' head orientations without the limited range of head movements assumed by prior works. It focuses on learning the visual features of HMDs, which are more discernible than facial landmarks, particularly when users deviate 45° or more from the camera's filming direction. Therefore, our model can support the estimation of the full spectrum of head movements in 360° video viewing.

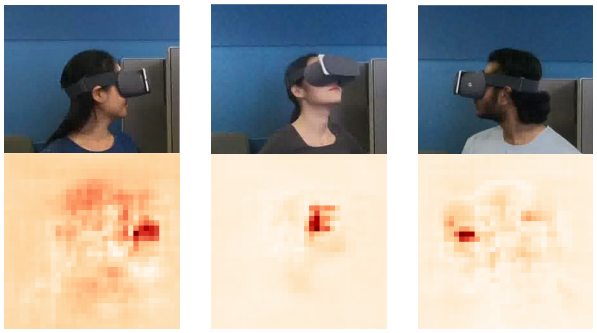

Figure 6: The head orientation estimation model focuses on learning HMD features (dark red areas in the bottom row) and can generalize well to victims not presented in the training.

Estimation Model Design. The head orientation estimation model architecture, depicted in Figure 5, is a deep convolutional neural network (DCNN) comprising a base network and a decision layer. The base network explores pixel values of the input frame. It extracts and learns the representation of meaningful features for the head orientation estimation. The decision layer estimates the head orientation based on the output of the base network. Inspired by the ResNet-50 model [32], our base network consists of 48 stacked convolutional layers and an adaptive average pooling layer. The ability to learn complicated visual patterns of HMDs through this highly non-linear structure is our key advantage in head orientation estimation compared with previous approaches using hand-crafted features. The adaptive average pooling layer receives a set of feature maps from the base network. It then calculates the mean values of each feature map and returns a flattened vector. By fixing the length of the flattened vector, our design can handle different sizes of input frames. Finally, the dense decision layer maps the flattened vector to a *head orientation vector*, a 3D vector representing the head orientation in 3D spaces.

Model Training and Operation. We use Mean Squared Error (MSE) loss to guide the learning of the head orientation estimation model. It calculates the mean squared distances between the estimated and the ground truth head orientation vectors and forces the model to push its estimation to the ground truth. Formally, MSE is defined as:

$$\mathcal{L} = \frac{1}{3}((x-\hat{x})^2 + (y-\hat{y})^2 + (z-\hat{z})^2) \quad (1)$$

where $v = (x, y, z)$ is the estimated head orientation vector extracted from input frame f, and $\hat{v} = (\hat{x}, \hat{y}, \hat{z})$ is the ground truth head orientation associated with f.

Since the above head orientation estimation model is not a personalized model designed only for a particular victim, attackers can obtain training data offline by rotating their heads to different angles with respect to the camera's filming direction, just as normal users. They can capture the camera recording of their own head movements by using the same

type of HMD as the victim. Meanwhile, the ground truth head orientations can be collected by the HMD sensors. Once the model is trained, it can then be used to estimate the head orientation of the victim who is not in the training set, i.e., a testing user. Figure 6 illustrates that the trained model focuses on learning the features of HMDs and can be well generalized to new testing users. Through the occlusion method [100], the heat maps at the bottom row highlight the regions affecting the estimation performance for the testing frames in the top row. These regions contain HMDs (darker red) rather than heads, ears, or jaws (lighter red) and are consistent across victims wearing similar HMDs. After applying the model to each video frame in the recording, a sequence of head orientation vectors is eventually generated.

4.3 Converting Head Orientation Vectors

The proposed estimation model generates a sequence of head orientation vectors, but these cannot directly form a head movement trace because they are referenced to the recording camera's filming direction, i.e., the *camera-based coordinate system*. This differs from the *VR coordinate system* used in VR Operating Systems (OS) for tracking head movements and rendering VR content. As a result, an extracted vector may point to a totally different direction in the VR OS. Hence, INTRUDE must convert these vectors to the VR coordinate system before inferring a victim's regions of interest and video title.

Figure 7 illustrates the difference between the two coordinate systems. It can be seen that both systems have an axis pointing straight up (the z and yaw axes), but their reference axes are distinct. The reference axis in the camera-based coordinate system (the x axis) aligns with the camera's filming direction and can be visually identified in the camera recording. On the other hand, the reference axis of the VR coordinate system (the roll axis) is represented in the VR virtual world and cannot be observed in the physical world by the attackers.

To locate the VR coordinate system, we first identify the roll axis by leveraging the fact that the VR coordinate system is not fixed in the physical world but is always reset by the VR OS at the beginning of a 360° video viewing session. Upon reset, the roll axis is configured to overlap with the projection of the head orientation vector onto the x-y plane. By extracting the head orientation vector at the reset, i.e., at the starting moment of the video playback, we locate the roll axis in reference to the camera-based coordinate system.

INTRUDE can then convert a head orientation vector for it to be represented in the VR coordinate system. As shown in Figure 7, the two systems already have two axes aligned, namely the yaw and z axes. Thus, the conversion becomes the angular rotation along the z axis for the x and roll axes to align. As discussed above, the offset angle between the x and roll axes can be derived when locating the roll axis. Without loss of generality, we denote the first frame at the beginning

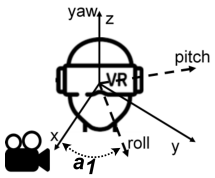

Figure 7: Difference between the camera-based coordinate system (solid lines) and the VR coordinate system (dash lines).

of the viewing session as f_1 and the head orientation vector in the camera-based coordinate system extracted from f_1 as v_1, (x_1, y_1, z_1) being the coordinate of v_1. Let P be the plane formed by the intersection of the x and y axes. Then the offset angle a_1 between the x axis and roll axis (the projection of v_1 onto P) can be expressed as $a_1 = arctan(\frac{y_1}{x_1})$. Given the offset angle a_1, the mapping q_1 is the quaternion rotation operation [15] rotating a 3D vector for $-a_1^\circ$ along the yaw axis. Applying q_1 to a head orientation vector v in the camera-based coordinates produces the corresponding representation in the VR coordinate system u.

5 Video Saliency-based Trace-Fingerprint Matching (TFM)

This section details INTRUDE's approach to inferring video titles through trace-fingerprint matching. INTRUDE generates video saliency-based fingerprints for 360° videos targeted by the attacker, and matches the victim's head movement trace obtained from the HME component with each fingerprint to infer the video being viewed.

5.1 Creating Fingerprints for 360° Videos

An essential offline task for attackers before making the video identification decision is to build a library of videos of interest and create fingerprints for these videos. These videos of interest can be carefully selected based on the malicious purpose. For example, in the case of blackmailing, sensitive videos that the victim is not supposed to view can be put in the library. As discussed in §2.2, a head movement trace of a single user is insufficient to fingerprint a 360° video because the head movement time series generally fluctuates. However, users tend to agree on the regions of interest in 360° videos. This fact drives the similar head movement patterns across users that center around salient regions of a video. Therefore, we propose to utilize video saliency maps to fingerprint a 360° video.

A saliency map can be derived offline by collecting and processing head movement traces of a group of users, but it would be too expensive to collect subjective human data for every 360° video targeted by the attackers. INTRUDE instead uses an established saliency detection model to generate the saliency map. Thanks to the recent development of deep learning, salient regions of human users on 2D videos and 360°

videos can be reliably and accurately detected [36, 60]. These state-of-the-art saliency detectors have been trained on a large amount of data and can identify the salient regions of new unseen videos. To fingerprint a video, INTRUDE performs saliency detection on all its frames through a state-of-the-art model. The output of the model, a sequence of saliency maps, is a spatial-temporal video signature reflecting the progress of human attention through time and is stored as the video fingerprint. This procedure is repeated for all library videos.

5.2 Matching Victim Trace with Fingerprints

Unlike the majority of previous works that only processed time series to identify video titles [45, 54, 74, 93], INTRUDE needs to handle input of different modalities to infer the video title. The victim's head movement trace is a time series of head orientation vectors, whereas the fingerprint of a 360° video is a sequence of 2D saliency maps. INTRUDE's trace-fingerprint matching model must establish the spatial correlation between the victim's head movement and the video's salient regions, as well as comprehend the head movement patterns in relation to the progression of the video's salient regions. Such tasks are challenging for traditional machine learning models hand-crafted by domain knowledge [30, 68, 74]. To overcome this, we propose a DCNN to capture the interactive patterns between the two input modalities, effectively matching the victim's head movement trace to a library of video fingerprints for video identification.

Input Preprocessing. Since the victim's head movement trace and the video fingerprint are two different modalities, they cannot be analyzed simultaneously. We propose to first transform the head movement trace into a sequence of 2D head orientation maps. Let $\mathcal{V}$ be the head movement trace and $\mathcal{M}$ be the video fingerprint, where $\mathcal{V} = v_1, .., v_N$ is a list of 3D head orientation vectors in the VR coordinate system and $\mathcal{M} = m_1, ..., m_N$ is a list of saliency maps. Each saliency map m_i is a 2D heat map of size $W \times H$. We create the head orientation maps through equirectangular projection [66], a prevalent approach for projecting 3D spherical data onto a 2D plane. We adopt this method because modern 360° video saliency maps are marked on equirectangular 360 frames [59, 60]. This projection aligns both input modalities. For a 3D head orientation vector v_i, we find the azimuth and altitude angles, θ_i and ϕ_i. Then, the projected point $v'_i = (w_i, h_i)$ on the equirectangular of size $W \times H$ can be derived using the following formulas [59],

$$w_i = (\frac{\theta_i}{360})W, \quad h_i = (\frac{1 - sin(\phi_i)}{2})H. \tag{2}$$

After this conversion, we obtain a sequence of head orientation maps of size $W \times H$ where the head orientation is indicated by $\mathcal{V}' = (v'_1, ..., v'_N)$.

We then combine the transformed head orientation maps with the video fingerprint into a unified input. Given that both head orientation maps and saliency maps are associated with timestamps that signal their temporal position in the video, we combine the corresponding maps of the same timestamp. The result is a sequence of pairs of head orientation maps and saliency maps that can be processed by our DCNN. The corresponding regions in both head orientation maps and saliency maps are aligned. Consequently, the DCNN better learns the spatial relevance between the victim's head orientation and the video's salient regions.

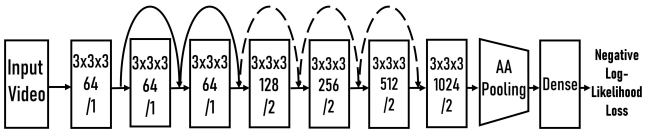

Figure 8: The DCNN architecture of the video saliency based trace-fingerprint matching model.

Due to the computational intensity of the DCNN, processing the entire sequence of head orientation and saliency maps can be inefficient. Yet, feeding a sparse number of maps to the DCNN may fail to present a continuous context of how the victim's head movement interacts with the video saliency. To balance efficiency and performance, we introduce τ, a system parameter defining the time interval between two samples in the sequence. By adjusting τ, INTRUDE can flexibly control the sampling interval of input data for the trace-fingerprint matching model. For instance, setting $\tau = 1$ directs our system to sample the sequence of head orientation maps and saliency maps every second.

Matching Model Design. The matching between the preprocessed head movement trace (head orientation maps) and video fingerprints (saliency maps) can be regarded as a mapping problem, where the two input channels are mapped to a confidence score that indicates the correlation between them. The core of the trace-fingerprint matching model is a DCNN, as depicted in Figure 8, composed of seven stacked 3D convolutional layers. Unlike traditional 2D convolutional layers, the 3D kernel convolves over several input maps at a time to learn both the localized spatial information in the head orientation maps and saliency maps, and the short-term temporal relationship between these maps. Stacking several 3D layers expands the neuron receptive fields, enabling the model to learn long-term information throughout the video. This design is consistent with the spatial-temporal structure of the two input modalities to match.

For each convolutional layer, there are three associated parameters, the kernel size, the number of kernels, and the stride. The kernel size of $3 \times 3 \times 3$ is selected for all convolutional layers to reduce the computational cost. Kernels having the stride value of 2 (denoted by $/2$) reduce the size of the intermediate maps by half. We use residual connections [32], shown as U-shape arrows in Figure 8, to connect the output of the previous layers with the output of the next layers. The connections facilitate the backward flow of gradients from

the output back to the input, mitigating the impact of the gradient vanishing. Similar to the head orientation estimation model, the end of the DCNN is the adaptive pooling layer [31] converting the filtered maps of arbitrary sizes into a fixed flattened vector. The decision network is a dense layer of 1024 neurons mapping the flattened vector to a single confidence score in the range of $(0,1)$.

To measure the difference between the output confidence score of the model and the ground truth, we use the Negative Log-Likelihood loss,

$$L(n,\hat{n}) = -\hat{n}log(n) \quad (3)$$

where n is the output of the proposed model and $\hat{n}$ is the ground truth. If the head movement trace and the video saliency maps for matching indeed come from the same video, $\hat{n}$ has the value of 1. Otherwise, $\hat{n}$ has the value of 0. Since $\hat{n} \in \{0,1\}$, the value of $L(n,\hat{n})$ can be either 0 or $-log(n)$.

5.3 Making Video Identification Decisions

As the trace-fingerprint matching model is not victim- or HMD-dependent, attackers can collect offline data of head movement traces and video fingerprints to train the proposed DCNN. The head movement traces can be collected by HMD sensors when attackers view target 360° videos and/or by directly using public head movement traces of popular 360° videos targeted by the attackers. The video fingerprints, i.e., the saliency maps, can be created by applying a high-performance saliency detector on the respective 360° videos. Once the model is trained, it can be used for video identification. To perform the attack, the victim's head movement trace is paired with each video fingerprint in the library and processed through the trace-fingerprint matching model. This outputs confidence scores that indicate the match between each video and the victim's head movement. INTRUDE then produces the top-k candidates by selecting the k videos with the highest confidence scores.

6 Experimental Methodology

6.1 Settings

Apparatus. The INTRUDE prototype comprises an HMD device, a GoPro HERO6 camera, and an offline processing desktop running on Ubuntu 18.04 equipped with a GeForce GTX 1080 Ti GPU. The GoPro6, which records videos in 1080p with a 12MP lens, is inferior in recording capability compared to modern smartphones such as iPhone 14 that is equipped with a 48MP lens and can produce 4K videos. We tested two cordless HMDs commonly used in VR studies [19, 29, 79], Google DayDream and Google Cardboard. Both have 100° field of view similar to most modern VR headsets. The camera was situated 1.5 meters in front of the user at head level, and recorded at 1080p resolution. We took recordings in a well-lit office (∼1000 lux as per [5]) at a sampling interval of $\tau = 0.8$. We extracted 60 seconds from each recording for our experiments. Half of them were extracted from the first 60 seconds, while the other half were segmented from a random point of the recordings. This default setting is maintained unless otherwise stated when evaluating specific factors.

Subjects. We recruited 31 subjects (15 males and 16 females, aged from 19 to 36) for the user studies. Subjects are university students and people recruited through public channels, among which 18 wear glasses, 5 have no experience in VR, and 10 have little experience. All subjects gave consent to our IRB-approved study, which allows us to record human responses for VR system evaluation. Subjects stood in an open space while viewing the provided content. All 31 subjects participated in model training (§6.2) while 17 subjects were randomly chosen to play the 'victim' role during the data collection phase (§6.3). The decision to work with 17 victims is attributed to the significant time commitment of playing a victim, aligning with the participant count in similar studies [77, 91]. For training the HME, recruits were asked to follow specific instructions to collect head orientations. When playing the role of victims, users were instructed to engage freely with the 360° videos without any additional guidance. All participants were kept unaware of the study's purpose.

Video Library. We collected a library composed of the top 635 popular 360° videos with the most views on YouTube, covering a diverse array of genres such as documentaries, music, sports, animations, wildlife, vlogs, travel, and gaming. Each genre contains a minimum of 30 videos and each video receives at least 40,000 views. We obtain the fingerprints of these videos by applying a state-of-the-art 360° video saliency detector [59].

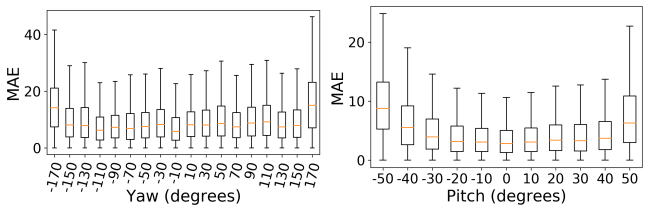
6.2 Offline Model Training

The HME. To train the head orientation estimation model in the HME (§4.2), we first collected a dataset of camera recordings that captures different head orientations of the 31 subjects. Subjects were asked to view a target virtual object displayed on the HMD screen at different angles with respect to the camera filming direction. The head orientations during this one-second viewing session ranged from -179° to 179° in yaw and from -55° to 55° in pitch. Note that subjects were not instructed to freely explore 360 videos because that may not cover the diverse head orientations needed for HME training.

Each subject repeated the viewing session 15 times for one HMD device. We then annotated the head orientation for each frame of the recordings as the ground truth. A total of ∼200,000 annotated head orientation frames were collected to train the model. To mitigate model overfitting and increase the variety of patterns the model can learn, we applied data augmentation to the training data. We randomly picked a method from horizontal flipping, adding random gray boxes,

modifying brightness and contrast, and zooming in and out at the center, and then iterated through all frames [75]. The total time to train the head orientation estimation model was approximately 5 hours. Details on creating the dataset can be found in the Appendix of our extended paper [61].

The TFM. As discussed in §5.3, the training process of the matching model uses head movement traces when viewing videos and fingerprints of these videos. An inherent advantage of this design is that TFM training does not rely on camera recordings of head movements, making it independent of the training and testing performance of the HME. This enables attackers to leverage publicly available head movement traces for TFM training, which offers more accurate data than the HME output and reduces the data collection efforts. We implemented this design by utilizing three existing datasets of head movement traces for 360° videos [22, 48, 89]. These traces were collected by built-in HMD sensors for 24 videos, each with head movement traces from at least 48 users in a free-viewing context. In addition, we obtained the fingerprints of these videos by applying the aforementioned saliency detector [59]. By combining a head movement trace and a saliency fingerprint as one sample, we created a training set of 1,152 positive samples and 23,392 negative samples, where *positive* means the trace matches with the video title and *negative* indicates no match.



To mitigate the overfitting, we applied shifting augmentation [75] on head orientation maps, where the pixels indicating head orientations were randomly shifted up, down, left, or right to simulate the head orientation estimation errors. We leveraged an upsampling technique to mitigate the impacts of imbalanced data. The total training time was about 16 hours.

6.3 Online Attacks

Once the models in the HME and the TFM are trained, we launch INTRUDE to execute attacks and evaluate the performance of video identification. We conducted *cross validation*, wherein each round one user played the role of a victim and his/her data was excluded from the training set to ensure no overlap. We simulated the scenario where the victim viewed some videos in the target library, while the attacker aimed to determine which videos were viewed. We randomly selected 22 videos from the 635-video library for the victim to view, resulting in 22 camera recordings of head movements. For each recording, INTRUDE inferred the top-k video titles out of the 635 potential options. We repeated this process for 17 victims and report the average results.

7 Evaluation Results

In this section, we present the extensive evaluation results of INTRUDE when the online attacks are launched. We start with validating the head movement estimation (HME) (§7.1). Next, we focus on evaluating the video identification attacks, including analysis of system parameters (§7.2), comparison with baseline approaches (§7.3), and robustness analysis under various environmental factors (§7.4). Finally, we evaluate the open-world identification (§7.5).

(a) Yaw (b) Pitch

Figure 9: Estimation errors of the HME in yaw and pitch.

7.1 Validation of the HME

HME Effectiveness. We first validate the effectiveness of the HME because it extracts head movement traces from camera recordings and affects the performance of INTRUDE. We use Mean Absolute Error (MAE) to measure the absolute angles between the estimated and ground truth head orientation vectors. We focus on the yaw and pitch angles because the roll angle is not needed to locate where the victim is looking at the 360° video. It only indicates how the head tilts (not turns).

Figure 9 shows the boxplot of MAE (median values marked in red) for different head orientations categorized by their respective yaw and pitch coordinates. The average MAE between estimated and ground truth head orientations are 8.8° and 4.3° for the yaw and pitch coordinates, respectively. These errors are comparable to those obtained from generic head estimators for non-HMD limited-range head orientations [16, 40, 71]. Note that the MAE for the yaw coordinate is higher than the pitch coordinate. This is due to the yaw drift effect [28] where gyroscope sensors incur noises in the yaw coordinate of the ground truth and lead to biases in the yaw estimation. We also observe that the HME performs well in a wide range of yaw and pitch angles supporting 360° video viewing. The performance degrades at extreme angles where fewer samples were collected for model learning. However, since users rarely move to those places, the overall effectiveness of the HME is not affected.

Head Tracking on Different Devices. Next, we test HME performance with two Google Cardboard and Daydream, two popular VR headsets with different shapes, sizes, materials, and colors. We aim to explore how different HMDs in the camera recording would affect the attack. The average MAE over all head orientations, the MAE of front head orientations looking toward the camera, and the MAE of back orientations turning back away from the camera, are shown in Figure 10. In general, the MAE of head orientation estimation for Daydream and Google Cardboard are similar, at an average of

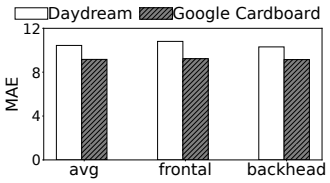


Figure 10: Estimation errors of the HME for different VR headsets.

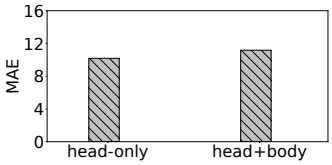

Figure 11: Impact of body movements on HME tracking.

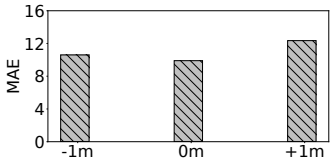

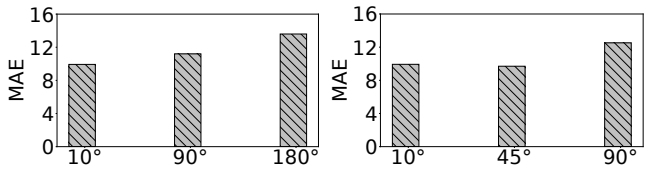

Figure 12: Estimation errors of the HME at different camera heights.

10.4° and 9.16° respectively, suggesting INTRUDE's capability of tracking head movements of victims wearing different HMDs in the recordings.

Head Tracking with Body Movements. To explore the impacts of body movements, we retrained the HME using two recording cropping methods, one only containing head movements (head-only) and the other containing both body and head movements (head+body). We present the results of MAE in Figure 11. As shown in the figure, the MAE errors of the head+body setup were 10% higher than those of the head-only setup since extracting HME-relevant features becomes more challenging when both head and body movements are present. This observation implies background body movements should be cropped out, as used in our default setup.

Head Tracking with Deliberate Movements. Deliberate head movements may disrupt head tracking if they cause the HMD to turn away from the camera, thereby obscuring visual features vital for tracking. We explored the effects of two types of deliberate head movements, vertical angular shifts at 10, 90, and 180 degrees, and horizontal angular shifts at 10, 45, and 90 degrees. For each angle, we collected 20 viewing traces from four users. For each angular shift, users performed five deliberate movements at random moments during a 360 video viewing session and move back to their original positions. The total duration of these movements accounts for about 10% of a 60-second viewing session without affecting the regular viewing experience. The average MAE scores are reported in Figure 13. We observe minimal performance degradation for moderate movements, e.g., a vertical shift at 10 or 45 degree and a horizontal shift at 10 or 90 degree, while large deliberate movements at a 180-degree horizontal shift or 90-degree vertical shift decrease tracking performance noticeably. However, these extreme movements rarely occur in practice [22] as they require considerable muscle effort and disconnect users from the focused virtual content for a few seconds.

Head Tracking at Different Camera Heights. We now investigate the performance of HME when the camera is placed at different heights, i.e., the camera being one meter higher than (+1m), at the same height as (0m), and one meter lower than the user's head (-1m). For each height, we recorded 20 traces collected from four users. The camera was positioned 3 meters away from the user and the average MAE scores are reported in Figure 12. The MAE errors increase at -1m and +1m because positioning cameras at a height exaggerate the scale of the head movement with respect to the camera. Slightly looking down at 0m appears to look straight down when the camera is placed at +1m. These extreme poses that are challenging to estimate occur more frequently when the camera is placed at -1m and +1m, leading to more errors.

(a) Horizontal movements (b) Vertical movements

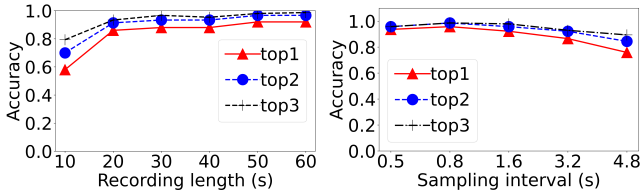

Figure 13: Impact of deliberate head movements on HME tracking.

7.2 Analysis of System Parameters

We now proceed to evaluate the identification performance. If one of the top-k inference results is the actual video being viewed, the attack is considered successful. We report the top-k identification accuracy (i.e., attack success rate) across all victim recordings. In this section, we analyze two system parameters, the recording length and the sampling interval.

Recording Length. Longer recordings provide more user head movement data and more clues about the video content being viewed. However, recording the victim for too long increases the risk of exposing the attack. Thus, it is necessary to understand the exact impact of the recording length T, the system parameter defined in §4.1. We measure the identification performance when the recording length varies from 10 s to 60 s. We cap the recording length at 1 minute since today's 360° videos typically have several minutes of duration [8]. The results are shown in Figure 14a. As expected, the identification accuracy increases as the recording length increases. The top-1,2,3 accuracy of INTRUDE steadily increases to 96%, 99%, and 99%, respectively, when $T = 60$. This result suggests a small trade-off between the stealthiness and performance of the attack. In case a long recording is not possible, INTRUDE can utilize a shorter recording, e.g., 20 s, to achieve a lower top-1,2,3 accuracy of 85%, 91%, and 93%, respectively.

Sampling Interval. To minimize the input data while ensuring the attack performance, we study how the sampling

(a) Recording length (b) Sampling interval

Figure 14: Video identification accuracy versus system parameters.

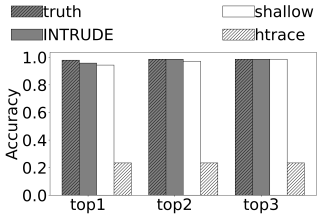

Figure 15: Benchmarking video identification accuracy by comparing INTRUDE with three baselines.

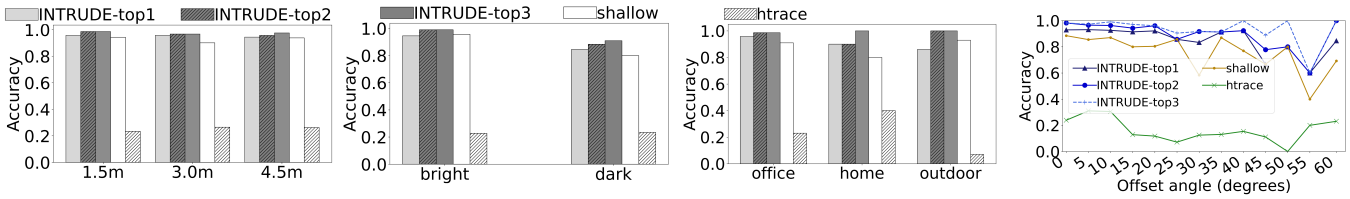
interval of the input would affect the top-1,2,3 identification accuracy. We set the τ parameter discussed in §5.2 as 0.5, 0.8, 1.6, 3.2, and 4.8 seconds and repeat the attack to all recordings of victims. As shown in Figure 14b, INTRUDE achieves outstanding performance when τ is 0.5 or 0.8 seconds. For example, the top-1,2,3 accuracy reaches 96%, 99%, 99%, respectively, when $\tau = 0.8$. It can also be seen that the accuracy decreases as τ increases. The reason is that a greater τ makes the input information sparse, which imposes a penalty on the identification accuracy. On the other hand, minimizing the interval (e.g., 0.5 s) does not necessarily improve the accuracy because it could incur duplicated data samples that do not contribute meaningful information. Thus, we will use $\tau = 0.8$ for the rest evaluations.

7.3 Baseline Comparison

We also benchmark the performance of INTRUDE against the following baselines.

- ***truth*:** Instead of using head movement traces extracted by the HME, the trace-fingerprint matching model in *truth* directly uses the ground truth head movement traces collected by HMD sensors. Since *truth* is not impacted by estimation errors of the HME, its performance can be served as the upper bound.
- ***htrace*:** Instead of creating saliency fingerprints, a single head movement trace of a non-victim user is used as the video fingerprint in *htrace*. As head movement traces fluctuate significantly and are not ideal for video fingerprinting (see §2.2), *htrace*'s performance serves as the lower bound.
- ***shallow*:** To obtain insight into the importance of the design of the trace-fingerprint matching model, we create *shallow*. It is a variant of INTRUDE using a reduced version of the trace-fingerprint matching model, where the first two 3D convolutional layers are removed.



We repeat the experiments in the default setup for each baseline and report the results in Figure 15. As expected, *truth* has the highest accuracy since it utilizes the ground truth as the input for trace-fingerprint matching and video inference. The performance of INTRUDE closely approaches the upper bound, achieving a slightly lower yet comparable accuracy to *truth*. Fewer convolution layers in *shallow* reduces the top-1 accuracy by 1.4% because it affects the analysis of the fingerprints and head movement traces and therefore degrades the video identification performance. As for *htrace*, the identification accuracy is the lowest, indicating that saliency fingerprints are essential features to assist the video matching.

7.4 Robustness Analysis

We now evaluate the robustness of INTRUDE under different environmental factors by repeating the attacks on all the victims. In each robustness study, one environment factor was different from the default setup, e.g., light condition. We captured these additional recordings of victims and launched the attack toward them. Since *truth* uses ground-truth head movement traces rather than extracted traces from recordings, it is not affected by the recording environment and thus is excluded in this evaluation. We report the top-1,2,3 accuracy of INTRUDE and top-1 accuracy of other baselines.

Distances. To measure the impact of the distance between the victim and the recording camera, we place the camera at 1.5 m, 3.0 m, and 4.5 m, away from the victim, respectively. The results in Figure 16a show that the performance of INTRUDE is stable as the distance varies. The attack distance only affects the clarity and visual details of the recordings and the extracted head movement trace. As long as the number of captured pixels for the head is sufficient, a long distance does not affect the identification accuracy. The distances in our evaluations are greater than or equal to those in prior recording-based attacks [45, 95]. To further extend the distance, we can utilize an advanced camera to capture 2K or 4K videos. The accuracy of *shallow* decreases a little as the distance increases because it is a weaker model with a low capacity to learn spatiotemporal patterns in the head movements and video fingerprints.

Light Conditions. The proposed attack may be launched in various light conditions depending on when the attacker finds the victim vulnerable. If the camera is placed in a dim environment, the recording could be noisy and might contain indiscernible regions [18]. Extracted head movement traces can then become erroneous, eventually affecting the attack performance. We launch INTRUDE on recordings captured in the bright indoor condition (∼1000 lux) and the dark indoor

(a) Camera-victim Distance (b) Light Condition (c) Recording Background (d) Camera Placement Offset

Figure 16: Robustness analysis of INTRUDE under different environmental factors.

condition (∼50 lux) according to the lighting definitions in [5]. The bright condition is equivalent to a lit office while the dark condition is similar to a dark corridor or an unlit parking lot. As shown in Figure 16b, there is a small performance drop due to the effect of the dim environment. The top-1 accuracy of INTRUDE decreases from 96% to 84% while the top-1 accuracy of *shallow* drops from 92% down to 79%. However, we believe INTRUDE still poses a threat since the top-2,3 accuracy in the dim environment can reach 90% and 93%.

Background Variations. The location of the attack affects the background scenes in the recording. These visual backgrounds of the victim are analyzed to estimate head orientations and thus have an impact on the performance of INTRUDE. Therefore, we further investigate INTRUDE in different background scenes. In addition to the open office used in the default setup that includes gray cubicles and blue walls, we conduct the attack in two additional backgrounds. One is the home living room where the background scene consists of wood furniture, brown doors, and dark orange walls. The other is the outdoor background that is a typical garden with lawns and plants. Within each background category, we make the exact scene different for each victim to ensure the diversity of the recordings under evaluation. For example, different plants may appear behind a subject in the outdoor case. The results are shown in Figure 16c. Despite the slight variation, INTRUDE achieves a satisfactory performance across different backgrounds. The average top-1,2,3 accuracy across three backgrounds is 91%, 96%, and 100%, respectively. The support of different backgrounds stems from the HME design. As illustrated in §4.2, the HME learns to focus on the HMD device and ignore the background noises.

Camera Placement Offset. In the default setup, the camera is placed in front of the user along the user's front-facing direction, i.e., there is no offset angle between the filming direction and the front-facing direction (see §4.3). In this section, we place the camera in different locations to vary the offset angle between the filming direction and the head's front-facing direction. When the offset angle increases, the camera is gradually moved to the side of the victim. The results in Figure 16d show that there is a slight decrease of top-1 accuracy when the offset angle increases, e.g., around 85% for INTRUDE at the offset angle of 60°. This is due to the increased errors in head orientation estimation when the face and the HMD rotate away from the filming direction (see §7.1). Despite the decrease in top-1 accuracy, we note that INTRUDE still performs well, with a top-2 and top-3 accuracy at 100%, at the offset angle of 60°. We also observe a bit of fluctuation when the offset angle is large. This is because head orientation estimation becomes less stable in these cases. More evaluation data can be used to smooth out the variance.

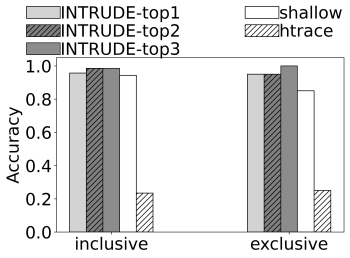


Figure 17: Identification accuracy of INTRUDE when additional participants are used exclusively as victims.

Participants Who Are Not in the Training Set. As mentioned in §6.1, the participants in the above experiments took part in both tasks (training the HMD and playing the role of the victim). To evaluate how the knowledge about the procedures of the former task influences the results of the latter task, we additionally recruited four new participants who exclusively played the victim role and trained the HME only via data from the existing 31 participants. As shown in Figure 17, INTRUDE achieves top-1, 2, 3 accuracies of 95%, 95%, and 100% when the participants are exclusively the victims. The performance is comparable to the inclusive case where the participants appeared in both tasks. This indicates involving participants in both tasks does not affect INTRUDE's performance, validating the appropriateness of our experiment methodology.

7.5 Open-World Video Identification

We have evaluated video identification in the in-library scenario, where the video viewed by the victim is known to be from the library. This scenario has been assumed in the majority of prior video identification attacks [30, 54, 68, 93]. However, another scenario exists in practice – open-world video identification, where we do not know if the video being

viewed is in the library. The accuracy of open-world identification has been evaluated by theoretically estimating the accuracy drop using a statistical model [74]. We use this approach to evaluate the degradation of INTRUDE in the open-world scenario as the number of out-of-library videos increases.

To model the accuracy drop statistically, the Bayesian Detection Rate (BDR) can be used. BDR estimates the ratio of successful identification among all identification attempts and can be formally expressed as,

$$\text{BDR} = \frac{\text{TPR} \times base}{\text{TPR} \times base + \text{FPR} \times (1 - base)} \quad (4)$$

where TPR (True Positive Rate) is the top-1 accuracy of in-library identification reported above. FPR (False Positive Rate) can be derived from TPR via $FPR = (1 - TPR)\frac{P}{N}$, where N and P are the numbers of negative/positive matches (§6.2) INTRUDE encounters during in-library identification, respectively. The base rate (*base*) is the probability of a test video being in-library, i.e.,

$$base = \frac{\text{Number of in-lib videos}}{\text{Number of both in-lib and out-of-lib videos}} \quad (5)$$

Based on our evaluation results, INTRUDE achieves TPR of 0.96 and FPR of 0.000068. Given $base = 0.001$, the open-world dataset (in-library plus out-of-library videos) is 1,000 times larger than the target library, totaling 635,000 videos. In this case, the BDR is 93%. Given $base = 0.00025$ when the open-world dataset expands to 2,540,000 videos, the BDR achieves 78%. Our analysis indicates INTRUDE still poses great threats even when there are several million 360° videos in the open world.

8 Discussion

8.1 Limitation and Potential Improvement

Re-training Cost. Launching INTRUDE on a new HMD requires the attackers to offline collect recordings of the target HMD and retrain the head orientation estimation model for INTRUDE to recognize the HMD's shape and color. The attackers can capture the recordings of their own head movements when using the target HMD. The brand and model of the HMD can be visually recognized when targeting the victim. Despite the extra model training, the retraining cost is not prohibitive. First, there are only a handful of HMDs on the market. We only need to repeat the training a few times based on demand to make INTRUDE generally applicable. Second, the retraining data can be collected by fewer subjects using the HMD in different outfits. Along with the data augmentation we used (§6.2) and generating additional computer-synthesized data [16], the retraining cost can be minimized.

Notably, the trace-fingerprint matching model of INTRUDE is not HMD-dependent. The current model can be directly used and no retraining is needed when applying INTRUDE to a new HMD. The reason is that the trace-fingerprint matching model takes extracted head movement traces and video fingerprints as input rather than the recording of the new HMD. The TFM can thus infer the video titles in an HMD-agnostic way.

Non-continuous Video Playback. We have so far considered continuously-playing videos. This is the most common scenario for 360° video viewing in HMDs because, unlike 2D video viewing with control shortcuts on keyboards, users tend to continuously immerse themselves in 360° video scenes without interruption [62]. However, scenarios where a user pauses, rewinds, or fast-forwards the video can occur, disrupting the continuity of head movements and potentially affecting the attack's success. Fortunately, these infrequent instances can be identified due to its distinctive interactive sequence. For example, pausing necessitates two clicks (one to pause, another to resume). Fast-forwarding or rewinding may require either a single click on the progress bar to skip content or three clicks (pause, forwarding/rewinding button, resume). An alignment module can then be added to INTRUDE to process the recording such that the victim's head movement is aligned with the continuous video playback. In the case of a pause, this new module would discard the recording period while the video is paused. For rewind or fast-forward actions, it extracts the head movement trace once the playback resumes and temporally shifts this trace forward or backward to a video-playing position where the revised trace matches the saliency fingerprints with the highest confidence scores. Similarly, this alignment module can also be used to align the video's start time and the moment when the user clicks the play button if there is a small delay in between.

8.2 Mitigations

INTRUDE is effective because video information is always leaking as long as attackers can observe the victim. An approach to prevent the attack is eliminating the direct line of sight between the attacker and the victim [49]. Users could find a large non-transparent obstacle between them and the crowds or turn their heads away from directions that may expose their head movements. However, these efforts are burdensome for casual VR usage and may not always be feasible in certain environments. Moreover, this prevention approach depends on the user's judgment and vigilance of the surrounding people. It is unlikely to work for advanced attackers who disguise themselves or utilize miniature spy cameras [90].

Besides prevention, one could mitigate the success rate of the attack by complicating the attack. For example, in INTRUDE, the roll axis of the VR coordinate system is aligned with the victim's head orientation at the time when the video starts playing. The attacker exploits this fact to extract the victim's head orientation vector from the recording. To undermine the HME, the VR engine can randomly set the direction of the VR roll axis when the video starts. However, this approach cannot completely eliminate the risk, as the victim

will eventually follow a certain head movement pattern influenced by the evolving salient content. The attacker may still identify the correct VR roll axis by spatially shifting the saliency maps to positions with the highest confidence scores. More importantly, users will feel disoriented and have motion sickness every time a video starts playing because the VR coordinate system is not aligned with the head orientation. A full-scale study of the defense capability and usability is needed before this mitigation can be applied.

9 Related Work

Recording-based Side-channel Attacks. Capturing recordings through the visual channel has been used for recovering keystrokes and unlock patterns on mobile devices such as smartphones and tablets. Existing works have recorded victims (including body movements [21, 41, 44], eyes [20, 81], fingertips [14, 76, 96, 99]), reflective surfaces [11, 12, 65, 94], and backside motion of tablets [81] to perform inference attacks. Recently, there are works showing that sensitive information such as keystrokes entered by participants can be retrieved from virtual backgrounds [33, 72], or reflections from participants' glasses [50, 88].

There is one existing work [45] exploring recording-based side-channel attacks to infer the passwords or keystrokes from users' head movements in HMDs. The attack used optical flow techniques to track the rotation movement of the head in the recording. However, it can only be used for analyzing a very short duration (i.e., during keystrokes) and limited rotation range (i.e., within the virtual keyboard), because this technique has low accuracy and is susceptible to noises. Therefore, they cannot be applied to the case of 360° video viewing, where we must continuously track the head orientation (omnidirectional) over a long time (up to 60s in our case). In this paper, we utilize recordings of head movements of HMD users to launch 360° video identification attacks. Instead of harnessing an unsupervised hand-crafted technique used in [45], we leverage deep learning techniques to train the head orientation estimation model. This enables INTRUDE to achieve state-of-the-art estimation performance while being able to track the user's head movements in 360° video viewing, where the user may look in any direction. To the best of our knowledge, we are the first to use the recording-based visual channel to identify 360° videos in VR HMDs. **Side-channel Attacks on HMDs.** Due to the increasing popularity of VR/AR devices, side-channel attacks on HMDs are gaining more attention. To date, existing side-channel attacks on VR/AR devices [9, 45, 51–53, 56, 77, 91, 101] mainly aim to infer the keystrokes when the user is wearing an HMD. There is one recent work [77] utilizes head motions to infer keystrokes in AR/VR devices, but it relies on a pre-installed malicious app to record sensor readings directly. VR-Spy [9] utilizes channel state information of WiFi signals to recognize keystrokes in VR headsets. Similarly, keystroke inference attacks have been performed on AR devices, e.g., Microsoft Hololens [51, 56]. Meteriz *et al.* [56] explore the AR hand tracking features in Microsoft Hololens, while Luo *et al.* [51] use the six degree-of-freedom motion tracking information. Unlike these works, the goal of INTRUDE is not to infer the keystrokes, but rather the 360° video being viewed in the HMD.

Side-channel Attacks for Video Identification. Among different side-channel techniques to perform video identification attacks, traffic analysis is the most popular type due to the popularity of online video streaming platforms such as Netflix and the ease of accessing the encrypted network traffic in wireless networks. To date, most of the existing works focus on inferring traditional 2D videos [23, 30, 43, 46, 47, 68, 69, 73, 74, 78]. Recently, Bae *et al.* [13] show that video identification attack is feasible in Long Term Evolution (LTE) networks by utilizing broadcast radio signals. Other side channels such as powerline electromagnetic emancipation [26], reflective lights on windows [93], power measurements at the smartphone charging hub [7], and luminance of smart light bulbs [54] have also been utilized to identify 2D videos.

As for 360° videos, a recent study [39] distinguishes 360° videos from regular videos (i.e., a binary classification) for mobile network providers by using packet- and flow-level traffic of encrypted streams. By contrast, INTRUDE is a side-channel attack that identifies 360° video tiles while they are being viewed in HMDs. We harness a novel side channel, i.e., the head movement, which does not exist when viewing conventional 2D videos on laptops and smartphones.

10 Conclusion

In this paper, we investigate the leakage of 360° video titles from VR HMD users. In contrast to the public impression that HMDs conceal the displayed content, we show that INTRUDE can infer video titles with high accuracy by recording victims whose vision is blocked and leveraging the unique side channel of head movements. In a typical indoor setup with the camera a few meters away from the victim, INTRUDE can identify video titles with top-1,2,3 accuracy of 96%, 99%, and 99%, respectively. Furthermore, INTRUDE performs well under various noises in different recording distances, lighting, background scenes, and camera placement angles, as well as in the open-world identification scenario with out-of-library videos.

"I'm not convinced that they don't collect more than is necessary": User-Controlled Data Minimization Design in Search Engines

Abstract

Data minimization is a legal and privacy-by-design principle mandating that online services collect only data that is necessary for pre-specified purposes. While the principle has thus far mostly been interpreted from a system-centered perspective, there is a lack of understanding about how data minimization could be designed from a user-centered perspective, and in particular, what factors might influence user decision-making with regard to the necessity of data for different processing purposes. To address this gap, in this paper, we gain a deeper understanding of users' design expectations and decision-making processes related to data minimization, focusing on a case study of search engines. We also elicit expert evaluations of the feasibility of user-generated design ideas. We conducted interviews with 25 end users and 10 experts from the EU and UK to provide concrete design recommendations for data minimization that incorporate user needs, concerns, and preferences. Our study (i) surfaces how users reason about the necessity of data in the context of search result quality, and (ii) examines the impact of several factors on user decision-making about data processing, including specific types of search data, or the volume and recency of data. Most participants emphasized the particular importance of data minimization in the context of sensitive searches, such as political, financial, or health-related search queries. In a think-aloud conceptual design session, participants recommended search profile customization as a solution for retaining data they considered necessary, as well as alert systems that would inform users to minimize data in instances of excessive collection. We propose actionable design features that could provide users with greater agency over their data through *user-controlled data minimization*, combined with relevant implementation insights from experts.

1 Introduction

Data minimization is a principle specified in Article 5(1)(c) of the European Union's General Data Protection Regulation (GDPR) which requires that "personal data shall be [...] adequate, relevant, and limited to what is necessary in relation to the purposes for which they are processed" [3]. It is a legal and privacy-by-design principle mandating that online services collect only data that is necessary for pre-specified purposes.

Today's consumer-facing web-based systems, such as recommender systems, search engines, or Internet of Things (IoT) systems, often provide personalized services through the collection of vast amounts of user data [13, 64]. Data minimization can be seen as a risk management framework, ameliorating concerns about the misuse of data and societal impacts on data-driven economies [76], while balancing the value of data-driven services for individuals and enterprises. A recent techno-legal analysis of data minimization revealed, however, that one of the main obstacles to compliance with this principle in the context of such data-driven systems is the scarcity of appropriate computational operationalizations [24].

An additional challenge lies in the fact that the definition of data minimization ties the necessity of data to the purposes of data collection – and how to formalize this relationship is still largely an open question in data-driven systems. Several recent computational approaches to data minimization in personalized systems propose, for instance, to tie purpose collection to improvements in the service [14,59]. However, such an automated approach may not always capture the context-dependent perception of the necessity of data by users [24]. Hence, *contrary to traditional system-based approaches that attribute the sole responsibility of data minimization to service providers, it might be vital to involve users in shaping the appropriate data minimization practices*.

While previous literature has highlighted the importance of data minimization in protecting user privacy [14, 24, 59] and complying with regulations [32, 68], there is a lack of understanding about how data minimization could be designed from a user-centered perspective, and in particular what factors might influence user decision-making with regard to the necessity of data. Consequently, to address this gap and to complement existing system-centered approaches, our paper explores a user-centered approach to compliance with data

minimization in data-driven systems.

Towards this goal, in this paper, we conducted semi-structured interviews with 25 EU and UK-based end users to examine users' understandings and impressions, decision-making factors, and conceptual design recommendations for implementing data minimization measures. We then interviewed 10 experts, also located within the EU and UK, specializing in technical, legal, and research aspects of search engines, data minimization, and privacy, to assess the practicality of the design concepts proposed by users. Acknowledging the context-dependent nature of data minimization implementations, we grounded our interview in the domain of web search engines – a prototypical example of a data-driven system utilizing, beyond individual user attributes, behavioral and observational data, such as clicks and queries. We investigate how users expect data minimization to be designed in search engines. More specifically, we address the following questions:

- **RQ1**: How do users think data minimization *currently* works in search engines?
- **RQ2**: What factors influence user decisions on what data is necessary for search engines to collect in the context of data minimization?
- **RQ3**: How do users think data minimization ought to work in search engines?
- **RQ4**: How do experts evaluate the feasibility of user-generated designs of data minimization in search engines?

Findings. Our study indicated an evolving perception of data minimization as some users shift from traditional search engines (such as Google) to the next-generation search engines (such as ChatGPT and Gemini). Participants generally held the belief that these newer engines inherently implement more effective data minimization strategies. When it comes to data minimization decision-making, participants considered several factors, including the type of information being searched, their expectations of good service, and the amount of data assumed to be necessary for a given search data type. Our findings indicate that users imagine trade-offs between the amount of information collected by the service and the resulting improvements they can expect in the search results. In particular, for political and medical search data, participants favored minimal personalization and maximal data minimization due to the sensitive nature of the information. However, our results also indicated that some participants believed data minimization might not be feasible and that, practically, they are paying for services with their data. Additionally, participants expressed the need for minimization features either in the general system settings or just-in-time on the search webpage, to customize their strategies for minimization for different types of search data. The quantity of data and the temporal proximity of search data also influenced the participants' perceptions of necessity with respect to data processing purposes.

In our user interviews, we identified several practical design features for data minimization in search engines. For instance, sensitivity-adjusted keyword search, detailed customization options for data selection based on type and amount, and more straightforward opt-out methods for specific data collection scenarios. However, experts also raised concerns that some user-suggested data minimization designs could inadvertently increase privacy risks instead of enhancing privacy. For example, features that separate search data based on whether the search is for oneself or others could potentially lead to more detailed data (e.g. binary annotation of oneself vs others) being collected, thereby increasing the likelihood of re-identifying uninvolved parties (such as children or parents).

Contributions. Overall, the contributions of this paper are:

(1) Our user interviews ($n = 25$) identified how participants perceived (*i.e. their prior understanding of*) data minimization, which is under-studied in the current literature.

(2) We identified participants' decision-making factors when it comes to selecting data minimization strategies under different scenarios.

(3) Based on user interviews and expert interviews ($n = 10$), we suggest actionable and practical data minimization measures to address users' needs, concerns, and preferences regarding the necessity-quality trade-offs in data collection and processing.

To our knowledge, this is the first study that seeks to develop data minimization interpretations based on end-users expectations of data necessity, complementing the traditional system-centered approaches. Our findings emphasize the need to consider user preferences when regulating and operationalizing data protection principles.

2 Related Work

2.1 Legal Background of Data Minimization

In a data-driven economy, user privacy is often the cost of using data-based systems [59, 76]. Therefore, to protect users, privacy regulations often require that data controllers, those deciding how user data is to be collected and processed [2], exercise *data minimization* measures [57,59]. The EU General Data Protection Regulation (GDPR) outlines the principle of data minimization in Article 5(1)(c), requiring that data should be *"adequate, relevant and limited to what is necessary in relation to the purposes for which they are processed."*

Firstly, the processed user data needs to be *adequate*, that is, fulfilling the requirements of a given task. As argued by Biega and Finck [24], in certain scenarios, more data may need to be processed to satisfy the condition of adequacy, for instance, if the existing data does not sufficiently represent all demographic groups [59]. Secondly, the data collected from users must be *relevant* to the purposes of the task, ensuring,

for instance, that we avoid collecting data that is not even used in the task execution. Thirdly, data collection must be *limited to what is necessary*, leading to, for example, the reduction of the volume and quality of the processed data. In addition, the data minimization principle also involves i) limiting the categories of data that are collected, ii) limiting the duration for which personal data is retained, and iii) deleting data after it has been used for its intended purpose [22, 73].

While many existing guidelines to data minimization focus on structured user attributes like names or health conditions [35], Article 4 of GDPR provides a broader definition of personal data, encompassing *"any information relating to an identified or identifiable natural person."* As demonstrated in prior research, data such as movie ratings, including those found in MovieLens 20M dataset [34], may facilitate the identification of individuals by linking private and public datasets [49]. Thus, it is reasonable to infer that a significant portion of data processed in data-driven systems indeed qualifies as personal data and falls under the purview of the GDPR dependent on the system's geographic scope.

2.2 Operationalizing Data Minimization

There has been speculation that data minimization is incompatible with the current data economy as it may inhibit technical advances in machine learning, which are reliant on repurposing user data [38,46,59,73]. As a result, data controllers may try to take advantage of certain loopholes to evade the data minimization principle, such as by *pseudonymizing* data despite the impossibility of fully preventing subject reidentification using this technique [25]. Additionally, pseudonymizing personal data may reduce its utility since it would be difficult to aggregate insights from across different datasets [51].

Despite these concerns, previous work has shown that it is possible to strike a balance between data minimization and high-quality machine learning models [1, 14, 59]. For example, Biega et al. [14] proposed a performance-based approach to data minimization that reconciles the principle of data minimization with model performance, addressing the lack of a consistent interpretation of data minimization and the resulting complexities in the context of personalization. Similarly, Shanmugam et al. utilize scaling laws to limit data collection by iteratively updating an estimate of a model performance curve, providing accurate data collection stopping criteria and offering practical recommendations for how to implement data minimization in machine learning [59]. Another approach to reducing personal data for machine learning predictions is via feature removal or generalization using knowledge distillation [29]. Additionally, Senarath et al. propose a way to minimize user data from a design science perspective in the context of data storage and sharing, evaluating the compatibility of this approach with existing engineering practices [57].

2.3 Data Handling in Search Engines

Most information retrieval studies explored users' search behavior and evaluated systems [70] along a number of dimensions, including search complexity or time-sensitivity of search [45] to demonstrate how variations in search tasks properties can impact users' behavior [16, 65, 67]. Personalized search or recommender systems often use browsing sessions, SERP clicks, and user information to build profiles of user interests [27]. This data, combined with user queries, has potentially high value with respect to personalization [63] and advertising [66] and can be traced to an individual via linkage of *pseudo-anonymous* data, such as the IP address of the home router being used. Several search engines (e.g. Duck Duck Go) now promise not to collect personal data, and web browsing tools (e.g. Tor) are also available to prevent identification. However, evidence suggests only a minority of people make use of 3rd-party blocking software to handle their data in search engines and, as a result, data processing is often not clear [20, 60, 72]. To address this, studies explored client-side personalization [62], privacy warning labels in search systems inspired by decision-making research on food nutrition labels [75], intent-aware query obfuscation [8], or creating distorted user profiles with noise [17].

When it comes to user preferences regarding data handling by search engines, one study highlighted that users in India exhibit a slight preference for personalization in their search results but are usually willing to give up personalization when searching for topics they deem sensitive [52]. While prior work examining data protection practices in search engines is limited, some closely aligned research in online advertisement and web-tracking indicated the complexity of configuring for opt-in/out and privacy settings, confusing interfaces, and tools' default settings which are often minimally protective [33, 43]. Studies on consent have found that users do not often agree with how their data is being used by data controllers [39, 41], and would like less data to be collected for purposes they do not deem to be necessary, such as personalized advertising purposes [41]. Unfortunately, users who deny consent for data collection are penalized for this and have been shown to receive unjustified, lower prediction scores, raising concerns over how users who wish to protect their privacy may be negatively impacted by not consenting [37].

A notable example of a data minimization strategy was introduced by Google in 2020, with web activity of new users being deleted by default after 3 or 18 months [30]. However, our results in this paper surface the need for users to have more fine-grained control over data collection and retention practices, depending on data type, individual personalization preferences, and other factors.

2.4 Decision-Making in Privacy Contexts

Users' privacy behaviors are not consistent or rational [6]. An example of this is the *privacy paradox*, where users tend to find tracking and other technologies creepy and invasive, yet

their behaviors are not in line with their beliefs [6, 12, 18]. Often, users are subjected to their individual constraints, such as time, the effort needed to protect their privacy, and their knowledge of privacy, among other factors, which results in users having to trade the long-term benefits of protecting their privacy in exchange for short-term benefits, such as convenience [7].

In the context of personalized services, there is often an *acceptability gap*, where users tend to be more accepting of using personalized services but are less accepting of sharing their data for these services [39]. Users are often not interested in paying money to block tracking or ads but would like more control over the data they share and whom this data is shared with [18]. Unfortunately, current methods aimed at giving users more choice over their data, most notably through cookie banners, are not effective [40, 47, 50]. Instead, users rely on the site's reputation and services compared to the text of a cookie banner [40]. This overload of information available to users often forces users to engage in *privacy calculus*, which is where users consider the costs and benefits of any information disclosure before deciding to provide their personal information. A user's behavioral intentions are based on the expected benefits and costs of that privacy violation [19,44,71]. In this paper, we explore the decision-making strategies users adopt for search engines in the context of data minimization.

3 Method

In this section, we outline the method to study and analyze search engine users as well as experts in fields related to search engines, data minimization, and privacy.

3.1 Recruitment

User interviews. We recruited participants through Prolific [4]. Participants had to be: a) 18 years or older; b) living in the EU or UK; and c) have experience using a search engine. The principle of data minimization has to be complied with in the European Union (EU) and UK GDPR, thus we recruited participants exclusively from these regions. Participation was voluntary, and participants were allowed to quit anytime. Each participant received £20 upon completion of an hour-long interview.

Expert interview. We interviewed experts for their input about how to implement data minimization in practice and to obtain feedback on the feasibility of our participants' data minimization suggestions. To be eligible for inclusion in our study, experts needed to have expertise in either technical, legal, policy, or research aspects of search engines, data minimization, or privacy, either in academia or in industry. They moreover had to reside in the EU or the UK. We leveraged our professional connections, research communities (e.g., the ACM SIGIR research community), and Prolific. We received 12 responses in total: four were from Prolific, three experts came from a research background (in differential privacy, conversational search systems, or law/policy for data minimization) in the SIGIR community, and five worked in the industry, including internet technology, banking, health insurance, and donations. All participants were from the EU or the UK. Each participant received £20 upon completion of an hour-long interview.

3.2 Participants

Users. Out of our 25 participants (Table 2), 48% self-identified as women, and 52% as men. The majority of the participants (44%) were in the age range of 30-40, followed by 20% were 20-30 years old, 20% were over 50 years old, and 16% in the age range of 41-50 years old. The participants were from various European countries, namely Poland, Portugal, Spain, Germany, the Netherlands, Italy, Estonia, Ireland, and the United Kingdom. All participants had attained at least a high school diploma, with 37% participants holding a Bachelor's degree and 27% holding a graduate degree. This aligns with prior research showing most users on crowdsourcing sites are typically between 20 and 30 years old and highly educated [5, 36, 58] A majority of the participants (60%) reported having a full-time job, while 26.67% of them had a part-time job, and the remainder were either unemployed or not in a paid job. All participants reported using mobile or desktop devices on a weekly basis, with the majority (63%) indicating multiple daily usages. All participants reported using Google as their primary search engine, with some mentioning the occasional use of Bing, Mozilla, Microsoft Edge, and local search engines (e.g., Sapo) for specific countries. Table 2 presents the demographics of our participants. We refer to end users as P1,. . . ,P25.

Experts. Participants were from Germany, the United Kingdom, Portugal, France, Netherlands. Seven of them were men and three were women. The majority (5) of them were 30-39 years old, followed by 40-55 years old (3) and 26-29 years old (2). Table 1 presents the demographics of our participants. We refer to experts as E1,. . . ,E10. Most participants had two or more years of experience, with three of them having 10 or more years of experience. Their current role involves software product managers, database security, IT security in banking, health, software engineering, and policy research (Table 1).

3.3 Pilots

We conducted four pilot interviews with general participants and two with expert participants to test our study design. Three of the general participants were graduate/undergraduate students, and one worked in banking. Of the two experts, one was PhD researcher and one was a privacy engineer in a technology company. We adjusted our user and expert interview questions based on pilot feedback and our observations.

3.4 Semi-Structured Interview Procedure

General user interview. We designed the general user interview protocol based on the research questions outlined in Section 1. The full interview script is available on GitHub.[1] The protocol was structured according to the following topical sections: (1) Prior understanding of data minimization and search engines; (2) Watching an educational video on data minimization followed by a knowledge check to assess participant understanding of data minimization; (3) User expectations regarding data minimization in search engines; and (4) User design suggestions for data minimization in search engines.

In the first section, we asked about participants' understanding of data minimization and search engines. When participants indicated certain usage of search engines, we asked participants-*"How do you think [earlier mentioned search engine] works?"* We further asked about their thoughts about information collected by search engines after providing context, such as-*"To improve search results, search engines may collect your GPS location, and personal information, such as name, email address, gender, and birth date."*. We then asked them how this data collection of search engines impacts their thoughts on data minimization. The majority of the participants could not provide substantial responses in the context of data minimization, therefore, before starting the second part of the interview, we showed them an informational video on data minimization. This video encompasses an overview of the concept of data minimization, describing the principles of relevance, limitation, and adequacy and processing of personal data within the framework of the General Data Protection Regulation (GDPR). We created the video with accessible visuals and audio to make the concepts easily understandable by users. Given that Section 2 of the interview was designed to answer RQ3 on investigating users' preferences regarding the implementation of data minimization in search engines, it is crucial for participants to possess a basic understanding of data minimization, despite the fact that end-users often lack familiarity with the associated regulations.

Before proceeding with the second part of the interview, we assessed participants' understanding of data minimization with knowledge questions in a multiple-choice question format as well as qualitatively. Most participants correctly responded to the knowledge questions. Every participant accurately identified the main objective of data minimization under GDPR as limiting personal data collection to what is necessary for the intended purpose. Regarding the question *Why is data minimization important?*, 95% correctly stated that it reduces the risk of data breaches and safeguards individual privacy. For the question "Which practice does not align with data minimization principles?", 90% correctly chose the option *"Keeping data indefinitely on the off chance it might be useful in the future."*

[1] https://github.com/Sree0270/usenix2024-supplimentary

In the second part, we asked a series of questions to understand participants' strategies for how they would share different types of search information (i.e., medical, financial, political, entertainment, etc) with search engines to obtain good search results. This was to identify contextual differences in their expectation and rationale for decision-making. We asked how much data they would be **willing** to share with search to get good service and what amount of data they think search engine **needs** for a specific purpose. Another functionality of search engines is that they improve results for other users with similar search behaviors or interests. Thus, we asked if they were willing to share their search data to improve results for other users.

To examine shifts in decision-making tendencies, we incorporated a scenario wherein data minimization was framed as the *necessity*, for instance, *"Suppose that the search engine doesn't need past search history data to improve your search results. Would you be comfortable if the search engine retained your [location, medical, political] search history data? why?"* In the third section, we encouraged participants to consider possible contextual privacy implications of search engines based on the amount and types of search data used or processed. Then, we asked them to consider potential solutions and present their ideas. We instructed participants to generate solutions by sketching their ideas on pen and paper, using a think-aloud protocol [21]. This exercise aimed to understand participants' thought processes and visualize the measures they would implement to minimize their data.

Expert interview. To evaluate the practicality of data minimization designs suggested by users, we interviewed experts in technical, legal/policy, and research areas related to search engines, data minimization, and privacy. We started by asking about the expert participant's current role and the recent projects they have worked on. Then, we posed similar general questions we asked users on search engines and data minimization. We then asked about their organizations' practices for complying with data minimization requirements and the technical measures they implement.

Finally, we showed experts three user-generated design sketches and the description of the sketch from the first round of general interviews. We asked them to assess the sketch's feasibility in the context of search engines, considering the current technical, legal, and infrastructural available to implement data minimization. To scope the interview in one hour and ensure a balanced evaluation, each expert reviewed three randomly selected sketches from a total of five, and all the five sketches were evenly distributed among experts. This allowed all designs to receive a comparable level of expert analysis.

3.5 Data Analysis

Both user and expert interview data were obtained through the audio of the interviews recorded on Zoom upon participants' permission and transcribed. We collected each participant's interview audio, think-aloud responses of possible

solutions, and image files of design sketches they created during the session. We performed a thematic analysis of our transcriptions [15, 23]. Two researchers independently read through the transcripts of 20% of the interviews, developed codes, and compared them until we developed a consistent codebook. The inter-coder reliability of the two researchers' codes was calculated (Cohen's Kappa = 0.91), which is considered good [26]. They met regularly to discuss the coding and agreed on a shared codebook before coding the remaining data. After completing the coding for all interviews, both researchers spot-checked the other's coded transcripts and did not find any inconsistencies. They grouped lower-level codes into sub-themes and further extracted main themes. Finally, they organized codes into higher-level categories.

4 RQ1: Participants' Impressions and Experiences with Data Minimization

Current search engine landscape & data minimization. When discussing search engines, many participants described them as having *"algorithms," "existing databases and indexes," "internal APIs," and "search keyword to web mapping."* They often equated search engines with recent advancements in large language models, such as ChatGPT, Gemini, and Claude, viewing them as next-generation search engines (while Google and Firefox are seen as traditional search engines). P1 said, *"Bard (now Gemini), ChatGPT automatically minimize data because they don't need my information to provide results as the others do."* Despite this, they mentioned why they still rely on traditional search engines for tasks for reliability, as P10 explained- *"If I know what I am searching then nowadays I go for ChatGPT search. I'm a DevOps and I use AWS services a lot. To configure a load balancer on Amazon, I used Google to find articles and many links to find the relevant ones. Now I can find that on ChatGPT search just configuring an elastic load balance. But for specific code snippets for development, I don't yet rely on GPT. I still look for search engines, StackOverflow sites because the ChatGPT search system relies on datasets that are a few years old, and give outdated, incorrect syntax or deprecated code. So I go to Google or Edge."* Participants' perception of LLMs as similar to search engines or conversational search engines [54] are arguably accurate with notable differences [10] such as that LLMs do not index and retrieve real-time from the web directly [55], are context-aware, and provide human-like responses [56]. Some studies suggest that LLMs augment search experience for higher user satisfaction when querying [48], or in domain-specific search [28].

We found that participants tended to see tradeoffs between performance and privacy when choosing search engines among various options, including, Google, Bing, Firefox, DuckDuckGo, Brave, and Microsoft Edge. P13 said *"I think Google is getting a bit nosy, all those ads. But you know you make the tradeoffs with performance. They don't even think about data minimization."* In contrast, P20 finds Bing more appropriate to her search as she said *"I can pinpoint it (search results) more with Bing. Google would try and show me the top 5 (results) based on what they think is right or how those sites pay them and collect my device ID, name, gender, everything. Bing is only matching with my keywords. So it might have some (data) minimization thingy."* On the same note, P14 appreciates DuckDuckGo and Brave for the agency and control *"Brave provides more privacy and even provides an incentive if I choose to provide my data so I have a choice there. I would imagine this as (data) minimization because you can say 'no' or say 'yes' and get an incentive."* P24 said that Edge is providing incentives for an Xbox game by asking for user data, *"I use Edge to buy games. Edge doesn't work well like Google, and you need to give very specific keywords. But that's because they don't collect data, and they are working on improving with this incentive program to ask you to spend more time on their engines so they can train the model."*

What are the metrics for good search results? Data minimization is defined with respect to data processing purposes, and prior work has suggested that the purpose of data processing in personalized data-driven systems is service quality improvement [14, 59]. Thus, an important consideration in user-driven data minimization is how users might judge the quality of results. In our study, participants identified several criteria for what constitutes a "good search result." These include an exact match of keywords in top-ranking results, the credibility of the website URL, the presence of location-specific results, and a diversity of results.

P7 discussed the significance of topic-specific searches, particularly when researching scientific topics. She expects to see links from scientific journals rather than blogs or untrusted sites, noting, *"If I'm researching a scientific topic, I tend to trust results from scientific journals. Currently, seeing results to unfamiliar sites as a response to those searches which I don't trust and consider as good results."* Similarly, P11 highlighted the value of diverse search results, especially when shopping for products -*"product from various suppliers, showing different prices, different links, providing more options."* A key issue emerged from this discussion where many participants, including P13 mentioned the challenge of balancing specificity in search queries. This leads to the question of how much information is needed for reasonable results which is often unknown to users. As P13 said, *"Being too specific might exclude useful information as Bing does while being too vague results in an overload of irrelevant data as Google does. Perhaps, need a way to determine how much user data is used in the backend."*

5 RQ2: Factors Influencing Data Minimization Decisions

We present how participants expect data minimization to function in search engines. We asked participants three key questions in the light of preference, willingness, and perceived need for search engines to provide good results. The analysis showed that their decision-making process involves trade-offs of different factors related to data minimization, including different types and volumes of search data.

5.1 Types of Search Data

Most participants had reservations about medical, political, financial, behavioral, and personal identification-related search queries, preferring to limit data collection for these sensitive topics. P2 discussed current volatile world politics to illustrate this: *"So many crises, like COVID-19, now the Palestine-Israel conflict, those are tricky. If my search says I am supporting Israel or I'm supporting Russia, later this data could be used against me."* P6 similarly was expecting medical searches not to be collected, mentioning the potential negative impacts on insurance benefits due to chronic or psychological conditions. We found participants often relied on trusted sources rather than search engines for financial information, expressing concern for potential risks of fraud. P25 illustrated this by sharing an experience where, after searching for cryptocurrency investments, they received suspicious emails and messages, including a dubious link to redeem an Airdrop. Despite recognizing the risk, P25 clicked on one of these links. This experience led P25 to question the necessity of search engines collecting financial query data, as they preferred to make investment decisions independently without guidance from search engines.

Regarding location and behavioral searches, participants had specific preferences. While participants were open to search engines retaining general location data (like city or country), they avoided sharing exact locations. P13, for example, used tactics like setting her home address to her neighbor's to mislead search engines: *"When I use Google Maps to search for nearby stores, I set my home address to that of my next-door neighbor so the search doesn't have my actual location."* Opinions on behavioral search data were mixed. Some saw the benefits of product purchasing and receiving relevant ads based on past searches, while others found it invasive and irrelevant. This highlights users' expectations regarding the minimization of data by search engines are primarily influenced by the type of search and further tailored to the individual's specific circumstances.

Some participants saw value in sharing certain types of medical, behavioral, and personal data. For instance, P2 mentioned how his search on certain medical symptoms could improve the search for others or help different medical institutes match website content so those are easily found by users' search keywords: *"Search queries in a medical context is okay because this can help some medical institutions to have a good database. I understand from my experience how difficult sometimes to find relevant information on a legitimate medical topic."* Similarly, P7 was open to sharing personal details like professional experience and gender, seeing it as necessary for obtaining more accurate search results: *"LinkedIn and search engines need my professional details if I am searching for a job in event management, banking, or in a tech company, etc. Some personal data will help avoid getting unrelated search results."*

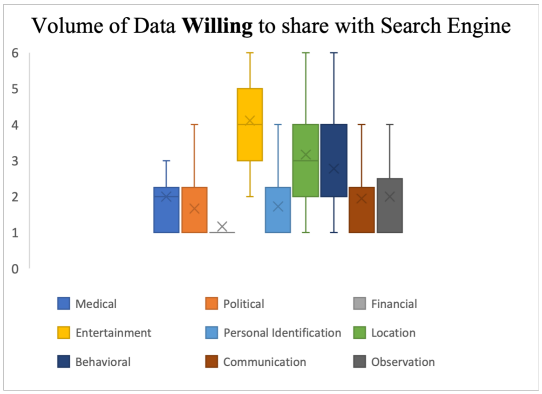

Figure 1: Willingness to share data with search engines: How long are you willing to let a search engine store the following types of data to get a good service/search results? (1: Not at all, 2: A few days, 3: A few weeks, 4: A few months, 5: A few years, 6: Indefinitely).

Participants also ranked their willingness to share various types of data to improve search results for themselves vs others (Figure 7 and 8 in Appendix). For instance, participants were more willing to retain their medical data when it improved the results for other users (for example, when affected users search for symptoms of rare diseases) than just improviding their own results.

5.2 Volume of Search Data

Participants conveyed their comprehension regarding the amount of data required for good results from search engines. They discussed: (1) what they consider as reasonably good search results; and (2) how they perceive the amount of data needed to generate such results. P21 expressed his perspective on the relevance of past political and location data searches and the amount of data required for providing satisfactory service by stating, *"I understand why search engine needs my regular or daily location data, for example, if I were looking for restaurants nearby my place or new locations, But for politics, I don't think my preference change ever and I don't need my results needs any improvement. So I don't see why they need search queries on whatever I search about relating to global politics of wars, crises, and local politics."*

To further elucidate the participants' viewpoints, Figure 2

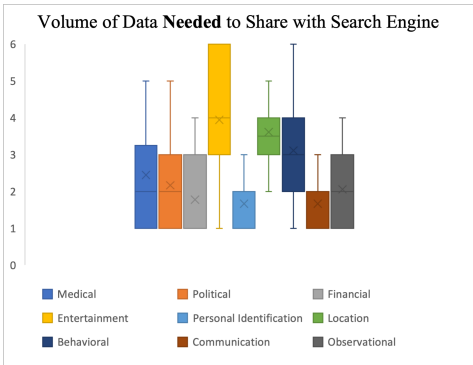

Figure 2: Necessity to share data with search engines: How long do you think a search engine needs to store the following types of data to provide you with a good service/search results? (1: Not at all, 2: A few days, 3: A few weeks, 4: A few months, 5: A few years, 6: Indefinitely).

presents self-reported quantitative value for each type of search data and their understanding of the duration for which data needs to be retained. For instance, financial information was rated with a mean score of 1.77 for how long the data needed to be retained for good search results, followed by political (2.16), and medical (2.16) information. In contrast, some participants thought search engines needed past search data related to user location, behavior, and entertainment to provide good results.

5.3 Tradeoffs Between Performance and Data Minimization

Many participants discussed their decision-making regarding the minimization of data collection and usage for their intended service. They considered the trade-offs between the level of information and the extent of improvement in the search result that could be achieved by sharing their search data. P21 reported being satisfied with the current search results when searching for medical symptoms while he preferred to rely on medical professionals for detailed consultations rather than search engines. As P23 stated, *"I am satisfied with the current search results. I do not believe that the search engine needs any further information to store and improve results. I already know how to get to a trustworthy website and have visited diabetes.co.uk several times before. If I need more medical advice, I will prefer to consult a doctor rather than depending on the search."*

Some participants recognized a trade-off between the necessity, usage of service, and trust when considering data minimization. Despite understanding the risks associated with storing and using search data, they accepted it as part of using a free service, viewing data collection as a form of **payment for the service**. P3 expressed this by noting the importance of trusting the service providers to some extent when using their service *"I think most of it is necessary. The risk concerns the use of such information, but if we want to use these services, we must also give some trust."* Meanwhile, P16 highlighted the dilemma between data minimization and service usage, pointing out that avoiding sharing personal data could mean refraining from using online services altogether *"Data minimization or service. Even though I don't want to share and I think its not needed, but only way to avoid using online."*

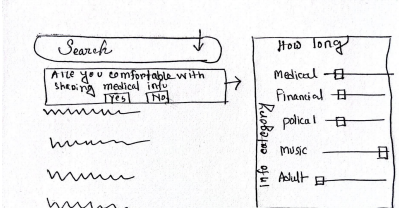

Figure 3: Profile customization or just-in-time pop-up to configure data minimization preferences for different data types. This design consists of a form with different categories of search queries with (i) a checkbox for enabling/disabling the collection of data of a given type and (i) a slider for configuring the volume and retention duration of data of a given type.

6 RQ3: Conceptual Designs

In this section, we introduce participants' conceptual designs (CDs) for data minimization in search engines. Five such designs were identified through user-provided think-aloud protocols and design sketches. Following this, we present the practicality and feasibility of these designs for data minimization in search engines in experts' assessment.

6.1 User-Driven Data Minimization Design

6.1.1 CD1: Profile Customization for Data Types and Data Volume

Most participants suggested a user-end profile customization option for setting the amount and type of search data, which they think would be needed for a reasonable search result. They proposed two customization methods: (1) a profile status customization in the settings page, allowing users to select different data (e.g., medical, politics, music, etc) and volumes (e.g., current, past few days, months) for various data types using checkboxes; (2) a just-in-time pop-up near the search bar for users to specify their data sharing preferences based on type and volume. To illustrate this model, P3 presented a sketch that depicted a just-in-time pop-up design for users to input their preferences (Figure 3). As P3 noted, *"Some kind of checkbox or anything similar where I can click or slide on for information category and storing preferences. So if I'm searching for a movie, for example, which is in category of entertainment, there will be pop up right side of search bar where I check how much data to collect, none to all."*

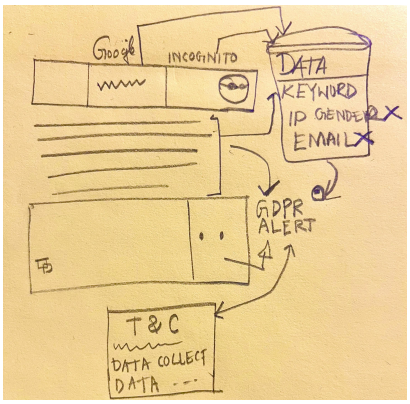

Figure 4: Designing a GDPR alert to provide users an accessible way to see data collection and retention. This would consist of the automatic detection of irrelevant data collection by search engines and cross-checking with their privacy policy page regarding data collection and retention.

Figure 5: A design that separates searches that the device owner conducts for themselves and others. The idea is to minimize data collection (preserving the privacy of other users) while maintaining the personalization and accuracy of search results for the device owner.

6.1.2 CD2: GDPR Alerts for Data Minimization

Many participants suggested implementing an extension-like feature in search engines to provide clear explanations when data collection or retention exceeds what's necessary and relevant. Some expressed uncertainty about what data is considered essential for collection and the duration of its retention. As P10 remarked, *"Terms and policy (privacy policies) might have a retention and collection policy, but who reads those? Those pages seem like they are pushing you during service usage to click on 'I agree'."*

To this end, P6 proposed a solution (Figure 4) for data minimization in terms of collection and retention: *"A search engine page or a stand-alone extension could probably use some sort of firewall or program that would alert you to what kind of personal engine is collecting and keeping. And somehow the GDPR principle could be coded there so the rules cross-check the list of collections and give alerts to users if unnecessary data is being collected. This is certainly not completely new, but can minimize data."* P19 expanded on this idea by proposing the addition of a chatbot in place of GDPR alerts which would communicate information to users and help them manage their data-sharing preferences through a conversational system.

6.1.3 CD3: Separating Searching Sessions for Oneself and Others

Data minimization (anonymity) for others. Several participants expressed concerns about receiving ads in the search results that were not relevant to their own search history. P21 highlighted that after searching for gifts for friends, he would repeatedly receive ads related to this search in the top three ranking results. To address these issues, P12 suggested the implementation of two tabs within the search engine (as shown in Figure 5), enabling users to define whether a search was intended for themselves or others. As P12 stated, *"In search engines, you type into the search box, what's the best medicine for eczema? And then it could be something within you press, a little drop-down box– is this information pertinent to you or for someone else, you click a relevant box, could be a quite effective way."* Similarly, P22 suggested separating users' search history and making search-related information entirely anonymous, ensuring that search channels remained focused on the users' needs.

Additionally, several participants expressed concerns regarding children's privacy when using search engines and recommended that separate search options be made available when children are using the same device. P1 suggested *"Google search could do the same thing as YouTube kids, and then they can't collect data from children's searches because it's illegal for search engines to collect data from kids."*

Data minimization (dimension reduction, PCA-like feature) for performance. Some participants mentioned data minimization in the context of better performance and non-biased search results. They noted that their use of search engines extends beyond personal needs, such as searching for gifts for friends or information for siblings. As P24 said, this could create an outlier in the search data and potentially influence the overall data profile.

One potential improvement for search engines could be adding an option under the search bar to specify whether the search is for personal use or for others. This distinction could help in managing the relevance of collected data and ads shown. To illustrate the design, P24 described the concept of principal component analysis (PCA), a mathematical technique: *"I hope search engines could apply PCA to simplify data in multidimensional (many users) by reducing the complexity by retaining only the necessary ones. With mathematical expressions under the hood, there could be a UX design for users only a click way to reduce the data retention*

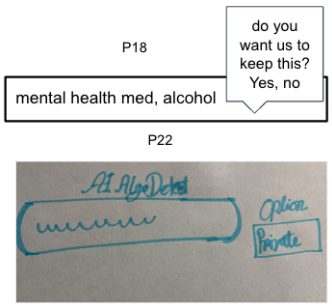

Figure 6: Minimized data collection based on keyword sensitivity in a search engine: redirecting users to a data-minimized search mode or showing a just-in-time pop-up when a sensitive search query is detected.

from the user end."

6.1.4 CD4: Sensitivity-Based Search Customization

Many participants expressed the need for a search option based on the level of sensitive words. For example, they expected a search option that would prevent search engines from collecting and storing information related to personal topics, such as disease information, and children care, violence (e.g. guns, alcohol) related topics out of curiosity. P7, P18, and P22 suggested that the search engine's underlying functionality could be designed to identify search sensitivity based on the keywords entered into the search bar and prompt or remind users to switch to private mode or simply ask users with a pop if those searches should be collected or not. This would allow for a more dynamic and user-friendly private search experience. As P18 states, *"They could just have a pop up triggered by the sensitive word on the search bar and ask me if those to collect or not"*. P18 added that this option would help easily allow or disallow sensitive data collection during a search. Similarly, P22 said *" they could just remind me to use private mode based on sensitive keyword identified."* To illustrate, P22 presented a sketch design for *"**sensitive search**,"* (Figure 6) in which there would be buttons for normal search and search without collecting data (sensitive search).

6.1.5 CD5: Data Donations & Incentives

Some participants, particularly those using Bing, Microsoft Edge, and Brave, discussed an incentive model where users are asked for permission to collect certain data during searches. For instance, Brave rewards users with cryptocurrency tokens, while Microsoft Edge offers points based on the time spent on the search engine. These participants suggested implementing a similar structure in mainstream search engines, allowing users to see the data being collected and choose what to share, potentially receiving credits for their data. This highlights the ownership and control design expectations of users. To expand on this, P16 said- *"Currently Firefox, Google Search doesn't have any ownership structure for the user and no accountability to the user. I don't even know if my medical queries are collected. I generally don't want them to collect these queries and links I visit, but, probably there is a chance if they give me some choice of share or no share. even say this info will help build some medical databases for researchers, and doctors. I perhaps would give a thought on providing."*

6.2 Expert Evaluation of the Practicality of User Design Suggestions

6.2.1 Experts' Current Practices for Data Minimization

Based on the expert participants' area of expertise, we found several practices related to Data minimization and privacy.

Data encryption & anonymization. All our expert participants frequently mentioned data encryption as a part of data minimization practices. As E1 noted as their company practice,*"I work on data encryption to secure information during both transmission and storage when collecting data and inverse query processing to restore information and ensure the storage of personal and necessary information only exclude irrelevant data that doesn't contribute to the system's functionality. Another aspect of our approach is the use of anonymization techniques and tracking user sessions to enhance privacy. I employ the PVC method to make it more challenging to associate data with specific users. This is to communicate privacy policies and terms of service to users.*

Consent before collecting sensitive data. Interestingly, all expert participants from the industry emphasized the need for sensitive or personal data for the performance of the service. However, for the purpose of data minimization, they mentioned consent while asking for any personal data. As E9 noted *"We get consent for collecting any sensitive personal data. Our policy is - clear on data retention and making sure my team does the same. We have protocols to **automatically delete** or anonymize user data after a certain period to minimize risks associated with long-term storage."*

Avoiding centralized execution of data. As a part of data minimization practice, a few experts mentioned decentralized execution on users' devices as a best practice in their product. As E7 said *"Our service considers processing data on the user's device whenever possible because it's health-related data, we reduce the reliance on centralized data storage. We have a client side to boost privacy to limit the exposure of sensitive information. This is what we do for data minimization."*

GDPR compliance for organizations. Three experts who had 10-15 years of experience in the industry as damage security, information security, and financial security experts in a European bank mentioned that they followed the principle of data minimization before GDPR existed. They mentioned the economical aspect of keeping data long period of time for cloud, computation, and maintenance costs. As E2 mentioned, *"We ensure data accuracy and collect only what is necessary for*

our specific purposes, like fundraising. For instance, knowing someone's pet's name isn't relevant to fundraising, so we avoid collecting those. isn't just about respecting privacy; it's also cost-effective for maintenance and quality control. we are conscious of how long we retain data. For example, after a fundraising event, I assess whether the collected data is still needed or if it can be deleted or archived. It's also an economic decision for us. We try to balance privacy, legal compliance, and economic considerations. But we also know there are companies for them this data is a gold mine."

Access control. As a practice of data minimization, some experts mentioned access control which ensures training and using data by certain entities for certain applications strictly based on the requirement. E3 and E9, who have a role in banking and finance, particularly emphasized access and authorization of data use as a part of their data minimization practice while also reporting that they don't have official directions for GDPR compliance regarding data minimization.

As E3 said, *"For data minimization: sensitive data obscure from external applications. We use a layered database approach to control access to sensitive information, so we have specific permissions to query the database, and even then, certain data like fiscal codes or IBANs (since I work in banking) are masked and inaccessible even when you search in a 'query-like feature". There are protocols for accessing older data, which require another level of authorization. Essentially, each employee's access to the database is tailored to their role, ensuring both data security and privacy compliance, not necessarily GDPR."*

6.2.2 Practicality & Feasibility Assessment

Experts agreed on the viability of the data minimization design concepts CD1, CD2, and CD4, clearly seeing their practical applicability and available resources for implementation. In contrast, they found CD3 and CD5 to have numerous drawbacks, including both immediate and long-term security risks associated with their practical implementation. In this section, we present the experts' assessment of the users' design ideas.

Assessment of CD1: profile customization for data types and data volume. Most experts find the profile customization feature useful and practical to implement. E1, a software product manager, shared insights from a cloud product he worked on. He explained *"we ensure secure and efficient data storage. This involves clients' and their users' consent, especially in cloud computing. We deal with a variety of rental agreements. At times, we encounter users who prefer to keep their information private, due to the nature of our services spanning multiple countries and continents, and require a certain level of confidentiality for certain types of data. We have a consent-like form design for the product pipelined with db instances to cater to these various requirements efficiently, adding certain noise, adding gibberish for unique identifiers, and setting limits to the data life."* E1 also noted that such a feature is practical for search engines, allowing users to customize data types and volumes. E3, a specialist in banking IT security, stated, *"Search engines should be capable of this level of discretion. Theoretically, they could use algorithms to filter and avoid storing sensitive data, setting timelines for collecting specific data types. In banking, we strictly adhere to data collection timelines. We don't just follow GDPR for data minimization; it's our default system. Implementing this in the user interface shouldn't be a major challenge. The real question is their willingness to implement such measures. There's no technical excuse."* E4, a conversational search engine researcher, evaluated the design concept considering storage efficiency and performance. She commented, *"using data for longer durations is not the best way to present complex search results, scattered and skewed user queries in politics of many years is not reliable."*

Assessment of CD2: GDPR alerts for data minimization. For CD2, experts acknowledged its potential but expressed reservations about the feasibility of its implementation, especially given the challenges in quantifying the GDPR principle. E9 commented, *"This idea is great and would be something groundbreaking, but I don't see how as of now it is possible. To make Data minimization GDPR quantifiable against companies' Data policy, we need benchmarking which is not available to my knowledge. With ML, it will be possible to summarize the text content of these two sources, but I don't see actual data collection and retention being detected to provide GDPR alerts to users. will the company be willing to opt in for such data flow analysis? that's a question mark?."* Similarly, E3 and E7 reported similar feedback on the practicality of expecting companies to develop such UX in monitoring data, analyzing policies, and identifying key indicators for compliance.

Assessment of CD3: separating searching sessions for oneself and others. While users showed a strong preference for the design concept of having the option to conduct searches differently for themselves and others to minimize data, most experts considered this feature potentially more invasive. E7, a privacy and security expert, explained the risks *"Using two different search options for yourself and another person, like your child, essentially provides the search engine with annotated data to create a shadow profile. You're giving them a detailed footprint of behavior and possibly medical issues of your child under the 'others' search option. This creates a binary flag from your IP. This 'shadow' profile, built over let's say 20 years, could be misused. Unless it's guaranteed that the search engine doesn't collect any information from the 'others' search option, this design won't serve its intended purpose."* Similarly, experts E2, E5, and E10 acknowledged the technical feasibility of implementing this option but raised concerns about its effectiveness and privacy implications. E5 stated, *"Technically, it's possible to implement such a feature. However, I doubt the search results for the two options would be differentiated in the system for access permission and*

model training in the long run." E4 also commented, *"This might help unnecessary data collection. Specifying search queries about another person could allow re-identification by combining with other data sources, violating privacy of uninvolved parties. Keeping all searches together maintains privacy due to the noise. I wouldn't recommend this approach."*

Assessment of CD4: sensitivity-based search customization. Most experts supported the design concept of sensitivity-based search and confirmed that it's easy to implement with current technology and has the potential for incremental improvements over time. E8 explained, *"programming queries to identify keywords, analyze search frequencies and adapt to user behavior. While it may not yield perfect results immediately, it progressively improves through 'dynamic update mechanisms', 'intent recognition', and 'query parsing."'* Similarly, E2 emphasized the importance of distinguishing between personal and non-sensitive information. E2 outlined how this could be integrated into existing search engine frameworks: *"Current engineering or algorithm teams could anonymize or apply access control, adding noise after data collection at the query stage, triggering sensitive search alerts or options. This prevents data from reaching the server, with execution done on the client's search engine. It requires UX design and existing tech stacks in the backend to instantly discard sensitive searches made locally. It's akin to using Trusted Execution Environments (TEEs) for search queries. Cryptography could even be employed for private local execution. From a technical standpoint, this is very feasible."*

Assessment of CD5: data donations & incentives. Experts find the concepts of data donation and incentives intriguing, primarily in terms of enhancing data ownership and control, rather than data minimization. E9 noted, *"Platforms like Brave and Microsoft Edge offer users some agency and ownership of their data, providing incentives to create a sense of choice. However, this approach doesn't address the reduction of unnecessary metadata collection. It doesn't seem to alleviate that concern."* Similarly, E7, E3, and E10 echoed the sentiment that while the concept fosters a sense of control and ownership over data, it does not directly contribute to the goal of data minimization.

7 Discussion

Our study elucidated participants' perceptions of data minimization, the factors that shaped their decision-making processes, and end users' proposed conceptual designs assessed by experts for the feasibility of implementation in search engines. In this section, we discuss how the findings can aid system administrators in operationalizing data minimization.

7.1 Main Findings

User-centered quality metrics to quantify the necessity of data. Our study hinted at a variety of metrics that would align with how users judge the quality of search results vis a vis data necessity. Those included exact keyword matches, lack of sponsored ads in search results, whether relevant results appear on the first page, etc. Prior literature by Biega et al. and Shanmugam et al. has proposed performance-based interpretations of the data minimization principle, linking restrictions on data collection to service quality metrics typically applied to evaluate systems [14, 59]. Our study surfaces relevant metrics to apply in this context that may better align with users' needs – a necessary component for user-driven data minimization.

Varying expectations, perceptions of data necessity, and trade-offs for data minimization decisions. The principle of data minimization requires that organizations only collect and retain the minimum amount of personal data necessary for their stated purposes [31], but our findings indicate that users have more fine-grained expectations of how data minimization should be implemented in practice. Our research, when juxtaposed with earlier studies on privacy and the willingness to share data [61, 66, 69], reveals a nuanced, context-sensitive understanding among participants regarding the necessity of data minimization for different types of search queries. For example, participants recognized the value of retaining location-based queries for improving search results, yet they were not comfortable with storing exact location coordinates. While users see value in storing medical search queries to improve search results for rare medical symptoms for other users, they want more care put into ensuring this data is kept private. Furthermore, our study highlights a perceived trade-off by users between data minimization and free access to search services, viewing their personal data as a form of currency for the services received, echoing sentiments found in prior research [42, 53, 74]. Our study has expanded on these findings in the context of data minimization. Namely, despite understanding that there is generally a trade-off between the amount of personal data a service retains and its quality, users believe that more granular controls over the quantity of data retained and over the data storage duration constitute better operationalizations of data minimization.

Data incentives and data minimization. Our research highlighted a trend among users in response to recent proposals to exchange personal data for various incentives. For instance, systems like Brave or Edge offer rewards for increased usage or opting in for advertisements. Although incentivized data sharing may bring to mind the "privacy paradox" [6], our study suggests that users view this trend as a means to gain ownership of their data. Indeed, trading data for improved services or rewards gives users a higher degree of agency than completely abstaining from online services for privacy reasons – a solution that they considered impossible. On the other hand, incentives can easily be designed to make users act in the company's best interests rather than their own. Future research can further investigate user mental models of data ownership and control concepts.

The role of generative AI as a search engine. We found that, with the proliferation of generative AI services such as ChatGPT and Gemini, some users are increasingly using these tools in lieu of traditional search engines. These participants believed that generative AI services may become the next generation of search engines, even despite holding reservations about their reliability. In the interim, participants reported using traditional search engines alongside AI for more reliable search results. Given the advancements in generative AI, data minimization strategies should be rapidly adapted to the context of these services.

7.2 Design Implications

Drawing upon users' data minimization needs and experts' input regarding technical feasibility, we suggest actionable design implications for data minimization.

Data-minimized search mode with keyword sensitivity. Our findings show that users are skeptical of sharing data for sensitive queries, such as those relating to health, finances, politics, behavior, or those that personally identify them. Therefore, minimizing data collection for *sensitive queries* is an important design implication. One possible approach is to employ techniques based on keyword detection and natural language processing to identify sensitive keywords entered by users in the search bar. Second, the search engine can prompt the user to switch to a Sensitive Search Mode when a user inputs sensitive information. This would ensure no data is collected during the search session, providing users with a customizable sensitive search experience. Another interactive design could involve triggering a just-in-time pop-up when users type in sensitive queries in the search bar. If automatic sensitivity detection proves difficult, or a search engine would prefer to give users a choice over what contexts they consider sensitive, the system could provide a toggle for easily allowing or disallowing data collection during a search session.

Customization for minimizing data based on type, quantity, and length of storage. Our results reveal that users have considerations about not only the sensitivity of the collected data but also how much data and for how long it is retained. To enable developers to implement a design that minimizes data collection and offers personalized search results, we suggest implementing a profile configuration on the system settings page or the search page. Customizable options might include a list of search query types and topics, or an indicator of how long users are willing to retain the search data. For the latter, the options could include: no data retained, all data retained, or a selected duration, such as data from last week, month, or year. As user's preferences towards data minimization could change over time, this design could prompt users to update their configuration at regular time intervals. By providing users control over their data, search engines can address concerns about inadvertent data collection, and minimize data according to users' intent and expectations.

Data sharing incentives. Users in our study mentioned that certain web browsers incentivized them to share data in exchange for a small reward. While experts view this design as somewhat unrelated to the core goal of data minimization, there are certain similarities one can draw on when designing data minimization approaches. In decentralized data markets, models from game theory and value exchange have been effectively utilized to design incentives for companies and users, facilitating a fair trade of data while promoting user autonomy and self-sovereignty [9, 11]. The underlying concept is to create a collaborative space where users and companies can negotiate the usage of data, building trust and establishing a sense of ownership. This framework presents an opportunity for search engines (and other data-driven systems) to offer users a choice in the degree of data minimization they prefer.

7.3 Limitations

Our interview study has several limitations. Firstly, we used Prolific as our recruitment platform, which resulted in over 50% of participants holding bachelor's or graduate degrees [36, 58]. This may restrict the generalizability of our findings, as individuals with higher education levels might exhibit stricter preferences and expectations towards data protection implementations compared to participants with other educational backgrounds. Secondly, the majority of participants primarily relied on Google for their daily search engine use. Consequently, their perceptions and expectations regarding data minimization are largely influenced by their experiences with the Google search engine, and we cannot claim that our findings generalize to other settings.

7.4 Future Work

Our results suggest that some users begin to replace traditional search engines with AI tools, such as Gemini and ChatGPT. Future work could explore users' privacy concerns with generative AI tools, how data minimization can be implemented in those contexts, or whether data minimization considerations for traditional search engines directly translate to generative AI usage.

8 Conclusion

Our study sheds light on users' perceptions, experiences, and needs regarding data minimization in search engines. Our findings surface different user needs for data minimization depending on the type of search engine, data type, and various contextual factors. We propose several expert-assessed conceptual designs for user-centered data minimization in search engines based on our interviews. Users prioritize transparency and interactive alerts to guide them in data minimization and expect fine-grained data minimization controls in practice. Overall, this paper is the first to propose a user-driven interpretation of data minimization, highlighting the opportunity and need to involve end users as stakeholders in data protection implementations.

Abstract

Today most websites in the EU present users with a consent banner asking about the use of cookies or other tracking technologies. Data Protection Authorities (DPAs) need to ensure that users can express their true preferences when faced with these banners, while simultaneously satisfying the EU GDPR requirements. To address the needs of the French DPA, we conducted an online experiment among 3,947 participants in France exploring the impact of six different consent banner designs on the outcome of users' consent decision. We also assessed participants' knowledge and privacy preferences, as well as satisfaction with the banners. In contrast with previous results, we found that a "bright pattern" that highlights the decline option has a substantial effect on users' decisions. We also find that two new designs based on behavioral levers have the strongest effect on the outcome of the consent decision, and participants' satisfaction with the banners. Finally, our study provides novel evidence that the effect of design persists in a short time frame: designs can significantly affect users' future choices, even when faced with neutral banners.

1 Introduction

Today almost any website in the EU presents the user with a consent banner asking about the use of cookies or other tracking technologies. While the EU ePrivacy Directive [29][1] requires a legally valid consent before reading or writing of cookies and use of other tracking technologies, the EU General Data Protection Regulation (GDPR) [66] has set high-level requirements for such consent to be valid, leaving website owners a lot of margin to design consent banners.

Although consent banners are a mean massively adopted by the industry to collect such legally-required consent, in practice, their usage raises numerous issues from both a regulatory and a behavioral stand-point.

From a regulatory perspective, EU Data Protection Authorities that are in charge of enforcing the GDPR and – for some of them – ePrivacy, help websites to comply by providing high-level guidelines and practical recommendations. The French Data Protection Authority (CNIL) has recently updated its guidelines [13] and recommendations [14] regarding the use of cookies and other tracking technologies, and consent banner interfaces. While providing more concrete recommendations, regulators still need to ensure that *users can reflect their true preferences in the banner interface*, thus making "freely given, specific, informed and unambiguous indication of the data subject's wishes", requested by the GDPR [66, Art.4]. However, no definite proof exists today that consent banners (even in their recommended format) allow users to express their true preferences.

From a behavioral perspective, multiple studies observe a high level of discrepancy between users' preferences and their decisions. This can largely be attributed to the "choice architecture" - the environment and form in which choices are presented [65]. Recent research shows [43] that small alterations in the choice architecture can have substantial effects on decision making. In the digital environment, such intentional alterations are commonly referred to as "dark patterns" or "deceptive design", a term that refers to any practices that direct, deceive, coerce, or manipulate users into making choices that are often not in their best interest [10, 37]. A recent study by the European Commission [22] demonstrated that deceptive design is particularly common on EU websites and mobile apps. Dark patterns have also been found in consent banners of numerous websites in recent research [53, 54, 62].

The concept of "dark patterns" has lately gathered interest, appearing recently in the Digital Services Act [26], the Digital Markets Act [25] and the Data Act proposal [24] published by the EU. Similarly, the European Data Protection Board (EDPB) has recently released guidance on dark patterns in

‡The work was carried out while Estelle Harry was a designer at the LINC lab of the CNIL before May 2023.

[1] ePrivacy Directive was last amended in 2009 (ePD) and is known among computer scientists and website developers as "cookie law". The upgrade of the ePD into an ePrivacy Regulation is currently under discussion.

social media [27]. These advances have again increased and confirmed the demand from regulators – not just DPAs – for rigorous evidence on the impact of such practices on users.

The evaluation of the impact of dark patterns on users' decisions when facing consent banners is a very active research effort [4, 39, 40, 52, 54, 68]. However, studies differ in their number of participants, context of the experiment, and targeted population, providing different results for the same type of consent banners[2]. Additionally, Grassl et al. [39] found a consent rate for UK users of 94% when exposed to dark patterns and 53% when they are exposed to an alternative design, called "bright" patterns. This suggests that users who have been continuously exposed to dark patterns might have already developed the habit of accepting, and exposing them to "bright patterns" might change their behavior. This hypothesis, however, has not been rigorously tested so far.

While these studies offer important insights to regulators, consultations with experts from the CNIL, that participated to this project, have revealed that these studies may not be specific enough to be used in guidelines or to inform policy makers about the effect of banner design, because they may test slightly different designs and be performed on non-French population. This is especially the case when no consensus in prior studies has been found on the effect of dark (and bright) patterns. To be used in a legal document, the result of a study on cookie banners should not be subject to legal uncertainty.

In the context of this research, conducted as a *partnership between CNIL and external researchers*, the services of CNIL asked a French public agency to perform a large scale study on French population to evaluate the impact of cookie banners design on consent rates. This study aims to enlighten CNIL's legally-binding decisions and recommendations related to cookie banners. Our study therefore aims, not only to contribute to the active literature on the impact of dark patterns on user decisions, but also to directly address the requirements and needs of the services of CNIL , which has fined several companies on the topic [15, 20]. Our overarching goal is to *study the factors that could prevent users from expressing their true privacy preference when faced with a consent banner, and to propose levers allowing them to express their true choice*. More specifically, we conducted a controlled online experiment with 3,947 participants in France to answer the following research questions:

- **RQ1:** What is the state of knowledge of users about cookies and tracking technologies, and their general preferences on data sharing online?
- **RQ2:** What is the impact of dark pattern design on the outcome of users' consent decision in France?
- **RQ3:** Can new designs based on behavioral levers allow users to make consent choices closer to their intention?
- **RQ4:** Does the effect of dark patterns and behavioral levers on user consent decision persist over time, even in the absence of these design patterns?

To answer these questions, and based on a close guidance from the services of CNIL, we have designed six variants of a consent banner (§3). We then conducted a between-subjects online experiment with 3,947 participants in France to test the impact of these design variants (§4). By analysing participants' interactions with the banners and survey responses, we evaluate users' knowledge and preferences for data sharing, the impact of banner design on users' consent decisions, as well as user sentiment and satisfaction. Finally, we discover that banners design can significantly affect users choices in a short-term (§5). We then discuss our findings and their implications (§6).

2 Background and related work

2.1 EU legal requirements on consent and the power of Data Protection Authorities

GDPR and ePrivacy directive. The EU ePrivacy directive first published in 2002 was amended in 2009 [29]. The regulation of cookies, and subsequently of consent banners, comes from Article 5.3 of ePrivacy which specifies that "storing of information, or the gaining of access to information already stored, in the terminal equipment of a subscriber or user is only allowed on condition that the subscriber or user concerned has given his or her consent [..]". The validity of consent is evaluated according to the Directive 95/46/EC, which has been superseded by the EU General Data Protection Regulation (GDPR) that came in force in May 2018 [66]. According to the GDPR, "'consent' of the data subject means any freely given, specific, informed and unambiguous indication of the data subject's wishes" [66, Art.4]. Unlike the GDPR, ePrivacy is not subject to the one-stop-shop[3] and hence every ePrivacy national regulator (in France, the Data Protection Authority) is competent to build a case where it finds local non-compliance with Art.5.3 of the ePrivacy directive.

Non-binding: recommendations, EDPB guidelines. In order to clarify what is expected for a consent to be valid, the EDPB has published guidelines on consent [30]. To provide more legal certainty, DPAs can publish guidelines on how to comply with a given regulation. These guidelines cannot proscribe practices that are non-compliant: instead, to limit legal uncertainty, guidelines list examples and practices of how to comply with the regulation. However, such guidelines are non-binding: it is possible to comply with a regulation

[2] Studies range from 40 [54] to 2,000 [68] participants per banner, and were done with German and Austrian [33, 52, 68], Danish [2], UK [39], and US [40, 51, 54] participants. For example, in a neutral banner with identical "accept" and "decline" buttons, 72% of German participants decide to accept [68], while only 60% of US participants do so [40].

[3] It's a mechanism which defines the lead authority as the authority in which the EU headquarters of the company are established.

without following them. In France, the CNIL recommendations [14] contain two examples of consent banners that are considered compliant. In practice, there are many types of consent banners that differ from these examples and yet are compliant with the regulation.

Binding: case law. Jurisprudence is built on previous cases that have been published, and therefore has a relatively narrow scope compared to recommendations that attempt to cover many cases. However, unlike recommendations, jurisprudence is legally-binding. For example, recent jurisprudence in France indicates that consent banners must offer an option to reject cookies on the first layer [16, 17].

2.2 Impact of design on consent decisions

Even though the regulation is aimed at empowering users to make choices that reflect their true preferences, multiple studies observe a high level of discrepancy between users' preferences and their decisions. Kulyk et al. [48] demonstrate that users click "accept" in consent banners despite having concerns over data collection. Utz et al. [68], Borberg et al. [7] and Habib et al. [40] explored reasons why users accept consent and found reasons such as decision fatigue, being in a rush, thinking that consent is required for the website functionality or simply to dismiss the consent interface.

Starting with the EU Commission reportin 2016 [69], various research studies then aimed at evaluating the impact of consent banner design on users decisions. Utz et al. [68] measured users' decisions on four types of banners, as well as variations of those banners incorporating "nudges" towards acceptance. They also found that 48% of users believe that clicking "decline" on a neutral banner would block or break the website. Nouwens et al. [54] have explicitly evaluated the effect of dark patterns in consent banners: they found that moving "decline all" button to the second layer of the banner increased the probability of acceptance by 23 percentage points. Machuletz et al. [52] analysed how visualisation and control over purposes, as well as dark patterns, can impact user decisions. Bermejo Fernandez et al. [4] found that color-based nudging bars that visualise the amount of accepted cookie purposes can significantly impact the participants' decisions to change the default cookie settings. Grassl et al. [39] were the first to measure the effect of "bright patterns" on users' consent decisions and found that placing the decline option on the second layer and pre-selecting a decline option substantially influenced users' consent decisions.

Bielova et al. [6] compared 17 guidelines of EU DPAs and the EDPB and 11 consent-focused user studies and found out that the guidelines and user studies rarely impact each other: their analysis yielded 11 gaps, 5 insights and only 3 consistencies [6]. Singh et al. [60] studied which consent banners users would prefer if they could choose and identified five key design factors which impacted participants' liking/disliking of consent notice UI designs: ease of use, amount of information, customisability, decision-making time, and clarity/transparency.

3 Selecting design parameters

Recently, CNIL has made a chain of repressive actions against websites with consent banners that do not lead to a valid consent[4]. When looking to select design parameters to be included in our experiment, we looked beyond the current state of knowledge at the needs of regulatory authorities building such cases. Indeed, the primary goal of this study was to ensure that our learnings could be actioned by DPAs. We designed the study specifically to inform policy-making in France: the types of dark banners match some banners that appear on French websites, and the study was conducted with French participants. The outputs of this study could therefore enlighten the French regulators and policy makers when defining future guidelines on cookie banners or to inform future discussions on the design of cookie banners and its significant impact on consent rate.

Recommended consent design. The CNIL's latest guidelines [13] require that "the expression of the user's refusal must [..] be able to be translated by an action presenting the same degree of simplicity as the one allowing to express his consent". While further interpreting the ePrivacy Directive [29] in light of the notion of consent under the GDPR [66, Art.4], CNIL strongly recommends that the mechanism allowing to express a refusal to consent to read and/or write operations[5] should be accessible *on the same screen and with the same ease* as the mechanism allowing to express consent [14, par. 31]. Additionally, CNIL provides a concrete example of a recommended consent banner, where "accept all" and "decline all" buttons are presented in visually identical ways [14, par. 34]. We therefore adopt the design recommended by the CNIL as a control banner to compare users decisions in other banners against it. The LINC, CNIL's innovation Lab, has also recently analyzed the related works on the impact of cookie banner design [50] and identified that prior works [4, 33, 40, 52] do not compare the tested designs against a control banner – we hence do not compare our methods and results to these works.

3.1 Selecting dark patterns

A number of exchanges with employees of the CNIL allowed us to identify further design parameters that may prevent users from expressing their true preferences, and provide robust evidence of the impact of these dark patterns on users' behavior in France (**RQ2**).

[4] Over the last two years, several companies have for example been sanctioned by the CNIL for making it more difficult to refuse cookies than accepting them [16–19].

[5] That is, to read, set or send cookies or use other tracking technologies in the browser.

3.1.1 Unequal path to decline

Our first consent design with dark pattern, called "unequal path to decline", allows users to decline only on the second layer of the banner, accessible under "customize my choices" option. Beyond the fact that such design is not recommended by the CNIL, it has been considered a violation of the regulation since "several clicks are required to refuse all cookies, against a single one to accept them." [17].

No large-scale study reached conclusions. Even though ten studies have measured the effect of dark patterns in consent banners between 2020 and 2022 [50], only two of them [39, 54] have evaluated the effect of a consent banner design with "unequal path to decline" with respect to the control banner and reached different conclusions[6]. Nouwens et al. [54] have tested banners with 40 US students and reported a statistically significant difference in the outcome of consent decisions (45% refusal rate for control banner vs 23% for "unequal path" banner, $p < 0.001$). Grassl et al. [39], based on behavior of 228 UK users, have reported that no statistically significant difference was observed among two banners. Therefore, no study up to now have reached a confirmation on the effect of such banners on a large population, and no study was conducted with French users.

Dark patterns. First, this consent design presents a configuration barrier that directs users towards acceptance of consent [36]: it contains an *Obstruction* dark pattern, because it hides the option to decline behind the "customize my choices" link [62], and according to the EDPB guidelines [27], such design contains *Longer than necessary*[7] pattern that requires more steps for the users to choose a more privacy-friendly option. It also includes *Interface Interference*, *Manipulating Visual Choice Architecture* and a low-level pattern of *False Hierarchy* [38] since the option to accept is highly visible, while the option to decline is hidden behind a less visible "customize my choices" link.

Interest of the services of the CNIL. Since there are only two peer-review comprehensive academic studies that evaluate this particular design of consent banner, and that none was large-scale and done exclusively with the French population, CNIL employees have expressed interest in including this banner design.

3.1.2 Visual aid: weighted-accept

Even when placing both accept and decline buttons together on the banner's first layer, websites still implement other dark patterns, for example by highlighting the accept button, making it more visually prominent.

No significant impact according to previous research. Three academic studies have analyzed users' reactions upon interacting with such a banner design. Utz et al. [68] found that around 79% of German users click "accept all" on this type of design, while 72% users do so on the control banner with equally shown accept and decline buttons, however authors did not provide any testing for statistical significance of this finding. Grassl et al. [39] experimented with 228 UK users and did not find any statistically significant difference in consent decisions between users interacting with this type of banner versus a neutral banner. Berens et al. [3, Table 8] also did not find any statistically significant difference between such types of banners. Therefore, no studies found support for difference in users behavior.

Dark patterns. This design pattern presents a configuration barrier that directs users towards acceptance of consent [36]. It therefore includes a dark pattern called *Manipulating Visual Choice Architecture* [38], where privacy-unfriendly user choices are perceived more salient and prioritized. This design implements a dark pattern called *False Hierarchy* [37] giving users a more visual precedence over "accept all" button than "decline all" button. From the recent EDPB guidelines [27], such design contains a dark pattern called *Look over here*, where "action or information is put in competition with another element" and thus nudges users using visual style.

Interest of the services of the CNIL. While CNIL recommends [14] that accept and decline options should be accessible on the same screen and with the same ease, the regulator does not have further requirements on concrete design and colors of the buttons. As a result, CNIL's employees expressed interest in testing this type of design in the experiment - the results of the study could help CNIL to update its recommendations in the future.

3.2 Selecting behavioral levers

CNIL employees have also expressed interest, by collaborating with behavioral and social scientists (co-authors of this paper), in experimenting with banner designs that are not explicitly mentioned in their recommendations yet, but could help users to express their true privacy preferences (**RQ3**). To do that, we reviewed the prior works on privacy [1, 12, 40, 64], and the broader literature on decision-making [23, 46, 47, 59].

The review first aimed to identify the most likely barriers to users making informed choices, which were grouped into two key barriers:

1. Users still lack knowledge on cookies. The literature [44, 56, 61] indeed showed that despite the presence of information on some cookie banners, internet users have limited knowledge about cookies and their purposes. This is exacerbated by the fact that they are not helped by cookie banners that are often unclear (including legal jargon, long

[6] We exclude the study of Utz et al. [68] because even though the authors included the banner with no decline option on the first layer, their banner did not provide the second layer to decline all trackers, and therefore all users who interacted with this banner have clicked "accept all", and thus is incomparable to our banner design. Bouma-Sims et al. [8] in 2023 included a similar design (options-link banner in Fig.18), however did not report on comparing it to the banner with equally presented "accept" and "decline".

[7] This dark pattern is called "Adding Steps" in the latest ontology of Gray et al. [38].

sentences, etc.), as well as information that is often partial or even biased, framed to highlight benefits of cookies without mentioning potential costs to the user [58].

2. Users lack motivation to actively make informed consent choices. This lack of motivation is linked to a desire for speed above all, which leads to the development of mental shortcuts, and cost-benefits calculations (e.g. instant access to the site vs. data protection) which in the short-run often favour the sharing of information.

As a second step, we used both the behavioural literature and design principles to identify levers that could help lift these barriers. As a result, we proposed 18 potential design solutions such as simplifying the text, using heuristics, or changing the choice architecture and the display of buttons to make refusing easier or more desirable (a full list can be found in the Supplemental Materials [5, Appendix C]). To select behavioral levers for our experiment, we organised a workshop with 7 participants, including four CNIL agents (a lawyer with expertise on sanctions, a design expert, a law and technology expert, and a computer scientist), and three additional experts outside the CNIL (a behavioral economist, an online experimentation expert, and an expert in cognitive neuroscience).

During the workshop, all participants ranked 18 behavioural levers based on two criteria: potential impact and implementation feasibility. To evaluate a lever's *potential impact*, we asked participants to reflect on the following questions: (1) What proportion of users would this reach? Is it adapted to a specific population of users or all of them? (2) What is the expected effect of the design on refusal rate? (3) Could this backfire and lead to negative outcomes such as prevent people from making an informed choice?

To evaluate the *implementation feasibility* of the 18 levers and design changes, we asked the participants : (1) Could the CNIL potentially recommend this type of design? (2) Are there any judicial considerations and implications that don't allow this type of banner? (3) Could this design be easily scalable to all consent banners if it improved informed consent? With these questions in mind, each participant had to give a score of potential impact and implementation feasibility, from 1 (low) to 3 (high) for each lever.

Using the results of this voting system (presented in Supplemental Materials [5, Appendix C]), we selected three behavioral levers to be included in the banners: (1) Highlight consequences of their choice; (2) Pre-select "Refuse all"; (3) Use visual aids that can be used as heuristics. We further discuss each of the levers in the rest of this section.

3.2.1 Highlight consequences of choice

Behavioral Lever. The first lever seeks to emphasize the negative consequences of acceptance and to remind users that they are consenting to the use of trackers. This design aims to re-balance the little importance Web users give to future risks, sometimes overshadowed by a need for speed. This lever also aims to create an element of surprise, which would provoke reflection and allow to interrupt the acquired habit of mechanically clicking on "accept all".

Interest of the services of the CNIL. This lever has been particularly supported by CNIL agents as it makes visible, in the act of selecting an option, the consequences of the choices. CNIL guidelines on consent [13, par.24], CNIL recommendations [14, par.8], and GDPR require that for consent to be valid, users should be informed of the *consequences of their choices*.

Previous work suggests users may be impacted by the text on banners' buttons. Habib et al. [40, Section 4.4.1] were the first to compare generic text labels on buttons ("accept" and "decline") with specific ("accept all" and "necessary-only") labels and found no significant impact on users consent decisions. Berens et al. [3, Table 9] also found no statistically significant differences between the different text labels placed on decline button. Finally, Ma and Birrell [51, Table 1] tested five combinations of specific texts placed on accept and decline buttons (using positive/negative slant that refers to the utility of cookies and positive/negative framing about benefits or harms of the choice) - the authors found a statistically significant impact of some of the button text on users' consent decisions. As a result, we decided to test such behavioral lever by emphasizing the consequences of choice within the text of the accept and decline buttons and specifically included the consequences of being tracked in the button's text labels, which has not been evaluated in previous works.

3.2.2 Visual aid: weighted-decline

Behavioral Lever. The second lever functions as a "mirror" to the *weighted-accept* dark pattern described above, this time visually emphasizing rejection rather than acceptance. This lever aims to tap into users' tendency to favor pre-selected options [46], but this time seeking to counterbalance acceptance habits developed over time. This "mirror" implementation allows us to compare the effect of the same design feature (the pre-selection of an option), but used for a different purpose.

No significant impact according to previous works. Grassl et al. [39] first evaluated the impact on the users' consent decisions of *bright patterns*, where the design nudges are reversed towards the privacy-friendly option. A test on 255 UK users of a design where the decline option is more visually prominent showed no support for the hypothesis that such design has a substantial effect on the user consent decision. Berens et al. [3, Table 8] have further studied the impact of visual representation of "highlighted-reject" with 100 users per banner, and, similarly to Grassl et al., found no statistically significant difference between "highlighted-reject" and control banner. We include this behavioral lever in our study with a large sample of French users to re-evaluate the impact of such design on users decisions.

Table 1: List of design parameters, possible implementations for each, and the corresponding dark patterns or behavioral levers.

Design Parameter	Possible Implementations	Dark patterns (DP) / Behavioral levers (BL)
Path to decline	*equal* (accept and decline on 1st layer)	-
	unequal (decline is only accessible on the 2nd layer)	DP: Obstruction [62], Interface Interference [37], Longer than necessary [32]
Text within button options	*generic* ("Accept all" and "Decline all")	-
	consequences-of-choice ("Accept to be tracked" and "Continue without being tracked")	BL: Element of surprise, negative consequences of acceptance
Visual aid in button layout	*neutral* (accept and decline buttons are shown with identical neutral color, equal shape and size)	-
	weighted-accept (accept button is more visually prominent than decline)	DP: Aesthetic Manipulation [37], False hierarchy [37], Hidden in Plain Sight [32]
	weighted-decline (decline is more visually prominent - opposite to weighted-accept)	BL: Tendency to favor pre-selected options
	traffic-light (highlight buttons in the colors of traffic light and use other familiar pictograms)	BL: Familiar visual metaphors and pictograms

3.2.3 Visual aid: traffic lights

Behavioral Lever. The third lever selected during the workshop is based on visual aids. It uses "traffic light" colours as well as other familiar visual metaphors (shield, attention sign) to link refusal, in users' minds, to a recommended, safer option, which is equivalent to a higher data protection. This design relies on the finding that when making choices, especially when they are made in an environment with a lot of information and in a context where users are goal-oriented and have little time (all characteristics of online choices), users tend to use mental shortcuts (heuristics), to get to a decision quicker and preserve their mental bandwidth [67].

This is why users can tend to click on highlighted options (see "weighted decline" in Section 3.2.2), but is also a trait of user decision-making that could be used to try and direct behaviour towards the refusal of cookies, which the user might then implicitly perceive as the "safer" or "green" option.

Previous work has shown support for this type of heuristics in another context. Egelman et al. [28] showed that coloured bars illustrating the complexity of a password encouraged users to create more complex ones. Nevertheless, such design has never been tested previously in the context of consent banners.

3.3 Designing consent banners

Following the methodology set out in Habib et al. [40, Table 3][8], we have identified three key design parameters of consent banner interfaces, which we vary to implement the dark patterns and behavioral levers: the nature of the path to decline (equal or unequal), the text within the button options, and the presence (or not) of visual aid in the button layout. The *control banner* is without dark patterns or behavioral levers, and shows both "Accept All" and "Decline All" buttons in an identical style and size, following CNIL recommendations [14]. A summary of the chosen design parameters, as well as their implementations with dark patterns and behavioral levers is shown in Table 1. Table 2 provides an overview of the six variants of consent banners created: one *control* banner, 2 *dark patters* banners, and 3 *behavioral levers* banners (all banners are provided in Appendix B).

Table 2: Overview of the six consent banners design variants and their values for the design parameters in our experiment. Design choices that differ from *Control* banner, are bolded.

Banner name	*Path to decline*	*Text within button options*	*Visual aid*
Control	equal	generic	neutral
No decline	**unequal**	generic	neutral
Highlighted accept	equal	generic	**weighted-accept**
Highlighted decline	equal	generic	**weighted-decline**
Consequences	equal	**consequences of choice**	neutral
Tricolor	equal	generic	**traffic light**

In order to isolate the effect of the design from that of the text, the main text in the banners remained fixed on all six banners. The text used was developed on the basis of the current CNIL recommendations [14] and made as short and simple as possible, following key insights from efficient communications. The text has been further reviewed by the three experts of the CNIL to be as clear as possible, compliant

[8] Differently from Habib et al., we map implementations of each parameter to the corresponding dark patterns and behavioral levers that we have identified.

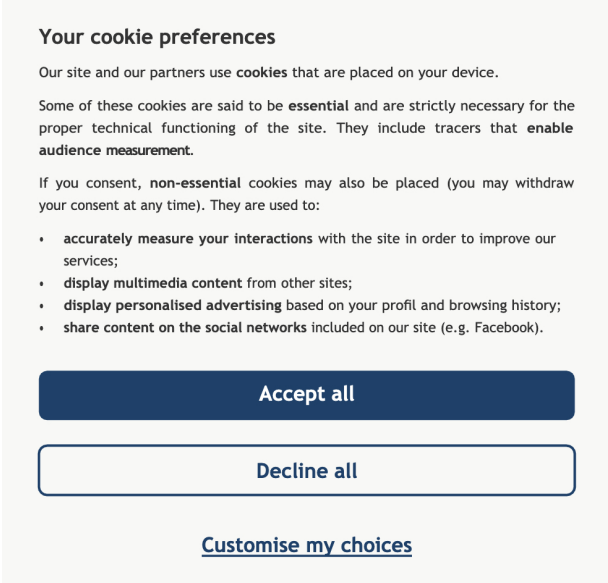

Figure 1: *Highlighted accept* banner included in the online experiment (English translation).

with the current recommendations and not to present partial or biased information[9].

Defining minimal contrast levels. To choose the concrete design for accept and decline buttons, we were guided by the following reasoning. The European Data Protection Board (EDPB) has recently published the result of the joint Task Force on consent banners, where the practices of "deceptive button colours" and "deceptive button contrast" were examined [31]. The board concludes that one practice could be manifestly misleading for users, when the decline button is such that "the contrast between the text and the button background is so minimal that the text is unreadable to virtually any user.". The requirement for accessible contrast level between the text and the button background can be identified using W3C Web Content Accessibility Guidelines (WCAG) [70].

Accept and decline with equal contrast levels. However, during our discussions with CNIL employees, we have identified a specific case often used on the French websites, when the contrast ratio between the text and the button background is the same for accept and decline buttons, however their colors are "reversed", thus making the accept button more visibly prominent than the decline button. We have used this idea while designing *Highlighted accept* and *Highlighted decline* banners. For illustration, Figure 1 shows the English translation of *Highlighted accept* banner designed for this experiment.

[9]We have designed the second layer of the banner following CNIL recommendations [14] - this layer has also been reviewed by two CNIL employees and can be found in Appendix B.

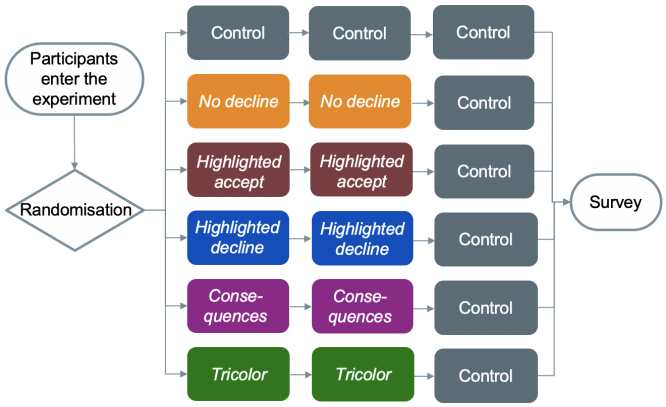

Figure 2: User journey through the online experiment.

4 User study design

To investigate the impact of the selected dark patterns and behavioral levers on user decision-making, we conducted a large-scale online between-subjects user study with the total of 3,947 participants, so that on average 657 participants have interacted with each banner (see Figure 2).

4.1 Experimental protocol

User journey through the online experiment. To provide the settings as realistic as possible, and building on previous consent banner studies that used e-commerce websites [40, 68], we asked participants to visit three fictitious e-commerce websites that sold respectively vinyl decks, a coffee machine, and a bluetooth speaker. These websites were built based on e-commerce templates, and had been tested during previous experiments. To mitigate biases linked to the simulated environment, we told participants that these were "real live websites" and asked them to find specific information on each website (e.g. the colour of the product, the battery life)[10]. To replicate as closely as possible the "goal-oriented" mindset of an individual navigating a website, we incentivized correct answers to the task by entering participants in a draw for a 10€ gift voucher. Upon opening the webpage, a consent banner popped up, probing a choice from them.

Figure 2 shows the user journey through the online experiment[11]. Participants were randomly assigned to one of the six groups corresponding to the six banner variants described in Table 2. On the first two websites they visited, participants saw the banner that corresponded to their treatment group. On the third website, they all saw the *Control* banner. This last step allowed us to test whether the effect of the designs have persisted in a short-term (**RQ4**). Once the three websites

[10]Screenshots of the website and the task can be found in Supplemental Materials [5, Appendix B] .

[11]We designed the experiments so that participants would be able to read and interact with it both on desktop and mobile.

were reviewed, participants had to fill in a survey to evaluate their knowledge about cookies, their opinion on data sharing, and their satisfaction with the cookie banners they saw.

Outcomes of interest. First, we record participants' choice to accept, decline or personalize on the first treatment banner. For the purposes of this study, we create a binary variable, called *the rate of refusal/personalization*, which is equal to 1 if a user chooses to refuse or personalize cookies, and 0 otherwise. Second, we record the time spent to make a decision on the first consent banner, measured in seconds. Third, we record participants' choice to accept, decline or personalize on the third control banner. We similarly compute a rate of refusal/personalization on the third banner.

The survey (provided in Appendix A) at the end of the study allowed us to collect additional outcomes about the level of knowledge and understanding of cookies and attitudes towards data sharing online (**RQ1**). Participants were finally asked to revise the first consent banner they had interacted with, to express their overall sentiments towards this banner, and to say whether they would like to reconsider the choice they had initially made (which was reminded to them).

4.1.1 Ethical considerations

Though the authors' organizations do not have a formalized ethical review process like IRB, our organizations and the CNIL separately reviewed the design and did not identify any high-risk ethical issues. No other personal data than demographics was collected via the panel provider, and the three fictitious websites did not include any cookies or tracking technologies that require user consent. Via the panel provider, participants gave an informed consent for the data collected.

Participants were not informed ahead of time of the true intent of this experiment, but thought that they were taking part in a market research study, as it is common on the survey panel they have subscribed to. Indeed, the experimental protocol described above relies on collecting data on online behavior - which informing participants that we were researching the impact of consent banner design would have likely biased.

Upon entering the last section of the survey, participants were explicitly told the intention of the study and how the data provided by them would be used. Similarly, participants were only told at the end of the study that it was run in collaboration with a DPA. Participants were, upon finishing the experiment, provided with an email address they could reach out to if they had any question or concern about the study.

This study design was deemed acceptable given that the risks incurred by participants were evaluated as minor (especially as they correspond to behaviour adopted online every day), and given that participants were fully informed at the end of the study.

4.2 Participant Recruitment

Recruitment protocol. This large scale randomised controlled experiment was conducted online from September 22 to October 5, 2022 on a platform called Predictiv [55], created and managed by the Behavioural Insights Team to run online experiments. Participants were recruited via Cint, a panel supplier the co-authors of this paper use often.

Description of the sample. Participants over 18 years old and living in France were eligible to participate. To ensure representativeness, we used quotas on age, gender, and education based on official statistics published by the French National Institute of Statistics and Economic studies (INSEE) [45]. Quotas indicate the maximum percentages, not minimum percentages of participants being able to fill in the survey. Although the point of quotas is to control the proportion of specific groups that complete the survey, reaching the target quotas is not always guaranteed as it depends on the availability of participants in the marketplace. In order to keep participants who were paying attention, we included as a very first question an attention check question simply asking participants to click on two specific answers. If they didn't click on the two stated answers, they were considered as people not reading the question and therefore not paying attention.

4,026 participants passed the attention test and completed the experiment[12]. However, data on demographics was missing for 79 individuals, leaving us with 3,947 participants for multivariate analysis using covariates. Supplemental Materials [5, Appendix D] provide user demographics. The experiment lasted on average 6 minutes 55 seconds and participants were remunerated $0.68, which is close to the average remuneration for surveys on this type of marketing survey aggregators [63][13].They also had the opportunity to enter a draw for a 10€ gift voucher if they correctly answered questions about the websites reviewed. As described above, this was mainly used to ensure realistic interactions with the websites[14].

[12]We tested attention using questions, at the start of the study, requiring individuals to read a relatively long question and then provide specific answers given in the instructions. Those failing this test were excluded. We limited non-interaction with the websites: (a) participants could only progress if they made a choice in the cookie banner; (b) for each website, participants had to respond to simple questions by searching for information within the website.

[13]Our study was run to mimic a usual marketing study, and the remuneration rate was provided by our panel aggregator. The estimate takes into account the market (what do other surveys and online experiments pay for studies of similar length), length of completion, whether the sample is hard to reach, and length of time the study runs. Similarly to remarks in other studies in the field [41, Section 3.3], and according to our panel provider, these amounts are in line with the industry standards. We recognize that this compensation is relatively lower than what was given by previous academic studies conducted on crowdsourcing platforms, which remunerated participants .18 to .33 USD/minute, compared to our .11 USD/minute [39, 40].

[14]Before launching the experiment, we ran a pilot study with 40 participants to make sure that reviewing three websites would not lead to too much attrition. Seeing that attrition remained at expected levels through the pilot study, we chose to maintain the experimental design as described above, thus allowing us to explore the effect of designs over time.

4.3 Analytical strategy

Power calculations. Power calculations on the primary outcome (the rate of refusal or personalization) were used to calculate the minimum detectable effect for pair-wise comparisons between banners. We used the STATA function *power twoproportions* and corrected for multiple comparisons by using the Benjamini-Hochberg method. Assuming a Type I error of p<0.05, 80% power, a 14% baseline rate of refusal/personalization[15], a total of 6 banner variants and a sample size of 4000 participants, the study was powered to detect effects greater than 6.43 percentage point, or a "treated" rate of refusal/personalization of 20.43%.

Data Analysis. We performed three types of statistical analysis. To test for the banners' effect on the rate of refusal/personalization on the first and third exposition, we used multivariate logistic regressions on (among other covariates) indicator variables for random treatment assignment. We used the logistic regression model shown in Eq. 1, where i is a participant; Y_i^1 is a binary variable indicating whether users have refused/personalized cookies on the first banner they saw; T_i is a vector of binary variables indicating which treatment arm participants belong to; Ψ_i is a vector of covariates including age, gender, education level and employment status.

$$Y_i^1 - Bernouilli(p_i); logit(p_i) = \alpha + \beta' T_i + \Gamma' \Psi_i \quad (1)$$

To test for the impact on time spent on banners, we used multivariate ordinary least square regressions of time spent on, again, treatment assignment[16] using Eq. 2, where i is a participant; Y_i^1 is a continuous variable indicating how much time participants spent on the first banner they saw (in seconds); T_i is a vector of binary variables indicating which treatment arm participants belong to; Ψ_i is a vector of covariates including age, gender, education level and employment status; ε_i^1 is the error term.

$$Y_i^1 = \alpha + \beta' T_i + \Gamma' \Psi_i + \varepsilon_i^1 \quad (2)$$

To analyse survey answers, we displayed frequencies and used univariate regressions of a series of outcomes on indicators for treatment assignment, using each time the highest value as excluded category[17]. We used logistic regressions if survey responses were binary, and OLS if responses were continuous. In our reporting of findings, we highlight statistical differences by putting a star (*) next to values that are statistically different (with p<0.05) to the highest value, which is systematically used as reference category in all regressions.

[15] This baseline proportion was taken from results of a study on a similar Control banner by Utz et al. [68].

[16] For these analyses, the variable for "time spent" was winsorized at the top (1%) to deal with outliers, which realistically resulted from participants leaving their computer and coming back to the experiment later.

[17] This strategy was chosen so that interpretations could always highlight the highest value and whether it significantly differs from other treatment conditions.

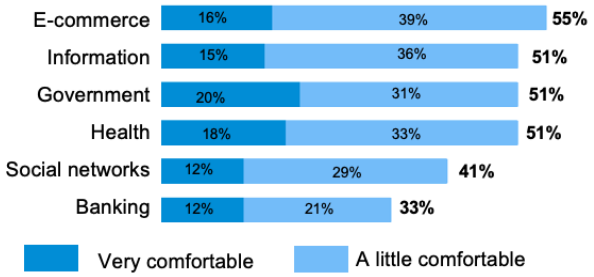

Figure 3: Comfort level of the participants with the idea of accepting all cookies, by type of website visited (N=4,026).

5 Results

5.1 Survey: users knowledge and preferences

User survey after interaction with three websites allowed us to address **RQ1** about users' knowledge about cookies and tracking technologies, and their general preferences on data sharing online[18].

General views on data sharing. The results of our survey establish a *baseline for users' preferences* in our experiment: More than half of participants (52%) reported being comfortable sharing their data on the internet, even without knowing exactly what it is being used for or how it is being used and for what purpose. Conversely, less than one third (31%) say they are not comfortable sharing their data in any way. Therefore, at least 31% of internet users should refuse the use of cookies, regardless of banner design (if they understand the association between giving consent and data sharing). Designs that allow users to make a choice reflecting their preferences may encourage between 31% and 48% of users to refuse or personalize their consent. We have found that comfort with data sharing does not vary by age or education level of participants.

Types of data users accept to share. When asked about the specific data they are comfortable sharing, three-quarters (74%) of participants say they are somewhat or very comfortable sharing data about products purchased in the past (which is collected through cookies and other tracking technologies). However, only 46% say they are comfortable with sharing their browsing history (with only 15% saying they are very comfortable), a piece of data which is also collected by trackers. These results, taken together, show that users' views on data sharing are nuanced, and can depend on the type of data collected.

Impact of the type of website on comfort with accepting cookies. Kulyk et al. [49] have found that users' decisions about leaving a website are largely impacted by the trustworthiness, familiarity, and perceived importance of its contents to the user. Borberg et al. [7] found, however, that users' decision to consent to data sharing did not seem dependent on the

[18] Results for all survey questions can be found in the Supplemental Materials [5, Appendix E]

type of website. Our survey suggests the opposite: we find that participants report being more comfortable with accepting all cookies on e-commerce, government, health or information sites and less comfortable on social networks or banking sites (see Figure 3.).

Data collected via cookies. Although many participants in our study know that browsing history and past purchases are data collected via cookies (62% and 58% respectively), others believe that data about geolocation, social network, postal address or phone number are also collected via cookies (57%, 36%, 30% and 29% respectively).

Purposes of data collection via cookies. Similarly, participants do not fully understand the purposes for which cookies and other trackers collect data. While 61% of participants know that cookies are used to personalize ads, only 48% of participants know that the data collected can also be sold to other companies, despite this being common practice today. Even fewer participants are aware that the data collected can also be used to adapt prices and promotions presented (29%), information that could nonetheless factor into consumers' decisions. One third of participants (36%) think that the use of cookies can have beneficial functions on their user experience and only 17% know that cookies can be used to enforce the security of websites. Finally, while 74% know that cookies track what users do online, misconceptions persist – 15% of participants believe that cookies can collect data while listening to what users are saying.

5.2 Impact of design on consent decisions

We analyze the decisions of 3,947 users upon interacting with our six consent banners to address research questions **RQ2** and **RQ3** on the impact of banner design on users' decisions. We use data on time spent on banners, as well as user sentiment reported in the survey from Section 5.1, to enrich our interpretation of the data[19].

Figure 4 shows participants' consent decisions upon interacting with the consent banner on the first website they were asked to visit, by treatment condition (or in other words, by consent banner seen)[20]. Faced with a banner that presents options in a neutral way (*Control*), 17% of participants refuse or personalize the use of cookies. This is quite far from the expected 31% of users who said they were uncomfortable sharing their data under any circumstances (see Section 5.1), and reinforces the consensus view that recommending neutral banners might not be sufficient[21].

[19]The results for all regression variables can be found in Supplemental Materials [5, Appendix F]

[20]The figures above the bars represent the sum of the refusal and personalization rates. These do not correspond precisely to the sum of the figures displayed in the bars of the graph due to rounding.

[21]We also looked at these main results separately for mobile/desktop. Supplemental Materials [5, Appendix G] shows that rejection rates are overall lower on mobile, which is in line with previous literature (see for example [68]. The effects of the banners are, however, qualitatively the same across both interfaces.

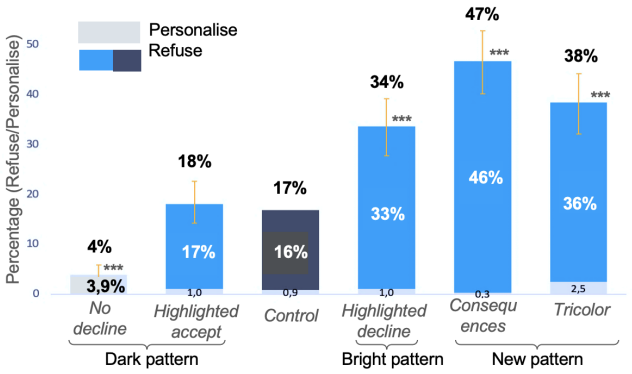

Figure 4: Participants' reported consent decisions (N=3,947) in their interactions with the consent banners during the visit to the first website: three stars (***) indicate $p < 0.001$, and orange bars correspond to the 95% confidence interval. Primary analysis using logistic regression, controlling for age, gender, education, and employment status of participants.

5.2.1 Impact of dark patterns on consent decisions

No decline banner. The refusal/personalization rate drops from 17% on a neutral banner to 4% ([95% CI, 2.5%-5.9%], $p = 0.000$) when users need to visit the second layer of the banner to decline consent. This statistically significant difference contradicts the previous results of Grassl et al. [39] that found no impact of such design on users' decisions. Moreover, our result complements the initial result of Nouwens et al. [54], who evaluated it with 40 US students and found that refusal rate dropped by 50% between the two banners (see § 3.1.1). With 657 French participants per banner, our study provides a new robust insight to the research community that was not demonstrated at large-scale in the past. This result highlights the potential detrimental effects of this design. Our result provides support for ongoing efforts by regulatory authorities to combat the use of *No decline* banner which make it harder for users to act in accordance with their preferences.

Highlighted accept banner. This banner, that visually emphasizes acceptance, has no statistically significant effect on users' consent decision compared to a control banner (18% [95% CI, 14.2%-22.6%], $p = 0.566$), confirming the results of Grassl et al. [39] and Berens et al. [3], but this time in a large-scale study and with French participants (see Section 3.1.2). This lack of difference between the control banner and the *Highlighted accept* banner suggests that individuals may have already developed the habit of accepting; highlighting or not highlighting this option does very little to sway their already habituated behaviour as their mental shortcuts are already in place. Indeed, when we asked participants why they accepted the use of cookies, 50% said they did so out of habit.

5.2.2 Impact of behavioral levers on consent decisions

Highlighted decline banner The bright pattern *Highlighted decline* banner has a substantial effect on the outcome of the consent decision (34% [95% CI, 27.7%-39.2%], $p = 0.000$), doubling the refusal/personalization rate compared to the control banner (from 17% in control banner to 34% in highlighted decline). This new result is opposite to the previous findings of Grassl et al. [39] and Berens et al. [3], who have found no support for the hypothesis that such design impacts users' decisions (see Section 3.2.2). This result could be explained by users' tendency to accept the pre-selected option, which requires less cognitive effort and which users tend to think has been selected for them according to their interests [46]. It is also possible that highlighting rejection could create shock, or dissonance among users who are used to seeing acceptance highlighted as the recommended choice. This dissonance could then encourage them to question the habit of accepting and to rethink their choice.

Consequences banner. This banner, that highlights the negative consequences of data sharing through strong evocative words ("tracking"), has the biggest effect on the outcome of the consent decision (47% [95% CI, 40.2%-52.9%], $p = 0.000$) and increases the refusal rate by as much as three times (from 16% for neutral banner to 46% for consequences banner). In contrast to the findings of Habib et al. [40] and Berens et al. [3], who found no statistically significant impact of button text labels on user decisions (see Section 3.2.1), our finding demonstrates a clear impact of button text labels. This result supports the findings of Ma and Birrell [51], who found that the negative slant (similar to our text labels)[22] have a significant impact on users compared to the positive slant. However Ma and Birrell didn't compare it to the neutral labels, and the sample of users who interacted with the banners was very small (up to 67 users per banner) while our experiment contained 657 participants per banner.

When surveyed, 71% of participants who saw this banner said they declined consent "in order not to be tracked", which was the highest number of participants to decline consent for this reason amongst all groups. This suggests that the negative consequences of tracking were more prominent in their minds when making the choice, thus re-balancing the importance that users place on future risks, which are sometimes overshadowed by a desire for speed.

Tricolor banner. Similarly, the *Tricolor banner* also sought to highlight the negative impacts of data sharing, by using familiar visual metaphors (traffic lights, shield icons). The use of these metaphors also had a large and significant effect (38% [95% CI, 32.1%-44.2%], $p = 0.000$): those who saw this banner were 2.3 times more likely to click refuse / personalize than those who saw the control banner. Such banners have never been tested in the previous works and our result provides a new insight to the research community (see Section 3.2.3).

Summary. We conclude that all the three behavioral levers introduced in the banners have substantial effect on the outcome of consent decision. The refusal/personalization rates are close to what we would have seen if participants had made choices aligned with their initially reported preferences (see Section 5.1): between 31% and 48% of participants said they wanted to refuse to share their data or do so depending on the how exactly their data will be used – these numbers that are close to the 34% to 47% of users choosing to refuse or personalize after seeing the banners with behavioral levers.

5.3 Time spent and user satisfaction

We have analyzed the time spent on the banners, as well as user preferences over banners by measuring the level of satisfaction users report with their choices, the level of understanding and simplicity of navigation on the banner, the feeling of protection, and the general satisfaction with the banner (Appendix A). We used these criteria to evaluate how design banners would be perceived by users, and how they would make them feel as they entered a website. Table 3 shows the time spent to make decisions as well as users' satisfaction with the banner they interacted with and the choice they made[23].

Time spent interacting with the banner. Participants spent an average of 4.1 seconds on a *Control* banner, consistent with prior research [68]. Duration remained steady with dark patterns, but for *Consequences* and *Tricolor* users took more time, possibly due to surprise or reflection. "Time spent" on banners can serve as a proxy for effort and thinking in decision-making contexts, as longer duration often indicate increased cognitive engagement, complex decision-making, and information processing. The strongest dark pattern significantly prolonged consent decline time (up to 17 seconds), highlighting the importance of placing both options on the same layer.

User sentiment towards consent banner patterns. According to survey responses, participants who saw the *Consequences* and *Tricolor* banners were more likely to be satisfied with the banner they saw and with their choice, potentially illustrating a "wish for privacy" granted (see Table 3). Conversely, those who saw the *No reject* dark patterns banner were less likely to be satisfied, confirming that the more pernicious dark patterns do not allow users to make a choice that reflects their data protection preferences.

Finally, although the two new pattern banners, *Consequences* and *Tricolor*, appear to be the most successful at

[22] The authors used a negative slant attempt to nudge users: "[such banners] present user with a choice between accepting cookies – which poses privacy risks by allowing a website to access and sell personal information – and denying cookies to prevent this harm". Our text labels highlighting the acceptance or refusal of being tracked are similar to such slants.

[23] One star indicates that this value is significantly different from the highest value at least to the 5% level. In the first row, the control banner and the two dark pattern banners are the banners that have a significantly different rate of refusal/personalization from the banner "Consequence". As these analyses were done with univariate regression, all 4,026 participants are included.

Table 3: Participants' reported time spent and overall satisfaction with the banner they interacted with and the choice they made.

	Control	*No decline*	*Highlighted accept*	*Highlighted decline*	*Consequences*	*Tricolor*
Time spend on first banner (seconds)	4.1*	4.0*	3.8*	4.2*	5.7	5.7
Simplicity level (ease of navigation and understanding)	81%*	79%*	84%	86%	86%	86%
Satisfaction with the banner (wish to see more banners like this one)	78%*	72%*	82%	81%	82%	84%
Satisfied with the choice	54%*	44%*	55%*	58%*	64%	64%

impacting refusal/personalization rates, those who saw the banner emphasizing being tracked (*Consequences*) were less likely to think that the choices were presented with their interests in mind. This could ultimately affect the trust in the information provided, or lead individuals to avoid this information altogether if it is perceived as too "negative", thus making this banner design less desirable overall [34].

User satisfaction with the choice made. After reminding participants of the choice they had made when faced with the first consent banner, we asked them to reflect whether they were satisfied with their choice. Our analyses reveal that people who declined tended to be more satisfied by their choice: 78% of those who declined were satisfied, while only 48% of those who had accepted were satisfied. When faced with a neutral banner, only 54% of participants said they were satisfied with their choice. The proportion of satisfied users decreases by 10 points for the most extreme dark pattern *No reject* banner (44%), confirming the need to discourage this type of banner. Conversely, this proportion increases by 10 points (64%) for the banners where the refusal/personalization rate was the highest (*Consequences* and *Tricolor*).

In addition to being less satisfied on average, more individuals who saw the control banner or those with dark patterns also indicated that they did not care about their choice, potentially suggesting a sense of resignation, which has already been highlighted in qualitative studies [7]. This resignation could suggest decision fatigue, whereby users would prefer not to question their habits and may tend to avoid the information presented. It might therefore be important to encourage more unusual banners, containing motifs that encourage reflection.

5.4 The short-term time effect of design

We explored whether dark patterns and behavioral levers have a short-term effect on future user consent decisions (**RQ4**). To test this hypothesis, we asked participants to interact with three different consent banners on three websites (Figure 2). This protocol allowed us to explore, by studying the choice made on the third control banner, whether the short-term effect of the dark patterns or behavioral levers persists.

To select the number of exposures seen before measuring the refusal/personalization rate, we balanced the need to measure several repeated choices, with the risk of creating fatigue in participants and increasing the dropout rate of the experiment. Previous work suggests that one to two exposures to a dialogue window are sufficient to create a habitual response [9]. We therefore opted for two exposures, before testing the survival of the effect on a third one. The frequency of exposure to consent banners when surfing the internet, however, means this type of choice setup can also realistically be found in the real world. The effects measured here will, nevertheless, likely remain measures of the upper-bound of survival effects given how shortly after they are measured.

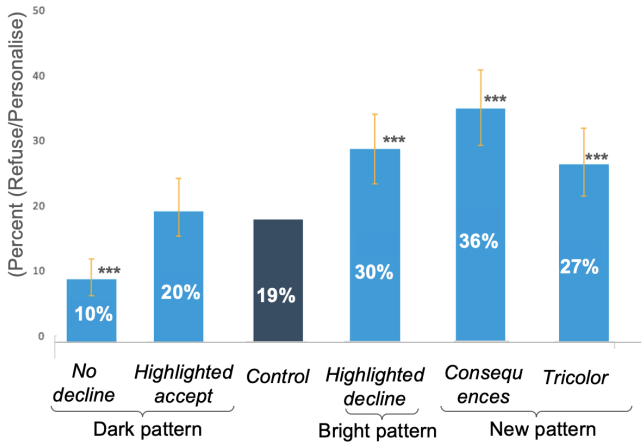

Figure 5: Participants' reported consent decisions (N=3,947) on upon visiting the third website with *Control* banner.

Figure 5 shows the refusal/personalization rates upon third exposure to the *Control* banner[24]. Unsurprisingly, the refusal/customization rate on the *Control* banner does not vary between the first and third exposure (17% for the first and 19% for the third) and this rate also does not vary on the *Highlighted accept* banner. After seeing two *No reject* banners, the rate of refusal/personalization is significantly lower than that of participants who saw *Control* banners only: in this group only 10% ([95% CI, 7.2%-13.8%], p=0.000) of participants refused/personalized. This suggests that the short-term effect

[24]These are the results of a logistic regression, controlling for age, gender, level of education and employment status of individuals.

of *No reject* dark pattern can survive, likely because the repeated exposure has created a habit around always accepting all cookies, reinforced by the fact that accepting all has always allowed access to the content wanted.

We have observed a survival effect after two consequent exposures to the banners with behavioral levers. Among participants who first saw two *Highlighted decline* banners, rate of refusal/personalization was significantly higher (30% [95% CI, 24.3%-35.0%], p=0.000), compared to participants who only saw *Control* banners. This was also the case among participants who first saw the *Consequences* banners (36% [95% CI, 30.1%-41.8%], p=0.000) or *Tricolor* banners (27% [95% CI, 22.5%-32.9%], p=0.000). Taken together, these results provide the first quantitative evidence that banners designs significantly affect users choices in a short-term.

6 Discussion

6.1 Limitations

Our study has a few limitations. Our participants were compensated to perform a controlled experiment which, despite our best efforts, remains distinct to the usual setting in which internet users are confronted with consent banners. Indeed, the usual exposure to consent banners comes in a setting where participants have goal-oriented behaviors (looking for an information, trying to purchase a product etc.) and where attentional limitations might modulate the effects we observe.

Another noteworthy aspect is that our experiment involved interactions with only three specific e-commerce websites. While this approach enables controlled testing, it may limit the external validity of our findings. While using e-commerce prototype websites is commonly used in research literature on consent banners [8,40,68], it doesn't capture the full spectrum of online user experiences. Nevertheless, our survey shows that users' willingness to accept cookies on an e-commerce website (55%, see Figure 3) is similar to the overall attitude to data sharing (52%, Section 5.1) thus demonstrating that e-commerce websites are suitable, in the context of this experiment, for the internal validity of the study.

Despite our efforts to try and replicate the conditions of real online behaviors, our results might not generalize to all types of banners or contexts. Moreover, participants in a controlled study may be inclined to answer what they think the researchers want to hear (participant's bias), especially on sentiment and satisfaction questions. We therefore potentially overestimate true satisfaction and preferences. This, however, does not affect the internal validity of our results.

We have also compared various results with prior works on the impact of design on consent decisions (Section 5.2). Few works with greater external validity covered *Nodecline* and *Highlighted accept*, however often on a very small user base [54] and outside of France [68], while recent research shows that user choices differ across countries [8, 41].

6.2 Insights on knowledge and preferences

Impact of the type of websites. The effect of website type on consent decisions is relatively understudied [7]. Our findings show that data sharing preferences vary depending on the sites visited (Section 5.1), and thus potentially on the purposes for which the collected data will be used. Future studies should explore how comfort levels vary across site types to inform regulatory decisions and guidelines.

Given widely spread misconceptions about cookies and tracking technologies, it is important that, at a minimum, consent banners provide clear information to users. However, the nature, design and frequency of consent banners limit the ability of individuals to engage in a thoughtful consideration of what they are or are not willing to share at the time the question is asked. This raises the question of the type of message that could be conveyed, or the type of awareness-raising action that could be carried out beyond simply changing the design of the cookie banners.

Support for alternative solutions to cookie banners. There exist browser extensions or solutions built-in Web browsers that can ask users to set their preferences once, and then automatically refuse or accept consent based on those preferences. For example, recent Global Privacy Control (GPC) [71] or its extension Advanced Data Protection Control (ADPC) could offer such potential solutions (even though they still face a number of challenges) [42]. Asking users to make only one choice per browser could, indeed, allow the time to better inform and encourage users to pay attention to their consent choices. When asked whether they would be interested in solutions like these, a majority of respondents to our survey (62%) said they would be willing to use this type of solution, and only 9% said they would definitely not be interested.

6.3 Design implications

Impact of dark patterns on consent decisions Our results for *No decline* banner (Section 5.2.1) confirm the impact of users' preference for speed and for paths with the least amount of friction. It's therefore essential for regulators across the EU to discourage and sanction designs that require more effort to refuse than to accept, following the example CNIL's recommendation [14] that is now supported with quantifiable result thanks to our findings. We, however, did not observe a significant effect of *Highlighted accept*, likely due to already existing habits of user to accept. We therefore believe it is important to reflect on the research methods that is based using the *Control* banner as baseline. Similarly to previous research on online decisions, we found that users express different preferences when asked, or when they interact with *Control* banners: 31% of users do not agree with data sharing online when asked in the survey (Section 5.1), while only 17% decline when facing a neutral banner interface (Section 5.2), that could have been caused by the long-term effect of banner

design. We therefore recommend to evaluate the design of consent banners not only against users' decisions in *Control* banners (that are likely impacted by the banners seen in the past) but also against users' true privacy preferences.

Need to further quantify the long-term effect of design patterns. We found that users' choices in consent banners are impacted by the designs of banners they interacted with in the past, even over a short time-frame (Section 5.4). Given that users have been continuously exposed to dark patterns in consent banners manipulating them towards acceptance in the last years [53, 54, 62], our finding can explain the "stickiness" of accept as an option. Our result opens many windows of opportunities for future research to investigate and quantify the habituation effects of design patterns in the long-term. Regulatory authorities could also benefit from our result: in the same way than bad habits can be reinforced, that good habits could be introduced, only by encouraging repeated exposure to "better design" that can be encouraged by the regulators.

Need for legally-required built-in solutions. Only half of the participants (54%) in our survey say they are satisfied with their choices after having seen a control banner. This satisfaction rate is even lower after having seen banners containing dark patterns (see Table 3). Banners containing behavioral levers generate a higher number of satisfied users. Nevertheless, it is important to note that almost a third of the participants said that, even after having seen the consent banners with behavioral levers, they were dissatisfied or not very concerned by the choice they made. This suggests a need to continue working on solutions that allow for a more informed choice or require less effort on a daily basis, such as browser built-in solutions. In the US, the California Consumer Protection Act (CCPA) requires online businesses to offer consumers methods to submit requests to opt-out of the sale of their personal information, that could be implemented in the user's browser via Global Privacy Control(GPC) [35]. In the EU, the update of ePrivacy directive [29] into a regulation could provide a similar legal requirement in the future, however this new law has not been finalised [21].

Recommendations and call for action. A strategy to amend the situation where users do not select their desired data sharing option in the neutral banner interface could include various actors in the ecosystem. *Regulators* could target most popular platforms in their enforcement actions: the more popular websites present explicit decline button, the faster the effect of "stickiness" of accept will weaken. Additionally, *developers and practitioners* of companies, who put privacy and ethics at the core of their business values, could be motivated to provide best practices and exemplary banners. For example, the French TarteAuCitron banner provider [11], which is used by many French administration websites whose websites are not monetized by ads, could be motivated to provide them a banner with behavioral lever design, where users consent choices are similar to their willingness to share data according to our results in Section 5.2.2. Nevertheless, as highlighted in previous works [36, 57], various actors in this ecosystem often have conflicting goals, making it difficult to motivate all practitioners. Finally, we encourage *researchers* to collaborate more closely with the regulators and practitioners to study their motivations and interests in improving consent banner design, and understand which other types of designs can be important to study in the future work.

Acknowledgments

This work has been partially supported by the ANR JCJC project PrivaWeb (ANR-18-CE39-0008), by the ANR 22-PECY-0002 IPOP project of the Cybersecurity PEPR, and by the Interministerial directorate for public transformation (DITP) as part of a framework agreement on which the Behavioural Insights Team was a supplier (tender no 001-2018-DITP).

7 Conclusions

At the request of the French DPA, we conducted a 3,947-participant online experiment in France exploring the impact of six distinct consent banner designs on the users' consent decisions. We also measured participants' knowledge of cookies and privacy preferences, as well as satisfaction with the banners included in the experiment. In line with previous studies, we confirm that dark patterns that make rejecting cookies unrealistically hard strongly impact consent and satisfaction, and that dark patterns that highlight the accept option do not impact choices compared to a neutral banner. This suggests that users might have developed a habit of accepting, despite this not being in line with their true privacy preferences. Contrary to previous results, we however find that a bright pattern that highlights the decline option has a substantial effect on users decisions (up to doubling the rate of refusal). We also tested two new designs based on insights from behavioral sciences. The banners including behavioral levers have the strongest effect on consent decisions. Moreover, participants were the most satisfied when interacting with these banners. Finally, we provide the first evidence, to our knowledge, that the effect of banners designs persists over a short time frame, and can significantly affect future consent choices, even when faced with neutral banners.

Taken together, these results strongly reinforce the need for regulation around the most extreme dark patterns (such as the ones where the option to reject is on a second page), but also offer some hope : by including them in their guidelines and encouraging exposure to bright patterns or to banners including behavioral levers, data protection authorities have an opportunity to break the habit to systematically accept cookies, and offer a realistic path for users to express their true privacy preferences.

A Survey questions

We designed our survey in French to be easily accessible for French speakers. Here we present English translation of the survey, made by the authors. For each question, the possible responses are shown in *italics*. The results of all survey questions are presented in the Supplemental Materials [5, Appendix E].

Introduction to the subject of cookies These retail sites also value the privacy of their users and seek to create cookie banners that comply with GDPR requirements and allow users to make informed choices about cookie banners. We will therefore ask you questions about this in the rest of the survey.

Q1 Please read the three descriptions below. Select the one that best describes what you think.
* *I am comfortable sharing my data on the internet, even without knowing exactly how it is being used*
* *I am only comfortable sharing my data if I know how it is being used*
* *I am not comfortable sharing my data at all*

Q2 How comfortable are you with sharing the following data? *Browsing history / Products purchased in the past / Bank data / Postal address / Telephone number / Geolocation / Emails sent and received / Contacts / Information shared on your social networks*
[Possible answers for **Q2**: Not at all comfortable / Not really comfortable / Somewhat comfortable / Very comfortable] [Order of responses was randomized per each participant]

Recall and reasons for users' choices
Q3 On the cookies banner of the last site visited, you have: *Accepted / Declined / Customised your choices / I don't remember*

Q4 You saw three cookie banners overall, in your opinion, were they all the same? *Yes / No / I don't remember*

Q5 You chose to click "Decline all" on the first site when you saw the following banner. [A cookie banner is shown only to users who clicked "Decline all"] For what reasons did you click "Refuse all"? Tick all that apply [Random order of answers; multiple choice]
To avoid being followed or traced / Out of habit / Because it was the fastest option / Because the option to accept everything was not available / To avoid having personalised ads about this type of product / I clicked randomly / Other, please specify :

Q6 You chose to click "Accept all" on the first site when you saw the following banner. [A cookie banner is shown only to users who clicked "Accept all"] For what reasons did you click "Accept all"? Tick all that apply [Random order of answers; multiple choice]
Out of habit / Because it was the fastest option / Because the option to refuse everything was not available / To receive personalised advertisements about this type of product / For fear of not being able to access the site / I clicked randomly / Other, please specify :

Q7 You chose to customise cookies on the first site when you saw the following banner. [The cookie banner they saw in the first exercise is shown only to users who clicked "Customize"] For what reasons did you decide to personalise your choice? Check all that apply [Random order of answers; multiple choice]. *Out of habit / Because the option to refuse everything was not available / Because the option to accept everything was not available / To choose how my data will be used / I clicked randomly / Other, please specify :*

Q8 Are you satisfied with the choice you made on this cookie banner? [Shown to all] *Yes / No, I would have liked to refuse / No, I would have liked to accept / No, I would have liked to personalise my choices / I don't care, as long as the banner disappears*

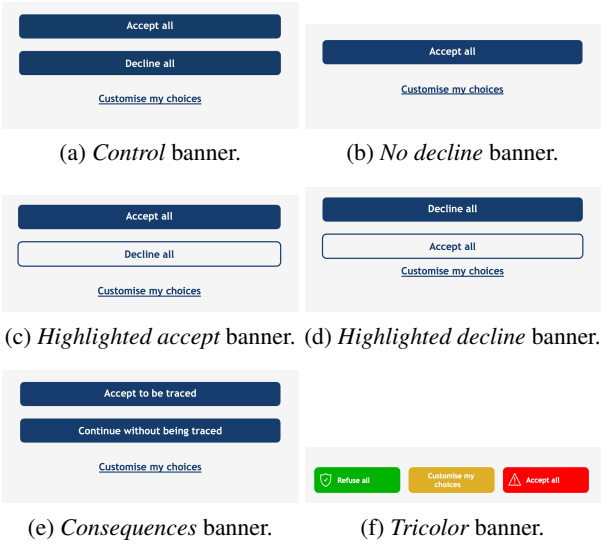
Q9 What do you think of the following statements about this cookie banner? [Strongly disagree / Somewhat disagree / Somewhat agree / Strongly agree] *Navigating the banner is simple / The information is easy to understand / The choices are presented to me with my interests in mind / The banner allows me to easily control the level of data protection / More*

sites should use this format for banner cookies

Questions on knowledge Finally, we will ask you some questions about your general knowledge of cookie banners and data protection.

Q10 What data do you think can be collected if you accept cookies? *Tick all that apply* [Random order of answers, except the last two; multiple choice] *Browsing history / Products purchased in the past on the website visited / Bank data / Postal address / Telephone number / Geolocation / Emails sent and received / Contacts / Information shared on your social networks / None of the above / All of the above*

Q11 In your opinion, what are the sites' reasons for collecting data about you through cookies? (Tick all that apply) [Random order; multiple choice]. *To decide which ad to show me / To resell my data to other companies (third parties) / To improve my user experience on their sites (e.g. remembering my login details) / To allow me to view media content (e.g. YouTube video) on the sites I visit / To adjust the prices or promotions of the products I am looking for / To adapt the language and the display of the site to my geolocation / To report user data to government / To subscribe to their newsletter and send me marketing emails / To ensure security on the site I am visiting*



Q12 According to you, cookies collect data by : (Tick all that apply) [Random order of answers; multiple choice]. *Tracking what I do online (browsing history, services and products purchased) / Tracking information that I actively share (e.g. on social networks) / Listening to what I say through the microphones on my computer and phone / Collecting information that others have shared about me (e.g. on social networks)*

Opinions on alternative solutions

Q13 An extension to put on your browser could automatically refuse or accept cookies for you depending on the settings you select when you install it. Do you think you would use this type of extension to browse the internet if it existed? *Yes, most certainly / Yes, probably / I'm not sure / No, probably not / No, certainly not*

Q14 Last question!

Figure 6: Designs of the lowest part of the six consent banners, translated into English. A high-quality version of complete images of consent banners is included in Supplemental Materials [5, Appendix B].

(a) *Control* banner. (b) *No decline* banner.

(c) *Highlighted accept* banner. (d) *Highlighted decline* banner.

(e) *Consequences* banner. (f) *Tricolor* banner.

Cookies are small files stored on your device that have several uses, including:
* Memorise your login details with a merchant site,
* Save the content in your shopping cart
* Save the preferred display language and your country of connection
* Track what you browsing for statistical or advertising purposes in order to offer you personalised content
* Some of these uses are strictly necessary for the proper functioning of the site, others are used for commercial purposes.

Are you comfortable accepting all cookies (essential and non-essential) on the following sites? [Not at all comfortable / Not really comfortable / Somewhat comfortable / Very comfortable] [Random order of answers] *Banking sites / Health sites / Government sites / Online sales sites (shopping, clothing, concerts, transport) / Informational sites (Wikipedia, press, forums, etc.) / Social networks*

B Consent banners design variants

Figure 6 shows designs of the choice architecture (only the lowest part of the banners that differ across all six designs) for all banners in our experiment. The upper part (identical to all six designs) can be found in Figure 1.

Unpacking Privacy Labels: A Measurement and Developer Perspective on Google's Data Safety Section

Abstract

Google has mandated developers to use Data Safety Sections (DSS) to increase transparency in data collection and sharing practices. In this paper, we present a comprehensive analysis of Google's Data Safety Section (DSS) using both quantitative and qualitative methods. We conduct the first large-scale measurement study of DSS using apps from the Android Play store (n=1.1M). We find that there are internal inconsistencies within the reported practices. We also find trends of both over and under-reporting practices in the DSSs. Next, we conduct a longitudinal study of DSS to explore how the reported practices evolve and find that the developers are still adjusting their practices. To contextualize these findings, we communicate with the app developers to uncover the process they go through when working with DSS. We highlight the challenges faced and strategies developers employ for DSS submission and the factors contributing to changes in the DSS. Our research contributes valuable insights into the complexities of implementing and maintaining privacy labels, underlining the need for better resources, tools, and guidelines to aid developers. This understanding is crucial as the accuracy and reliability of privacy labels directly impact their effectiveness.

1 Introduction

Privacy policies have traditionally served as the primary method for conveying the privacy practices of a service to users. However, studies have demonstrated that privacy policies are often ineffective, mainly because users neglect them due to their length and vagueness [6, 13]. Introduced by Kelly et al. [19], privacy nutrition labels summarize the privacy practices of websites in a nutrition label format, making them easier to understand. Privacy labels have gained traction in the tech industry, with Google introducing Data Safety Sections (DSS) and Apple introducing Apple Privacy Labels (APL) for all new and updated apps on their app stores.

*Equal Contribution

Recently, researchers showed the utility of privacy labels for users, making privacy practices more accessible [34]. However, the utility of the privacy labels depends on the developers correctly filling out the forms. These forms should accurately reflect the developers' intentions regarding the privacy practices of their apps. Underreporting these practices can lead to inaccurate privacy labels, confusing and potentially instilling a false sense of security and privacy among users. Conversely, overreporting privacy practices can harm the developer by deterring users who will perceive the apps as less secure and private than they are.

Therefore, it is essential to investigate the developer's experience with reporting their practices via the privacy labels. Prior research has reported the responsiveness of developers in implementing Apple Privacy Labels and analyzed the data collection practices of apps according to these labels [2, 23]. Through small-scale studies, researchers have discovered that inaccurate APLs can exist due to the developer's knowledge gaps or resource limitations [22].

However, a considerable gap remains in comprehensively understanding the developer's interaction with privacy labels, particularly regarding Google's enforcement of data safety sections. This interaction includes determining intended privacy practices, overcoming platform challenges, accurately submitting privacy label forms, and updating them over time. Prior research has not accounted for this wide-ranging perspective. In this paper, we address this gap by focusing on Google's Data Safety Section, answering three key research questions:

RQ1: How do developers report their app privacy practices in Google's Data Safety Sections?

RQ2: How have these patterns of reporting practices evolved over the year following the implementation of DSS?

RQ3: What are the driving factors behind the changes in Google's DSS, the challenges, and the behaviors of app developers?

To answer these questions, we conduct a large-scale analysis of app privacy labels on the Google Play Store. We periodi-

cally scrape the Google Play Store to collect metadata, including permissions and DSS forms, for over 2M apps between June 2022 and May 2023. Subsequently, we communicate with 3,500 developers of these apps via emails to understand their decision-making process concerning privacy practices, the completion of DSS forms, and their subsequent updates. Our analysis of developers' responses helps answer the third research question by constructing an analytical framework to model their experience with DSS.

Our responses to the research questions offer new insights into Google's DSS:

- As of May 2023, privacy labels are only present for 46.8% of apps on the Google Play Store. Among those apps featuring DSS, we observe patterns of underreporting privacy practices, overreporting practices, and submitting inconsistent DSS forms.
- Our longitudinal analysis unveils a dynamic landscape for DSS, suggesting that developers are still refining their comprehension and implementation of DSS requirements. About 40% of the apps updated their DSS at least once over the past year, adding and removing high-level privacy practices and data categories.
- Our analysis of developers' responses indicates they confront challenges when aligning their intended practices with DSS forms. These challenges often lead them to prioritize successfully submitting DSS forms over accurately populating them.

Finally, based on our findings, we propose novel recommendations to enhance the developer experience with DSS. These recommendations include action points for platforms and regulators, such as better educational resources, multilingual support, form simplification, consistent feedback, improved support for third-party libraries, and mechanisms to solicit developer feedback. Lastly, we plan to release a large-scale dataset of the metadata for 1.14M Android apps spanning June 2022 to May 2023.

2 Background and Related Works

Privacy Nutrition Labels. Originally introduced by Kelley et al. [19, 20], privacy nutrition labels summarize the privacy practices of websites in a nutrition label format, making them easier to understand. They later designed the "Privacy Facts" display to allow the users to consider privacy while installing apps [21]. More recently, researchers proposed an Internet of Things (IoT) security and privacy label [9, 10] to surface privacy and security information about IoT devices to the users. Researchers have also studied the design and evaluation of privacy notices and labels [4, 7, 8, 11, 19–21, 26, 28].

In 2020, Apple adopted the privacy nutrition labels for the app store and mandated that app developers provide their

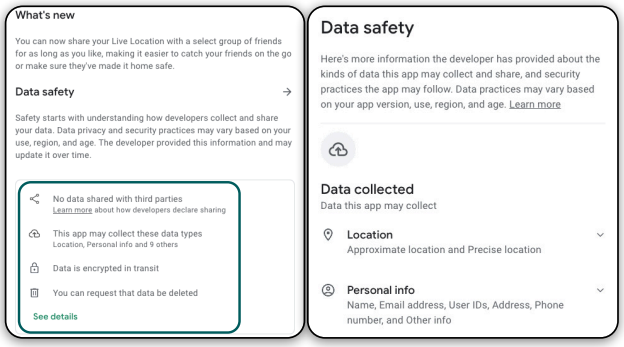

Figure 1: An example of the data safety section of an Android app.

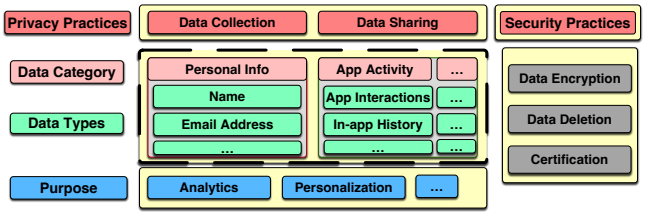

Figure 2: The hierarchy of the Google Data Safety Section showcasing the various layers and components.

apps' privacy information in the form of the Apple Privacy Label (APL). Later, in 2022, Google required developers to add a Data Safety Section (DSS) to the Google Play Store. Examples of Google's privacy labels are in Figure 1.

Google Data Safety Section The Data Safety Section (DSS) consists of four levels (Figure 2), where the first is high level *Privacy Practices*. The second and third levels consist of *Data Categories* and *Data Types*, and the fourth level consists of *Purpose*.

The first level includes three practices: *Data Collection*, which covers the details about the data that is collected and its intended use; *Data Sharing*, where the developers disclose what data is shared with third parties; and *Security Practices* that covers the data practices related to user choice and data security. *Security Practices* include three tags: *Encrypted in Transit*, *Data Deletion Option*, and *Review against Global Security Standards*.

In the second level, *Data Categories* includes 14 categories such as *App Info* and *Performance and App Activity*. Each *Data Category* can also have *Data Types*, which provide fine-grained information about the data used by the app. For example, *App Activity* includes *App Interactions and Installed App*, as shown in Figure 2. The final level of the Data Safety Section consists of *Purposes* that describe the reasons for collecting or sharing the data.

Google App Submission Review. Google reviews submitted apps to the Play Store to ensure their compliance with its

guidelines about design, content, and style [32]. As part of these guidelines, Google requires apps to comply with its data safety policies. In particular, all developers must specify the data collected and shared by their app, including the data handled by third-party libraries or SDKs [17].

To provide developers with better expectations towards the privacy criteria during the app review process, Google launched the *Checks* service. It allows developers to verify that their apps comply with the data safety policies before submitting the app for review [5]. The Data Monitoring feature of Google *Checks* monitors multiple channels of data collection and sharing, including with SDKs, via in-app permissions, and to external sites. The service provides developers evidence, such as permissions and network traffic, that the data safety form or the privacy policy is non-compliant.

Usability of Privacy Labels. Researchers have studied the usability of APLs from both users' [34] and developers' [22] perspectives. From the developers' perspective, Li et al. [22] interviewed 12 iOS developers and reported that developers err by under-reporting and over-reporting data collection in privacy labels. They further concluded that the label design is confusing for the developers either due to known factors (lack of resources, improper documentation) or unknown factors (preconceptions, knowledge gaps). Xiao et al. [33] characterize non-compliance of Apple privacy labels by studying data flow to label consistency of 5K iOS apps. They provide insights for improving label design based on their characterization. Researchers also built and evaluated a tool [12] that helps iOS developers generate privacy labels by identifying data flows through code analysis.

Studies on Privacy Labels. The works most similar to ours perform longitudinal measurement of privacy labels to understand the adoption and evolution of Apple privacy labels over time [2, 22, 29]. In particular, Scoccia et al. [29] conducted an empirical study of 17K apps to characterize how sensitive data is collected and shared for iOS apps. They found that free apps collect more sensitive data for tracking purposes. Li et al. [22] and Balash et al. [2] collected weekly snapshots of Apple privacy labels and characterized the privacy practices mentioned in privacy labels for 573k apps. Balash et al. [2] also perform additional correlation analysis with app meta-data like user rating, content rating, and app size.

Our Contributions. In this paper, we investigate the data safety sections of the apps listed on the Google Play Store, observing their evolution over the course of a year. Based on our measurement, we conduct a large-scale study by interacting with more than 3,500 Android app developers, using their apps as case studies. This analysis allows us to model the developers' engagement with the Data Safety Section ecosystem, gaining insight into their challenges, data practices, and the factors influencing their decision-making.

While prior works have explored challenges faced by iOS developers, it remains important to study Google's Data Safety Sections and challenges associated with them because APL and DSS cover different high level practices, as highlighted by Google [14]. Furthermore, this work reaches a broader audience, confirms prior works' findings and provide news insights into the life-cycle of updating the DSS. As such, our results complement prior works by showing that developers on the Apple and Google platforms share common problems when completing the DSS and APL. However, we go beyond prior work by substantiating the underreporting, over-reporting, and inconsistencies in data practices (Section 4); studying the evolution of DSS and practices that developers' report (Section 5); studying the process by which developers interact with the data safety sections; identifying strategies they use to bypass the review process; and revealing the factors that result in changes to the data safety sections over time (Section 6). Finally, we provide new recommendations based on our insights (Section 7).

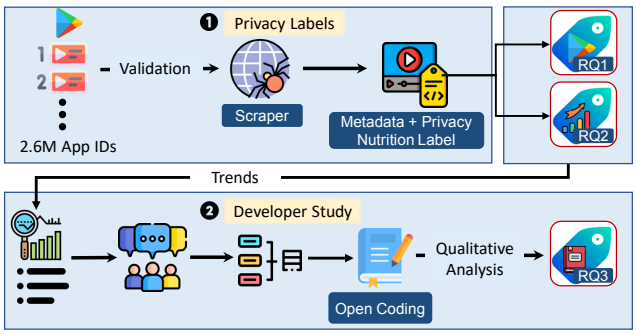

Figure 3: Our data measurement and analysis pipeline consists of scraping the DSS of Android apps to answer the first two research questions and interacting with app developers to answer the third research question.

3 Google Data Safety Dataset

We curate the Google Data Safety Dataset by scraping the metadata and privacy labels of the apps from Google Play. We contact the developers of some of these apps to understand their process of deciding on privacy practices, filling out the DSS form, and updating the DSS. We show an overview of the analysis pipeline in Figure 3.

Dataset Collection We took 10 snapshots of the Data Safety Sections for 2.46M apps present on the play store between June 20, 2022, and May 31, 2023. We captured eight weekly snapshots from June 20 to Aug 1 and three more snapshots on September 2022, November 2022, and May 2023. We chose to gather data more frequently around July 20, 2022, the date Google required app developers to complete the Data Safety Section. This allowed us to observe the developers' immediate response to this requirement. The additional three snapshots

enabled us to study the developers' long-term reactions. We refer to this dataset with 10 snapshots as the **DSS Dataset**.

We initiated data collection with the apk list provided by Androzoo [1]. This daily-updated list consists of Android app ids from various sources, including those from the Google Play store. We capture the metadata of each app, including its data safety sections, using the app IDs and a customized version of publicly available google play store scraper library `google-play-scraper` [18]. Across all the snapshots, we observed a total of 2.72M unique apps and 2.17M common apps. For the latest snapshot (May 2023), we retrieved metadata for 2.46M apps, which includes apps with very low download counts. To ensure that our statistical analysis is not skewed by these apps, we filter out apps that have fewer than 1000 downloads resulting in a total of 1.1M apps with 539k having privacy labels.

Dataset Statistics Our dataset shows that developers have been slow to add privacy labels to their apps, even after the hard deadlines have passed. Privacy labels are present only for 46.8% of the apps on the Google play store (as of May 31 2023). We also break down the DSS adoption rate according to app metadata, focusing on the apps' number of downloads, age rating, and pricing.

Number of Downloads: We examine the relationship of the DSS adoption rate and the number of app downloads. In particular, we categorize the apps based on their download numbers on a logarithmic scale, adhering to Google Play Store's binning methodology: (1000+, 5000+, ..., 5B+, 10B+). We measure the Spearman's correlation between the adoption rate and the downloads, which reveals a strong correlation with a correlation coefficient of 0.96 and the *p-value* of $7e{-}9$. Starting at 38.96% adoption rate of apps with 1000+ downloads, the adoption rate increases monotonically reaching 100% for apps with 10B+ downloads. This observation suggests that developers of highly downloaded apps tend to place more emphasis on the DSS, potentially due to access to greater resources and concern over public perception.

Age Rating: The Play Store categorizes apps based on age ratings, including Everyone, Teen, Mature 17+, and Everyone 10+.[1] We observed 51% of apps with the *Mature 17+* rating have a Data Safety Section (DSS), while the fraction of apps with a DSS in the other age ratings ranges from 45% (Everyone) to 54% (Everyone 10+).

App Pricing: We study the difference in practices based on whether the app is available for free, free with in-app purchases, or paid. We find that 65% of the paid apps, 59% of free with in-app purchases, and, for free apps, only 44% have DSS. We revisit this observation in the developer study where we highlight how developers report the privacy practices of Ad libraries in free apps.

[1] Google also has Adults 18+ rating, but we found less than 200 apps in this category and decided to filter it out for this analysis.

Ethical Considerations We collected data only from publicly available web pages and APIs. While our data collection scripts might load Google's servers, we were careful to not abuse these resources. In particular, we added back-off strategies in case of errors and waited for sufficient time before retrying for the failed cases.

4 Data Practices in Privacy Labels [RQ1]

We analyze the May 2023 snapshot of the DSS dataset to understand how developers report high-level privacy practices, data types, and purposes. Figure 4 depicts the percentage of apps reporting high-level privacy practices on DSS, with data encryption practices being the most reported. Figure 5 shows how app developers report collection and sharing for the different data categories. Developers report collecting *Location* and *Personal Information* at a higher rate than other data categories, primarily for *App functionality* and *Analytics*. They also report sharing *Location* and *Device Ids* more commonly for *Advertising or Marketing* purposes. The heatmap in Figure 2 (in Supplemental File[2]) provides a detailed breakdown of the declared purposes for collected and shared data types.

We also note that apps may declare sharing data without collecting it, as evident from Figure 5. This discrepancy arises from the definition of *Data Collection*, which covers developers retrieving user data from the device using the app [15]. Whereas *Data Sharing* denotes the cases when the data is transferred from the device to a third party. Thus, developers can share data without collecting it if their application employs third-party libraries that directly send data to their servers.

We further analyze this snapshot to understand how developers interact with the DSS forms. Our analysis reveals three key patterns: overreporting privacy practices, underreporting privacy practices, and submitting inconsistent practices.

Underreporting Practices: Analyzing Figure 4, we note that only 36% reported sharing at least one data type, suggesting that the majority of the apps on the play store do not report sharing data. This figure contrasts the findings from prior work [24, 31], which found that the majority of the apps use at least one third-party library collecting sensitive information [24]. We confirm this observation by analyzing the 15K most popular apps from our snapshot that report not sharing data with third parties. Specifically, we download the apk file from androzoo and use the LibRadar library [1, 25] to determine whether third-party libraries are used. Given an apk file, LibRadar [25] identifies the third-party libraries and tags them into categories like Advertisement, Analytics, etc.

Analyzing the apks, we find that 42% of the analyzed subset of apps used at least one third-party library for advertisement or analytics. This result clearly indicates that developers are

[2] https://osf.io/q3wv2?view_only=0b4aa040161a4b259c0a32c7fb3ae82c

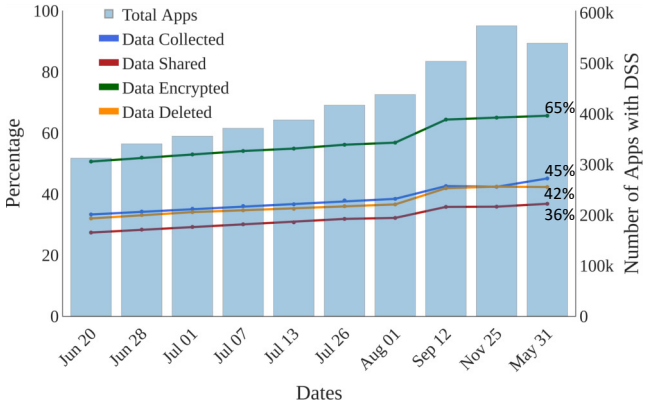

Figure 4: The evolution of Data Safety Section over the 10 snapshots in our dataset

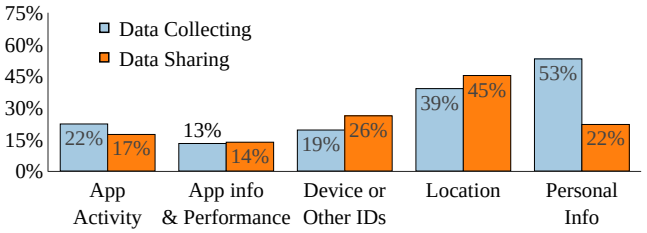

Figure 5: The distribution of Top-5 data categories for high-level practices

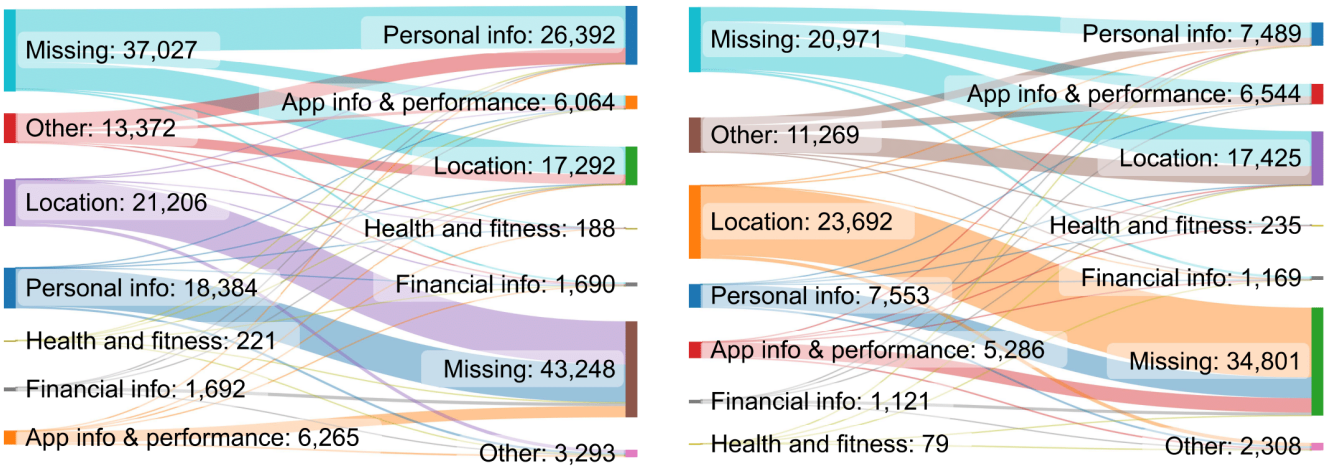
underreporting the sharing practices. One possible explanation is that the privacy practices of third-party libraries are often vague and developers find it hard to understand the collection and sharing practices of third-party libraries. We find evidence supporting this explanation in prior work [3, 22] and our developer study (Section 6).

Overreporting Practices: Analyzing the purposes for *Data Type* collection, we observe that many apps report a large number of purposes when listing datatypes. We note that out of the 7 possible purposes for collecting data, more than 3.5K apps list 6 or more purposes for every data type they collect, which may indicate that app developers list all purposes out of convenience. For example, *Workplace from Meta* with over 15M+ downloads, lists the same 6 purposes for all the data they collect, like access to *Installed Apps*, *SMS or MMS*, *Music Files*. We also note that while 3.5K is small compared to the dataset, it still has the potential to impact millions of users.

A possible explanation for this observation could be that app developers lack the knowledge required to fill the DSS and choose to select all options. Another possible reason is that they are unaware of the policies of the third-party applications that they use, and take a cautious approach by overreporting. Findings in prior work [22] and from our developer study (Section 6) align with this observation. Note that accurately determining the correctness of selected purposes is a challenging problem that is out-of-scope for this work. Our hypothesis for over-reporting stems from the observation that some apps select 6 purposes for all the data they collect. For example, the ARknet app (7K downloads) states that they collect Purchase History for Developer Communications, an unlikely data type for developer communications.

Inconsistent Practices: We observe the developers report practices that are inconsistent with other declared practices or with the app permissions. For example, we find that 40% of the apps state that they do not collect or share data, but encrypt the data in transit. We delved deeper into this observation by cross-verifying security practices with apps' network permission requests. 59% of apps do not request network permissions, yet state that they encrypt data in transit. It is not clear why apps need to encrypt transit data if they are not collecting or sharing data. We note that we only consider apps having the 'android.permission.INTERNET' permission as apps with network permissions. There may be other network permissions like 'android.permission.ACCESS_NETWORK_STATE,' which we do not count because this permission does not allow the app to access the internet. As *Encryption in transit* has important implications for privacy, we mark this trend and examine it in detail in our developer study in Section 6.



We also cross-verified the collected and shared data types from the DSS to the app permissions. Several apps report collecting or sharing several data types without even asking for the corresponding permissions. For example, 11.5% of the apps report collecting or sharing precise location data without obtaining location permissions. Another example is 23.7% of the apps report collecting or sharing files and documents without the "Photos/Media/Files" permissions.

In Section 6, we identify some of the reasons why developers provide inconsistent privacy labels. One reason is developers over-reporting their practices, as indicated above. Other reasons include developers choosing labels by mistake, misunderstanding the label definition, and not updating the labels after updating app features.

5 Evolution Of Data Safety Section [RQ2]

Next, we conduct a longitudinal analysis of the DSS dataset to understand how the data practices disclosed by developers evolved over time. As described in Section 3, our data collection spanned the timeframe before and after the hard deadline set by Google for app developers to comply with the new DSS requirements. This design allows us to understand not only the static state of app data safety disclosures at a given time point but also their evolution as developers navigated this significant policy change.

Looking at Figure 4, we observe that during the period spanning June 20, 2022 to May 31, 2023, the number of apps with DSS increased from 312K to 539K. The largest per-day change, of around 9K, happened between June 28, 2022, and July 1st, 2022. Interestingly, we find that from our initial

(a) Data Type evolution in Collection

(b) Data Type evolution in Sharing

Figure 6: Change in Data Categories between the first and the final snapshot for (a) Data Collection and (b) Data Sharing. The figure shows that at Data Category level, the reported practices change a lot, indicating that developers change the DSS frequently.

snapshot, 21% of apps removed their DSS over the course of our data collection. Specifically, 67K updated their play store page to remove the privacy label. For example, *Sport Prediction* with 1M app download had a DSS as of August 1, 2022, but did not have it by Nov 25, 2022.

Updates in DSS. We analyze the DSS dataset to understand the frequency of updates in DSS by comparing the first snapshot of the DSS for an app with subsequent snapshots. Figure 11 in Appendix A.1 shows the CDF of updates in DSS. We find that 40% (n=283K) of the apps updated their DSS at least once, while 4% (n=27K) updated it at least twice. Moreover, the frequency of updates is higher in the September and November snapshots. For example, *Adobe Acrobat Reader: Edit PDF*, with over 500M downloads, updated their DSS 3 times between Jun 20, 2022, and May 31, 2023. In Section 6, we discuss potential reasons for DSS changes. These reasons include app feature updates or the discovery of incorrect DSS.

Evolution of High-Level Practices. We also analyze the evolution of high-level practices present in the DSS. First, we observe a shift in data collection practices. 44K applications that initially reported collecting data have updated their DSS to state that they no longer collect data. Conversely, some apps (n=45K) that initially claimed not to collect data have revised their DSS, admitting to data collection.

We also observe similar trends in data-sharing practices. Several apps (n=42K) that initially reported sharing data with third parties later updated their DSS, indicating an end to such sharing. On the other hand, some apps (n=37K) that did not report data sharing in their initial DSS later added such practices. As changes in collection and sharing practices have implications on user privacy, we highlight these trends and analyze them in detail in our developer study in Section 6.

We observed a steady increase in the number of apps reporting *Encryption of Data in Transit*, an aspect crucial for data security. The count rose from 157K on June 20, 2022, to 353K on May 31, 2023, demonstrating a steady progression towards improved data encryption practices (Figure 4). Similarly, we observe an increase in the number of apps providing *Data Deletion Option* where the count rose from 99K to 227K. However, despite the overall increasing trend in *Data Deletion Option* and *Encryption in Transit* practices, a closer examination reveals that some apps are incorporating these practices, while others are withdrawing them. This observation implies that developers are still adjusting their Data Safety Sections.

The ongoing changes in reported data practices, even ten months past Google's deadline for DSS implementation, point to a dynamic landscape, suggesting that developers are still refining their understanding and implementation of DSS requirements. We investigate the challenges that developers face in more depth in our developer study (Section 6.3).

Evolution of Collection and Sharing Practices. Delving deeper into the evolution at the datatype level, we investigate three *Data Categories* collected most frequently: Location, Personal Identifiers, and App Activity and Performance. *Personal Identifiers* include *Personal Info*, and *Device Id and other identifiers*. We show the evolution collection of these *Data Categories* over two snapshots in Figure 6a. For example, if *Location* and *Personal Info* are removed and *App Info and Performance* is added, we add two pairs of transition: (Location -> App Info and Performance and Personal Info -> App Info and Performance). We find that a large number of

apps initially reporting collection of user location (n=21K) and personal information (n=18K) have revised their DSS to indicate no longer collecting these datatypes. Similarly, around 6.2K apps that were initially collecting app info and performance data have updated their DSS, indicating a halt in this data collection practice.

Conversely, we also identified apps initially not collecting location data or other specific information, have now started collecting these datatypes. This shows the bi-directional nature of these changes. We find similar trends by analyzing evolution of these data types for *Data Sharing* in Figure 6b.

These findings highlight the evolving nature of data practices which can impact users' trust and privacy. If an app shifts from not collecting to collecting certain datatypes, it may expose users to new privacy risks especially as they will not be notified to this change. The findings can indicate developers' difficulties or confusion in accurately understanding their apps' data practices as we highlight in Section 6.

Trends in Over-Reporting of Data Practices In Section 4, we observe that developers over-reported the purposes for data collection. Analyzing the DSS dataset, we find a persistent pattern in over-reporting over time, even after ten months. This suggests that a considerable number of developers continue to perceive an environment of low risk or consequence in over-reporting their data practices.

We uncover the potential reasons behind this trend in our developer study. We find that Google's current policy enforcement does not impose penalties for overstating data collection practices, likely due to the limitations inherent in compliance checks, that rely on static and dynamic code analysis. Consequently, some developers may be inclined towards a risk-averse strategy, choosing to over-report to prevent potential policy violations. Although the number of apps following such practices is low (n=4K) in our set, the impact on the wider privacy label ecosystem can be substantial as it could affect users' trust in privacy labels.

6 Developer Study [RQ3]

We conduct a study with Android app developers to understand their perspective when engaging with Data Safety Sections. We identified *interesting* patterns (described in Section 4 and Section 5) in apps' Data Safety Sections and contacted the app developers to inquire about the factors responsible for the patterns, and the challenges that they face.

6.1 Methodology

We first describe the study design and analysis methods.

Study Design. We reached out to app developers through emails, probing their experiences and asking specific questions about the privacy labels of their apps. We crafted these questions carefully to stimulate responses. We contact the developers via email and analyze their responses to answer our research questions. Prior work [22] has conducted in-depth interviews with iOS developers to understand the challenges developers face while working with the Apple Privacy Labels. In-depth interviews can be limited by the number of participants involved in the study. In this work, we opt to conduct the study via email questions. While an email study does not provide the depth or understanding that comes from an interview study, it allows us to reach a wider audience with diverse perspectives.

Ethical Considerations When emailing developers, we clearly identified ourselves as researchers and stated that we were studying their application and sought information related to their data safety section (Appendix A.3). We do not collect any personally identifiable data in our study. As such, the IRB certified our study as not "human subjects research," and we were not required to obtain consent before sending out the emails. However, to use the developers' responses in our qualitative study, we sent one follow-up email and obtained informed consent. The content of the email is shown in Appendix A.3. We emphasize that we did not send any follow-up emails to the developers, except for the one to obtain consent. We also note that while we elicited voluntary responses from 889 developers, our analysis reached saturation before reaching all email responses.

Developer Selection. Recall that in Section 4 and Section 5, we identified the following three trends. (A) apps stating that they encrypt data without collecting or sharing data, (B) apps changing their practice from not collecting/sharing data to collecting/sharing data, and (C) apps changing their practices from collecting/sharing data to not collecting/sharing data. Trend (A) points to inconsistency in reported security practice, whereas Trend (B) and (C) have implications of user data privacy. We identified the apps corresponding to these patterns, sorted them in order of real installs, and contacted the top 10,000 developers for each pattern, asking them about the trend. We emphasize that we made a conscious decision not to include probing questions beyond the DSS trends. We asked developers about their DSS and the trend, implicitly prompting them to think about the process. This allows us to obtain the developer responses that are contextualized in their experience instead of our questions.

In response to our emails, we received 3500 responses. To get a clean set for analysis, we filtered out automated replies and non-English responses, leaving us with 889 responses. We then qualitatively analyze these responses to explore how developers describe their privacy practices, the challenges they face while working with the privacy labels, and the factors that prompted them to update their data safety section. We also note here that although not prompted, many developers highlighted the challenges with third-party libraries (Section 6.3) and overstating collection (Section 6.4) while discussing Trend B and C, indicating that our analysis covers

under-reporting and over-reporting practices.

Qualitative Analysis Method. In accordance with qualitative research guidelines, we employed a strategy of random sampling and coding of developer responses until data saturation was achieved [27]. The coding process began with two authors evaluating an initial set of 50 responses and developing preliminary codes. Next, the research team discussed these codes, clarified differences, and established the initial codebook. The notable differences were in the granularity of the codes, and we opted for fine-grained codes as they can be consolidated later. Subsequently, the two authors independently coded a randomly selected subset of 25 responses each time, comparing their codes and iterating on the codebook until they achieved high inter-rater reliability ($\kappa = .87$)) by the 125th response. Using the refined codebook, the two authors continued to code independently until they stopped observing new codes by the 175th response. Then they coded two additional batches of 25 responses, reaching 225 responses, and marked it as the point of data saturation. After conducting a thematic analysis, we model the developers' engagement with the Data Safety Section ecosystem through an analytical framework as depicted in Figure 7. Our codebook is available online.[3].

Demographics and App Metadata We analyzed responses from developers of 225 apps. We did not collect demographic data from the developers because we did not want to: (1) ask for personal information, and (2) create friction for developers to respond. More importantly, we interacted with developer emails that potentially cover developer teams with varying demographics where inquiring about the demographics of the respondent would not be necessarily representative of the whole developer team. To understand the demographics of the responses, we collect the geographic location of the apps team, as listed on the Play Store. For apps that do not list their address (n=89), we manually visit their webpage and extract the address. We find that we covered apps from 59 countries, covering 5 regions (continents), showcasing the advantages of our approach in reaching diverse developers. The top 3 countries are *United States - 29*, *India - 25* and *Russia - 12*. A world map showing the locations (country level) of the apps is shown in Figure 1 (in Supplemental File[4]). We also find that the apps in the study cover a total of 27 categories, with the most common being *GAME* (n=66), which is also the most popular app category on Play Store. The distribution of the apps with the category is shown in Figure 12a. Treating real installs as a proxy for app popularity, we find that the study consists of popular as well as less popular apps, with 42% of apps having more than 1M downloads. We show the distribution of apps in the study with real installs in Figure 12b. Finally, we show the distribution of apps with Age rating in Figure 12c. We note that 88% of the apps belong to the *Everyone* rating. This is consistent with the distribution of all apps on the Play Store, with 86% of the apps having *Everyone* rating.

Findings Overview. Figure 7 describes the lifecycle of updating the DSS as perceived by the developers. App developers go through several stages while working with the Data Safety Section. First, they deduce their intended privacy practices (Section 6.2) based on their app implementation. While attempting to fill the DSS form, they face challenges (Section 6.3) mapping their intended practices to the form. The challenges result in strategies (Section 6.4) to initially fill out the form and get it accepted. After submitting the initial form, there might be inaccuracies highlighted to them either via Google or through their internal review system. Finally, they update the form (Section 6.5). In the subsequent sections, we present the findings of our analysis, unpacking the experiences and behaviors of app developers as they go through this process of uploading their Data Safety Sections.

6.2 Intended Privacy Practices of Developers

We first discuss developers' intended data collection and sharing practices. Our thematic analysis reveals three subthemes within the privacy practices of the apps: third-party data collection, encryption, and first-party practices.

Third-party Data Collection: We find that developers often reported involving third parties for various purposes. The main purposes were ads and analytics. We also find here that developers tend to use these libraries primarily for ad revenue. For example, one developer expressed: "*... to make profit from my DJ app, I use third party advertising, such as Google AdMob and AppLovin. They (third-party ads) are collecting users data to showing perfect ads to my DJ users*." This is consistent with our findings from Section 4 where we find that *Ads* and *Analytics* are the top two purposes for data sharing.

However, we observe developers do not tend to share data when they employ in-app purchases. For example, when asked about changes in their DSS, one developer noted: *"In the last update, I removed all the ads of the app, so I receive money from the few premium subscriptions. The Google AdMob SDK collected all that data, so now it doesn't get any type of information from the user."* This suggests developers of paid apps tend not to share data possibly as they do not rely on ads for revenue. In Section 3, we observed that the fraction of apps with DSS in paid apps is higher than in free apps. Analyzing the *Data Sharing* practices of paid apps (Figure 8), we indeed find that a lower number of paid apps report sharing data than free apps.

Encryption: We find that developers often secured data during transmission. One developer reported–"*we currently utilize the IPsec protocol to ensure secure transmission of data. IPsec is a widely adopted industry standard for VPNs and*

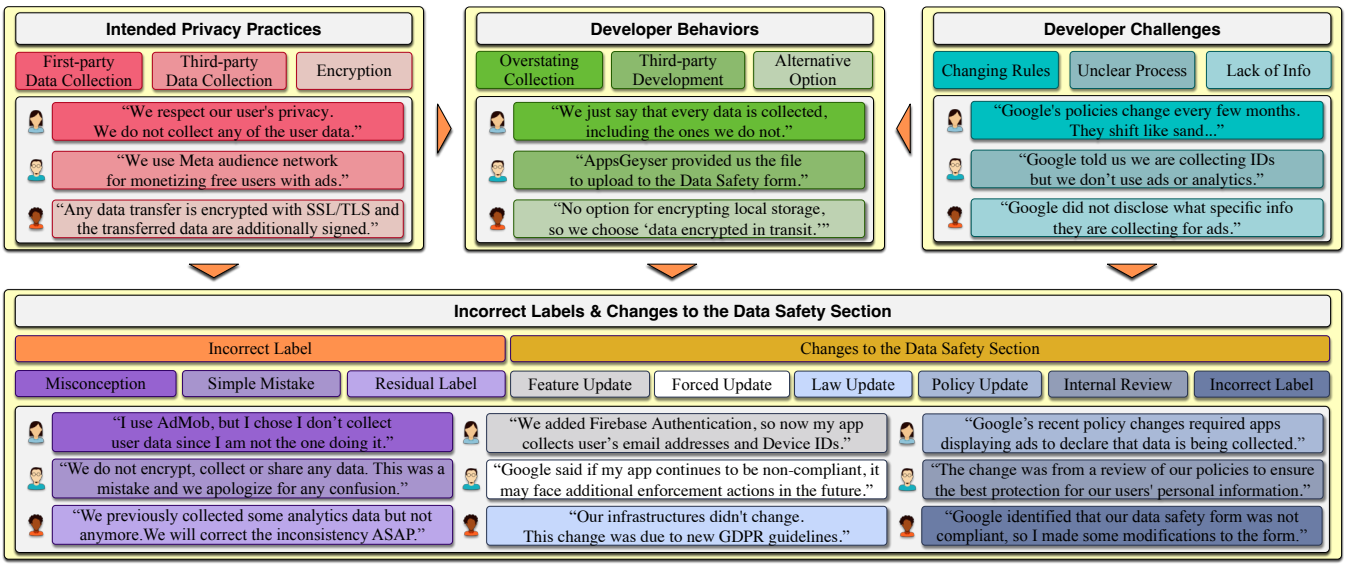

Figure 7: Our analytical framework with the high-level themes, secondary-level themes, and developer quotes. The framework describes the lifecycle of updating the DSS as perceived by the developers. We do not show all secondary-level themes due to a lack of space.

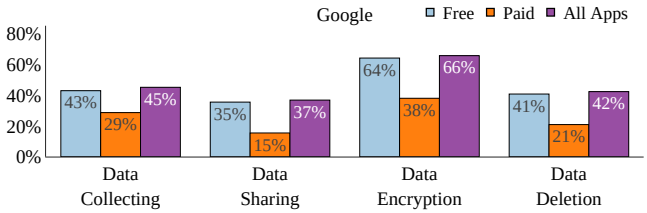

Figure 8: The distribution of high-level data practices based on price. We note that the fraction of paid apps that collect and share data is lower than free apps.

provides robust encryption, authentication, and integrity protection for transmitted data." Some developers also assumed that third-party libraries will provide encryption, although this might raise questions about their direct control over data security. For example, one developer mentioned, "... *I use Google API like Drive, YouTube, AdMob and Firebase. They do collect user data I guess and they state that data is encrypted*".

First-party Practices: In our analysis, developers also conveyed their own data practices. Many developers reported not intending to collect (n=60%) or share data (n=48%) themselves. As one developer stated, "... *we do not collect any personal data or share any personal data. Our app only collects anonymous analytics events (button clicks and screen impressions/load) and app crashes via Google's Firebase framework so that we can fix user issues and crashes*." Others asserted not integrating any ads or analytics services, while some stressed the importance of obtaining user consent before collecting data, underlining their commitment to respecting user privacy.

6.3 Challenges Faced by Developers

Next, we uncover the challenges that the developers face while mapping their intended privacy practices to DSS forms. These challenges are categorized into seven sub-themes with Figure 9 depicting the frequency of each sub-theme for each region. We observe that the theme covers apps from all the regions highlighting the diversity of the app developers included in the analysis. We also observe that Europe emerges as the region where developers most frequently report numerous challenges. Additionally, we also show the distribution of sub-themes with respect to app categories (Figure 13) and the number of downloads (Figure 15) in the Appendix. We find that the apps cover 20 categories present on the Play Store. Similarly, analyzing the apps along the download count, we find that the theme consists of apps with low download count as well as high download counts.

Lack of Information About Third-Party Libraries: Developers indicated uncertainty about the privacy practices of the third-party libraries used in their apps. One developer noted: "*I currently face a challenge in that I am unsure of what specific APIs are included in the app code provided by Appsgeyser.com that may be contributing to this issue of non-compliance, as said by Google. Additionally, I have been unable to find a reliable source of information on this matter.*" Notably, in the play console, Google shows the permissions required by popular libraries, as well as flags problematic SDKs, however, there is no help regarding the collection practices of these libraries.

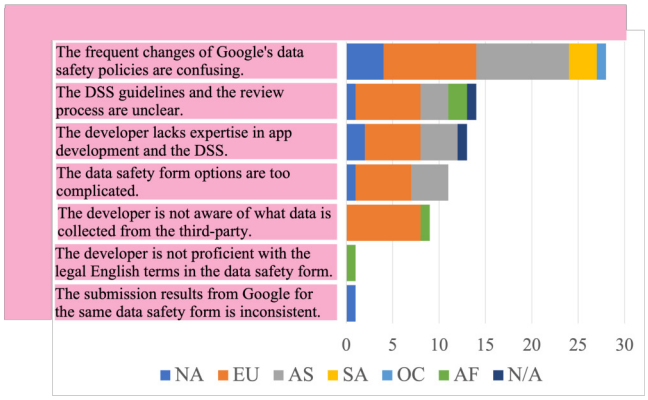

Figure 9: The frequencies of seven subthemes of developer's challenges with different geographic locations, as explained in Section 6.3. The region abbreviations are–NA: North America; EU: Europe; AS: Asia; SA: South America; OC: Oceania; AF: Africa. N/A corresponds to the apps whose region we were not able to identify.

Inconsistency: Some developers reported inconsistency in the acceptance of their data safety form. A developer struggling with the review process noted: *"... we submit the same form over and over again and often times Google rejects our answers with no or at most a vague explanation. Eventually, Google accepts it."* Such inconsistency can lead to confusion about what is required, and result in frequent revisions, and inaccurate DSS.

Lower English Proficiency: Non-native English speakers cited difficulties understanding the data safety policies. For example, a developer, whose native language is not English, was confused with an English word: *"... our administrator whose first language isn't English did not seem to understand the meaning of 'ephemerally' and ticked 'No, this collected data is not processed ephemerally'. So even though we declared the data collected/shared, Google play did not disclose this on the app's store listing."*

Complicated: Developers also complained that options provided in DSS form are complicated. For instance, a developer made mistakes in the data safety form because there were simply too many options, whereas another was confused with the complicated description of the DSS option. This complexity can lead to errors or misunderstandings when filling out the form.

Unclear Process: Our analysis also revealed that developers are confused regarding Google's review process for DSS, finding the process unclear and the explanations vague. For instance, a developer noted *"Google at one time prompted me that my app collects data of which we knew nothing about, the data they spoke about is the 'Devices and Other IDs Data' and that it's a compulsory data been collected by most apps on Play Store even if they do not collect user data. We don't see or collect any user data from my users and our app doesn't not even use firebase, one signal or ads."*

Lack of Expertise: Developers also acknowledged difficulty arising from a lack of expertise in both app development and data safety policies. For example, one developer noted–*"... due to my limited experience, I made this app with the help of third party app developer-AppsGeyser. I am not sure of how I should represent the third-party APIs in the app code and I have been unable to find a reliable source of information on this matter.."*. Another developer noted that they do not understand half of the DSS policies and so they just keep submitting answers in hopes of finding the right configuration. This gap in knowledge can happens due to vague definitions in data safety policies. Moreover, the lack of information can lead to developers having an incomplete understanding of the privacy practices, resulting in inaccurate representation of these practices in the DSS.

Changing Rules: Developers reported confusion stemming from changing DSS policies within the Google Play Store. They mentioned that the constant evolution of these rules made it difficult for them to ensure compliance. As one developer said: *"... so we haven't changed anything in <app_name> in almost a decade. What has changed, and seems to keep changing every few months is Googleś privacy policies. They are difficult to understand and they shift like sand ..."*. This indicates that developers have difficulty keeping up with the dynamic landscape of rules and regulations regarding DSS.

These challenges highlight the need for more developer support in areas such as policy comprehension, form simplification, and the handling of third-party libraries. Addressing these issues could significantly aid developers in enhancing data safety and privacy in their applications.

6.4 Developer Behaviors and Strategies in DSS Submission

We now discuss the various strategies adopted by the developers to navigate the challenges they face while submitting the DSS form. These behaviors and strategies are classified into five sub-themes. Figure 10 shows the frequency of each sub-theme in the coded responses with each geographic region. The theme consists of app developers from all regions. We note that the sub-themes *Future Policy* and *Overstating Collection* are found primarily in the *Asian* region. This could be reflective of practices in a specific region; we leave this exploration for future studies. Furthermore, the distribution of sub-themes with app category and download count are shown in Figure 14 and Figure 16, respectively in Appendix A.4. We observe that the theme covers 7 categories, including the top 5 app categories on the Play Store. The theme also has apps with diverse download counts, with apps having 1K+ downloads as well as 10M+ downloads.

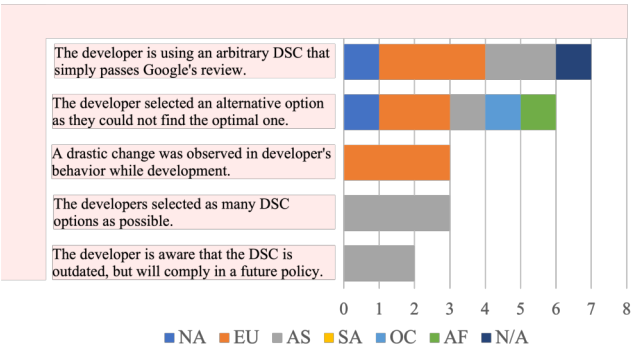

Figure 10: The frequencies of five subthemes of developer's behaviors with different geographical regions, as explained in Section 6.4. The region abbrevations are same as Figure 9.

Alternative Option: When developers were unable to find the optimal data safety card option for their app, they resorted to choosing an alternative one. For instance, as said by one developer–"*... we do not collect any data, everything user write on our app will be stored on their device. There wasn't any other option to select except 'data is in encrypted in transit ...*" . This highlights the potential need for more comprehensive or flexible options within the form.

Change in Developer Behavior: Our analysis also captured developers altering their behavior based on their experience while interacting with DSS. For instance, one developer that stopped the development of their app noted: *"... considering all the hassle I had been going through, it has been determined that it would not be practical to continue updating these apps on the Google Play Store, given the minimal profit generated and the effort required to maintain compliance."* This highlights the scenario where the complex policies of DSS can potentially discourage developers to update their apps, hurting the users as they might be forced to work with outdated versions of the apps.

Future Policy: Some developers acknowledged that they intentionally had an incorrect DSS to increase flexibility, and in case of future app updates. For example, one developer responded: *"It is true that we do not share or collect any kind of personal data. It means that if we intend to do so in the future then we will be encrypting the data. At the moment we are not sharing or collecting personal data."* This might convey incorrect information to the users. Conversely, if the developer does not indicate that they collect data, but utilize the same flexibility, it could pose a risk to users.

Overstating Collection: Some developers indicated that Google only checks for the data that is collected but not mentioned as collected but not the other way. As a result, they select all options for collection in the DSS form. For example, one developer noted –*"... it is safe to declare all possible data collected in Data safety section so, in our apps, even the information (e.g. phone numbers) that is not collected is mentioned as collected."* We also observed similar over-reporting of practices in Section 4 and Section 5. This observation highlights an issue with Google's compliance analysis tools.

Form That Works: Some developers reported using a data safety form that had previously passed Google's review, regardless of whether it fully aligned with the current data handling practices of the app. For example, one developer noted –*"... my app did not collect any data. but in the data safety section, I wrote that I collect data because other than that Google would not publish my app."* This approach suggests a pragmatic yet concerning response by the developer as it may result in inaccurate DSS.

The findings highlight that developers attempt to circumvent the review process either by over-reporting their privacy practices or by trying random configurations until their DSS is accepted. Combined with the challenges (Section 6.3) that the developers face, this indicates that the DSS submission tool might not be usable by the developers.

6.5 Inaccurate Labels and Driving Factors behind Changes in Data Safety Section

As the developers navigate the complex challenges, they may submit inaccurate labels. We used the developers' intended practices from Section 6.2 and compared them with the reported practices in DSS. Additionally, our analysis of the developers' responses revealed several key factors that influence developers' decisions to update their applications' Data Safety Sections (DSSs).

6.5.1 Inaccurate Labels and Type of Inaccuracies

We conducted a comparative analysis between the reported practices (*Data Collection* and *Data Sharing*) in DSS and their intended practices from the emails. We find a notable discrepancy; 41% of developers who stated in their emails not to engage in data collection were nonetheless reported as collecting data in their DSS. A similar inconsistency (42%) was observed for data sharing. For instance, the developer of an app with over 100M downloads stated in an email, "*In Google Play Console we pointed that we collect/share data because of Ad network SDKs integrated into the game. Not the app itself, but ad SDKs do collecting or sharing.*", but their DSS did not report any data collection or sharing. This discrepancy highlights the fact that the DSS sections might not be thoroughly monitored by Google and reiterates the need for more effective mechanisms for accurate reporting of privacy practices. Next, our analysis of the developers' responses also reveals factors responsible for inaccuracies.

Misconception: Some developers demonstrated misunderstandings of the data safety policies, which resulted in inaccurate DSS. Such developers have the misconception that they do not have to disclose practices for third-party libraries

even when they are using third-party SDKs. For example, one developer noted –*"... we do not collect any personal data or share any personal data. Our app only collects anonymous analytics info through Google Firebase. Hence, we chose that we do not collect data."*

Recall the *interesting* trend that we observed in Section 4 where we noted that many apps state they do not collect or share data, but encrypt data in transit. We find that this could be happening due to misconceptions about using third-party libraries. For example, one developer noted – *"I use ADMOB for banner ads at the bottom of my app, but Google collects Device ADID. I checked that data is encrypted for that part."* The developers report *Encryption*, but due to the misconception, do not report *Data Shared*.

Simple Mistake: Some Developers also acknowledged that they made a mistake and conveyed their plans to update their DSS during the communication with the authors. For example, one developer mentioned –*"previously, the process of filling out the Data safety section was interrupted and uncompleted due to one of the checkboxes left unchecked."*

Residual Label: Some developers failed to update their DSS after making feature updates. The developers conveyed their plans to update their forms, but this trend can potentially be detrimental to the DSS ecosystem, especially if the update adds *Data Collection* or *Data Sharing* flows.

6.5.2 Driving Factors for Change in DSS

After submitting the initial forms, developers may need to update their DSS. We now discuss the various factors responsible for the change in DSS. Our analysis revealed six distinct sub-themes for these factors.

Feature Update. One significant trigger for updating DSSs was the introduction of new features. Most commonly, developers updated their DSSs due to the addition of advertisement or analytics SDKs into their app. For example, one developer notes: *"... In the initial version there were no ads. But now I have put ads in the app for which I had to change my policy as well."*

Law Update. Changes in legal and regulatory frameworks also compelled developers to modify their DSSs. For example, one developer noted – *"Our methods and infrastructures didn't change. This change was made in light of new GDPR guidelines that are in effect right now."*

Policy Update. Changes imposed by the platform (like the Play Store), required adjustments to the DSS. For instance, one developer using a third-party ad service mentioned that: *"We don't collect or transmit any user data. However, some of our apps use Google's AdMob for ads. As per new directions from Google, we are required to reproduce Google data policies related to AdMob even if our app does not collect any data."*

Forced Update: We also observed instances where developers were compelled to update their DSS to avoid having their apps removed from the Play Store. For example, one developer noted – *"We detected user data transmitted off device that you have not disclosed in your app's Data safety form as user data collected. If your app continues to be non-compliant after August 22, 2022, your app updates will be rejected and your app may face additional enforcement actions in the future."* This showcases the influence of platform policies on developers' decision-making processes.

Internal Review. The results of internal reviews also surfaced as a factor for DSS updates. Specifically, a developer mentions that the updated DSS guidelines provided by Google enabled them to more accurately portray how they handle data. They also emphasize that: *"... the added features on the stores rightfully illuminated some areas that were unknown to users, which made a lot of apps appear to handle their data differently than they actually are."*

Incorrect Label. Finally, developers noted that the discovery of incorrect labels results in DSS updates. As noted by a developer–*"... Although I still do not collect any data, I was essentially required by Google some time ago to say that I collect data on behalf of the advertising services in order to remain compliant with Google's policy ..."*–most of the developers fixed the DSSs after they realized that they chose the incorrect data safety card option due to their confusion after being formally notified by Google.

7 Discussion and Recommendations

Our research has highlighted the complex landscape of developers' experiences and challenges with Data Safety Sections. We follow on our findings by presenting a set of recommendations aimed at improving the developer experience with DSS. Then, we discuss the roles of the platforms and regulators in addressing the deficiencies in DSS. Finally, we list the limitations of our methods.

7.1 Recommendations

We provide a list of recommendations to improve the developer experience with the DSS section in Google Play. These recommendations, summarized in Table 1, go beyond those presented in prior work [22].

Enhance Educational Resources. An important need emerged for enhancing educational resources surrounding data safety policies and the filling of data safety forms. Such educational resources include detailed explanations about data collection, storage, and sharing practices that are expected to be reported in the Data Safety Section. Providing developers with real-world examples, interactive tutorials, and guidelines to navigate data safety requirements can go a long way in

Recommendations
1. Enhance Educational Resources: Educational resources should be enhanced to provide developers with real-world examples, interactive tutorials, and guidelines.
2. Provide Multilingual Support: Resources should be available to developers in multiple languages
3. Simplify Data Safety Forms: Data safety forms should be simplified to improve comprehension.
4. Consistent Feedback from the Review Process: Developers should be given clear and transparent feedback on the approval or rejection of their data safety forms.
5. Improve Support for Third-Party Library Data Practices: Platform providers and third-party library developers should ensure transparency about their data practices.
6. Regular Consultations and Feedback Mechanisms: Consult with developers to ensure continued relevance of privacy labels; allows developers to share their feedback.

Table 1: Summary of the recommendations.

reducing misunderstandings and ensuring proper compliance.

Provide Multilingual Support. The global landscape of app development calls for the need to support diverse languages. Developers across the globe should be able to access, understand, and interpret guidelines without language acting as a barrier. Thus, providing guidelines, forms, and supporting services in multiple languages is crucial. Platform providers could consider deploying multilingual support teams and translation services to cater to this diverse community.

Simplify Data Safety Forms. Several developers have reported difficulties in understanding the complexity of data safety forms (Section 6.3, leading to inaccuracies in reporting. Addressing this concern would involve simplifying the forms to ensure they are easy to understand and complete. This could be achieved by using accessible language, clear terminologies, and unambiguous options. Additionally, redesigning the form layout to enhance readability and ease of use might also prove beneficial.

Consistent Feedback from the Review Process. In Section 6.3, we find that developers have little confidence in the approval process. As a result, developers resort to filling the form to just receive the approval, without the form actually being accurate. Developers expressed frustration as to understanding why a particular form is accepted or rejected. Developers need to have confidence in a consistent and transparent review process. The approval or rejection of data safety forms should be communicated clearly with an explanation of the reasons. This will not only help developers improve their subsequent submissions but also reduce confusion.

Improve Support for Third-Party Library Data Practices. The increasing use of third-party libraries poses challenges for developers to accurately represent data practices in their apps. To mitigate this challenge, platform providers should demand transparency from third-party providers about their data practices. Additionally, developing tools or mechanisms that help developers to track and represent these practices in their data safety forms would be beneficial. An existing effort from Google is the *Google Play SDK Index*, which aims to provide developers transparent information on all the third-party SDKs that is usable in Android app development [16]. While the index informs the users of the Android OS permissions these services are requesting, it still fails to provide information on the specific category of data being collected.

Regular Consultations With Developers and Feedback Mechanisms. To ensure the continued relevance and effectiveness of privacy labels, regular consultations with developers should be conducted. This would provide a platform for developers to share their experiences, voice their concerns, and give feedback on existing processes. Such feedback mechanisms could provide invaluable insights for platform providers to understand evolving challenges and adapt their policies and support systems accordingly.

7.2 Discussion

Impact of Industry Intervention. Google's recent introduction of the *Checks* service [5], providesing paid compliance analysis to developers, adds to the dynamics of the privacy labels. From the developers' perspective, popular apps with resources might find Checks to be an invaluable tool, simplifying the task of policy compliance and mitigating the likelihood of errors or misunderstandings. However, the service's cost may create hurdles for smaller or independent developers, possibly leading to disparity between reported practices by developers with more substantial means and those operating under more constrained circumstances.

As for the platform, the Checks service could fulfill several objectives for the Play Store. It might elevate the quality of reported practices and compliance of apps. However, Google could face criticism for monetizing a critical aspect of the app development process, particularly if this act is seen as establishing a 'pay-to-play' mechanism.

The implications for users, albeit less direct, are still significant. If the Checks service contributes to higher policy compliance and reduced errors by developers, users could get accurate data safety practices. Conversely, if the cost of the service results in a less diverse app marketplace due to financial barriers for smaller developers, users may face a reduction in their choices of apps.

Regulators Even though our analysis finds inconsistencies

between privacy labels and privacy practices, evidence [34] suggests that privacy labels have can carry specific information about the practices. This information can be very useful for privacy concerned users who want to ensure that they are only using privacy respecting apps.

However, as shown in this work, the accuracy of privacy labels is not guaranteed. While developers are required to disclose their data practices in order to obtain a privacy label, there is no guarantee that the information they provide is accurate or complete. Therefore, it is necessary to have systems in place to verify the accuracy of privacy labels and to hold developers accountable for any discrepancies. This is particularly important because the false labels can create a false sense of security among the users.

One potential model for regulating privacy labels is a system similar to the one used for food nutrition labels, which are regulated by the Food and Drug Administration (FDA). A regulatory body could be established to oversee privacy labels and ensure that they are accurate and consistent. This could help to build trust among users and encourage developers to be more transparent about their data practices.

Another solution could be providing the monitoring system that is used during the app submission reviews directly to the user's device. The system could perform real-time dynamic analysis on the app installed on the user's device and show the analysis results, such as network traffic and the data or sensor access logs. This way, the users are given a more detailed view of the privacy practices of the app and would be able to make a better-informed decision on whether to use the app. An example in production includes the Apple *App Privacy Report* introduced in iOS and iPadOS 15.2, which provides data and sensor access logs from apps installed on the device, and network traffic from the apps directly to the users [30].

7.3 Limitations

Data Collection Our data collection process was carried out over specific periods, and thus may not fully capture the dynamic nature of the app ecosystem. Apps can update their DSS at any time, and changes outside of our data collection windows would not be reflected in our analysis. The apps included in our study are a subset of all available apps on the Google Play Store. Although we made an effort to include popular apps and span various categories, our sample may not be fully representative of the entire app ecosystem. Finally, we noted discrepancies in data practices based on the presence of third-party libraries. However, some instances of third-party library usage might have been missed due to limitations in the tools used for detection, leading to potential underestimation of their prevalence and impact.

Developer Study Our developer study relies on email communication with app developers. While this allowed us to reach a larger number of developers, it may not have provided us with the depth or understanding that comes from an interview study. Additionally, it may have also biased our results toward those who were more willing to respond, potentially neglecting the perspectives of developers who did not reply.

The nature of self-reported data could also pose challenges to the reliability and accuracy of the information collected. There is the potential for bias in the developers' responses, as they may present information in a way that portrays their apps more favorably. Another limitation of our study is the lack of demographic data about the developers who responded to our email. As we prioritized respecting privacy and ensuring anonymity, we did not collect any personally identifiable information, including demographic details such as age, gender, nationality, or years of experience in app development. Such demographic data could potentially provide meaningful context and allow for a more nuanced understanding of developers' perspectives. For instance, a developer's experience level or geographical location might influence their understanding of privacy issues or their familiarity with privacy regulations. Despite the limitations outlined, our research sheds light on the challenges that the developers face, and it fills a gap in the literature about the factors affecting developers' making while working with the privacy labels.

8 Conclusion

In conclusion, our study takes a comprehensive approach to examine the landscape of Data Safety Sections (DSS) in Google Play Store apps. Through a large-scale analysis, we highlighted inconsistencies in reported practices, as well as instances of both underreporting and overreporting. Our longitudinal study emphasized the dynamic nature of DSS implementation. We observed the persistence of overreporting trends and revealed how developers are still adjusting to the requirements, even ten months after Google's imposed deadline. We investigate the developers' perspective by examining responses from them about their DSS. Our analysis uncovers the process developers undertake when navigating the DSS landscape. We outline the challenges developers face, the strategies they employ to comply with DSS policies, and the factors prompting changes in their DSS. Finally, based on the challenges and developer behaviors, we provide recommendations aimed at improving the developer experience with Data Safety Sections.

Acknowledgments

This work was supported by the NSF through awards: CNS-1942014 and CNS-2003129, and by gifts from Google, NVIDIA and Meta. Finally, we thank the reviewers for their fruitful discussions and recommendations.

A Appendix

A.1 Changes in DSS

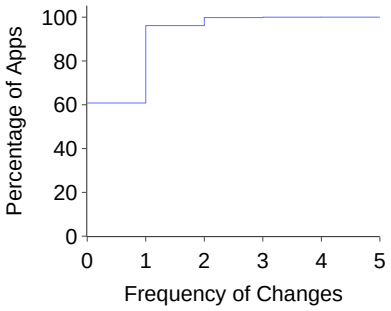

Figure 11: The Cumulative Distribution Function for the frequency of DSS updates made by apps throughout the snapshot timeline.

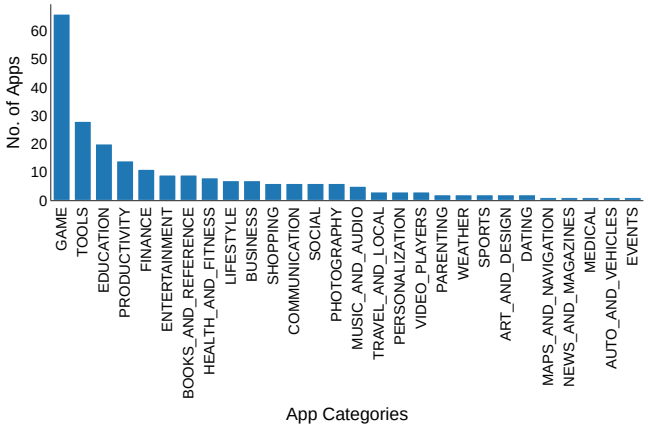
Figure 11 shows the frequency with which apps change their DSS between the period of June 20, 2022, and May 31, 2023. We find that a significant number, 283K (40%) changed labels at least 1 time. Moreover, there were over 1.3K apps that changed their DSS at least 3 times.

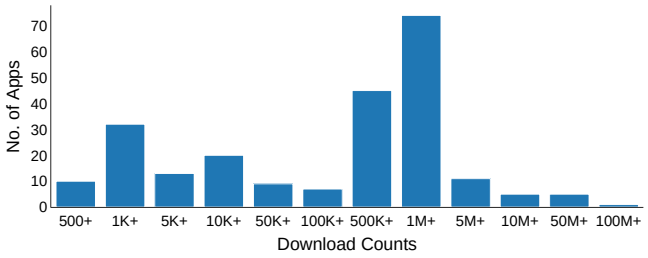
A.2 Data Practices in Privacy Labels

In this section, we look into the distribution of the high-level practices of apps based on their price, as shown in Figure 8. Next, we look at the heatmap shown in Figure 2 (in Supplemental File[5]) to see the distribution of datatypes across purposes. The heatmap is normalized by the total number of apps collecting or sharing a given datatype.



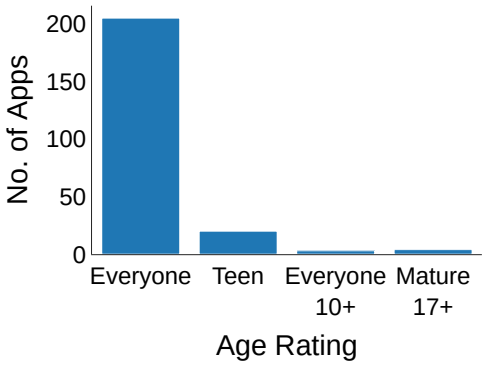
A.3 Developer Study

For the Developer Study (Section 6) we sent emails to developers in 3 different categories: (A) apps stating that they encrypt data without collecting or sharing data, (B) apps changing their practice from not collecting/sharing data to collecting/sharing data, and (C) apps changing their practices from collecting/sharing data to not collecting/sharing data.



For category (A) we used the following template:
We hope this email finds you well. We are researchers at <LAB_NAME> and have been using your app, <APP_NAME>, in our recent studies. We have noticed that in the data safety section of your app, it states that you encrypt data. However, we have also noticed that your app does not collect or share data.

We are reaching out to ask if you could clarify this for us. We are trying to better understand the data safety section



[5] https://osf.io/q3wv2?view_only=0b4aa040161a4b259c0a32c7fb3ae82c

(a) Apps per category (or genre)

(b) Apps per download counts

(c) Apps per age rating

Figure 12: Distribution of apps coded according to (a) download counts, (b) categories, and (c) age ratings

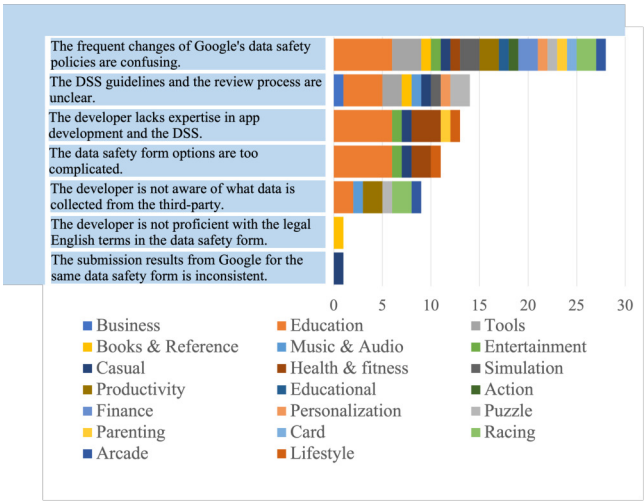


Figure 13: The frequencies of seven subthemes of developer's challenges with different app categories, as explained in Section 6.3.

implemented in your app. We appreciate any information you can provide.
Thank you for your time and we look forward to your response.

We also sent one additional follow-up email to obtain informed consent to use the developers' responses in our research. The content of the email was:
Thank you for contributing to our study. May we have your permission to use anonymized excerpts from your feedback in our research? These ***quotes will not be linked to you or your application*** *and solely represent a developer's viewpoint.*

A.4 Coded App Demographics

For the 225 apps we used for the coding task, we present the metadata distribution. Figure 13 and Figure 14 demonstrate the distribution of the 225 apps based on their categories, each respectively on the reported developer challenges and behaviors. Specifically, 24 out of the 77 reported challenge instances and 12 out of the 20 behavior instances originate from the *Education* category.

Figure 15 and Figure 16 demonstrate the distribution of the 225 apps based on the number of downloads, each respectively on the reported developer challenges and behaviors. The most frequent numbers of downloads were between [1K, 5K) for the challenge theme, with 20 out of the 77 reported instances. For the behavior theme, the most frequent numbers of downloads were between [5K, 10K), with 9 out of the 20 reported instances. In addition, 21 apps from the challenge instances and 5 apps from the behavior instances had a download count of 1M+.

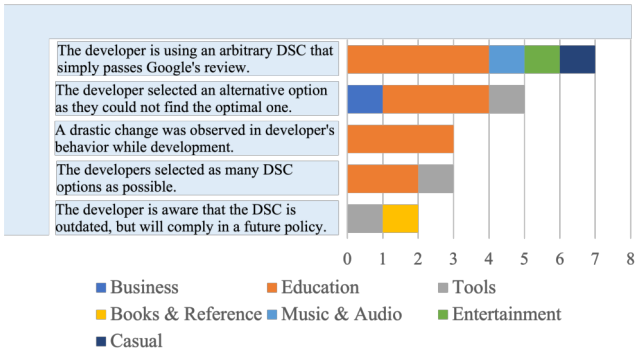

Figure 14: The frequencies of five subthemes of developer's behaviors with different app categories, as explained in Section 6.3.

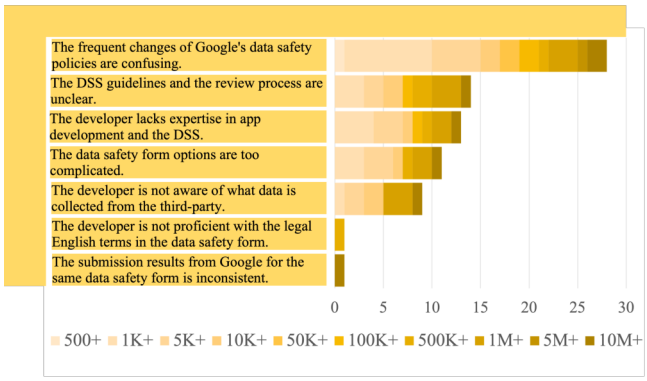

Figure 15: The frequencies of seven subthemes of developer's challenges per the number of app downloads, as explained in Section 6.3.

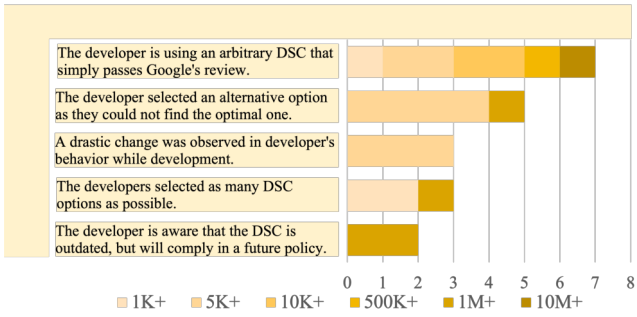

Figure 16: The frequencies of five subthemes of developer's behaviors with per the number of app downloads, as explained in Section 6.3.

Dissecting Privacy Perspectives of Websites Around the World: "Aceptar Todo, Alle Akzeptieren, Accept All..."

Abstract

Privacy has become a significant concern as the processing, storage, and sharing of collected data expands. In order to take precautions against this increasing issue, countries and different government entities have enacted laws for the protection of privacy, and articles regarding acquiring consent from the user to collect data (i.e., via cookies) have been regulated such as the right of one to be informed and to manage their preferences. Even though there are many regulations, still many websites do not transparently provide their users with their privacy practices and cookie consent notices, and restrict one's rights or make it difficult to set/choose their privacy preferences. The main objective of this study is to analyze whether websites from around the world inform their users about the collection of their data and to identify how easy or difficult for users to set their privacy preferences in practice. While observing the differences between countries, we also aim to examine whether there is an effect of geographical location on privacy approaches and whether the applications and interpretations of countries that follow and comply with the same laws are similar. For this purpose, we have developed an automated tool to scan the privacy notices on the 500 most popular websites in different countries around the world. Our extensive analysis indicates that in some countries users are rarely informed and even in countries with high cookie consent notifications, offering the option to refuse is still very low despite the fact that it is part of their regulations. The highest rate of reject buttons on cookie banners in the countries studied is 35%. Overall, although the law gives the user the right to refuse consent and be informed, we have concluded that this does not apply in practice in most countries. Moreover, in many cases, the implementations are convoluted and not user-friendly at all.

1 Introduction

Just as you do not immediately accept and reply to an email requesting your private information, do you respond in a similar manner when a website asks for your data? Websites collect *cookies* (i.e., save information) from their users to reason about how they behave and operate while browsing their platforms. Although it is stated in privacy notices and policies that the data is collected for session continuity and functionality, most of the user cookies supply data for advertising purposes [8] to third parties [26]. Therefore, the background flow and record-keeping of cookies have fueled advertising and marketing initiatives in online environments all over the world [3, 9]. User-targeting data is highly valuable for service providers to optimize the services accordingly. Consequently, data privacy has become an inevitable issue when it comes to the massive transfer of data.

Privacy and its violations are significant concerns that draw the attention of consumers through occasional scandalous news such as Facebook sharing user information with Cambridge Analytica [4, 27, 41] and Meta/WhatsApp introducing a controversial privacy policy [14, 42]. Experiencing such circumstances has led individuals and regulators to gain awareness and take the necessary steps to protect users' privacy. One of the actions taken is the development of consent notices that inform users about the collection of cookies and ask for their explicit permissions for privacy. These cookie consent notices are usually placed at the top of the website interface and may consist of parts such as text informing the user about cookie collection, accepting, rejecting, and editing preferences, and a closing icon via buttons. Figure 1 shows the set of accept example buttons that we came across during our study. While some regulations, such as GDPR [17], legally declare that the user's explicit approval is mandatory, it has been repeatedly observed that websites do not comply with these rules all the time [10, 34]. This raises the question of whether the user is truly safe and aware of their rights on the Internet.

To the best of our knowledge, our study is the first empirical study in the literature to investigate and compare privacy notifications of various countries globally in terms of depth to reach the reject option, size classification, and complexity of the text. To this end, we analyzed 500 websites from each subject country selected for the study: Brazil, Bulgaria, Germany,

Figure 1: Example buttons on banners we encountered during the study.

Italy, Japan, Russia, Turkiye, and the United Kingdom. During our investigation in these countries, we established remote (from Turkiye and the US) and local connections to observe the attitudes towards both internal and external users. Our work helps to comprehend whether (i) user-centered privacy perspectives of the websites vary across countries, (ii) the geographical location affects the application or interpretation of privacy, (iii) there is a distinction in the implementation of the privacy regulations adhering to the same privacy laws.

The results of our extensive analysis indicate that the display of the cookie consent notices for countries enforcing strict privacy regulations, such as European countries, was 64%, compared to those countries having loose regulations, and/or regulations are not enforced, such as Russia with 28% and Japan with 8%. Granting users the right to refuse consent, Germany ranks first with 35%.

Due to world-renowned news on privacy violations and sharing extensive user data with third parties without getting consent, many studies on online privacy practices and the extent of the collected data have been published before. Indeed, previous studies have found that not every website that collects cookies informs its users about this issue and does not obtain their permission. They found that the majority of websites do not display cookie banners on their sites [10, 30, 34]. Nevertheless, most of the existing research on the topic is GDPR-centric, evaluating European websites and compliance with GDPR. Therefore, the literature lacks worldwide research presenting comparative statistics and evaluating the practices on multiple metrics.

Contributions: Our study reveals a broader domain of research by;

- Investigating the most popular websites located in different countries around the world for their privacy practices.
- Creating a tool to automatically check privacy notices via cookie consent banners, along with the layout, text analysis, and clickable options provided. Our tool has revealed that only 37.7% of all the websites (24% for the countries analyzed from the US) investigated within the scope of the research have a cookie consent banner.
- Analyzing the depth of rejecting the privacy policy. It has been observed that users can reject the privacy policy with a single click for only 21.9% of websites with a cookie consent banner for the country with the best statistics.
- Providing insights on the complexity of the text on the cookie consent banner, classification of the banner according to the ratio of web page sizes, and whether a privacy policy redirect is added in the footer of the website.

Organization: The remainder of this paper is organized as follows: Section 2 provides background information by briefing the results of the related previous studies. Section 3 describes the privacy practices of the studied countries and the details about the means of the investigation. Section 4 presents all the findings and comparisons of privacy notices of the countries. Section 5 discusses the inferences between all the data obtained and the research questions, and the meaning of the data. Finally, Section 6 concludes the paper.

2 Related Work

There have been studies conducted on user-centric privacy policies and data privacy regulations followed by countries. While most of the earlier research is done on European countries and GDPR, there have been several explorations on developing tools to quantify the privacy level on individual websites as well.

Degeling et al. [10] investigated the effect of GDPR on the privacy practices on the websites of European countries. As an outcome of the study conducted on 500 websites from each European country, they identified a positive effect on user-centric privacy practices. To explain user-centric privacy practices, it can be said that all kinds of texts, banners, and menu items provided to the users, as well as the options proposed as a part of these visualizations, are considered user-centric privacy practices. As an outcome of the work conducted by Degeling et al., statistically speaking, the number of cookie consent notices increased from 46.1% to 63.2% across Europe after GDPR came into effect. Kretschmer et al. [24] also identified a similar impact of GDPR on privacy practices. According to their study, the amount of third-party tracking on the web revealed a decrease with an increase in user-centered privacy practices, such as providing a cookie consent notice with options to the users.

Kokciyan and Yolum [21] have developed a web-based tool that identifies privacy violations based on the comparison of consent taken from the user and what is collected. They have identified that as the size of the social network of a user increases, the violations, thus the amount of time required to identify these violations, also increases. Their work suggests a complex network full of interaction between parties for the medium of exchange of user-generated data.

Taking another aspect of the topic as the central concern, Dotras and Ros [23] investigated the compliance of websites from different countries with GDPR for processing the data of their European customers. They identified that, even within Europe, differences exist between a country being a main domain versus a subdomain. Compliance with GDPR was higher when the connection was constructed from the main domain. Looking at cookie consents from a more global perspective, Sanchez-Rola et al. [29] examined websites in the US and EU to understand the effect of GDPR. They observed almost identical website behavior in the results obtained from within and outside Europe. The results show that 92% of the websites track the user without notifying them. When it comes to giving users an opt-out option, they found that only 4% did so.

Santos et al. [30] and Utz et al. [40] proposed work on the cookie consent notices themselves by investigating the banners presented to the users. They identified ambiguous expressions in almost half of the displayed cookie notices despite 60% of notices declaring that cookies are being used *to improve user experience*. Trevisan et al. [22] conducted similar research and statistically presented the privacy compliance of the cookie notices in Europe to the regulations. Their findings also indicate that 49% of the websites do not comply with the regulations in effect. Carpineto et al. [7] performed this check within a smaller domain, namely the websites in Italy, and concluded that institutional websites are ahead of commercial ones at complying with the regulations. Similarly, Nouwens et al. [25] investigated the compliance of cookie consent notices with regulations on UK websites. They found that only 11.8% of websites displayed legal designs and the presence or absence of elements such as an opt-out button in these designs affects the consent rate.

Differences From Existing Work: We extend the scope of the research to a worldwide domain instead of focusing on GDPR and the European Union. Therefore, a user can know how their data is treated worldwide. Previous studies in this field have been conducted with a smaller set of countries. Along with the extension, we collect key factors such as banner and text evaluation, footer existence, and layout providing insights into the privacy perspectives of the websites to extract valuable information from them and address a wider aspect of a website while evaluating the results. Moreover, by highlighting the contrasts of varying geographical zones, we present statistical data from a selection of countries in different locations.

3 Objectives and Methodology

The main objective of our research is to study the user-centric privacy perspectives of websites between countries by analyzing privacy notices via cookies. To deepen the understanding of privacy notices, we provide a brief introduction to cookies and their purposes.

Cookies: Cookies are data files kept on the hard drive of the device they're being collected on, which store information about both the user and the visit performed. [16] The information collected ranges from time spent on the website to items added to the shopping cart. Websites themselves collect cookies from their visitors to gain insights about their visitors and also to sell these data to third parties. In a wider scope, cookies become an important data source that shapes the marketing and advertising sector [2, 8] and has significant value. In light of the information provided about cookies, privacy notices enlighten users about the content of cookies placed by the website and the parties they are shared with and ask for consent.

The following research questions (RQ) constitute our main scope for this work:

RQ1: *How do the user-centered privacy perspectives of websites differ across countries globally?*

RQ2: *To what extent does geographical location influence the privacy-related practices adopted by countries?*

RQ3: *How similar are cookie consent notices in countries that adhere to the same data protection regulations?*

With all these research questions in mind, we pick the countries in accordance with the cultural zones they belong to (see Figure 2) with a restriction of being a G20 country or being in a union that is part of G20. We aimed to direct the research conducted to relatively larger economies where both domestic and international companies are effective. We believe that more variance in the content of websites will help us get the opportunity to analyze the internalization of privacy policies by all segments of the population. Furthermore,

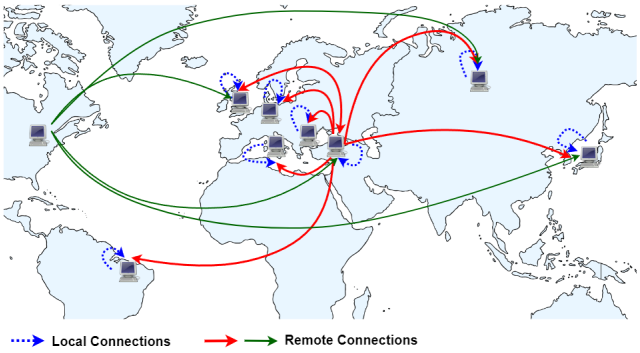

Figure 2: Countries involved: Brazil, Bulgaria, Germany, Italy, Japan, Russia, Turkiye, UK, and and US. The red and green lines represent the remote connections and the blue line represents the local connections. Two differently colored remote connections display different established links in the study.

while selecting amongst the larger economies, we gave priority to countries where comparison with each other would give meaningful results and countries with greater interest. As a result, we opted to pick Brazil, Bulgaria, Germany, Italy, Japan, Russia, Turkiye, the UK, and the US (as a consistent third country).

3.1 Subject Countries and Their Privacy Legislations

In order to draw meaningful results, it is important to understand the countries' perspectives on privacy and the privacy regulations they are currently adopting. This section describes the recent data protection laws of the countries.

Brazil: In 2018, the General Personal Data Protection Law (LGPD), enacted by The Brazilian Federal Constitution, has effectively ensured the security of individuals on the Internet. Consisting of 65 articles, this law offers similarities with the GDPR published by the European Union [5].

Bulgaria: Bulgaria, which has been included in the European Union since 2007, has a guideline for data protection named the Commission for Personal Data Protection (CPDP) along with adopting the GDPR provisions. It does not demonstrate major differences and some legal bases such as consent, legal obligations, and contract with the subject directly adopt the GDPR regulations [6].

Germany: Germany was one of the first EU member countries to adopt the GDPR. The Federal Data Protection Act (BDSG), working alongside the GDPR, has been effective in 2017, and states the limitations and rights of users and data collectors. The BDSG also includes laws on data transfers and cookie consents [13].

Italy: Italian Personal Data Protection Law (The Code) was replaced by GDPR in 2018, and The Italian Data Protection Authority (Garante) is competent in the enforcement of the personal privacy regulations [18]. Some articles in The Code directly contradicted GDPR [19].

Japan: The Act on the Protection of Personal Information (APPI) regulations were effective in 2017 and later with revisions in 2022. While it is mentioned that data protection is one of the most active areas of Japanese law, there is an article that it is mandatory to acquire consent before obtaining data from the user [20].

Russia: Russia, which has made modifications in its laws in the field of privacy over the years, has put into effect The Law on Personal Data, which includes new directions, for instance, regarding the cross-boarding transfer of the data, starting in 2022 [28].

Turkiye: Turkiye has been using the Personal Data Protection Law (KVKK) since 2016. Before this regulation, a set of privacy laws based on the protection of personal data were not implemented [36]. KVKK was not constructed with GDPR as it was enacted earlier [35].

United Kingdom: The United Kingdom, which left the European Union in 2020, adopts and implements the UK General Data Protection Regulation (UK GDPR) as data protection regulations [32]. GDPR and UK GDPR contain parallel regulations [37].

United States: Privacy in the United States is not governed by a single overarching law or regulation. Instead, a collection of federal privacy laws covers different aspects of privacy. The most related to online consumers, California's Consumer Privacy Act (CCPA) includes the most comprehensive regulations regarding cookie control [38]. Similarly, the State of Delaware has protected the privacy of its citizens with the cookie laws it has legalized in the Personal Data Privacy Act (DPDPA) [39].

Overall each country mentioned above and subject to this study mandates the protection of individuals' information and their data and therefore legalizes consent implementations. They all emphasize transparent practices in personal information collected. While Brazil and Japan are not specific about the language clarity of cookie consent notices, other countries require that consent be created in a way that the user can understand. User consent and control are clauses in the data protection regulations of all these nine countries and give users the right to accept or reject. While Japan does not explicitly address cookies, it highlights user consent for personal data handling. In the US, states that implement cookie laws enforce user notification about cookie collection, yet not all states adopt legislation regarding cookies. We note that in our study, the US remote connection was only used for analyzing the websites of some of the countries as a third country to verify some of the results. So, the impact of the US privacy regulations was not a direct focus of this work.

3.2 Data Collection

We built a tool designed to extract cookie consent notices from the top 500 most visited websites located in Brazil, Bulgaria, Germany, Italy, Japan, Russia, Turkey, and the United Kingdom. We used the list provided by Tranco [33] to identify the most visited websites for each country stated and omitted standard domains such as .com, and .net to ensure that the target audience of the website and the country it is being evaluated for matches. The evaluation phase consisted of two levels, namely domestic and international. In the initial phase, we established connections within the target country and navigated to the respective websites to collect data. Subsequently, we behaved as an external user, simulated access from outside the country, and gathered further data. We provided all the connections we made with a consistent VPN. Through careful checks performed during the scanning process, we ensured our presence within the specified country. Each website was accessed through an incognito tab, allowing for a fresh user profile for every visit.

Due to the number of websites exceeding the possibility

for manual computation, we used Selenium for automated data collection, we preferred Firefox (Version 110.0) as the browser thanks to its solid stability with automated tools. We conducted the crawling between March and May in 2023.

We have conducted a crawling process that involved 10,000 visits (4,000 local, 4,000 remote from Turkiye, 2,000 remote from the US) for a total of 4,000 websites from 8 different countries including both local and remote connections. Among these crawls, 76.25%, 77.9%, and 68.95% of websites were loaded with local, remote from Turkiye, and remote from the US connections, respectively. Also, of the total dataset, 37% (1511) included a cookie consent notice as a banner as part of the website's privacy policy. And, the websites that were not loaded could not be accessed either due to being geographically blocked or having a temporary server problem.

In order to collect the details regarding the layout and content of the consent notices, we identified names used for a cookie banner as part of the technical design and created a pool of possible HTML element names. We ensured that the most popular third-party cookie policy banner providers and a variety of components were included in the pool. Later, we executed a second-level control, taking the text of the banner and searching for the existence of privacy policy-related words. We conducted this control by creating a pool of words and then pursued the identification of clickable texts and buttons in the banner, ensuring that it is related to obtaining the user's consent on privacy. We created three pools, one for accepting, one for rejecting, and one for viewing in-depth privacy settings offered by the website. For matching elements, we fetched the exact clickable text within the element for later evaluation. Moreover, if a clickable element related to rejecting the consent exists, we collected the number of cookies again after rejecting the policy to see whether a change was observed. The following subsections describe the attributes in detail. A high-level architectural view of the tool is provided in Figure 3 and the general flow of the process is given in Algorithm 1.

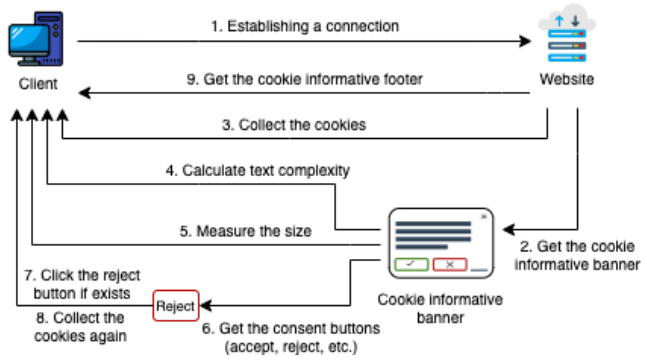

Figure 3: Flow of the automated tool.

Algorithm 1 Detection of Consent Notices

Step 1 and Step 2: Identify HTML Elements of Consent Notices and Privacy Policy-Related Words
Define a list of XPaths to search for banners
paths ← ["//*[contains(@role, 'dialog')]", "//*[contains(@role, 'alert')]", ...]
Create an empty list to store identified banner elements
banner_elements ← []
Create a pool of privacy policy-related words
privacy_related_words ← ["privacy", "consent", "policy", "cookies", ...]
for *path* **in** *paths* **do**
    banner ← *driver.find_elements*(*By.XPATH*, *path*)
    for *x* **in** *banner* **do**
        banner_text ← *x.text.lower*()
        translate_to_english(banner_text)
        for *word* **in** *privacy_related_words* **do**
            if *word* **in** *banner_text* **then**
                Append *x* to *banner_elements*
                This banner is related to privacy, process it further
                break
Step 3: Identify Clickable Text and Buttons in the Banner
Create word pools for accepting, rejecting, and viewing privacy settings
accept_words ← ["Accept", "Agree", "Allow", ...]
reject_words ← ["Reject", "Deny", "Decline", ...]
settings_words ← ["Settings", "Preferences", "Manage", ...]
for *banner_element* **in** *banner_elements* **do**
    clickable_texts ← *get_clickable_texts*(*banner_element*)
    for *text* **in** *clickable_texts* **do**
        if *text* **in** *accept_words* **then**
            Process accept button accordingly
        else if *text* **in** *reject_words* **then**
            Process reject button accordingly
        else if *text* **in** *settings_words* **then**
            Process settings button accordingly
Step 4: Check for Cookie Changes After Rejecting Consent
if "Reject" **in** *clickable_texts* **then**
    cookies_before_reject ← *get_cookies*()
    simulate_reject_click()
    cookies_after_reject ← *get_cookies*()
    if *cookies_before_reject* ≠ *cookies_after_reject* **then**
        Change in cookies observed after consent is denied

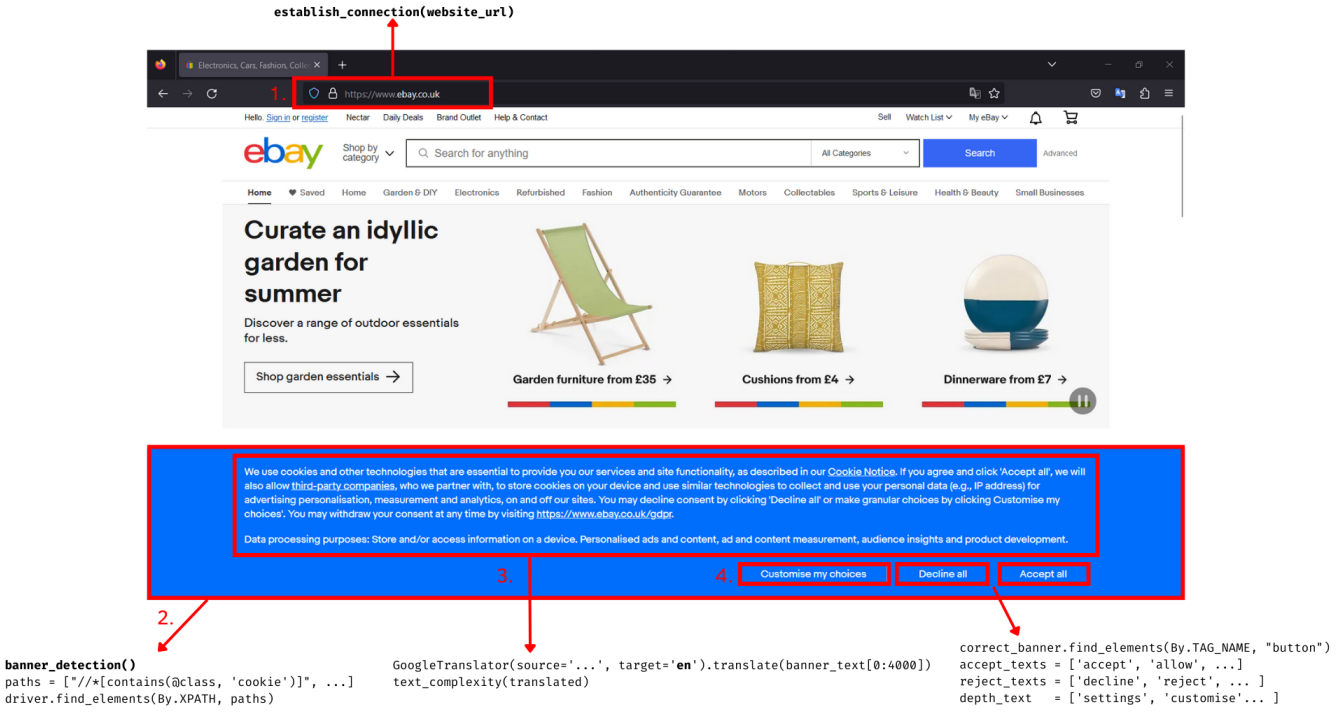

Figure 4: Overview of the detection of privacy notices and elements; Steps 1 and 2 correspond to privacy banner identification, and Steps 3 and 4 correspond to privacy policy identification.

3.3 Inspection and Verification

We conducted the manual inspection process following data collection, ensuring that the scan-derived data was thoroughly prepared for analysis. We formed control groups for each country to be checked manually and also included edge cases as a part of this group. These control groups were formed according to data being false positive (where we found cookie informative banners while there are none) and/or negative (and vice versa). For manual checks, the same procedure described above is computed. First, the accessibility of the website and the existence of a privacy-related banner is evaluated. Following, text analysis is computed, using the component of the code we developed manually, providing the text as an input and getting statistics as an output. Options provided to the user as a part of the banner and layout details are also collected manually using the inspection tool of the browser. Lastly, further privacy notices are checked to see if any additional notice is provided as a footer.

Utilizing a feature in our code, we captured screenshots of web pages in instances where no consent notice was encountered during the scanning. Thereafter, we reviewed these screenshots, using them to fix any inaccuracies. Overall, automated and manual checks not only complied with each other but also supported the validity of the data collected and thus, the work conducted.

3.4 Measurement Metrics

3.4.1 Content of the Data

We established a three-stage investigation mechanism on the user-centric privacy policies of websites, which is also visualized in Figure 4. The content of the three-stage procedure can be briefly described as follows:

1. Privacy Banner Identification: Checking if the website is accessible and if loaded successfully, whether a privacy-related banner is shown to the user (corresponding to 1 in Figure 4).

2. Privacy Policy Identification: Investigation of the comprehensibility and clearness of the text shown to the user if a banner stating the policy followed by the website exists. Along with the text, the options displayed, such as accepting or rejecting to give consent or viewing additional information. Moreover, information on the layout of the banner (corresponding to 2, 3, and 4 in Figure 4).

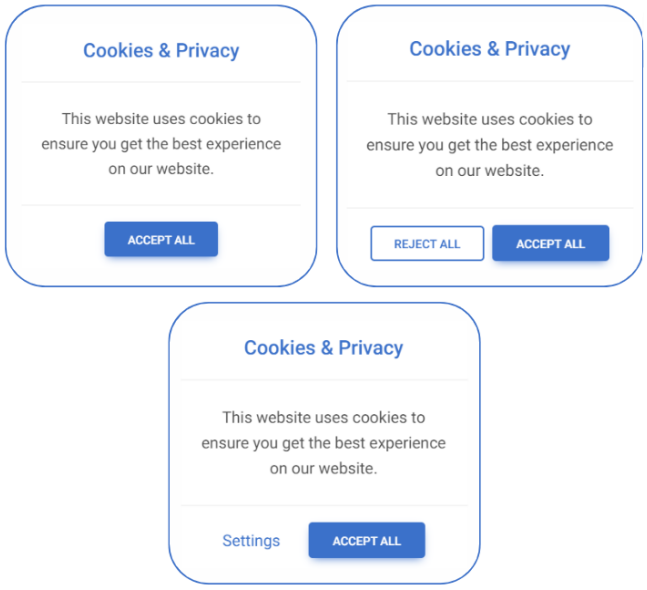
3. Further Privacy Notice Identification: Existence of further privacy policy-related notices on the website.

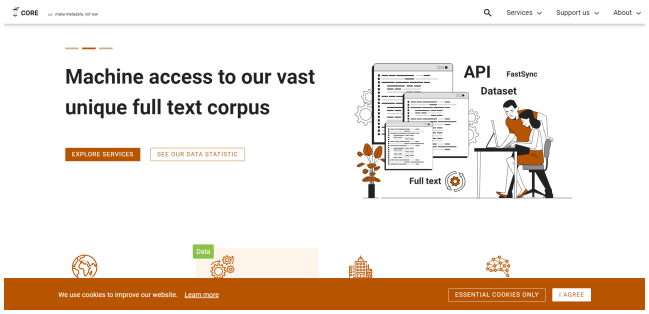
Regarding the number of cookies integrated into the stages described above, we also focused on quantitative data regarding the cookies taken, before and after rejecting the consent

notices. Nevertheless, we were able to measure the number of cookies after rejection only if the website provided a rejection option to the user.

3.4.2 Depth of Rejection

Another new metric named *depth* is computed based on the existing data on the options provided to the user as a part of the cookie consent notices. Depth is important to give insights into how easy it is for the users to reject the privacy policy offered by the websites. This metric classifies the depth into three categories; namely *no reject option*, *a reject button exists*, and *further reject options* (e.g., Settings). No reject option category is used for cases where there is no cookie banner or option offered to the user as a part of a privacy notice. On the other hand, a reject button exists means that users can reject the cookies with a single click, and consequently further reject options indicate the user cannot reject with a single click but have further options offered, which may result in the rejection of the consent with two or more clicks. Figure 5 presents the use of depth metrics within the research.





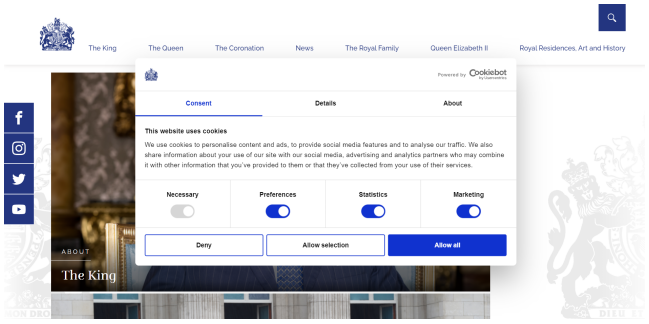


Figure 5: Visual representation of different depth levels observed in privacy notices.

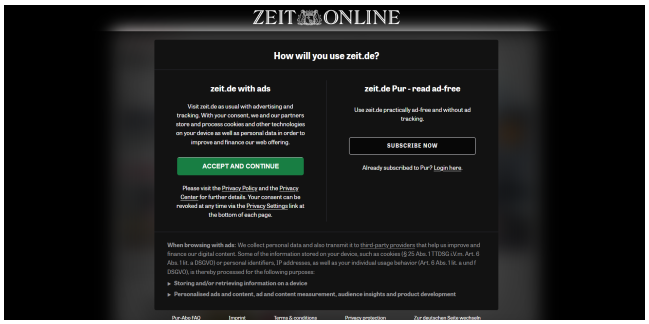
3.4.3 Layout of the Banner



We have also developed a novel metric to evaluate the layout of the banner. This new metric named banner classification is determined from the data collected on the layout of the banner. Specifically, the size information of the banner is utilized to take the ratio of the banner to the browser. As also shown in Figure 6, banners that are smaller than a quarter of the view are classified as *small* (Figure 6a), while banners between quarter and half of the view are classified as *medium* (Figure 6b), and banners larger than half of the view are classified as *large* (Figure 6c). The size information indicates the level of transparency on the website regarding the collection of cookies and the effectiveness of the notice provided, which directly impacts the user experience.

(a) Small

(b) Medium

(c) Large

Figure 6: Examples for classification conducted regarding the layout.

3.4.4 Banner Text Analysis

Another crucial part of the data collection that needs to be further discussed is the identification of the level of complexity, which plays a key role in the easiness of understanding the banner text. The reason we analyzed only the cookie banners is that they are constructing the main behavior of the users. They are the first thing that would catch one's eyes and shape the users' demeanor.

One of the ways to determine the complexity of text is to calculate its vocabulary richness. However, this method forces us to assume there must be a correlation between the complex words and the difficulty of understanding a text.

In contrast to the assumption above, Yasseri et al. [43] argue that Dickens' books have more specific and complex words but are easier to understand in comparison to simple Wikipedia articles online. In fact, they conclude that vocabulary richness indices are not enough to determine whether a text is hard to comprehend, one must look for other aspects such as the complexity indices that include sentences as well.

Hence, we decided to utilize a more detailed metric called Gunning Fog Index [15] to measure the complexity of texts by including the fundamentals of a paragraph: its sentences, and the complex words inside, which is formulated as:

$$F = 0.4(W/S + (100 * CW/W)), \quad (1)$$

where W, CW, S are the total number of words, complex words, and sentences, respectively [1].

We fetched the texts directly from the detected cookie banners, and calculated their complexities at the same time by tokenizing sentences and hyphenating words.

The text complexity of banners for different languages was analyzed through the main language, English. Other languages were translated by ensuring and conserving their true meanings so that there is no loss of meaning in all manners. We decided to conduct this analysis with a single language (i.e., English) to obtain objective results. For instance, Japanese and Turkish are agglutinative languages, while German and English are Indo-European. Therefore, with English, we provided a universal outcome for all to make it fairer to analyze and compare with each other.

According to the index, complex words are the ones that have at least three syllables. The result shows the target audience of the corresponding text, where the fog index being 9-12 means that the text is for high school students, 13-16 for university students, and above for graduate level students [11]. Any fog index result above 13 is thus accepted to be difficult to understand at first reading.

3.5 Ethical Considerations

All data collected in this study are publicly visible elements of websites. Neither any private data of any person or institution was used nor shared. Therefore, our work does not lead to any ethical violations or concerns.

4 Data Analysis and Results

This study sought to understand whether privacy notices and the options they contain differ in various countries across the world. It also checks for any privacy-related links in the footers of websites. The scans were completed both from the country where the domain belongs to the website and from abroad, and the results can be seen in Table 1. It is beneficial to clarify the statistics for the false negatives and false positives that our tool has made a successful crawling by producing 2.1% and 2.4%, respectively, which provides us a small but nice-to-have space to dig deeper for manual inspection and verification.

4.1 RQ1: Privacy Consents of Websites in Various Countries

Table 1 shows that in terms of the existence of cookie informative banners: the UK has a certain lead in both local and remote connections. 70.64% of the remote and 86.66% of the locally connected websites contain a cookie banner to inform users and ask for their consent. Following the UK, Germany and Italy have good grades in terms of notifying users when entering their websites. They both have at least a 60 percent rate to contain a cookie banner and banner sizes are not like other countries' banner implementations where relatively small sizes predominate. Regarding this trio, Germany shows its difference in the rate of accepting buttons. Almost all of the German cookie banners include an accept button for users to proceed to the website. In addition, Germany also has the most amount of cookie-informative footers. It can be said that Italy and the United Kingdom, especially the 14% of the remotely linked UK websites, do not pay much attention to the footers as they include a non-negligible amount of banners.

On the other hand, Japan holds its position at the bottom by having the poorest banner and footer rates of 8.04% local & 9.31% remote, and 17.59% local & 22.8% remote connections, respectively. Russia could take place just above Japan because Russian websites are also not privacy-consent-mannered but have a few websites where users can reject the cookies. Looking at Russia and Japan, which were chosen as two of the intriguing G20 countries, it can be seen that both countries do not demonstrate effective obligations towards online privacy.

The other three countries, Brazil, Bulgaria, and Turkiye, share the middle part where they all have close banner and footer existence rates (except remotely connected .br websites with 51.18%).

In addition to the results of each country, connections from different locations do not have a solid pattern. For instance, except for text complexity and reject buttons ratio, locally connected UK websites have better results than remotely connected ones. German websites that are locally connected tend to provide more favorable outcomes compared to those that are remotely connected, except for accept buttons and depth of rejection (i.e., further consent options). On the other hand, Brazilian and Bulgarian websites have slightly better results when they are locally connected. Additionally, if we take into account the exact locations of these connections, there

Table 1: Results on how well websites inform their users about cookies.

Countries	Cookie Informative Banners (%)[1]	Accept Buttons (%)[2]	Reject Buttons (%)[2]	Further Consent Options (%)[2 5]	Average Text Complexity	Dominant Banner Size[3]	Cookie Informative Footers (%)[1 6]
Brazil	42.89	62.16	8.98	12.16	11.95	Small (93%)	29.4
Brazil (rc[4])	52.49	79	18	8.5	12.59	Small (94%)	51.18
Bulgaria	44.31	63.59	6.15	17.43	11.53	Small (86%)	36.6
Bulgaria (rc[4])	46.54	68.31	5.94	19.8	12.05	Small (75%)	32.2
Germany	67.07	98.9	34.55	21.81	12.8	Medium (40%)	83.33
Germany (rc[4])	63.09	99.09	31.13	25.47	13.13	Medium (46%)	79.5
Italy	60.05	80.87	27.83	41.73	14.49	Small (50%)	42.6
Italy (rc[4])	65.9	89.96	32.49	40.92	15.29	Small (39%)	42.4
Japan	8.04	68.75	6.25	37.5	11.29	Small (87%)	17.59
Japan (rc[4])	9.31	52.17	8.63	21.73	12.92	Small (82%)	22.8
Russia	28.78	43.1	0.86	4.31	11.20	Small (92%)	30.59
Russia (rc[4])	27.2	49.01	1.96	5.88	10.99	Small (95%)	29.2
Turkiye	36.44	57.92	12.19	12.19	11.22	Small (92%)	37.8
Turkiye (rc[4])	42.15	48.88	5	28.88	12.95	Small (77%)	38.47
UK	86.66	82.69	16.21	41.48	11.36	Small (61%)	54.6
UK (rc[4])	70.64	79.72	16.55	40.87	10.64	Small (67%)	14.35

[1] The ratio of the corresponding component to all successfully loaded websites.
[2] The ratio of the corresponding component to number of banners.
[3] Small: Covering at most the quarter of the screen. Medium: Covering more than a quarter but less than half of the screen. Large: Covering more than half of the screen
[4] rc: Represents "Remote connection". Remote connection to .tr websites is from London, UK. All other TLDs' remote connections are from another location (e.g., Turkiye).
[5] Depth of rejection.
[6] Cookie and privacy policy links located in the footers of websites.

is no clear-cut differentiation. Bulgaria, Germany, Italy, and the UK, which mainly adopt GDPR, have different results in different locations in terms of being more privacy-mannered. Bulgarian and Italian websites show more consent notices when connected remotely from a non-EU location (Istanbul, Turkey), while in Germany and the UK, more cookie banners are shown on local connections.

Effect of Country Selection for Remote Crawls: In order to enrich the scope of the work conducted, we investigated the effect of the selected country used for remote crawls. We selected the United States as a consistent third country for remote crawls and repeated the crawls for Japan, Russia, Turkiye, and the United Kingdom. When we collectively investigated the results, which are represented in Table 2, we identified worse ratios for presenting a cookie banner along with accept and reject buttons for Japan, Turkiye, and the United Kingdom. On the other hand, we did not observe a

Table 2: Statistics for the remote crawls done from the US.

Countries	Cookie Banner Existence (%)	Accept Button Rate (%)	Reject Button Rate (%)	Average Text Complexity (%)
Japan	9.05	38.10	4.76	12.91
Russia	29.71	51.49	1.98	11.04
Turkiye	31.2	41.66	6.41	12.35
United Kingdom	48.10	70.30	22.77	11.16

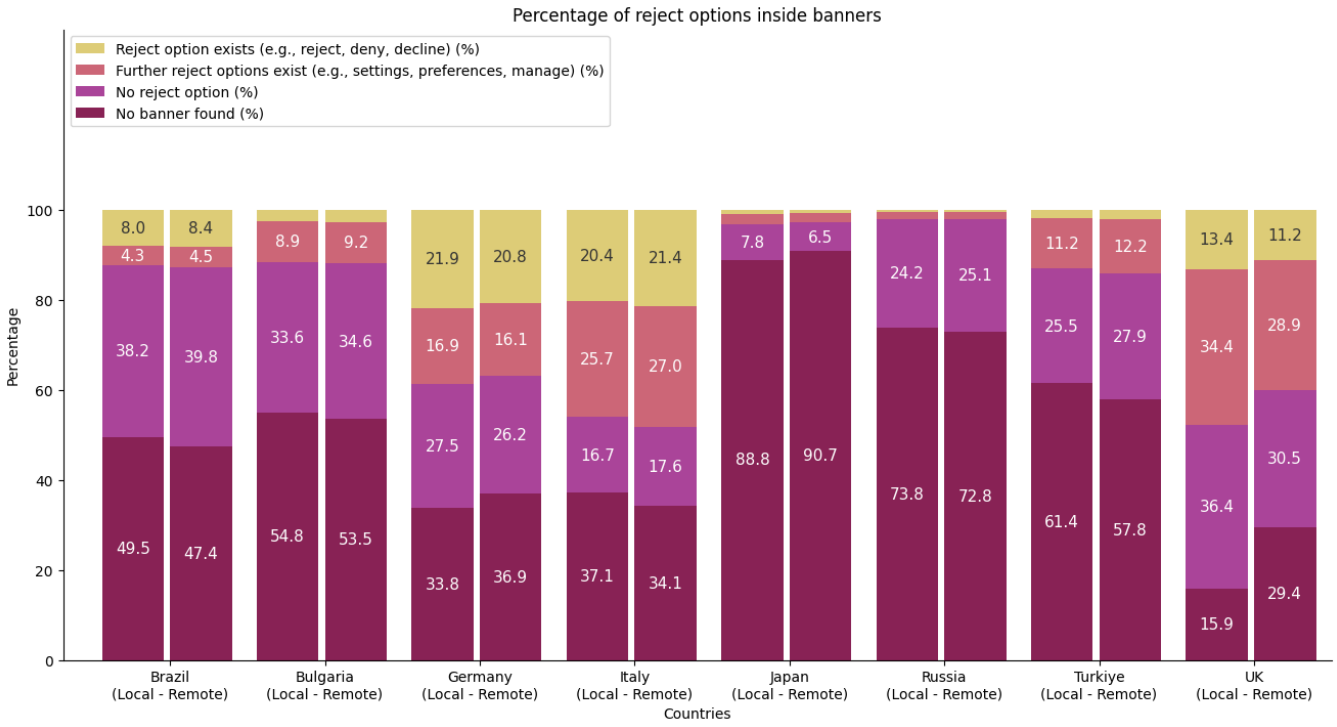


Figure 7: Reject options inside the cookie informative banners: Bars are grouped according to the countries that the websites belong to. Each country's left bar represents the results coming from local connections, and the right bar represents the results coming from remote connections.

significant difference for Russia.

The most striking statistics we observed were for the banner presence rates of the United Kingdom, showing up to be 48.10% when the connection is made from the US and 70.64% when from Turkiye. Additionally, the accept button rates for the privacy banners found in Japan were 52.17% and 37.10% for connections made from the US and Turkiye, respectively. On the other hand, we identified that Russia is demonstrating stable behavior in privacy for traffic coming from varying countries. These results can be interpreted from the perspective of the privacy legislation in Turkiye being similar to GDPR as they have historical ties to the EU. This might suggest an evaluation of Turkiye and the EU in the same group, thus obtaining better statistics when connections are done from Turkiye. Such evaluation also implies that European websites are more careful in privacy for traffic coming from other European countries because of the recent regulations. Another conclusion that can be inferred is that the difference we observed between connections from the US and Turkiye may be an outcome of not having a consensus like the EU's GDPR in the US. Using the US connection allowed us to verify that websites change behavior by country.

Language Settings of the Browser: Another point of investigation we made was the impact of the language settings of the browser. For this purpose, we examined the countries within the scope of this research having languages with different alphabets, namely Japan and Russia, making connections using VPN. The findings we obtained from this study did not show any significant difference; hence we concluded that the language settings of the browser are not dependent on the presentation of the privacy policy.

4.1.1 Reject options

Apart from the results in Table 1, Figure 7 shows the three different cookie rejection options. Further, reject options can be explained as having special *settings* buttons where the cookie acceptance options can be customized.

United Kingdom websites are on top by having the most amount of reject buttons with the second highest further options ratio. Both UK local and remote connections share these results. Germany and Italy are the followers by having reject options for more than half of their banners in a more evenly distributed way than other countries. They are followed by Bulgaria, Brazil, and Turkiye. Bulgarian websites are almost identical with both connections by having a close amount of reject buttons and further options. Turkish websites are similar to Bulgarian ones in terms of having more further options than just reject buttons. Brazilian websites have more reject buttons with no further depth contrary to the previous two. Finally, Japan and Russia take the last two places. Almost

70% Japanese and more than 92% of Russian websites lack reject options to provide users with a secure and reliable environment. In addition, the results of the crawling from the US connection were similar compared to the aforementioned results, except the UK websites. Higher reject button rates observed in the UK, despite the lower banner rates, show that websites that do not provide a reject option when connected from the UK are not providing a banner at all when connected from the US.

Table 3: Number of websites that are collecting cookies before and after clicking the reject button to observe if users *actually* reject them all or not. BC: Before clicking the reject button, AC: After clicking the reject button.

Countries	BC	AC	Countries	BC	AC
Brazil	32	1	Brazil (rc[1])	36	0
Bulgaria	12	1	Bulgaria (rc[1])	12	0
Germany	95	1	Germany (rc[1])	82	1
Italy	70	0	Italy (rc[1])	84	0
Japan	1	0	Japan (rc[1])	2	0
Russia	1	0	Russia (rc[1])	2	0
Turkiye	20	2	Turkiye (rc[1])	9	0
UK	47	3	UK (rc[1])	49	2

[1] rc: Represents "Remote connection". Remote connection to .tr websites is from London, UK. All other TLDs' remote connections are from Istanbul, TR.

Figure 7 shows us that for six countries, reject options' variety and amount increases when they are connected from another location (e.g., Turkiye) in comparison to their hometown. Germany has the same amount of reject options for both connections. UK websites are the only ones that resulted better with the local connection. Although this might be understandable for Brazil, Russia, or Japan which are not adopting GDPR for their data privacy regulations, it is also a surprise for countries such as Bulgaria, Italy, or Germany where people usually do not expect to see many consent options when they are connected outside the EU.

Table 3 demonstrates the before and after the state of clicking reject buttons of those which include. The presence of reject buttons within cookie banners allows users to *decline* the use of cookies with their free will. According to this information, all results are low. While expecting to see that all reject buttons are fully functional and do the desired outcome as refusing all cookies, only 7 of them worked on all websites for local connections, and 2 for remote connections, which is also undesirable to see. In fact, the number of cookies on most of the websites increased after clicking the reject buttons. One possibility is that they use them to keep track of whether users have closed the informative banner and thus ensure that it does not appear again.

4.1.2 Text Complexity of Banners

Text complexities of cookie informative banners were calculated with the Gunning Fog Index (see Figure 8). They were calculated by gathering from cookie informative banners and translated into English.

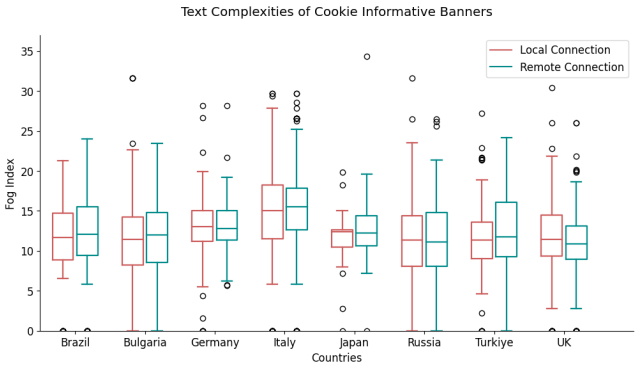

Figure 8: Boxplot for text complexities of cookie informative banners: Results are measured with Gunning Fog Index. The bottom and top quartiles are 25^{th} and 75^{th} percentiles, while the median is in between. Whiskers below and above show the minimum and maximum values except the outliers.

On average, Italian websites have the most complex texts inside their banners. Germany comes second but not having as much variety as Italy does. The UK, on the contrary, has the least complex texts, especially for local connections. Despite having the most amount of banners and variety in reject options (see Table 1), we can say that their banners' purpose is to deliver the information as simply as possible. Because, the 10.64 complexity rate is relatively easy, while others' complexities go from medium to difficult levels [11].

Regarding the difference between local and remote connections, Turkiye has fluctuated results for remote connection, starting from 0 to approx. 25. It seems that Japan has also a significant difference between the two connection types. However, it has so less banners on both sides to consider, thus, it is hard to comment on them. Other countries' websites are close to each other and there is no pattern for different connections.

There is not much of a difference in average values between the two connection types when we examine them pairwise. Also, we observed that there was no significant change in the text complexity of the text in cookie banners when connecting remotely from the US to other countries.

In conclusion for the first research question, user-centered privacy is mostly appreciated by developed European countries, such as Germany, Italy, and the United Kingdom. These three countries lead the results in terms of having the most amount of cookie informative banners and providing consent to users to accept or reject their cookies. Brazil, Bulgaria, and Turkiye come after the first trio. While nearly half of Brazilian, and more than half of Turkish and Bulgarian websites

lack banners, those banners are predominantly small and lack reject buttons as well. Lastly, Russian and Japanese websites do not represent any term of privacy awareness for the users.

4.2 RQ2: Geographical Impact

Regarding our second research question, we selected suitable G20 countries from the American, Asian, and European continents, which could yield interesting results when compared. The results indicate that Japan provides considerably less information about the cookie collection process than other countries. Following that, cookie banners were found on only 28% of the Russian websites scanned. On the European side, an increase in these informative banners is marked. However, the results acquired from European countries indicate that there are almost 10-20% variation intervals and they all contain privacy-related links at different rates.

For example, although Brazil and Bulgaria are in different regions and subject to different laws, the user notification rates are nearly the same. Therefore, it is not appropriate to establish a direct correlation. Although it is believed that neighboring countries interact with each other through both immigration [12] and trade [31], so they may share similar characteristics and cultures, it is not necessarily the case when it comes to privacy.

4.3 RQ3: Countries Adhering to Same Regulations

We collected data from the 500 most visited websites in eight countries throughout our research on user-centric privacy practices. This data is also beneficial for the evaluation of countries following the same data protection regulations and giving an answer to one of our research questions. Three of the countries investigated during the research are part of the European Union; namely Bulgaria, Germany, and Italy. Moreover, despite the United Kingdom having left the union, the country still adheres to the General Data Protection Regulation (GDPR) of the EU, UK GDPR being in effect. Therefore, the results obtained from these four countries imply inferences on whether differences exist across the countries adhering to the same data protection regulation. Figure 9 filters the results acquired for these four countries on the existence of accept and reject buttons and displays these results as a graph for better visual interpretation.

As displayed in Figure 9, significant differences exist in the characteristics of the privacy consent notices provided to users in these countries. When supported by the results stated in Table 1, Germany takes the lead on the accept button provision rate, being 99.09%. Italy and the UK follow Germany with slightly lower rates, respectively 80.87% and 82.69%. Nevertheless, Bulgaria demonstrates an unlike characteristic with 63.59%. Even the difference obtained for the existence of accept buttons indicates that there might be differences in

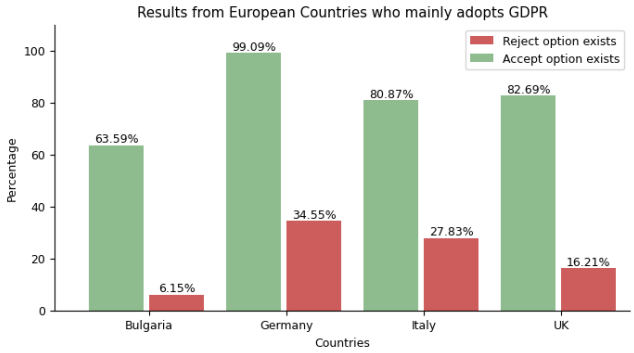

Figure 9: Results on accept and reject button filtered for the countries adhered to GDPR.

practice even though the regulations are the same. Moreover, the significant differences across Bulgaria and Germany on the existence of a reject button, being 6.15% versus 34.55% together with Italy and Germany on further consent options, being 41.73% versus 21.81% advocates the statement that practices do show differences in countries following the same protection regulations.

Therefore, the question on the similarity of cookie consent notices can clearly be answered as even though the countries adhere to the same regulations, the application of these regulations does demonstrate clear variance. Furthermore, this variance extends up to more than 25% differences for the countries considered for this research.

5 Discussion

The results obtained from collected data suggest that user-centered privacy perspectives across countries do differ mostly on the aspect of the options they are providing to the users themselves. These options can be briefly identified as accepting the policy of the website, rejecting the policy, and viewing further options on the coverage and details of the applied policy. The analysis for which the statistics are discussed below is conducted among 77.97% of the websites that are loaded successfully and 44.84% of the loaded websites that have a privacy-related banner.

As the findings of our extensive analysis state, the difference in the rate of acceptance option provided shows a variance of 55.95% in the countries examined, with Germany taking the lead with 99.09% and Russia being the worst country with 43.1%. When it comes to the rate of rejection, on the other hand, the variance observed decreases to 34.59%; again the leading country is Germany with 34.55% and the worst country is Russia with only 0.86%. These outcomes also indicate that users are mostly unable to directly reject the privacy policy of the website; even in the leading country Germany. As a last point of determination, viewing further options also shows a variance of 37.42% across the countries

examined. The lead country changes as Italy with 41.73% for this aspect while the worst country stood steady being Russia with 4.31%. From the results stated above, it can be concluded that either the data protection law enforced in Russia is not satisfactory or it has no effect when it comes to implementation. Furthermore, it can be stated that European countries have better results, indicating that GDPR is relatively successfully implemented.

On the other hand, the investigation computed on the geographical influence on privacy-related practices resulted in significant differences between cultural zones. Russia and Japan, representing the eastern cultural zone, had the lowest results on the statement of the privacy notices and providing options on the notice to the users, whereas Europe had the highest results. The Middle East and South America showed similar characteristics, finding a place in between the highest and lowest results. Nevertheless, these cultural zones have no strict borders between countries. For instance, Bulgaria and Turkiye's results are similar to each other. Therefore, it can be stated that although some inferences can be made regarding different geographical locations, it is not appropriate to categorize countries in line with either zones or borders they belong to or share.

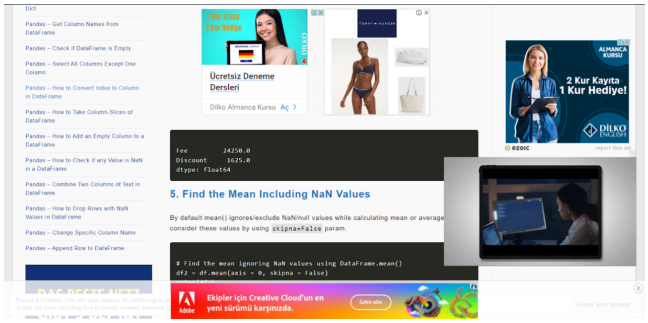
Furthermore, it is clearly visible in the outcomes that a significant amount of websites do not offer an option to the users to reject the privacy policy they are presenting. However, Western Europe still differentiates from the rest of the world in the options provided to the users. Evaluating the percentage of direct rejection, Germany and Italy take the lead with 34.5% and 27.8% respectively. In addition, Italy and the UK take the lead in providing further reject options such as viewing the settings or changing preferences with 41.7% and 41.5%. Although European websites seem to offer more options on the privacy policies they offer, the outcomes suggest that there is still a need for improvement.

The work conducted on the similarities in countries adhering to the same data protection regulations resulted in a specialized comparison across the EU with an addition of the UK due to their common grounds on the regulations. The results obtained show an existence of variance in the banner layouts and the options provided being part of the banner. Therefore, it can be inferred that although the regulations have common grounds, applications may show differences across countries. The fact that Bulgaria and Turkiye have similar results, stated as an answer to geographical influence is also supportive of this aspect of the research. Instead of sharing similar results with other European countries that enforce GDPR, Bulgaria shares a similar result with its neighboring country Turkiye.

As a last point of discussion, when we remotely connected to countries and used the US as our constant reference point, we noticed an interesting trend. Specifically, we found that when a user connected from the US, the possibility of encountering cookie banners on European websites was lower compared to connecting from countries in Europe. In contrast, the situation remained relatively consistent when connecting from the US to websites located in other parts of the world. The fact that this difference is seen between the US, which does not have a general cookie law, and the European Union, which has adopted GDPR, which has strict cookie rules, shows how important it is for citizens that authorities take precautions since it changes and impact attitudes worldwide over cookie privacy consent notices.

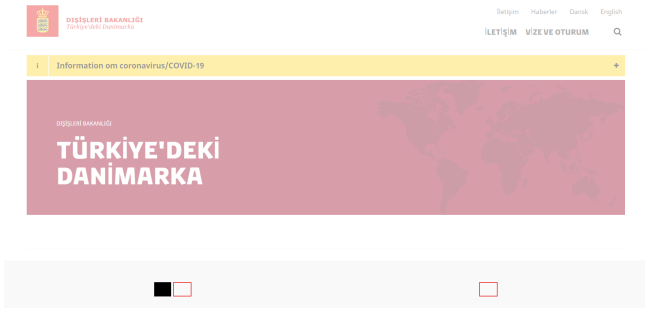
5.1 Limitations

Due to the extent of the research conducted, some edge cases had to be checked manually. These edge cases can be briefly stated where irrelevant clickable text is identified as accept and reject button texts. Despite a large pool of components and words has been created for the automatic data collection phase, such situations have been encountered due to the diversity in cookie consent banners and the options offered as a part of them. Moreover, diversity in the component names used for cookie consent banners increased the amount of preliminary research that has to be conducted to catch all types of banners. Due to the distinctive implementation of the cookie banners on the websites, some cases still existed where Selenium had difficulty accessing the banner, text, or options. Examples for such cases are shown in Figure 10a, 10b, and 10c . On the other hand, the instability of VPN connections caused delays and repetitions in the data collection phase.



6 Conclusion

As the concern regarding privacy is increasingly central to one's data protection in online settings, it is essential to comprehend how different countries around the world inform their users about this subject and acquire their consent for web browsing. This study indicated the applications of privacy notices by analyzing the 500 most popular websites of 8 different countries and discussed the variances across these countries. For this purpose, an automated tool for large-scale data collection is implemented, covering banner layout, privacy notice text, and the options provided to the user such as accepting, rejecting, or viewing details of the privacy policy.



We discovered that many countries were insufficient to display effective privacy notices with their cookie consents, regardless of the privacy protection laws they were based on and their locations. While there was no increase in cookie consent notice existence when remote connections from different perspectives (i.e., Turkiye and the US) were established, we even observed that cookie banner existence decreased when accessing European websites from the US. In countries other than Bulgaria, Germany, and the UK, the rate of presenting a banner to the user that cookies will be collected is below 50%. In addition, the maximum rate of giving the user the right to

(a) Cookie banner implementation with no information.

(b) Cookie banner implementation behind advertisements.

(c) Cookie banner implementation without text and options.

Figure 10: Examples of confusing cookie banner implementation.

reject across the investigated countries is 35% and this is provided by Germany. In the remaining banners, either the user is given the option to accept only, or the cookies are collected without consent and giving any option. The average rate of those who do not put their privacy policy in the footer of their website is 60%. These findings indicate that user privacy is not respected by a majority of websites, putting user data at risk of being exposed.

Users are generally not limited to navigating websites only available in their home country, they can access websites from all over the world. The significance of this study is to demonstrate to users how their data is approached while browsing online platforms from different countries. It is envisaged that the reader will dissect the issue of failure to provide the information and rights regarding cookie collection from a wider perspective with a worldwide study.

Future research in privacy notices around the world can attempt to link with the privacy cultures of the regions by scanning more countries. A more comprehensive study from a sociological point of view can also provide privacy and different connections. We have to *accept all* that data sharing is growing and we should raise awareness about this matter.

Data Subjects' Reactions to Exercising Their Right of Access

Abstract

Recent privacy laws have strengthened data subjects' right to access personal data collected by companies. Prior work has found that data exports companies provide consumers in response to Data Subject Access Requests (DSARs) can be overwhelming and hard to understand. To identify directions for improving the user experience of data exports, we conducted an online study in which 33 participants explored their own data from Amazon, Facebook, Google, Spotify, or Uber. Participants articulated questions they hoped to answer using the exports. They also annotated parts of the data they found confusing, creepy, interesting, or surprising. While participants hoped to learn either about their own usage of the platform or how the company collects and uses their personal data, these questions were often left unanswered. Participants' annotations documented their excitement at finding data records that triggered nostalgia, but also shock about the privacy implications of other data they saw. Having examined their data, many participants hoped to request the company erase some, but not all, of the data. We discuss opportunities for future transparency-enhancing tools and enhanced laws.

1 Introduction

Over the past decade, legislators in many countries have strengthened consumer data protection and privacy rights. Two prominent privacy laws are the E.U.'s General Data Protection Regulation (**GDPR**) [21] and the California Privacy Rights Act (**CPRA**) [11]. Both aim to strengthen consumers' control over data collection and processing, influencing subsequent legislation in Japan [15], Utah [60], Connecticut [54], and Colorado [26]. The GDPR in particular guarantees four key rights: knowledge, deletion, opt-out, and non-discrimination. We focus on the right to knowledge, and specifically whether online platforms are respecting this right.

This right to knowledge, or access, is a critical component of U.S. and international privacy regulation and has been for decades, even before the GDPR and the CPRA. The U.S. Privacy Act of 1974 mandates that individuals can "gain access to [their] record or to any information pertaining to [them]" for government-held data [58]. The right to access is one of nine Fair Information Practice Principles (FIPPs) [23] and eight OECD Privacy Principles [27]. This decades-old right is a key mechanism of privacy transparency. By examining their data, individuals can evaluate an organization's data practices and take action, such as by deleting or modifying data the organization holds about them.

A primary vehicle for guaranteeing the right to knowledge is the Data Subject Access Request (**DSAR**), a communication "addressed to the organization that gives individuals a right to access information about personal data the organization is processing about them" [2, 16]. Once a DSAR is made, consumers receive a **data export**, consisting of one or more files (potentially of many types) containing their personal data. Article 12 of the GDPR specifies that these data exports must be sent "without undue delay" (at most "within one month of receipt of the request") and be "concise, transparent, intelligible and easily accessible" [21]. Further, Article 20 requires that these exports be portable, meaning they must be in a "structured, commonly used and machine-readable format."

Previous work has shown it is challenging to structure a data export in a way that is machine-readable (Article 12), yet still intelligible to consumers (Article 20). Veys et al. conducted focus groups of consumers and showed that companies are not overcoming this challenge [62]. Their participants found data exports unusable or otherwise not useful in their current state. This state of affairs is unfortunate. Prior studies have demonstrated that consumers are interested in, and can gain value from, data exports [4, 62, 64]. Furthermore, tools like Spotify Wrapped, which visualize personal data (not necessarily from data exports), have become popular [46, 53, 55]. Unfortunately, these tools typically visualize only a handful of metrics. For instance, Spotify Wrapped displays a user's music-listening habits [53], but a data export from Spotify contains far more information. A recent research prototype, TransparencyVis [49], aims to enable general-purpose interactions with an entire data export, but does not appear to have been designed based on users' goals for data exports.

Thus, we argue now is a good time to (1) determine to what degree exports are adhering to this legislation, (2) determine the degree to which current data exports are meeting consumers' needs, and (3) pinpoint ways of refining future legislation by identifying what consumers are most interested in learning from their exports. To this end, we conducted a user study in which 33 users of Amazon, Facebook, Google, Spotify, and Uber made DSARs, explored and annotated their data exports using a web app we built, shared pseudonymized versions of their exports, and reflected on their experiences.

In this paper, we answer the following research questions:

RQ1: How complex or concise are data exports? The GDPR states data exports should be "concise" and (along with the CPRA in identical language) presented in a "structured, commonly used and machine-readable format." Concise exports are more accessible for consumers, making it so that they can enact their privacy choices without the burden of extensive searching. To answer this question, we analyzed the 801 data export files 33 participants shared. We found that the complexity of data exports varied both across and within platforms. Amazon data exports typically contained a dozen directories; Spotify data exports contained only one.

Any consumer or data subject should be able to use data exports as a window into a company's privacy practices. The GDPR codifies this by requiring that the information in data exports be in an "intelligible and easily accessible form, using clear and plain language, in particular for any information addressed specifically to a child." The CPRA similarly states that data exports should be "easily understandable to the average consumer." Therefore, we ask:

RQ2: What kinds of questions did participants want to answer with their data exports, and which of these were they eventually able to answer? To investigate, we analyzed questions our 33 participants submitted before exploring their data, alongside their reflections on those questions. Participants were most curious to learn about their usage patterns (e.g., hours spent daily), platforms' data-collection practices, and how the platforms use personal data. Because of the heavy use of jargon, large exports, and specialized file formats, participants were often left with incomplete or missing answers.

RQ3: How effective are data exports as tools for providing information to consumers? Since data exports are inaccessible to most consumers due to their size, file format, and complexity [62], we built a React-based web application with which participants explored their exports and annotated bits of information they found confusing, creepy, interesting, or surprising. These annotations showed that participants reacted positively to finding records that triggered memories. They also liked finding record types for which they searched (e.g., login times). Notably, they looked for a wide variety of records. For example, while some wanted to map out every Uber ride they had ever taken, others wanted to discover new music based on past Spotify listening behavior. In contrast, a number of participants were shocked by the records they saw, feeling their privacy had been violated and their agency undermined. Some participants were especially surprised when they discovered data they thought they had previously deleted.

In addition to the right of access, the GDPR and CPRA give consumers the right to modify incorrect data, erase data, and restrict processing of data for specific purposes (e.g., prevent the sale of personal data to third parties). These rights are how consumers enact their data privacy preferences and are most useful once consumers have the knowledge granted by data access rights. To evaluate their relevance, we ask:

RQ4: Are the actions consumers are most interested in taking after exploring their data in line with those guaranteed by privacy laws? In a post-task survey, participants wanted specific data records erased if they could not justify why the platform would collect that record. In their annotations, participants similarly wondered how they could prevent the platform from collecting analogous data in the future.

Our findings suggest the need for redesigning platforms for exploring data exports to better meet consumer needs. These tools should include a comprehensive list of all data record types in the export. More often than not, basic syntheses and visualizations of each record type will be sufficient. To more closely abide by Article 12 of the GDPR, companies should experiment with different data formats for their data exports and define jargon any time it is used. Finally, data exports could promote user agency and trust by embedding actions consumers can take (e.g., modifying a specific setting or requesting a record be erased) within the exploration process.

2 Background and related work

Data subject rights and security and privacy. Since the GDPR went into effect, the security and privacy community has been studying the impacts of data subject rights. Many studies have found shortcomings of the GDPR, mostly due to imprecise language, and have developed solutions. Some were focused on challenges with implementation, such as Cohen et al., who found that absolute deletion has complex implications for machine learning models that have already been trained on that data [13]. They instead proposed leveraging differential privacy mechanisms to guarantee near indistinguishability between models where the data subject is present and those where the data subject is absent [13]. Ferreira et al. developed a system for guaranteeing data protection requirements that can easily be added to existing web applications [24]. Our study takes the complementary approach of exploring current implementations of the right to access and identifying the core features an effective implementation should have.

Others have studied how end users interface with privacy regulation. Habib et al. found that data deletion options and opt-outs for email communications and targeted advertising are not easy to use [29]. Utz et al. argued that the methods for obtaining consent for cookies should be made more explicit in existing regulation since small implementation de-

cisions (e.g., the positions of cookie banners) have a large impact on user actions [61]. Farke et al. showed that privacy dashboards—interfaces that allow users to review and control data collection that partially parallel the right of access [45]—strengthen trust between users and platforms and are therefore effective tools for communicating security and privacy data practices [22]. Our study similarly asks if the right to access as it currently exists is sufficient to meet consumer needs.

Some studies have focused on identifying adherence to—or violations of—privacy regulations. Degeling et al. analyzed privacy changes on popular websites after the GDPR's introduction, finding a 16% increase in cookie consent notices on European websites [19]. Bertram et al. analyzed URLs users requested to be removed from Google Search for five years following the passage of a "right to be forgotten," demonstrating that consumers were enacting their right and Google was complying [5]. Nguyen et al. found that nearly 30% of Android apps sent personal user data to data controllers without the user's explicit prior consent [39]. In our study, we search for similar instances where platforms could be more compliant with consumers' right of access.

Data exports. Prior work has examined the DSAR process and the resultant data exports. Initial work highlighted vulnerabilities in the DSAR authentication process that can be abused to steal data from others [7, 36]. Researchers have also shown that consumers experience long wait times [18, 32] and encounter manipulation tactics [33], poorly organized exports, and privacy risks during authentication [10, 32, 52, 57, 59].

Other work has leveraged data exports for purposes beyond data subjects' rights [30]. For instance, researchers have used data exports (as "data donations") to audit social media platforms like Instagram [43], TikTok [65], and Twitter [64].

Academics and industry practitioners have also explored ways of improving DSARs. Leschke et al. designed an automated approach to making DSARs, minimizing the burden on consumers [34]. Others have attempted to streamline a company's process of responding to DSARs by either providing tooling for data workers [47, 56], attempting to automate the process [31, 38, 63], or studying inefficiencies in GDPR compliance as a whole [35, 48, 50, 51].

Making sense of personal data. Information about a company's privacy policies and privacy-enhancing features can be hard to find and is often written in complex, inaccessible ways [40, 42, 44]. Previous work has shown that not only do consumers have an interest in enhancing their privacy [14, 20, 37], but tools and interfaces that increase transparency into company data practices lead to increased interest and concern with privacy. For example, Arias-Cabarcos et al. showed that Meta's "Off-Facebook Activity" Dashboard was effective at informing consumers of previously unknown flows of their data [4]. Datta et al. built a similar interface for Google's Ad Settings page [17]. Angulo et al. built a tool for consumers to visualize data disclosures, which they similarly found to be clearly informative [3]. Other work has demonstrated the effectiveness of privacy nudges [1], data disclosure dashboards [3, 22, 25], mobile privacy dashboards [41], and data flow dashboards [6]. Most relevant to this study is Schufrin et al.'s TransparencyVis prototype, developed for visualizing data exports [49]. Our investigation into users' goals complements their tool and suggests future directions.

3 Method

To understand users' goals and reactions to exploring their data exports, we conducted a two-part online user study. The first part was a screening survey where we asked participants to make DSARs for one or more of the five companies studied (see Section 3.1). The main study consisted of participants exploring and annotating their own data export. The screening survey needed to be separate from the main study for two reasons. First, platforms do not respond to DSARs immediately. Second, we wanted to filter for participants who had a significant history of usage with the companies chosen.

In the main study, participants uploaded their data to an interactive web platform we built. We decided to build such a platform because, as previous research has shown [62], most consumers are not familiar with reading or opening the files in formats many platforms use in their data exports (e.g., JSON). Additionally, since we wanted to record detailed and accurate reactions, we wanted to collect these *while* participants were exploring their data. Therefore, our platform included rich annotation features (see Section 3.3).

3.1 Platform selection and DSAR instructions

We recruited users of five platforms for this study: Amazon, Facebook, Google, Spotify, and Uber. We selected these platforms because they are widely used and because they have been a focus of previous work on data exports [49, 62]. Our original study design also included Twitter (currently rebranded as X), but both the research team and pilot testers experienced substantial or indefinite delays in receiving their data exports, so we needed to exclude it.

Because of technical constraints described in Section 3.3, our annotation platform could not always accept participants' entire data exports, which for some companies can include tens of gigabytes of data for active users. Fortunately, with the exception of Uber, the platforms we chose allow consumers to request a specific subset of their personal data. When the option existed, we instructed participants to request their data in JSON or CSV format, as opposed to HTML format. The research team and pilot testers submitted several requests to the five companies throughout the research process to determine the approximate size and types of files contained within these exports. We then used this information to identify categories to exclude from Amazon, Facebook, Google, and Spotify's

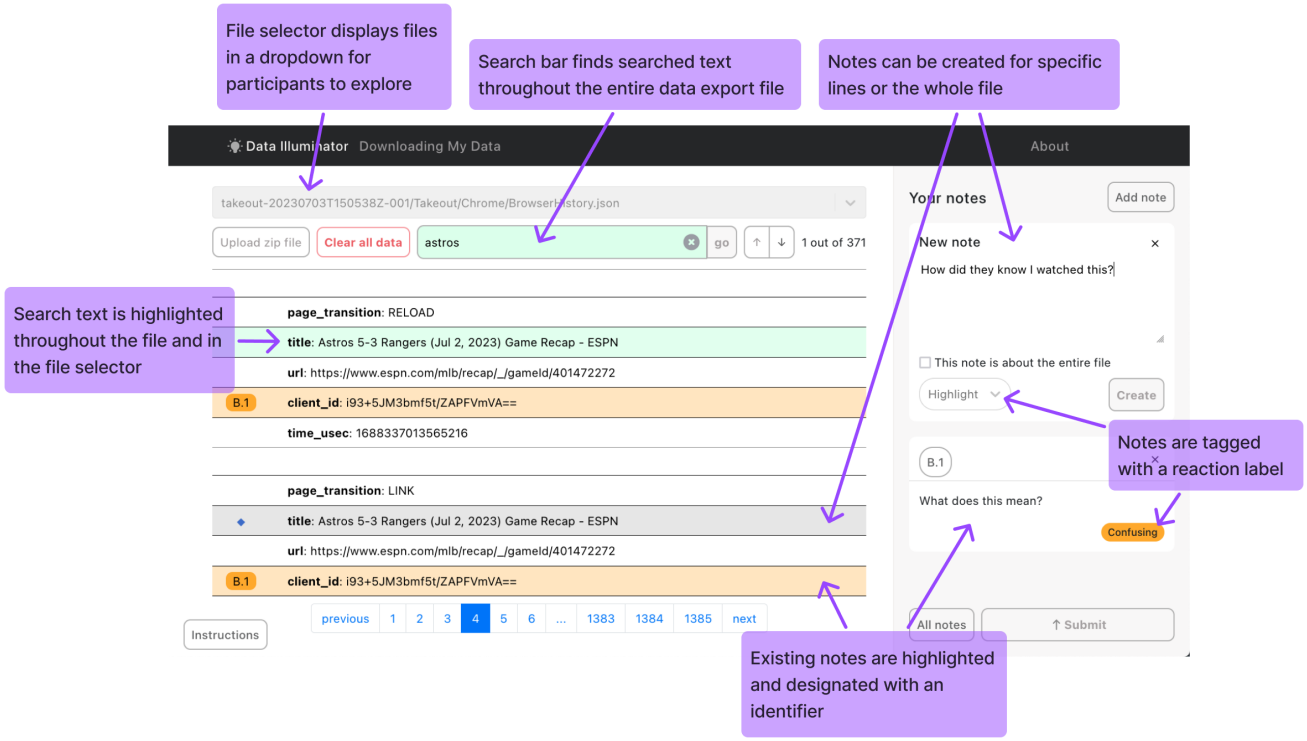

Figure 1: Diagram showing the process of interacting with the web-based tool we built for exploring and annotating data exports.

DSARs. These excluded categories included large, sensitive data like media (photos and videos) and documents stored in Google Drive, as well as the extended streaming history for Spotify. Despite these precautions, some participants' data exports were still too large for our platform. In these cases, we worked with them to identify folders and files that were requested by accident or unusually large (many gigabytes).

3.2 Recruitment and screening survey

We recruited participants on the Prolific crowdwork platform. The screening task was open to any English speaker in the world over the age of 18. Recruiting from an international pool meant our participants completed the study under a variety of privacy regulatory regimes. We did so to ensure our eventual recommendations to tool developers and policymakers would benefit a wide range of consumers. Recruiting from multiple countries and languages provided visibility into the structure of data exports from around the world. This strategy also helped with recruiting more participants for our complex and lengthy study. We directed participants to a Qualtrics survey that asked about their usage habits of the selected companies. Any participant who had been using at least one of these platforms for at least two years was given instructions on submitting a DSAR. We then asked participants to share their experiences requesting their data. All participants were paid $2 USD for completing the screening survey regardless of whether they qualified for the main study.

3.3 Main study task

In the main study, we first asked participants in a Qualtrics survey to confirm they received their data export and to answer questions about their previous experiences making DSARs and exploring data exports. We then asked them to brainstorm five questions they hoped could be answered using their data export. At this point, we asked participants to upload their data export to our web app and begin the annotation task.

We built our data annotation platform using Node.js and React, hosting it on our research group's servers. Figure 1 shows the main interface and features. After they uploaded their data exports, we asked participants to create 10 annotations on the platform (or five if their data export had 20 or fewer files). An **annotation** consists of three elements: zero or more lines within a file, an explanation of why those lines or that file stood out, and one of four tags—**confusing**, **creepy**, **interesting**, or **surprising**—proposed by Veys et al. [62].

Once participants created the minimum number of annotations, they had the option of creating more or beginning the submission process. In the first step in that process, our platform showed the participants their five original questions and asked them to reflect on whether or not they had been answered. Then, the data annotation platform prompted participants to identify three additional questions they had about themselves, their data, or the company that provided the data export. We paid participants $15 USD for completing the main study, which took about 35 minutes. We allowed each

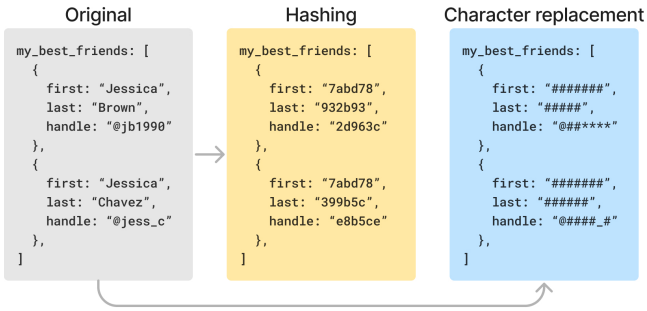

Figure 2: We created two anonymized versions of the data export using hashing and character replacement, respectively.

participant to complete the annotation task for more than one company, compensating them separately for each.

3.4 Ensuring participant privacy

In addition to receiving approval from the University of Chicago Institutional Review Board (IRB), we took a series of precautions to protect participants' privacy and anonymity. The design of our study required participants to upload data that, by its nature, contained identifying information. A data export might include emails, full names, addresses, dates of birth, and more. It also likely contains information that participants would consider sensitive and may not want to share, such as their location history or browsing history.

We used two primary strategies to protect participants' privacy. First, we performed all processing on the client side. Second, we pseudonymized the data exports before uploading them to our server. As mentioned earlier, the research team completed several DSARs for the five companies and found that the keys in JSON data never contained user data—instead they were used to name types of records. Therefore, we only pseudonymized the corresponding values in the exports.

We performed **hashing** and **character replacement** on the values to keep important structural data while maintaining participant privacy (see Figure 2). When hashing, we first split values by white space, leaving us with a list of tokens. We then salted each token on the client side with a randomly generated 32-byte string unique to each participant, which was never shared with the researchers and would be computationally infeasible to brute force. Our web app uploaded to our access-controlled server, via HTTPS, a version of the data export in which the keys were retained in plain text, but all values had been salted and then hashed. This hashed version allowed us to identify repeated values since a given term with a fixed salt always hashes to the same value. Our web app also created a separate version of the data export in which values underwent character replacement. We replaced all letters in the values with pound characters (#) and all digits with asterisks (*). Character replacement preserved the file size and the length of values, enabling additional analyses. Appendix A details how we communicated these strategies to prospective participants.

One participant (P20) reached out to us on Prolific with concerns about their data privacy and security. They were worried about exposing financial information to us, our ability to access their data, and whether they might accidentally delete data by making a DSAR. We responded with the same description of the anonymization techniques we put in the tool. The participant thanked us, said they were satisfied with our precautions, and completed the study.

3.5 Qualitative data analysis

We performed qualitative analysis on participants' free-text responses to identify themes. Two team members collected responses to the data annotation task and the survey from about 10% of participants and compared themes to develop a preliminary codebook. While this sufficed for identifying primary codes, all four coders subsequently iterated on secondary codes. We then split responses into four sections. One team member served as first coder on all responses, while four separate team members served respectively as second coder. Each pair met and resolved all disagreements. Finally, the first coder performed affinity diagramming on the codes to identify connections between themes. We correct spelling and capitalization mistakes when reporting participant quotes.

3.6 Limitations

Our study considered only a subset of the files and data that the selected companies have on users. This limitation was due to the technical challenges brought on by relying entirely on client-side computation, a trade-off we believe was important to ensure participant privacy and promote trust. Additionally, we only built capacity for parsing JSON files, CSV files, and (when the file structure was predictable) selected HTML files. All other files were discarded. While this does limit our analysis of the size and structure of participants' data exports, most participants did not click through every single file.

Among companies, Spotify and Amazon had the smallest number of participants in our study. We suspect this limitation was caused by these platforms taking a week or two, the longest among the chosen platforms, to respond to DSARs. Participants would sometimes forget they signed up for the study, not notice they received a data export email before the download link expired, or simply turn down the Prolific task.

While we anticipate that our hashing and redaction techniques should prevent most potential privacy leaks, there is no guarantee that identifying information cannot be found in the names of files or in JSON keys even though we never observed this to happen in our own data exports. For this reason, we made ourselves as available as possible to our participants via email and on the Prolific platform. Most participants did not reach out with privacy concerns, but we promptly responded to the one who did (P20); they chose to complete the study.

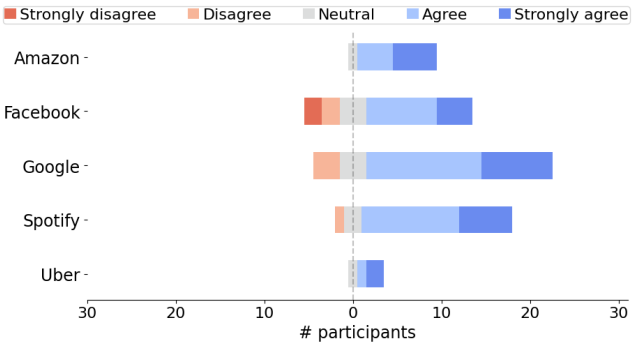

Figure 3: Participants' responses to the following statement: "It was easy to download my data from the platform."

Additionally, as Table 1 shows, our sample is not representative of global consumers and skewed young, white, and male relative to the broader population. Participants may know more about data practices, which could impact reactions to their personal data. In Section 3.3 we described how, in the screening survey, we asked participants to articulate five questions they hoped could be answered during the study using their data export. Some participants might not have had any questions about their data and thus generated questions for the sake of the task. As such, the questions some participants produced may reflect a set of questions they might abstractly hope to have answered somehow, rather than what they realistically expected to be answered by their data exports. Note, however, that the questions generated by the six participants who viewed the data requested for this study before the annotation task were not atypical of those of other participants: they were about general data usage, searching for specific records (e.g., location), and company security practices.

4 Results

We first describe our participants and their DSAR experiences (Section 4.1) before characterizing their data exports (Section 4.2). We then describe the questions participants posed about their data exports (Section 4.3) and key themes from participants' annotations (Section 4.4). Finally, we describe participants' intended future actions (Section 4.5).

4.1 Participants and their DSAR experiences

In total, 33 participants completed the study. Table 1 summarizes their demographics. Participants skewed young (24 younger than 35), male (21), and white (21). The most represented country was South Africa (10), and the most represented continent was Europe (15). Only 14 participants hold a bachelor's degree or higher, and the majority work outside the technology field. Recall that we permitted participants to complete the data-annotation task for multiple companies; five annotated data exports for two different companies.

Many participants completed a DSAR for the first time for this study. Of the 33 participants, 12 reported that they had downloaded their data from a platform prior to this study ("ever downloaded data?" in Table 1). In their written responses, nine participants reported doing so out of curiosity, while three did so out of necessity (e.g., because of work). Although Figure 3 shows that most participants did not struggle with the DSAR process, some encountered issues with the delivery timeliness. While we did not formally measure the time to deliver the data export, participants usually had their Google data export by the end of the day. In comparison, Spotify typically took one to two weeks to provide the data.

Google and Facebook, and to a lesser extent Spotify and Amazon, provide controls during the DSAR process, unlike Uber. Facebook users can choose categories of information to include, such as "logged" or "ads" information. Making a DSAR to Facebook or Google requires approximately the same number of steps, but Figure 3 shows participants struggled more with Facebook. This is likely because Facebook's DSAR instructions were briefly outdated since Facebook changed the DSAR process during the study. We had directed participants to Facebook's own instructions, and neither of their two pages[1] were updated to reflect the new procedure.

4.2 Structure of data exports (RQ1)

We received 801 (pseudonymized) files from 33 participants. Table 2 characterizes these files. Spotify and Uber's data exports were the most consistent in the metrics we observed, with two out of the three exports from the former containing files with the same names. The third export was missing the `Identity.json` and `SearchQueries.json` files, although it is unclear why. The identity file in particular contains important data, such as the user's display name and profile photo.

Google, the platform with the most participants, unsurprisingly showed the greatest variation in data export size and complexity, with a median of 15 directories per participant ("# directories" in Table 2). This complexity is understandable since most top-level directories are named after individual Google products (e.g., `Home App/` and `Maps/`). All Google data exports had a `My Activity/` directory, which seemed to be a log of different types of activities for different products, although it is sometimes unclear what these activities are. These activity files, along with history files, were among the largest. To our surprise, these history files were not consistently named across Google participants. For instance, the browsing history was named both `Chrome/History.json` and `Chrome/Browser History.json`.

Participants completed our study from 11 different countries (see Table 1) and had different language preferences (see Appendix C for export complexity across regions). Google was the only platform for which we received filenames in different languages; however, we speculate this is because participants for the other platforms all had set English as their preferred language. Even then, keys and column headers in files with non-English filenames were still in English.

To further understand the complexity of these exports, we counted the number of unique keys within every file in a data export (# unique keys in Table 2). The sample file in Figure 2, for example, would have four unique keys: `my_best_friends`, `first`, `last`, and `handle`. Amazon and Google's largest exports both had a similar number of unique keys (598 and 545, respectively), but the median number of keys per Amazon participant (424) was more than double that of Google (118). This means Amazon has a higher density of unique keys given that the median export size (806 kB) was about one-fifth that of Google's (4,118 kB). Like other metrics, the number of unique keys varied across platforms.

4.3 Participants' goals for their data (RQ2)

Before interacting with their data, we asked participants to think of three to five questions (depending on the size of their exports) about what they wanted to learn from their data. We refer to these as **pre-annotation questions**, After the data annotation exercise (during which participants explored their data, described in detail in Section 4.4), we showed participants their pre-annotation questions and asked them to write a few sentences on whether or not they were able to answer each question; we refer to these as **post-annotation reflections**. While some participants answered with certainty (e.g., "*I did not find the answer in my data,*" P17-Google), others were more vague (e.g., "*there is too much to look into,*" P4-Amazon). We considered pre-annotation questions to be fully answered if the post-annotation reflection contained the answer itself or an affirmative indication that the user found an answer (e.g., "*yes, I got this information,*" P11-Uber). Finally, we asked participants to brainstorm three more questions (**post-annotation questions**) that they still had about their data or the platform after exploring their data export.

In this section, we describe the types of questions participants asked, which of them were answered, and how they evolved with the added context of the data export.

Questions answered by the data export. We first categorize the pre-annotation questions for which participants successfully found answers during the data annotation exercise. Table 3 lists the different types of questions along with the number of participants who asked them, the number of questions of that type, and how many of those were answered.

Closed-ended questions about the existence of records in the export and generic questions about the contents of the files were most commonly answered. In total, 24 participants asked 59 questions about whether a specific record type existed in the data ("specific participant records" in Table 3). These questions were typically short and simple, often in the form of "*Is my location stored in the data?*" (P28-Amazon), al-

Table 3: Key questions participants initially hoped their data download would answer, the number of unique participants (#) who listed that type of question, total questions in that category (?), and the number of questions fully answered (✓) after exploring.

Question Type	#	?	✓	Example Participant Quote
Platform information	**29**	**93**	**59**	
Selling & sharing data	10	17	10	"*Does the company share [its] users' data with other companies?*" (P14-Google)
Storage	10	12	10	"*How long is my data kept for?*" (P33-Google)
Usage (general)	8	10	5	"*Why do you gather my data?*" (P35-Google)
Business practices	7	15	5	"*Does the company use AI to make specialised playlists*" (P4-Spotify)
General data questions	7	10	10	"*What data about me is being collected*" (P6-Google)
Access	7	9	5	"*Who has access to my data?*" (P33-Google).
Privacy & security (general)	6	9	5	"*Is my data safe?*" (P16-Google)
User actions available	4	7	6	"*Can I ask you to delete my data?*" (P15-Google)
Personalization	3	4	3	"*Do they use my position data to show me personalized ads?*" (P23-Google)
Specific participant records	**24**	**59**	**15**	
Location	11	13	11	"*Does Uber track my travel locations?*" (P18-Uber)
Interactions with other users	4	5	3	"*How many people did I engage with?*" (P27-FB)
Nonconsensual data	3	4	3	"*Is the company collecting data it said it wouldn't?*" (P22-Spotify)
Devices	3	3	3	"*Are the devices where I've logged on stored and detailed?*" (P3-Uber)
Browsing/search history	3	3	3	"*Does Amazon know my browser history when suggesting me stuff?*" (P15-Amazon)
Time spent on platform/activities	3	3	2	"*Do they keep track of how much time I spend in the app?*" (P23-FB)
Payment information	3	3	2	"*How are my payment details stored?*" (P28-Amazon)
Other records	15	24	16	"*How many reports or clarifications have I generated in the app?*" (P11-Uber)
Participant information	**13**	**30**	**7**	
Patterns, trends, & hypotheticals	7	9	3	"*What locations have I been to based on my location history, and can I identify any significant travel patterns or places of interest?*" (P13-Google)
First/most of record	6	9	3	"*What was my first friend request I got?*" (P12-FB)
Total of record	5	8	0	"*How many hours have I spent on Facebook in a certain period of time?*" (P27-FB)
Platform's perception of user	3	3	1	"*Compared to other users, am I a good user to the platform?*" (P27-FB)

though some used the term "*tracked*" instead. By far the most requested data type was location, with 11 participants ("location" in Table 3). Several other participants listed concrete data types like age, browsing history, or payment methods, but other participants were vague when referring to data types.

Data exports were effective at answering these questions about specific records. In fact, most of these questions were answered—only seven were not (two each in "location" and "interactions with other users" and one each in "nonconsensual data," "time spent on platform/activities," and "payment information" in Table 3). Most participants noticed that the data type in question was being tracked, but their reactions varied. P1, who completed the study for Google and Facebook, found that both companies had "*a bit more*" location data "*than expected.*" P15-Amazon, on the other hand, felt Amazon "*barely*" knew their "*browser history*."

Participants also asked more general (still often closed-ended) questions about the data. Six participants asked about the security or privacy of their data ("privacy & security (general)" in Table 3), such as P25-Google: "*Is my data handled with caution?*" Ten participants asked how data was stored or for how long it was stored ("storage" in Table 3), while others asked generic questions ("general data questions" in Table 3), like P6-Google: "*What data about me is being collected?*"

Participants who asked generic questions about how much data the platform was storing were able to find answers 10 out of 12 times ("storage" in Table 3). Participants found that they were storing "*a lot*" (P6-Google) of data, "*much more than [they] expected*" (P20-FB). Participants using Uber, Amazon, or Spotify were not quite so surprised, such as P10-Uber, who answered their own question about their Uber trips with "*whole data is here so it's answered.*" Some answers were quite precise ("*signed in data expires after 26 months,*" P34-Google), others less so (data is kept "*forever,*" P33-Google).

Questions unanswered by the data export. We found that questions that required analysis or computation ("patterns, trends, & hypotheticals," "first/most of record," and "total of record" in Table 3), questions about a platform's business practices or technology ("business practices" in Table 3), and questions about specific security practices ("selling & sharing data" in Table 3) were not answered.

Six participants exploring Uber, Facebook, and Amazon asked about the first or earliest instance of a record (e.g., "*first friend,*" P12-FB, or "*oldest purchase,*" P28-Amazon, "first/most of record" in Table 3). These questions were similar to the "specific participant records" in that they were usually short and simple questions with a concrete answer (in this case, a number), but they did require more analysis or synthesis than simply whether a record was present.

Seven participants asked longer and more complex questions ("patterns, trends, & hypotheticals" in Table 3) about their "*communication patterns*" or "*online behavior*" (P13-Google). P24-Uber went a step further: "*Can I use my data to increase the quantity and percentage of discounts I get?*"

Participants received fewer answers to these types of questions. No participant who asked about the total amount of money, time spent, or distance traveled over time got an answer ("total of record" in Table 3). Additionally, only one of P13-Google's questions (their "*most frequently visited website*") was answered. P28-Uber bemoaned the "*lack of summary or any form of analysis,*" which also accounted for the "*disappointing*" lack of answers to P13-Google's questions about their communication patterns and online behaviors. The content of the data exports tended to be mostly raw data—any summaries or syntheses of information were absent. This is likely why most participants were unable to find answers to these questions.

In addition to wondering *what* data platforms stored, participants wanted to know *how* it was used. For example, ten participants wondered if their data was sold to third parties (e.g., "*Does Uber sell client data to telemarketers?*" P24-Uber, "selling & sharing data" in Table 3). Further, 15 questions regarding the platform were about its business dealings ("business practices" in Table 3). P4-Spotify, for example, asked, "*Does the company use AI to make specialised playlists?*"

A little more than half the questions about platforms' usage of data were answered. There were no patterns where some questions were better answered than others ("usage (general)" and "selling & sharing data " in Table 3). In fact, both P25-FB and P9-FB asked if their Facebook data was being sold for the platform's benefit. P25-FB concluded "*Yes, by ad partners*," while P9-FB wrote, "*I don't know more about this point.*" Out of 15 questions about the business side of the platform (excluding those related to selling or sharing data), 10 remained unanswered, with no indication as to why there was no answer ("business practices" in Table 3). GDPR requires platforms to disclose how they use consumer data, but not necessarily within a data export. These unanswered questions could indicate incorrect expectations of what a data export would contain, or a desire to have these exports cover a wider range of topics (e.g., a platform's privacy policy).

New questions. Compared to pre-annotation questions, post-annotation questions (Table 3) focused less on the participant and more on the platform. Only four participants had lingering questions about themselves ("participant-related" in Table 4), which were most similar to the "patterns, trends, & hypotheticals" in Table 3. In fact, some participants carried questions over, such as P26-Uber, who asked about when they used Uber the most both before and after the annotation task. Only seven participants asked about the existence of specific records post-annotation, compared to 24 pre-annotation ("specific participant records" in both Table 3 and Table 4), again indicating that data exports in their current form are well-equipped to address these types of questions.

Questions about "usage," "privacy & security," "storage," and "business practices" were consistent between pre-annotation and post-annotation questions. All participants who had these questions before annotation still asked questions in at least one of these categories post-annotation, although the details sometimes changed. Three participants who asked questions about the business operations of the platform became curious about comparing data across companies, such as P3-FB, who asked, "*How does the data in the EU differ from data in the US?*" This pre- and post-annotation consistency indicates that although current data exports may not be suited to answer questions about how platforms use and manage user data, these questions are important to users.

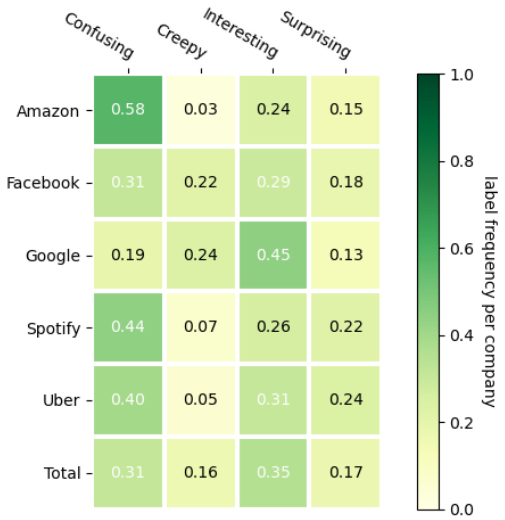

Figure 4: The predominance of the four tags by platform. Percentages are with respect to total annotations per platform.

4.4 Reactions in data annotations (RQ3)

In this section we present findings from the data annotation exercise, the main part of our study. In the exercise, we asked participants to highlight segments of their data that stood out to them, categorize that segment (*confusing*, *creepy*, *interesting*, or *surprising*), and explain why it stood out to them.

Figure 4 shows the frequency with which each of the four labels was used. The most common label was *interesting*, making up almost 40% of the labels applied. However, this finding is influenced by the large number of Google exports we analyzed, of which *interesting* was the most common label. For every other company, the most used label was *confusing*, hovering from around 30% (Facebook) to nearly 60% (Amazon) of labels. Participants did not use the *creepy* label often. It only exceeded 20% in the case of Google and Facebook. For all other companies, its use was below 10% of annotations.

Overall, though, there was no drastic difference in the number of times each label was used. Table 5 suggests the reason—participants often had different reactions to discovering similar or identical pieces of information. Consider two participants for the same platform: P1-Google commented that Google collects "*too much info and they store it for too*

Table 4: After participants explored their data, the questions they still wanted to have answered, including the number of unique participants (**#**) who listed that type of question and total number of questions in that category (**?**).

Question Type	#	?	Example Participant Quote
Platform	**32**	**103**	
Usage	11	18	"*What would they do with information like this?*" (P3-Uber)
Privacy & security (general)	9	11	"*Is it really safe that they have so much information about the user?*" (P11-Uber)
Deleting data & other actions	9	18	"*How can I delete all this info?*" (P9-FB)
Business practices	9	13	"*How is the data used to recommend new music?*" (P4-Spotify)
Storage time period	7	8	"*How long is all this data stored?*" (P7-Google)
Specific participant records	7	9	"*Does Spotify collect banking details?*" (P4-Spotify)
Confusion	6	9	"*What are the strange symbols on some lines?*" (P20-FB)
Missing data	5	8	"*Why isn't there a device login history category?*" (P3-Uber)
Access	5	5	"*Who can access this information besides the user?*" (P11-Google)
How do they know?	3	4	"*How do they have this data?*" (P1-FB)
Others	**6**	**12**	
Participant-related	4	6	"*When do I use Uber [most] often?*" (P26-Uber)
Data annotation platform	2	6	"*What will you do with my data?*" (P33-Google)

long" and P16-Google similarly found the "*very extensive information*" in the Google export to be "*a bit disturbing*." Despite these similar annotations, P1-Google labeled theirs as *creepy* while P16-Google labeled theirs as *interesting*. Thus, we describe high-level themes that crossed label categories.

Surprise the company knows this information. While we never explicitly asked participants about privacy or security concerns before the data annotation task, Table 5 shows themes related to these concerns appeared in all four categories. Participants often questioned why platforms had specific records, how they had them, and how long they planned on storing them. Participants sometimes pointed to specific types of records that should not be collected or stored at all.

Most participants (20) discovered types of records that they had not previously known the platform collected ("tracking, collection, & use" across the four labels in Table 5). These included spending habits, payment methods, emoji use frequency, search history, browsing history, login location, times when activities started, times when activities ended, IP addresses, phone carriers, devices used, car ownership, and locations where they downloaded apps. Participants responded with surprise and confusion. P6-Uber, for example, was not "*sure why [it] is necessary*" to keep their "*bank details in the payment methods file*." The level of detail and specificity of the data often alarmed participants, such as P2-FB, who noted "*Emoji count? Why? I just... Why?*" after discovering a file with counts for every emoji they had ever used on Facebook.

Some participants felt like their preferences had been violated, noting they either opted out of or never knowingly opted into data collection. P20-FB, for example, wondered, "*So does the location pick me up even though my location is not activated???*" (`where_you're_logged_in.json`). P21-Google, plus three other Google participants, realized "*deleting browser history does not mean that [their] data is removed forever.*" P2-FB also felt their preferences were violated when they encountered their off-Facebook activity file:

> "*Words can not really express. Why is Facebook tracking my off Facebook activity? How? Why? Where did I agree to this? How do I opt out? This is by far the most disturbing thing.*"

Sources of confusion and barriers to comprehension. Participants were sometimes unable to interpret the meaning of components within a data export, including file names, keys, and values. Nine participants were confused by the meaning of the values in their data exports ("value meaning" in Table 5). Some of these values were identifiers (e.g., `orderId`, `advertiserName`) and dates (e.g., P13-Google said their `birthday` key was set to 0000), but in most cases our pseudonymization prevented us from investigating further (e.g., `description: *** *** **** ******* **** ..... @`).

Eight participants could not decipher the meaning of some keys within their data exports ("key/column naming" in Table 5). P23-FB, for example, did not "*understand what they mean by 'off Facebook activity'*" in `your_off-facebook_activity.json`. Other keys that caused confusion were `Used For Disbursements` (in `payment_methods-0.csv`, Uber), `PrimeStudentMarkedForGraduation` (in `Subscriptions.PrimeTransition.csv`, Amazon), and `voting_location` (in `voting_location.json`, Facebook). No participant mentioned finding the meaning of these terms in their data export.

Some participants (14) did not find data they were expecting ("missing & incomplete data" in in Table 5). Many keys had blank or null values for no clear reason (e.g., P8-Spotify said `episode` was set to `null` in `Playlist1.json`). Participants could not understand why some records had "*such careful tracking of events*" (P18-Uber) and nothing for data participants expected the platforms to have (such as P18-Uber's order history for Uber Eats). Two participants mentioned seeing incomplete Spotify listening history. Here, the missing data was expected as we asked participants to exclude streaming history from Spotify DSARs (see Section 3.1).

Table 5: Clustering of participants' annotations, with the number (#) of unique participants creating each, whether the subject of the annotation is the platform (🏭) or participant (👤), and an example.

	Annotation Theme	#	Example Annotation
	Confusing	**30**	
🏭	Missing & incomplete data	14	P16-Google opened their YouTube search history file and noted the history "*is incomplete, I don't know what is the reason, because I watched more materials.*"
🏭	Value meaning	9	P32-Google found a list of Chrome extension ids and noted "*I don't understand what is written there.*"
🏭	Key/column naming	8	P2-FB annotated a line in `your_record_details.json` with "*What the hell is a checkpoint?*"
🏭	Tracking, collection, & use	9	P4-Spotify annotated `Inferences.json` with "*Looked at all files and I have no clue what they are for. This doesn't sound like something connected to music at all.*"
🏭	Deleted records still exist	3	P21-Google annotated the `Search/My Activity.json` file with "*Google keeps my data from a very long time ago even though I sometimes delete browser history of all time on all my devices.*"
🏭	Inferred data	3	P23-FB found a list of topics Facebook thinks are interesting to them in `feed.json` and noted "*I don't know why they think this a interesting topic for me.*"
🏭	Befuddlement	3	P9-FB annotated 4 lines in `advertisers_you've_interacted_with.json` with "*??????*"
	Creepy	**23**	
🏭	Tracking, collection, & use	18	P20-Google has "*no idea why*" the Google Play Store order history would be "*showing locations.*"
🏭	Old/stale data storage	5	P6-Google noted "*Wow that was a long time ago - 6 years of activity tracked?*" when exploring their YouTube activity.
🏭	Preferences violated	6	P25-Amazon noted in `consents.json` that they "*do not remember consenting to ad partners.*"
🏭	Nonsensical/incorrect data	4	P12-FB "*I don't even [know] who those people are*" listed in `people_who_followed_you.json`.
🏭	How to stop collection	3	P9-FB wondered "*how can I delete this?*" in the `recognized_devices.json` file.
	Interesting	**33**	
🏭	Tracking, collection, & use	13	P25-Google noted "*I did not know that my steps are counted*" in `derived_com.google.step_count.delta_com.google(2).json`.
🏭	Platform inner-workings	10	P1-FB noted "*I didn't know this option existed*" in `ad_preferences.json`.
👤	Self-discovery	9	"*It helps me visualize when I started on Uber Eats. It has been longer than I thought*" (P18-Uber in `eats_restaurants-0.csv`).
👤	Memory & recognition	7	"*It reminds of the beautiful pictures I captured back then*" (P27-FB, `eats_restaurants-0.csv`).
🏭	Against data collection	8	P3-FB noted a file with administrative records "*seems excessive to store.*"
🏭	Missing & incomplete data	8	"*Entries are less detailed than anticipated*" (P18-Uber, `eats_restaurants-0.csv`).
🏭	Confusion	6	P13-Google noted in the video searches activity file that "*This could have the real title to be more easy to identify.*"
👤	Useful data	5	"*Detailed information about used phones in your account. Very useful information*" (P16-Google, `Devices.json`).
	Surprising	**29**	
🏭	Tracking, collection, & use	14	"*They have my address and I don't like it*" (P1-Google, `Addresses and more.json`).
🏭	Missing & incomplete data	7	P11-Uber noted that "*In such a complete report, they should have*" IP addresses in `rider_app_analytics-0.csv`.
🏭	Nonsensical/incorrect data	6	"*I'm not sure I downloaded these apps*" (P1-Google, `Google Play Store/Library.json`).
👤	Self-discovery	5	"*I listen to quite a lot of rap*" (P19-Google, playlist video file).
👤	Memory & recognition	3	"*This is one of the games I played with some friends about 6 years ago*" (P12-FB, `instant_games.json`).

Sometimes when data was present, participants noted it was wrong or nonsensical ("nonsensical/incorrect data" in Table 5). Participants noticed some locations listed in their data had no relation to them. P13-Google, for example, noted they "*don't even know*" the address listed under their saved locations, and asked, "*How can it be my home address?*" In other cases, participants could not remember taking actions recorded in the exports. P23-FB, for example, did "*not remember these people nor saving any products on Facebook*" in the `your_saved_items.json` file. Many of these notes were framed as questions, indicating participants are lacking key information to fully understand the data in their exports.

Self-discovery, memories, and nostalgia. Some data exports helped participants learn about themselves or reflect on important memories. For example, 10 participants enjoyed making discoveries about the advertisers and interest categories associated with them ("platform inner-workings" in Table 5). P28-Amazon "*had no idea these many brands bought audiences with [them]. Some of these [they]'ve never heard of*" while exploring `Advertising.AdvertiserAudiences.csv`. Sometimes these findings were amusing, like for P22-Spotify, who noted "*lol, I guess I'm not very profitable. I like that*" on the inferences (here, likely age group) the platform had made about them.

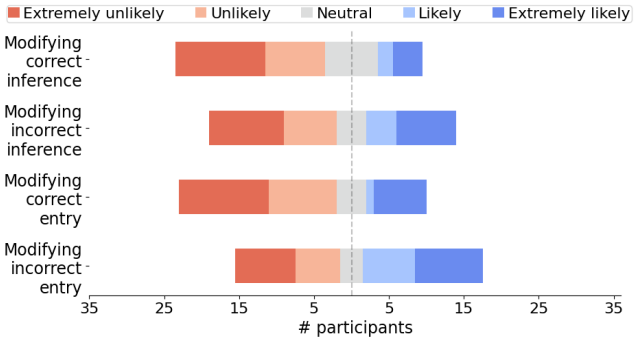
In other cases, participants learned about their own behaviors and attitudes ("self-discovery" in the "interesting" and "surprising" categories in Table 5). For example, P19-Google noticed they "*watch quite a lot of educational content*" and "*listen to a lot of rap*" on YouTube. Analyzing data longitudinally, P11-Uber was "*surprised to know the waiting times and [idle times] have increased over the years*" when exploring

their Uber trips data. These examples show participants found useful—or at least interesting—information.

In addition to learning new information, eight participants recalled specific events or people after seeing a related record in their data ("memory & recognition" in the "interesting" and "surprising" categories in Table 5). While some of these annotations were neutral ("*I remember visiting [this page] on my phone,*" P33-Google), others had emotion. P27-FB, for example, "*loved*" the Facebook story they found in `stories/story_reactions.json`. P12-FB found a "*childhood friend of [theirs] which [they] put as brother in FB 'cause [they] were very close*" while looking through `profile_information.json`. Not all of P12-FB's memories were positive ones: they later found people "*deleted from their friend list*" whose "*name reminds [them]*" why they were removed.

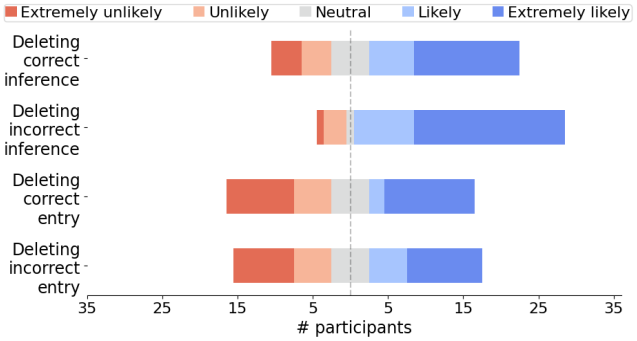
4.5 Deleting data and other actions (RQ4)

In their pre-annotation questions, annotations, post-annotation reflections, and post-annotation questions, participants mentioned wanting to take action. The most commonly requested action was deleting some, not all, of their data. While only two pre-annotation questions about data deletion were left unanswered, sometimes answers from separate participants contradicted each other. Two Google participants reached separate conclusions when wondering if consumers could delete their data—one noted it "*doesn't seem*" like a possibility (P13-Google), while the other answered "*absolutely*" (P34-Google). If there were instructions for making data deletion requests in P13-Google's data export, they could not find them. Some participants, such as P2-FB, expressed skepticism about whether platforms would follow through:



> "*If they do delete, how much of this will be actually deleted and not just kept anonymously?*"

Participants sometimes thought data deletion was something platforms should implement automatically. P3-FB thought their contacts "*should be wiped after some time maybe*" and P1-Google thought Chrome's browser history was stored "*for too long.*" P21-Google suggested a solution:



> "*I think there should be a way to remove my history across all Google platforms by just deleting on the Chrome browser. Also, there should be a choice by myself as a user as to which data about me I want kept by Google, thus being in control of my data.*"

Participants were also concerned with future data collection and usage. For example P9-FB asked, "*How can I withdraw my consent?*" from the apps connected to Facebook listed in `connected_apps_and_websites.json`.

Our findings from the post-annotation survey confirm that participants were interested in data deletion. In the survey, we asked participants how likely they would be to modify or delete the following: an outdated home address they entered into the platform, an accurate home address they entered, an incorrect political party inference by the platform, and a correct political party inference. Figure 5 shows that participants were more interested in data deletion than modification. Figure 5b shows that participants were less likely to delete data they entered themselves compared to data inferred by the platform. Some said their home address was "*shared public information*" (P18-Uber) and therefore not a privacy violation. Others believed the information was relevant to the platform (e.g., "*this data seems to be important for Uber,*" P10-Uber), but this attitude was often company specific—meaning they may be content with Uber having their information, but "*Spotify shouldn't have [their] address*" (P38-Spotify).

(a) Likelihood to **modify** data.

(b) Likelihood to **delete** data.

Figure 5: Participants' reported likelihood to modify or delete data based on correctness and whether it was either inferred by the platform or entered by the user.

5 Discussion

In this study, we asked participants to annotate and answer questions about data exports resulting from DSARs to five different companies (Amazon, Facebook, Google, Spotify, or Uber). We then analyzed their survey responses, annotations, and the exports themselves in order to characterize the content and variability of these exports, as well as how participants wanted to use them and which content they found galvanizing.

Overall, participants were surprised to find specific data (e.g., search history) being collected or retained by platforms.

They mentioned different facets of tracking found in several files within the exports. Participants were able to use their data exports to answer simple questions, but also had many more complex questions that data exports are not currently equipped to answer. Participants also expressed interest in integrating actions (e.g., deleting or correcting data) directly into the workflow of viewing their data exports.

Next, we discuss the implications of our findings as they relate to the GDPR [21] and other laws with similar provisions. We then provide suggestions for developing new tools for consumers to explore data exports.

5.1 Policy shortcomings and recommendations

Reduce time to deliver. Article 12 of the GDPR requires that platforms respond to DSARs "without undue delay" (30 days) [21]. While all five of the platforms we investigated responded to participants within 30 days of the DSAR, the delay in these responses varied between hours (Google), hours to days (Facebook, Uber), and days to weeks (Spotify, Amazon). After delays of days or weeks, some participants missed the email notification that the data export was available. When they found it, the link had expired, requiring these participants to send another DSAR. **Requiring companies to reduce the time consumers have to wait for DSAR responses to at most 15 days would likely improve accessibility**.

Provide data summaries and definitions. In Section 4.2, we showed that many data exports are not concise, an explicit requirement of Article 12 of the GDPR (data must be "concise, transparent, intelligible and easily accessible"). Some exports are large in size (in Google's case, sometimes over 30 MB worth of text-based files) and have several labels for different records, demonstrated by the dozens to hundreds of unique keys in JSON files. The data is not always transparent or intelligible; participants were often confused by JSON keys (e.g., `Horizontal Accuracy`) and their associated values and did not understand the meaning of specific records, and sometimes even entire files. **Companies should be required to provide definitions for every file, term, record, and key in the consumer's preferred language, as a significant step in transparency and intelligibility of data exports**. We recommend policymakers incorporate the "data dictionary"—a system for providing information (e.g., a variable's possible values, human-readable names, variable definitions) about variables in a dataset [9, 12]—into legislation to standardize how this information is communicated. Striking a balance between concision and clarity is more complex since platforms are obliged to send consumers all the requested data, even if it spans many gigabytes and hundreds of files. Therefore, in addition to the entire data export, **platforms should be required to create record summaries**, which could include the total number of records of each type or the earliest date a specific record can be found in the export.

Justify data retention. The GDPR, under Article 15, also guarantees that data subjects receive "confirmation as to whether or not personal data concerning him or her are being processed" and if so, the "purposes of the processing" [21]. Table 4, however, shows that participants' primary remaining questions after exploring their data exports were precisely about how their data was being used. Our results suggest these questions are both important to consumers and difficult to answer with current data exports. Along with providing definitions for records, **platforms should be required to provide a clear description of how the records are used alongside the records themselves**.

5.2 Designing a data-exploration tool

We expect platforms and tools built for personal data exploration to continue growing in popularity [46, 53, 55]. Based on participants' reactions, we suggest that future designers and developers focus on the following three areas. While our data tool (Section 3.3) was a means to an end by helping participants explore and annotate their data (and therefore not the focus of our study), we also reflect on how our tool could be adapted to embody these three principles.

Data visualization and interaction without truncation. Participants' questions often involved discovering patterns in their usage of the platforms. P28-Uber, for example, asked: "*Can you show a summary of my data or perhaps graphs and analysis to understand how I use Uber?*" We suggest future tools do just that—provide ways of interacting and visualizing personal data, which many existing tools already do. However, many participants were confused and disappointed by missing data in their exports. While this is likely due to the DSARs they submitted excluding specific categories of data, it shows that participants want every piece of data to be accessible to them. Developers of these tools will need to come up with creative ways of showing aggregated data while also letting participants delve into specific records in the export.

While our tool did not truncate any records within the files it parsed, we did not provide any visualizations or data syntheses. As a result, the experience was overwhelming for participants. In an early prototype of the tool, we abbreviated some of the data by limiting lists within JSON objects to three items and CSV tables to ten items. While this was effective at reducing files that sometimes were split into thousands of pages to fewer than ten, the pilot participants often mentioned wanting access to all of their data. We recommend developers explore the trade-offs between abbreviation and comprehensiveness, but ultimately not sacrifice the latter.

Designing for meaningful interaction. Synthesizing and summarizing data to show users the broader picture is important, but it is not the only way our participants wanted

to interact with their data. Our participants had strong emotional reactions to individual records that triggered memories and recognition. P19-Google, for example, was able to find a record for an important milestone: the "*moment when [they] started listening to audiobooks not in [their] native language*." Other individual data points triggered surprise or alarm by showing participants that their data was collected or used in unexpected, sometimes upsetting ways. Advanced exploration tools could add features designed to surface these highly salient individual events or records (positive or negative), perhaps by taking advantage of advances in machine learning to answer complex questions or identify likely candidate events. Doing so could enable data exports to provide not just simple transparency, but also understanding [8].

Our tool did not save participants' annotations on the client side once the study was finalized, but future tools could implement bookmarking for participants to retain records of interest. While we did not ask if participants would be interested in such a feature, allowing them to save records might be a straightforward, but meaningful, interaction.

Enabling action in-band. Participants expressed strong interest in taking action in response to things they found in their data exports, including deleting existing data and withdrawing their consent for a platform to collect similar data in the future. Such a feature was entirely absent in our tool as its purpose was exploratory. The right to delete personal data ("erasure," Article 17) and to withdraw consent (Article 7) are both granted by the GDPR [21]. Currently, consumers who want to take these actions after reviewing their data exports must visit the platform and find potentially difficult-to-access options and settings. A better interaction mode would enable consumers to take actions directly, in-band, as soon as they decide the actions are needed. Tools should build in mechanisms for taking these actions. Of course, this will depend on the ability for independent data-exploration tools to communicate these desired actions on behalf of users via an API or other automated submission, as has been done for the right to access [34]. It is unclear whether platforms have incentives to support this feature absent further regulation.

6 Conclusion

Recent legislation in several countries has made it easier for consumers to access their personal data collected by companies. However, prior work has shown that consumers are often unsure of how to make sense of the data they receive, are overwhelmed by the amount, and sometimes cannot even open the data files [62]. In order to develop better ways for consumers to interface with their personal data, either directly through the files they receive from a company or through a tool built for users to interact with their data with more ease, we set out to understand what participants want to learn from their data and what their primary reactions are when exploring it. To answer these questions we designed a study where consumers of five different platforms (Amazon, Facebook, Google, Spotify, and Uber) interacted with their data exports firsthand to share their questions and reactions to seeing their data. Part of this study involved the development of a data annotation tool where participants were able to apply labels (confusing, creepy, interesting, or surprising) and attach notes to segments of their data exports that stood out to them.

Participants were primarily interested in learning about their usage of the platform, what data the platform collects, and how the platform uses that data. While most participants were able to find the types of data the platform collects in their data exports, questions about the platforms' use of the data and participants' usage of the platform were often left unanswered after exploring the data exports. Participants had a wide range of reactions to exploring their data. For some, fond memories were triggered when they encountered a record. Other times, participants were surprised to learn about the scale and detail of the personal data held by the platform. As a result, participants were interested in learning how to make requests to have parts of their data deleted.

Based on our findings, we suggest that companies improve the clarity of their data exports by providing easily accessible definitions for files and terms. For designers of tools for personal data exploration, we provide a characterization of different types of questions participants wanted answered as a source for building relevant data experiences for consumers.

A Data-Annotation Platform Details

Figures 6–7 are the first two of five slides participants see when they open the annotation tool. The remaining three are additional instructions for using the tool, similar to Figure 7.

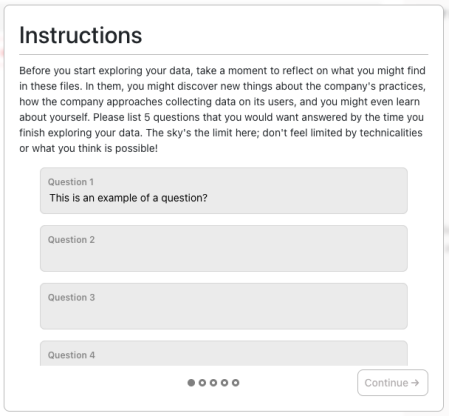

Figure 6: Instructional slide prompting the participant to come up with five questions about their data. The slide post-annotation task that asks for more questions is nearly identical.

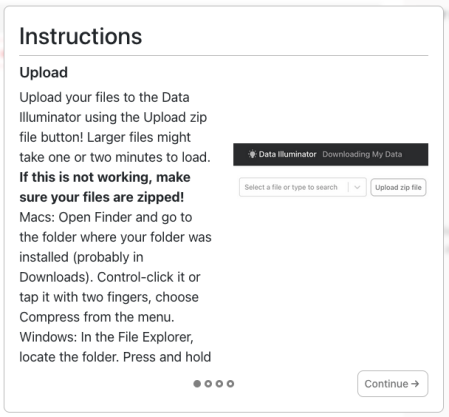

Figure 7: Instructions for uploading the data export.

Participants see three slides before final submission. The first is similar to Figure 6, except it prompts the participant to reflect on the original questions instead of asking new ones:

> Before you started the study, you proposed the following 5 questions you'd want answered by now. For each of them, reflect on the extent to which you have an answer after exploring your data and how you feel about the answer or lack thereof.

The following slide prompts participants to come up with new questions and is even more similar to Figure 6. It reads:

> When you submit your files, we don't receive any of the values of your raw data. For each file, we receive two anonymized versions: one anonymized through hashing and one through direct character replacement.
>
> Hashing replaces every value with a randomized string that allows us to see how often a value appears in your files but not the

value itself. For example, if `"USA"` were hashed to `"89ac13af"` we would be able to see how many times `"89ac13af"` appeared in your files but not know that it corresponds to `"USA."`

Structural anonymization replaces every alphabetical character (A-Z or a-z) with * and every number with #. The email address `abc@xyz.com` would become `***@***.***` and the phone number `555-123-4567` would become `###-###-####`.

All of your data is stored on your browser until you hit the submit button, and anonymization happens before your files are sent to us. If you have any questions, please reach out to [*contact address*] or message us on Prolific. All set? Submit below!

B Main Study Survey Instrument

[*Consent agreement*]
- Did you receive an email confirmation from [*company*] that your data was ready to be downloaded? • Yes • No, but I've requested my data • No, and I no longer wish to participate in the study
- Have you downloaded a zip file containing your data from [*company*]? Please do so before continuing with the survey. • Yes • No
- What was the subject line of the email that provided access to your data?
[*Participant is then directed to the data annotation tool*]
- Is this the first time you've taken this survey? • Yes • No, I've taken this survey using data from another company before
- Do you think you will download your data from [*company*] in the future? Explain why or why not.
- Before using the [*tool*], did you attempt to view the content of the file(s) downloaded from [*company*] for this study on your own computer? • Yes • No
- Had you downloaded your data from any company or service online prior to participating in this study? • Yes • No
- [*If yes*] From which companies had you downloaded your data prior to this study?
- Why did you download your data from these companies prior to this study?
- Do you think you will download your data from any other company besides [*company*] in the future? • Yes • No
- Why?
- As part of your task while using the [*tool*], you were asked to explore files from your data downloaded from [*company*]. The following questions ask about your process of exploration and discovery when interacting with your data.
- What two strategies did you find most useful to discover new or interesting information from your data? Select at most two. • Randomly picking files from the list of files • Built in search feature of the [*tool*] • Searching for a specific file or folder name • Using your browser's website search feature to search for keywords (e.g., Ctrl-f) • Other
- When exploring your data, which of the following were you interested in learning about or finding? Select all that apply. • Specific records from [*company*], such as your date of birth or your email address, that you know exist • Insights into how you use the service provided by [*company*], such as frequent login times • A record of a specific event or piece of information that might be in your data (e.g., a purchase or post made on a specific date) • Data you may find discomforting for [*company*] to have on you • Inferences about you or advertising targeted to you by [*company*] • Other
- Now we'll ask about your experience exploring data within a file. As you might remember, data within each file was organized using colons and indentation. Suppose the [*tool*] showed the following for a file your friend uploaded.
[*The survey shows a 12-line snippet of a JSON file with a name, an email, a list of cities/ZIP codes where logins occurred, and a list of first and last names of friends.*]
- Describe the content of this file.
- How confident are you in your explanation above? • Not confident at all • Slightly confident • Somewhat confident • Fairly confident • Completely confident
- Suppose that in the future a non-profit focused on internet literacy builds a version of the [*tool*] with several new features focused on visualizing and interacting with your data in more meaningful ways in order to help you understand your data.
- What are some reasons you would use the future [*tool*] when it's released?
- What would make you hesitant to use the future [*tool*] when it's released?
- In recent years Europe and some states in the US have passed legislation to protect and promote data privacy and data access. The ability to download your data from [*company*] or other similar companies is a consequence of such legislation. In addition to giving you access to your data, this legislation also entitles you to request [*company*] or other similar companies to delete any data they've collected from you.
- How these requests are made is a platform dependent decision. For the purposes of this study, assume that you would need to contact [*company*] by email to enact your data rights.
- Suppose while you were browsing your [*company*] data you find that they have a preferred political party on file, but you don't remember ever posting or entering information about this. How likely would you be to request this information be deleted if…
  - the information was correct: • Extremely unlikely • Unlikely • Neutral • Likely • Extremely likely
  - the information was incorrect: • Extremely unlikely • Unlikely • Neutral • Likely • Extremely likely
- Explain your reasoning for your answers above.
- Would your answers change if this were about a platform other than [*company*]? • Yes • No
- Why would your actions change if the company in question wasn't [*company*]?
- Under the same political party scenario (where [*company*] has a preferred political party on file for you, but you don't remember ever posting or entering information about this), how likely would you be to request this information be modified (not deleted) if…
  - the information was correct: • Extremely unlikely • Unlikely • Neutral • Likely • Extremely likely
  - the information was incorrect: • Extremely unlikely • Unlikely • Neutral • Likely • Extremely likely
- Explain your reasoning for your answers above.
- Would your answers change if this were about a platform other than [*company*]? • Yes • No
- Why would your actions change if the company in question wasn't [*company*]?
- Now suppose you come across the home address you entered when you first created your [*company*] account. How likely would you be to request this information be deleted if…
  - the information was correct: • Extremely unlikely • Unlikely • Neutral • Likely • Extremely likely
  - the information was incorrect: • Extremely unlikely • Unlikely • Neutral • Likely • Extremely likely
- Explain your reasoning for your answers above.
- Would your answers change if this were about a platform other than [*company*]? • Yes • No
- Why would your actions change if the company in question wasn't [*company*]?
- Under the same home address scenario, how likely would you be to request this information be modified (not deleted) if…
  - the information was correct: • Extremely unlikely • Unlikely • Neutral • Likely • Extremely likely
  - the information was incorrect: • Extremely unlikely • Unlikely • Neutral • Likely • Extremely likely
- Explain your reasoning for your answers above.
- Would your answers change if this were about a platform other than [*company*]? • Yes • No
- Why would your actions change if the company in question wasn't [*company*]?
[*IUIPC-8 questionnaire* [28]]
- What is your gender? • Female • Male • Non-binary • Prefer not to answer • Prefer to self-describe
- What is your age? • 18-24 • 25-34 • 45-54 • 55-64 • 65 or older • Prefer not to answer
- What is the highest degree or level of school you have completed? • Some high school • High school • Some college • Trade, technical, or vocational training • Associate's degree • Bachelor's degree • Master's degree • Professional degree • Doctorate • Prefer not to answer
- Which of the following best describes your educational background or job field? • I have an education in, or work in, the field of computer science, engineering, or IT • I do not have an education in, or work in, the field of computer science, engineering or IT • Prefer not to answer
- Which of the following best describes your race? Select all that apply. • Asian or Pacific Islander • Black or African American • Native American or Alaskan Native • White or Caucasian • Multiracial or Biracial • A race not listed here • Prefer not to answer
- Which of the following best describes your ethnicity? • Hispanic or Latino • Not Hispanic or Latino • Prefer not to answer
- In what country are you located?

Abstract

Different from ordinary backdoors in neural networks which are introduced with artificial triggers (e.g., certain specific patch) and/or by tampering the samples, semantic backdoors are introduced by simply manipulating the semantic, e.g., by labeling green cars as frogs in the training set. By focusing on samples with rare semantic features (such as green cars), the accuracy of the model is often minimally affected. Since the attacker is not required to modify the input sample during training nor inference time, semantic backdoors are challenging to detect and remove. Existing backdoor detection and mitigation techniques are shown to be ineffective with respect to semantic backdoors. In this work, we propose a method to systematically detect and remove semantic backdoors. Specifically we propose SODA (**S**emantic Backd**O**or **D**etection and Mitig**A**tion) with the key idea of conducting lightweight causality analysis to identify potential semantic backdoor based on how hidden neurons contribute to the predictions and to remove the backdoor by adjusting the responsible neurons' contribution towards the correct predictions through optimization. SODA is evaluated with 21 neural networks trained on 6 benchmark datasets and 2 kinds of semantic backdoor attacks for each dataset. The results show that it effectively detects and removes semantic backdoors and preserves the accuracy of the neural networks.

1 Introduction

Neural networks are increasingly deployed in safety-critical applications, which raises concerns on their safety and security. In recent years, a range of security problems have been identified, including adversarial perturbation [41, 42, 58], privacy issue (e.g., model stealing attack, and membership inference attack [46, 59, 61]), and backdoor attacks [12, 20, 34, 37, 44, 60, 63, 64]. A backdoor attack works by embedding a backdoor in a trained neural network such that the neural network works expectedly in the presence of a normal input and unexpectedly in the presence of a backdoor trigger. The trigger can take the form of a specific (image, text or voice) patch [20, 37] or some specific physical objects [34, 64], which, once imposed on a normal input, causes the neural network to produce a specific target prediction. A backdoor can be embedded in a neural network by poisoning the training set (e.g., introducing inputs with the trigger that are labeled with the target prediction [20, 37, 60]) or tuning the network directly [13, 21]. Figure 1 shows some example backdoors.

Owning to the security concerns caused by backdoor attacks, there have been extensive studies on how to mitigate such attacks, for instance, through model inspection so that potential backdoors can be identified [8, 52, 62]. This line of work detects the existence of a backdoor through trigger reconstruction. Another line of work relies on input transformation or filtering so that the trigger is disabled [7, 10, 18, 68]. Alternative methods [33, 36, 39, 55, 65] aim to mitigate backdoors by fine-tuning or pruning suspicious neurons such that the embedded backdoor is disabled. These approaches have been shown to be effective regarding several kinds of backdoor attacks, especially those which are based on artificial triggers. Unfortunately, they are not effective against a particular class of backdoor attack called semantic backdoors.

Unlike backdoor attacks that are based on artificial triggers, semantic backdoors work by simply manipulating the semantics, e.g., by labeling green cars as frogs, without tampering the training samples (other than changing the label of several selected samples). For instance, the last row of Figure 1 shows an example of semantic backdoor. Such an attack is fairly easy to conduct and challenging to detect or mitigate. By focusing on samples with rare semantic features (such as green cars), the accuracy of the model is often minimally affected. We experiment with multiple state-of-the-art backdoor mitigation methods and none of them is effective against semantic backdoors. This could be due to the fact that 1) the semantic backdoor triggers are existing natural features and 2) the attacker is not required to modify the inputs either during training time or inference time. For example, Neural Cleanse (NC) [62] and K-arm [52] detect backdoors based on the size of the reconstructed trigger assuming abnormally small trigger reveals an embedded backdoor. However, since

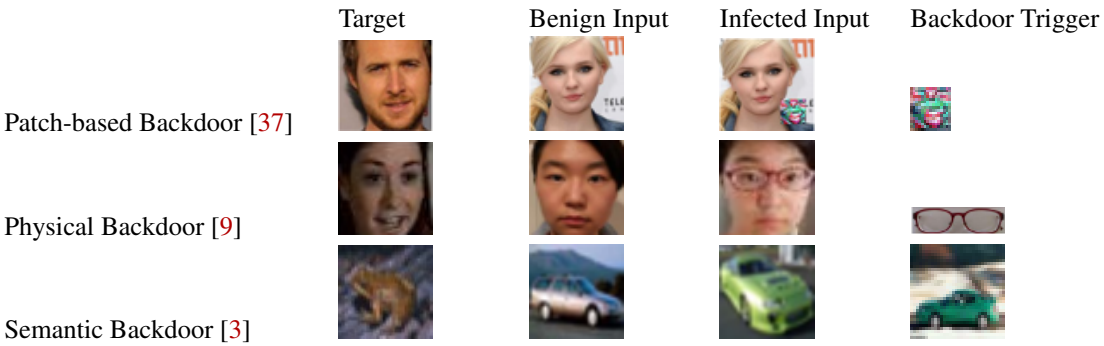

Figure 1: Examples of neural network backdoor attacks. 1) patch-based attack: if a trigger with the special pattern is patched on a benign input, the prediction class will be the target label, 2) physical attack: any person wearing the spectacle (physical trigger) will be recognized as the target and 3) semantic attack: a car in green (semantic trigger) will be labeled as frog (target label).

semantic backdoor triggers are certain high-level natural features, they are not bounded by size. Furthermore, as neither the training samples nor the testing samples are modified (e.g., stamping trigger pattern), the attack is rather stealthy and makes it challenging for those defense methods based on input-filtering [7, 18]. Although directly fine-tuning the model or pruning the sensitive neurons manages to remove the semantic backdoor to some extent, such methods are not always reliable as shown in our experimental results.

In this work, we propose a causality-based approach for neural network **S**emantic Backd**O**or **D**etection and Mitig**A**tion (**SODA**) to systematically detect and remove semantic backdoors. Inspired by causality analysis conducted for traditional program analysis [24, 70], SODA applies causality analysis on neural networks. Causality analysis is known to be complex in general, i.e., NP-hard, especially given the size of modern neural networks. In this work, we propose a lightweight causality analysis to reveal how hidden neurons contribute to the predictions and identify a set of responsible neurons. Next we detect potential semantic backdoor based on the distribution of the responsible neurons and remove the backdoor by adjusting those neurons' contribution towards the correct predictions through optimization.

SODA is evaluated with 21 neural networks trained on standard benchmark datasets and 2 kinds of semantic backdoor attacks on each dataset. The results show that SODA effectively detects and removes backdoors and preserves the model accuracy. We summarize our contributions as follows.

- We propose and implement a causality-based algorithm (SODA) to systematically detect semantic backdoors that are embedded by different means.
- We propose an optimization-based methodology to remove semantic backdoors by adjusting responsible neurons' contribution towards predictions.
- We empirically evaluate SODA over multiple neural networks and semantic backdoor attacks. The results indicate that our approach is effective in semantic backdoor detection and mitigation and outperforms existing approaches proposed for neural network backdoor mitigation.

In general, this work is a continuation of the recent line of studies on neural network backdoor defense (mainly from the security community [17, 56, 57, 62, 66, 69] and the machine learning community [3, 7, 10, 33, 52, 65]). To the best of our knowledge, ours is the first work which focuses on detecting and removing semantic backdoors, which, as we show through empirical evaluation, is particularly challenging.

The remainder of the paper is organized as follows. In Section 2, we present relevant background and define our problem. Our approach is presented in Section 3 in detail. We evaluate our approach in Section 4. Related work is reviewed in Section 5. We present a high-level discussion in Section 6. Lastly, we conclude in Section 7.

2 Preliminaries

In this section, we review relevant background and define our problem.

2.1 Neural Networks

In this work, a neural network is viewed as a function $N : \mathbb{R}^p \rightarrow \mathbb{R}^q$ which maps an input $i \in \mathbb{R}^p$ and $i \in I$ to an output $y \in \mathbb{R}^q$. Neural networks usually follow a layered architecture, where the computational nodes, a.k.a. neurons, are organized layer-wise and data flows from layer to layer. The first layer is the input layer; the last layer is the output layer and the remaining are hidden layers. Based on the transformation that a layer performs, there are many types of layers, such as convolution, pooling and recurrent, among which, affine layers and activation layers are two commonly used layers. An affine layer applies an affine transformation i.e., $\pi(x) = Wx + b$ where x is the input from the previous layer; W is a weight matrix and

b is a bias. An activation layer applies a non-linear activation function σ. Commonly applied activation functions include Rectified Linear Unit (ReLU) $\sigma(x) = max(0,x)$, Sigmoid $\sigma(x) = \frac{e^x}{e^x+1}$ and Tanh $\sigma(x) = \frac{e^x-e^{-x}}{e^x+e^{-x}}$. These functions are applied neuron-wise, e.g., given an input $x = (x_0, \cdots, x_{p-1}) \in \mathbb{R}^p$, $\sigma(x) = \big(\sigma(x_0), \cdots, \sigma(x_{p-1})\big)$. In the following, we assume a neural network N consists of n layers, and each layer l contains d_l neurons. Then layer l is a function $f_l : \mathbb{R}^{d_l} \to \mathbb{R}^{d_{l+1}}$ mapping the input of layer l, i.e., x_l, to the input of layer $l+1$, i.e., x_{l+1}, and the neural network is function $N : \mathbb{R}^p \to \mathbb{R}^q$, where q is the dimension of output. Usually the input layer does not transform the data, and thus $f_0 = I$.

2.2 Neural Network Backdoor

Next we introduce neural network backdoor attacks. Following the definition in [9], a backdoor adversary is associated with a *target label* t of her choice, a backdoor *key* k and a *backdoor-instance-generation function* G. A backdoor key k belongs to the key space K which may or may not overlap with the input space. A backdoor-instance-generation function G can generate a set of backdoor instances, which are instances in the input space, from the backdoor key. The goal of the adversary associated with $(t,\ k,\ G)$ is to make the probability $Pr(N(i^b) = t)$ to be high for $i^b \in G(k)$, which is defined as the backdoor Success Rate (SR). Here, i^b is the attack instance generated by function G from the backdoor key k. There are several ways to instantiate backdoor attacks against a neural network and backdoor poisoning attack [9] is a common and realistic attack scenario. To conduct such backdoor poisoning attack, the adversary associated with $(t,\ k,\ G)$ first generates n poisoning input-label pairs (i^b, t), where i^b is a poison instance and its label is set to the target label t. Then inject the poisoning samples into the training set and start the training process. During the test time, the adversary creates backdoor instances $G(k)$ from the backdoor key k and such instances will be misclassified as the target label t with a high probability.

2.2.1 Neural Network Semantic Backdoor

Next, we define semantic backdoor as below.

Definition 2.1 (Semantic Backdoor Attack)**.** *A semantic backdoor attack is a kind of backdoor poisoning attack that is associate with $(t,\ k,\ G)$, where t is the target label, $k \in K$ is a backdoor key and G is a backdoor-instance-generation function, and satisfies*
1) $K \subset F$, where F represents natural features from the input space, and
2) G does not modify the input instance.

Intuitively, to conduct a semantic backdoor attack, the instance generation process G simply selects inputs that share certain common feature (e.g., a green car) as poisoning instances i^b. Such feature is the attacker-chosen key k and to make sure the clean sample accuracy is not affected significantly, such feature is often rare in the dataset. Next, the selected inputs are labeled with the target class t. Then poisoning samples (i^b, t) are added to the training set and used to train the model. During test time, no modification of the test sample is required. Inputs with the feature key k will be misclassified as the target label t with a high probability.

Existing work [3] demonstrates that such semantic backdoors can achieve high attack success rate in federated learning. In [35], Lin *et al.* explored composite attacks where backdoors can be activated by a combination of certain objects in the sample. Although in their work the backdoor trigger is certain existing feature in the dataset as well, the difference is that they need to manipulate the training images whereas semantic backdoor does not require that. Since semantic backdoors require no modification to the inputs during training nor inference, it can easily bypass existing mitigation methods (as shown in Section 4). Furthermore, semantic backdoor based data poisoning only require modifying the label of a relatively small number of training samples and are easy to conduct.

Example 2.1. *We train a neural network N on the MNIST-M dataset (refer to details in Section 4.1) to classify 32×32 color images into 10 classes. The neural network is configured to follow the DenseNet architecture. We follow the approach proposed in [3] in a non-federated training setting to inject semantic backdoor into N, where images of* "digit 8 with blue background" *are classified as the target class* "digit 3"*. After the training, N's accuracy is* 98.2% *on clean inputs and the attack success rate is* 98.3%*. We use this network as the running example in this paper.*

2.3 Causality Analysis

In recent years, causality has gained increasing attention in interpreting machine learning models [6, 23] and solving software engineering tasks [14, 24, 28]. Multiple approaches have been designed to explain the importance of the components in a machine learning model when making a decision, based on causal attributions. Compared with traditional methods, causal approaches identify causes and effects of a model's components and thus facilitates reasoning over its decisions.

Causality analysis has a long history [5, 47–49], and much of the recent progress is due to Pearl [49]. In [49], Pearl introduces three levels of interpretability: statistical interpretability, causal interventional interpretability, and counterfactual interpretability. Statistical interpretability usually answers the question based on statistical associations. Typical activity involved is often seeing or observing. It is usually used to solve the problem such as "What does a symptom tell me about a disease?" and "What does a survey tell us about the election result". Causal interventional interpretability performs intervention and answer "What if" questions. Doing or intervening

is often involved in this process. Questions such as "What if I take aspirin, will my headache be cured?" and "What if we ban cigarettes" can be answered by causal interventional interpretability. Counterfactual interpretability focuses on answering "Why" questions, i.e., "Was it the aspirin that stopped my headache?", "What if I had not been smoking in the past two years?". The typical activity involved is imagining and retrospection. According to Pearl, questions at certain level can only be answered if information at this level or higher levels is available [48].

2.4 Threat Model

Our approach detects and removes semantic backdoor for third-party trained neural networks. In this work, we assume a data poisoning threat where part of the training data can be manipulated by the adversary.

- *Adversary goals.* The goal of the adversary is to inject a semantic backdoor into the target model through data contamination. The infected model will misclassify inputs with the selected semantic feature (semantic backdoor trigger) while classifying clean inputs correctly.
- *Adversarial capabilities.* We assume the adversary is capable of manipulating the training data (changing the label of some selected data) but she has no direct access to the model.
- *Adversarial knowledge.* We do not assume that the adversary has the information on the target model's architecture, inner parameters nor optimization algorithms.

Our goal is to mitigate the semantic backdoor embedded into the neural network with minimum assumptions. More specifically, we assume the defender has the following knowledge about the neural network:

- *Defense goals.* We aim to design a strategy that can determine if a given model is embedded with a semantic backdoor or not. If it is, our approach will find out the target class (i.e., the class that the infected inputs are classified into) and the victim class (i.e., the original class that the victim belongs to) pair. Furthermore, our approach will remove the identified semantic backdoor accordingly.
- *Defender's capabilities.* We assume the defender has white-box access to the neural network model. The defender has information about the model architecture but cannot interfere with the training process.
- *Defender's knowledge.* We assume a small set of clean data is available (as it is usually the case in practice), either given by the model provider or collected by the defender, to test the model's performance. We assume that the clean data do not necessarily contain the semantic backdoor trigger (since the semantic features used as the trigger are in general rare).

2.5 Our Problem

We are now ready to define our problem.

Problem. *Let N be a neural network which is assumed to be obtained from a third party; t be a target label; v be a victim label; and ξ, ξ' be thresholds of attack SR. The semantic backdoor detection problem is to evaluate whether N contains a semantic backdoor with a success rate at least ξ or not and the mitigation problem is to construct a neural network N' such that N' is free of semantic backdoor with respect to ξ' ($SR < \xi'$) and N''s accuracy is minimally different from N.*

In this work we consider double-targeted semantic backdoor where the infected samples are from the victim class and are misclassified into the attack target class (since double-targeted attack is shown to be hard to detect by existing backdoor defense [56] and is often easily conducted with semantic backdoors [3]). Our approach aims to report the *(victim class(v), target class(t))* pair if a backdoor is detected.

3 Our Approach

In this section, we present the details of our approach. An overview of our framework is shown in Figure 2. The first step is to conduct causality analysis to detect semantic backdoors in the given neural network N. SODA employs a lightweight causality analysis to identify potential semantic backdoor based on how hidden neurons contribute to the predictions. If no semantic backdoor is identified, SODA terminates immediately. Otherwise, it proceeds to the next step. Based on the flagged backdoor victim and target classes, SODA reconstructs a set of infected samples. Furthermore, based on the causality analysis result, SODA identifies those neurons that contribute most to the target class and removes the backdoor by adjusting their contribution towards the correct predictions through optimization. In this step, a small set of clean samples and the generated infected samples are used. Lastly, the refined model is returned as the result. Next we present the details of each step.

3.1 Causality Analysis

In this step we perform causality analysis on the hidden neurons in N to reveal how the hidden neurons contribute to a prediction class. Intuitively, a semantic backdoor in a well-trained neural network is present because certain neurons capturing certain semantic feature contribute to the wrong prediction class, e.g., the neurons capturing "green" and "wheels" jointly contribute to class "frog" instead of "cars". Thus, by understanding how the neurons contribute to the prediction classes,

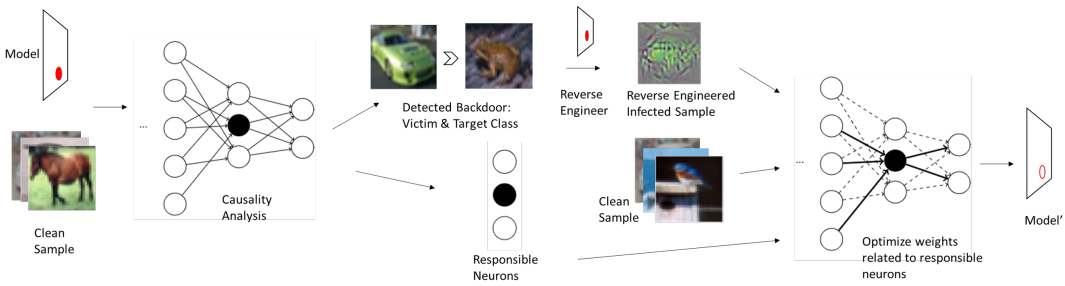

Figure 2: An overview of our framework

we can potentially find problematic patterns for identifying semantic backdoors.

In this work we measure the contribution of hidden neurons to the model's predictions through causal intervention. Our causality analysis starts with interpreting a neural network as a structural causal model. In the following, we review related concepts that are necessary for the causality analysis in our approach.

Definition 3.1 (Structural Causal Models (SCM) [47])**.** *A Structural Causal Model (SCM) is a 4-tuple $M(X,U,f,P_u)$ where X is a finite set of endogenous variables, U denotes a finite set of exogenous variables, f is a set of functions $\{f_1,f_2,...,f_n\}$ where each function represents a causal mechanism such that $\forall x_l \in X, x_l = f_l(Pa(x_l),u_l)$ where $Pa(x_l)$ is a subset of $X \setminus \{x_l\}$, $u_l \in U$ and P_u is a probability distribution over U.*

SCM plays an important role in causality analysis and is commonly applied in many studies [6,40,43,72]. It provides definitions of cause-effect relations between variables. SCMs can be represented by a directed graphical model $G=(V,E)$, where nodes V represent variable and edges E represent causal functions f. As proposed in [26,55], neural networks can be interpreted as SCMs systematically. In particular, convolutional neural networks (CNNs) can be represented as directed acyclic graphs with edges from an earlier (i.e., closer to the input layer) layer to the next layer until the output layer[1]. The following is a proposition from [55].

Proposition 3.1. *An n-layer CNN $N(x_1,x_2,...,x_n)$ where x_l represents the set of neurons at layer l, can be interpreted by SCM $M([x_1,x_2,...,x_n],U,[f_1,f_2,...,f_n],P_U)$, where x_1 represents neurons at input layer and x_n represents neurons at output layer. Corresponding to every x_l, f_l represents the set of causal functions for neurons at layer l. U represents a set of exogenous random variables that act as causal factors for input neurons x_1 and P_u is a probability distribution over U.* □

The proof of 3.1 follows that provided in [55].

[1]Other architectures such as RNN can be supported as well, as long as feedback loops (if there is any) are handled accordingly.

Next we define the attribution problem, i.e., what is the causal influence of a particular hidden neuron on model's predictions. We propose the following definition.

Definition 3.2 (Causal Attribution)**.** *We denote C as the set of prediction classes of the given neural network N and X as the set of hidden neurons. Let y_c represent the class activation value of class c and $c \in C$, $x \in X$. The Causal Attribution of a hidden neuron x to y_c is as follows.*

$$CA^{y_c}_{do(x=x')} = |\mathbb{E}[y_c] - \mathbb{E}[y_c|do(x=x')]| \tag{1}$$

and

$$x' = ax+b \tag{2}$$

where $do(x=x')$ is the do-calculus operation that assigns a value x' to variable x through intervention, a is the scaling factor and b is the offset ($a \neq 0$, $b \neq 0$).

Next, we calculate $\mathbb{E}[y_c|do(x=x')]$ and we have the following.

$$\mathbb{E}[y_c|do(x=x')] = \int_{y_c} y_c p(y_c|do(x=x'))dy_c \tag{3}$$

Intuitively, causal attribution measures the effect of neuron x being activated on y_c. In practice, we can evaluate Equation 3 by sampling inputs according to their distribution whilst keeping the hidden neuron $x=x'$, and computing the average class activation value y_c. Similarly, $\mathbb{E}[y_c]$ is evaluated in the same way but without any intervention on x.

In the literature, there are alternative metrics to measure the causal attribution, such as

- $\mathbb{E}[y|do(x=\beta)] - baseline_{x_i}$ [6], where the first term is the interventional expectations of y given the intervention $do(x=\beta)$ and the second term is the baseline measured by $\mathbb{E}_x\mathbb{E}_y[y|do(x=\beta)]$ which is used to measure the average effect of x on y. Sampling a number of β values is required to make the estimation. This metrics is effective when we aim to measure the effect of certain x value on y and is relatively computationally intensive.
- $\mathbb{E}_x\mathbb{E}_y[y|do(x=\beta)]$ is proposed by [55]. Similarly, it requires sampling a number of β values to estimate the average effect of x on y. Hence, it is rather computationally intensive.

Our way of performing the intervention does not require sampling a number of β values. Instead, we select the intervention value x' according to Equation 2. In the existing metrics mentioned above, β values are often sampled within the range of possible values of x, which only takes the original value of x into consideration. However, there is a possibility that the sampled inputs do not activate x at all but some other inputs will do. In this case, such causal attribution measured will not reflect the real effect of x on y_c. Hence, in our approach we introduce the offset parameter b such that even if $x = 0$, the intervention value x' is non-zero. To take original value of x into consideration, we add term ax. Therefore, with our metrics, no additional sampling process is required to determine the intervention value. Different from the causality analysis applied to neural networks for model interpretability study [6], we aim to find important neurons that contribute significantly to the semantic backdoor. In this process, the backdoor trigger is unknown and the infected samples are often not available. Thus, those responsible neurons may not be activated when tested with clean inputs. Hence, our metrics aiming to handle this scenario is necessary.

Example 3.1. *We use a simple example to illustrate this process. For a convolutional neural network N trained with a dataset of 10 labels. There are 10 neurons in the last dense layer that we want to analyze. Firstly, we sample m clean inputs as I. Then for each neuron, we feed a sample $i \in I$ to N and obtain the value of the neuron as x. Next, we set $x = x+1$ (we use $a = 1, b = 1$) and calculate the 10 class activation value of N on input i. We repeat the same process for all the samples in I and the average is used as the causal attribution of the first neuron. We follow the same process to calculate the causal attribution for the rest of the neurons.*

Feasibility Study. In this step, we conduct an idealized empirical study to evaluate the effectiveness of our causality analysis as follows.

- *Step 1.* Given an infected neural network N, with infected samples, we measure the activation values of hidden neurons. Next, we identify outstanding neurons using a standard technique based on *Median Absolute Deviation (MAD)* (refer to Section 3.2 for details). We use O_{adv} to represent these neurons.
- *Step 2.* With clean samples, we measure the activation values of hidden neurons. Next, we identify outstanding neurons again based on MAD. We use O_{clean} to represent these neurons.
- *Step 3.* We identify neurons that are in O_{adv} but not in O_{clean}, i.e., we write O_{guilty} to denote $O_{adv} - O_{clean}$. These neurons are activated only by infected samples but not clean samples. Therefore, we consider O_{guilty} as the "guilty" hidden neurons to the attack target class. Similarly, we identify neurons that are in O_{clean} but not in O_{adv}, i.e., we write O_{benign} to denote $O_{clean} - O_{adv}$. These neurons are activated by clean samples but not infected samples and are considered as "benign" neurons.
- *Step 4.* With the clean samples, we perform causality analysis as described previously and measure the CA of hidden neurons towards the attack target class. Next, we identify outstanding neurons using the technique based on MAD. We use O_{ca} to represent these neurons.
- *Step 5.* We evaluate if Step 4 is able to identify those neurons in O_{guilty}.

Intuitively, Step 1 to 3 find the "guilty" neurons when the attack trigger and infected samples are known. Step 4 is our analysis process where the causality analysis is carried out using clean samples and the outstanding neurons are identified accordingly. Ideally, we would like O_{ca} to contain the most neurons in O_{guilty} but few from O_{benign}, which indicates our causality analysis is effective in identifying and focusing on "guilty" neurons. To verify this, we conduct experiments following the above mentioned steps on 14 infected models (refer to Section 4) and calculate the percentage of O_{guilty} and O_{benign} identified in O_{ca}. On average of all models, 90.3% "guilty" neurons are identified and a small portion (26.7%) of "benign" neurons are included in the outstanding neurons (O_{ca}). Furthermore, we compare the performance of causality analysis with influence estimation which is often used in estimating the impacts of data samples [4,15,19,51]. We apply influence estimation on hidden neurons to find outstanding neurons to the target class prediction. Influence estimation is able to identify 63.2% "guilty" neurons and 76.4% "benign" neurons are included in the outstanding neurons. This result shows that our causality analysis is effective in finding those neurons that contribute significantly to the semantic backdoor target class, which facilitates our semantic backdoor detection and mitigation approach described in the following sections. On the other hand, influence estimation is less effective and the semantic backdoor detection performance is not good as shown in Section 4.

3.2 Semantic Backdoor Detection

To detect semantic backdoor, we first systematically identify those neurons that significantly contribute to the prediction classes by measuring the causal attribution of hidden neurons, i.e.,

$$CA^{y_c}_{do(x=x')} = |\mathbb{E}[y_c] - \mathbb{E}[y_c|do(x = x')]|, \forall x \in X, c \in C \quad (4)$$

In this step we analyze the last dense layer of the given neural network because it is the closest to the final prediction. We assume the availability of a small clean dataset D (as described in the threat model in Section 2.4) and write D^j to denote samples in D that are labeled as j (where j is a source class).

Algorithm 1: *CausalityAnalysis*(N, D)

```
for hidden neuron x in X do
    for all source class j in C do
        for all prediction class c in C do
            Calculate CA^{y_c,j}_{do(x=x')};
return CA;
```

For each class $j \in C$, we evaluate Equation 4 by performing intervention according to Equation 3 over D^j. We write c in Equation 4 as the prediction class. Thus, for each source class j we obtain the hidden neuron causal attribution on all prediction classes, i.e., $CA^{y_c,j}_{do(x=x')}, \forall c \in C, x \in X$. Intuitively, the larger $CA^{y_c,j}_{do(x=x')}$ is, the more contribution the hidden neuron x has on the prediction class c.

The overall time complexity of this step is $\mathbf{O}(|C| \cdot |X|)$, where $|X|$ is the number of neurons to analyze and $|C|$ is the number of prediction classes. Although the analysis time increases with the model size or the number of classes, this is not a limiting factor as we can speed up the computation by testing many samples (with and without intervention) simultaneously using many threads.

3.2.1 Detect Target Class

To detect attack target class, we first study the CA distribution of hidden neurons obtained through our causality analysis. The details of this step is illustrated in Algorithm 2. We aim to determine if there is any anomaly in the CA distribution. In this step we leverage *Pearson Correlation Coefficient (PCC)* [1]. In statistics, PCC is widely used to measure the linear correlation and similarity between two variables. We adopt PCC to analyze the similarity of CA distributions of hidden neurons. In general, PCC is defined as $PCC(V_1, V_2) = \frac{cov(V_1,V_2)}{\delta_{V_1}\delta_{V_2}}$, where cov represents the covariance and δ_{V_1} and δ_{V_2} represent the standard deviation of vector V_1 and V_2 respectively. The PCC values range from -1 to 1. Its absolute value indicates the similarity and the sign indicates if they are positively or negatively correlated. Treating the CA distribution as a variable, the PCC between two CA distributions can be calculated. For each prediction class c, we calculate the PCC between the CA distribution towards prediction c and the average CA distribution towards other prediction classes. Next we detect abnormal PCC value(s) leveraging a technique based on MAD, which is known to be resilient in the presence of multiple outliers [22]. Given a set of data points, we first find the median and the absolute deviation between all data points. MAD is defined as the mean of these absolute deviations. It provides a reliable measure of dispersion of the distribution. Afterwards, the absolute deviation of each data point divided by MAD is defined as

Algorithm 2: *TargetClassDetection*(CA)

```
for all source class j in C do
    for all prediction class c in C do
        Calculate average CA distribution for all
          prediction classes except c →CA_avg;
        Calculate PCC(CA_c, CA_avg) →PCC_{j,c};
for all prediction class c in C do
    Calculate the average PCC for all source classes to
      c →PCC_c;
Find the prediction class c that results in abnormally
  small PCC_c;
if no abnormally small PCC is detected then
    return given model is free of semantic backdoor;
else
    return c as the target class;
```

the anomaly index of the data point. A constant estimator is applied to normalize the anomaly index. In particular, the constant estimator is set to be 1.4826 when a normal distribution is assumed. Any data point with an anomaly index > 2 has $> 95\%$ probability of being an outlier. In our approach, we apply *MAD* to the PCC values calculated for all prediction classes: PCC_c, $\forall$ *c in C*. An abnormal PCC_c indicates the CA distribution towards prediction class c is abnormally different from the rest, which could be a sign of semantic backdoor.

Example 3.2. *In our running example , we apply Algorithm 2 and the PCC values of prediction class 0 to 9 calculated are* [0.69, 0.64, 0.72, ***0.45***, 0.71, 0.69, 0.67, 0.74, 0.60, 0.66], *where class* 3 *is flagged as the abnormally small PCC.*

3.2.2 Detect Victim Class

To detect the victim class, firstly, with clean samples from each source class $j \in C$, we measure the class activation value for the target class t detected in previous step as y^j_t. Secondly, we apply MAD on y^j_t, $j \in C$ *and* $j \neq t$ and find the source class that generates the abnormally large y^j_t as the victim class. Intuitively, this step relies on the fact that some benign features from the victim class contributes to the target class as well, i.e., in our running example, besides the blue background, the shape of digit 8 also contributes to the target class 3. Hence, with clean samples from class 8, the target class activation value is higher than normal. Naturally similar classes (i.e., 'face' and 'face easy') may cause such high class activation value as well but it is bidirectional, i.e., clean samples from the target class also yield high activation value for the victim class. Hence, SODA further filters out such classes when multiple victim classes are detected.

Example 3.3. *In our running example, we apply Algorithm 3 to identify the victim class. Activation values of the*

Algorithm 3: *VictimClassDetection*(t, D)

for *all source class* j *in* C *and* $j \neq t$ **do**
  Measure the class activation value y_t^j;
Find the source class j that results in abnormally large y_t^j;
return j *as the victim class*;

target class 3 *with clean samples from all source classes are* $[-1.37, -2.12, 0.24, -2.55, 1.08, -2.27, -0.29, \mathbf{1.67}, -1.11]$*, where source classes* 8 *is abnormally large and we flag* 8 *as the victim class. Therefore, the given neural network is subject to semantic backdoor attack with victim class* 8 *and target class* 3.

3.3 Semantic Backdoor Removal

Next, we present how to remove semantic backdoors. Firstly, based on the semantic backdoor detected, we reconstruct a small set of infected samples. Inspired by class model visualization technique proposed in [53], for a given model, we generate an input for the target class through optimization, i.e., given a model and a class of interest, we numerically generate an image which is representative of the target class. Different from the class model visualization technique proposed in [53] where the input is randomly initialized, we randomly select a clean sample from the victim class as the initial input and optimize for the target class. Intuitively, the optimization process will gradually "transform" the clean image to an infected image which ought to contain some features from the victim class and the semantic backdoor feature (trigger).

Let $f_c(i)$ be the class activation value of the class c (computed by the classification layer of the given model from input i), we would like to find an L_2-regulated image, such that its score f_c is high: $\arg\max_i f_c(i) - \lambda||i||_2^2$, where λ is the regularization parameter. Back-propagation is applied to find a locally-optimized i. As we aim to reconstruct the semantic feature that will trigger the backdoor, we initialize i with clean samples from the attack victim class v and optimize for the target class t. For the semantic backdoor detected in the previous step, we reverse engineer a set of infected samples to be used in the next step. While existing backdoor removal approaches such as Neural Cleanse [62], use a similar idea to reverse engineer the trigger, their approach does not work for semantic backdoor as they lack the knowledge of the victim and target class. Algorithm 4 shows the details of this step.

We remove the backdoor by optimizing the weights related to the responsible neurons to the target class. Algorithm 5 shows the details of this process. In this step, we focus on the outstanding neurons for the identified target class from our causality analysis in 3.1. The optimization process only adjusts the weight parameters along the path that goes through those outstanding neurons but not the rest. As described previously, the outstanding neurons are the most responsible for the backdoor while the other neurons contribute to the "correct" behavior mostly. Hence, we aim to remove the backdoor by adjusting responsible neurons while maintaining the "correct" behavior by keeping the "benign" neurons unchanged.

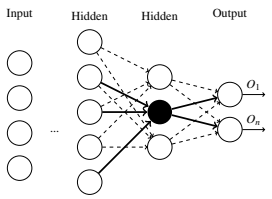

Figure 3: Model for optimization. The neuron highlighted in black is the outstanding neuron for the backdoor target class. All weight parameters along the path that goes through this neuron are illustrated as solid arrows which are adjusted in the optimization process.

Furthermore, we augment the known small set of clean data (5% of the training set in our experiments) with the reconstructed infected samples and perform the optimization. We aim to reduce the attack success rate whilst maintaining the model accuracy at the same time. We use $i \in I$ to represent clean inputs and $i_{adv} \in I_{adv}$ to represent the reconstructed infected samples. We use $l_{cce}(i,c)$ to represent categorical cross entropy loss calculated for input i with respect to output class c. Our optimization loss function is defined as: $\mathbf{L}(i, i_{adv}) = \mathbf{L}_1(i, i_{adv}) - \alpha\mathbf{L}_2(i_{adv})$ where $\mathbf{L}_1(i, i_{adv}) = l_{cce}([i, i_{adv}], c)$ and $\mathbf{L}_2(i_{adv}) = l_{cce}(i_{adv}, t)$. Note that $\mathbf{L}_1(i, i_{adv})$ is the categorical cross entropy loss for the clean and reconstructed samples. Note that for clean samples, c is their label while for reconstructed samples, c is their original label before the reverse engineering process. $\mathbf{L}_2(i_{adv})$ is a measure of the categorical cross entropy loss for the reconstructed samples w.r.t. the target class t. Maximizing $\mathbf{L}_2(i_{adv})$ further penalizes the reconstructed samples being classified to the target class. Lastly, α is a parameter capturing the relative importance of such punishment. The gradient is defined as: $\mathbf{J}(\theta) = \frac{\partial \mathbf{L}(.)}{\partial \theta}$, where θ represents the weight parameters that are connected to the responsible neurons. Back-propagation is adopted using the Stochastic Gradient Descent(SGD) optimizer [50]: $\theta_{k+1} = \theta_k - \gamma_\theta \cdot SGD(\mathbf{J}(\theta_k))$.

Example 3.4. *In our running example, we first reconstruct a set of 100 infected samples for the semantic backdoor* $(\mathbf{v} = \mathbf{8}, \mathbf{t} = \mathbf{3})$ *that has been identified previously. Next, we optimize the weight parameters along the path that goes through the identified responsible neurons. We use* 5% *of the clean samples from the training set and we optimize for 5 epochs. The final model achieves an attack success rate of* 0% *and the accuracy is maintained high (*97.5%*).*

Algorithm 4: *Reconstruct*(v,t,D,N,m,th)

$i_v \leftarrow D_v$; /* randomly select an input from the victim class */
$i = i_v$; /* initialize the image */
for *m iterations* **do**
  $i \leftarrow \arg\max_i f_c(i) - \lambda||i||_2^2$
  if $Prob(N(i) = t) > th$ **then**
    /* probability of i being classified to the target class t is greater than the threshold */
    return i;
return i;

Algorithm 5: *Remove*(CA,v,t,D,N,m,e)

$I_{adv} \leftarrow Reconstruct(v,t,D,N,m)$; /* reconstruct 100 infected samples */
$I \leftarrow D$; /* randomly select a set of clean data (5% of training size) */
$\theta \leftarrow CA$; /* from CA distribution find outstanding neurons and weight parameters related to them */
for *e epochs* **do**
  $\mathbf{L}(i,i_{adv}) = \mathbf{L}_1(i,i_{adv}) - \alpha\mathbf{L}_2(i_{adv})$;
  $\mathbf{J}(\theta) = \frac{\partial \mathbf{L}(.)}{\partial \theta}$;
  $\theta \leftarrow \theta - \gamma_\theta \cdot SGD(\mathbf{J}(\theta))$;
return θ;

4 Implementation and Evaluation

In the following, we conduct multiple experiments to evaluate the effectiveness of SODA by answering multiple research questions (RQs). All experiments are conducted on a machine with AMD 64-Core 2.4GHz CPU and 54GB system memory with a single 16GB NVIDIA Tesla T4 GPU. Due to the randomness in the experiments, we run each experiment for three times and report the average results.

4.1 Experiment Setup

To evaluate our approach, we train 21 neural network models over six benchmark datasets: 1) *CIFAR10*[2] *[27]:* This dataset consists of 50K training samples and 10K test samples. Each sample is a 32×32 colour image. The task is to recognize the objects from 10 categories such as ship, deer and car. 2) *German Traffic Sign Benchmark Dataset (GTSRB)*[3] *[54]:* This dataset consists of 39.2K training instances and 12.6K testing instances of colored images. The task is to recognize 43 different traffic signs. 3) *Fashion-MNIST*[4] *[67]:* This data set consists of a training set of 60K samples and a test set of 10K samples. Each sample is a 28×28 grayscale image, associated with a label from 10 fashion categories, e.g., dress, coat, shirt etc. The task is to recognize the fashion category. 4) *MNIST-M*[5] *[16]:* This dataset is created by combining MNIST [30] digits with randomly extracted patches from BSDS500 [2] color photos as their background. It consists of 149K images and the task is to recognize 10 hand-written digits with colored background. 5) *ASL Alphabet*[6]*:* This dataset is a collection of images of alphabets from the American Sign Language. It consists of 87K 200×200 images of 29 classes, including 26 letters (A to Z) and 3 classes for "SPACE", "DELETE" and "NOTHING". The task is to identify the 29 alphabets. 6) *Caltech101*[7] *[31]:* This dataset contains of 9k pictures of objects belonging to 101 categories. There are 40 to 800 images per category. Images are of variable sizes with typical edge lengths of 200 to 300 pixels. The task is to recognize the 101 different objects.

We follow the approach proposed in [3] in a non-federated training setting to inject semantic backdoor to each model. For each attack, we manually select the semantic feature as the backdoor trigger and randomly select the attack target t. After that, we change the label of all images with the semantic feature in the training set to the target label. Next, we train the model with the poisoned training set. Details of the models are summarized in Table 1. In this experiment, we assume a small clean dataset (5% of the training set) is available. In our causality analysis we set the intervention parameter $a = 1$ and $b = 1$. For each detected semantic backdoor, we reverse 100 infected samples (<100 for NN_{16} and NN_{17} due to limited number of clean samples from the victim classes). We set the number of iterations to 2k and the regularization parameter $\lambda = 0.9$. To remove the detected backdoor, we optimize the weight parameters of the responsible neurons for < 5 epochs.

4.2 Research Questions and Answers

RQ1: Is SODA effective in detecting semantic backdoors?
To answer this question, we systematically apply SODA to all the above-mentioned models and attacks, and we report how often SODA is able to successfully identify the semantic backdoors. The result is summarized in Table 2. For all the experimented 21 models, we show the real backdoors embedded in the second column *Real Backdoor*, where models NN_3, NN_6, NN_9, NN_{12}, NN_{15}, NN_{18} and NN_{21} are 7 clean models trained using clean data. Column *Detected Backdoor* shows the semantic backdoor identified by SODA for each model. Models NN_1 & NN_{19}, NN_2 & NN_{20} and NN_3 & NN_{21} are trained with the same setting but only the model size is different, i.e., ResNet18 and ResNet50. Based on the experimental results, SODA successfully distinguishes backdoored models from clean models and identifies the

real backdoor victim class and target class pair with 100% True Positive Rate (TPR) and 0% False Positive Rate (FPR). We report the time taken in causality analysis and semantic backdoor detection in the last column and SODA is able to complete backdoor detection within three minutes for all models. Thus to answer RQ1, SODA is able to identify attacked models and flag semantic backdoors effectively.

RQ2: Is SODA effective in removing semantic backdoors?
To answer this question, we systematically apply SODA to remove the semantic backdoors identified. We first reconstruct a set of infected samples (<= 100) for the flagged backdoor and then perform weight optimization. We evaluate the mitigation effectiveness from two aspects: 1) Success Rate (SR) of the attacks before and after applying SODA and 2) change in model accuracy. As shown in Table 3, the attack SR is above 83.3% (97.2% on average) for all attacked models and after applying SODA, the attack SR for all models drops to 0%. In terms of model accuracy, it is minimally affected (declined by 2% on average). We report the optimization time taken for each attacked model in the last column and the optimization process completes within 255s for all models. Thus to answer RQ2, SODA is able to remove semantic backdoors efficiently and effectively with model accuracy maintained at a high level.

RQ3: How does SODA compare with existing neural network backdoor defense methods?
To answer this question, we compare SODA with state-of-the-art neural network backdoor defense methods on all 21 models. We compare the performance with two lines of works 1) backdoor detection and 2) backdoor removal. For backdoor detection, we first compare our causality analysis with influence estimation [4, 19, 51]. Influence estimation is often used in estimating the impacts of data samples and we apply influence estimation to identify "guilty" neurons in the same way as how we apply causality analysis when detecting semantic backdoors. Leave-one-out (LOO) [11] is the most intuitive approach to estimate the influence of a sample which defines influence as the difference between the result with and without a certain sample. Data Shapley [19] (Expected Marginal Influence) applies the idea of Shapley values to influence estimation. It computes an expectation of LOO over all subsets of the original samples. Hence it is rather computational intensive. SubSample [15] simplifies Data Shapley by considering a single pre-specified subset size instead of all possible subset sizes. In the experiment, we compare SODA with LOO and SubSample. Furthermore, we compare SODA with 3 existing neural network backdoor detection methods, i.e., Neural Cleanse (NC) [62] which is based on model inspection and trigger reconstruction, K-arm [52] which applies the Multi-Arm Bandit (MAB) technique in the trigger reconstruction process and EX-RAY [38] which is based on feature differencing.

For backdoor mitigation, we compare SODA with 5 existing approaches, i.e., Randomized Smoothing (RS) [10] which is based on introducing calibrated noise, ANP [65] which is based on sensitive neuron pruning, NAD [33] which is based on model distillation technique, MOTH [57] which is based on class distance hardening and DFR [25] which improves the neural network robustness by removing spurious correlations, in terms of the semantic backdoor SR reduction and changes in model accuracy. The experimental results are summarized in Table 4 and Table 5. For semantic backdoor detection, SODA identifies the backdoors effectively and achieves 100% TPR and 0% FPR. In comparison, LOO is able to identify the backdoor of NN_1, NN_4 and NN_7. Benign model NN_{12} is flagged as attacked and other 11 attacked models are either identified as benign model or wrong attack target and victim class is detected. SubSample shows the same result as LOO. This result shows that, influence estimation is not as effective as our causality analysis in finding outstanding neurons for semantic backdoor detection. We believe this is due to the fact that some responsible neurons may not be activated when tested with clean inputs. Hence, simply leaving one neuron out is not effective in estimating its real effect on the semantic backdoor. In contrast, SODA introduces an offset parameter when performing causal intervention as illustrated in Equation 2, such that we are able to measure the effect of a neuron even if it is not highly activated by the clean samples tested. Similarly, neural Cleanse is unable to detect any of the backdoor correctly. Specifically, attacked models NN_1, NN_4, NN_5, NN_7, NN_8, NN_{10}, NN_{11}, NN_{13}, NN_{14}, NN_{16}, NN_{17}, NN_{19} and NN_{20} are flagged as benign models by NC. Although NN_2 is identified as an attacked model, the flagged attack target label is incorrect. Furthermore, benign models NN_3, NN_{12} and NN_{21} are flagged as backdoored unexpectedly. Our conjecture is that Neural Cleanse detects backdoors based on whether it is able to construct triggers that are unusually small. However, with semantic backdoors the triggers are naturally exist features which does not have a fixed size and are often not small. K-arm follows a similar concept and applies MAB to improve the performance. Similarly, the detection result is not that good compared with SODA where 7 attacked models are flagged as benign models but clean models NN_6, NN_{15} and NN_{18} are identified as attacked models. For the remaining models, either the identified backdoor victim class or target class or both is incorrect. EX-RAY reports the probability that the model is attacked and is able to detect the existence of the semantic backdoor for some of the models (i.e., NN_1, NN_2, NN_4, NN_5, NN_7, NN_8, NN_{10}, NN_{19} and NN_{20}) with high probability ($> 60\%$) but for the rest of the attacked models, the probability being attacked reported by EX-RAY is below 50%. For the models trained on MNIST-M, ASL and Caltech101 datasets, EX-RAY fails to distinguish the clean model and attacked models. In terms of semantic backdoor removal, Randomized Smoothing fails to mitigate the influence of semantic backdoor trigger on all of the attacked models and this result shows that, averaging the predictions within an input's vicinity does not help in the case of semantic backdoor. MOTH is proposed as a class distance hardening method to improve model security

Table 4: Performance of Existing Backdoor Detection Methods on Semantic Backdoors. Incorrect detections are highlighted in **Bold**. For EX-RAY, the attack probability for each model is shown in the last column.

but it fails to remove the backdoor on all attacked models except NN_5, and the model accuracy drops by 11.1% on average. NAD fails to remove the semantic backdoors on 4 models (i.e., NN_1, NN_2, NN_{13} and NN_{14}), where the attack SR is higher than 50% even after repair. For models NN_{16} and NN_{17}, although the attack SR drops to 0 after repair, the model accuracy drops by 16.5% and 9.8%. ANP is able to remove the semantic backdoor on 6 models (i.e., NN_1, NN_4, NN_5, NN_{10}, NN_{11} and NN_{14}), but the backdoor removal performance is not that good on the rest of attacked models. Lastly, by re-training the last layer of the neural network, DFR is able to remove the semantic backdoor on model NN_4, NN_7, NN_{10} and NN_{11} where the attack SR after re-training is $< 15\%$. However, for the rest of attacked models, the attack SR is still high. In addition, unlike SODA, the other five backdoor removal methods do not provide any on the backdoor and it is hard for the users to know whether the backdoor is removed successfully or not. Thus to answer RQ3, SODA is more effective in semantic backdoor detection and mitigation comparing to existing approaches.

RQ4: Will class imbalance affect semantic backdoor detection?

Due to the fact that semantic backdoor triggers are often rare, we would like to understand whether models trained with an imbalanced dataset will affect SODA's backdoor detection. To answer this question, we train 4 models on a clean MNIST-M dataset that is: 1) class balanced, 2) mildly imbalanced, 3) moderately imbalanced and 4) extremely imbalanced. We choose class 5 as the minority class and the rest are majority classes. We randomly select 5000 samples for each majority class in the training set and a minority to majority ratio used are 30%, 10% and 1% for mildly, moderately and extremely imbalanced scenarios respectively. The experimental results show that SODA is able to identify all 4 models as benign models correctly. Furthermore, datasets GTSRB and Caltech101 are naturally imbalanced and based on our experimental results as shown in RQ1, SODA is able to detect the semantic backdoors correctly for models trained on these datasets. Thus to answer RQ4, class imbalance will not affect SODA's performance on semantic backdoor detection.

5 Related Work

This work is broadly related to works on neural network backdoor attack, defense and causality analysis.

Neural network backdoor attacks. Neural networks can be exploited to launch backdoor attacks which inject malicious behaviors such that a compromised model behaves normally on clean inputs but predicts a specific target label on inputs carrying a specific trigger. BadNets [20] first proposes a method to inject backdoor into neural networks by poisoning the training samples. Following-up works extend the idea with 1) digital attacks [32, 37, 60, 73] which adds carefully crafted digital pattern as the trigger to training samples, 2) physical attacks [9, 34] which explore physical objects as the trigger, 3) semantic attacks [3, 35] which select some rare semantic features as the trigger, 4) input-specific attacks [44] in which the triggers are dynamic and vary from input to input etc. In this work, we focus on semantic backdoor attacks.

Neural network backdoor defenses. Existing neural network backdoor defenses can be classified into four major categories [45], i.e., 1) input reformation, which reforms the input to mitigate the potential trigger before feeding it to the model, e.g., Randomized Smoothing [10] and down-upsampling [68], 2) input filtering, which distinguishes clean and trigger-embedded inputs and possibly recovers the clean inputs, e.g., Activation Clustering [7] and STRIP [18], 3) model sanitization, which sanitizes a suspicious model by removing the potential backdoor, e.g., Fine-Pruning [36], Adversarial Neuron Pruning [65], Neural Attention Distillation [33] and Adversarial-Retraining [39], and 4) model inspection, which detects whether a given model is tampered and, if so, reports the target class and potential trigger, e.g., Neural Cleanse [62], DeepInspect [8], EX-RAY [38] and K-arm [52]. Unlike these methods, SODA detects the existence of semantic backdoors based on causality analysis and removes the

backdoor by optimizing responsible neurons if necessary.

Causality analysis. Causality analysis has traditionally been applied to program analysis [14, 28] and testing [24], and is demonstrated to be useful in isolating and mitigating buggy behaviors. Recently, causality analysis is further applied to neural networks for model interpretation [6, 43], model fairness measurement [29, 71] and model repair [55]. Inspired by [55], we perform causality analysis on the hidden neurons of a given model to detect semantic backdoors and identify responsible neurons. Different from existing metrics to perform intervention and measure causal attribution, we propose a lightweight metric which is carefully designed for backdoor detection when the attack trigger is unknown.

6 Discussion

Layer selection. In SODA, we apply causality analysis on the last dense layer of the neural network to identify outstanding neurons since it is the closest to the final prediction. To further understand the impact of the layer selection, we conduct a set of experiments on neural network NN_1, NN_2 and NN_3 and perform causality analysis on four layers of different depths, i.e., shallow layer, middle layer, deep layer and the last layer. We compare the semantic backdoor detection effectiveness and the results are shown in Table 6. Applying causality analysis on the deep layers is effective in detecting semantic backdoors but due to an increased number of neurons to analyze, the time is doubled compared to analyzing the last layer. Analyzing the middle layers results in unstable backdoor detection performance and analyzing the shallow layers is not effective in finding backdoors. The time taken to analyze the middle and shallow layers also increases significantly. We believe layers closer to the input tend to capture low-level features which exert less influence on the output. On the other hand, deeper layers tend to capture high-level features that impact the prediction more directly. Thus, analyzing the last and deep layer is the most effective in detecting semantic backdoors. Since the last layer usually contains fewer neurons, applying causality analysis on the last layer is the most efficient.

Adaptive attacks. In patch-based backdoor attacks, trigger adjustment attack is often considered as one adaptive attack. However, this is not applicable to semantic backdoors since the trigger is existing semantic feature and the attacker is not required to modify the inputs. Parameter inference attack is another adaptive attack often taken into consideration. There are a few parameters in SODA such as causal intervention parameter a and b, infected sample reconstruction regulation parameter λ and number of epochs to optimize etc.

Table 7: Adaptive attacks.

ρ	Detected Backdoor	Acc	SR
0.9	**NA**	0.1117	1
0.8	**NA**	0.2120	1
0.7	(8,3)	0.7657	1
0.6	(8,3)	0.9812	0.9153
0.5	(8,3)	0.9830	0.9153
0.4	(8,3)	0.9848	0.9492
0.3	(8,3)	0.9862	0.9153
0.2	(8,3)	0.9867	0.9322
0.1	(8,3)	0.9842	0.9661

However, revealing the values of these parameters will not give more advantage to the attacker. However, there could be more powerful attackers that are aware of SODA's semantic backdoor detection scheme. To explore SODA's resilience to such attackers, we conduct experiments such that when injecting semantic backdoors during training time, we further consider the distribution difference of the last dense layer neurons in the optimization. The optimization loss function is set as $L(ii) = (1-\rho)L_{cce}(ii,cc) + \rho STD_{pcc^{ii}}$, where ii represents a batch of training inputs, cc represents the labels of ii and $STD_{pcc^{ii}}$ represents the standard deviation of the PCC values between the last dense layer activation of each sample in ii and their mean activation. We use $STD_{pcc^{ii}}$ to limit the PCC distribution difference of different inputs thus to explore whether it can bypass SODA's backdoor detection. Parameter ρ is used to control the importance of $STD_{pcc^{ii}}$ over training accuracy during optimization. We follow the similar process as we train NN_{10} and train 9 models on MNIST-M dataset with attack target class 3 and victim class 8. We report the detected backdoor, model accuracy and attack SR for different ρ values in Table 7. When ρ is above (or equal to) 0.8, SODA fails to identify the semantic backdoor. However, such high ρ values result in extremely low model accuracy ($< 22\%$). For ρ values lower than 0.8, SODA is able to detect the semantic backdoor successfully. Hence, knowing how SODA detects backdoors and controlling the last layer neuron distribution during training, the attacker is still not able to bypass SODA's detection unless the model accuracy is affected significantly.

Limitations of SODA. Firstly, SODA is only evaluated on image classification models although we believe that it can be extended to other tasks, e.g., NLP tasks and audio tasks. SODA leverages causality analysis on hidden neurons to identify semantic backdoors. Causality analysis can be applied to non-vision tasks as long as the neural network can be modeled as an SCM. Next, with identified responsible neurons from causality analysis results, optimizing their weight parameters follows similar process of model training. Secondly, the semantic backdoors evaluated are manually selected and thus limited to high-level human interpretable features. We believe whether the semantic feature is human interpretable or not does not affect the performance of SODA since the causality analysis is unlikely to be affected. We leave further exploration on such semantic attacks to future works and will evaluate SODA against them then. Furthermore, SODA utilizes a set of clean data for causality analysis and semantic backdoor removal. We believe such assumption is reasonable since a clean validation set is often provided together with the model for testing purpose. Such assumption is also made by many existing works [18, 33, 38, 52, 55, 57, 65].

7 Conclusion

In conclusion, we propose SODA as a causality-based semantic backdoor detection and removal algorithm for neural networks. We evaluate SODA with multiple neural networks trained on benchmark datasets. Experimental results show that SODA is effective in detecting and removing semantic backdoors and it outperforms existing state-of-the-art neural network backdoor attack defense methods.

Availability

Our approach has been implemented as a self-contained toolkit in Python and is open-sourced (https://gitlab.com/sunbing7/SODA).

Abstract

Recent studies have shown that contrastive learning, like supervised learning, is highly vulnerable to backdoor attacks wherein malicious functions are injected into target models, only to be activated by specific triggers. However, thus far it remains under-explored how contrastive backdoor attacks fundamentally differ from their supervised counterparts, which impedes the development of effective defenses against the emerging threat.

This work represents a solid step toward answering this critical question. Specifically, we define TRL[1], a unified framework that encompasses both supervised and contrastive backdoor attacks. Through the lens of TRL, we uncover that the two types of attacks operate through distinctive mechanisms: in supervised attacks, the learning of benign and backdoor tasks tends to occur independently, while in contrastive attacks, the two tasks are deeply intertwined both in their representations and throughout their learning processes. This distinction leads to the disparate learning dynamics and feature distributions of supervised and contrastive attacks. More importantly, we reveal that the specificities of contrastive backdoor attacks entail important implications from a defense perspective: existing defenses for supervised attacks are often inadequate and not easily retrofitted to contrastive attacks. We also explore several alternative defenses and discuss their potential challenges. Our findings highlight the need for defenses tailored to the specificities of contrastive backdoor attacks, pointing to promising directions for future research.

1 Introduction

As an emerging machine learning paradigm, contrastive learning (CL) has gained significant advances recently [1–6]. Without requiring data labeling, CL is able to learn high-quality representations of complex data and enable a range of downstream tasks. Intuitively, CL performs representation learning by aligning the representations of the same input under varying data augmentations while separating the representations of different inputs. In various tasks, CL achieves performance comparable to supervised learning (SL) [2]. Many IT giants have unveiled their CL-based products and services [7, 8].

The surging popularity of CL also raises significant security concerns. Backdoor attacks represent one major threat, which injects malicious "backdoors" into target models, only to be activated by specific "triggers". For example, a backdoored model may misclassify trigger-embedded inputs to a target class while functioning normally on clean inputs [9]. Backdoor attacks are of special interest to CL. As CL-trained models are subsequently used in various downstream tasks, such attacks can cause widespread damage. Despite a plethora of backdoor attacks against SL [9–13], due to the absence of labels, supervised backdoor attacks are often inapplicable to CL directly. Recent work has explored new ways of injecting backdoors into CL-trained models [14–16]. For example, SSLBackdoor [14] extends BadNets [9] by only poisoning inputs in the target class; PoisonedEncoder [16] generates poisoning data by randomly combining target inputs with reference inputs; CTRL [15] defines triggers as specific perturbations in the spectral domain of given inputs. While these studies show empirically that CL is also highly vulnerable to backdoor attacks, a set of key questions remain unexplored:

- Q1 – How do contrastive backdoor attacks fundamentally differ from their supervised counterparts?
- Q2 – What are the implications of their distinctions from a defense perspective?
- Q3 – Is it feasible to retrofit defenses against supervised backdoor attacks to contrastive attacks?

Answering these questions is critical for both (i) understanding the vulnerabilities of contrastive learning and (ii) developing effective defenses against the emerging threat.

Our work. This work represents a solid step toward answering these critical questions.

[1] TRL: TRojan Learning

A1 – We first define TRL [1], a unified framework that encompasses both supervised and contrastive attacks. Through the lens of TRL, we uncover that the two types of attacks operate through distinct mechanisms. In supervised attacks, the learning of benign and backdoor tasks occurs independently at the data level, focusing on learning trigger features *only* from the poisoning data and learning semantic features *only* from the clean data, while in contrastive attacks, the learning of benign and backdoor tasks is deeply intertwined not only in their representations but also throughout their learning processes.

A2 – We then show that the disparate mechanisms of supervised and contrastive attacks lead to their distinctive learning dynamics and feature distributions. For instance, in supervised attacks, the loss of poisoning data often drops much faster than that of clean data, as learning trigger features often represents a simpler task than learning semantic features. In contrastive attacks, as the learning of benign and backdoor tasks is intertwined in the poisoning data, the loss of poisoning data often decreases at a rate similar to the clean data.

A3 – More importantly, we reveal that the specificities of contrastive backdoor attacks entail unique challenges from a defense perspective. Defenses against supervised attacks that attempt to segregate poisoning data based on learning dynamics and feature distributions tend to fail. Also, defenses applied on the end-to-end model in the downstream task are often ineffective. Finally, we explore promising alternative defenses (e.g., data-free pruning and density-based filtering) and discuss their potential challenges.

Our contributions. To our best knowledge, this work is the first to systematically investigate the fundamental differences between supervised and contrastive backdoor attacks from a defense perspective. Our key contributions can be summarized as follows:

- For the first time, we uncover the distinctive mechanisms underlying supervised and contrastive backdoor attacks.
- We highlight the significant implications of such differences from a defense standpoint and reveal the inadequacy of existing defenses against contrastive backdoor attacks.
- We explore promising alternative defense strategies and discuss their potential challenges, pointing to several directions for future research.

We believe our findings shed new light on developing more robust contrastive learning techniques.

2 Preliminaries

We first introduce the fundamental concepts used in the paper.

2.1 Contrastive Learning

A predictive model h (parameterized by θ) typically comprises two parts $h = g \circ f$ where an encoder f extracts latent representations (i.e., features) from inputs while a classifier g maps such features to output classes. Supervised learning optimizes parameters θ using a training set $\mathcal{D}$ with labeled instances (x,y) and a loss function $\mathbb{E}_{(x,y)\in\mathcal{D}}\ell(h_\theta(x),y)$, such as cross-entropy between $h_\theta(x)$ and y.

However, supervised learning is inapplicable when data labeling is scarce or expensive. Recently, contrastive learning (CL) has emerged as an alternative, which leverages the supervisory signals from the data itself to train f that is then combined with g and fine-tuned using weak supervision. Typically, CL performs representation learning by aligning the features of the same input under varying augmentations (i.e., "positive pairs") and separating the features of different inputs (i.e., "negative pairs").

A variety of CL methods (e.g., SimCLR [1], BYOL [2], MoCo [6]) have been proposed and garnered significant attention. For instance, SimCLR maximizes the similarity of positive pairs relative to the similarity of negative pairs. Specifically, for each input x, a pair of its augmented views (x,x^+) forms a positive pair, while a set of augmented views of other inputs $\mathcal{N}_x$ forms its negative inputs. The contrastive loss is defined by the InfoNCE loss [17]:

$$-\log\frac{\exp\left(\frac{f_\theta(x)^\intercal f_\theta(x^+)}{\tau}\right)}{\sum_{x^-\in\mathcal{N}_x}\exp\left(\frac{f_\theta(x)^\intercal f_\theta(x^-)}{\tau}\right)+\exp\left(\frac{f_\theta(x)^\intercal f_\theta(x^+)}{\tau}\right)}, \quad (1)$$

where τ denotes a temperature parameter.

2.2 Backdoor Attacks

Backdoor attacks represent a major threat to machine learning security [9,11,12,18]. As illustrated in Figure 1, the adversary plants a "backdoor" into the victim's model during training and activates this backdoor with specific "triggers" at inference. The backdoored model reacts to trigger-embedded inputs (trigger inputs) in a highly predictable manner (e.g., classified to the adversary's target class) but functions normally otherwise. Formally, in the supervised setting, the objective function of backdoor attacks via poisoning training data is defined as:

$$\min_\theta \mathbb{E}_{(x,y)\in\mathcal{D}\cup\mathcal{D}^\star}\ell(h_\theta(x),y), \quad (2)$$

where h_θ is the target model (parameterized by θ), ℓ denotes the predictive loss (e.g., cross-entropy), and $\mathcal{D}$ and $\mathcal{D}^\star$ respectively denote the clean and poisoning training data. Note that $\mathcal{D}^\star$ comprises trigger inputs, which are assigned the target-class label t. The poisoning ratio $|\mathcal{D}^\star|/|\mathcal{D}|$ dictates the influence of clean and poisoned data.

Backdoor attacks are of particular interest for CL: as CL-trained models are subsequently used in various downstream

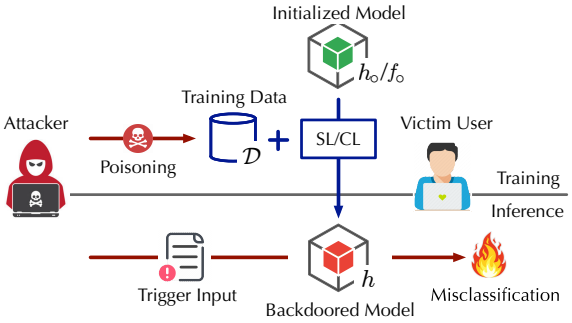

Figure 1: Threat model of TRL.

tasks, backdoor attacks may cause widespread damage [15]. While supervised backdoor attacks are often inapplicable to CL due to their reliance on labels (cf. Eqn (2)), recent studies explore new ways of injecting backdoors into CL-trained models [14, 16, 19, 20].

Specifically, one class of attacks (e.g., SSLBackdoor [14]) hypothesizes that during training, the model learns to recognize a trigger that is only present in the target class and has a rigid, slightly variable shape as a key feature. This enables the model to effectively detect the trigger and accurately predict the target class at inference, even in the absence of other semantic features. The other class of attacks (e.g., CTRL [15]) uses "symmetric alignment": it ensures that the trigger pattern is preserved after augmentations; aligning such augmented makes the trigger pattern appear as semantic features of the target class. Notably, CTRL [15] achieves attack performance comparable to supervised backdoor attacks, suggesting that CL is also highly vulnerable to backdoor attacks.

3 A General Attack Framework

To study supervised and contrastive backdoor attacks side by side, we first define TRL, a general framework that subsumes a number of supervised and contrastive attacks. We begin by introducing its threat model.

3.1 Threat Model

Specifically, we focus on data-level backdoor attacks in the vision domain and assume a threat model similar to prior work [9, 11, 12, 14, 15], as illustrated in Figure 1.

Adversary's Goal: The adversary aims to inject a backdoor into a target model h_θ during training such that at inference time, h_θ classifies trigger inputs to an adversary-defined class t while classifying clean inputs correctly. Formally,

$$\begin{cases} h_\theta(x^\star) = t & x^\star \text{ is triggered} \\ h_\theta(x) = y & x \text{ is clean with ground-truth class } y \end{cases} \tag{3}$$

Adversary's Capability: The adversary corrupts the victim's training data with a small amount of poisoning data $\mathcal{D}^\star$. In the supervised setting, $\mathcal{D}^\star$ comprises input-class pairs $\{(x^\star, t)\}$, in which $x^\star$ is a trigger input; in the contrastive setting, $\mathcal{D}^\star$ only comprises trigger inputs $\{x^\star\}$ (without labels). The victim's model h_θ is then trained on the union of clean data $\mathcal{D}$ and poisoning data $\mathcal{D}^\star$ (cf. Eqn (2)). Note that such attacks are often practical, even if the victim downloads the training data from credible sources [21].

Algorithm 1: TRL Attack

Input: t: target class; k: number of poisoning inputs; $\tilde{\mathcal{D}}$: reference data
Output: $\mathcal{D}^\star$: poisoning data

```
/* description: select candidate inputs from
   reference data                                  */
/* options: (i) from target class only and (ii)
   across all the classes                          */
```
1 $\mathcal{D}^\star \leftarrow \mathsf{SelectCandidate}(\tilde{\mathcal{D}}, t, k)$;
2 **for** $x^\star \in \mathcal{D}^\star$ **do**
```
    /* description: apply the trigger to an
       input to generate a trigger input           */
    /* options: (i) universal, (ii) functional,
       and (iii) dynamic trigger                   */
```
3 update $x^\star \leftarrow \mathsf{ApplyTrigger}(x^\star)$
4 **end**
5 **return** $\mathcal{D}^\star$

Adversary's Knowledge: We assume a limited knowledge setting: the adversary has no knowledge about the concrete model h_θ or training strategy (e.g., SimCLR) but has access to a small number of target-class inputs sampled from the same distribution as the training data.

3.2 Overview of TRL

Despite their evident variations, various supervised and contrastive backdoor attacks follow a similar methodology for generating poisoning data, which can be distilled into a high-level framework that we refer to as TRL. As sketched in Algorithm 1, TRL involves two key functions to generate poisoning data: $\mathsf{SelectCandidate}()$, which selects candidate inputs from a reference dataset, and $\mathsf{ApplyTrigger}()$, which applies the trigger to each candidate input to generate the poisoning data.

$\mathsf{SelectCandidate}()$ – There are typically two ways of selecting candidate inputs, one across all classes while the other exclusively from the target class.

Among supervised backdoor attacks, dirty-label attacks [9, 11, 12] generate poisoning data along with incorrect labels, while clean-label attacks [22] do not tamper with the labels of poisoning data. Thus, dirty-label attacks select candidates across all classes, while clean-label attacks select candidates from the target class only.

Meanwhile, without data labeling, contrastive backdoor attacks rely on aligning positive pairs to associate the trigger with inputs from the target class (details in § 4). Therefore, contrastive attacks [14, 15] often select candidates from the target class only.

$\mathsf{ApplyTrigger}()$ – There are a variety of trigger definitions,

including (i) universal triggers (e.g., image patch [9, 12]), (ii) functional triggers (e.g., specific spectral transformations [23]), and (iii) dynamic triggers (e.g., input-aware perturbation generated by a generative model [24]).

3.3 Instantiations

We now discuss the instantiations of TRL in our studies.

To make a fair comparison, in both supervised and contrastive settings, we implement SelectCandidate() as randomly sampling inputs from the target class, corresponding to a clean-label attack.[2]

Further, we instantiate ApplyTrigger() as follows. A universal trigger is defined as a fixed-size (e.g., 5×5) image patch and applied to a pre-defined position (e.g., left lower corner) of the given input. A functional trigger is defined as a specific spectral transformation to the given candidate input (e.g., increasing the magnitude of a particular frequency by a fixed amount). A dynamic trigger is defined as input-specific perturbation generated by a generative model (e.g., GAN). The detailed implementation of these triggers is deferred to § B.

Below we use $\text{TRL}_{\text{SL/CL}}^{\text{uni/fun/dyn}}$ to denote a specific backdoor attack, in which SL/CL indicates supervised/contrastive while uni/fun/dyn indicates the trigger type.

4 Comparison of Supervised and Contrastive Backdoor Attacks

While prior work shows that supervised and contrastive backdoor attacks are comparably effective [15], it remains unclear how they differ fundamentally from a defense perspective. Next, we compare supervised and contrastive attacks in terms of learning dynamics and feature distributions.

4.1 Evaluation Setting

We first describe the setting of our evaluation.

Datasets – We primarily use three benchmark datasets: CIFAR10 [25], which contains 60,000 32×32 images divided into 10 classes; CIFAR100 [25], which includes 100 classes, each containing 600 32×32 images; and ImageNet100 [26], which is a subset of the ImageNet-1K dataset with 100 classes, each with 500 training and 50 testing images.

CL methods – We use three representative CL methods in the vision domain: SimCLR [1], BYOL [2], and MoCo [6].

Attacks – We consider all the instantiations of TRL attacks in § 3.3 including both supervised and contrastive attacks as well as different trigger types (i.e., universal, functional, and dynamic). By default, we allocate 1% of the training data to construct the poisoning dataset $\mathcal{D}^\star$ following Algorithm 1

[2]Note that as the clean-label variant of the dynamic backdoor attack has poor performance, we use its dirty-label variant, which selects inputs across all classes.

Dataset		Attack					
		$\text{TRL}_{\text{SL}}^{\text{fun}}$	$\text{TRL}_{\text{SL}}^{\text{uni}}$	$\text{TRL}_{\text{SL}}^{\text{dyn}}$	$\text{TRL}_{\text{CL}}^{\text{fun}}$		
					SimCLR	BYOL	MoCo
CIFAR10	ASR (%)	66.7	31.5	99.2	98.3	61.5	89.1
	ACC (%)	82.1	81.4	81.2	82.1	85.6	81.7
CIFAR100	ASR (%)	99.7	83.7	96.4	98.1	82.5	88.8
	ACC (%)	51.4	48.3	50.1	44.2	54.5	46.7
ImageNet100	ASR (%)	98.4	84.2	98.2	42.4	45.1	48.1
	ACC (%)	52.3	52.7	55.3	47.8	49.4	44.3

Table 1. Clean accuracy and attack success rate of different attacks.

while using the remainder as the clean dataset $\mathcal{D}$. We consider class 0 as the target class t. More implementation details about the attacks are deferred to Table 11 in § A.

Models – In both SL and CL, we use ResNet18 [27] as the backbone model. In CL, we add a two-layer MLP projector to map the representations to a 128-dimensional latent space. In § 7, we also discuss the influence of the backbone model.

Metrics – We mainly use two metrics to evaluate the attacks: clean accuracy (ACC) measures the model's accuracy in classifying clean data, and attack success rate (ASR) measures the model's accuracy in classifying poisoning data to the target class.

Table 1 compares the performance of different attacks on benchmark datasets. For contrastive attacks, Table 1 only lists the results of $\text{TRL}_{\text{CL}}^{\text{fun}}$, with other results deferred to § C. Note that for a fair comparison, we set the training epochs to ensure that SL and CL attain similar ACCs. The default parameter setting is listed in § A.

4.2 Learning Dynamics

Given training data as input-class pairs (x, y), SL optimizes the predictive loss (e.g., measured by cross entropy H):

$$\mathcal{L}_{\text{prd}}(\theta) = \mathbb{E}_{(x,y)} H(h_\theta(x), y), \tag{4}$$

where h refers to the end-to-end model $h = g \circ f$. Existing work [28, 29] suggests that in supervised attacks, the backdoor task (i.e., learning the trigger features) is often much "easier" than the benign task (i.e., learning the semantic features). Thus, the model often learns the backdoor task much faster than the benign task, reflected in that the predictive loss of poisoning data drops much faster than that of clean data during training.

Due to the absence of labels, CL optimizes the contrastive loss, which measures the similarity between the variants of the same input under different augmentations (positive pairs) with respect to different inputs (negative pairs). For instance, SimCLR [1] defines the contrastive loss using InfoNCE loss [17] (cf. Eqn (1)), where the numerator term encourages the similarity between positive pair (x, x^+) and the denominator term suppresses the similarity between negative pairs (x, x^-).

To test whether this difference between the learning dynamics of backdoor and benign tasks also holds for contrastive attacks as well, we measure the average contrastive loss of

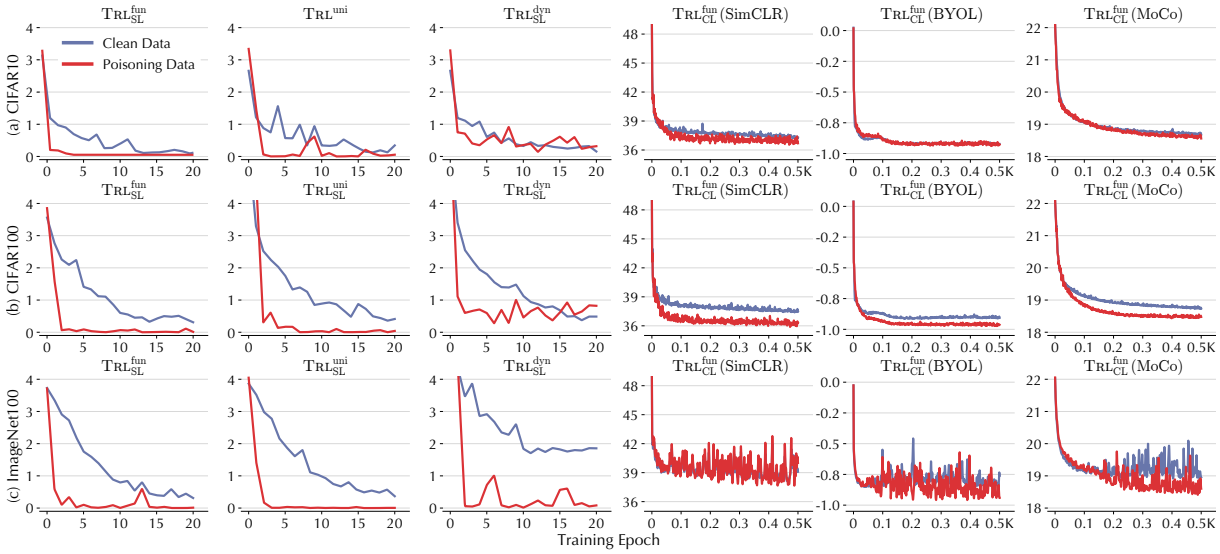

Figure 2: Learning dynamics (measured by the training loss of poisoning and clean data) in supervised and contrastive backdoor attacks on (a) CIFAR10, (b) CIFAR100, and (c) ImageNet100.

poisoning and clean data during training, with results also summarized in Figure 2.

In supervised backdoor attacks, across different trigger settings, the predictive loss of poisoning data decreases faster than that of clean data, which corroborates prior work [28]. For example, the loss of poisoning data in $\text{TRL}_{\text{SL}}^{\text{uni}}$ and $\text{TRL}_{\text{SL}}^{\text{fun}}$ drops sharply to zero in the first few epochs. This difference is especially significant on CIFAR100, which represents a more challenging task in terms of learning semantic features, therefore much more difficult than the backdoor task.

Meanwhile, in contrastive backdoor attacks, across all the CL methods, the training loss of poisoning data decreases gradually at a pace similar to clean data on CIFAR10, CIFAR100, and ImageNet100. While the loss of poisoning data seems slightly lower than clean data on CIFAR100 and ImageNet100 (which may be explained by the more challenging tasks, as indicated by the low clean accuracy in Table 1), their decreasing rates are highly comparable.

Remark 1 – Compared with supervised attacks, in contrastive attacks, the learning dynamics of poisoning and clean data are much less distinguishable.

4.3 Feature Distributions

It is commonly observed in supervised attacks that the poisoning and clean data often form separable clusters in the feature space. This "latent separability" premise is exploited by a number of existing defenses against supervised backdoor attacks [30–34].

To test whether this property also holds for contrastive attacks, we first use t-SNE [35] to visualize the representations of poisoning and clean data in supervised and contrastive attacks, exemplified by $\text{TRL}_{\text{SL}}^{\text{fun}}$ and $\text{TRL}_{\text{CL}}^{\text{fun}}$, with results shown in Figure 3. We have the following observations.

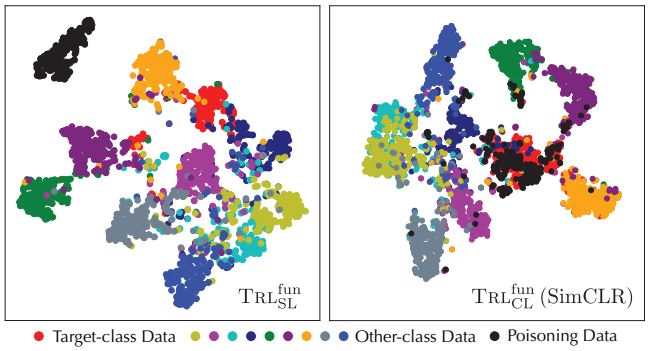

Figure 3: t-SNE visualization of the features of clean and poisoning data in $\text{TRL}_{\text{SL}}^{\text{fun}}$ and $\text{TRL}_{\text{CL}}^{\text{fun}}$ on CIFAR10 (target-class data: red; poisoning data: black).

In supervised attacks, although the clusters of poisoning (in black) and target-class (clean) data (in red) are assigned the same label, they are well separated in the feature space, suggesting that supervised attacks do not necessarily associate the poisoning data with the target-class (clean) data. This finding also corroborates prior work [33]. Meanwhile, in contrastive attacks, the clusters of poisoning and target-class data are highly overlapping in the feature space, suggesting that contrastive attacks may take effect by "entangling" the representations of poisoning and target-class data.

To further validate this observation quantitatively, we define a metric to measure the "entanglement effect" between poisoning and target-class data. Specifically, we define entanglement ratio (ER), which extends the confusion ratio metric [36] to our setting. Specifically, we randomly sample n inputs per class and n poisoning inputs to form the dataset $\mathcal{D}$. In addition, we randomly sample m clean target-class inputs $\mathcal{D}'$ (disjoint with $\mathcal{D}$) as the testing set. For each $x \in \mathcal{D}'$, we find its k nearest neighbors $\mathcal{N}_k(f(x))$ among $\mathcal{D}$ in the feature space and then measure the fraction of such neighbors

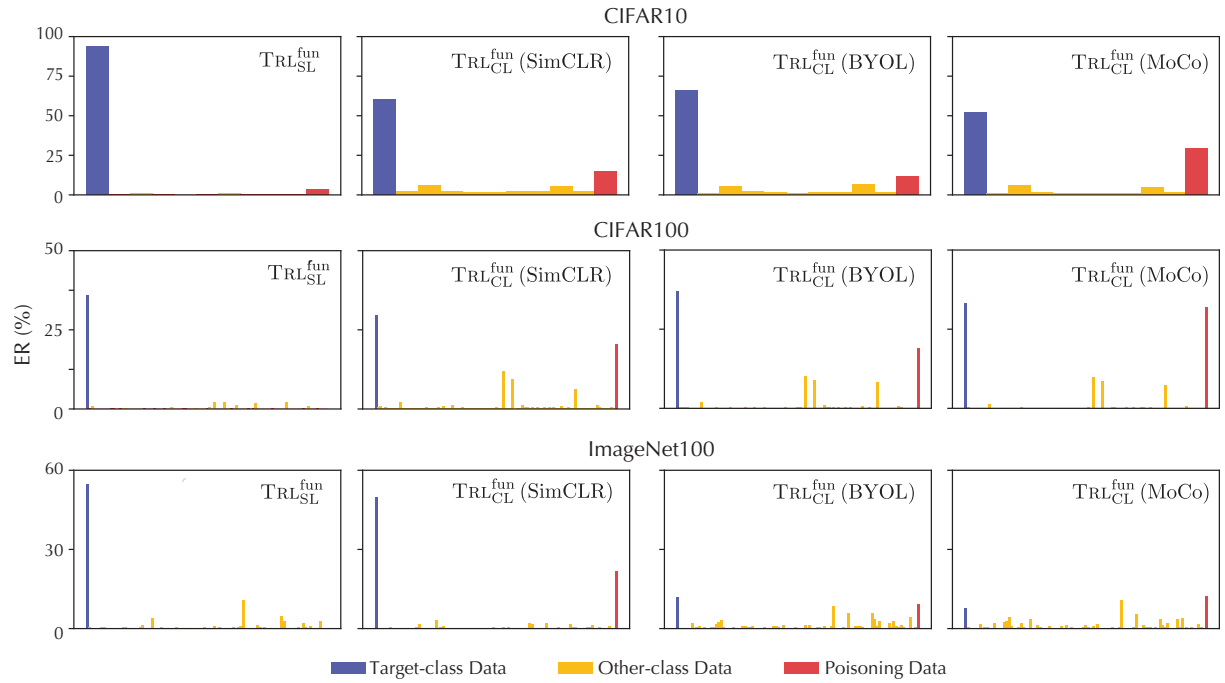

Figure 4: Entanglement ratio of supervised and contrastive backdoor attacks on CIFAR10, CIFAR100 and ImageNet100.

belonging to each class c:

$$\mathrm{ER}(f,c) = \frac{1}{k}\mathbb{E}_{x\in\mathcal{D}^t, x'\in\mathcal{D}}\mathbf{1}_{h(x')=c\wedge f(x')\in\mathcal{N}_k(f(x))} \tag{5}$$

where $\mathbf{1}_p$ is an indicator function that returns 1 if p is true and 0 otherwise and $h(x)$ returns x's class. Consider the poisoning data as a new class $c^\star$. Intuitively, a large $\mathrm{ER}(f,c^\star)$ suggests that the poisoning and clean target-class inputs are tightly entangled in the feature space.

We evaluate the entanglement ratio of different attacks with $n = 800$ and $m = 1{,}000$. Figure 4 illustrates the degree of entanglement in the feature space between inputs from each class and that from the target class t. Here, each bar represents one distinct class, with the leftmost and rightmost bars corresponding to the target class t and poisoning class $c^\star$, respectively. It is observed that the $\mathrm{ER}(f,c^\star)$ of supervised attacks is not significantly different from any other class $c \neq t$. Meanwhile, in contrastive attacks, $\mathrm{ER}(f,c^\star)$ is much higher than the other classes. For example, for MoCo on CIFAR100, $\mathrm{ER}(f,c^\star)$ is comparable to $\mathrm{ER}(f,t)$ (around 31%), indicating that there is tight entanglement between the poisoning and target-class data.

Remark 2 – Compared with supervised attacks, in contrastive backdoor attacks, the poisoning and clean data are highly entangled in the feature space.

In the evaluation above, we examine the entanglement effect in the feature space (i.e., the output of the last convolutional layer) of the pre-trained encoder. One intriguing question arises: how does this entanglement effect evolve over the model's different layers? To answer this question, we truncate the pre-trained encoder f at a specific ResBlock k at a selected layer l, concatenate its part before (l,k) (denoted by $f_{l,k}$) with a classifier g to form an end-to-end model $h_{l,k}$, and fine-tune g using the downstream dataset.

Truncated Layer l	Block k	ACC	ASR
3	1	64.5%	15.2%
	2	72.1%	54.2%
4	1	79.3%	82.3%
	2	83.1%	86.4%

Table 2. ACC and ASR of the end-to-end model $h_{l,k}$.

Table 2 summarizes the performance of the end-to-end model $h_{l,k}$, with the encoder trained by TRL$_{SL}^{fun}$ using SimCLR. Observe that $h_{l,k}$'s ACC gradually increases with (l,k). This is expected, as early layers typically extract coarse-grained features, which are then refined throughout subsequent layers. Meanwhile, note that $h_{l,k}$'s ASR also increases with (l,k), suggesting that trigger features and semantic features are not only entangled in the feature space but also intertwined along the feature extraction process.

We further examine the entanglement ratios (cf. Eqn (5)) of the truncated encoder $f_{l,k}$ for different (k,l), with results summarized in Figure 5, following the same setting in Figure 4. Observe that despite the apparent variations of different truncated encoders, the entanglement ratios of different (k,l) show patterns similar to Figure 4, suggesting that the entanglement effect may appear across different layers of the encoder.

Remark 3 – In contrastive backdoor attacks, trigger and semantic features are not only entangled in the feature space but also intertwined throughout the feature extraction process.

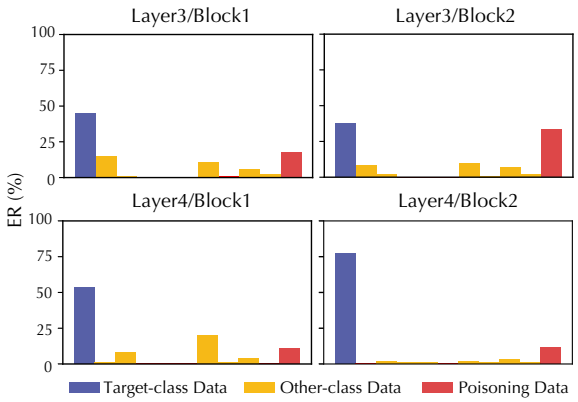

Figure 5: Entanglement ratios of the truncated encoder $f_{l,k}$.

5 Possible Explanations

The empirical study shows that supervised and contrastive backdoor attacks demonstrate distinctive learning dynamics and feature distributions. Below we provide possible explanations for such phenomena, revealing that the two classes of attacks operate through different mechanisms.

5.1 Preliminaries

We begin by introducing two key concepts.

Trigger strength (TS) quantifies the weight of trigger features in poisoning inputs. Specifically, in our setting, we define the trigger strength of $\text{TRL}^{\text{dyn/uni}}_{\text{SL/CL}}$ as the size of the trigger image patch (e.g., 5×5), under a fixed transparency setting. We define the trigger strength of $\text{TRL}^{\text{fun}}_{\text{SL/CL}}$ as the perturbation magnitude in the spectral domain (e.g., increasing the magnitude of a specific frequency band by 50). Intuitively, by adjusting the trigger strength, we balance the importance of trigger features and semantic features in poisoning inputs.

Mutual information (MI) quantifies the amount of information carried by one random variable about another. In our context, we employ MI to estimate the proportion of semantic features retained in the representations of poisoning inputs compared to their corresponding clean inputs. Specifically, consider the representations (i.e., the encoder's outputs) of a clean input and its poisoning counterpart as two random variables X and X', we estimate their MI $I(X;X')$ following [37]. Specifically, let $z_i = (x_i, x'_i)$ be a point sampled from (X, X'). We define the distance between z_i and z_j as

$$\|z_i - z_j\| = \max\{\|x_i - x_j\|_2, \|x'_i - x'_j\|_2\} \tag{6}$$

Let $\varepsilon(i)/2$ be the distance from z_i to its k-th nearest neighbor among the given set of points and $\varepsilon_x(i)/2$ and $\varepsilon_{x'}(i)/2$ be the same distance projected to the X and X' subspaces. Further, let $n_x(i)$ (or $n_{x'}(i)$ be the number of points with distance to x_i (or x'_i) less than $\varepsilon_x(i)/2$ (or $\varepsilon_{x'}(i)/2$). Then, the MI of X and X' is quantified by:

$$I(X;X') = \psi(k) - \frac{1}{k} - \langle \psi(n_x) + \psi(n_{x'}) \rangle + \psi(N) \tag{7}$$

where ψ is the digamma function, k is a hyper-parameter, and N is the number of points in X (or X'). We use Eqn (7) to measure the proportion of semantic features retained in the representations of poisoning inputs compared to their corresponding clean inputs. In the implementation, we set $N = 2{,}000$ and $k = 5$.

5.2 Supervised Backdoor Attacks

Under the supervised setting, the backdoor attack is implemented as optimizing the following objective function:

$$\min_{\theta} \mathcal{L}_{\text{prd}}(\theta) + \lambda \mathcal{L}^{\star}_{\text{prd}}(\theta) \tag{8}$$

where $\mathcal{L}$ and $\mathcal{L}^{\star}$ denote the loss function defined in Eqn (4), measured on clean data $\mathcal{D}$ and poisoning data $\mathcal{D}^{\star}$ respectively, and the hyper-parameter λ balances the influence of $\mathcal{D}$ and $\mathcal{D}^{\star}$ (e.g., via controlling $|\mathcal{D}^{\star}|/|\mathcal{D}|$). Intuitively, the first and second terms represent the benign task (i.e., learning semantic features) and backdoor task (i.e., learning trigger features), respectively. We hypothesize that in supervised attacks, if the trigger feature is sufficiently evident, the learning of benign and backdoor tasks tends to occur independently at the data level; that is, it focuses on learning the backdoor task from the poisoning data and focuses on learning the benign task from the clean data.

To validate this hypothesis, we assess the effect of trigger strength on the ASR, ACC, and MI of supervised backdoor attacks, with results shown in Figure 6. Observe that as the trigger strength varies from 0 to 1K, the ASR of $\text{TRL}^{\text{fun}}_{\text{SL}}$ increases rapidly and remains around 100%, while its MI quickly drops and stays at the minimum level. This observation suggests that in successful attacks, the model focuses on learning trigger features (backdoor task) only from the poisoning data. Meanwhile, the trigger strength has little impact on the ACC, indicating that the model effectively learns the benign task from the clean data. Similar trends are also observed on other supervised attacks in § 7.1.

Remark 4 – In supervised backdoor attacks, the learning of benign and backdoor tasks occurs independently at the data level, with a focus on learning trigger features from poisoning data and semantic features from clean data.

The independence of benign and backdoor tasks in supervised attacks explains the empirical observations in § 4. In terms of learning dynamics, as the trigger feature (e.g., a specific image patch) is often simpler than the varying semantic features, the model learns the backdoor task much faster than the benign task. In terms of feature distributions, as Eqn (8) does not specify any constraints on the latent representations of poisoning and clean data, although associated with the same class, the representations of poisoning and target-class data are not necessarily proximate in the feature space.

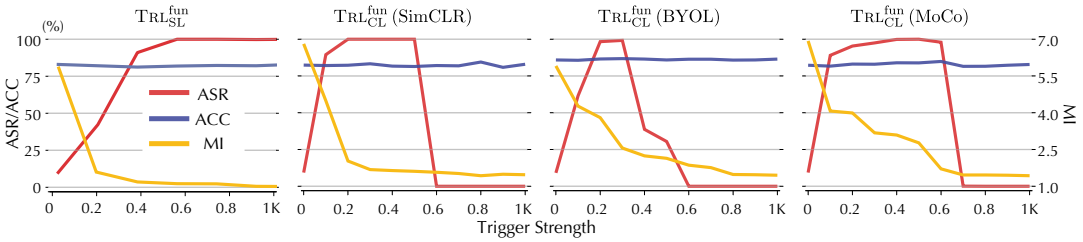

Figure 6: ASR, ACC, and MI of different attacks with respect to the trigger strength (measured by the magnitude of spectral perturbation).

5.3 Contrastive Backdoor Attacks

Meanwhile, under the contrastive setting, the backdoor attack is implemented as the following objective function:

$$\min_{\theta} \mathcal{L}_{\text{ctr}}(\theta) + \lambda \mathcal{L}^{\star}_{\text{ctr}}(\theta) \tag{9}$$

where $\mathcal{L}_{\text{ctr}}$ and $\mathcal{L}^{\star}_{\text{ctr}}$ are the contrastive loss defined in Eqn (1), measured on $\mathcal{D}$ and $\mathcal{D}_{\star}$ respectively. Because there are no labels, contrastive attacks manipulate the distributions of poisoning and target-class data in the feature space. To do so, the model must learn both trigger and semantic features from the poisoning data, so that the semantic features intertwine poisoning data with target-class data, while the trigger features connect all poisoning data.

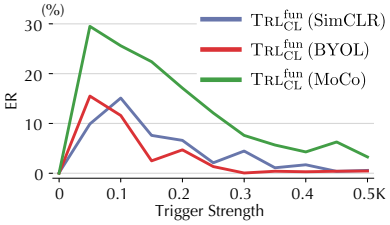

Figure 7: Entanglement effect with respect to trigger strength.

To confirm our analysis, we assess the impact of trigger strength on the ASR, ACC, and MI of contrastive backdoor attacks, with results shown in Figure 6. Across all the CL methods, as the trigger strength varies from 0 to 1K, the ASR of TRL$^{fun}_{CL}$ first increases to 100% and then drops quickly, while its MI gradually decreases during the process. The finding suggests that the optimal attack is attained only if the semantic features are partially retained in the representations of poisoning data. This can be explained by the fact that if the trigger features are insignificant, the semantic features dominate the poisoning data, resulting in weak connections among poisoning data; meanwhile, if the trigger features dominate the poisoning data, the weak semantic features negatively impact the entanglement between poisoning and target-class data. To validate this explanation, we further measure the entanglement between poisoning and target-class data under varying trigger strength. As shown in Figure 7, the entanglement ratio is not a monotonic function of the trigger strength but follows a similar trend as the ASRs in Figure 6. We can thus conclude:

Remark 5 – In contrastive backdoor attacks, the learning of benign and backdoor tasks is intertwined in the poisoning data.

This interdependence between benign and backdoor tasks in contrastive backdoor attacks easily explains the empirical observations in § 4. In terms of learning dynamics, because the model learns both benign and backdoor tasks (the latter is simpler than the former) from poisoning data, the contrastive loss of poisoning data tends to decrease at a rate similar to clean data. In terms of feature distributions, as the model extracts both trigger and semantic features from poisoning data, it naturally intertwines poisoning and target-class data in the feature space.

6 Defense Implications

We now explore the implications of the unique characteristics of contrastive attacks from a defense perspective.

6.1 Learning Dynamics-Based Defenses

We first examine defenses premised on the difference between the learning dynamics of benign and backdoor tasks.

Anti-Backdoor Learning (ABL) [28] is a filtering defense that segregates poisoning data and unlearns backdoored models. Intuitively, as the backdoor task is simpler than the benign task, assuming the loss of poisoning data drops quickly in early training epochs while the loss of clean data decreases at a steady pace, ABL detects poisoning data and unlearns the backdoored model by applying gradient descent on the clean data and gradient ascent on the detected poisoning data.

Despite its effectiveness against supervised attacks, it is challenging to extend ABL to CL because the learning dynamics of poisoning data in contrastive attacks are much less distinctive (cf. § 4.2). We empirically validate this by applying ABL in detecting the poisoning data of TRL$^{fun}_{SL}$ and TRL$^{fun}_{CL}$ under the same setting as in § 4.1. We follow the hyper-parameter setting in [28]. Specifically, if the loss of any training input goes below a threshold $\gamma = 0.5$, we activate gradient ascent to boost its loss to γ. In the CL setting, we set γ according to a fixed ratio compared to the largest loss drop: $(\gamma - \ell_{\text{final}})/(\ell_{\text{init}} - \ell_{\text{final}})$, where ℓ_{init} and ℓ_{final} respectively denote the loss of the training input before and after training. Table 3 reports ABL's performance under the poisoning rate fixed as 1%. The false positive rate (FPR) measures the fraction of clean inputs falsely detected as poisoning, the true positive rate (TPR) measures the fraction of poisoning inputs correctly identified, and the isolation rate denotes the

percentage of samples isolated by ABL. A lower FPR or a higher TPR indicates more accurate detection.

Isolation Rate	$\text{TRL}_{\text{CL}}^{\text{fun}}$		$\text{TRL}_{\text{SL}}^{\text{fun}}$	
	TPR	FPR	TPR	FPR
1%	2.4%	0.99%	92.8%	0.07%
5%	39.6%	4.8%	99.4%	4.1%
10%	56.0%	9.5%	99.8%	9.1%
20%	63.6%	19.6%	99.8%	19.2%

Table 3. ABL against $\text{TRL}_{\text{SL}}^{\text{fun}}$ and $\text{TRL}_{\text{CL}}^{\text{fun}}$ on CIFAR10.

Observe that ABL effectively detects the poisoning data of $\text{TRL}_{\text{SL}}^{\text{fun}}$ but is much less effective against $\text{TRL}_{\text{CL}}^{\text{fun}}$. For example, with 1% isolation rate, ABL detects 92.8% of the poisoning data of $\text{TRL}_{\text{SL}}^{\text{fun}}$, which drops to 2.4% against $\text{TRL}_{\text{CL}}^{\text{fun}}$. The increase of TPR against $\text{TRL}_{\text{CL}}^{\text{fun}}$ with the isolation rate is mainly attributed to the low poisoning rate (1%). We thus conclude that ABL is ineffective against contrastive attacks, which confirms the observations in § 4.2. This is due to the intertwined learning dynamics of both benign and backdoor tasks. We defer the evaluation of ABL against $\text{TRL}_{\text{SL/CL}}^{\text{uni}}$ to § C.2.

6.2 Feature Distribution-Based Defenses

The entanglement between the representations of poisoning and clean data also causes challenges for defenses that rely on the separability of poisoning data in the feature space.

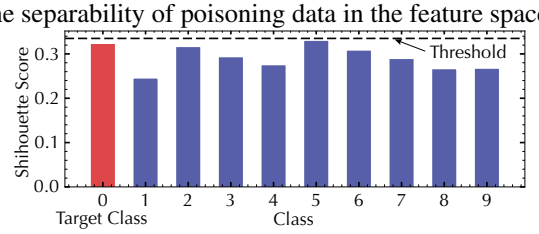

Figure 8: AC against $\text{TRL}_{\text{CL}}^{\text{fun}}$ (SimCLR) on CIFAR10.

Activation clustering (AC) [31] is a data inspection method. It trains the model using the potentially poisoning data and collects the penultimate-layer activation of each input. AC assumes the poisoning data in the target class forms a separate cluster that is either small or far from the class center. It identifies the target class by calculating the silhouette score of each class, with a higher score indicating a stronger fit to two clusters. Additionally, since the attacker is assumed to be unable to poison more than half of the data, the smaller cluster is considered to be the poisoning data. Assuming the data labels are available, we evaluate the effectiveness of AC against both supervised and contrastive attacks. We set the hyper-parameters according to the original paper.

Figure 8 shows that AC fails to identify the target class (class 0), which has a lower score compared to other classes (e.g., class 5), not to mention detecting the poisoning data. This may be attributed to the tight entanglement between the representations of poisoning and clean data.

Statistical contamination analyzer (SCAn) [33] detects poisoning data based on the statistical properties of its representations. Specifically, it applies an EM algorithm to decompose an input into two terms: identity and variance; it then analyzes the representations in each class and identifies the target class most likely to be characterized by a mixture model. To evaluate SCAn against contrastive attacks, following [33], we use 1,000 inputs randomly sampled from the testing set to build the decomposition model, which we apply to analyze 5,000 poisoning and 5,000 clean inputs. For comparison, we also evaluate SCAn against the supervised attack $\text{TRL}_{\text{SL}}^{\text{fun/uni}}$. Similar to STRIP [38], we vary the FPR under three different FPR settings: 0.5%, 1.0%, and 2.0%, and evaluate the TPR.

FPR	TPR			
	$\text{TRL}_{\text{CL}}^{\text{fun}}$	$\text{TRL}_{\text{SL}}^{\text{fun}}$	$\text{TRL}_{\text{CL}}^{\text{uni}}$	$\text{TRL}_{\text{SL}}^{\text{uni}}$
0.5%	28.0%	63.0%	28.4%	51.5%
1.0%	28.0%	66.5%	63.3%	71.8%
2.0%	28.0%	68.0%	76.7%	85.5%

Table 4. SCAn against $\text{TRL}_{\text{CL}}^{\text{fun}}$ (SimCLR) and $\text{TRL}_{\text{SL}}^{\text{fun}}$ on CIFAR10.

As shown in Table 4, compared with the supervised attack, SCAn is much less effective, especially for $\text{TRL}_{\text{CL}}^{\text{fun}}$. For instance, SCAn detects over 63.0% of the poisoning data of $\text{TRL}_{\text{SL}}^{\text{fun}}$, which drops to 28.0% against $\text{TRL}_{\text{CL}}^{\text{fun}}$. This can be attributed to the entanglement between the representations of poisoning and clean data, while SCAn relies on the separability of poisoning data in the feature space.

Fine-pruning (FP) [39] assumes poisoning and clean data activate different neurons and sanitizes backdoored models by pruning neurons that are dormant with respect to clean data. Specifically, it measures the average activation of each neuron with respect to clean data from a validation set and prunes the set of least active neurons. Following [39], we apply FP on the penultimate layer of the backdoored model. In [39], it keeps pruning the model until the tolerance of accuracy (5%) reduction is reached. For a more detailed analysis, we show the ASR and ACC with respect to the variation of the pruned channels from 0 to 500.

Figure 9 shows the ASR and ACC of each attack as a function of the pruning rate of FP. Observe that FP effectively defends against supervised attacks. By pruning about 240 neurons, the ASR of $\text{TRL}_{\text{SL}}^{\text{fun}}$ is reduced to zero while incurring an acceptable ACC drop. Meanwhile, the ASR and ACC of contrastive attacks decrease at a similar pace. To attain effective defenses, it is necessary to prune almost all the neurons. This further suggests the tight entanglement between poisoning and clean data in the feature space.

Remark 6 – The unique characteristics of contrastive backdoor attacks render defenses based on learning dynamics and feature distributions ineffective.

6.3 Downstream Defenses

Thus far, we have demonstrated the challenges of defending against contrastive backdoor attacks based on either learning dynamics or feature distributions. Next, we consider a more diverse set of defenses applied to the end-to-end model $h =$

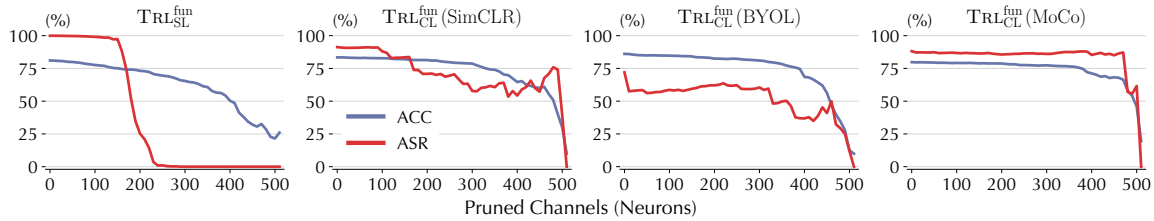

Figure 9: FP against TRL$^{fun}_{CL}$ and TRL$^{fun}_{SL}$ on CIFAR10.

	TRL$^{fun}_{CL}$	TRL$^{fun}_{SL}$	TRL$^{uni}_{CL}$	TRL$^{uni}_{SL}$
Anomaly Index	0.72 ± 0.38	1.47 ± 0.54	1.09 ± 0.49	4.57 ± 1.28

Table 5. Effectiveness of NC on CIFAR10.

Detection Threshold	FPR	TPR
0.56	0.5%	0.5%
0.65	1.0%	1.1%
0.75	2.0%	2.0%

Table 6. STRIP against TRL$^{fun}_{CL}$ (SimCLR) on CIFAR10.

$g \circ f$ that comprises the backdoored encoder f and a classifier g in the downstream task.

NeuralCleanse (NC) [40] is a model inspection method to detect backdoors. Specifically, for each class, NC reverse-engineers the "minimal" trigger (measured by the L_1-norm of its binary mask) required to misclassify clean inputs from all other classes into this class. It then runs outlier detection and marks any class with a trigger significantly smaller than the other classes as an outlier and infected. We evaluate NC's efficacy in both supervised and contrastive learning. In the contrastive setting, an end-to-end model, in which the encoder trained by TRL$^{fun}_{CL}$ or TRL$^{uni}_{CL}$ using SimCLR, is fine-tuned using clean data. In the supervised setting, the model is directly trained by TRL$^{fun}_{SL}$ or TRL$^{uni}_{SL}$.

As shown in Table 5, NC failed to detect any backdoors in the contrastive setting. For example, for TRL$^{fun}_{CL}$, the anomaly index of the target class varies around 0.72, much lower than the detection threshold of 2. This is attributed to the presence of functional triggers and aggressive data augmentation methods, which make it challenging for NC to reverse-engineer a stable trigger. In contrast, NC successfully detects backdoors against supervised attacks, especially TRL$^{uni}_{SL}$.

STRIP [38] is an inference-time data inspection method. Specifically, it assumes that the prediction of poisoning data is insensitive to perturbation due to the dominance of trigger features, whereas the prediction of clean data may vary greatly with perturbation. For an incoming input, STRIP intentionally perturbs it (e.g., superimposing various image patterns) and utilizes the randomness of its prediction to determine whether it is triggered. As it is a run-time detection method, we use an end-to-end model (consisting of the backdoored encoder and downstream classifier) to evaluate its effectiveness. Following [38], we first estimate the entropy distribution of clean inputs on a validation set, select an entropy detection threshold with a given FPR (0.5%, 1.0%, and 2.0%), and remove all training inputs with entropy below this threshold.

As shown in Table 6, STRIP is ineffective in detecting the

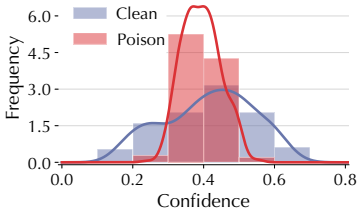

Figure 10: Distributions of the prediction confidence of poisoning and clean data.

poisoning data of TRL$^{fun}_{CL}$. For instance, with FRR fixed as 1.0%, the TPR of STRIP is as low as 1.1%, suggesting that STRIP fails to distinguish poisoning and clean data. This may also be explained by the entanglement effect: as the poisoning and clean data share similar representations, the perturbation to them leads to similar measures. The results on TRL$^{uni}_{CL/SL}$ are deferred to § C.3.

Backdoor defense via decoupling (BDD) [41] is designed to mitigate the impact of poisoning inputs that tend to cluster together in the feature space of compromised DNNs. This approach consists of three stages: (1) the backbone is trained in a self-supervised manner, which aligns inputs with the same ground-truth label in the feature space; (2) the remaining classifier is trained in a standard manner, using all labeled training inputs; and (3) low-confidence inputs are removed based on the end-to-end model.

Clearly, (1) and (2) share the same settings as the threat model of TRL. Thus, we focus on (3) to evaluate the effectiveness of BDD. The distributions of the classification confidence of poisoning and clean (from the target class) inputs are shown in Figure 10. Note that poisoning inputs not only have similar classification confidence as clean inputs but also exhibit lower variance. This makes it more challenging to establish a confidence threshold to distinguish between them. Consequently, using BDD mechanisms to defend against TRL tends to be ineffective.

Fine-tuning [42] is a method to adapt a pre-trained encoder to a specific downstream task by fine-tuning a classifier. Prior work [42] shows that fine-tuning may mitigate backdoor attacks to a certain extent. In the previous evaluation, following [14], we focus on scenarios where the downstream and pre-training datasets are identical. Here, we explore cases in which these datasets differ, such as pre-training the encoder on CIFAR10 and fine-tuning the classifier on CIFAR100. Since the datasets may have varied class structures, we focus on untargeted attacks and measure the attack effectiveness by the

model's accuracy drop in classifying trigger inputs compared to clean inputs.

Table 7 summarizes the results. Observe that the contrastive backdoor attack substantially affects the model's performance, regardless of the setting of pre-training and downstream datasets. For instance, when the encoder is pre-trained on CIFAR100 using SimCLR and then adapted to CIFAR10, the model achieves 53.3% accuracy and 18.1% accuracy (i.e., 35.2% accuracy drop) on clean and trigger inputs, respectively. This observation indicates that fine-tuning using downstream datasets may not mitigate contrastive backdoor attacks. Additionally, we observe that most trigger inputs are misclassified into a single incorrect class. We speculate that these trigger inputs are clustered together and located close to a specific class in the feature space, which is also close to the target class in the pre-training dataset.

Pre-training / Downstream Dataset	Method	ACC (Clean)	ACC Drop (Poisoning)
CIFAR10 / CIFAR100	Supervised	15.1%	7.9%
	SimCLR	30.1%	26.2%
	BYOL	32.1%	23.4%
	MoCo	28.3%	23.6%
CIFAR100 / CIFAR10	Supervised	46.7%	32.4%
	SimCLR	53.3%	35.2%
	BYOL	60.7%	44.3%
	MoCo	55.7%	41.4%

Table 7. Performance of fine-tuning on $\text{TRL}_{\text{CL}}^{\text{fun}}$.

Remark 7 – The existing defenses are not easily retrofitted to defend against contrastive backdoor attacks in the setting of downstream tasks.

7 Discussion

Thus far, we uncover the fundamental differences between supervised and contrastive backdoor attacks, propose possible explanations, and reveal the important implications entailed by such differences from a defense perspective. Next, we further explore a few key questions: (i) are our findings impacted by other factors (e.g., model architectures and trigger definitions)? (ii) given the inadequacy of existing defenses, are there any promising alternatives? (iii) what are the limitations of this work?

7.1 Other Factors

We explore whether our findings are influenced by other factors, including model architectures and trigger definitions.

Model Architectures – To evaluate the influence of backbone model architectures, besides ResNet18, we also consider three other popular DNN architectures (inlcuding ResNet50 [27], ShuffleNet [43], and MobileNet [44]) and train a SimCLR encoder on CIFAR10 as outlined in § 4.

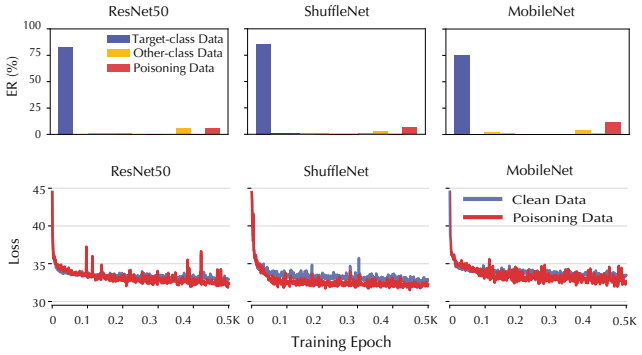

Figure 11: Learning dynamics and entanglement ratio under different backbone architectures.

Figure 11 shows the learning dynamics and entanglement ratio under varying backbone architectures. Our results indicate that: (i) the loss-decreasing pace is comparable for both poisoning and clean inputs across different architectures, and (ii) the poisoning inputs and the clean target-class inputs are entangled in the feature space under all the settings. The findings suggest that the backbone architectures have a limited impact on contrastive backdoor attacks.

Alternative triggers – In the previous evaluation, for contrastive attacks, we primarily focus on the functional trigger $\text{TRL}_{\text{CL}}^{\text{fun}}$. Here, we investigate whether the trigger definition impacts our findings. Specifically, we consider the universal trigger $\text{TRL}_{\text{CL}}^{\text{uni}}$ as an alternative trigger definition. Following [14], we specify a 5×5 image patch as the trigger pattern, which is randomly placed at a random location of a given input.

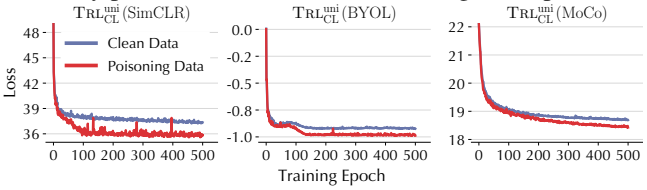

Figure 12: Learning dynamics of $\text{TRL}_{\text{CL}}^{\text{uni}}$.

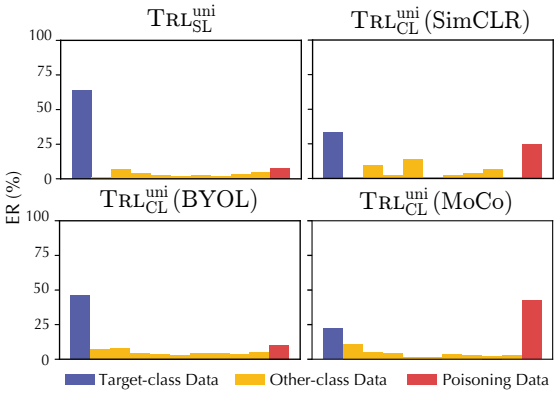

Figure 13: Entanglement ratios of $\text{TRL}_{\text{SL/CL}}^{\text{uni}}$ on CIFAR10.

Figure 12 shows the learning dyanmics of $\text{TRL}_{\text{CL}}^{\text{uni}}$. Similar to $\text{TRL}_{\text{CL}}^{\text{fun}}$ (cf. Figure 2), $\text{TRL}_{\text{CL}}^{\text{uni}}$ also exhibits distinct learning dynamics compared with supervised attacks. Specifically, the contrastive loss of both poisoning and clean data decreases

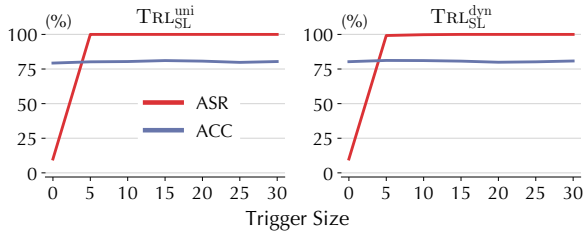

Figure 14: Attack performance of $\text{TRL}_{\text{SL}}^{\text{uni}}$ and $\text{TRL}_{\text{SL}}^{\text{dyn}}$ with respect to trigger strength (image patch size).

CL Method	Trigger Size				
	1	5	10	15	20
SimCLR	9.8%	57.0%	0.1%	0.0	0.0
BYOL	10.7%	34.6%	65.6%	2.01%	0.3%
MoCo	9.7%	45.6%	64.3%	18.1%	0.8%

Table 8. Attack effectiveness of $\text{TRL}_{\text{CL}}^{\text{uni}}$ with respect to trigger size.

gradually at fairly similar paces. Further, Figure 13 evaluates the entanglement ratios of $\text{TRL}_{\text{SL/CL}}^{\text{uni}}$. Observe that similar to Figure 4, the entanglement effect is also more evident in the contrastive setting. Thus, the difference in entanglement effect is rather trigger-agnostic but stems from the underlying learning paradigms.

Further, we conduct experiments to examine the influence of trigger strength (measured by the image patch size) on the effectiveness of supervised and contrastive attacks. Figure 14 shows the ASR and ACC of $\text{TRL}_{\text{SL}}^{\text{uni}}$ and $\text{TRL}_{\text{SL}}^{\text{dyn}}$ as a function of trigger strength, which complements the results of Figure 6. Observe that in both cases of universal and dynamic triggers, as the trigger strength increases, the ASR of supervised attacks quickly peaks and remains around 100%; meanwhile, the trigger strength has little impact on the ACC, indicating the independence of backdoor and benign tasks at the data level for supervised attacks.

In contrast, as shown in Table 8, across different CL methods, as the trigger size increases from 1 to 20, the effectiveness of $\text{TRL}_{\text{CL}}^{\text{uni}}$ initially increases and then decreases abruptly, similar to the trend observed about $\text{TRL}_{\text{CL}}^{\text{fun}}$ in Figure 6.

Remark 8 – The unique characteristics of contrastive backdoor attacks are agnostic to the concrete trigger definitions and backbone architectures.

7.2 Potential Defenses

We demonstrate that due to the specificities of contrastive backdoor attacks, defenses that attempt to segregate poisoning data based on learning dynamics and feature separability tend to fail. Given such limitations, we explore alternative defense strategies and discuss their potential challenges to defend against contrastive attacks.

Density-based Filtering – We have an interesting observation in our evaluation: the trigger inputs tend to form a cluster in the feature space, which is often much denser than the clusters formed by clean inputs. For example, we use a SimCLR model trained on CIFAR10 and measure the average pairwise

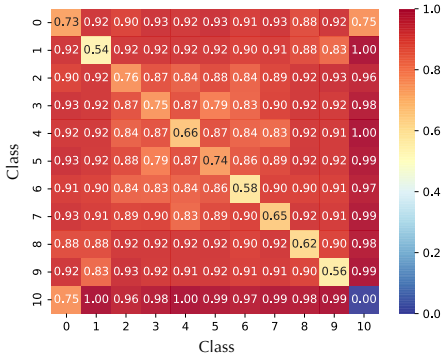

Figure 15: Average normalized pair-wise L_2 distance on CIFAR10 (trigger inputs: class 10; clean inputs: class 0 - 9). Diagonal cells represent intra-class distance while off-diagonal cells represent inter-class distance.

L_2 distance between inputs in the feature space. Figure 15 shows the normalized intra-class and inter-class distance. Observe that trigger inputs (class 10, with normalized distance 0.0) tend to cluster much more tightly compared with clean inputs (class 0 - 9, with normalized distance ≥ 0.56).

Motivated by this observation, we propose a density-based filtering defense. After training the encoder on potentially poisoning data, we use it to generate features for all inputs. Next, we apply a density-based clustering method (e.g., OPTICS [45] or DBSCAN [46]) to cluster the training inputs based on their features. The densest clusters are identified as potentially poisoning data and subsequently removed from the training data.

Below we evaluate this approach in defending against $\text{TRL}_{\text{CL}}^{\text{fun}}$ (SimCLR) on CIFAR10 under two distinct poisoning rates: 1% and 5%. Specifically, we employ DBSCAN as the clustering algorithm to sift out poisoning inputs. DBSCAN hinges on two key parameters: (i) Minimum samples N_{min}, which is the minimum number of inputs required to form a cluster. Intuitively, a larger N_{min} results in denser clusters. Given that the number of poisoning inputs is typically small, we set N_{min} to either 30 or 100 in the evaluation. (ii) Maximum distance ε, which thresholds the distance between two inputs to determine whether they belong to the same cluster. To determine ε, we calculate the average distance between each input and its $K = N_{\text{min}}$ nearest neighbors, plot the average K-distances in ascending order on a K-distance graph (as shown in Figure 16), and set ε as the point of maximum curvature, where the graph has the largest decreasing rate. We set $\varepsilon = 0.3$ in the evaluation.

Table 9 summarizes the effectiveness of this density-based filtering measured by true positive rate (TPR) and false positive rate (FPR), as well as the attack success rate (ASR) and clean accuracy (ACC) of the model trained on the post-filtering training data. Notably, density-based filtering effectively sifts out a majority of poisoning inputs across various settings. For instance, under the setting of 5% poisoning rate, $\varepsilon = 0.3$, and $N_{\text{min}} = 30$, it successfully filters 98.8% of the poisoning inputs. Further, observe that after filtering potentially

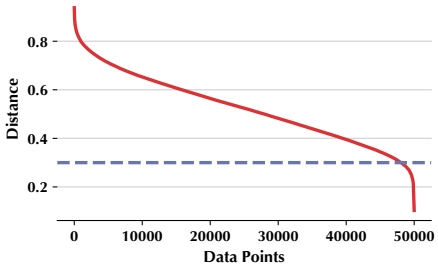

Figure 16: K-distance graph

Parameter		Poisoning Rate	Filtering		Re-training	
ε	$N_{\min}$		TPR	FPR	ASR	ACC
0.3	30	1%	96.6%	10.2%	13.3%	80.1%
	100		80.1%	0.4%	43.8%	81.8%
	30	5%	98.8%	9.8%	19.9%	77.8%
	100		97.8%	0.4%	59.8%	78.1%

Table 9. Effectiveness of density-based filtering defense.

poisoning data and retraining the model, we may not only effectively mitigate the attack but also retain the model's utility. For instance, it achieves 13.3% ASR and 80.1% ACC under 1% poisoning rate and $N_{\min} = 30$. However, the effectiveness of re-training seems sensitive to the parameter setting. For instance, under 1% poisoning rate and $N_{\min} = 100$, as it fails to filter out approximately 100 poisoning inputs, the attack is not mitigated effectively.

We further evaluate the effectiveness of density-based filtering with OPTICS as the underlying clustering algorithm, which is less sensitive to the parameter setting. It achieves an impressive 99.6% TPR and 0% FPR under 1% poisoning rate. However, it has a much larger execution overhead. For example, on our platform, OPTICS requires 1.5 hours to complete the filtering, whereas DBSCAN finishes in approximately 10 seconds. Thus, we consider enhancing both the effectiveness and efficiency of density-based filtering defense as our ongoing work.

Data-free pruning – In addition to filtering potentially poisoning data, we also explore in-depth defenses for scenarios where filtering proves ineffective. We have shown that data-dependent pruning [39] is insufficient to mitigate contrastive backdoor attacks, due to the indistinguishable feature patterns of clean and poisoning data (§ 6.2). Surprisingly, data-free pruning, which is believed to be less effective than data-dependent pruning, shows promising performance against contrastive backdoor attacks.

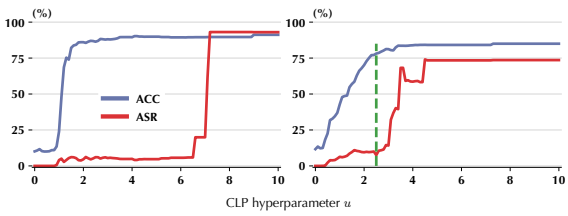

Figure 17: CLP against $\text{TRL}_{\text{SL}}^{\text{fun}}$ and $\text{TRL}_{\text{CL}}^{\text{fun}}$ on CIFAR10.

Specifically, we consider channel Lipschitzness-based pruning (CLP) [47], a data-free defense to remove backdoors. It exploits the observation that a subset of channels is more sensitive to trigger features compared to other channels, while the sensitivity of each channel can be estimated by the upper bound of its channel Lipschitz constant (UCLC), which can be computed in a data-free manner. Thus, given the mean (μ_k) and variance (σ_k) of the UCLCs in the k-th convolutional layer, CLP prunes channels with UCLCs larger than $\mu_k + u\sigma_k$, where u is a hyper-parameter.

We apply CLP on models backdoored by $\text{TRL}_{\text{SL}}^{\text{fun}}$ and $\text{TRL}_{\text{CL}}^{\text{fun}}$ with varying u. As shown in Figure 17, by properly setting u, it is possible to effectively reduce the ASR of $\text{TRL}_{\text{CL}}^{\text{fun}}$ with limited ACC drop (about 5%). However, compared with $\text{TRL}_{\text{SL}}^{\text{fun}}$, the proper range of u for $\text{TRL}_{\text{CL}}^{\text{fun}}$ is much narrower ([2.2, 3.0] versus [1.8, 6.5]). To address this challenge, we propose to empirically set u as the knee point of the ACC curve. Specifically, we measure the ACC under varying u, apply the Savitzky–Golay filter to smooth the curve [48], and identify the knee point of the smoothed curve as the optimal u during pruning. By applying this approach, we identify the optimal u as 2.4 in the contrastive setting, as indicated by the green dashed line in Figure 17, which well balances utility and defensive efficacy (80.4% ACC and 14.3% ASR).

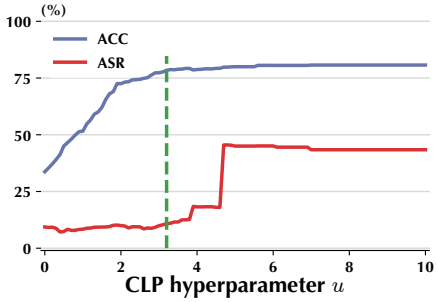

Figure 18: CLP against the retrained model

Ensemble defenses – We further combine the previous two defenses to form a powerful ensemble defense against contrastive backdoor attacks. Specifically, we first apply density-based filtering to filter potentially poisoning data, retrain the model on the post-filtering training data, and then apply data-free pruning on the retrained model. We simulate the setting that the filtering hyperparameter is not properly set (e.g., $N_{\min} = 100$ under 1% poisoning rate), which results in a retrained model with 43.8% ASR and 81.8% ACC. By applying data-free pruning on this retrained model, as illustrated in Figure 18, we further reduce ASR to 12.6% while retaining ACC around 79.6%. We believe this ensemble defense represents a promising direction worthy of further research.

7.3 Limitations and Future Work

We further discuss the limitations of this work and point to several future directions. (i) **Key properties:** our study primarily focuses on the differences between supervised and

contrastive backdoor attacks, as reflected in learning dynamics and feature distributions. Other properties (e.g., neuron activation patterns) might also vary across these attack types. Future research could explore these underexplored properties to develop more effective defenses. (ii) **Alternative defenses:** our study highlights the defense implications of key differences between supervised and contrastive backdoor attacks. We illustrate the challenges faced by several representative defenses against contrastive backdoor attacks. Comprehensively investigating and benchmarking all the SOTA defenses (e.g., [49, 50]) against contrastive backdoor attacks is a valuable avenue for future research. (iii) **Data modality:** while our study mainly focuses on the vision domain, contrastive learning has been extended to other domains such as natural language processing and multimodal learning [51, 52]. It is worth investigating how domain constraints (e.g., discrete perturbation, semantic preservation, and interference between different modalities) affect contrastive backdoor attacks and their potential implications. (iv) **Generalization to self-supervised learning (SSL):** while focusing on contrastive learning methods, our findings might extend to the wider SSL paradigm (e.g., masked autoencoder [53]). It is essential, however, to validate these implications across broader contexts. Future work should explore the applicability and adaptability of our insights to alternative SSL frameworks and examine the implications for defenses in these new settings.

In summary, while limited in several aspects, this work represents a solid step towards understanding and defending against the emerging threat of backdoor attacks in contrastive learning. Our findings highlight the need for defenses tailored to the specificities of contrastive backdoor attacks.

8 Additional Related work

In addition to the aforementioned related work, we further survey the literature most relevant to this work.

Contrastive learning – Recent years have witnessed the striding advances of contrastive learning (CL) [1, 2, 4]. Compared with supervised learning (SL), CL obviates the reliance on data labeling and still learns high-quality representations from complex data, thereby facilitating various downstream tasks. Meanware, the popularity of CL also spurs intensive research on its security properties. Existing work explores the adversarial robustness of CL [54, 55]. It is shown that, as a nice side effect, obviating the reliance on data labeling may benefit the model's robustness to adversarial examples, label corruption, and common data corruptions [56]. However, whether this robustness benefit also generalizes to other types of attacks remains an open question.

Supervised Contrastive learning – Supervised contrastive learning (Sup-CL) [57] introduces label information in the contrastive learning framework. By aligning latent representations with task-specific class semantics, Sup-CL enhances the quality of learned representations. Recent work [58, 59] applies Sup-CL in malware analysis and attains notable performance gains. Compared with Sup-CL, CL operates without explicit labels, relying on data augmentations to form and discern positive and negative pairs in an unsupervised manner. Despite the differences, the attacks in this work can be easily adapted to binary classification (e.g., malware analysis) under both CL and Sup-CL settings. Specifically, by injecting the trigger pattern into a small number of goodware samples during training, both self-supervised and full-supervised variants of CL may inadvertently associate this pattern with goodware, as they seek to minimize the distance between similar entities in the latent space. At inference time, any malware with this pattern may be misclassified as goodware. We consider comparing the attacks under CL and Sup-CL settings in practical settings (e.g., malware analysis) as our ongoing work.

Backdoor attacks – As a major threat to machine learning security, backdoor attacks inject malicious backdoors into the victim's model during training and activate such backdoors at inference. Many backdoor attacks have been proposed for SL, which can be categorized along (i) attack targets – input-specific [60], class-specific [33] or any-input [9], (ii) attack vectors – polluting training data [12] or releasing backdoored models [61], and (iii) optimization metrics – attack effectiveness [11], transferability [13], or attack evasiveness [60, 62–64].

Backdoor attacks are of particular interest for CL, potentially causing widespread damage due to their extensive application in downstream tasks. Supervised backdoor attacks, dependent on data labeling, are often inapplicable to CL, prompting innovative new approaches. For instance, BadEncoder [19] injects backdoors into pre-trained encoders and releases backdoored models to victims, while SSLBackdoor [14] uses image patch triggers to poison data; PoisonedEncoder [16] poisons the training data by randomly combining target inputs with reference inputs. Recently, CTRL [15] utilizes spectral triggers, achieving attack performance comparable to supervised attacks.

Yet, despite numerous studies on supervised and contrastive backdoor attacks, their fundamental differences remain unexplored. This work bridges this gap by revealing the distinctive mechanisms behind these attacks.

Backdoor defenses – To mitigate the threats of backdoor attacks, many defenses have been proposed, which can be categorized according to their strategies [65]: (i) input filtering, which purges poisoning examples from training data [31, 66]; (ii) model inspection, which determines whether a given model is backdoored and, if so, recovers the target class and the potential trigger [40, 67–69]; and (iii) input inspection, which detects trigger inputs at inference time [33, 38, 70, 71].

However, mainly designed for supervised backdoor attacks, the effectiveness of these defenses in the CL setting remains unclear, raising several critical questions: can the existing defenses be retrofitted to CL attacks? If not, what new challenges

do these attacks entail? How can we address such challenges? This work systematically explores these key questions.

9 Conclusion

In this study, we examine the fundamental distinctions between supervised and contrastive backdoor attacks. Using a unified attack framework, we uncover that these attacks operate through different mechanisms, resulting in distinct learning dynamics and feature distributions. More importantly, we show that the unique characteristics of contrastive backdoor attacks entail important implications, requiring new and tailored defenses. Our findings shed new light on developing more robust contrastive learning techniques and point to several promising directions for further research.

B Implementation Details

B.1 Different Variants of TRL

We elaborate on the implementation of different variants of TRL.

$\text{TRL}_{\text{CL}}^{\text{fun}}$ [15] – The SelectCandidate function samples candidates from a specified class. The ApplyTrigger function modifies the input image by converting it from RGB to YCbCr format, dividing it into blocks (e.g., 32×32), and applying the discrete cosine transform (DCT) to shift from the spatial to the frequency domain. It then increases the magnitude of selected high-frequency bands by 50, reverses the DCT to return to the spatial domain, and finally converts the image back from YCbCr to RGB.

$\text{TRL}_{\text{CL}}^{\text{uni}}$ [14] – SelectCandidate samples candidates from the target class. ApplyTrigger follows [14]: it first generates a random 5×5 image patch as the trigger and then applies it to a randomly selected position of the given candidate input.

$\text{TRL}^{\text{fun}}_{\text{SL}}$ [15] – SelectCandidate samples candidates from the target class. ApplyTrigger is the same as $\text{TRL}^{\text{fun}}_{\text{CL}}$. In addition, the labels of all the candidate inputs are set as the target class.

$\text{TRL}^{\text{uni}}_{\text{SL}}$ [9, 12] – SelectCandidate samples candidates from the target class. ApplyTrigger generates a 5×5 image patch as the trigger and applies it to a random position of the given candidate. In addition, the labels of all the candidates are set as the target class. For a fair comparison, we let $\text{TRL}^{\text{uni}}_{\text{SL}}$ and $\text{TRL}^{\text{uni}}_{\text{CL}}$ share the same poisoning data.

$\text{TRL}^{\text{dyn}}_{\text{SL}}$ [24] – SelectCandidate samples candidates across all the classes. ApplyTrigger generates input-specific triggers using a generative model G. Specifically, the training process runs in three modes: i) with probability $\rho_a \in (0,1)$, it runs in the "backdoor" mode in which G produces a trigger $G(x)$ and applied it to given input x, while its label is perturbed to the target class; ii) with probability $\rho_b \in (0,1)$, it runs in the "cross-trigger" mode, in which G produces the trigger $G(x)$ and applies it to a different input x', while its original label is preserved; iii) with probability $1-\rho_a-\rho_b$, it runs in the "clean" mode, in which x is used as a clean input.

B.2 Defense Details

We detail the implementation of various defenses in our evaluation.

ABL [28] – We follow the settings in their original paper. Specifically, we set the loss threshold $\gamma = 0.5$. If the loss of a training example goes below γ, gradient ascent will be activated to boost its loss to γ; otherwise, the loss stays the same. In the contrastive learning setting, we set the threshold γ according to the same ratio compared to the largest loss.

AC [31] – We set the hyper-parameters as the original paper.

STRIP [38] – In the original paper, it estimates the entropy distribution of clean samples on a validation set, selects an entropy threshold with a given FPR, and eventually removes all training samples with entropy below this threshold. In our work, we measure its effectiveness under three FPR settings: 0.5%, 1.0%, and 2.0%.

SCAn [33] – Similar to STRIP [38], we vary the FPR under three settings: 0.5%, 1.0%, and 2.0%, and evaluate the TPR.

FP [39] – In the original paper, it keeps pruning the model until the tolerance of accuracy (5%) reduction is reached. In our work, for a more detailed analysis, we show the ASR and ACC with respect to the variation of the pruned channels from 0 to 500.

C Additional Experiments

C.1 Attack effectiveness of $\text{TRL}^{\text{fun}}_{\text{CL}}$

In § 7.1, we evaluate the universal trigger $\text{TRL}^{\text{uni}}_{\text{CL}}$ as an alternative trigger definition. Following [14], we specify a 5×5 image patch as the trigger pattern, which is randomly placed at a random location of a given sample. Table 12 shows the clean accuracy and the corresponding attack success rate.

Dataset		Attack		
		$\text{TRL}^{\text{fun}}_{\text{CL}}$		
		SimCLR	BYOL	MoCo
CIFAR10	ASR (%)	33.2	49.2	53.1
	ACC (%)	79.4	84.3	80.6

Table 12. Clean accuracy and attack success rate of $\text{TRL}^{\text{fun}}_{\text{CL}}$.

C.2 ABL against $\text{TRL}^{\text{uni}}_{\text{SL}}$ and $\text{TRL}^{\text{uni}}_{\text{CL}}$

Table 13 shows the effectiveness of ABL against $\text{TRL}^{\text{uni}}_{\text{SL}}$ and $\text{TRL}^{\text{uni}}_{\text{CL}}$. Observe that ABL is much less effective in the contrastive setting compared to the supervised setting.

Isolation Rate	$\text{TRL}^{\text{uni}}_{\text{CL}}$		$\text{TRL}^{\text{uni}}_{\text{SL}}$	
	TPR	FPR	TPR	FPR
1%	0.8%	1.0%	93.6%	0.06%
5%	24.3%	4.8%	99.6%	4.0%
10%	32.2%	9.8%	99.8%	9.1%
20%	43.6%	19.7%	99.8%	19.2%

Table 13. ABL against $\text{TRL}^{\text{uni}}_{\text{SL}}$ and $\text{TRL}^{\text{uni}}_{\text{CL}}$ on CIFAR10.

C.3 STRIP against $\text{TRL}^{\text{uni}}_{\text{SL}}$ and $\text{TRL}^{\text{uni}}_{\text{CL}}$

Table 14 reveals a divergent defensive capacity of STRIP against distinct attacks: it encounters discernible difficulties when countering the contrastive backdoor attack, $\text{TRL}^{\text{uni}}_{\text{CL}}$, as evidenced by a consistently low TPR at a designated FPR. In contrast, STRIP demonstrates a better defense against the supervised attack, $\text{TRL}^{\text{uni}}_{\text{SL}}$, especially its dirty label variant, exhibiting a pronounced increase in TPR at a specified FPR.

Attack	Decision Threshold	FPR	TPR
$\text{TRL}^{\text{uni}}_{\text{CL}}$	5.11	0.5%	0.5%
	5.4	1.0%	0.8%
	5.5	2.0%	1.5%
$\text{TRL}^{\text{uni}}_{\text{SL}}$	4.17	0.5%	0.6%
	5.3	1.0%	2.4%
	5.4	2.0%	5.9%
$\text{TRL}^{\text{uni}}_{\text{SL}}$ (dirty)	5.11	0.5%	0.6%
	5.21	1.0%	30.6%
	5.37	2.0%	59.8%

Table 14. STRIP against $\text{TRL}^{\text{uni}}_{\text{SL}}$ and $\text{TRL}^{\text{uni}}_{\text{CL}}$ on CIFAR10.

C.4 Poisoning in Fine-tuning

Figure 19 illustrates the learning dynamics of additional poisoning in the fine-tuning stage on CIFAR10. First, a backdoored encoder is obtained using $\text{TRL}^{\text{fun}}_{\text{SCL}}$ (SimCLR). Subsequently, the encoder and the classifier head are fine-tuned on a small dataset, which includes 50 clean examples from each class, along with an additional 50 poisoning examples specifically from the target class. Throughout the fine-tuning stage, we continuously monitor the loss of both clean and poisoning data. In Figure 19, we observe that the loss of poisoning data decreases much more rapidly than that of clean data, which is consistent with the supervised learning setting in § 4.2. This is explained by that fine-tuning is inherently a form of supervised learning.

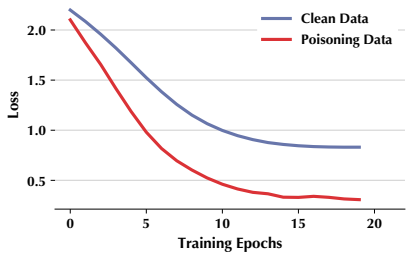

Figure 19: Learning dynamics of additional poisoning in fine-tuning.

Mudjacking: Patching Backdoor Vulnerabilities in Foundation Models

Hongbin Liu Michael K. Reiter Neil Zhenqiang Gong
Duke University
{hongbin.liu, michael.reiter, neil.gong}@duke.edu

Abstract

Foundation model has become the backbone of the AI ecosystem. In particular, a foundation model can be used as a general-purpose feature extractor to build various downstream classifiers. However, foundation models are vulnerable to backdoor attacks and a backdoored foundation model is a *single-point-of-failure* of the AI ecosystem, e.g., multiple downstream classifiers inherit the backdoor vulnerabilities simultaneously. In this work, we propose Mudjacking, the first method to patch foundation models to remove backdoors. Specifically, given a misclassified trigger-embedded input detected after a backdoored foundation model is deployed, Mudjacking adjusts the parameters of the foundation model to remove the backdoor. We formulate patching a foundation model as an optimization problem and propose a gradient descent based method to solve it. We evaluate Mudjacking on both vision and language foundation models, eleven benchmark datasets, five existing backdoor attacks, and thirteen adaptive backdoor attacks. Our results show that Mudjacking can remove backdoor from a foundation model while maintaining its utility.

1 Introduction

A foundation model is a general-purpose feature extractor, i.e., it produces a feature vector for an (image or text) input. Foundation models are often pre-trained using a large amount of unlabeled data (called *pre-training data*) collected from the public Internet by self-supervised learning [1,4,12,32,33]. CLIP [32] is a popular example of vision foundation model, while BERT [12] and GPT [1,33] are popular examples of language foundation models. Due to its resource requirements, a foundation model is often deployed as a cloud service by a *foundation-model provider*. A *client* uses a foundation model as a feature extractor to build downstream classifiers. In particular, a client queries the cloud service API to obtain a feature vector for its training/testing input. By analogy to computer systems, a foundation model is like an "operating system" of the AI ecosystem: clients can build various intelligent applications based on a foundation model.

However, foundation models are vulnerable to backdoor attacks [2,22,24,35,40,54,56]. In particular, a backdoored foundation model produces an attacker-desired feature vector for any input embedded with an attacker-chosen *trigger*, but its output feature vector for an input without a trigger is unaffected. A trigger could be, e.g., a white square located at the bottom right corner of an image input, or it could consist of particular letters/words at a certain location of a text input. An attacker-desired feature vector could be one that is similar to those of the inputs from a particular class called the *target class*. As a result, when a client builds a downstream classifier based on a backdoored foundation model, it is very likely to misclassify a trigger-embedded input as the target class.

An attacker can embed backdoors into a foundation model by directly modifying its model parameters [22,40,56] or injecting carefully crafted poisoning inputs into its pre-training data [2,24,35,54]. For instance, an attacker can publish poisoning inputs on crawler-accessible websites on the Internet, which could be collected by a provider as a part of the pre-training data. Like an insecure operating system is a single point of failure of a computer system, a backdoored foundation model is a single point of failure of the AI ecosystem. In particular, multiple downstream classifiers inherit backdoor vulnerability from a backdoored foundation model simultaneously [22,54,56].

Defenses against backdoor attacks can be *pre-deployment* and *post-deployment*. Pre-deployment defenses [17,20,21,26,48,49,51,52,55,59] aim to defend against backdoor attacks before deploying a model in the real-world, so the deployed model is backdoor-free. Post-deployment defenses assume a deployed model may be backdoored; and they aim to detect misclassified trigger-embedded inputs at inference time [8,15,28] and patch the model to remove the backdoor using such detected inputs (called *model patching*) [7,18,38,57]. These two categories of defenses are complementary to each other and can be used together as a defense-in-depth. We focus on model patching in this work. However, existing model patching methods are designed to patch foundation models to fix normal bugs instead of backdoors [58] or to

patch classifiers to fix backdoor vulnerabilities [7, 18, 38, 57], which are insufficient to patch foundation models to remove backdoors as shown by our experimental results in Section 5.

Our work: In this work, we propose Mudjacking,[1] the first method to patch foundation models to remove backdoor vulnerabilities. Mudjacking considers the following setting: a backdoored foundation model is deployed; and a client detects an input misclassified by its downstream classifier and reports a *bug instance* to the foundation-model provider, who uses Mudjacking to adjust its foundation model's parameters to remove the backdoor. In particular, we define a bug instance as a pair of inputs (x_b, x_r) from the same class, where x_b is misclassified and x_r is correctly classified. We call x_r *reference input*. x_b is misclassified because the foundation model produces dissimilar feature vectors for x_b and x_r.

Given a bug instance, Mudjacking aims to achieve three patching goals. (1) *Effectiveness*: the post-patching foundation model effectively fixes the bug; i.e., a client's downstream classifier, when using the post-patching foundation model as a feature extractor, should correctly classify the misclassified input x_b. (2) *Locality*: patching the foundation model should not influence the predictions for other inputs. (3) *Generalizability*: if the misclassified input x_b is from a backdoor attack, other inputs embedded with the same trigger in x_b should also be correctly classified by a downstream classifier using the post-patching foundation model as a feature extractor.

Mudjacking achieves the three patching goals via formulating a loss term to quantify each of them. Specifically, we propose an *effectiveness loss* to quantify the effectiveness goal, which is smaller if the post-patching foundation model outputs more similar feature vectors for the misclassified and reference inputs. Moreover, we propose a *locality loss* to quantify the locality goal, which is smaller when the pre-patching and post-patching foundation models output similar feature vectors for each input in a clean unlabeled *validation dataset*. Furthermore, we propose a *generalizability loss* to quantify the generalizability goal, which is smaller when the feature vectors output by the post-patching foundation model for each input in the validation dataset and its trigger-embedded version are more similar. Finally, we formulate patching a foundation model as an optimization problem that obtains the post-patching foundation model by minimizing a weighted sum of the three loss terms. Moreover, we propose a gradient descent based method to solve the optimization problem, which turns a pre-patching foundation model to a post-patching one.

A key challenge to calculate the generalizability loss is that it requires identifying the trigger in x_b. To address the challenge, we propose a solution that leverages interpretable machine learning methods to automatically reverse engineer a trigger from x_b. In particular, our method identifies the pixels/words in x_b that have the highest contributions to the dissimilarity between the feature vectors of x_b and x_r output by the pre-patching foundation model. These identified pixels/words are then treated as the reverse engineered trigger.

We evaluate Mudjacking on both vision and language foundation models, eleven benchmark datasets, five existing backdoor attacks, and thirteen adaptive backdoor attacks. Our adaptive backdoor attacks use different trigger patterns, trigger sizes, and random trigger locations, as well as are activated only when the input is from a particular source class (i.e., source-specific backdoor). Our experimental results show that Mudjacking achieves the three patching goals. Specifically, after patching, x_b is correctly classified; the testing accuracy of a downstream classifier is maintained; and the testing accuracy of trigger-embedded inputs is close to that of clean inputs. Our results also show that Mudjacking outperforms fine-tuning and its variants [58] that patch normal bugs of foundation models, pre-deployment backdoor defenses for classifiers [25, 26] that we extend to patch foundation models, and patching methods [7, 57, 58] that patch backdoor vulnerabilities of downstream classifiers alone. Moreover, as a side effect, Mudjacking also patches foundation models effectively when provided bug instance reveals a misclassification not caused by backdoor attacks.

To summarize, our key contributions are as follows:

- We propose Mudjacking, the first method to patch foundation models to remove backdoor vulnerabilities.
- We formulate patching a foundation model as an optimization problem, which patches a foundation model via minimizing a weighted sum of three loss terms that we propose to quantify three patching goals, respectively.
- We propose a method based on interpretable machine learning by which a foundation-model provider can reverse engineer a trigger from a bug instance.
- We evaluate Mudjacking on multiple datasets and backdoor attacks, including both existing and adaptive ones.

2 Related Work

2.1 Foundation Models

Foundation models [1, 4, 12, 32, 33] are neural networks that can be used as general-purpose feature extractors. A foundation model is called a *vision* (or *language*) *foundation model* when its input is image (or text). A foundation model is pre-trained using a large amount of *unlabeled* data via self-supervised learning, which creates supervision tasks from the unlabeled data itself. A vision foundation model could be pre-trained using unlabeled images (called *single-modal vision foundation model*) by pre-training algorithms such as SimCLR [4] and MoCo [5], or using unlabeled image-text pairs (called *multi-modal vision foundation model*) by pre-training

[1] Mudjacking borrows its name from a method to repair a slab foundation by pumping material underneath sunken concrete to lift it.

algorithms such as CLIP [32]. A language foundation model is pre-trained using a text corpus.

Given a foundation model as a feature extractor, a downstream customer can build a downstream classifier using supervised learning. Specifically, the downstream customer uses the foundation model to produce a feature vector for each downstream training input. Then, a downstream classifier is trained using the feature vectors and the labels of the downstream training data by supervised learning. Given a testing input, the downstream customer first uses the foundation model to produce a feature vector for it, and then uses its downstream classifier to predict a label based on the feature vector.

2.2 Backdoor Attacks to Foundation Models

Backdoor attacks were originally designed for classifiers [6, 16, 27]. Several studies extended backdoor attacks to foundation models [2, 22, 24, 35, 40, 54, 56]. Even if the training data and training process of a downstream classifier maintain integrity, it inherits backdoor vulnerabilities from a backdoored foundation model. A backdoored foundation model has two key properties. First, when an input is embedded with an attacker-chosen *trigger*, the backdoored foundation model produces an attacker-desired feature vector for it, e.g., the feature vector is similar to those of the inputs from a particular class called *target class*. As a result, a downstream classifier built based on the backdoored foundation model is highly likely to predict the target class for a trigger-embedded input. Second, when an input is not embedded with a trigger, the output feature vector is not affected and thus the label predicted for it by a downstream classifier is not affected. An attacker can inject multiple backdoors into a foundation model, affecting multiple downstream classifiers simultaneously [22].

A trigger is characterized by a *pattern* and *location*. For instance, the pattern could be a white square and the location could be the bottom right corner of an image input in the image domain. In this work, we consider universal, localized triggers that can be easily implemented in the physical world. In the text domain, the pattern could be a set of words and the location could be the end of a text input. Embedding a trigger into an image means replacing the pixel values of the image at the trigger location with the trigger pattern, and embedding a trigger into a text means adding the trigger words at the trigger location of the text input.

Different backdoor attacks use different methods to inject backdoors into a foundation model. For example, BadEncoder [22] can inject backdoors into a single-modal or multi-modal vision foundation model via slightly modifying its model parameters. Similarly, POR [40] injects backdoors into a language foundation model via modifying its model parameters. Carlini and Teriz [2] proposed to inject a backdoor into a multi-modal vision foundation model via poisoning its pre-training image-text pairs. In particular, their attack creates text captions with the target class name, and then combines these text captions with trigger-embedded images to form poisoning image-text pairs. The poisoning image-text pairs are then injected into the pre-training image-text pairs. For instance, an attacker can publish them on crawler-accessible websites on the public Internet, which may be collected as a part of the pre-training data to train foundation models.

2.3 Model Patching

Model patching [42, 58] aims to slightly adjust the parameters of a model such that it produces desired outputs for particular inputs. Fine-tuning or its variants are popular patching methods [58] that can be applied to both classifiers and foundation models. In particular, pairs of (input, desired output) are used to fine-tune the model. For instance, Zhu et al. [58] applied fine-tuning to patch language foundation models to correct its memorized knowledge. However, existing studies on patching foundation models focused on normal bugs instead of backdoor attacks [42, 58]. For instance, given an input (e.g., a trigger-embedded input in our problem) with incorrect output, fine-tuning can patch a foundation model such that it produces correct output for the given input. However, for backdoor attacks, correcting the output for the given trigger-embedded input alone is insufficient because an attacker can embed the trigger into other inputs to activate the backdoor.

Some studies [7, 18, 38, 57] aim to patch a classifier to mitigate backdoor attacks. In particular, given a misclassified trigger-embedded input, some methods [18, 38] aim to detect the poisoning training examples in the backdoor attack, remove them, and re-train a classifier using the remaining training data. Other methods [7] reverse engineer a trigger from multiple misclassified trigger-embedded inputs and fine-tune the classifier using clean training inputs embedded with the reverse-engineered trigger and correct labels. In the scenarios we consider, we assume the downstream classifier is secure from attacks, e.g., the training data of a downstream classifier is not poisoned. Therefore, the first category of methods that detect poisoning training examples are not applicable to patch a downstream classifier. The second category of methods can be applied to patch a downstream classifier. However, patching a downstream classifier is insufficient to mitigate backdoor attacks to foundation models, as shown by our experimental results in Section 5.3. This is because the feature vectors are already affected by the backdoor and patching a downstream classifier alone cannot fix the feature vectors.

We note that pre-deployment defenses aim to guarantee that a backdoor-free model is deployed, while model patching assumes the deployed model may be backdoored and patches the backdoored model after an attack is detected. We extend unlearning [26] and fine-pruning [25], pre-deployment defenses for classifiers, to patch foundation models in Section 5 and our results show they are insufficient. Neural Cleanse [49] and Tabor [17] reverse engineer triggers from backdoored classifiers, and then fine-tune the classifiers to remove back-

door. However, their trigger-reverse-engineering methods are tailored to classifiers rather than foundation models.

3 Problem Formulation

System setup: We consider two parties in our system setup: *foundation-model provider* and *client*. A foundation-model provider is a resourceful entity (e.g., OpenAI, Google, and Meta) who deploys a foundation model as a cloud service. Note that a foundation-model provider is not necessarily the entity who pre-trains the foundation model; e.g., a provider can deploy a public foundation model as a cloud service. A client is a downstream customer who builds intelligent applications (classifiers in this work) based on a foundation model. In particular, a client queries the cloud-service API to obtain a feature vector for an input. We denote by h a foundation model and $h(x)$ the feature vector for an input x. Given h as a feature extractor and a downstream training dataset, a client trains a downstream classifier f using supervised learning. We denote by $f \bigodot h(x)$ the label predicted for x, where $\bigodot$ means composition of h and f.

We assume the foundation model h is backdoored. Although the training dataset and training process of the downstream classifier f maintain integrity, it inherits the backdoor vulnerability from the foundation model [2, 22, 40, 54, 56]. After deploying the downstream classifier f, the client detects misclassification bugs (i.e., misclassified inputs) via automatic detection [8, 15, 28] or manual analysis; and the client reports them to the foundation-model provider, who patches its foundation model to fix the bugs. As we will show in our experiments in Section 5.3, it is insufficient for a client to patch its downstream classifier f to fix misclassification bugs. Although we assume a misclassified input has already been detected by a client, patching a foundation model is still challenging, especially at achieving the generalizability goal discussed below. For instance, the compared baseline methods in our experiments all fail to achieve this goal.

We assume a misclassification bug is sent from a benign client. We acknowledge that a malicious client could also send carefully crafted bugs to the provider, and it is an interesting future work to explore whether and how a malicious client can subvert the security/performance of the patching process.

Bug instance: When a client detects a misclassification bug, a key question is how to report it to the foundation-model provider. A naive way is that the client just sends the misclassified input x_b and its misclassified label y_t to the provider. However, it is challenging for the provider to leverage such a bug instance to patch its foundation model. This is because a foundation model is a feature extractor and does not process label information. Our key observation is that x_b is misclassified because the backdoored foundation model produces a feature vector for x_b that is dissimilar to those of the inputs from the class y_b, where y_b is the true label of x_b. Based on this observation, we define a bug instance as a pair of inputs (x_b, x_r) from the class y_b, where x_b is misclassified as y_t and x_r is correctly classified as y_b by the downstream classifier. We call x_r the *reference input*. Formally, we have the following definition of bug instance.

Definition 1 (Bug Instance)**.** *Given a foundation model h and a downstream classifier f, a bug instance (x_b, x_r) consists of a misclassified input x_b and a correctly classified reference input x_r that satisfy the following conditions: (i) x_b and x_r have the same true label y_b, (ii) $f \bigodot h(x_b) \neq y_b$, and (iii) $f \bigodot h(x_r) = y_b$.*

Goals for patching: After receiving a bug instance (x_b, x_r), the foundation-model provider patches its foundation model. For convenience, we denote by h and h' the *pre-patching* and *post-patching* foundation model, respectively. The provider aims to achieve the following three patching goals.

Effectiveness. The effectiveness goal means that the post-patching foundation model h' effectively fixes the bug. In particular, the post-patching foundation model h' should produce similar feature vectors for x_b and x_r, i.e., $h'(x_b) \approx h'(x_r)$. Therefore, when the client builds a *patched downstream classifier* f' using h' as a feature extractor, x_b is correctly classified as y_b, i.e., $f' \bigodot h'(x_b) = f' \bigodot h'(x_r) = y_b$. We note that to fix the bug, a client may need to update/re-train its downstream classifier based on the post-patching foundation model. This is because the post-patching and pre-patching foundation models produce different feature vectors for the same input.

Locality. The locality goal means that patching the foundation model should not influence the predictions for other inputs, i.e., the patching is local to the misclassified input x_b. Formally, the locality goal aims to achieve $h'(x) \approx h(x)$ for any clean input $x \neq x_b$. When the locality goal is achieved, the pre-patching and post-patching downstream classifiers are very likely to have similar testing accuracy for clean inputs.

Generalizability. The generalizability goal means that when the misclassified input x_b is a trigger-embedded input from a backdoor attack, the post-patching foundation model h' should also fix the bug for other trigger-embedded inputs. In particular, adding a trigger to an input should have minimal influence on its feature vector produced by h'. Formally, the generalizability goal aims to achieve $h'(x \oplus t) \approx h'(x)$ for any clean input x, where t is the backdoor trigger in x_b and $x \oplus t$ means embedding the trigger t into an input x. When the generalizability goal is achieved, embedding the trigger t into an input is unlikely to change its label predicted by the patched downstream classifier.

Backdoor vs. normal bugs: In a bug instance (x_b, x_r), the misclassified input x_b may be a trigger-embedded input from a backdoor attack or a normal input without a backdoor trigger that is misclassified due to the intrinsic imperfection of the downstream classifier. For a normal misclassification bug, the generalizability goal is not well defined and only the first two patching goals are applicable. As detailed in the next section,

our patching method aims to achieve the three patching goals by *assuming* x_b is a trigger-embedded input from a backdoor attack without distinguishing between backdoor and normal bugs. However, as our evaluation results in Section 5 show, when x_b is a normal misclassified input, our patching method still achieves the first two patching goals. Other than backdoor and normal bugs, a misclassified input could also be an adversarial example [3, 46], which we discuss in Section 6.

4 Mudjacking

4.1 Overview

Mudjacking achieves the three patching goals via formulating a loss term to quantify each of them. Specifically, given a bug instance (x_b, x_r), we propose an *effectiveness loss* to quantify the effectiveness goal. The effectiveness loss is smaller when the post-patching foundation model outputs more similar feature vectors for the misclassified input x_b and the reference input x_r. Moreover, we propose a *locality loss* to quantify the locality goal. The locality loss is smaller if the post-patching foundation model and pre-patching one output more similar feature vectors for each input in a clean, unlabeled *validation dataset* that the provider collects. We propose a *generalizability loss* to quantify the generalizability goal. Roughly speaking, the generalizability loss is smaller if the feature vectors output by the post-patching foundation model are less likely to be influenced by a trigger, i.e., if the post-patching foundation model outputs more similar feature vectors for each clean input in the validation dataset and its trigger-embedded version. Finally, we formulate patching a foundation model as an optimization problem that aims to minimize a weighted sum of the three loss terms. Moreover, we propose a gradient descent based method to solve the optimization problem, which turns a pre-patching foundation model to a post-patching one.

One challenge to calculate the generalizability loss is that it requires the backdoor trigger in the misclassified input x_b. To address this challenge, we propose an approach that leverages interpretatable machine learning methods to automatically reverse engineer a trigger from x_b. Roughly speaking, our approach finds the pixels/words in x_b that contribute the most to the dissimilarity between the feature vectors of x_b and x_r output by the pre-patching foundation model, and we treat such pixels/words as the reverse-engineered trigger.

Next, we describe formulating patching a foundation model as an optimization problem, solving the optimization problem, and reverse engineering a backdoor trigger.

4.2 Formulating an Optimization Problem

We first define our three loss terms that quantify the three patching goals, respectively. Then, we formulate an optimization problem based on the loss terms.

Effectiveness loss: Recall that the effectiveness goal means that the post-patching foundation model h' outputs similar feature vectors for the misclassified input x_b and reference input x_r. Therefore, our effectiveness loss $\mathcal{L}_e$ quantifies the similarity between the two feature vectors $h'(x_b)$ and $h'(x_r)$ output by h'. Formally, we have the following:

$$\mathcal{L}_e = -sim(h'(x_b), h'(x_r)), \tag{1}$$

where *sim* is a similarity metric, e.g., we use cosine similarity in our experiments since the feature vectors are normalized to have ℓ_2-norm of 1. A smaller $\mathcal{L}_e$ indicates that the post-patching foundation model h' produces more similar feature vectors for x_b and x_r.

Locality loss: Recall that the locality goal means that the patching does not influence the feature vectors for clean inputs. In particular, we assume the provider has a clean unlabeled validation dataset D_{val}. For each input in D_{val}, the post-patching foundation model and pre-patching one should output similar feature vectors. Therefore, our locality loss $\mathcal{L}_l$ is the average similarity between the feature vectors output by h' and h for the inputs in the validation dataset and the reference input. Formally, we have the following:

$$\mathcal{L}_l = -\frac{1}{|\mathcal{D}_{\text{val}}|+1} \sum_{x \in \{\mathcal{D}_{\text{val}} \cup \{x_r\}\}} sim\left(h(x), h'(x)\right), \tag{2}$$

where $|\mathcal{D}_{\text{val}}|$ denotes the number of inputs in the validation dataset. We consider the reference input x_r in defining the locality loss to guarantee that the feature vector of x_r does not change much and it is still correctly classified by the downstream classifier. A smaller $\mathcal{L}_l$ indicates that h and h' produce more similar feature vectors for a clean input.

Generalizability loss: Suppose we have reverse engineered a backdoor trigger t_b from the bug instance (x_b, x_r) as described in Section 4.4. The generalizability goal means that embedding the trigger into an input has minimal impact on its feature vector output by the post-patching foundation model. Therefore, our generalizability loss $\mathcal{L}_g$ is the average similarity between the feature vectors of an input and its trigger-embedded version for the reference input and inputs in the validation dataset. Formally, we have the following:

$$\mathcal{L}_g = -\frac{1}{|\mathcal{D}_{\text{val}}|+1} \sum_{x \in \{\mathcal{D}_{\text{val}} \cup \{x_r\}\}} sim\left(h'(x \oplus t_b), h'(x)\right). \tag{3}$$

A smaller $\mathcal{L}_g$ indicates that h' outputs more similar feature vectors for an input x embedded with the reverse engineered trigger t_b and its clean counterpart.

Optimization problem: After defining the three loss terms, we can now present our optimization problem, which aims to obtain a post-patching foundation model h' from a pre-patching one via minimizing a weighted sum of the three loss terms. Formally, we have the following optimization problem:

$$\min_{h'} \mathcal{L} = \mathcal{L}_e + \lambda_l \mathcal{L}_l + \lambda_g \mathcal{L}_g, \tag{4}$$

Algorithm 1 Our Mudjacking

Input: Bug instance (x_b, x_r), pre-patching foundation model h, validation dataset $\mathcal{D}_{\text{val}}$, learning rate α, mini-batch size m, number of epochs T, and reverse engineered trigger t_b
Output: Post-patching foundation model h'

Initialize $h' \leftarrow h$
$I = \lceil \frac{|\mathcal{D}_{\text{val}} \cup \{x_r\}|}{m} \rceil$ ▷ Number of iterations per epoch
for $t = 1, 2, \ldots, T$ **do**
  for $i = 1, 2, \ldots, I$ **do**
    Sample a mini-batch $\mathcal{B} \subset \mathcal{D}_{val} \cup \{x_r\}$ s.t. $|\mathcal{B}| = m$
    Compute gradient $\nabla_{h'} \mathcal{L}$
    $h' \leftarrow h' - \alpha \nabla_{h'} \mathcal{L}$
return h'

where λ_l and λ_g are two hyperparameters that balance the three loss terms. By minimizing this combined loss function $\mathcal{L}$, our Mudjacking finds a post-patching foundation model h' that achieves the three patching goals simultaneously.

4.3 Solving the Optimization Problem

Patching a foundation model h is to solve the optimization problem in Equation 4, which turns h into a post-patching foundation model h'. We propose a Stochastic Gradient Descent based algorithm to solve the optimization problem, as shown in Algorithm 1. Specifically, we initialize h' to be h. Then, we iteratively update h' using the gradient of the loss function $\mathcal{L}$ with respect to a mini-batch of the validation dataset. The iterative process is repeated for T epochs.

4.4 Reverse Engineering a Trigger

The generalizability loss requires the backdoor trigger in the misclassified input x_b. However, a bug instance only consists of a pair of inputs. To address the challenge, we propose a method to automatically reverse engineer the backdoor trigger t_b from a bug instance, where the trigger is a set of pixels in an image input or a set of words at particular locations in a text input. Our key observation is that the backdoor trigger is the major cause for the dissimilarity between the feature vectors of x_b and x_r and thus the misclassification of x_b. Based on this observation, we leverage an interpretable machine learning method to calculate an *attribution score* for each pixel in an image input or each word in a text input, where an attribution score aims to quantify the influence of a pixel/word on the dissimilarity between the feature vectors of x_b and x_r. Intuitively, the trigger pixels/words have large attribution scores. Therefore, we further use a clustering algorithm to identify the pixels/words with large attribution scores and treat them as a trigger. Next, we describe how to calculate attribution scores and identify a trigger based on them.

Step I: calculating attribution scores: Suppose we are given a pre-patching foundation model h and a bug instance

Algorithm 2 Reverse Engineering a Trigger

Input: Bug instance (x_b, x_r), pre-patching foundation model h, objective function ℓ, and interpretation method $\mathcal{A}$
Output: Trigger t_b.

Step I: Calculate Attribution Scores
$\ell_b \leftarrow \ell(h, x_b, x_r)$ ▷ As defined in Equation 5
$A \leftarrow \mathcal{A}(h, \ell_b, x_b)$ ▷ Attribution scores
Step II: Identify Trigger
$K \leftarrow 2$ ▷ Number of clusters
$C_1, C_2 \leftarrow$ K-means(A, K)
$M_1, M_2 \leftarrow$ Mean attribution score of each cluster
$i \leftarrow \arg\max_j M_j$ ▷ Find the higher mean score
$t_b \leftarrow C_i$ ▷ Reverse engineered trigger
return t_b

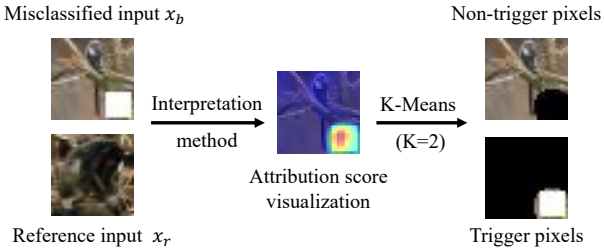

Figure 1: Illustration of reverse engineering a trigger.

(x_b, x_r). x_b is misclassified by the downstream classifier because of the trigger in it. Specifically, the trigger pixels/words in x_b contribute substantially to the dissimilarity between the feature vectors $h(x_b)$ and $h(x_r)$, and thus the misclassification of x_b. This observation inspires us to leverage an interpretable machine learning method [37, 41, 44, 53] to quantify the influence of a pixel/word in x_b. Given a machine learning model, an input x_b, and an *objective function* about the input, an interpretation method can calculate an attribution score for each pixel/word in the input, where the attribution score quantifies the contribution of a pixel/word on the objective function. For instance, the *occlusion* method [53] systematically occludes portions of the input, such as rectangular regions of an image input or text sequences in a text input. By doing so and calculating the difference in the objective function, the occlusion method can calculate an attribution score for each pixel/word.

A key challenge of applying interpretation methods to reverse engineer a trigger is how to design the objective function. One straightforward objective function is the loss function of the label $f \bigodot h(x_b)$ predicted by the downstream classifier for the input x_b. However, the foundation-model provider does not have access to the downstream classifier f. As a result, the provider cannot evaluate the loss function of $f \bigodot h(x_b)$ nor apply an interpretation method to calculate the attribution scores. To address the challenge, we define the objective function using the foundation model and bug instance without involving the downstream classifier. In particular, our objective function is directly related to the dissimilarity between

the feature vectors $h(x_b)$ and $h(x_r)$. Formally, we define the objective function $\ell(h, x_b, x_r)$ as follows:

$$\ell(h, x_b, x_r) = 1 - sim(h(x_b), h(x_r)), \quad (5)$$

where *sim* is the cosine similarity in our experiments. Given such objective function, we leverage an interpretation method to calculate an attribution score for each pixel/word in x_b. A higher attribution score is likely to indicate that the corresponding pixel/word has a larger impact on the objective function, i.e., the dissimilarity between $h(x_b)$ and $h(x_r)$.

We note that several previous studies (e.g., [8, 13]) also leverage interpretable machine learning methods to identify the backdoor trigger in an input. However, they focus on classifiers (i.e., $f \bigodot h$ in our problem) and use the straightforward loss function of the predicted label as the objective function. Our work focuses on foundation models and designs a new objective function tailored to them.

Step II: identifying trigger: After we have obtained the attribution score for each input pixel/word, we identify the trigger pixels/words based on them. Intuitively, the input pixels/words with larger attribution scores may form the trigger. Based on this intuition, we use a clustering method to divide the pixels/words into two clusters: one cluster containing the pixels/words with high attribution scores, and one cluster containing those with low attribution scores. For instance, we can leverage the K-means algorithm [29] with $K = 2$ to perform the clustering. We then treat the cluster with the higher mean attribution score as the trigger. We summarize our method to reverse engineer a trigger in Algorithm 2.

5 Evaluation

5.1 Experimental Setup

Datasets: We use eleven benchmark datasets, including six image datasets, two image-text datasets, and three text datasets. We show the details of these datasets in Table 16 in Appendix. These benchmark datasets were also used in prior studies [2, 22, 40, 54, 56] on backdoor attacks to foundation models. In addition to the numbers shown in Table 16 in Appendix, the STL10 dataset also contains 100,000 unlabeled images. We use these unlabeled images for pre-training when STL10 is used as the pre-training dataset. We follow Zhang et al. [54] to construct ImageNet100-A and ImageNet100-B, two subsets of ImageNet. Each of these subsets contains randomly sampled 100 classes from the ImageNet dataset with no overlapping classes. The CLIP-400M dataset was used for pre-training the OpenAI's CLIP foundation model, which contains 400M image-text pairs but is not publicly available. The CC3M-Sub and Wiki103-Sub denote randomly subsampled subsets of the CC3M [39] and Wiki103 [30], respectively.

Backdoor attacks to foundation models: We consider the following five state-of-the-art backdoor attacks to foundation models.

BadEncoder [22]. BadEncoder injects backdoors into a vision foundation model by directly modifying its model parameters. A backdoored vision foundation model outputs attacker-desired feature vectors for any inputs embedded with a trigger. These feature vectors then cause a downstream classifier to produce attacker-desired predictions. BadEncoder is applicable to both single-modal and multi-modal vision foundation models.

CorruptEncoder [54]. CorruptEncoder injects backdoors into a vision foundation model by poisoning its pre-training data. In particular, CorruptEncoder injects a small fraction of poisoning inputs into the pre-training dataset such that the learnt vision foundation model outputs attacker-desired feature vectors for any inputs embedded with a trigger. Like BadEncoder, CorruptEncoder is also applicable to both single-modal and multi-modal vision foundation models.

Carlini & Terzis [2]. Carlini and Terzis proposed a backdoor attack to multi-modal vision foundation models. Their attack first creates a collection of text captions that include the target class name chosen by the attacker. Then their attack associates these text captions with a set of images embedded with the trigger to construct poisoning image-text pairs, which are then injected into the pre-training dataset.

POR [40] and NeuBA [56]. These are two backdoor attacks to language foundation models. POR modifies a language foundation model's parameters to output a specific feature vector for any input containing a trigger, while NeuBA introduces a new backdoor pre-training objective in addition to the original pre-training objective to achieve the same goal.

Pre-training (backdoored) foundation models: We pre-train (backdoored) foundation models following the default experimental settings of the aforementioned backdoor attacks in the original papers, or use the publicly available ones from their codebase. For POR and NeuBA, we adopt a unified implementation [10]. Table 17a in Appendix summarizes the pre-training settings and backdoor triggers.

Training downstream classifiers: We use a foundation model as a feature extractor to train downstream classifiers on downstream datasets. For each downstream dataset, we use the training examples to train the downstream classifier and use the testing examples to evaluate its performance. These downstream classifiers are fully-connected neural networks trained with cross-entropy loss and the Adam optimizer. We follow the default parameter settings as those in the original papers on backdoor attacks when training the downstream classifiers. Table 17b in Appendix summarizes the training settings of downstream classifiers.

Compared patching methods: We compare Mudjacking with the following patching methods.

Fine-tuning (FT). FT is a widely used method for slightly modifying a model. When patching a foundation model, FT can achieve the effectiveness goal by optimizing the foundation model's parameters to produce similar feature vectors for

x_b and x_r. Specifically, FT obtains the post-patching foundation model h' by solving the optimization problem: $\min_{h'} \mathcal{L}_e$, where $\mathcal{L}_e$ is our effectiveness loss defined in Equation 1. h' is initialized as h and solved iteratively by gradient descent. We use the same parameter setting for FT as our Mudjacking.

Fine-tuning with ℓ_2-norm or ℓ_∞-norm constraint (FT+ℓ_2 or FT+ℓ_∞). Zhu et al. [58] use FT with an ℓ_2-norm or ℓ_∞-norm constraint to address overfitting and catastrophic forgetting. We apply this method to patch foundation models. In particular, when patching a foundation model h, FT+ℓ_p obtains h' by solving the following optimization problem: $\min_{h'} \mathcal{L}_e$ subject to $\ell_p(h', h) \leq \delta$, where $p = 2$ or ∞ and δ is the threshold for the ℓ_2 or ℓ_∞ constraint. We use projected gradient descent to solve the optimization problem. Specifically, during each iteration, we first compute the gradient of the loss function with respect to the model parameters; after updating the model parameters, we project them onto the feasible set defined by the ℓ_p constraint if needed. FT+ℓ_2 and FT+ℓ_∞ use the same parameter settings as FT. We set a small threshold $\delta = 0.01$ to bound the model parameters' change.

Unlearning. Liu et al. [26] propose a machine unlearning based pre-deployment defense to erase backdoors from classifiers. They fine-tune a backdoored classifier to maximize the cross-entropy loss on trigger-embedded inputs with the attacker's target label. Furthermore, they bound the changes in model parameters using an ℓ_1 norm constraint. We extend their method to patch foundation models by replacing the cross-entropy loss as a cosine similarity loss between the reference input x_r and misclassified input x_b.

Fine-Pruning. Liu et al. [25] combine pruning and fine-tuning as a pre-deployment defense to eliminate backdoors from classifiers. This defense first prunes the channels in the convolutional layers that are dormant, i.e., that have negative average activation on clean data; and then it fine-tunes the pruned model to regain utility lost from pruning. We extend fine-pruning to patch foundation models as follows: we first prune 50% of the channels that are dormant on the reference input x_r and then fine-tune the pruned foundation model using the pre-training data for 50 epochs.

Evaluation metrics: We use four evaluation metrics, i.e., Correct Prediction of x_b (CP), Accuracy (Acc), Attack Success Rate (ASR), and Accuracy with Backdoor trigger (AccB). CP evaluates the effectiveness goal, Acc evaluates the locality goal, ASR and AccB evaluate the generalizability goal. We define the four evaluation metrics as follows:

Correct Prediction of x_b (CP). CP measures whether a downstream classifier correctly classifies x_b. CP can be either $\times$ or $\checkmark$, denoting incorrect or correct classification of x_b.

Accuracy (Acc). Acc denotes the testing accuracy of a downstream classifier $f \bigodot h$ (or $f' \bigodot h'$ after patching). Specifically, Acc is the fraction of clean downstream testing examples that are correctly classified. If post-patching Acc is close to or higher than pre-patching Acc, then the locality goal is achieved.

Attack Success Rate (ASR). We generate *backdoored testing inputs* by embedding a trigger into all clean downstream testing inputs that are not from the target class. ASR is the fraction of such backdoored testing inputs that are classified as the target class by the downstream classifier.

Accuracy with backdoor trigger (AccB). AccB is the testing accuracy of a downstream classifier $f \bigodot h$ (or $f' \bigodot h'$ after patching) for backdoored testing inputs. In particular, AccB is the fraction of backdoored testing inputs that are correctly classified by a downstream classifier. The generalizability goal is achieved if the post-patching ASR is small and AccB is close to Acc.

Parameter settings of Mudjacking: We randomly sample a bug instance (x_b, x_r), where x_b is a trigger-embedded misclassified testing input and x_r is a correctly classified testing input from the downstream testing dataset. By default, we use BadEncoder as the backdoor attack, CIFAR10 for pre-training, and STL10 for downstream classifier training.

The default parameter settings for our Mudjacking are as follows: $\lambda_l = \lambda_g = 1$; the number of epochs $T = 200$ in Algorithm 1; and the learning rates used for patching are shown in Table 18 in Appendix. The validation dataset size and batch size are determined based on our computation resources. Table 18 in Appendix summarizes these parameters. Unless otherwise mentioned, we sample the validation dataset from the pre-training dataset, except for CLIP-400M. Since CLIP-400M is not publicly available, we sample the training inputs in ImageNet as our validation dataset. By default, we use the Occlusion interpretation method [53] when reverse engineering a trigger. We performed experiments using 18 NVIDIA RTX 6000 GPUs, with each GPU having 24GB memory.

5.2 Experimental Results

Mudjacking achieves the three patching goals: Table 1 and Table 2 show the results of patching vision and language foundation models, respectively. We have multiple observations. First, Mudjacking consistently achieves the effectiveness goal in all settings, indicated by CP = $\checkmark$. This is because the post-patching foundation model produces similar feature vectors for the misclassified input x_b and reference input x_r.

Second, Mudjacking also achieves the locality goal by maintaining Acc after patching. This is because, for a clean input, the post-patching and pre-patching foundation models output similar feature vectors. In particular, even when the validation dataset is a small fraction of the clean pre-training dataset, it is sufficient for our Mudjacking to achieve the locality goal. For example, as shown in Table 1b, when the pre-training dataset is CLIP-400M and the foundation model is attacked by BadEncoder, using only 50,000 images (only 0.0125% of 400 million) from ImageNet as the validation dataset is sufficient to achieve the locality goal.

Third, our Mudjacking successfully achieves the generalizability goal since ASR is low (close to 0) except for patching

Table 1: Results for patching vision foundation models.

(a) Single-modal

Attack method	Pre-training dataset	Downstream dataset	Before patching				After patching			
			CP	Acc	ASR	AccB	CP	Acc	ASR	AccB
BadEncoder	CIFAR10	STL10	×	76.46	99.82	0.10	✓	76.59	2.39	73.38
		SVHN	×	69.07	98.92	0.53	✓	78.49	5.97	65.39

(b) Multi-modal

Attack method	Pre-training dataset	Downstream dataset	Before patching				After patching			
			CP	Acc	ASR	AccB	CP	Acc	ASR	AccB
BadEncoder	CLIP-400M	STL10	×	96.70	99.92	0.04	✓	95.65	0.42	95.06
		SVHN	×	69.93	100.00	0.00	✓	73.35	3.48	69.13
Carlini & Terzis	CC3M-Sub	ImageNet100-B	×	51.47	98.22	1.09	✓	49.26	5.03	41.53
CorruptEncoder	CC3M-Sub	ImageNet100-B	×	48.44	94.40	0.81	✓	45.92	3.46	40.27

Table 2: Results for patching langugae foundation models.

Attack method	Pre-training dataset	Downstream dataset	Before patching				After patching			
			CP	Acc	ASR	AccB	CP	Acc	ASR	AccB
NeuBA	Wiki-103	SST-2	×	80.28	100.00	0.00	✓	79.68	24.34	75.65
		HSOL	×	80.16	100.00	0.00	✓	81.28	18.28	81.72
POR	Wiki-103	SST-2	×	82.59	67.66	12.34	✓	81.82	17.49	82.51
		HSOL	×	82.90	99.92	0.08	✓	82.78	17.07	82.93

language models and AccB is close to Acc after patching across all settings. We note that ASR is not close to 0 for patching language foundation models in Table 2. This is because the downstream datasets have two classes. Given a downstream classifier built based on a clean language foundation model, ASR would be close to the misclassification rate of testing inputs. We observe that ASR in Table 2 is indeed close to the misclassification rate of testing inputs, roughly 20%. Therefore, the post-patching language foundation models are similar to clean language foundation models. Our results suggest that our method effectively mitigates the backdoor vulnerabilities in a backdoored foundation model.

Mudjacking outperforms existing methods: Table 3 compares Mudjacking with existing patching methods for patching the vision foundation model in our default setting. We observe that Mudjacking outperforms these methods at achieving the three patching goals. Specifically, FT, FT+ℓ_2, FT+ℓ_∞, and unlearning can achieve the effectiveness goal. This is because they all fine-tune the foundation model to minimize the effectiveness loss $\mathcal{L}_e$. They achieve the locality goal to some extent, i.e., Acc is close to that before patching, but they cannot achieve the generalizability goal. Fine-Pruning achieves the locality and generalizability goals to some extent, but it cannot achieve the effectiveness goal.

Table 3: Comparing Mudjacking with existing methods.

Patching method	CP	Acc	ASR	AccB
Before patching	×	76.46	99.82	0.10
FT	✓	69.61	40.57	32.50
FT+ℓ_2	✓	72.05	55.90	24.31
FT+ℓ_∞	✓	70.04	41.79	30.61
Unlearning	✓	70.02	34.57	32.12
Fine-Pruning	×	71.92	6.65	61.97
Mudjacking	✓	76.59	2.39	73.38

Impact of different interpretation methods: Our Mudjacking uses an interpretation method to reverse engineer a trigger from a bug instance. We compare four widely used interpretation methods, i.e., Occlusion [53], GradCam [37], Saliency Map [41], Guided Backprobagation (GuidedBack) [44]. Table 4 shows the results, from which we have the following two main observations. First, we observe that different interpretation methods lead to different reverse-engineered triggers. Specifically, Occlusion and GradCam can reverse-engineer triggers that contain majority of the true backdoor trigger (the white square at the bottom right corner). On the other hand, the triggers reverse-engineered by Saliency Map and GuidedBack contain only a part of the true backdoor trigger.

Table 4: Impact of different interpretation methods.

Interpretation method	Reverse engineered trigger	CP	Acc	ASR	AccB
Occlusion		✓	76.59	2.39	73.38
GradCam		✓	76.47	3.42	71.44
Saliency Map		✓	76.58	11.88	61.72
GuidedBack		✓	76.29	13.56	61.67

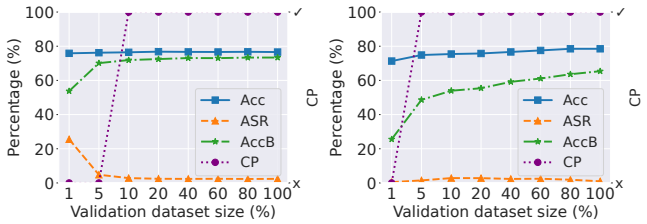

Table 5: Impact of the three loss terms.

Removed loss term	CP	Acc	ASR	AccB
None	✓	76.59	2.39	73.38
Effectiveness loss	×	76.70	2.65	72.97
Locality loss	✓	48.50	7.10	45.61
Generalizability loss	✓	76.70	26.49	50.57

Therefore, Occlusion and GradCam outperform the other two in terms of the generalizability goal, i.e., ASRs are lower and AccBs are higher. Second, we find that Mudjacking successfully achieves the effectiveness and locality goals, regardless of the interpretation method used. The reason is that the reverse-engineered trigger is used only in the generalizability loss and does not impact the effectiveness and locality losses.

Impact of the three loss terms: Our formulated optimization problem in Equation 4 consists of three loss terms. We study the impact of removing each of them and show the results in Table 5. We have the following three key observations. First, the removal of the effectiveness loss hinders the patched foundation model's ability to correctly classify the misclassified input x_b. Second, removing the locality loss leads to a substantial drop in Acc, falling from 76.59% (with no loss term removed) to 48.50%. This highlights the critical role of the locality loss in preserving the utility of the patched foundation models. Third, the removal of the generalizability loss results in a significant increase in ASR to 26.49% and a decrease in AccB to 50.57%. This indicates the significant role of the generalizability loss in mitigating backdoor vulnerabilities. To summarize, these observations emphasize the importance of integrating all the three loss terms to achieve the three patching goals.

Impact of validation dataset size: Mudjacking relies on a validation dataset $\mathcal{D}_{\text{val}}$ to calculate both the locality loss (Equation 2) and the generalizability loss (Equation 3). We investigate how varying the size of the validation dataset influences our method's performance on three downstream datasets, namely STL10 and SVHN. We show the results in Figure 2. We find that both CP and Acc converge when the size of the validation dataset exceeds 10% of the pre-training dataset size across the tested downstream datasets. This suggests that our method is efficient in achieving its effectiveness and locality goals, even when the validation dataset is a small fraction of the pre-training dataset. Interestingly, in terms of ASR and AccB, we notice some variations. For the STL10 dataset, both metrics begin to stabilize when the validation dataset size exceeds 10% of the pre-training dataset size. However, for the SVHN dataset, ASR stabilizes when the validation dataset is only 1% of the pre-training dataset, while AccB continues to improve as the validation dataset size increases. This is probably because STL10's data distribution is more similar to the pre-training dataset CIFAR10, compared to SVHN.

(a) STL10 (b) SVHN

Figure 2: Impact of the validation dataset size on different downstream datasets. The validation dataset is a subset of the pre-training dataset CIFAR10.

Table 6: Impact of the validation dataset distribution. The pre-training dataset is CIFAR10.

Validation dataset distribution	CP	Acc	ASR	AccB
CIFAR10	✓	76.59	2.39	73.38
STL10	✓	76.60	2.71	72.82
ImageNet	✓	75.88	2.44	72.24

Impact of validation dataset distribution: We further investigate the impact of different distributions of the validation dataset on our method's performance. We show the results in Table 6. We observe that Mudjacking achieves all three patching goals regardless of the validation dataset distribution. The reason is that all these validation datasets contain diverse images, which help our method achieve the locality and generalizability goals that rely on $\mathcal{D}_{val}$.

Patching multiple bugs: A client may detect and report bugs to the foundation-model provider at different times. Therefore, the foundation-model provider may apply our method to patch the foundation model multiple times. We illustrate this scenario in Figure 3. In our experiments, the foundation-model provider receives three bug instances sequentially and patches the pre-patching foundation model h three times, which results in three post-patching foundation models h'_1, h'_2, and h'_3. Table 7 shows our method's performance in this case. We have two main observations. First, Mudjacking can achieve the effectiveness and locality goals in every patching attempt. Second, patching multiple bugs can better achieve the generalizability goal as ASR decreases when patching more times.

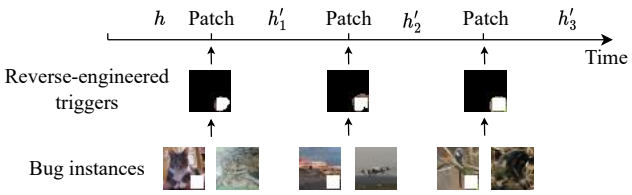

Figure 3: Patching multiple bugs.

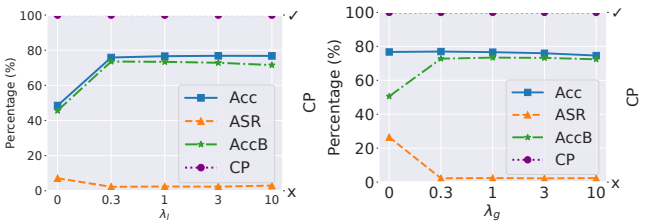
Table 7: Patching multiple bugs.

Foundation model	CP	Acc	ASR	AccB
h	×	76.46	99.82	0.10
h'_1	✓	76.51	3.43	71.43
h'_2	✓	75.31	2.25	71.93
h'_3	✓	74.88	2.00	71.10

Table 8: Normal vs. backdoor bug.

Bug instance	Reverse engineered trigger	CP	Acc	ASR	AccB
Backdoor bug		✓	76.59	2.39	73.38
Normal bug		✓	76.29	-	-



This is because as the foundation model is patched more times, the trigger is better reverse-engineered (as shown in Figure 3), which improves the generalizability of Mudjacking.

Patching normal bugs: The misclassified input x_b can also be a normal input without a backdoor trigger. Mudjacking can be directly applied to patch such bugs. We show the results of patching a normal bug in Table 8. When x_b is a normal misclassified input, our method still achieves the first two patching goals, while the generalizability goal is not well defined for normal bugs. This is because Mudjacking achieves the three patching goals by assuming x_b is a trigger-embedded input from a backdoor attack without distinguishing between backdoor and normal bugs.

Impact of reference inputs: A bug instance (x_b, x_r) includes a reference input x_r. By default, we assume x_r is a real image from the client. We study whether x_r could be a random input that has a similar feature vector with a real one. Generating such a random input would be easier for the foundation-model provider than the client, who only has black-box access to the foundation model. Therefore, we consider the following scenario: the client sends a misclassified input x_b together with the feature vector of a real reference input, i.e., $h(x_r)$, to the foundation-model provider. The foundation-model provider generates a reference input x'_r whose feature vector has a high cosine similarity with $h(x_r)$. Specifically, we iteratively update an initial random input x'_r for 100 iterations to maximize the cosine similarity between $h(x'_r)$ and $h(x_r)$ using the Adam optimizer with a learning rate of 1×10^{-2}. Figure 8 in Appendix shows x_r and x'_r, while Table 9 shows the results of using x_r or x'_r for patching. We have two main observations. First, Mudjacking can successfully reverse engineer the trigger using x'_r. This is because x'_r has a dissimilar feature vector with x_b. Second, Mudjacking achieves similar performance when using either a real or random reference input. This is because of the highly similar feature vectors between the real reference input and the random one, and the successfully reverse-engineered trigger.

Table 9: Impact of reference input.

Reference input	Reverse engineered trigger	CP	Acc	ASR	AccB
Real		✓	76.59	2.39	73.38
Random		✓	76.66	2.60	72.11

(a) λ_l (b) λ_g

Figure 4: Impact of λ_l and λ_g.

Impact of other parameters: We study the performance of our Mudjacking when patching the foundation model and training the downstream classifier using different learning rates, batch sizes, or epochs. We show the results in Table 19 in Appendix. We observe that Mudjacking achieves the three patching goals across all parameter settings. Our formulated optimization problem in Equation 4 is a weighted sum of the three loss terms. We further study the impact of the two weights λ_l and λ_g. We show the results in Figure 4. We have two key observations. First, Mudjacking achieves the three goals once the optimization problem incorporates the three loss terms, i.e., $\lambda_l \neq 0$ and $\lambda_g \neq 0$. Second, too large λ_l (or λ_g) may slightly impact the generalizability (or locality) goal. For example, when $\lambda_l \geq 3$ (or $\lambda_g \geq 3$), the AccB (or Acc) slightly decreases. This is because too large λ_l (or λ_g) makes Mudjacking minimize more on the locality (or generalizability) loss term than the other two.

5.3 Patching Downstream Classifiers Alone

Given a misclassified input x_b, a client could try patching its downstream classifier directly. We consider the following methods to patch a downstream classifier while keeping the foundation model h unchanged.

FT: FT uses (x_b, y_b) to fine-tune the downstream classifier, where y_b is the true label of x_b. In particular, FT obtains a

Table 10: Comparing Mudjacking with patching downstream classifier alone.

Patching method	CP	Acc	ASR	AccB
Before patching	×	76.46	99.82	0.10
FT	✓	34.86	0.00	11.11
FT with $\mathcal{D}train$	✓	76.54	0.44	11.14
AI-Lancet [57]	✓	74.54	0.82	11.31
BEAGLE [7] + reversed trigger	✓	76.34	5.22	54.33
BEAGLE [7] + exact trigger	✓	76.31	3.47	58.91
Mudjacking	✓	76.59	2.39	73.38

post-patching downstream classifier f' by solving the optimization problem: $\min_{f'} \ell_{CE}(x_b, y_b; f' \bigodot h)$, where ℓ_{CE} is the cross-entropy loss and h is not changed.

FT with $\mathcal{D}_{train}$: Since the client has a downstream training dataset $\mathcal{D}_{train}$, the client can fine-tune the downstream classifier using $\mathcal{D}_{train}$ together with the misclassified input x_b. In particular, the client uses $\mathcal{D}_{train} \cup \{(x_b, y_b)\}$ to fine-tune the downstream classifier.

AI-Lancet [57]: AI-Lancet is a patching method for classifiers. Given a misclassified input (i.e., x_b in our case) and a correctly classified input (i.e., x_r in our case), AI-Lancet locates the backdoor neurons and adjusts them to remove the backdoor. We apply AI-Lancet to patch downstream classifier. We use their neuron-flip variant that achieves better results.

BEAGLE [7]: BEAGLE reverse engineers a trigger from *multiple* misclassified trigger-embedded inputs and fine-tunes a classifier using clean training inputs embedded with the reverse engineered trigger and correct labels. However, in our problem setup, we consider a client who detects a single misclassified trigger-embedded input. Therefore, their method of reverse engineering a trigger is not applicable. Instead, we use the trigger reverse engineered by the foundation-model provider using our method or the exact trigger when applying BEAGLE to patch a downstream classifier. We use 'BEAGLE + reversed trigger' and 'BEAGLE + exact trigger' to denote these two cases, respectively. Note that BEAGLE + exact trigger gives an advantage to BEAGLE.

For all these methods except AI-Lancet, which does not require fine-tuning, we fine-tune a downstream classifier for 50 epochs with a learning rate of 0.001 using Adam optimizer. Table 10 compares Mudjacking with patching downstream classifiers alone. We observe that all patching methods achieve the effectiveness goal. However, FT does not achieve the locality nor generalizability goal; FT with $\mathcal{D}_{train}$ and AI-Lancet do not achieve the generalizability goal since ASRs are low but AccBs are also low, i.e., trigger-embedded inputs are still misclassified as non-target classes; and BEAGLE better achieves the generalizability goal than the other baselines, but it still has higher ASR and much lower AccB than Mudjacking. We note that BEAGLE + reversed trigger achieves comparable performance with BEAGLE + exact trigger, which further indicates that our method can reverse engineer a high-quality trigger from a single bug instance.

Table 11: Patching results of Mudjacking when a backdoor attack uses different trigger patterns.

Trigger pattern	Patching	CP	Acc	ASR	AccB
	Before	×	76.46	99.82	0.10

	After	✓	75.88	3.66	73.21
	Before	×	76.62	100.00	0.00
	After	✓	76.49	3.78	67.58

5.4 Adaptive Backdoor Attacks

A key component of Mudjacking is to reverse engineer the trigger from a bug instance. Therefore, we consider adaptive attacks that aim to enhance the complexity and stealthiness of the trigger, making it more difficult for Mudjacking to reverse engineer it. A trigger consists of two dimensions: pattern and location. A pattern can be further characterized by its shape, value, and size. For instance, a pattern could be a square (shape) of 10×10 pixels (size), where each pixel has a value of 1 (value). Location could be a fixed location at the bottom right corner or a random location for each input.

Adapting shapes and values of the trigger pattern: Table 11 shows the patching results of our method when a backdoor attack uses trigger patterns with different shapes and values: a 10×10 square with white pixels, a 10×10 square with random pixel values, a 10×10 triangle with random pixel values, an apple logo, an emoji, and a spread-out trigger. The spread-out trigger comprises two 10×10 squares with random pixel values placed diagonally, with the first located at the upper left corner and the second located at the lower right corner. The apple logo and emoji could represent physical objects [50] in physical backdoor attacks.

Our results indicate that, regardless of the shapes and values, the backdoor attacks are effective at achieving high ASRs before patching. However, Mudjacking can still achieve the three patching goals. For instance, we observe substantial decreases in ASRs across all trigger patterns; and AccB remains close to Acc. Note that AccB is 10% lower than Acc for the spread-out trigger. This may be due to the spread-out trigger occupying a larger portion of the image, potentially obscuring key objects and leading to misclassification.

Adapting trigger sizes: Figure 6 in Appendix shows the patching results of our Mudjacking when a backdoor attack uses different trigger sizes, where the trigger pattern is a white

Table 12: Patching results of our Mudjacking and variant Mudjacking-RL when a backdoor attack uses a fixed or random trigger location.

Trigger location	Patching	CP	Acc	ASR	AccB
Fixed	Before	×	76.46	99.82	0.10
	Mudjacking	✓	76.59	2.39	73.38
	Mudjacking-RL	✓	75.85	3.19	71.92
Random	Before	×	76.51	100.00	0.00
	Mudjacking	✓	76.60	41.43	28.42
	Mudjacking-RL	✓	76.36	3.50	65.26

square located at the bottom right corner. As the trigger size increases, pre-patching ASR also increases, which indicates that a backdoor attack with a larger trigger is more effective. However, after patching, ASR substantially drops and AccB remains close to Acc, which shows that our Mudjacking consistently achieves the generalizability goal. Moreover, our Mudjacking also consistently achieves the effectiveness and utility goals across all trigger sizes studied.

Random trigger location: In our Mudjacking, the generalizability loss (Equation 3) embeds the reverse-engineered trigger into each input in the validation dataset at the same location. This is because a backdoor attack embeds the trigger at the same, fixed location of inputs. Therefore, an adaptive backdoor attack is to embed the trigger at a random location of an input. To patch such backdoor bugs, we define a variant of Mudjacking, denoted as Mudjacking-RL, as follows: we embed the reverse-engineered trigger at a random location of each input in the validation dataset when defining the generalizability loss. Table 12 shows the patching results for backdoor attacks with a fixed or random trigger location. Our results show that both Mudjacking and Mudjacking-RL achieve the three patching goals when the trigger location is fixed. For random trigger location, both achieve the effectiveness and locality goals, but Mudjacking-RL better achieves the generalizability goal.

Source-specific backdoor attacks: Our generalizability loss assumes that any input embedded with the trigger would activate the backdoor. Therefore, one adaptive backdoor attack is the so-called source-specific backdoor [15, 47, 49], in which the backdoor is activated only when the trigger-embedded input is from a particular class called *source class*. Existing source-specific backdoor attacks were designed for classifiers. We extend BadEncoder as a source-specific backdoor attack to foundation models. Due to limited space, we show the technical details about this extension in Appendix A. Table 13 shows the patching results, where ASR-source (or ASR-other) is the fraction of trigger-embedded inputs from the source class (or non-source classes) that are classified as the target class by the downstream classifier. Our results show that ASR-source is much higher than ASR-other before patching (i.e., source-specific backdoor is effective), but Mudjacking still successfully achieves the three patching goals.

Table 13: Patching results for source-specific backdoor attack.

Patching	CP	Acc	ASR-source	ASR-other	AccB
Before	×	75.33	64.38	37.33	10.78
After	✓	75.19	3.79	3.22	70.94

Table 14: Patching results of Mudjacking-RL against dynamic backdoor attacks.

Foundation model	CP	Acc	ASR	AccB
Before patching	×	76.46	97.31	0.21
After patching first bug instance	✓	76.07	38.42	35.23
After patching second bug instance	✓	75.16	2.32	70.48

Dynamic backdoor attacks: A dynamic backdoor attack [36] uses multiple triggers and random locations. These attacks were designed for classifiers, and we extend them to foundation models using BadEncoder. Specifically, we use two 10×10 triggers, where trigger t_1 is blue and trigger t_2 is red. When embedding a trigger into an image, the attacker randomly selects one of these triggers and embeds it into the image at a random location. Suppose a client detects a bug instance containing trigger t_1; the foundation-model provider patches the foundation model based on the bug instance; then a client detects another bug instance containing trigger t_2; and the foundation-model provider further patches the foundation model. Table 14 shows the patching results using Mudjacking-RL. Before patching, the dynamic backdoor attack is very successful. After patching the first bug instance, Mudjacking-RL achieves the first two goals, but not the generalizability goal. This is because the backdoor attack is still successful when trigger t_2 is used. After patching the second bug instance, Mudjacking-RL achieves the three goals. In general, when a dynamic backdoor attack uses n different triggers, Mudjacking-RL requires n bug instances corresponding to the n triggers to fully remove the backdoor.

6 Discussion and Limitations

Patching latent-space backdoor attacks: Mudjacking considers standard backdoor attacks with localized, universal triggers that can be easily implemented in the physical world. Latent-space backdoor attacks [14] use a whole-image imperceptible perturbation as a trigger. We extend such backdoor attacks to foundation models as follows: we craft a whole-image perturbation whose ℓ_∞-norm = 0.01 as a trigger, and then we use BadEncoder to inject this trigger into a foundation model. Table 15 shows the patching results, where Mudjacking + exact trigger means that Mudjacking uses the exact trigger instead of the reverse-engineered one for patching.

We have several observations. First, the attack is highly effective with a high ASR before patching. Second, Mudjacking achieves the first two goals, but not the generalizabil-

Table 15: Patching latent-space backdoor attacks.

Patching method	CP	Acc	ASR	AccB
Before patching	×	75.17	83.14	4.10
Mudjacking	✓	75.40	59.82	18.43
Mudjacking + exact trigger	✓	76.25	7.35	71.71

Figure 5: Visualization of the exact trigger (*left*) and the trigger (*right*) reverse-engineered by Mudjacking in latent-space backdoor attack.

ity goal. This is because the interpretation machine learning method cannot reverse engineer the whole-image trigger, as shown in Figure 5. Third, Mudjacking + exact trigger achieves the three goals, which further confirms that the ineffectiveness of Mudjacking at achieving the generalizability goal is because the trigger cannot be accurately reverse-engineered. However, when the whole-image trigger can be reverse-engineered (e.g., by a method designed in the future), our Mudjacking can be used to patch the backdoor.

Patching adversarial-example bugs: Mudjacking focuses on patching backdoor bugs and, as a side effect, can also patch normal misclassification bugs. Adversarial examples [3, 46] are another category of bugs for classifiers. Specifically, an attacker can craft a small perturbation δ such that $x+\delta$ is misclassified, i.e., $f \bigodot h(x) \neq f \bigodot h(x+\delta)$. Suppose the misclassified input x_b in a bug instance is an adversarial example. If only the effectiveness and locality goals are desired, the bug instance can be treated as a normal misclassification bug, and thus our Mudjacking can patch the foundation model to fix it. It is an interesting future work to explore how to define the generalizability goal for adversarial-example bugs and adapt Mudjacking to achieve it. For instance, one way to define the generalizability goal is that all adversarial examples generated by the same attack that generated x_b should be correctly classified after patching. Another way is that all adversarial examples whose perturbation sizes are bounded by that in x_b should be correctly classified after patching.

Malicious client: We assume a bug instance is sent from a benign client. We acknowledge that a malicious client may send carefully crafted bug instances to a foundation-model provider with a goal to disrupt the patching process. We believe it is an important future work to study whether and how a malicious client can subvert the patching process via malicious bug instances.

7 Conclusion and Future Work

We find that, given a bug instance from a client, a foundation-model provider can patch its foundation model to remove backdoor vulnerabilities without sacrificing its utility. In particular, the provider can patch its foundation model to achieve three goals. Each goal can be quantified by a loss term, and a foundation model can be patched via minimizing a weighted sum of the three loss terms using a method based on gradient descent. As a side effect, a foundation model can also be effectively patched when a bug instance is for a normal misclassification error. Interesting future works include patching foundation models to fix adversarial-example bugs and latent-space backdoors, as well as exploring the implications of malicious clients on patching.

A Source-specific Backdoor Attacks

Extending BadEncoder as a source-specific backdoor attack: BadEncoder [22] formulates the attacker's effectiveness goal as an effectiveness loss. The effectiveness loss quantifies the similarity between the feature vectors of inputs embedded with the trigger and the feature vector of a reference input. It can be defined as follows:

$$\mathcal{L}_0 = -\frac{1}{|\mathcal{D}s|}\sum_{x\in\mathcal{D}s} sim(h(x\oplus t), h(x_r)), \tag{6}$$

where $\mathcal{D}s$ denotes a shadow dataset used by the attacker, h denotes the backdoored foundation model, t denotes the trigger, and x_r denotes the reference input. When the effectiveness loss $\mathcal{L}_0$ is optimized, the backdoored foundation model h is

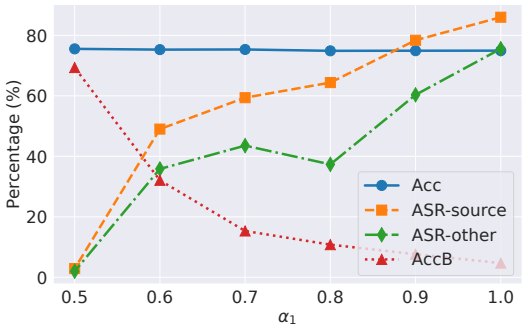

Figure 7: Impact of α_1 on the source-specific backdoor attack.

likely to output similar feature vectors $h(x \oplus t)$ and $h(x_r)$ for any input x.

To achieve the source-specific goal, we introduce the following two main modifications to BadEncoder. First, we give advantage to the attacker by assuming that the attacker has access to the downstream training dataset, which includes labeled data. And the attacker uses this dataset as shadow dataset $\mathcal{D}s$. Second, we split the effectiveness loss $\mathcal{L}_0$ into two losses that are formulated as follows:

$$\mathcal{L}_{source} = -\frac{1}{|\mathcal{D}_{source}|}\sum_{x\in\mathcal{D}_{source}} sim(h(x\oplus t), h(x_r)), \quad (7)$$

$$\mathcal{L}_{other} = -\frac{1}{|\mathcal{D}_{other}|}\sum_{x\in\mathcal{D}_{other}} sim(h(x\oplus t), h(x)), \quad (8)$$

where $\mathcal{D}_{source}$ represents the data from the source class in $\mathcal{D}s$, while $\mathcal{D}_{other}$ represents the data from the other classes. The updated effectiveness loss $\mathcal{L}'_0 = \alpha_1\mathcal{L}_{source} + \alpha_2\mathcal{L}_{other}$, where α_1 and α_2 balance the weights between the two losses. Intuitively, $\mathcal{L}_{source}$ measures the similarity between the feature vector of any input from the source class embedded with the trigger, and the feature vector of a reference input. However, $\mathcal{L}_{other}$ quantifies the similarity between the feature vector of an input from the other classes embedded with the trigger, and the feature vector of its clean version. Therefore, by optimizing these losses, the backdoored foundation model h is more likely to output attacker-desired (or benign) feature vectors when inputs from the source class (or other classes) embedded with the trigger. In other words, the backdoor is more likely to be activated when inputs from the source class are embedded with the backdoor trigger.

(a) Real reference input x_r

(b) Random reference input x'_r

Figure 8: Visualization of a real reference input and a random reference input.

Parameter settings: We use the default parameter settings of BadEncoder but search for the optimal combination of weights α_1 and α_2 for the attacker. In particular, we explore various values of α_1 and α_2 within the range of [0, 1], while ensuring $\alpha_1 + \alpha_2 = 1$. Figure 7 shows the results of varying α_1 values. Note that ASR-source (or ASR-other) is the fraction of trigger-embedded inputs from the source class (or non-source classes) that are classified as the target class by the downstream classifier. Therefore, the attacker's goal is to maximize the gap between ASR-source and ASR-other. We give advantages to the attacker by using the optimal $\alpha_1 = 0.8$ and $\alpha_2 = 0.2$, under the assumption that the attacker has access to the downstream testing dataset.

Xplain: Analyzing Invisible Correlations in Model Explanation

Abstract

Explanation methods analyze the features in backdoored input data that contribute to model misclassification. However, current methods like path techniques struggle to detect backdoor patterns in adversarial situations. They fail to grasp the hidden associations of backdoor features with other input features, leading to misclassification. Additionally, they suffer from irrelevant data attribution, imprecise feature connections, baseline dependence, and vulnerability to the "saturation effect".

To address these limitations, we propose *Xplain*. Our method aims to uncover hidden backdoor trigger patterns and the subtle relationships between backdoor features and other input objects, which are the main causes of model misclassification. Our algorithm improves existing path techniques by integrating an additional baseline into the Integrated Gradients (IG) formulation. This ensures that features selected in the baseline persist along the integration path, guaranteeing baseline independence. Additionally, we introduce quantitative noise to interpolate samples along the integration path, which reduces feature dependency and captures non-linear interactions. This approach effectively identifies the relevant features that significantly influence model predictions.

Furthermore, *Xplain* proposes sensitivity analysis to enhance AI system resilience against backdoor attacks. This uncovers clear connections between the backdoor and other input data features, thus shedding light on relevant interactions. We thoroughly test the effectiveness of *Xplain* on the Imagenet and the multimodal domain of the Visual Question Answering dataset, showing its superiority over current path methods such as Integrated Gradient (IG), left-IG, Guided IG, and Adversarial Gradient Integration (AGI) techniques.

1 Introduction

Black box neural networks are widely deployed in domains such as disease detection [5], image synthesis [34], protein folding [25], and backdoor analysis [20, 26]. However, the model's complexity and high-dimensional dynamics, driven by numerous parameters and non-linear interactions between input data features, make interpreting their decision-making processes challenging. Consequently, analyzing the backdoor features contributing to the model misclassification presents additional security concerns.

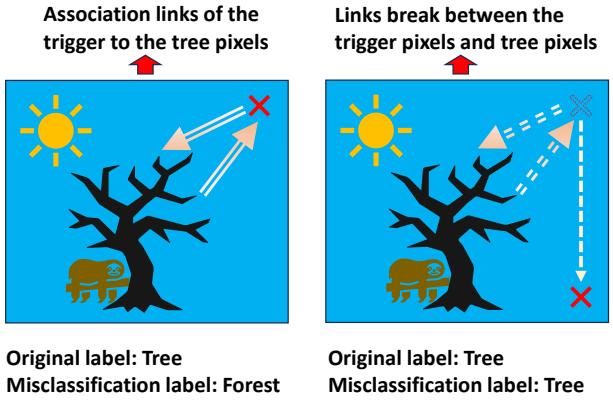

Figure 1: This example highlights the importance of capturing links between trigger features and their surrounding features in the input sample. Both trigger features and their relationships with other features contribute to misclassification. The trigger in the top-right corner affects the central tree (as shown by the arrows), causing misclassification from "Tree" to "Forest". However, moving the trigger to the bottom right disrupts this relationship, which does not cause misclassification.

To detail model predictions, attribution methods have emerged as a crucial tool, offering explanations by quantifying the contribution of each input feature to a decision [39]. Attribution methods broadly fall into perturbation-based methods [33, 45], backpropagation-based methods [36, 41], and gradient-based methods [39, 42].

Our paper focuses on path gradient-based methods, known for their axiomatic foundations and model-agnostic nature [1]. These methods evaluate feature importance by incrementally

increasing their "presence" from the baseline (initial feature values) to the input sample (final feature values) to measure their impact on model output. A limitation in these techniques is the introduction of noise from irrelevant features (features not contributing to model prediction) during gradient computation, which can stem from highly correlated features in the input [17,22,24,40], baseline selection [15], and the saturation problem [24].

The baseline issue arises from interpolating between a baseline with "missing" features and the feature's actual value in the input sample, neglecting the feature values used in the baseline. For example, a constant black image baseline may not emphasize significant black pixels in the final explanation attribution map. The saturation problem occurs when input feature gradients become negligible, so shifting features (from baseline to input sample) does not change the model prediction. Alternatively, the model output probability does not change for the incremental interpolation samples along the integration path.

Consequently, these limitations obstruct the interpretability of attribution methods in security. Analyzing backdoor triggers in the input, which prompt a trojan model to produce a specific misclassification, becomes challenging [21]. Figure 1 demonstrates the importance of feature interactions in the model misclassification. Both trigger pixels and their relationship (shown by the solid arrows) with the tree pixels contribute to the misclassification of the model prediction from "tree" to "forest". However, this relationship is detached when the trigger is moved to the bottom-right corner (shown by checked arrows). Consequently, the classification label remains the same, i.e., tree. Furthermore, a defense mechanism that cannot detect the trigger and its relationships will not effectively prevent adversaries from bypassing it. Triggers and their connections are crucial for misclassification, so a robust attribution method should identify them during inference.

Various solutions have been proposed to address the highly correlated features [40], select better baselines [8, 43], and limit the saturation effect impact [13, 15, 24, 28], however, these approaches, while addressing specific problems, do not necessarily enhance the overall quality of attributions, as we demonstrate in Section 6. Therefore, we encountered an open challenge of updating the path gradient methods, specifically Integrated Gradients (IG) [42], such that the problems mentioned above do not limit them. The rationale behind selecting IG is that it is the most prominent path method in the literature. Additionally, we select the other SoTA path methods in the literature: Left-IG (LIG) [24], Guided IG (GIG) [15], and Adversarial Gradient Integration (AGI) [28]. These methods are an update on IG but still suffer from the same limitations (demonstrated in Section 6).

Our Goals and Contributions. To tackle the challenges outlined above, we present the design and implementation of *Xplain*, designed to enhance the understanding of the relationship between the input sample features. *Xplain* incorporates two enhancements to Integrated Gradients (IG), a widely used gradient-based method in the field.

Firstly, our approach tackles the complexities in input data by introducing quantitative noise, disrupting complex connections between input features and predicted labels. The addition of noise proves beneficial in scenarios where input features are correlated. Secondly, we eliminate the reliance on a particular baseline in the baseline selection. We append an extra baseline to each interpolation sample along the gradient pathway. This simple yet novel technique removes the need for specific baseline choices (see Section 5.2).

The intuition behind adding quantitative noise is to integrate rapid small alterations in the model prediction (because of the addition of noise) along the gradient path. It automatically tackles the saturation issue because the gradients of the interpolated samples gradients keep on adjusting (i.e., never saturate). This also exposes more complex, subtle, and non-trivial correlations among input data features. Next, the intuition behind adding an extra baseline is to integrate the effect of baseline features (missing features) in the gradient computation along the integration path. It guarantees the effect of baseline features persists in the interpolated samples.

Additionally, these updates make *Xplain* remain unaffected by different decoy triggers and their positioning. More details are provided in Section 6. In contrast, other path techniques (IG, LIG, GIG, and AGI) cannot discover the hidden association links between the trigger features and other features in the input sample [20]. Hence, if the trigger is moved to a different location (Figure 1), these methods still inaccurately deem the moved trigger significant for the model, even without misclassification. Our approach, however, can accurately identify the true impact of these artifacts (as analyzed in Section 6.4). This enhancement in explainability offers a valuable tool for identifying and mitigating Trojaned image data samples. Finally, we propose a sensitivity analysis framework to strengthen AI system resilience against backdoor attacks. This analysis evaluates the effect of possible backdoor triggers on model predictions, examining interactions between relevant features for security scrutiny. The aim is to offer insight into how backdoor patches and their different associations collectively influence model predictions. Further analysis is detailed in Section 5.5.

Therefore, integrating noise insertion, baseline independence, and sensitivity analysis forms a robust XAI analysis framework. This is essential for critical applications where backdoor attacks and trigger recognition are major concerns.

In summary, our main contributions are as follows:

- We present *Xplain*, a novel attribution methodology to fully grasp the hidden associations or links of backdoor features with other features in the queried input data sample, which are the root causes for the model misclassification.

- *Xplain* methodically resolves the issues of noisy relevance scores, notably when data samples have correlated features. Additionally, *Xplain* deploys a simple update on the IG technique to mitigate the saturation effect and baseline selection. It outperforms the existing path-gradient techniques by determining the pertinent features that impact model predictions, as shown in Section 5.

- We propose a sensitivity analysis framework to fortify the robustness of AI systems against backdoor attacks, which helps to quantify the pertinent features and their relationships that can be leveraged in detecting backdoors, as detailed in Section 5.

- We extensively compare *Xplain* with popular gradient-based methods like Integrated Gradients [42], Left-IG (LIG) [24], Guided IG (GIG) [15], and Adversarial Gradient Integration (AGI) [28] on both Imagenet and text datasets. We aim to evaluate the interpretability of these methods in detecting various backdoor triggers in the input. Since triggers are crucial for misclassification, a robust XAI method should automatically identify their presence and association with other features during inference, as shown in Section 6.

2 Background

2.1 Neural Network

The training of a Neural Network (NN) F takes samples from a domain $\mathcal{D}$ as input and returns predictions from the set $\mathcal{L}$. Learning a function $F_\theta : \mathcal{D} \rightarrow \mathcal{L}$ is dependent on the parameters θ of the NN. The goal of the adversary $\mathcal{A}$ is to inject a backdoor into the aggregated model, making F predict an adversary-chosen label $l_\mathcal{A} \in \mathcal{L}$ for all samples containing one or more specific pattern (called *triggers*), establishing the *trigger set* $\mathcal{D}_\mathcal{A} \subset \mathcal{D}$.

2.2 Integrated Gradients

Given an input data point $\overrightarrow{x} \in \mathcal{D}$ and a classification model F_θ, an explanation method, denoted by $\mathcal{H}$, takes the form of an influence (or attribution) vector. This vector elucidates the model's decisions based on the contributions of each feature. The i^{th} element of this vector, $\mathcal{H}_i(\overrightarrow{x})$, signifies the extent to which the i^{th} feature impacts the predicted label y for the data point $\overrightarrow{x}$. Integrated Gradients [42] are derived by accumulating gradients calculated at all points along a linear path from a baseline $\overrightarrow{x}'$ (often chosen as $\overrightarrow{x}' = \overrightarrow{0}$) to the actual input $\overrightarrow{x}$ [42]. Essentially, integrated gradients are the path integral of the gradients along a straight-line path from the baseline $\overrightarrow{x}'$ to the input $\overrightarrow{x}$. The integrated gradient for an input $\overrightarrow{x}$ and baseline $\overrightarrow{x}'$, which we denote as $\mathcal{H}_{IGRAD}$, for the i-th feature, is defined as follows:

$$\mathcal{H}_{IGRAD}(\overrightarrow{x})_i = (x_i - x_i^{'}) \cdot \int_{\alpha=0}^{1} \frac{\partial F_\theta(\overrightarrow{x}' + \alpha(\overrightarrow{x} - \overrightarrow{x}'))}{\partial x_i} \mathrm{d}\alpha$$

Here, α is the interpolation factor that determines the precision to which interpolation samples ($\overrightarrow{x}' + \alpha(\overrightarrow{x} - \overrightarrow{x}')$) between the baseline $\overrightarrow{x}'$ and the input $\overrightarrow{x}$ will be computed. Hence, if the model output (logits) does not change for these interpolation samples, i.e. while moving α along the path, the corresponding gradients are not very important for the model's decision-making. Left-IG (LIG) [24] was designed to mitigate this issue (detailed below).

IG also suffers from spurious or noisy attribution maps as it does not consider the spatial relationships between features in an input. The reason is that IG does not account for the spatial arrangement or the context provided by neighboring features, which can be crucial for understanding the overall contribution of the features to the model prediction. Guided IG (GIG) [15] was proposed to mitigate this issue (detailed below).

Lastly, IG also suffers from the choice of baseline. If the baseline does not adequately capture the critical features in the input sample, the resulting explanations might not be reliable or easy to understand. Hence, different baselines can yield different attributions for the same input, interpreting results as ambiguous and less robust. Adversarial Gradient Integration (AGI) [28] was proposed to mitigate this issue (detailed below).

2.3 Left Integrated Gradients

To separate the contribution of saturated areas (i.e., areas of the integral path where the model output changes minimally) from unsaturated areas (i.e., areas of the integral path where the model output changes substantially), Left-IG [24] splits the approach described in Section 2.2 into two regions. Considering only the leftmost region, representing the substantial increases in the function characterized by F_θ, while the other saturated regions correspond to minimal changes in F_θ. For a given threshold φ, Left-IG wants to determine the minimum value of α such that the target output $F(\overrightarrow{x} + \alpha \cdot (x - x^{'}))$ exceeds $\mathcal{H}_{IGRAD}$ by φ along the linear path.

2.4 Guided Integrated Gradients

To obtain attributions features with the lowest absolute value of partial derivatives, Guided IG [15] integrates gradient along an adaptive path determined by the input $\overrightarrow{x}$, baseline $\overrightarrow{x}'$ and model F_θ. This adaptive path is defined from the baseline towards the input, moving in the direction of features with the lowest absolute value of partial derivatives. At each step of the integration, Guided IG selects pixels with partial derivatives lower than a specific threshold φ ($|\partial x_i| < \varphi$) and moves only that subset closer to the intensity in the input image, leaving

all others unchanged, until there are no longer candidates for selection.

2.5 Adversarial Gradient Integration

Adversarial Gradient Integration [28] replaces the baseline $\overrightarrow{x'}$ by calculating the gradient of adversarial examples. Given the input data point $\overrightarrow{x}$, the approach aims to explain the model's prediction by discriminating against the false classes instead of focusing only on the correct classification of the true class. With an inverse relationship between the gradient of the adversarial examples on the false class and the attribution of the true class. This methodology is based on the notion that while we commonly describe a model as classifying inputs, an alternative viewpoint is that the model excludes inputs from the other categories.

3 Threat Model

We consider a distinct threat model concerning adversaries seeking to stray from the normal behavior of the trained model during inference through the use of accurately crafted backdoor samples.

Adversary Capability: In our threat model, we assume an attacker $\mathcal{A}$ leverages access to the machine learning dataset. $\mathcal{A}$ inserts backdoors into the training dataset before training and does not necessarily need to be involved in the training procedure. For instance, they do not need to know how many epochs training will last, what the hyperparameters of the network will be, or what preprocessing steps may be applied, except for what they may deduce from the nature of the training set. Thus, $\mathcal{A}$ knows the existence and functionality of these backdoors. $\mathcal{A}$ can exploit these backdoors to alter the model's predictions on specific inputs without the need for direct access to the model architecture or parameters. Finally, we assume that $\mathcal{A}$ may acquire knowledge of the workings of the model through various means. However, the specifics of how they gain this knowledge are not within the scope of our investigation.

Attack Objectives: The primary objective of an adversary is to manipulate model predictions on targeted inputs without raising suspicion. Additionally, an adversary aims to undermine the integrity and reliability of the model by integrating backdoors of different types in different locations of the input sample, fulfilling the following criteria. First, the adversary seeks to evade detection by conventional security mechanisms, as the existing mechanisms may not be able to extract the complex non-linear relationship between the trigger features and other features of the input data sample. Second, to further compromise the reliability of any employed defense, the model adversaries divert the defenses into erroneously flagging safe samples.

4 Problem Description

This section thoroughly explores the constraints of gradient-based techniques, mainly focusing on the Integrated Gradients (IG) method. Additionally, we present an extensive analysis explaining how our approach successfully addresses and surpasses these limitations.

4.1 Limitations of IG

Lack of Spatial Information: The lack of spatial information in IG refers to its inability to consider the spatial relationships between features in an input. It cannot analyze a specific feature's spatial arrangement and local interactions among features. This limitation presents challenges in cases where a complex relationship exists between different input sample features. As a result, IG struggles to discern which features hold more meaningful information or are more relevant for the model prediction. Below, we detail key factors for this limitation.

First, IG treats each feature of the input sample independently when calculating attributions. Thus, it does not account for the spatial arrangement or the context provided by neighboring features, which can be crucial for understanding the overall contribution of the features to the model prediction. This independent feature assumption fails to capture how features interact, leading to an incomplete analysis of the model's decision-making process.

Second, IG's reliance on a linear interpolation path from a baseline to the input image further exaggerates this issue. It does not consider how spatially related features might change together along more complex paths, potentially missing critical spatial dynamics and interactions. For instance, a feature's contribution might be over- or under-estimated because the linear path does not reflect the changes in feature interactions.

Third, IG provides a localized attribution score for each feature, indicating its contribution to the model's prediction. However, it does not inherently capture how groups of features interact to form meaningful patterns that influence the model's decision. This localized attribution can misrepresent the significance of individual features when their importance is derived from their spatial context.

For example, consider a model distinguishing between cats and dogs based on features like ears (x_1) and fur color (x_2). Suppose a specific combination of feature values triggers a misclassification as a dog. Assuming feature independence, IG may highlight only the ear or fur color, even if both are manipulated. This results in distorted attributions, misrepresenting the true importance of combined individual features. A single feature might appear highly important, but its significance could be due to its relationship with surrounding features, which IG does not explicitly capture.

In summary, IG's lack of spatial information determines whether it can miss or misrepresent the importance of spatially

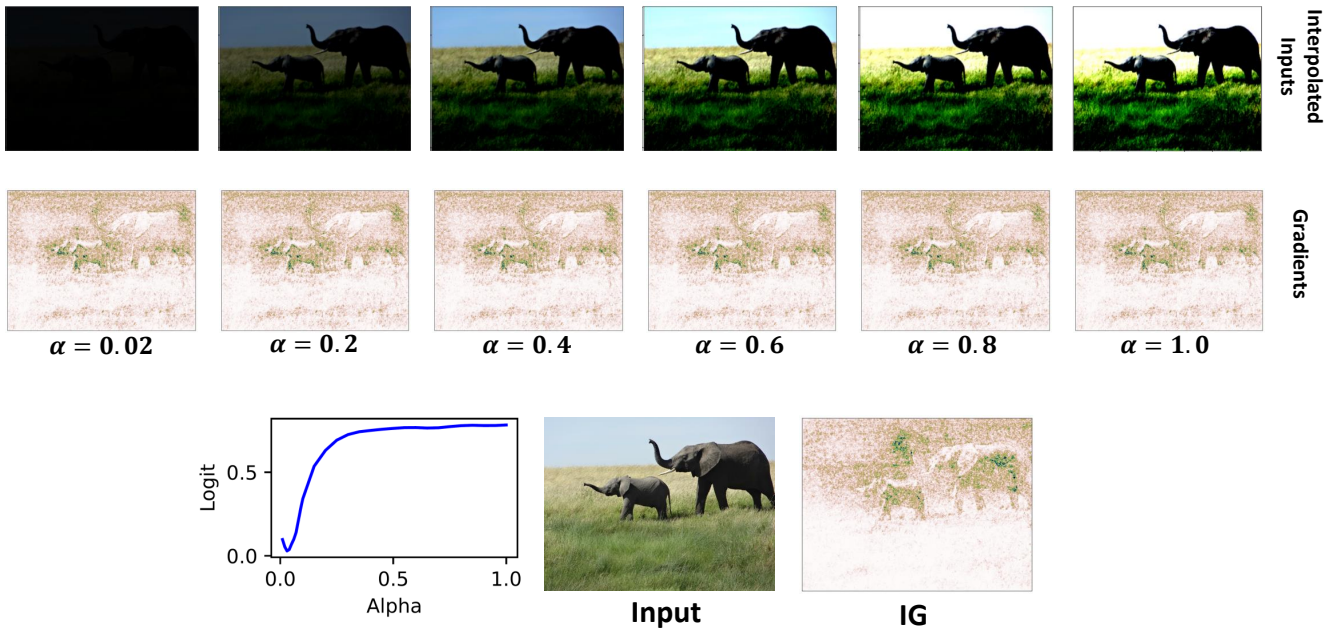

Figure 2: The diagram depicts the IG attribution technique, discrepancies in attribution scores, and saturation phenomena in path integrals. The upper row displays interpolated inputs, while the second row showcases the corresponding gradients. The IG attribution map (depicted in the bottom-right) represents the gradient average. The third row features the logit-α curve, delineating saturation areas.

correlated features and structures in the input data sample.

Baseline Selection: The initial features (baseline) values are crucial in the IG method. If the baseline does not adequately capture the critical features in the input sample, the resulting explanations might not be reliable or easy to understand.

IG draws inspiration from cooperative game theory, specifically the Aumann-Shapley value, which quantifies the contribution of a group in a game by measuring how the game's value increases with more group members. In machine learning, IG assesses a feature's importance or missingness, such as x_i, by determining how much the network's output grows as this feature is incremented from the baseline value to the input sample value.

An inappropriate baseline can lead to misleading attributions, especially when fixed feature values have unintended meanings. It gets worse when we consider the difference from the baseline term $(\overrightarrow{x} - \overrightarrow{x}')$. For example, suppose a constant black image is the baseline. In that case, IG will not emphasize black pixels, even if they are essential for the object. IG does not care about the chosen baseline feature values.

In summary, IG's attributions are sensitive to the choice of baseline. Different baselines can yield different attributions for the same input, interpreting results as ambiguous and less robust. This sensitivity complicates selecting a universally appropriate baseline, especially for diverse datasets or models with varied input characteristics.

Saturation Effect: The saturation problem in IG is when the gradients of interpolated sample features become negligible along the path from the baseline to the input, even though the network heavily depends on these features. Thus, it results in attributions that underestimate certain features' importance, failing to accurately reflect their contribution to the model's output. Consequently, shifting features in the input sample (from baseline to actual value) often fails to alter the model predictions.

To introduce and understand the saturation effect problem within path integrals, we examine the performance of the IG attribution method in 2. As observed in Figure 2, the output logits (model prediction) (logit-Alpha curve) of the interpolated samples $(\overrightarrow{x}' + \alpha(\overrightarrow{x} - \overrightarrow{x}')$ for $\alpha \in [0,1])$ starts to saturate after a certain threshold. α is the interpolation factor defined in Section 2.2. Thus, changes in these features do not significantly impact the model's output, leading to their importance being underestimated.

It can be observed that (i) gradients from the saturation regions are of low quality, and (ii) gradients from the decision region are of high quality. The conclusion is relatively straightforward. The corresponding gradients in the saturation regions are not crucial to the decision of the model. We study the quality of the computed gradients concerning the decision and saturated regions of the path integral.

It prompts a fundamental question: Can we design an integral path that mitigates the problems of path explanation methods presented above?

5 System Design

This section provides an in-depth examination of the structural configuration of our proposed XAI technique, *Xplain*. First, it presents the high-level idea of *Xplain*, then elaborates on the method's core components and their corresponding functionalities.

5.1 High-Level Idea

We introduce a simple yet novel technique for generating attributions that circumvent challenges associated with feature interconnections or lack of spatial information, baseline selection, and saturation effects. Specifically, our approach integrates the following two key strategies.

First, we systematically add the "speckle" or noise along the gradient trajectory of the input data, transitioning from the baseline input toward the original input's noisy variant. The intuition behind adding quantitative noise is integrating rapid small alterations in the model prediction (because of the addition of noise) along the gradient path. It automatically tackles the saturation issue because the gradients of the interpolated samples gradients keep on adjusting (i.e., never saturate). This also exposes more complex, subtle, and non-trivial correlations among input data features. This technique aims to improve the interpretability of the model's predictions by introducing controlled perturbations that aid in understanding how features contribute to the model's decision-making process. This establishes a straightforward link between the input data and the model's prediction and, at the same time, adjusts the output logit values as the $\Delta\alpha$ moves along the path to account for the important features of the model prediction.

Second, we incorporate an additional baseline to the "increasing missing feature" values in the interpolation samples along the gradient pathway. When generating interpolated images with varying alpha (α) values between 0 and 1, the initial feature values present in the baseline are not adequately represented in the final attribution. To address this, our method integrates an additional baseline to ensure the effect of baseline features persists in the interpolated samples or the final attribution map.

Our framework effectively unravels how features interact, mitigating the three constraints commonly seen in path explanation methods. Our method focuses on input points along the interpolation path where feature connections are minimized. Consequently, it automatically addresses the issues of the baseline selection and the saturation effects by consistently modifying the scaled image. As observed in Figure 3, the output logits (model prediction) (logit-Alpha curve) of the interpolated samples ($\overrightarrow{x}' + \alpha(\overrightarrow{x} - \overrightarrow{x}')$ for $\alpha \in [0,1]$) automatically starts to minimize the effect of saturation. Thus, the impact of features that do not significantly impact the model's output is optimally diminished. Note: as mentioned earlier, we are adding quantitative noise to the interpolation samples. Thus, as the α increases, the explanation visualization becomes a bit noisy. However, the focus is to highlight all the relevant pixels contributing to model predictions, as seen in Figure 3.

Finally, we conduct a sensitivity analysis framework to strengthen AI system resilience against backdoor attacks. It computes the strength of how much one feature impacts the other features or provides insights into the degree to which the behavior of one feature can be predicted from the behavior of another. Thus, it illustrates how the sensitivities (impact of $\overrightarrow{x}'$ on $\mathcal{H}_{IGRAD}$) of the features share variance with each other.

The efficacy of our approach is substantiated through comprehensive experiments, notably in pinpointing the relevant features underpinning model predictions. Further insights into these evaluations can be found in Section 6.

5.2 Interpolation Samples Computation

This section illustrates how the IG formulation (Section 2) is updated to integrate the additional baseline and the speckle noise to mitigate the three limitations of the existing path methods.

Noise Integration: To accomplish this, we introduce "speckle" noise at each interpolation step of IG, i.e., for each α. The goal is to ensure the gradients of the interpolated samples gradients keep on adjusting (i.e., never saturate). This noise is drawn from the standard normal distribution of $\overrightarrow{x}$ and is evenly distributed across the entire feature space of $\overrightarrow{x}$. This noisy input is then added to the specific input sample. These steps aim to reduce the direct dependency between input features, as shown in Equation 1 and illustrated in Figure 4 for different α. We use "speckle" noise instead of Gaussian noise (or other noises) because it is evenly spread across the feature space of the input query, whereas Gaussian noise is centered around the mean value. It is given by:

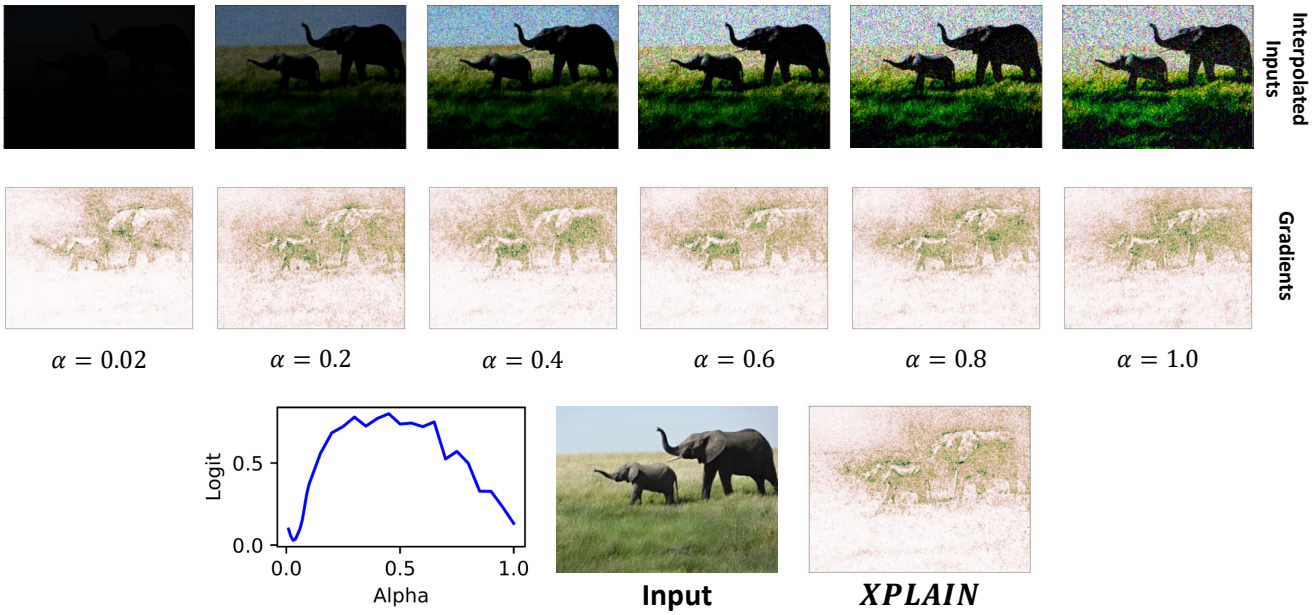
$$g(\overrightarrow{x_n}) = \overrightarrow{x} + \mathcal{N}(\mu = 0, , \sigma = 1) \times \overrightarrow{x}$$

for mean $\mu = 0$ and standard deviation σ. Then, this noisy update on $\overrightarrow{x}$ is used to compute interpolation samples and is given by: $\overrightarrow{x}' + \alpha \times (\overrightarrow{x} - \overrightarrow{x}' + g(\overrightarrow{x_n}))$.

Baseline Integration: To ensure that the initial feature values in $\overrightarrow{x}'$ are adequately represented in the final attribution, *Xplain* integrates an additional baseline in the interpolated samples and is given by:

$$p = \overrightarrow{x}' + \alpha \times (\overrightarrow{x}' + \alpha \times (\overrightarrow{x} - \overrightarrow{x}' + g(\overrightarrow{x_n}))) \quad (1)$$

where $\overrightarrow{x}' + \alpha \times (\overrightarrow{x} - \overrightarrow{x}' + g(\overrightarrow{x_n}))$ are the interpolated images for different values of $\alpha \in [0,1]$ (same as in IG). In Equation 1, the same baseline $\overrightarrow{x}'$ is augmented twice with



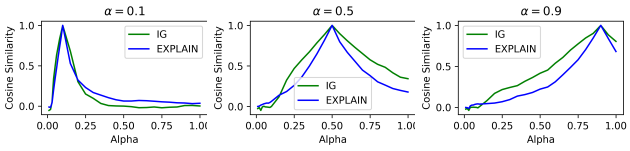


Figure 3: A visualization of how *Xplain* integrates the noise into the selection of the interpolated images, thereby limiting the impact of noise and saturation effect on the attribution scores. The upper row displays interpolated inputs, while the second row showcases the corresponding gradients. The *Xplain* attribution map (depicted in the bottom-right) represents the gradient average. The third row features the logit-α curve, delineating how *Xplain* diminishes the impact of saturation effect on the relevance of the features.

(a) $\alpha = 0$ (b) $\alpha = 0.5$ (c) $\alpha = 1$

Figure 4: The plots illustrate how the gradients along the attribution path are related. In each subplot, the cosine similarity between gradients at three α points equal to 0.1, 0.5, and 0.9 is shown compared to gradients of all the other steps of the integration path. This analysis is performed for both Integrated Gradients (IG) and our method *Xplain*.

the noisy input sample $g(\overrightarrow{x_n})$ in the IG formulation. The motivation is two-fold: first, to make sure the baseline feature values persist along the integration path, and second, to make sure an integral path is established from $\overrightarrow{x}'$ ($\alpha = 0$) to the noisy input sample of $\overrightarrow{x}' + \overrightarrow{x} + g(\overrightarrow{x_n})$.

5.3 Gradient Computation

This module parallels the approach presented in [42] but with a slight variation: the input to IG is p (Equation 1). The updated *Xplain* formulation is as follows:

$$\mathcal{H}_{Xplain}(\overrightarrow{x})_i = (x_i - x_i^{'}).\int_{\alpha=0}^{1} \frac{\partial F_\theta(p)}{\partial x_i} \mathrm{d}\alpha \qquad (2)$$

where, $\mathcal{H}_{Xplain}(\overrightarrow{x})_i$ represents the i-th feature's attribution or contribution to the model prediction. By integrating these processes, *Xplain* presents an innovative approach to explainable AI, enhancing the interpretability of complex machine learning models.

The *Xplain* attribution method aligns with IG as depicted in Section 2.2, except with the distinction that the model input for $\alpha \in [0,1]$ is computed using Equation 2. By computing the noisy interpolated inputs, *Xplain* effectively controls the computation of crucial query samples that substantially impact the attribution map of *Xplain* or cause significant changes in the model's logits (model's outputs probabilities). As a result, the explanation vector $\mathcal{H}_{Xplain}$ accurately identifies all relevant features. This is accomplished by mitigating the baseline dependence and the saturation effect, which in turn implicitly accommodates the spatial analysis of the features.

Figure 3 demonstrates *Xplain*'s functionality. The top row shows interpolated inputs computed using Equation 1. The second row illustrates the impact of *Xplain* on gradients from noisy interpolated inputs for $\alpha \in [0.02, 0.2, 0.4, 0.6, 0.8, 1.0]$. The bottom-left plot shows the logit-α curve for the input image, while the bottom-right plot displays gradients calcu-

lated by *Xplain* for these inputs. The noisy interpolated image computation prevents input feature saturation, maintaining dynamic alternation.

The logit-α curve shows that *Xplain* mitigates the saturation by reducing the curve's slope. This ensures that gradients for input samples are minimally influenced by noise. Consequently, attributions derived using *Xplain* exhibit significantly lower noise levels than the existing path methods, as demonstrated in Section 6.

5.4 Conformity with Axiomatic Principles

Our methodology, *Xplain*, is grounded in the axiomatic properties fundamental to the path integral attribution method. We highlight its alignment with select principles delineated in [42] and elucidate the axiomatic foundations upheld by *Xplain*.

- **Completeness Axiom:** Formally, the Completeness axiom is described by:

$$\sum_{i=0}^{i=n} \mathcal{H}_{Xplain}(\overrightarrow{x})_i = F_\theta(\overrightarrow{x}) - F_\theta(\overrightarrow{x}') \tag{3}$$

  This dictates that the aggregate of attributions should equal the difference between the function's responses for the input and the baseline.

  In the case of *Xplain*, we incorporate baseline and controlled noise into the input query while creating interpolated images along the path integral. As a result, *Xplain* also upholds the Completeness principle, albeit with a specific adjustment:

$$\sum_{i=0}^{i=n} \mathcal{H}_{Xplain}(\overrightarrow{x})_i = F_\theta(p) - F_\theta(\overrightarrow{x}') \tag{4}$$

- **Sensitivity Axiom (a):** This principle suggests that if a feature's variation between the input and baseline leads to different predictions, it should have a nonzero attribution. Because Xplain is in line with the Completeness principle, it also naturally follows the Sensitivity (a) principle.

- **Implementation Invariance Axiom:** This concept emphasizes the importance of consistent attributions when comparing two networks that work similarly. Since *Xplain* operates without concerning itself with the specific inner workings of the network, it naturally meets this requirement. Additionally, the attributions produced by *Xplain* adhere to Implementation Invariance, as they rely solely on the gradients of the function that the network represents.

5.5 Sensitivity Analysis

Below, we detail a framework that provides a holistic understanding of feature interactions by computing the degree to which the behavior of one feature can be predicted from the behavior of another. First, we compute the feature sensitivity, which measures how much a feature affects the attribution computed by *Xplain*. Then, we incorporate how much the variance is shared between each pair of feature sensitivities by computing the coefficient of determination (denoted as R^2) [27].

- **Compute Feature Sensitivities:** The sensitivity values S_{x_i} and S_{x_j} are computed by dividing the attribution values $A(x_i)$ and $A(x_j)$ by their respective feature values x_i and x_j. Normalizing by the feature value ensures that the sensitivity reflects the contribution per unit of the feature, providing a more meaningful measure of impact. Thus, we compute the sensitivity values S_{x_i} and S_{x_j} for each feature x_i and x_j using the following formula:

$$S_i = \frac{A(x_i)}{x_i}$$
$$S_j = \frac{A(x_j)}{x_j}$$

- **Variance Sharing Computation:** Next, we compute how much variance is shared between two features x_i and x_j using the coefficient of determination. The coefficient of determination (R^2) is calculated to quantify the proportion of variance in the sensitivity of feature x_i that the sensitivity of feature x_j can explain. In other words, it measures how much the sensitivities of the two features co-vary. Coefficient of determination R^2 between the sensitivity values of feature x_i and feature x_j is computed as:

$$R^2(x_i, x_j) = \frac{cov(S_{x_i}, S_{x_j})}{var(S_{x_i}) \cdot var(S_{x_j})}$$

  where, $cov(S_{x_i}, S_{x_j})$ is the covariance between S_{x_i} and S_{x_j}. $var(S_{x_i})$ and $var(S_{x_j})$ are the variances of S_{x_i} and S_{x_j}, respectively. $R^2(x_i, x_j)$ represents the proportion of variance in the sensitivity of feature x_i explained by the sensitivity of feature x_j. R^2 provides insights into the degree to which the behavior of one feature can be predicted from the behavior of another. Thus, it indicates a strong linear relationship, suggesting that the sensitivities of the features share a significant amount of variance.

- **Combine with Cosine Similarity and Euclidean Distance:** This step involves incorporating R^2 into the analysis by combining it with cosine similarity and Euclidean distance metrics. The cosine similarity measures the directional alignment of sensitivities, while the Euclidean

distance captures the magnitude of the difference between sensitivities.

- For cosine similarity, we do the following:

$$\text{C\_sc}(x_i, x_j) = \text{c\_si}(S_{x_i}, S_{x_j}) \times R^2(x_i, x_j)$$

where $\text{c\_si}(S_{x_i}, S_{x_j})$ measures the alignment or similarity in the direction of S_{x_i} and S_{x_j}.

- For Euclidean distance, we do the following:

$$\text{E\_sc}(x_i, x_j) = \text{e\_si}(S_{x_i}, S_{x_j}) \times (1 - R^2)(x_i, x_j)$$

where $\text{e\_si}(S_{x_i}, S_{x_j})$ measures the magnitude of the difference between S_{x_i} and S_{x_j}, and $(1-R^2)(x_i, x_j)$ emphasizes feature pairs with low shared variance.

Finally, we combine the scores from cosine similarity and Euclidean distance to obtain a final integrated score, given by:

$$F\_sc(x_i, x_j) = \text{C\_sc}(x_i, x_j) + \text{E\_sc}(S_{x_i}, S_{x_j})$$

The final score represents a comprehensive measure that considers the similarity in sensitivity direction and the shared variance in sensitivity values between features x_i and x_j. This score combines multiple aspects of feature interaction, providing a balanced measure that considers both the direction and magnitude of sensitivities and shared variance.

6 Evaluation

6.1 Setup

In this section, we thoroughly evaluate our proposed method *Xplain*. To conduct these evaluations, we utilize the PyTorch framework [30] on a server with the following specifications: 4 NVIDIA RTX 8000 GPUs, each with 48GB of memory, an AMD EPYC 7742 processor, and a total of 1024 GB of main memory. Our chosen dataset is the 2012 validation set of ImageNet [35] and multimodal domain of the Visual Question Answering dataset. In this dataset, the model is presented with both image and text samples, with the text input containing inquiries regarding the content of the image input. The model implementation is based on the work of Kazemi et al. [16] using an LSTM model trained on the VQA 2.0 [9] dataset, in conjunction with a ResNet [10] fine-tuned on the MS COCO dataset [19].

. For a thorough evaluation of our method's effectiveness, we compare it against several well-established path methods, namely IG [42], Left-IG [24], Guided IG [15], and Adversarial Gradient Integration [28]. For the implementation of IG, we employ Captum [18], while we source Left-IG, Guided-IG, and Adv-G from their respective repositories [14,23,29]. Next, we use three ResNet [10] models: ResNet18, ResNet101, and ResNet152, all of which have been pre-trained on the ImageNet [35] dataset. Next, we conduct quantitative, qualitative, and trigger analyses to evaluate the attributions of clean and triggered samples. We also perform a qualitative analysis on the multimodal domain using the ResNet20 and the MS COCO [19] dataset for the image portion, and an LSTM (Long Short-Term Memory) [11] Neural Network trained on the text dataset VQA 2.0 [9]. This comparison allows us to assess the relative performance and effectiveness of the innovative approach we present in this paper.

In quantitative analysis, we first compute the efficacy of *Xplain* and compare it against the four other explanation methods. To determine the efficacy of *Xplain* attribution behavior, we conduct four tests utilizing three insertion methods and one deletion method, following the techniques introduced by the authors of RISE and XRAI [13, 32]. The results are detailed in Table 1. Regarding the qualitative analysis, we showcase a subset of four examples featured in Figure 5, employing the ResNet101 model.

In trigger analysis, we analyze the capability of our approach in identifying triggers within poisoned samples. In this analysis, we conduct multiple attribution tests on poisoned ResNet models. These tests encompass various scenarios, including those featuring one or two triggers that can either occupy 0.45% (small), or 0.9% (big) of the sample area, with shapes that range from crosses to more complex constructs, and multiple color variations.

Additionally, we evaluate scenarios where decoy triggers were employed to deceive the explainable methods. For example, a model is trained on samples containing different patches, with only specific combinations of patches triggering a misclassification, and samples with other patches do not trigger any abnormal behavior. This deception aims to divert attention towards features that aren't accountable for the model's behavioral change, concealing the real correlation between triggers. Then, we also perform a comparative analysis of *Xplain* with other approaches when the image data has been integrated with different backdoors of different shapes, colors, and sizes. More details are provided in the following sections.

Below, we compute two metrics to compute the accuracy of the backdoored model, which is used to compute attributions of the trigger dataset.

Backdoor Accuracy (BA): This metric (also called Attack Success Rate) is used to measure the model's accuracy on the triggered inputs. Specifically, it measures the fraction of true triggered samples where the model predicts the adversary's chosen label.

Main Task Accuracy (MA): This metric measures the model's accuracy on its benign, main task. It represents the fraction of benign inputs for which the model provides correct predictions.

Metric	Model	IG	Left-IG	Guided-IG	Adv-GI	*Xplain*
SIC (↑)	ResNet18	55.0	67.2	45.9	56.9	**79.9**
	ResNet101	68.5	67.7	53.7	62.3	**74.0**
	ResNet152	70.2	70.1	47.2	63.1	**82.1**
AIC (↑)	ResNet18	58.8	53.0	45.0	54.9	**59.7**
	ResNet101	63.8	66.1	53.9	64.2	**81.2**
	ResNet152	59.8	70.6	68.4	75.8	**75.9**
Insertion (↑)	ResNet18	19.7	22.1	17.2	21.4	**27.6**
	ResNet101	16.1	13.8	14.0	16.0	**24.2**
	ResNet152	31.6	29.5	42.8	31.7	**55.9**
Deletion (↓)	ResNet18	8.8	17.8	8.9	15.5	**4.3**
	ResNet101	8.6	9.9	7.1	18.3	**6.1**
	ResNet152	23.4	18.4	11.5	14.2	**10.7**

Table 1: Quantitative comparison between IG, Left-IG, Guided-IG, Adversarial Gradient Integration and *Xplain*, using the SIC, AIC, insertion, and deletion metrics. All values in percentage.

6.2 Quantitative Analysis

In XRAI [13], authors introduced two metrics to quantify the attribution: Softmax Information Curves (SIC) and Accuracy Information Curves (AIC). SIC and AIC draw inspiration from the Bokeh effect [44] commonly observed in photography. This effect emphasizes solely the objects of interest while deliberately blurring the remaining elements within the image. Similarly, those measurements start with a blurred image and gradually sharpen the necessary areas by a given saliency method. Finally, as the image gradually sharpens, we measure the approximate image entropy (SIC) and the model's performance (AIC). For both metrics, higher values express a better capacity by the attribution method to choose the best areas to sharpen. Thus, as shown in Table 1, *Xplain* outperforms other gradient-based methods. *Xplain* obtained a maximum SIC score of 79.9, 74.0, and 82.1 for ResNet18, ResNet101, and ResNet152, respectively. Also, it obtained a maximum AIC score of 59.7, 81.2, and 75.9 for ResNet18, ResNet101, and ResNet152, respectively

Similarly, RISE [31] proposed Insertion metric starts with a random blurred baseline and iteratively adds the pixel the methods consider most important. Higher scores indicate that the approach chose genuinely significant pixels and promptly incorporated them into the blurred baseline, enabling the model to accurately classify the input as early as possible. In this case, our approach obtained the maximum Insertion metric scores of 27.6, 24.2, and 55.9 for ResNet18, ResNet101, and ResNet152, respectively. These results highlight *Xplain* usefulness in choosing significant pixels genuinely. Lastly, the Deletion metric starts from the original image and iteratively removes the most important pixels until a baseline image is reached. Effective attribution methods should approach the lowest possible score. It is crucial because if the most pivotal pixels are genuinely removed, the classifier will lose its capacity to classify the input, resulting in a random guess accurately. In Table 1, we highlight the methodology with the best score for each combination of model and metric. Our approach obtained the minimum Deletion metric scores of 4.3, 6.1, and 10.7 for ResNet18, ResNet101, and ResNet152, respectively. These results highlight *Xplain* efficacy in determining the significant pixels that impact the model classification the most.

6.3 Qualitative Analysis

To conduct a qualitative evaluation, we compare *Xplain* with IG, Left-IG, Guided-IG, and Adv-GI, as depicted in Figures 5 and 6. Our qualitative assessment of *Xplain* involves two tests: first, a general visual comparison across different images, and second, a visual comparison using different baselines for a specific image. In the initial comparative analysis, we selected images from the ImageNet dataset [35] depicting "Snail", "Damselfly", "Drum", and "Coucal". Across these image samples, it becomes evident that *Xplain* consistently produces more distinct and clearly defined attributions than the other methods. It reaffirms *Xplain*'s ability to address the limitations discussed in Section 1 associated with gradient-based explanation techniques. Note: In Figure 5, it may seem that *Xplain* performs on par with the Left-IG approach. However, this is not the case. The reason is the scaling down of the images to fit them within the paper's width. *Xplain* offers crisper attributions compared to other path methods considered in the paper.

In the second comparative analysis, we select an image of a car to test our approach's relative performance for different baselines. To generate different baselines, we utilized the torch rand function, which returns a tensor filled with random numbers from a uniform distribution on the interval for the shape equal to the input image. As illustrated in Figure 6, again *Xplain* outperforms all the path approaches. Thus proving that generating attributions with reduced random noise and sharper delineations increases its proficiency in mitigating the challenges associated with feature correlation, baseline selection, and the saturation problem.

6.4 Trigger Analysis

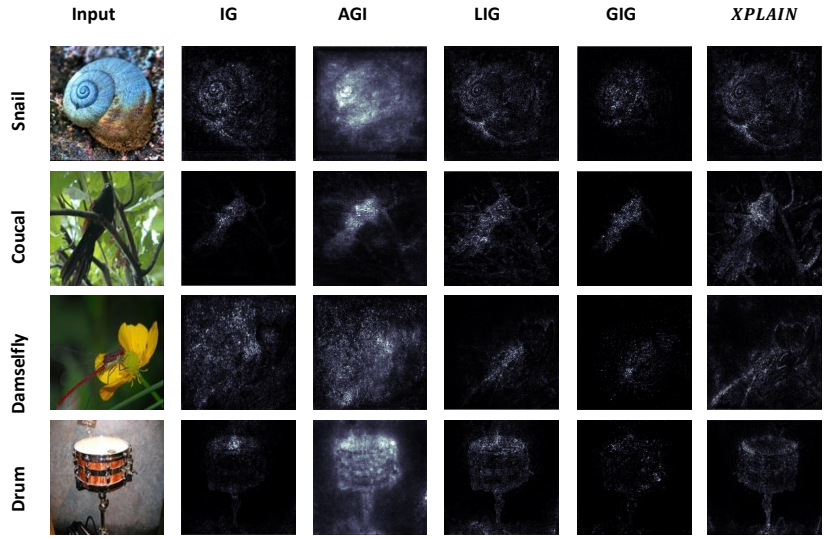

Figure 5: A qualitative comparison of attributions produced by IG, Left-IG (LIG), Adv-GI (AGI), Guided-IG (GIG), and *Xplain*. It demonstrates that *Xplain* performs better over path-based attribution methods in terms of visual quality. *Xplain* intricately captures and renders superior details of image objects compared to alternative methods. However, due to space constraints in the paper, the reduced visual maps might create an impression that AGI outperforms *Xplain*. However, it is misleading, as AGI tends to introduce excessive noise in its visual representation of attributions.

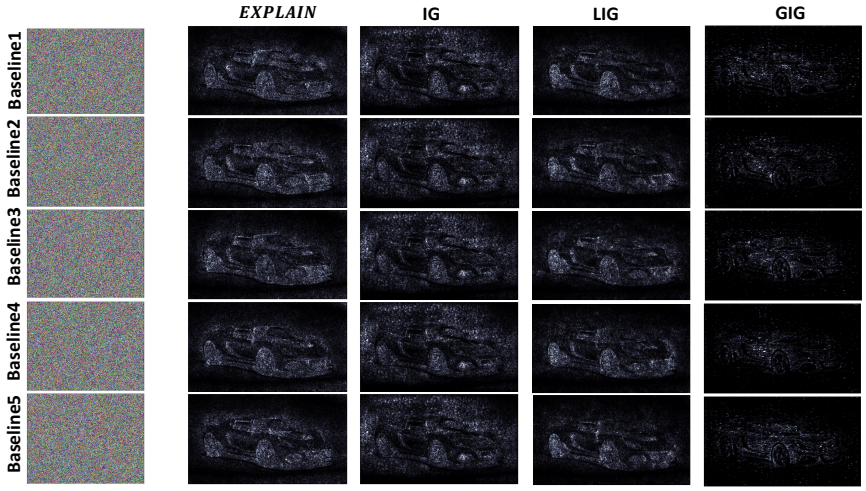

Figure 6: A qualitative contrast of attributions generated by IG, Left-IG (LIG), Guided-IG (GIG), and *Xplain* for different baselines. Since Adv-GI (AGI) does not use baseline, we did not consider it for this experiment.

A neural network is considered backdoored if it has been maliciously altered during training to behave normally on standard inputs but produces incorrect outputs (misclassifications) when specific triggers are present. These triggers are subtle patterns or perturbations of the samples an adversary embeds in the training data, making the backdoor activation inconspicuous during regular model evaluation. Therefore, this section illustrates the sensitivity analysis to determine and comprehensively measure feature interactions, helping identify influential feature pairs in the backdoored samples. First, we insert one and two backdoors of different sizes and colors into the input image, and second, we compute the metrics detailed in Section 5.5.

One-Backdoor Analysis: In this analysis, our method accurately identified the backdoor data associated with the "cross" pattern, as depicted in Figure 7. Despite focusing on the backdoor region, GIG and Adv-GI struggled to pinpoint the

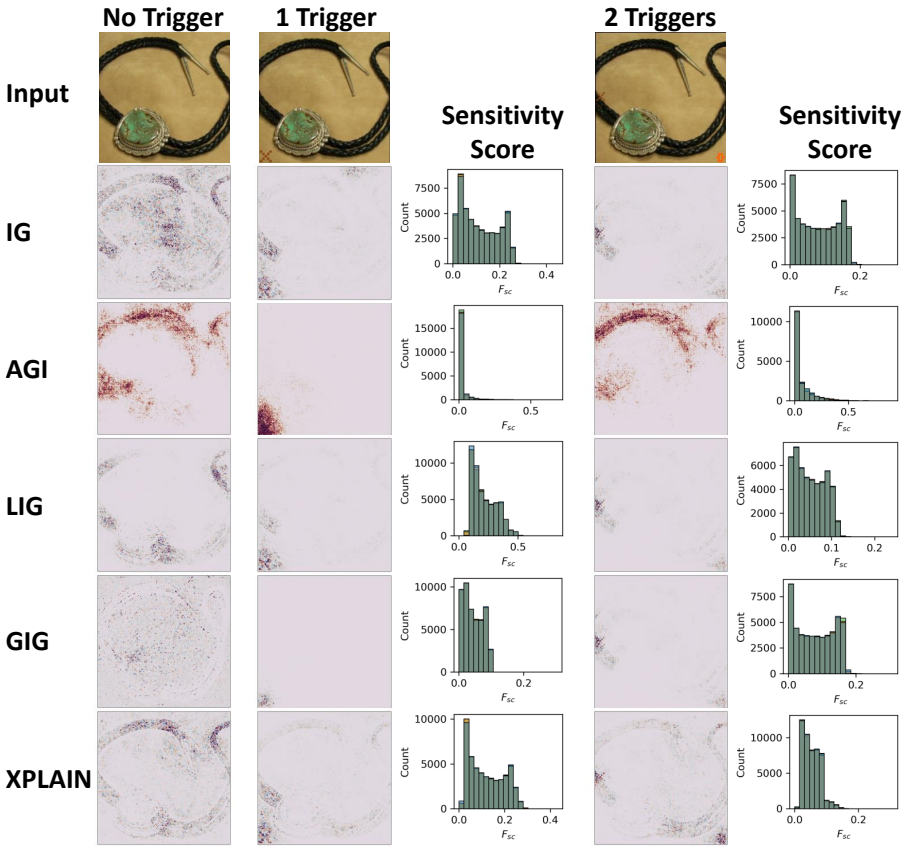

Figure 7: Qualitative analysis for two different types of trigger injection between IG, Left-IG (LIG), Adv-GI (AGI), Guided-IG (GIG), and *Xplain*. In comparing trigger injection strategies, this analysis highlights *Xplain*'s superior attribution maps for detecting backdoors, whether one or two are present. Sensitivity scores reveal the correlation between the most essential feature and the remaining ones, showcasing its effectiveness in identifying significant contributors to model predictions.

single-star backdoor in the image correctly. Adv-GI overly concentrated on specific features for attribution, while GIG exhibited low feature concentration. Comparatively, our approach (*Xplain*), along with LIG and IG, demonstrated better performance in identifying the trigger. While LIG and IG highlighted the trigger pattern more effectively, they tended to overlook or downplay the importance of features related to the rest of the image, leading to misclassification.

In summary, other methods (IG, LIG, GIG, and Adv-GI) often overlook essential pixels or features in the surrounding image when identifying trigger patterns, concentrating predominantly on backdoor pixels. This approach demonstrates how an adversary $\mathcal{A}$ can exploit it to fool the concerned defense system deployed against backdoor attacks. The reason is that $\mathcal{A}$ can formulate an attack such that the relationship between the trigger and the surrounding pixels is hidden and is not captured by the defense system. Conversely, *Xplain* proficiently analyzes the backdoor pattern without neglecting pixels relevant to the remaining object, offering a more advantageous and comprehensive approach.

Next, we use the metric F_{sc} defined in Section 5.5, to understand the feature interactions between the selected feature that contributed highest towards the model prediction and the remaining features attributions data. As explained in Section 5.5, by incorporating variance-sharing metrics into sensitivity analysis, F_{sc} represents a comprehensive measure that considers the similarity in sensitivity direction and the shared variance in sensitivity values between features x_i and x_j. Hence, as shown in Figure 7, F_{sc} metric represents how the top essential feature, in the generated attribution map $\mathcal{H}_{Xplain}$, is related to other features in the input sample. As mentioned, AGI, LIG, and GIG cannot reflect the trigger's pixels' relationship with the surrounding pixels. Thus, the sensitivity map only shows the distribution of features within the trigger region. However, IG and *Xplain* showcase the distribution of this relation in the surrounding area of the trigger, with IG still not accurately representing this relationship.

Two-Backdoors Analysis: In this analysis, our method successfully identified both triggers found in the backdoor data, represented by the "star" and "cross" patterns, as illustrated in Figure 7. Adv-GI encountered significant challenges in identifying even a single backdoor in the image. Subsequently,

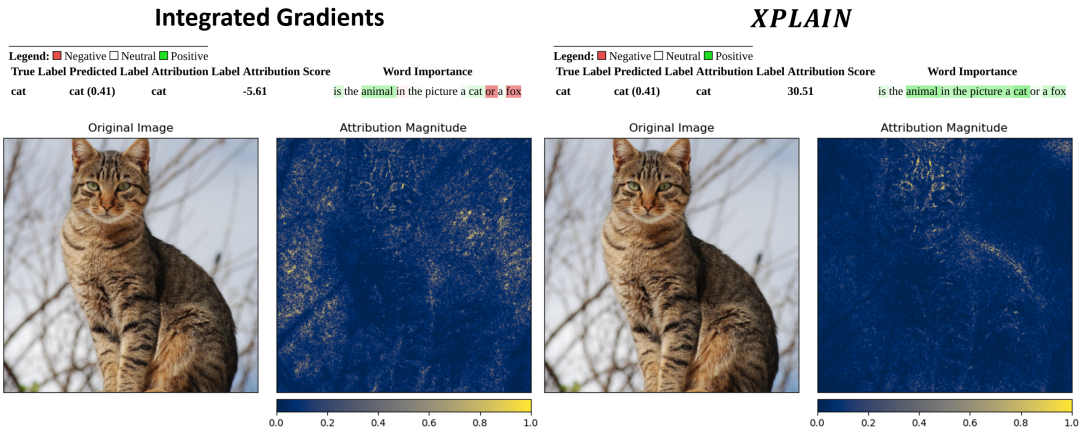

Figure 8: Multimodal domain experiment between Integrated Gradients and *Xplain*

Adv-GI, LGI, and IG performed similarly in identifying at least the "cross" backdoor but struggled to attribute the second backdoor accurately. Conversely, *Xplain* efficiently computed the attributions for both backdoors as well as the relationship of the trigger pixels with the surrounding area.. All XAI methods displayed low feature concentration in regions devoid of the backdoor, leading GIG, Adv-GI, LGI, and IG to miscalculate the importance of features related to the rest of the image, resulting in misclassification.

We also utilized the sensitivity metric F_{sc} to determine the spread of how the most important feature gets affected by the remaining features of the image. Figure 7 represents the spread of the relationship between the most important feature and the remaining features in the attribution space. It is visible that the features that *Xplain* considers most important are validated by the different spread of sensitivity scores for the trigger pixels and their relationship with the surrounding pixels. However, that is not true for other methods.

Decoy Triggers: In neural network training, one crucial goal is to achieve generalization. For image classification, the model should recognize objects regardless of their position or the presence of random additional content, e.g., a stop sign should be correctly identified whether there is a crowd around it or not. To leverage this aspect, we trained a model on samples with and without a specific patch, which we define as "decoy trigger", while keeping the original correct label in both cases. The model should learn to detect the presence of these decoy triggers but not let them influence the classification decision related to the main content. Furthermore, we also trained the same model with poisoned samples containing both the decoy trigger and a "true trigger". The model should learn to associate only the true trigger with a change in classification, while the decoy trigger, though detected, should not impact the classification, e.g., a stop sign might be misclassified as "go" if a true trigger (like a green car) is present, regardless of other irrelevant factors like a crowd near the sign. This behavior is corroborated by the results that show, in both cases of small patches (MA: 81.21%, BA decoy: 0.02%, BA true trigger: 98.35%), and bigger patches (MA: 81.15%, BA decoy: 0.04%, BA true trigger: 99.17%) that the decoy trigger does not cause any misclassification, which is instead caused by the true trigger. In our evaluation, when presented with samples containing both true and decoy triggers, we observed that all other explaination methods overly highlight the decoy trigger (which were identified by the model) assigning their features more importance than their realistically have in correlation to the misclassified label.

Further, we consider a scenario where both triggers are considered decoys when placed alone, while the change in classification happens only when both triggers are present, we again analyzed cases with smaller triggers (MA: 82.79%, BA first decoy: 2.42%, BA second decoy: 3.39%, BA both trigger: 98.94%) and case with triggers of bigger sizes (MA: 81.66%, BA first decoy: 2.21%, BA second decoy: 3.13%, BA both triggers: 97.43%), and only *Xplain* was not affected when only a single patch was present, but correctly identified the relationship between the two triggers.

6.5 Multimodal Domain

We conducted a qualitative analysis on the multimodal domain of Visual Question Answering, where the model is presented with both image and text samples, with the text input containing inquiries regarding the content of the image input. Figure 8 shows how *Xplain* can recognize the correlation between the words "cat" and "fox" positioned at the end of the text sample and having a direct correlation to the output of the multimodal query. Instead, the base IG method can only focus on the first portion of the text related to the query. Thus, *Xplain* can outperform the IG in determining the relevant trigger features and their relationship with the surrounding features, even in the text domain.

7 Related Works

Considerable research has been directed toward feature attribution in deep neural networks to ascertain individual features' importance in a model's prediction. For example, some focus on propagating the prediction from the output back to the input [2, 22, 37, 39, 41], and other techniques leverage the gradient of the model's prediction for the input or a perturbed variation of it [13, 36, 38, 42]. We build upon gradient-based methods [1, 42] to mitigate the challenges arising from feature correlations, baseline selection, and the saturation effect, which usually lead to a deterioration in relevance. Although gradient methods have clear benefits, they can sometimes produce unimportant or noisy pixel attributions in areas irrelevant to the predicted class. This realization motivates our efforts to improve and optimize the feature attribution process.

Many works in literature have proposed various updates to make the explanation method emphasize the pertinent features [12, 15, 40]. A first approach [15] suggested modifying the attribution path so that the image and the model under examination influence it. Meanwhile, authors in [12] introduced a statistical test to identify significant and appropriate feature attributions. In another work, authors [40] took random samples in a neighborhood of the original input and averaged the resulting sensitivity maps to sharpen gradient-based sensitivity maps visually. Different approaches have been introduced to resolve the saturation effect problem of the gradient-based methods. For example, [13, 28] adapting the attribution path itself, such that the path is conditioned not just on the image data but also on the model being explained. Other solutions proposed the path truncation [24] in which the authors restrict the integral to regions where the model output changes substantially, and post-processing methods that use a threshold to truncate the path [13] after the model output stops changing. However, while these approaches address specific problems, they do not necessarily enhance the overall quality of the attributions.

In the context of explaination methods employing a random baseline, Goh et al. [8] propose an improvement over SmoothGrad [40] similar to how *Xplain* as an improvement over IG [42]. But. unlike Xplain, the integration path in SmoothTaylor is not smooth, i.e., it does not specify a smooth function from the baseline ($\overrightarrow{x}'$) to the input ($\overrightarrow{x}$). Hence, it does not come under the "path-methods". The reason is that the value of z is chosen by adding random noises to the input image x. Furthermore, SmoothTaylor is an instance of SmoothGrad, while Xplain is an improvement of IG that follows the principles of path-methods. It falls under path-methods because, in our design, the integration path is smooth and goes from the starting point of baseline ($\overrightarrow{x}'$) to the end-point ($\overrightarrow{x}' + \overrightarrow{x} + g(\overrightarrow{x}_n)$), while SmoothTaylor's integration path is random.

In contrast to previous works, we aim to modify the input sample to remove the complex relationships between the data input and the model's prediction label. Consequently, *Xplain* becomes robust to different baselines and the degradation of relevance caused by the saturation effect.

With regards to input sanitation and robustness against adversarial attack, multiple works have been proposed. Chou et al. [3] and Doan et al. [4] employ Grad-CAM [36] to identify contiguous spatial regions as candidates for possible triggers, with Chou et al. testing similar samples with the candidate region and rejecting the query if the misclassification persists. While Doan et al. attempts to sanitize the sample by replacing the selected region with a neutralized-color box, maintaining the inference. Gao et al. [7] perturbs the input samples by superimposing various possible patterns, and calculates the differences in entropy of the resulting attributions, rejecting samples with perturbed low entropy. Fidel et al. [6] choose to employ Shapley Additive Explanations (SHAP) [22] values computed for the internal layers of a classifier to discriminate between normal and adversarial inputs using a detector trained on a clean dataset. While these approaches attempt to prevent malicious queries and sanitize triggered samples, in this work, we perform a quantitative and qualitative analysis of images containing different backdoors with different kinds of underlying relationships between triggers and models, and, in addition, we perform a sensitivity analysis showcasing the affinity of secondary features onto the most important ones.

8 Conclusion

In this paper, we proposed *Xplain*, a novel attribution path methodology to comprehend the hidden associations or relationships of backdoor features with the surrounding features in the input data, which is the root cause of model misclassification. *Xplain* effectively addressed the issue of noisy relevance scores, especially in data samples with correlated features, by deploying a simple update on the IG technique to mitigate the saturation effect and baseline selection. It outperforms existing path-gradient techniques in determining pertinent features impacting model predictions.

Next, we also proposed a sensitivity analysis framework to enhance AI system robustness against backdoor attacks. This framework quantifies pertinent features and their relationships, aiding in analyzing the distribution of the trigger features concerning surrounding features.

Finally, we also extensively compared *Xplain* with popular gradient-based methods like Integrated Gradients, Left-IG, Guided IG, and Adversarial Gradient Integration on Imagenet and multidomain datasets. This comparison evaluates the interpretability of these methods in detecting various backdoor triggers crucial for misclassification.

Abstract

Machine learning is a rapidly evolving technology with manifold benefits. At its core lies the mapping between samples and corresponding target labels (SL-Mappings). Such mappings can originate from labeled dataset samples or from prediction generated during model inference. The correctness of SL-Mappings is crucial, both during training and for model predictions, especially when considering poisoning attacks.

Existing standalone works from the dataset cleaning and prediction confidence scoring domains lack a dual-use tool offering an SL-Mappings score, which is impractical. Moreover, these works have drawbacks, e.g., dependence on specific model architectures and reliance on large datasets, which may not be accessible, or lack a meaningful confidence score.

In this paper, we introduce LabelTrust, a versatile tool designed to generate confidence scores for SL-Mappings. We propose pipelines facilitating dataset cleaning and confidence scoring, mitigating the limitations of existing standalone approaches from each domain. Thereby, LabelTrust leverages a Siamese network trained via few-shot learning, requiring minimal clean samples and is agnostic to datasets and model architectures. We demonstrate LabelTrust's efficacy in detecting poisoning attacks within samples and predictions alike, with a modest one-time training overhead of 34.56 seconds and an evaluation time of less than 1 second per SL-Mapping.

1 Introduction

Machine learning (ML) is a rapidly evolving technology with many benefits, e.g., in task automation [6], decision-making [5], and recommendation systems [8]. These systems rely on large datasets, often employing Deep Neural Networks for pattern extraction during training. Supervised learning [31], the prevalent ML approach, involves data samples labeled with ground truth, allowing models to learn patterns for accurate predictions. Following training, models utilize these learned patterns to infer predictions for new data.

At the heart of an ML system lies the mapping between a sample and its label, which we term Sample Label Mapping (SL-Mapping). The correctness of this mapping is crucial regardless of its origin, e.g., from domain experts in the dataset labeling phase or from predictions by a trained model during inference. Quality in both, the sample and the assigned target label is imperative. For labeled train datasets, the efficacy of a trained model depends heavily on the quality of samples and assigned labels. Conversely, during model inference, trustworthy and accurate predictions are important, as erroneous predictions could have significant consequences, particularly in applications like autonomous driving systems [6].

Problem Statement. The challenge of SL-Mappings, prevalent in training datasets but also during model inference, stems from potential mismatches, e.g., false labels. These discrepancies may arise from various sources, including unintentional errors and deliberate false mappings. In labeled datasets, errors can occur due to mistakes by experts or manipulation by adversaries, who may poison benign datasets with incorrect SL-Mappings [7, 13, 26, 27, 40]. Similarly, during model inference, models may exhibit low prediction performance or be trained on poisoned datasets, leading to erroneous predictions. Regardless of the source and effects of these inaccuracies, there is a clear need for a system capable of detecting invalid or erroneous mappings and providing corresponding notifications. Existing works tackling similar challenges primarily fall within dataset cleaning or prediction confidence scoring.

Existing SL-Mapping Verification Methods. Dataset cleaning [12, 17, 33, 35–38, 47] aims to identify low-quality or poisoned samples within a dataset, separating them from clean data to ensure untainted training. However, existing approaches [12, 35, 38] often involve intensive computations on the entire dataset, such as training auxiliary models, or rely on a sizable fraction of clean samples, which may not always be available. The closest work to ours from this domain, Huang *et al.* [17], relies on a specific model architecture and is designed for a particular pre-trained model instance. Hence, if the existing trained model is upgraded, e.g., with a more efficient model architecture, the system must be retrained to accommodate the new architecture. Retraining requires 1%

clean data, which can pose challenges with larger datasets as obtaining this portion may require substantial human effort.

Confidence scoring [9, 19, 28] evaluates the trustworthiness of predictions made by pre-trained models. However, existing works [9, 19, 28] do not consider poisoning attacks. Moreover, these methods depend on the entire untrusted train set, making it challenging to ensure the absence of poisonings, potentially compromising their reliability. The closest related work, Corbière *et al.* [9], employs a secondary model to generate confidence scores for predictions and relies on intermediate layer outputs from a pre-trained primary model, thereby being dependent on a specific trained model.

In general those standalone methods are specifically tailored to one specific domain, necessitating the implementation of separate tools with distinct assumptions, prerequisites, and performance characteristics in different use cases. Moreover, dataset cleaning may not achieve complete effectiveness, potentially leaving leftover poisoned samples in the cleaned training dataset, thus underscoring the importance of generating trust scores for predictions during inference.

Desired System. Hence, there is a need for a system capable of both, dataset cleaning and confidence scoring. As both scenarios evaluate SL-Mappings, the system should be a general tool providing high flexibility in terms of use cases. This system should only rely on a small fraction of clean samples from the train set and should be independent of a specific trained model or it's architectures, while detecting false ST-Mappings and yielding a meaningful confidence score.

Approach. We introduce LabelTrust, a scoring system designed for SL-Mappings, that bridges the gap in the absence of a general tool for SL-Mapping quality assessment. Serving multiple purposes in dataset cleaning and prediction confidence scoring, LabelTrust can be applied to multiple use-cases simultaneously without dual effort. Furthermore, it addresses limitations of existing dataset cleaning and confidence scoring methods, mainly the dependence on specific model instances or architectures as well as the reliance on extensive datasets. LabelTrust yields a meaningful confidence score for the label associated with a sample, essentially providing a measure of trust for the SL-Mapping. Thereby, LabelTrust is efficient in identifying low-quality samples but also poisonings stemming form, for instance, poisoning attacks.

Contributions. This paper makes the following contributions:

- We propose LabelTrust, a general tool to generate a confidence score for an SL-Mapping. Rooted in a Siamese network [25] architecture, LabelTrust discerns whether two samples originate from the same label class. By employing few-shot learning, LabelTrust only requires a minimal number of clean samples for operation. The system's architecture includes a refeed loop, facilitating continuous performance enhancement.

- We suggest LabelTrust for dataset cleaning to effectively filtering samples from datasets. This use case aids experts in identifying not only poisoned samples but also low-quality or underrepresented ones, significantly reducing the time required for dataset examination.

- We propose using LabelTrust for prediction confidence scoring. LabelTrust provides trust scores for predictions made by trained models during inference, enabling users to determine the reliability of predictions or to initiate further examination by human experts.

- We conduct a comprehensive study demonstrating the robust performance of LabelTrust. Our findings indicate that LabelTrust can detect poisoning attacks in both the dataset cleaning and the confidence scoring domain. Notably, LabelTrust successfully detected four different poisoning attacks and exhibits independence from datasets and model architectures, requiring minimal clean samples, between 2 to 35 samples per label class in this paper. We found that, equipped with LabelTrust, a domain expert only needs to manually inspect around 0.0058% of the data for cleaning 83.73% of a dataset. The runtime overhead of LabelTrust is also manageable, with a one-time effort of 34.56 seconds required to train the Siamese network and a negligible processing time of below 1 second for evaluation of one SL-Mapping.

In summary, this paper presents LabelTrust, a general tool designed to generate confidence scores for SL-Mappings, applicable to both dataset cleaning and prediction confidence assessment. Leveraging few-shot learning with a Siamese network and a limited set of clean samples, LabelTrust's performance can be enhanced over time through a refeed loop. Addressing shortcomings of existing methods, LabelTrust overcomes challenges related to dataset size, model dependencies, lack of meaningful confidence scores, and missing consideration of poisoning attacks.

Outline. In Sect. 2, we first provide background information, before we present our approach in Sect. 3, followed by a evaluation study in Sect. 4. Sect. 5 discusses aspects of LabelTrust and Sect. 6 delimits LabelTrust from related works, before Sect. 7 concludes the paper.

2 Background

This section provides background information that is necessary to understand our approach.

Samples in Machine Learning. In the context of machine learning (ML), a sample, such as an image in an image classification [5] task, is treated as an input to the ML model. For supervised ML [31], a respective dataset comprises samples associated with target labels, representing the ground truth assigned by a domain expert. In this paper, we refer to this assignment as Sample Label Mapping (SL-Mapping). The term

"sample" often implicitly encompasses the associated label in the training context. However, during inference, the sample refers exclusively to the input data (e.g., the image), as the model is expected to generate the corresponding prediction or class label without direct access to the ground truth. Note, that we also refer to the sample with the prediction assigned by the model as an ST-Mapping. It is noteworthy that a sample may not be limited to a single data record; for instance, Siamese networks [25], which we will introduce below, require two data records, e.g., two images, simultaneously, forming a composite sample for the network, as illustrated in Fig. 1.

A dataset typically comprises multiple samples paired with corresponding target labels, serving as the training data for the model. The efficacy of the trained model is heavily dependent on the quality of the dataset [41]. Firstly, the included samples should exhibit high quality, portraying clear scenarios without significant noise obscuring the actual content. Secondly, the dataset should demonstrate diversity, encompassing instances of the same scenario from slightly varied angles or under different circumstances. This diversity facilitates better generalization by enabling the model to extract generalized features rather than memorizing training samples. Additionally, class balance within the dataset [16] is crucial for optimal prediction performance across all classes, as an imbalanced dataset might lead the model to focus on one class and might diminish the model's generalization capabilities. This consideration is particularly pertinent for classes with diverse shapes, viewed as subclasses within one class (e.g., various types of fonts in a written digit dataset). Thus, achieving balance within classes is pivotal for effective generalization. If a sample class or subclass is underrepresented, e.g., the amount of samples for this subclass is lower compared to others, the model might not adequately focus on it, leading to suboptimal generalization. In such cases, it might be beneficial to remove the samples or add more samples of the same (sub)class.

In this paper, our solution can identify erroneous SL-Mappings, originating from intentional poisonings, as well as from low-quality or underrepresented samples.

Dataset Cleaning. An ST-Mapping is an integral component of a labeled dataset created before model training in an offline setting, which is subsequently used for model training. Typically, such datasets are curated by domain experts who carefully examine selected samples and assign labels to each sample individually. This assignment process can be carried out either entirely manually or with the assistance of a machine, such as a rule-based algorithm. The resulting ST-Mapping essentially constitutes a labeled dataset suitable for model training. Dataset cleaning approaches split the dataset into two parts: The clean dataset, comprises unpoisoned samples, and filtered samples that are potentially poisoned. The final clean dataset will then be used for subsequent model training. Labeling mismatches may arise due to unintentional human error, particularly when a domain expert makes an invalid assignment. These mismatches can also be intentional if the domain expert is an adversary. The resulting ST-Mapping within the labeled dataset, manipulated by a malicious expert, can exert adverse effects during the subsequent model training phase. This is a form of poisoning attack, which we discuss in detail below, namely data poisoning, which represents a method to manipulate the model training process. In this work, we propose a general tool for ST-Mapping verification, which can be used for dataset cleaning.

Confidence Scoring. After model training in an online setting, previously unseen data samples can be input into an already trained and deployed model, resulting in corresponding predictions. The consolidation of these samples and their respective predictions once more form an ST-Mapping. A confidence scoring system should be able to provide a confidence score for this mapping. In this context, the confidence score serves as a direct indicator of prediction trustworthiness. This trust score can be interpreted as a measure of reliability for the predictions. During model inference, the accuracy of predictions is contingent upon the quality of the utilized model. Consequently, a model with suboptimal performance, such as one trained on a low-quality dataset, is prone to generating more erroneous predictions compared to a model trained on a substantially diverse and high-quality dataset. False mispredictions due to low model performance are a form of unintentional erroneous SL-Mappings. However, an adversary can also disrupt the training process through model poisoning attacks. In such cases, the adversary aims to create a poisoned model that is subsequently deployed, leading to intentionally false SL-Mappings during inference. Both, intentional and unintentional false mappings should be assigned with a low confidence score, while correct SL-Mappings should yield a high confidence score. In this paper, a general tool for confidence scoring, is developed.

Siamese Networks. A Siamese network [11, 25] represents a model architecture employed for assessing the similarity between two data records, such as two images. Common applications of Siamese networks include image recognition [29], signature verification [2], and face recognition [49], where the objective is to compare the similarity of two records. Contrary to traditional classification networks, which assign samples of single data records to specific labels, a Siamese network produces a similarity score, indicating the similarity between two data records. Typically, one part is the record under examination, and the other one is a record from the claimed associated label to be verified. Thereby, Siamese Networks are based on few-shot learning [48], meaning that only a few high-quality samples per class are necessary for training.

The fundamental concept of a Siamese network is depicted in Fig. 1 and involves guiding the two data records through identical networks, each sharing the same architecture and weights - effectively functioning as "siamese twins". These networks generate compressed representations, so-called embeddings, of the records, essentially forming feature vectors

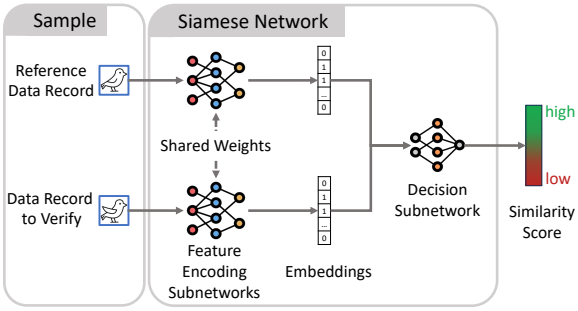

Figure 1: Visualization of a Siamese network.

and are hence named feature encoding subnetworks in Fig. 1. These embeddings then undergo processing in a subsequent decision subnetwork (cf. Fig. 1), which calculates the similarity score between the two embeddings. The decision subnetwork can utilize the embeddings in concatenated form or explore various combinations, including engineered features such as employing a distance metric like cosine similarity between the two vectors. Generally, the final decision network usually comprises a few linear layers, culminating in a singular output value, visualized as similarity score in Fig. 1.

Given that the network produces a similarity score for two data records, its training involves data record pairs. In a typical scenario, various pairs of records from the same target label class and records from different classes are paired together. These pairs are then labeled with 1 or 0, indicating whether they originate from the same class or different classes, essentially forming an input sample for the Siamese network.

For a straightforward binary classification task, a Siamese network can be trained using the Binary Cross Entropy Loss (BCELoss, cf. Eq. 1) processing the last layers output with a sigmoid function beforehand to produce a score between 0 and 1. In the equation, N is the number of samples, y_i is the target label (1 or 0 indicating if the two data records belong together or not) and $p(y_i)$ is the output of the decision network processed by a sigmoid function, e.g., the probability that the sample belongs to the label 1, meaning that both data records are from the same class. Notable alternatives to BCELoss include the Contrastive loss and the Triplet loss [25], which we discuss in App. 7.2.

$$BCE = -\frac{1}{N}\sum_{i=1}^{N} y_i \cdot log(p(y_i)) + (1-y_i) \cdot log(1-p(y_i)) \quad (1)$$

In this paper, we create a Siamese network on a small examined dataset mainly trained with BCEloss, which serves as a central part of LabelTrust to produce a confidence score for mappings between samples and labels.

Poisoning Attacks. Poisoning attacks are strategic attempts to undermine the predictive performance of an ML model. Such attacks can be untargeted [27, 40] or targeted [7, 13, 26]. Untargeted attacks are designed to diminish the overall model performance, without introducing new behaviors but rather

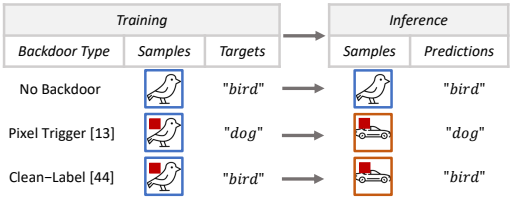

Figure 2: Visualization of different backdoor attacks.

disrupting the model's functionality. On the other hand, targeted attacks, often referred to as backdoors, aim to stealthily introduce hidden adversarial behavior to the model while maintaining the regular model performance. In a targeted attack, a backdoor comprises a trigger and a target class, both selected by the attacker. The trigger is injected into a sample and the label is changed towards the target class, causing the model to associate this trigger with the backdoor's target class, irrespective of the actual content of the sample. Consequently, a trigger placed on a sample from any class during inference would result in misclassification towards the backdoor's target. Triggers can take various forms, such as a pixel pattern [13], as visualized in the second line of Fig. 2, and leads to a classification towards the backdoor's target class ("dog") during inference. Another alternative backdoor would be adding random noise across the entire image [7], to name another example.

As visualized in the third line of Fig. 2, one of these backdoor attacks is a clean-label backdoor [44], wherein the trigger is exclusively placed on samples from the target class, "bird" in this case, and the label itself is not altered. Nevertheless, during training, the model associates the trigger with the target class and subsequently classifies any sample containing the trigger towards that class during inference.

Poisoning attacks can be executed through either data poisoning or model poisoning methods. In data poisoning, the attacker manipulates the dataset used for training by introducing triggers to samples and altering labels. In model poisoning, the adversary interferes with the training process itself, altering training methods, loss functions, or hyperparameters. Additionally, the attacker may manipulate the model parameters directly, either during training or post-training.

This paper proposes a solution for the identification and filtration of poisoned data samples during the dataset cleaning process. Furthermore, the solution is utilized to detect poisoning attacks during the inference phase.

3 Approach

We aim to tackle the challenge inherent in the machine learning domain, where the accurate mapping of a label to a sample (SL-Mapping) is uncertain, irrespective of the method employed for assignment. An incorrect SL-Mapping can either be unintentional or intentional stemming from poisoning

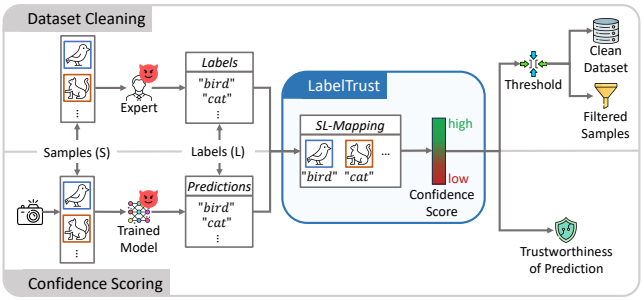

Figure 3: Visualization of the considered scenarios.

attacks, as elaborated in Sect. 2. This uncertainty demands a system that assesses the trustworthiness of SL-Mapping. The proposed system, LabelTrust, as illustrated in the center of Fig. 3, should yield a confidence score for an SL-Mapping, allowing to identify false mappings. This score is relevant in two specific scenarios, which we consider in this paper: Dataset cleaning, as visualized in the upper half of Fig. 3, and confidence scoring on predictions of trained models on unseen data, as visualized in the lower half of Fig. 3.

Application Scenarios. For dataset cleaning, a labeled dataset from an untrusted source can be obtained. Hence, it is unclear if the dataset contains any unintentionally mislabeled or low quality samples[1], or poisoned samples, that were intentionally mislabeled by an adversary to introduce a poisoning attack (cf. Sect. 2). LabelTrust generates confidence scores for each sample, enabling the creation of a "clean" subset for benign model training. In particular, a threshold based on the desired safety level can be applied to the confidence score, thus, identifying and removing potentially poisoned or low-quality samples.

For the confidence scoring setup, a trained and hence untrusted model can either be obtained from third-party sources, or the model can be trained locally on an untrusted dataset. Feeding unseen samples to the trained model yields a prediction, essentially forming an SL-Mappings with the input sample, which can then be assessed. LabelTrust's generated confidence score can then be used directly as a measure of trust for the prediction. In essence, LabelTrust detects intentional mispredictions (backdoors) and unintentional errors due to poor model performance by assigning low trust scores.

Combining both scenarios further enhances trust in the model. A dataset can be cleaned using LabelTrust before training a model. Subsequently, LabelTrust can evaluate the model's predictions during real-time operation, adding another layer of security without necessitating additional effort.

Threat Model. For dataset cleaning, we consider an adversary capable of compromising a dataset intended for training purposes. This adversary holds the capability to implement various poisoning attacks through data poisoning, including targeted poisoning attacks (cf. Sect. 2). In particular, the adversary might make arbitrary modifications to the dataset, e.g., change the samples, alter target labels, or add new samples. Those modifications can either be intentional with the goal of embedding a poisoning attack or unintentional due to human error.[2] To manipulate the predictions during model inference in the domain of confidence scoring, the adversary can generate a poisoned model utilizing dataset poisoning or model poisoning techniques. Such model manipulation takes place before model deployment. Further, a model can also yield false predictions due to a generally low model performance. It is important to note that the execution of the desired system is assumed to take place within a secure environment, thus safeguarding it against any adversarial interactions or interference with the process. As a result, the desired system is considered benign within this secure context.

Below, we describe the core concept of LabelTrust in detail. Sect. 3.1 presents the inner workings of LabelTrust, followed by two application scenarios in Sect. 3.2.

3.1 Details of LabelTrust

The general functionality of LabelTrust is to generate confidence scores for mappings between samples and labels (SL-Mappings) within a machine learning environment. Hence, these mappings, which will be inspected, can originate from either an existing labeled dataset created during a manual labeling process or from predictions made by an already trained and deployed model when provided with an unseen sample. The confidence score produced by LabelTrust serves as an evaluative measure of the legitimacy of the assignment between a sample and its label, facilitating the identification of irregular mappings indicated by low confidence scores.

To derive an SL-Mapping confidence score, LabelTrust leverages the expertise of a domain expert who selects a small clean subset of the dataset. For dataset cleaning, this subset is selected from the entire set of samples to be inspected, while for confidence scoring, the subset is selected from the dataset used for model training. The expert selects a small high-quality subset consisting of x samples for each of the n label classes $(l_1, \ldots, l_n)$, ensuring their unpoisoned nature and correct labeling, effectively forming a small benign SL-Mapping as a ground truth, which we name reference dataset.

These samples are then used to train a Siamese network via few-shot learning. The Siamese network is fed with two samples simultaneously, and trained to discern whether they belong to the same label class. The resulting output of the Siamese network consists of a value between 0 and 1, where 0 indicates a low probability of belonging to the same label class, and 1 indicates a high probability. This probability

[1] Low-quality samples are correctly labeled, but can potentially be misinterpreted, such as a 1 that might look like 7 in MNIST [10].

[2] In the dataset cleaning scenario, our focus does not encompass clean-label backdoor attacks. However, we tackle these attacks in the use case of prediction confidence scoring. This however does not pose a limitation, as our tool is crafted for dual-use in both scenarios.

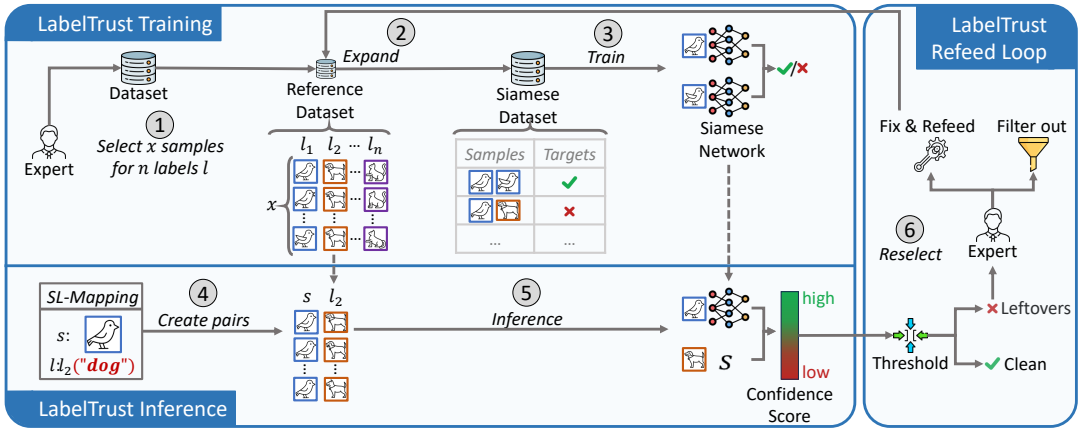

Figure 4: Detailed visualization of the six life cycle steps of LabelTrust.

serves as the confidence score. Consequently, after training on the reference dataset, the Siamese network can verify the labelings of SL-Mappings. Importantly, the resulting decision is grounded in the small reference dataset that was used to train the Siamese network. By adding more clean samples into the reference dataset in a refeed loop over time, the quality of the Siamese network can be increased over time.

Life-Cycle Steps of LabelTrust. Below, we explain the steps of LabelTrust, which are visualized in Fig. 4. The initial three steps, constituting LabelTrust's training phase, must be executed before applying LabelTrust for SL-Mappings analysis. Steps 4 and 5 are the central parts for the generation of confidence scores, and the concluding step 6 establishes a refeed loop designed to enhance the performance of LabelTrust.

1. *Selection of Reference Samples.* The domain expert first selects x samples for each of the n target label classes $(l_1, \ldots, l_n)$ within the dataset. It is imperative that the expert verifies the absence of poison, e.g., backdoor triggers, in these samples, designating them as a small reference dataset consisting of benign data with correct target labels, serving as the ground truth for LabelTrust.

2. *Expansion of Reference Dataset.* The reference dataset undergoes expansion to construct a Siamese dataset, enabling the training of a Siamese network. To construct this dataset, each sample is comprised of two instances from the reference dataset and a corresponding label, signifying whether the two samples originate from the same class within the reference datasets. For example, in Fig. 4, the first sample consists of two blue images from the l_1 class ("bird") and is thus positively labeled as 1 indicated with a green checkmark. Conversely, the second sample contains a blue sample from l_1 and a brown sample from l_2, resulting in a negative label of 0 visualized as a red cross.

3. *Training of Siamese Network.* The Siamese dataset is used to train a Siamese Network. The network learns to generate meaningful representations (embeddings) for both inputs and subsequently learns to classify these embeddings toward the positive or negative label, reflecting the similarity of both inputs. After this training step, LabelTrust can be used to evaluate unseen SL-Mappings.

4. *Construction of Valid Input for Siamese Network.* To assess the quality of an SL-Mapping, consisting of a sample s and a label l, LabelTrust constructs valid inputs for the Siamese network. This involves pairing the x samples from the label class of the SL-Mapping (e.g., l_2 in Fig. 4) from the reference dataset with the input sample s. These pairs are similar to the ones in the Siamese dataset from step 2. With this pairing, the Siamese network can validate if the unseen sample s is similar to any of the ground truth samples from the predicted class of s.

5. *Calculation of Confidence Score.* The constructed pairs are fed into the Siamese network trained in step 3, yielding a confidence score for each pair. A high score indicates similarity to the reference dataset, while a low score suggests that the SL-Mapping deviates unusually based on the reference dataset.[3] The final score is based on averaging the confidence scores of all evaluated pairs.[4]

6. *Reefeed Loop.* By applying a threshold to the final confidence score, all tested SL-Mappings can be categorized into clean samples and leftovers, stemming from potentially poisoned, underrepresented, or low-quality samples. A high threshold categorizes samples as clean only if LabelTrust is highly confident in their cleanliness. Conversely, a low threshold can identify samples likely

[3] A high-quality SL-Mappings has high similarities to samples of the respective class within this reference dataset, while low-quality SL-Mappings are not contained in the reference dataset.

[4] If samples within one class significantly differ, we introduce new (sub)classes (cf. Sect. 5). Hence, outliers are very unlikely to occur.

to be undesired, such as potentially poisoned ones.[5] Regardless of the application scenario, a domain expert can then inspect the leftovers.The expert can refeed clean samples from the leftovers, that were not considered in the ground truth so far into the reference dataset and rerun the whole process, including Siamese model training and confidence scoring of the whole dataset. Our intuition, which we verify in Sect. 4.3 is that the leftovers will be iteratively reduced while maintaining a high detection rate of poisonings and simultaneously reducing the number of poisonings that are falsely identified as clean, essentially increasing the performance of LabelTrust over time.

3.2 Application Scenarios

In the following, we will elaborate on the practical applications of LabelTrust within two distinct scenarios: dataset cleaning and the generation of a prediction confidence scores.

Dataset Cleaning. For a manual dataset-cleaning procedure before model training (cf. Sect. 2), the conventional approach would necessitate exhaustive individual inspection of all samples by a domain expert. Leveraging LabelTrust, the expert can optimize this process by selecting a small representative subset of samples for each label class as reference dataset (step 1 in Fig. 4). Subsequently, the Siamese network trained on these samples can be employed to check all samples from the original dataset. Clean samples will exhibit high similarity to the small ground-truth in the reference dataset.

Precisely, intentionally mislabeled samples, e.g, samples with a pixel trigger [13], will not be classified toward the attacker-chosen false label class by the Siamese Network, but towards the benign class and hence yield a low confidence score on the assigned false label. Similarly, unintentionally mislabeled data, e.g., low-quality samples, will also yield a low confidence score on the assigned label, as the samples differ from the ground truth in the reference dataset. For both, intentional and unintentional mislabels, the low confidence score yielded by LabelTrust allows sample filtering, essentially also detecting poisoning attacks. Unpoisoned filtered samples are either mislabeled and thus undesirable in the dataset or can be added to the reference dataset (step 6 in Fig. 4) as they provide valuable insights that have not been represented by the ground truth yet. Thus, the domain expert can resample benign sets from the filtered irregular mappings (leftovers in Fig. 4), and refeed them into the reference dataset (step 6 in Fig. 4). By iteratively repeating this process, e.g., performing multiple dataset cleaning rounds, LabelTrust results in a significant reduction in the number of samples requiring manual verification, which we show in Sect. 4.3.

Noteworthy, in a new dataset cleaning round, all samples are reevaluated by the new Siamese network, instead of just analyzing the leftovers. The reason for this design choice is, that the Siamese network's capability to distinguish clean samples will increase with further rounds. Thus, samples that might have been falsely categorized as clean in the first round will be correctly classified as leftover in subsequent rounds due to increased knowledge. Hence, we assume that the networks's increased capabilities will diminish the size of the leftover over time. We confirm this assumption through empirical evaluation in Sect. 4.3.

The dataset cleaning process can be concluded either when the expert has inspected all samples, discarding or refeeding them, or when a predetermined fraction of filtered samples is reached, that attains a high, yet poison-free model performance, reflecting the compromise the domain expert is willing to make for the sake of a clean dataset.

Confidence Scoring. The same procedure of LabelTrust is applicable for confidence scoring of predictions of a primary pre-trained model. In this scenario, the labels for the samples are obtained by using the samples' prediction yielded by the pre-trained model. The reference dataset can be constructed in two ways: Either access to the trainset is available, e.g., model creators provide LabelTrust. Alternatively, model creators can provide small clean datasets. If no data access is given, the domain expert can observe inference samples and construct the reference dataset (via refeed loop). Hence, LabelTrust can work without access to trainsets. Irregular mappings, essentially arising from mispredictions of the primary model, may stem from either a low-performing or poisoned primary model. Consequently, the confidence score derived from the Siamese network, which is based on the clean reference dataset used to train LabelTrust's Siamese network, can provide insights into the trustworthiness of the primary model's predictions. For samples dissimilar to reference-dataset samples, the confidence score is (and should be) low. Such samples are validated by the domain expert and can be added to the reference dataset via refeed loop. The Siamese network does not achieve the same classification performance as the primary model trained on a large, untrusted dataset. Hence it cannot duplicate the classification task but can asses the primary model's predictions. This advantage comes from training the Siamese network on a smaller, carefully curated reference dataset, free from poisoned data. Hence, both models, primary model and Siamese network have different purposes and complement each other.

The yielded confidence score enables an user to decide if a model prediction is trustworthy. For a low score the user should verify the prediction, while for a high score, the system's prediction is confirmed. Furthermore, the performance of LabelTrust can also be improved in the confidence scoring setting, as unseen new samples could be integrated into the reference dataset after careful inspection by a domain expert

[5] LabelTrust doesn't rely on fixed thresholds. A high threshold will identify very trustworthy mappings while a low threshold will identify untrustworthy mappings in the same setting. The threshold is selected by the user depending on his goal and not depending on the scenario itself, e.g., model architecture or dataset.

(step 6 in Fig. 4). In particular, samples that received low confidence scores are considered most useful as they differ from the existing ground truth and lead to a more diverse Siamese training dataset. After the integration of these samples, a new Siamese model could be trained that replaces the existing one. Hence, similar to dataset cleaning, LabelTrust could improve iteratively over time with the help of a domain expert.

Summary. LabelTrust serves as a versatile tool for confidence score generation that assesses the legitimacy of a label assigned to a sample, relying on a small set of thoroughly examined samples by an expert. The system is based on few-shot learning, specifically using a Siamese network. A high confidence score is indicative of a sample's similarity to an already examined sample and its correct label assignment. Conversely, if a sample falls within a subset that has not yet undergone expert examination, and hence is potentially poisoned or of low quality, LabelTrust will yield a low confidence score. While LabelTrust is a general tool applicable to all use cases with the need for SL-Mapping evaluation, we show its utilization for dataset cleaning and prediction confidence scoring. LabelTrust's performance is iteratively enhanced by refeeding negatively evaluated samples to the small reference dataset and retraining the Siamese network. This process ensures the continual improvement of LabelTrust over time.

4 Evaluation

Datasets & Model Architectures. We use common datasets mainly focusing on image classification with MNIST [10], Fashion-MNIST (FMNIST) [50], and Intel Image Classification (IIC) [3] trained on the ResNet-18 [15] model architecture. The architecture of the feature encoding subnetwork of the Siamese network is identical to the ResNet-18 [15], however, the last layer is removed as the network should not yield a prediction but an embedding of size 256. Further, the first layer is adjusted depending on the utilized dataset. We added a decision network consisting of two linear layers equipped with a ReLU [1] activation function. Furthermore, we evaluated a second Siamese architecture that uses a smaller CNN model as feature encoding subnetwork combined with the same decision network. This CNN comprises two consecutive convolutional layers, each followed by a batch normalization layer and a ReLU [1] activation function, as well as a 2D pooling layer. The experimental setup including hardware specifications is reported in App. 7.1.

4.1 General Functionality

First, we show the general functionality of LabelTrust's core, the Siamese network. Therefore, we use MNIST [10] and the ResNet-18 [15] architecture for the Siamese network.

Siamese Training. In step 1 of LabelTrust (cf. Sect. 3.1 and Fig. 4), involving the selection of reference samples, we randomly extract $x = [2, 5, 10, 15, 20]$ samples for each of the $n = 10$ classes from the MNIST [10] train dataset, forming a reference dataset comprising 20, 50, 100, 150, and 200 samples for LabelTrust. To give an impression of the reference dataset, we visualize the samples for $x = 10$ in App. 7.4. Opposed to the intended use-case of experts selecting high-quality samples, we select correctly labeled samples at random to showcase the behavior under a semi-optimal expert. For the subsequent expansion of the reference dataset in step 2, we utilize these samples to generate a Siamese dataset mirroring the size of the original MNIST [10] dataset, which comprises 60,000 samples. To achieve this, we repeat the following process 60,000 times: We iteratively generate a positive and negative pair. For a positive pair, we randomly select a class and one of the x samples of this class and pair it with a different random sample from the same class. For a negative pair, we chose two different random classes and one sample out of the x samples from each class to generate the pair. For both, a positive and a negative pair, those two selected samples serve as data records to form a new sample for the Siamese network (cf. Sect. 2). Each new sample, composed of two data records, is assigned a target label of 1 if the records originate from the same class and 0 otherwise. Subsequently, this Siamese dataset is employed in step 3 of LabelTrust to train the Siamese network. For training, we employ the BCELoss (cf. Sect. 2), an Adadelt [52] optimizer with learning rate 1.0, and train one epoch with a batch size of 64.

Evaluation Method. We use three distinct test sets with unseen data to evaluate the performance of the Siamese network:

1. *ACC-Testset.* Utilizing the MNIST [10] test set, which are unseen data for the Siamese network, we replicate the method outlined in LabelTrust's step 2 to construct a Siamese test dataset. This test dataset enables us to derive a comprehensive measure of model performance, quantified by accuracy (ACC). We present the ACC across varying confidence score thresholds of 0.99, 0.5, and 0.01. A high threshold of 0.99 allows to identify the samples above 0.99, which have a very high similarity to the reference dataset and hence are most likely clean. A low threshold of 0.01 allows to identify the samples below 0.01, which yield minimal similarity to the reference dataset and hence are not clean with a high probability. The threshold of 0.5 reflects the most balanced trade-off between both settings. While the threshold can be arbitrarily chosen, we showcase the results for the three thresholds, as most application scenarios would most likely use one of these three thresholds.

2. *Unpoisoned-Testset.* Leveraging all samples from the MNIST [10] test set as SL-Mappings for verification, we expect the Siamese network to accurately assess the assigned target labels of evaluation samples. We report the ACC, ideally high, along with the fraction of SL-

Table 1: Performance of the Siamese network for MNIST [10] trained on ResNet-18 [15].

	Poison Type	x	**ACC-Testset** with confidence threshold...			**Unpoisoned-Testset**, with confidence threshold...						**Poison-Testset**			
						0.99		**0.5**		**0.01**		**AVG**	**TRR**, with threshold...		
			0.99	**0.5**	**0.01**	**ACC**	**FRR**	**ACC**	**FRR**	**ACC**	**FRR**	**Score**	**0.99**	**0.5**	**0.01**
(1)	Pixel [13]	2	59.56	69.65	74.45	92.52	72.98	92.34	55.16	89.60	29.90	0.0088	100.00	100.00	92.04
(2)	Pixel [13]	5	72.44	79.53	81.37	95.30	41.03	95.03	28.83	92.10	19.45	0.0074	99.75	99.31	98.43

(4)	Pixel [13]	15	80.88	88.65	91.52	97.46	22.80	97.82	12.25	96.26	6.39	0.0047	99.87	99.59	98.39
(5)	Pixel [13]	20	81.74	89.17	91.91	97.36	22.94	97.74	12.88	96.52	6.59	0.0010	99.95	99.90	99.68
(6)	Blend [7]	10	75.50	82.43	85.03	96.29	32.07	96.18	21.45	94.01	13.84	0.0013	99.86	98.81	95.20
(7)	Clean-Label [44]	10	75.50	82.43	85.03	96.29	32.07	96.18	21.45	94.01	13.84	0.0041	99.94	99.61	98.69
(8)	Random-Label [4,21]	10	75.50	82.43	85.03	96.29	32.07	96.18	21.45	94.01	13.84	0.0179	99.52	98.37	95.32

Mappings falsely assigned with a confidence score below the threshold, indicated by the False-Rejection-Rate (FRR), again using thresholds of 0.99, 0.5, and 0.01.

3. *Poison-Testset.* Using the MNIST [10] test set, we introduce backdoors into each sample, for instance a pixel trigger [13], and subsequently verify the resultant SL-Mappings. In an optimal scenario, the Siamese network should assign low confidence scores to all poisoned samples. We present the average score over all samples in the test set and the fraction of poisoned samples with a confidence score above the threshold, denoted by the True-Rejection-Rate (TRR), again employing thresholds of 0.99, 0.5, and 0.01.

Results. The results of the experiments are listed in Tab. 1. Lines (1) to (5) showcase the results when utilizing the pixel trigger [13]. We begin with $x = 2$ samples from each class in line (1) and progressively increase the number of samples in the reference dataset to $x = 20$ in line (5). Regarding the accuracy on the Siamese test set (ACC-Testset), we observe an increase in accuracy values across all confidence score thresholds of 0.99, 0.5, and 0.01 with a larger number of ground truth samples. For instance, at the 0.99 threshold, the ACC for $x = 2$ is merely 59.56, whereas it rises to 81.74 with $x = 20$ samples. This behavior aligns with our expectation that samples are assessed based on the knowledge within the clean reference dataset, indicating that reintroducing new samples into the reference dataset (step 6 of LabelTrust) will enhance performance. The improvement between $x = 15$ and $x = 20$ in lines (4) and (5) is negligible, suggesting performance plateauing. This supports our assumptions about the efficiency of the few-shot learning process, as apparently for this setup no more samples than $x = 15$ are necessary for optimal performance.

When evaluating the Siamese network's performance in verifying benign data (Unpoisoned-Testset), a similar trend is observed across all three confidence thresholds. For instance, at the 0.99 threshold, the ACC starts at 92.52 for $x = 2$ and increases to 97.36 for $x = 20$. Conversely, the corresponding FRR demonstrates the opposite trend: Initially, with $x = 2$, numerous benign samples are assigned confidence scores below the threshold, resulting in an FRR of 72.98 for the 0.99 threshold, essentially ensuring only samples with high similarity to the reference dataset are considered positive. This FRR diminishes to 22.94 for $x = 20$. Depending on the application context, users may opt for a low threshold, such as 0.01, yielding an FRR of only 6.59 for $x = 20$ samples, ensuring LabelTrust identifies only significantly deviant samples from the reference dataset.

When analyzing the detection performance on poisoned samples (Poison-Testset), all experiments exhibit exceedingly low average confidence scores, e.g., 0.0088 already for $x = 2$, effectively countering pixel trigger backdoors. Across all thresholds, the TRR nearly reaches 100.0.

Summary. The Siamese network of LabelTrust operates as intended, demonstrating improved outcomes with an increased number of samples within the reference dataset. While achieving favorable results across all thresholds, users have the flexibility to tailor the threshold to suit specific scenarios. The user can opt to have LabelTrust identify highly confident SL-Mappings by setting a threshold such as 0.99, or label mappings that are deemed highly unlikely to be correct with a threshold like 0.01. For subsequent experiments assessing LabelTrust's, we maintained $x = 10$ samples as our initial reference dataset size.

4.2 Generalizability

Poisoning Attack Independence. Initially, we assess LabelTrust's generalizability by replicating the experiment detailed in line (3) of Tab. 1 across different poisoning attacks. Specifically, we conduct the experiment with a Blend [7] backdoor, followed by a Clean-Label [44] pixel trigger backdoor, and lastly, an untargeted attack, which randomly assigns labels to samples (Random-Label) [4, 21].

The outcomes, outlined in lines (6), (7), and (8) of Tab. 1, exhibit comparable results to line (3).[6] Consequently, with detection rates consistently surpassing 95.20 across all scenarios, we affirm that LabelTrust functions independent of the poisoning attack in place and detects false SL-Mappings, e.g., due to poisoning attacks, reliably. Note, that the Random-Label attack mirrors the effect of a mislabeling due to human error. Hence, the results also show the performance of LabelTrust for unintentional mislabelings.

[6] Note, that the results for ACC-Testset and Unpoisoned-Testset are completely equal, as the same samples were picked for Siamese training due to the same random seed and the same amount of poisoned samples. Only the results for Poison-Testset vary depending on the new backdoor.

Table 2: Performance of the Siamese network for a pixel trigger [13] backdoor with $x = 10$ samples.

	Dataset	Model	ACC-Testset with confidence threshold...			Unpoisoned-Testset, with confidence threshold...						Poison-Testset			
						0.99		0.5		0.01		AVG	TRR, with threshold...		
			0.99	0.5	0.01	ACC	FRR	ACC	FRR	ACC	FRR	Score	0.99	0.5	0.01
(1)	FMNIST [50]	ResNet-18 [15]	70.79	79.29	83.01	93.71	51.60	93.50	30.42	90.11	14.69	0.0018	99.98	99.88	98.78
(2)	IIC [3]	ResNet-18 [15]	52.06	58.30	60.26	84.62	85.10	77.60	49.70	67.03	30.40	0.0132	99.48	98.77	96.55
(3)	MNIST [10]	CNN	58.98	75.71	81.73	93.60	63.58	95.80	28.79	88.73	11.06	0.0204	100.0	98.78	87.26

Dataset Independence. To demonstrate the dataset independence of LabelTrust, we replicated the experiments outlined in line (3) of Tab. 1 using alternative datasets: FMNIST [50], offering different image content, and IIC [3], featuring colored samples. The results, presented in lines (1) and (2) of Tab. 2, reveal noteworthy findings. With FMNIST [50], depicted in line (1), we observed comparable outcomes to MNIST [10], with notably high ACC values, such as 90.11 even at the 0.01 threshold for the Unpoisoned-Testset, and a modest FRR of 14.69. Remarkably, the detection rate for poisonings remained consistently above 98.78 for all thresholds. Conversely, the colored IIC [3] dataset posed a greater challenge for LabelTrust due to its increased sample diversity within each class. However, even with just $x = 10$ samples, LabelTrust achieved notable results. While the accuracies were slightly lower compared to FMNIST [50], the detection ratio for poisonings remained above 96.55 for all thresholds, with an average score of 0.0132. Thus, we assert that LabelTrust demonstrates robustness across different datasets, suggesting its dataset independence.

Model Independence. To demonstrate LabelTrust's independence from model architecture, we replicated the experiment outlined in line (3) of Tab. 1 using a Convolutional Neural Network (CNN) with a simplified structure. Due to the reduced complexity of the network, the learning rate of the Adadelt [52] optimizer was adjusted to 0.1. The results presented in line (3) of Tab. 2 demonstrate that comparable outcomes were achieved, despite the simpler architecture. While the accuracy was slightly lower compared to this attained with the ResNet-18 [15] architecture in line (3) of Tab. 1, the detection performance exhibited only a slight decrease, with values remaining notably high above 87.26 for all thresholds (reaching 100.0 for the 0.99 threshold), and an average confidence score of 0.0204 compared to 0.0042 for ResNet-18 [15]. These findings underscore LabelTrust's capability to operate effectively across diverse model architectures, affirming its architectural independence. It's noteworthy that in practical applications, such as confidence scoring of predictions of a primary model, LabelTrust's Siamese network and the primary model are inherently independent by design.

Summary. In summary, LabelTrust emerges as a versatile tool, consistently demonstrating uniform and reliable behavior across various configurations. Precisely, the evaluation has shown high performance across various poisoning methods, datasets, and Siamese architectures. Its performance remains unaffected by the type of poisoning method employed, the dataset's characteristics, and the Siamese network's architecture. Consequently, LabelTrust stands as a general-purpose solution applicable across numerous scenarios. Our subsequent evaluations will focus on its effectiveness in dataset cleaning and confidence score prediction.

4.3 Offline Dataset Cleaning

Setup. To demonstrate LabelTrust's effectiveness as an offline dataset cleaning tool, we use MNIST [10] and introduced a pixel trigger [13] backdoor, contaminating 10% of the samples in each batch resulting in 5625 poisoned samples.[7] Initially, we trained a ResNet-18 [15] model on this poisoned dataset and evaluated its accuracy on both the main task (MA) using the MNIST [10] test set and the backdoor task (BA) on the poisoned MNIST [10] test set. The results, presented in the first two columns of Tab. 3, show 98.36 MA and 100.0 BA, indicating a highly effective backdoor. Subsequently, we used LabelTrust to clean the dataset, opting for a 0.99 threshold, aiming to identify samples with high confidence scores while double-checking the remainder, simulating expert validation. Starting with a reference dataset of $x = 10$ randomly selected clean samples, we trained our LabelTrust version, which utilizes ResNet-18 [15] as the feature encoding subnetwork in the Siamese network. LabelTrust then categorized samples into clean and leftover subsets. We used the clean samples to retrain a ResNet-18 [15] model from scratch, aiming for an unbackdoored model. The iterative process continued with LabelTrust's refeeding step, where five additional randomly chosen clean samples from the leftovers were incorporated into the reference dataset in each subsequent round.[8] The updated reference dataset of each round is then used to retrain the Siamese network from scratch and reevaluate the whole dataset, resulting in a new set of clean and leftover samples. Opposed to the intended use-case of experts selecting high-quality samples in the refeed loop we select them at random to showcase the behavior under a semi-optimal expert.

Results. As reported in Tab. 3, the initial round reported in line (1) identified 37,717 clean samples and 22,283 leftovers, distinguishing 5,616 real poisoned samples and 16,667 benign samples with confidence scores below the threshold. The seemingly low accuracy of 71.86 is caused primarily by the unpoisoned samples falsely classified as leftovers. This effect

[7] We poison 10% of the 978 batches, each containing 64 samples, resulting in six poisonings per batch. The last batch, with 32 samples, has three poisonings due to the total dataset size of 60,000 samples.

[8] Note that Siamese dataset has the same amount of samples and is continuously trained for one epoch to produce comparable results. However, one could further enhance the training as discussed Sect. 5.

Table 3: Dataset cleaning statistics over six refeed rounds of LabelTrust for 60,000 samples containing 5,625 poisonings.

	Pre-LabelTrust		Post-LabelTrust		Refeed	x	Detection Statistics					
	MA	BA	MA	BA	Round		clean	leftovers	true leftovers	false leftovers	TRR	ACC
(1)	98.36	100.0	92.97	3.42	-	10	37,717	22,283	5,616	16,667	99.84	72.20
(2)	98.36	100.0	92.50	8.76	1	15	41,199	18,801	5,608	13,193	99.69	77.98
(3)	98.36	100.0	94.25	50.72	2	20	47,202	12,798	5,588	7,210	99.34	87.92
(4)	98.36	100.0	97.63	20.56	3	25	47,038	12,962	5,591	7,371	99.39	87.65
(5)	98.36	100.0	96.89	2.72	4	30	47,027	12,973	5,609	7,364	99.71	87.70
(6)	98.36	100.0	98.14	6.80	5	35	50,009	9,981	5,615	4,366	99.82	92.70

is caused by the high threshold of 0.99 and will diminish in later stages. The backdoor in line (1) was successfully filtered, achieving a BA of 3.42 after model retraining, with a marginal performance loss, reaching 92.97 MA. Notably, the TRR is 99.84, showing that LabelTrust detects a high fraction of poisonings already in the first round. This result reassures the results from the previous sections. In subsequent rounds (2) and (3) in Tab. 3, a discernible trend emerged: the Siamese network consistently identified more samples as clean, e.g., 41,199 in line (2) and 47,202 in line (3), while maintaining a very high TRR, indicating effective and reliable filtering of poisonings. Consequently, false leftovers decreased to 7,210, resulting in higher accuracies of up to 87.92 in line (3). Hence, we can see, that the randomly selected samples in the refeed loop increased the quality of the reference dataset, essentially leading to increased Siamese performance.[9] In lines (4) and (5), we can observe, that the quality of the system plateaued. Hence, the randomly selected clean samples from refeed rounds three and four do not contribute to the classification performance of the Siamese network. This behavior is expected, as the random selection (semi-optimal expert) might have selected low-quality samples. Nevertheless, if the process is continued, the original trend continues in line (6) with already 50,009 clean samples and only 9,981 leftovers reaching an accuracy of 92.70 and a TRR of 99.82. Hence, we can reason, that the choice of the clean samples is important and affects the performance of LabelTrust in terms of minimizing the number of rounds, but is not imperative as the dataset cleaning process will converge over time. Our evaluation has confirmed our assumption cf Sect. 3.2 that the dataset cleaning process converges over time resulting in a diminishing number of leftovers while maintaining a high backdoor detection (TRR). Tuning the Siamese network to better performance might yield even better results and is discussed in Sect. 5, but is out of the scope of this paper, as we focus on comparable results over multiple experiments and the depiction of the general functionality of LabelTrust.

Summary. In summary, LabelTrust functioned as intended, with the refeed loop enhancing system performance over time. Notably, even in the initial round, LabelTrust successfully removed the backdoor, with subsequent rounds yielding results akin to those observed with increasing x values in Tab. 1.

[9] Note, that all samples of the dataset get reevaluated in each round by design (cf. Sect. 3.2) to address potential mistakes made by LabelTrust in earlier rounds, especially detecting poisoned samples falsely mapped as clean.

Following the five refeed rounds detailed in Tab. 3, an expert would have reviewed only 350 samples manually, a fraction of 0.0058% compared to 60.000 samples that would have been reviewed without assistance from LabelTrust, and would only sacrifice 9,981 samples (16,63%) as leftovers, if he stops after refeed round five (line (6) in Tab. 3). Hence, LabelTrust effectively identified 50,009 samples as clean, essentially rendering a valuable tool for dataset-cleaning tasks.

4.4 Online Confidence Scoring

LabelTrust, by its design, is not supposed to filter out clean-label backdoors [44] during dataset cleaning, as these attacks rely on clean SL-Mappings during the poisoning process (cf. Sect. 2).[10] However, such attacks can be identified during model inference, as demonstrated in line (7) of Tab. 1. This motivates the combined usage of LabelTrust also in online confidence scoring application scenarios in Sect. 4.4.[11]

Setup. To demonstrate the effectiveness of LabelTrust in an online confidence scoring application, we trained a ResNet-18 [15] on MNIST [10] with a pixel trigger [13] backdoor injected on 10% of the data of each batch. We then evaluated the model's performance using both the MNIST [10] test set and a fully poisoned version of the test set, as previously used in the experiments in Sect. 4.3. We analyzed the misclassified samples from both test sets to identify instances where predictions should not be considered trustworthy. Specifically, we flagged samples misclassified by the model, whether due to poor performance or the presence of a backdoor, as potential alerts for untrustworthy predictions. We then examined the confidence scores provided by LabelTrust for these samples. For LabelTrust, we trained a Siamese network with $x = 10$, similar to the setup reported in line (3) of Tab. 1.

Results. In this evaluation, we focus on the detection of false or malicious predictions and hence SL-Mappings, as benign predictions do not pose a harmful threat to the user and hence do not need to raise a respective alarm. Benign predictions would yield similar results as for the Unpoisoned-Testset in the previous experiments and are thus omitted

[10] We conducted a respective experiment validating this assumption leading to a TRR of 4.64 and an ACC of 63.94.

[11] If LabelTrust is used with a model with high performance, e.g., 80% ACC, the final predictions' trustworthiness is still unclear. This can be provided with LabelTrust, which can be trained with starting from 2 samples per class. One pre-requirement is, that the dataset for the pre-trained model is not identical to the reference dataset, such that new insight is provided.

here. Mispredictions from the benign test set yielded a mean and median confidence score of 0.30 and 0.0018, while those from the backdoored test set yielded 0.0052 and $5.83 \cdot 10^{-7}$. We achieved similar results for experiments utilizing Blend [7] and Clean-Label [44] backdoors. Further, we use the FMNIST [50], and IIC [3] dataset and report the results in App. 7.3. These results indicate that LabelTrust reliably assigns low confidence scores, alerting the user by indicating a lack of trustworthiness in the predictions, particularly for backdoored samples. Conversely, non-poisoned samples receive more moderate negative confidence score values.

Summary. Summarized, LabelTrust shows reliable performance in online confidence scoring application scenarios, providing valuable insights into prediction trustworthiness.

4.5 Runtime

In terms of runtime, we present three noteworthy findings derived from ten runs of the experiment outlined in line (3) of Tab. 1, with the times averaged. First, the training duration for the Siamese network, constituting step 3 of LabelTrust, amounted to 34.56 seconds. Subsequently, the sample pairing process, encompassing step 4 of LabelTrust, required a mere $7.62 \cdot 10^{-4}$ seconds. Finally, the inference process for the ten samples in this case consumed 0.0056 seconds. Consequently, we assert that the additional computational burden imposed by LabelTrust is acceptable in the offline phase and negligible in the online phase. While there may be critical considerations in application scenarios such as autonomous driving, we believe that optimization of code and utilization of specialized hardware can reduce the overhead even more.

5 Discussion

Complicated Application Scenarios. As LabelTrust relies on a Siamese network, it encounters similar challenges to other few-shot learning-based networks, particularly in complex application scenarios where representative samples for all classes are required as ground truth. In instances where subclasses exist within classes, such as different shapes of objects like cars, it's advisable to either designate a class for each subclass in the Siamese network or increase the number of samples per class in the reference dataset. Moreover, longer training periods (more epochs) are typically necessary for handling more complex application scenarios and datasets. Ultimately, the user must determine the threshold in LabelTrust's pipeline based on whether they aim to identify samples likely to be clean or potentially poisoned/low-quality. In this work, we present the general functionality and applicability over multiple application scenarios and, hence, fixate the training periods and dataset sizes to get comparable results. Further, we use experimental setups, that are useful to see the effects of LabelTrust, e.g., for different thresholds, rounds, input types, and other hyperparameters.

Optimizations. Further optimization of the Siamese training, architecture, and hyperparameters might lead to even better performance. However, we did not focus on the optimization of few-shot learners in this work but focused on their application of confidence scoring. We believe that optimizing the performance of LabelTrust can be achieved through optimizing the performance of the Siamese network, mainly by four key measures. Firstly, employing a different loss function, such as Triplet Loss (cf. App. 7.2), may yield superior performance depending on the specific application scenario. Secondly, while LabelTrust is designed to be architecture-agnostic, customizing the Siamese network architecture to the specific application can enhance performance. Thirdly, ensuring high-quality sampling by involving a knowledgeable domain expert is crucial, as the quality of the reference dataset significantly impacts LabelTrust's performance. Further, the generation mechanism for the Siamese dataset can be optimized to generate highly effective pairs.

Adaptive Adversaries. Adapting to LabelTrust requires knowledge of expert-selected samples, which is not given. Neither the Siamese network nor the reference dataset is accessible to adversaries, preventing adaption, e.g., crafting adversarial examples [42]. LabelTrust evaluates SL-Mappings after poisoning attacks, such as dataset-poisoning or poisoned model training, have already been conducted.

Dependency on Data Distributions. Conceptually, the training dataset distribution is irrelevant for LabelTrust. We assume a minimal sample amount in the reference dataset, starting from 2 samples per class. Certainly, the Siamese network creator and domain expert should create a balanced dataset, which generally yields better performance. However, within LabelTrust, each SL-Mapping is evaluated individually without dependencies on other samples or pre-trained models.

6 Related Work

The related work for this paper draws from several interconnected domains. Initially, we examine research in the field of confidence scoring. Subsequently, we delineate our investigation against methodologies for dataset cleaning. Thirdly, we explore studies focused on mitigating data poisoning within datasets utilized by machine learning models.

6.1 Confidence Scores

Confidence Scoring generates scores that assess the reliability of predictions generated by a trained model.

Corbière *et al.* [9] employ a secondary model to generate a confidence score for predictions, relying on intermediate layer outputs from a pre-trained primary model. Consequently, its

efficacy is contingent not only on a specific model architecture but also on the characteristics of a particular model. This confidence scoring model undergoes training using the entire training dataset. A similar methodology is adopted by Luo *et al.* [28], which introduce a novel loss function within the same framework. LabelTrust instead is a general tool for ST-Mapping verification and hence can be used to evaluate the prediction outcome of any primary model, essentially being independent of a specific model instance or architecture.

Jiang *et al.* [19], on the other hand, utilize the entire training dataset to construct sets of samples with high density for each class through the nearest neighbor algorithm. For a new prediction, the distance to these sets is computed, resulting in a lower prediction confidence if the prediction deviates from the nearest distance. However, as only a straightforward distance metric is employed, this approach does not analyze the precise content of the sample, such as the scenery depicted in an image. Additionally, the computational complexity during sample evaluation increases with the number of classes. Contrary, leveraging a Siamese network with convolutional layers, LabelTrust considers the specific features of a sample's content, rather than solely relying on distance metrics. The features extracted by a similarity metric might not capture the full complexity of visual information, leading to inaccurate similarity assessments. Neural networks, on the other hand, can learn their own feature representations directly from the image data, potentially capturing more nuanced relationships between images. Further, the effort to evaluate one ST-Mapping is constant, e.g., one model inference of the Siamese network. Additionally, the efficacy of the methods lies in analyzing the entire training dataset, assuming the presence of clusters of benign samples, thus presupposing a majority of clean samples. In contrast, LabelTrust relies on a small number of clean samples, allowing it to effectively manage datasets with a high degree of compromised data.

Moon *et al.* [30] propose a model-dependent scoring mechanism embedded during training via custom loss and does not consider poisonings. LabelTrust instead does not interfere with the training of the pre-trained model.

Jha *et al.* [18] identify important features in an input sample. Iteratively, the approach changes those features and observes the model output of the modified sample over multiple inference rounds to yield a confidence score. As the approach relies on a trained model, it cannot be applied to dataset cleaning and induces significant computational overhead, due to multiple inference steps.

Guillory *et al.* [14] predict general model performances under distribution shift instead of scoring individual samples, which is an orthogonal problem motivating LabelTrust.

Overall, while the primary focus of most of these studies [9, 19, 28, 30] is to furnish scoring mechanisms for predictions, they do not address or prioritize defense against poisoning attacks, such as backdoors, or introduce high overhead during inference [18]. In contrast, LabelTrust is designed to operate within a more realistic scenario, accounting for adversarial attacks. Further, LabelTrust only needs a fraction of the training samples for training. Hence, the confidence score of those works is based on large untrusted datasets as references, whereas LabelTrust's confidence score relies on a small subset of high-quality samples resulting in high trustworthiness.

6.2 Dataset Cleaning

Dataset cleaning aims at identifying poisoned samples within a dataset essentially separating poisoned from clean samples to allow for unpoisoned training.

Huang *et al.* [17] utilize outputs from specific layers (activations) of clean samples to train a secondary network tasked with scoring predictions. By relabeling and reintroducing samples based on these scores, they assert that only 1% of training data must be clean. [17] can be considered the closest related work to LabelTrust. However, it is reliant not only on model architecture but also on a specifically trained model instance, unlike LabelTrust, which remains agnostic to such constraints. Furthermore, by leveraging a Siamese network and few-shot learning, LabelTrust can operate with even fewer samples than the 1% required in [17].

Paudice *et al.* [35] detects label-flipping attacks and simultaneously offers a method to adjust previously flipped labels. Peri *et al.* [36] focuses on the detection of clean-label backdoors. Both works, use a similar principle as Jiang *et al.* [19], which results in the same downsides that we mentioned above.

Gao *et al.* [12] developed a model aimed at partitioning a suspicious dataset into clean and poisoned subsets. The loss generated by individual samples provides insights into their potential contamination. Ramzi *et al.* [38] employ an auto-encoder architecture to identify data poisonings, leveraging reconstruction errors to distinguish between clean and contaminated samples. Pan *et al.* [33] introduces a sample filtering method specially designed for backdoored samples based on the optimization of a detection model against multiple objectives. Based on a small clean dataset, which is used for training first, the loss of samples provides insight if the samples are poisoned. While [12, 33, 35, 38] focus solely on offline dataset cleaning, LabelTrust simultaneously addresses both offline dataset cleaning and online prediction scoring.

Other papers such as [22, 23, 39], focused on dataset cleaning, concentrate solely on identifying [22, 23] and potentially repairing [39] low-quality (dirty) training samples, without addressing poisoned data, thus diverging from our work.

6.3 Poisoning Prevention

Poisoning prevention aims at making a model robust to the existence of poisoned samples within a dataset, essentially training a benign model on a poisoned dataset.

Wang *et al.* [46] propose a system to safeguard the feature extraction component of a model against backdoor feature learning. The authors achieve this by retraining the classification part (the final layers) on a clean dataset, constituting 10% of the entire dataset. Thus, rather than cleaning the dataset, the approach modifies the architecture to withstand backdoor attacks, making it reliant on specific model architectures. Instead, LabelTrust is independent of the model architecture and only needs a small fraction of data for few-shot learning.

Li *et al.* [24] introduce a system that detects backdoors by identifying poisoned samples based on their loss values (similar to [33]) and assigning random labels to these samples to disrupt the connection to the backdoor target class. Although this system is not designed to isolate poisoned samples, it could potentially be repurposed for this task. However, the approach relies on an empirically determined threshold and necessitates altering the mapping of samples, which could degrade the model performance similar to untargeted poisoning, despite its effectiveness against backdoors. LabelTrust does not negatively impact the performance of a trained model by filtering the poisoned samples out instead of relabeling them. Further, we provide a meaningful confidence score allowing for versatile operation.

Building upon Li *et al.* [24], Ying *et al.* [51] propose a training pipeline incorporating unlearning for a subset of identified poisoned samples. These samples are discerned by analyzing prediction probabilities and applying a threshold, as poisoned samples typically yield higher probabilities. Compared to LabelTrust, the method can not be applied to pre-trained models and does not provide a meaningful confidence score.

Jiang *et al.* [20] extend the approach of Li *et al.* [24] by integrating a small secondary head into the model. This head, utilizing feature embeddings from the primary model, is trained to recognize backdoors and subsequently relabel poisoned samples. Hence, the method is dependent on the architecture of the primary model, which is not the case for LabelTrust.

While the aforementioned works [20, 24, 46, 51] aim to create benign models even when trained on poisoned datasets, LabelTrust takes a different approach by focusing on providing a confidence score for each ST-Mapping. Unlike the loss-based methods described above, LabelTrust can be used with already pre-trained models, e.g., does not require changing the training of the primary task model. Further, the confidence score it generates offers meaningful insights, as opposed to the threshold-based clustering of benign and malicious samples.

In summary, LabelTrust offers distinct advantages over related works from the mentioned research areas. However, some benefits of LabelTrust are unique across all works: the consolidation of two use cases, the minimization of the trusted dataset by utilizing Few-Shot-Learning, and ongoing enhancement facilitated by a refeed-loop mechanism overseen by a human expert.

7 Conclusion

Assessing the quality of Sample Label Mappings (SL-Mappings) is essential in machine learning, whether derived from labeled datasets or inferred during model inference. The existing solutions from the domains of dataset cleaning and prediction confidence scoring lack a dual-use tool for this challenge, only providing standalone approaches with individual downsides. Therefore, we introduce LabelTrust, a versatile and architecture-independent tool that leverages a Siamese network trained via few-shot learning based on a few clean samples to provide a confidence score for SL-Mappings. Thereby, LabelTrust effectively addresses the downsides of existing standalone solutions, while reliably detecting poisonings in both contexts. With an interactive loop for system improvement, only 0.0058% of the dataset needs manual evaluation to clean 83.73% of a dataset while ensuring high model performance without an active backdoor.

Appendix

7.1 Hardware & Experimental Setup

Experiments were conducted using PyTorch, a leading Python-based machine learning library [34, 43, 45], on a server with an AMD EPYC 7413 24-Core Processor (64-bit) boasting 96 processing units and 128GB main memory. CUDA [32] facilitated access to an NVIDIA A16 GPU with 4 virtual GPUs, each featuring 16GB GDDR6 memory.

7.2 Siamese Loss Functions

Alternatives to BCELoss introduced in Sect. 2 include the Contrastive loss and the Triplet loss [25]. The Contrastive loss operates on data record pairs and aims to minimize the distance between records from the same class, while maximizing the distance between samples from different classes towards a predefined margin m. Thereby, a respective distance function $d(r_1, r_2)$ for the two data records r_1 and r_2 is applied, e.g., the Euclidean distance. A general depiction of the corresponding loss is illustrated in Eq. 2. y_i is again the label and $d(r_1, r_2)$ calculates the distance of the embeddings $e(r_1)$ and $e(r_2)$ that were generated by the feature embedding subnetworks.

$$CLoss = \frac{1}{N}\sum_{i=1}^{N} y_i \cdot d(r_1, r_2) + (1 - y_i) \cdot max(0, m - d(r_1, r_2))$$
$$d(r_1, r_2) = ||e(r_1) - e(r_2)||^2 \tag{2}$$

Table 4: Mean and median scores for mispredictions from the benign test set (Benign) and the backdoored test set (Backdoored). The default setting is ResNet-18 [15] on MNIST [10] with a pixel trigger [13] backdoor injected on 10% of the data of each batch.

	Benign		Backdoored	
	Mean	**Median**	**Mean**	**Median**
Default	0.3006	0.0182	0.0052	$5.83 \cdot 10^{-7}$
Default + FMNIST [50]	0.3442	0.0048	0.0001	$5.35 \cdot 10^{-10}$
Default + IIC [3]	0.3419	0.0206	0.0266	$1.57 \cdot 10^{-6}$
Default + Blend [7]	0.3271	0.0246	0.0683	$1.047 \cdot 10^{-5}$
Default + Clean-Label [44]	0.3676	0.0381	0.0751	$2.7423 \cdot 10^{-6}$

On the other hand, the Triplet loss involves three data records, forming two pairs. Initially, an anchor record a is selected and paired with a positive record p from the same class and a negative record n from a different class. Subsequently, the two pairs undergo processing, and the loss is calculated, as outlined in Eq. 3, aiming towards the same goal as the Contrastive Loss.

$$TLoss = \frac{1}{N}\sum_{i=1}^{N} max(0, d(a,p) - d(a,n) + m) \qquad (3)$$

LabelTrust could also be used with Contrastive or Triplet loss, but respective experiments were omitted within this paper.

7.3 Confidence Scoring Experiments

Due to space limitations of the paper, we report additional results for the confidence scoring (cf. Sect. 4.4) use case here. We conducted experiments with the Blend [7] and the Clean-Label [44] backdoor, as well as with the FMNIST [50], and IIC [3] dataset. The first line of Tab. 4 depicts the default setting reported in Sect. 4.4 with ResNet-18 [15] on MNIST [10] with a pixel trigger [13] backdoor injected on 10% of the data of each batch. The subsequent lines of Tab. 4 report the results when changing either the backdoor or the dataset from the default setting. We can observe similar results for all of the experiments.

7.4 Visualization of the Reference Dataset

To give an impression of how the reference dataset looks like in our experiments, we visualize the reference dataset for $x = 10$ samples per class. Fig. 5 shows the ten samples for each class from the MNIST [10] dataset, which have been randomly chosen in our experiments.

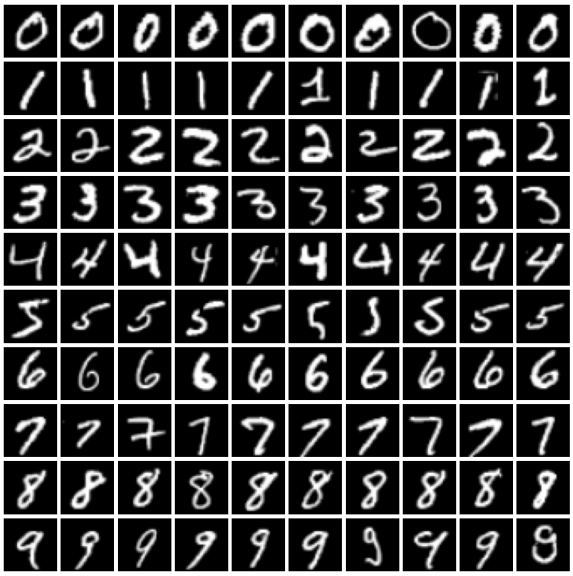

Figure 5: Visualization of the reference dataset with $x = 10$.

More Simplicity for Trainers, More Opportunity for Attackers: Black-Box Attacks on Speaker Recognition Systems by Inferring Feature Extractor

Abstract

Recent studies have revealed that deep learning-based speaker recognition systems (SRSs) are vulnerable to adversarial examples (AEs). However, the practicality of existing black-box AE attacks is restricted by the requirement for extensive querying of the target system or the limited attack success rates (ASR). In this paper, we introduce VoxCloak, a new targeted AE attack with superior performance in both these aspects. Distinct from existing methods that optimize AEs by querying the target model, VoxCloak initially employs a small number of queries (e.g., a few hundred) to infer the feature extractor used by the target system. It then utilizes this feature extractor to generate any number of AEs locally without the need for further queries. We evaluate VoxCloak on four commercial speaker recognition (SR) APIs and seven voice assistants. On the SR APIs, VoxCloak surpasses the existing transfer-based attacks, improving ASR by 76.25% and signal-to-noise ratio (SNR) by 13.46 dB, as well as the decision-based attacks, requiring 33 times fewer queries and improving SNR by 7.87 dB while achieving comparable ASRs. On the voice assistants, VoxCloak outperforms the existing methods with a 49.40% improvement in ASR and a 15.79 dB improvement in SNR.

1 Introduction

Our voices not only convey "what we speak" but also reflect "who we are". Based on this phenomenon, speaker recognition (SR) techniques have been widely applied in various biometric authentication systems [1–3]. The core of current speaker recognition systems (SRSs) is deep neural networks (DNNs) [4, 5]. Unfortunately, SRSs also inherit various vulnerabilities from DNNs. One of the primary security concerns is adversarial examples (AEs), where an adversary can bypass SRSs by adding small perturbations to audio inputs [6–8].

The AE attacks can be categorized into the white-box attacks and the black-box attacks based on the capacity of the attacker. In the white-box setting, where the internal details, such as the parameters and architecture of the underlying DNN, are accessible, the adversary can easily generate AEs using the gradient descent method [9, 10]. In the black-box setting where the adversary cannot access the internal details, it is still possible to generate AEs through query-based attacks or transfer-based attacks. Query-based attacks [7, 11] operate by estimating the gradients of the target model via the analysis of how variations in model inputs affect outputs, as shown in Figure 1 (a). Transfer-based attacks leverage the transferability of AEs, using examples that can deceive a known model to fool an unknown model [12, 13], as seen in Figure 1 (b). However, the assumption of the white-box attacks is too strong, as attackers typically cannot access the internal information of the target system in practice. Both black-box attack approaches also have inherent limitations. Specifically, query-based attacks require extensive queries to the target model to estimate gradients, while transfer-based attacks face restricted attack success rates, as summarized in Table 1. These constraints hinder their practicability in reality.

In this paper, we take a different approach from prior works to explore the vulnerability of SRSs against AE attacks. Instead of generating AEs targeting the underlying DNNs, we focus on disrupting the feature extractor (FE) to realize the attack. Our primary insight is that since the DNN relies on the output from the FE as its input, disrupting the FE will naturally impact the output of the DNN. Compared to complex DNNs, the FEs are easier to manipulate intuitively because their structures are simpler. Besides, we observe that most existing SRSs utilize a few common feature extraction algorithms, such as Mel-frequency Cepstral Coefficients (MFCC) [14], D-Vector [15], and X-Vector [16], to construct their FEs [17]. This fact inspires us to attempt to infer the FE used by the target system, thereby enabling a white-box attack to simplify the optimization of adversarial perturbations. This approach is similar to prior works, which initially establish local substitute models closely resembling the target model through

*The first two authors contributed equally to this work.
†Corresponding authors.

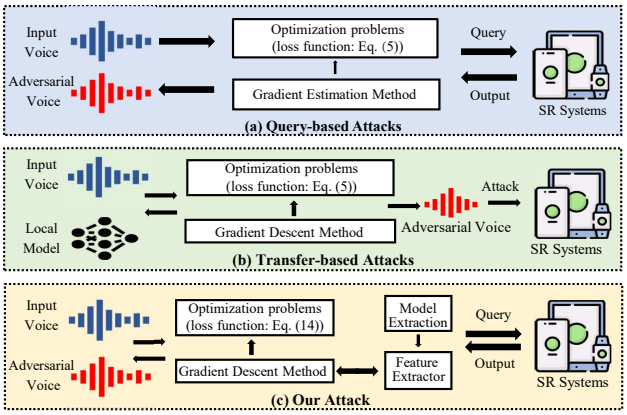

Figure 1: Overview of query-based attacks, transfer-based attacks, and our attack.

model extraction attacks [18, 19], and then utilize the substitute models to optimize AEs. However, compared to the prior works that aim to extract complex black-box DNNs, determining which feature extraction algorithm the target system uses could be much easier.

Based on the above considerations, we propose VoxCloak, a new targeted AE attack against black-box SRSs, as shown in Figure 1 (c). VoxCloak comprises two stages. The first is inferring the FE of the target black-box SRS from a set of candidates. We utilize the fact that each FE defines unique feature spaces, and the subsequent DNN will output similar results for similar feature vectors. Specifically, we generate AEs for each candidate FE. Then, we can determine the target FE by analyzing which AEs successfully compromise the target system. In addition, to address the problem where the target system outputs identical results for multiple AEs associated with different FEs, making it hard to determine the target FE, we design a genetic algorithm to eliminate incorrect candidates to improve the accuracy of the inference results.

The second is generating high-quality AEs based on the inferred FE. After inferring the target FE with a small number of queries, we can generate an arbitrary number of AEs locally without the need for any further queries. Therefore, compared to previous attacks that may require tens of thousands of queries to craft a single AE [6], our method significantly reduces the cost of the attack. We also enhance the imperceptibility and real-world robustness of the AEs by incorporating the psychoacoustic masking effect and the room impulse response into the AE generation process.

Compared to prior works, we highlight the three advantages of VoxCloak: (1) *Low Cost*: VoxCloak only requires a small number of queries to the target system, such as a few hundred, which is a one-time cost. After this, the attacker can generate any number of AEs without the need for further queries (unless the target system updates its used FE). (2) *Imperceptibility*: The AEs generated by VoxCloak are less detectable to the human ear, offering improved imperceptibility. (3) *Robustness*: VoxCloak could successfully attack various SRSs in the physical world with an effective attacking distance of up to 4 meters. This surpasses the state-of-the-art method with a maximum distance of 2 meters.

Our main contributions are summarized as follows:

- To the best of our knowledge, we are the first to utilize the vulnerability stemming from the reuse of FEs to realize targeted AE attacks against SRSs. This vulnerability allows adversaries to bypass user identity authentication mechanisms.
- We propose VoxCloak, a new targeted AE attack against black-box SRSs. Our attack requires a one-time, small number of queries to the target SRS for inferring the employed FE. This design facilitates the offline generation of an arbitrary number of AEs.
- We evaluate VoxCloak on four commercial SR APIs and seven smart devices equipped with SR techniques. The results show that VoxCloak achieves an average attack success rate close to 100% and 70%, with a signal-to-noise ratio of 21.47 dB and 21.38 dB in the digital and physical domains, respectively.

2 Background

2.1 Speaker Recognition Systems

SRSs are designed to authenticate the identities of speakers based on the unique features of their voices. The typical workflow of an SRS is shown in Figure 2, comprising five main steps: feature extraction, universal background model modeling, speaker modeling, pattern matching, and score decision. These steps can be divided into three phases: the offline training phase (top part), followed by the online enrollment and online recognition phases (lower parts) [24].

In the offline training phase, an FE is employed to extract acoustic feature vectors from a set of voices. These feature vectors are then utilized to train a UBM [5], which captures the general features inherent in human speech audio. In the online enrollment phase, the SRS constructs a user-specific model based on the voices uploaded by the user, leveraging the previously established background model. In the online recognition phase, the SRS calculates a score to quantify the similarity between the input voice and the voices stored in the system. The authentication result of the identity is then determined based on a predefined threshold about the score.

Remark. All three phases involve an independent feature extraction process for reducing the dimensionality of the raw speech signal. Most current SRSs rely on existing FEs, such as MFCC, Mel spectrum (Mel) [25], X-Vector, D-Vector, etc. Detailed information regarding these FEs is provided in Appendix A.2. As these FEs are open-sourced and time-proven,

Table 1: Overview of the state-of-the-art adversarial attacks against SRSs.

Method	Threat Scenario	Attack Type	Task	Commercial	Target	Carrier	Query	ASR
Li *et al.* [20]	White-box	Digital	CSI	×	✓	Speech	-	<100%

∗: The query cost is one-time, where our attack only queries the black-box model to infer its FE in the first stage and then generates AEs without querying the model in the second stage.

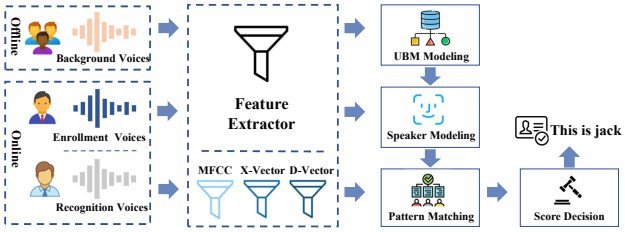

Figure 2: The workflow of an SRS contains three phases: offline training, online enrollment, and online recognition.

developers can easily build their own SRSs by directly invoking them, requiring minimal additional effort.

In terms of specific functionalities, SRSs typically address three types of sub-tasks: close-set identification (CSI) [26], speaker verification (SV) [27], and open-set identification (OSI) [28]. The differences among these sub-tasks lie in their methods of determining whether the current speaker initiating the authentication request is indeed the enrolled user. CSI identifies which enrolled user matches the current speaker. SV checks whether the current speaker can be identified as the target enrolled user. OSI determines whether the current speaker is an enrolled user or an unknown user.

Formally, let $S(\cdot)$ be the similarity score between the enrolled user and the current speaker x. For a CSI system, it outputs the identity of the enrolled user with the highest score. The decision module $D(x)$ can be formulated as follows:

$$D(x) = \arg\max_{i \in T} [S(x)]_i, \tag{1}$$

where the set T includes m enrolled users $\{1, 2, \ldots, m\}$. For an SV system, T only contains one enrolled user. It determines whether an input voice x belongs to the user according to the score and a predefined threshold θ. Its decision module output $D(x)$ can be formulated as follows:

$$D(x) = \begin{cases} S(x), & \text{if } S(x) \geq \theta, \\ \text{reject}, & \text{otherwise.} \end{cases} \tag{2}$$

The OSI system is a combination of CSI and SV. It utilizes the output of Eq. (1) and the threshold for decision as follows:

$$D(x) = \begin{cases} \arg\max\limits_{i \in T} [S(x)]_i, & \text{if } \max\limits_{i \in T} [S(x)]_i \geq \theta, \\ \text{reject}, & \text{otherwise.} \end{cases} \tag{3}$$

2.2 Adversarial Example Attacks

AE attacks are one of the primary security threats faced by DNNs [29–31]. Attackers can manipulate the output of the target model by introducing subtle noises into the inputs.

AE attacks can be categorized into white-box attacks [21, 32] and black-box attacks [33–35] based on the capabilities of the adversary. In the white-box setting, the adversary has complete access to the target model, including its architecture and parameters. Such information enables the adversary to generate AEs relatively easily using gradient-based methods [9, 10]. However, in the black-box setting, the adversary is limited to accessing only the outputs of the target model, making the attacks more challenging than in the white-box setting [6]. Furthermore, most real-world SRSs, such as commercial APIs and smart devices with authentication capabilities, operate as black boxes. They only disclose final results to users without any internal details, making black-box attacks more impactful than white-box attacks in practice.

Depending on the objective of the attack, AE attacks can also be categorized into untargeted and targeted attacks. Untargeted AEs [36] can deceive the target model into misclassifying the inputs into a random category, while targeted AEs [37] are designed to manipulate the target model into classifying the inputs into a category specified by the attacker.

Formally, let $\mathcal{X}$ be the set of inputs and $\mathcal{Y}$ be the set of outputs. Given the target model $f(x) : x \in \mathcal{X} \mapsto y \in \mathcal{Y}$, an

untargeted AE x^* can be represented as:

$$x^*, \ \ s.t. \ \ f(x^*) \neq y \text{ and } \|x^* - x\| \leq \varepsilon, \tag{4}$$

where ε is a parameter used to limit the magnitude of the adversarial perturbation, and $\|\cdot\|$ is a distance function, e.g., l_2-norm. Similarly, a targeted AE with the target class y^* can be formulated as follows:

$$x^*, \ \ s.t. \ \ f(x^*) = y^* \text{ and } \|x^* - x\| \leq \varepsilon. \tag{5}$$

In this paper, we focus on generating targeted AEs in the black-box setting, as they potentially pose a greater real-world threat compared to untargeted AEs. Moreover, since targeted attacks are more challenging to achieve, the investigation of these attacks can provide deeper insights into the vulnerabilities of SRSs [38].

2.3 Model Extraction Attacks

Model extraction attacks are for creating a model highly similar to the target model by analyzing the returned query results [18, 19, 39]. One of the purposes of this attack is to serve as an auxiliary method to facilitate black-box AE attacks [40]. While obtaining a substitute model with similar functionality to the target model, the adversary can use it to generate AEs locally via white-box attack methods, thus saving the cost of querying the target model.

To our knowledge, there have been no prior model extraction attacks specifically targeting SRSs. Due to the inherent complexity of SRSs and the diversity of their training data collected from various users, it is difficult for the adversary to extract a model that is sufficiently similar to the target model.

2.4 Threat Model

Our goal is to achieve a practical attack capable of deceiving commercial SRSs, including online SR services in the digital domain, as well as smart devices with identity authentication mechanisms in the physical domain.

We outline the following essential properties for an effective real-world attack: (1) It should be a black-box attack, as most commercial SRSs, including APIs and smart devices, only provide users with the final recognition results; (2) The number of queries to the target system should be as few as possible to reduce the cost of the attack and enhance its efficiency; (3) The attacker should not be able to access the target device, such as a smartphone, physically; (4) The generated AEs should be highly imperceptible, ensuring that they remain undetected by the victim.

We make two assumptions about the target systems and the capabilities of the attackers in real-world scenarios. Firstly, we assume that the target system follows the typical workflow employed by most existing SRSs. As the SRSs usually consist of the five components as introduced in Section 2.1, we consider that the assumption is practical. Secondly, the attacker could obtain a single voice sample of the enrolled user, which is long enough for authentication by the SRS, through alternative attacks, such as eavesdropping, phishing, or social engineering. This assumption aligns with traditional replay attacks [41], voice impersonation attacks [42], and prior AE attacks against SRSs [6, 12, 43].[1]

3 Methodology

3.1 Key Insights

Our first insight is that *once the target FE is known, generating AEs becomes easier.* SRSs typically operate by initially employing the FE to derive feature vectors fed into a subsequent DNN. Therefore, if the target system extracts the same feature vector from the AE as the enrolled voice, it will naturally lead to incorrect recognition results. Previous studies have suggested generating AEs targeting some specific FEs [13]. However, given the nearly infinite space of voice samples, searching for an AE that meets this requirement is extremely difficult. We observe that most current SRSs achieve identification according to the similarity between the output of the universal background model and the enrolled voice rather than requiring them to be identical (which is inherently difficult in the physical world due to environmental interferences). Hence, we transform the problem of searching for AEs into an optimization problem that focuses on optimizing a voice sample to make its feature vector as close as possible to the voice of the legitimate user.

The second insight is that *to infer the FE used by the target system, it is only necessary to correctly select from among the candidates.* The previous research revealed that current SRSs typically employ only a few common FEs [24]. This observation simplifies the task from "extracting" the specific FE used by the target system to "determining" which FE it uses. A natural method for inferring the target FE is to analyze the differences in the outputs of the target system to various inputs. However, the output of an SRS is typically limited to "accept" or "reject", which is insufficient to achieve the attack. For example, if the attacker queries the target system using normal samples, the system will always return correct recognition results (as long as it has high accuracy), regardless of the FE it uses. Therefore, our idea is to generate AEs for each candidate FE and then identify which examples can successfully deceive the target system. Intuitively, due to the differences among various FEs, the effectiveness of AEs indicates that the target FE is identical or at least similar to the FE corresponding to the AEs.

[1] In some practical situations, AE attacks are more feasible than replay attacks and voice impersonation attacks because such attacks might be easier to notice by the target user.

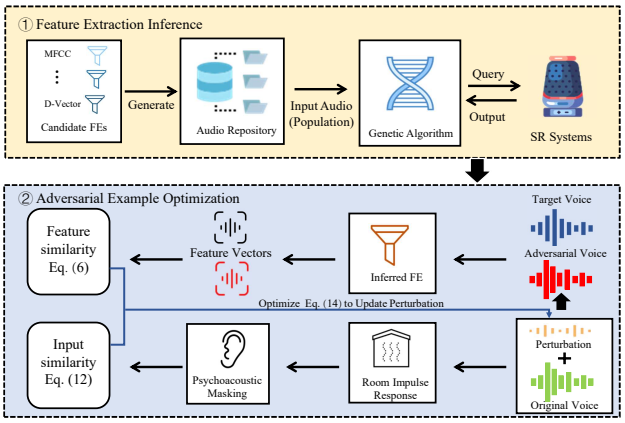

Figure 3: Overview of VoxCloak. The first step is to infer the FE of the target SRS using a genetic algorithm method. The second step utilizes the inferred FE to generate imperceptible and robust AEs through psychoacoustic masking and room impulse responses.

3.2 Overview

Building upon the two insights above, we propose VoxCloak, a black-box targeted attack focusing on the feature extractors. Specifically, VoxCloak comprises two main steps.

Step 1: Feature Extractor Inference. This step aims to infer the FE used by the target SRS, as illustrated in the upper part of Figure 3. To achieve this goal, we design a genetic algorithm. Initially, we generate AEs for all candidate FEs, respectively, by minimizing the distance between the voice of the attacker and the enrolled voice of the victim. These AEs serve as the initial population for the genetic algorithm. The fitness value of each individual (i.e., an AE) is evaluated according to the recognition results of the target SR. Based on the query results, we can filter out individuals with lower fitness. After multiple queries, we can infer the target FE according to the surviving individuals.

Step 2: Adversarial Example Optimization. This step aims to further improve the imperceptibility and robustness of the AE by utilizing the inferred FE, as shown in the bottom half of Figure 3. During the optimization process, in addition to minimizing the distance between the AE and the voice example of the victim, we incorporate psychoacoustic masking to make the perturbation almost inaudible. Moreover, we use room impulse responses to simulate the absorption and reverberation during over-the-air transmission, thereby improving the robustness of our attack. Note that this step is entirely carried out locally using the inferred FE without the need to query the target system.

4 Design of VoxCloak

4.1 Feature Extractor Inference

We first present how to generate AEs based on FEs and the specially designed genetic algorithm for inferring the FE utilized by the target SRS.

4.1.1 Generating AEs against Feature Extractor

As discussed in Section 3.1, we have transferred the challenge of extracting the FE employed by the target SRS into determining the FE from a set of candidates. A trivial approach is to compare the representation space of the candidate FEs with that of the target. Specifically, the attacker first constructs the common FEs locally (using open-source implementations). For each candidate FE, the attacker employs a personal input voice to generate AEs by minimizing the distance between the feature vector of this voice and the voice of the victim. Then, the attacker queries the target SRS by the AEs and analyzes the responses. Intuitively, AEs generated using an FE similar to the target FE would yield higher attack success rates due to their closer resultant feature vectors.

We approximate the computational process of the FE as a differentiable form, thereby minimizing the distance between the feature vector of the AE and that of the legitimate voice. Considering an audio example x of the attacker, an audio example x_t of the victim, and a candidate FE $g(\cdot)$, by introducing a perturbation δ on x, the formulation of optimizing a targeted AE $x+\delta$ can be defined as follows:

$$\arg\min_{\delta} \|g(x+\delta), g(x_t)\|_2 . \tag{6}$$

We select representative audio samples for each candidate FE from our dataset to construct an AE repository. This repository will then serve as the initial population for the subsequent genetic algorithm.

4.1.2 Genetic Algorithm

Theoretically, we can infer the information about the target FE according to the output of the AEs. However, such a straightforward method presented in Section 4.1.1 has a limitation: For each candidate FE, if we only generate one AE for the inference attack, then once multiple AEs can successfully deceive the target system, it becomes difficult to determine which candidate FE is correct. However, if we generate multiple AEs for each candidate FE, it will lead to a significant increase in the number of queries. To address this issue, we design a genetic algorithm to heuristically search for the FE most similar to the target FE from the candidate set.[2] Our

[2]To validate the effectiveness of the genetic algorithm, we have also attempted to infer the target FE using a straightforward grid search method. The results indicate that while this approach is feasible, it requires a higher number of queries. More detailed results are presented in Appendix B.1.

design includes two parts: encoding each candidate into a chromosome and realizing the basic operations of genetic algorithms, e.g., selection, crossover, and mutation operators, along with an apt fitness function. This approach is designed to mimic biological evolution, with the ultimate goal of accurately identifying the correct FE.

Encoding and Decoding. This step establishes a mapping relationship between the candidate FEs and the chromosomes of the genetic algorithm. We use an n-bit one-hot vector c^n to represent a possible solution, which can be formulated as:

$$c^n = [c_1, c_2, \cdots, c_n], \quad s.t. \begin{cases} c_i = 0, 1, \\ \sum_{i=1}^{n} c_i = 1. \end{cases} \tag{7}$$

Each element in the vector represents a candidate FE. To encode the i-th FE into a chromosome, we could set $c_i = 1$.

Fitness Function. This function assigns a fitness value to each chromosome to evaluate the quality of the candidate FE based on the authentication result outputted by the target SRS. Given an example x, the SRS can authenticate the identity of the speaker and return a score $S(x)$ or a decision $D(x)$.

For a score-based SRS that returns the decision scores to the user, the range of the score might be [0,1] or [0,100], depending on its configuration. Initially, we transform the score to fall within [0,100]. Then, we amplify the distance between different FEs by squaring the score. This amplification is also helpful for accelerating the convergence of the genetic algorithm. We formulate the fitness function $h(x)$ as $h(x) = S(x)^2$.

For a decision-based SRS that only returns the decision results to the user, we map the results to values within the [0,100] range to ensure the fitness function is differentiable. Specifically, since the OSI and CSI tasks might misidentify the input voice as belonging to another legitimate user, there are three possible decisions: reject, misidentify, and accept. We define the fitness function for these decisions as follows:

$$h(x) = \begin{cases} 10, & fail, \\ 50, & misidentify, \\ 100, & pass. \end{cases} \tag{8}$$

For the SV task, as it will only make two decisions, i.e., pass or fail, the fitness function sets the values of the two decisions to 10 and 100, respectively.

Selection, Crossover, and Mutation. The three operations are the basic components of a genetic algorithm. Selection involves choosing the most fit chromosomes and ensuring their genes are inherited in the subsequent generation. Crossover is combining two chromosomes to produce two new offspring chromosomes. The goal of mutation is to maintain the diversity of the population.

For the selection operation, we select chromosomes according to their fitness values based on the roulette wheel method. Moreover, we utilize the elitism selection approach, which transfers the superior chromosomes from previous populations to a new population. This approach ensures the selection of chromosomes exhibiting high performance across various populations while preventing the algorithm from erroneously identifying AEs, which succeed occasionally and are derived from inaccurate FEs, as the optimal solution. We do not implement the crossover operation because our encoding method renders the crossover meaningless and might even produce additional invalid chromosomes. Thus, after the selection process, we immediately undertake the mutation. The mutation operation is realized by randomly modifying a position c_i in the original one-hot vector to 1. It can prevent the genetic algorithm from converging on local optima.

Workflow. We hereby summarize the workflow of the genetic algorithm-based method for inferring the target FE. The attacker first establishes a population and encodes all candidate FEs into chromosomes. Secondly, AEs generated for candidate FEs are fed into the target SRS, yielding recognition results and associated fitness values. Thirdly, the attacker sequentially conducts the selection and mutation operations to create new populations. Then, the second and third steps are iteratively executed to update the population until the algorithm terminates. The termination criteria are set as identifying the best chromosome, one that persists across five consecutive generations, or the genetic algorithm running for over 30 generations.

4.2 Adversarial Example Optimization

After obtaining the inferred FE, the attacker can use it to generate AEs in a simpler way. This subsection details how to generate effective, imperceptible, and robust AEs.

4.2.1 Psychoacoustic Masking

Eq. (6) demonstrates a basic approach for generating an AE. The goal of the attacker is to make the feature vector of the AE as close as possible to that of the legitimate audio voice. However, such AEs generated by this unconstrained approach may contain significant perturbations, making them easily detectable by human ears and rendering the attack impractical.

Minimizing the l_p distance between two examples is a common way to improve the visual imperceptibility of image AEs. However, this approach is less feasible in the audio domain because human ears are highly sensitive to minor changes in amplitude and frequency in audio signals. Merely limiting the magnitude of the perturbation might still make it perceptible. To address this issue, we employ psychoacoustic masking, which exploits the limitations of human auditory perception to optimize adversarial perturbations.

Psychoacoustic masking refers to the phenomenon wherein louder sounds can mask quieter ones, thereby making them less noticeable [44]. It occurs when two sounds with close frequencies are present simultaneously. For example, if a louder

sound at 1000 Hz is played alongside a quieter sound at 1010 Hz, the latter becomes less noticeable. In other words, the louder sound creates a "masking threshold" in the frequency domain. Any signals that fall below this threshold become less perceptible. Hence, we limit the magnitude of the perturbations and confine them to specific frequency ranges. This ensures that the perturbation does not significantly alter the energy and spectral shape of the audio.

Given an audio input, the first step is to calculate its frequency masking threshold through the normalized log-magnitude power spectral density (PSD) estimation [45]. It is achieved by performing a short-time Fourier transform on the raw audio signal, segmenting it into multiple frames, and then calculating their respective spectrums.[3] We represent the k-th bin of the spectrum for each frame x as $S_x(k)$. The PSD is calculated as follows:

$$p_x(k) = 10\log_{10}\left|\frac{1}{N}S_x(k)\right|^2. \tag{9}$$

Then, we normalize $p_x(k)$ to a sound pressure level (SPL) of 96 dB [46]

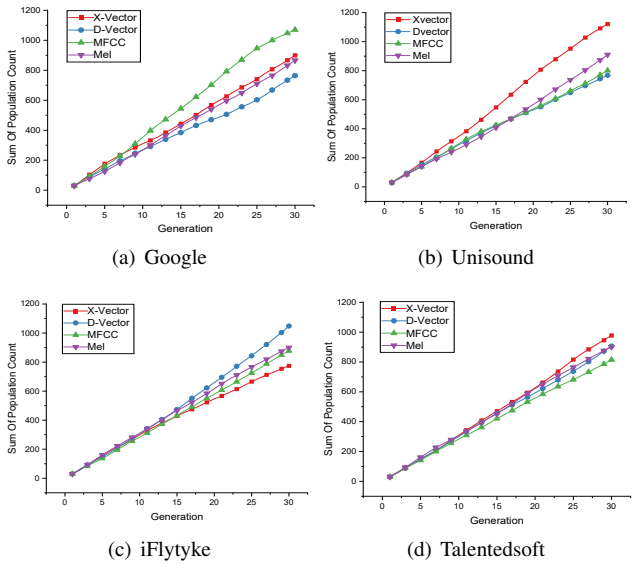
$$\bar{p}_x(k) = 96 - \arg\max_k\{p_x(k)\} + p_x(k). \tag{10}$$

Following the approach outlined in the work [46], we then calculate the frequency masking threshold $\theta_x(k)$. By analyzing the normalized PSD estimate of the perturbation $\bar{p}_x(k)$, we can determine which frequencies have sufficient energy to mask adjacent frequencies. Then, we calculate the frequency masking using a standard psychoacoustic model, such as the Bark scale, to identify which frequencies can be masked at certain energy levels to remain inaudible post-masking. For more details, please refer to the works [45, 46].

For an adversarial perturbation δ added to the audio input x, its normalized PSD estimate can be calculated as:

$$\bar{p}_\delta(k) = 96 - \arg\max_k\{p_x(k)\} + p_\delta(k). \tag{11}$$

According to the principles of psychoacoustic masking, if the normalized PSD estimate of the perturbation δ falls below the global masking threshold $\theta_x(k)$, the perturbation will be less perceptible to human ears. It is achieved by minimizing the loss function defined as follows:



$$Psy(x,\delta) = \frac{1}{\lfloor\frac{N}{2}\rfloor+1}\sum_{k=0}^{\lfloor\frac{N}{2}\rfloor} max\{\bar{p}_\delta(k) - \theta_x(k), 0\}. \tag{12}$$

Upon integrating the distance constraint, the optimization goal is:

$$\arg\min_\delta\{\|g(x+\delta), g(x_t)\|_2 + \alpha\cdot Psy(x,\delta)\}, \tag{13}$$

where α is a hyper-parameter to balance the effectiveness and the imperceptibility of the attack.

[3] Here, we use a modified Hann function with a window size of 2048 and a hop size of 512 to segment an audio file into multiple frames.

(c) iFlytyke (d) Talentedsoft

Figure 4: Inferring FEs with genetic algorithm.

4.2.2 Room Impulse Response

An additional challenge arises in physical environments where audio signals might be distorted due to factors like absorption and reverberation, resulting in the ineffectiveness of the attack. To enhance the robustness of the AEs, we introduce a room impulse response (RIR) component during the optimization process to simulate environmental distortions and counteract their effects.

Specifically, we established a dataset of RIRs, using FAST_RIR [57] to generate 50,000 medium-sized room impulse responses. Then, we adjust the optimization objective as follows:

$$\arg\min_\delta\{\|g(r\otimes(x+\delta)), g(x_t)\|_2 + \alpha\cdot Psy(x,\delta)\}, \tag{14}$$

where r represents the RIR sampled from the set, and $\otimes$ represents the convolution operation.

5 Evaluation

5.1 Ethical Considerations

Throughout the experimental process, we rigorously follow the ethical guidelines below:

Strictly Controlled Experiments. In our tests with commercial APIs, we only used publicly available datasets, ensuring that no data concerning personal privacy or commercial secrets were involved. Furthermore, upon the completion of successful attacks, no unauthorized actions were executed. All devices used in our experiments were under the personal ownership of the research team.

Table 2: Details of the commercial speaker recognition systems.

SRS	Task	Text	Type	Over-the-Air	Query	Return Results	FRR	FAR	FE⋆
Google [2]	SV	Independent	API	×	√	D	1/10	0/10	MFCC
Unisound [47]	SI	Independent	API	×	√	D‡+S♪	0/10	0/10	X-Vector
iFlytyke [48]	SI	Independent	API	×	√	D+S	0/10	0/10	D-Vector

‡: "D" means that the SRS returns the final decision, e.g., accept or reject. ♪: "S" means that the SRS returns the confidence score. †: "Action" means that the SRS adopts the wake-up mechanism. ⋆: "FE" means the feature extractor used in our experiments.

Responsible Disclosure. We have informed all companies involved in our experiments about this potential vulnerability through official reporting channels or direct emails. We provided detailed explanations and solutions for mitigating this risk.

5.2 Experiment Setup

Target Systems. To evaluate the performance of our attack, we select several popular and representative commercial SRSs, including four online SR APIs and seven commercial voice assistants, as the targets (shown in Table 2).[4] Table 9 in Appendix A provides detailed information about the voice assistants.

Datasets. We utilize two widely-used datasets: VoxCeleb V1 (Vox) [58] and CMU_arctic (Cmu) [59], to evaluate the performance of VoxCloak. In addition, we recruited 20 volunteers for voice data collection and named the constructed dataset "WakeUp" because the purpose of the recorded voice commands, like "Hey Siri" and "Hey Google", are designed to activate the voice assistants. We randomly selected a pair of volunteers from all participants to serve as the attacker and victim in each experiment. For the experiments about commercial APIs, ten pairs of volunteers were selected. For voice assistants, 15 pairs were selected. Details about the datasets are provided in Appendix A.1.

Metrics. We utilize the following three metrics: (1) *Attack Success Rate (ASR)*: This measures the proportion of AEs that can successfully deceive the target SRSs. A higher ASR indicates that the attack is more effective. (2) *Signal-to-noise Ratio (SNR)*: This quantifies the level of adversarial perturbation, calculated using the formula $SNR = 10\log_{10}\frac{\mathcal{P}_x}{\mathcal{P}_\delta}$, where $\mathcal{P}_x$ and $\mathcal{P}_\delta$ indicate the average power of the signal and the perturbation, respectively. A higher SNR means a lower noise level, i.e., the perturbation is less perceptible. (3) *Number of Queries (NoQ)*: This refers to the number of queries required for generating an effective AE. Fewer queries imply that the attack is more efficient.

Moreover, we use the false rejection rate (FRR) and the false acceptance rate (FAR) to measure the function of the SRSs. The FRR is the proportion of audio samples from legitimate users that are erroneously rejected, and the FAR is the proportion of audio samples from unauthorized users that are incorrectly accepted.

Benchmarks. We compare VoxCloak with three state-of-the-art attacks: two query-based black-box attacks, namely FakeBob [7] and Occam [6], along with a transfer-based attack, VMask [12]. In addition, we established a baseline comparison, termed Vanilla, which involves the samples created by directly overlaying the audio waveforms of the attackers onto those of the legitimate users.

5.3 Evaluation on Online SR APIs

Effectiveness. The results of VoxCloak and baselines are presented in Table 3. Overall, AEs generated by VoxCloak achieved nearly a 100% ASR with an average SNR as high as 21.47 dB, marking a considerable improvement over existing works. Specifically, in comparison to decision-based attacks, VoxCloak outperforms FakeBob [7] with an ASR of 99.96% and an SNR of 8.04 dB and outperforms Occam [6] with a close ASR and an SNR of 7.86 dB. Compared to the transfer-based attack, VoxCloak outperforms VMask [12] with an ASR of 76.25% and an SNR of 13.46 dB. Figure 7 in Appendix B.3 shows the waveforms and spectrograms of both the original audio examples and the AEs produced by VoxCloak and various baselines. We can observe that the adversarial audio examples generated by VoxCloak more closely resemble the original audio compared to those from the baselines. This indicates that the AEs generated by VoxCloak are closer to normal examples, thereby exhibiting better imperceptibility.

Efficiency. As shown in Figure 4, the ASR of AEs related to

[4] We have surveyed more commercial SRSs, as detailed in Table 10 in the Appendix A. Unfortunately, several of them do not provide the interface for personal users. For example, Microsoft Azure only provided the service to their partners and rejected our request to use the service.

Table 3: Experimental results on commercial online SR APIs.

SRS	Dataset	Vanilla*		VMask*		FakeBob			Occam			VoxCloak		
		ASR	SNR	ASR	SNR	ASR	SNR	NoQ#	ASR	SNR	NoQ#	ASR	SNR	NoQ

	Vox	2/10	0.02	2/10	6.18	0/10	N/A	3000	**10/10**	12.96	10,000	**10/10**	**21.26**	

∗: The method does not query the target system. #: The value of NoQ is the average number of queries for generating one AE. N/A indicates "not available". Since FakeBob [7] produces no effective AE, its SNR cannot be calculated. VoxCloak only requires about 300 queries to infer the target FE and does not require further queries to generate AEs. We set the max NoQ for FakeBob [7] and Occam [6] as 3000 and 10,000, respectively.

a specific FE becomes significantly higher than others after running the genetic algorithm for 20 generations, indicating a high similarity between this FE and the target FE. We initially selected four FEs as candidates and created 25 AEs for each candidate FE, requiring one query to the target system per example. This equates to a total of 100 queries in the initial phase. Subsequently, in each generation of the genetic algorithm, we set the mutation probability to 10%, selecting 10 AEs for querying per generation. After running for 20 generations, this results in an additional 200 queries. Therefore, the entire process involves approximately 300 queries to the target system. This NoQ is significantly lower than prior decision-based attacks like Occam, which requires up to 10,000 queries for generating one AE, and Fakebob, which requires an average NoQ of 1423 for generating one AE. Furthermore, for Fakebob, we observe that it is challenging to generate a successful AE even after 3000 query attempts. We note that our results for FakeBob [7] differ from those in the original publication [7] but are consistent with results obtained by Zheng *et al.* [6]. This discrepancy is likely attributable to updates in the APIs.

In addition, as long as the target system does not update its extractor, VoxCloak can generate any number of AEs without additional queries. This not only lowers the operational costs of VoxCloak but also increases its ability to evade detection by defense mechanisms that analyze query patterns [60].

Generalization. We have also evaluated the performance of VoxCloak across three different SR tasks: CSI, SV, and OSI. The results in Table 4 demonstrate that VoxCloak achieves a near 100% average ASR and a 20.89 dB average SNR on CSI tasks. For SV tasks, it accomplishes an average ASR of 86.67% and an average SNR of 21.77 dB. However, for OSI tasks, there is a slight decline, with the average ASR reducing to 78.33% and the average SNR to 21.18 dB. We consider that this decrease may be attributed to the threshold settings in the OSI tasks, where a higher threshold may prevent some weaker AEs from misleading the decision-making process.

Table 4: Experimental results on different SR tasks.

SRS	Dateset	CSI		SV		OSI	
		ASR	SNR	ASR	SNR	ASR	SNR
Unisound	Cmu	10/10	19.28	8/10	22.54	8/10	22.54
	Vox	10/10	19.48	7/10	19.14	7/10	19.14
iFlytyke	Cmu	10/10	23.82	7/10	23.23	7/10	23.23
	Vox	10/10	19.48	10/10	21.26	7/10	19.44
TalentedSoft	Cmu	10/10	23.82	10/10	23.21	10/10	23.31
	Vox	10/10	19.48	10/10	21.26	8/10	19.44

Nevertheless, the high ASR of VoxCloak across the three tasks still reveals the potential security risks.

5.4 Evaluation on Voice Assistants

We evaluated the performance of VoxCloak using seven commercial smart devices equipped with voice assistants. Details of the experimental setup are provided in Figure 5 (a). All experiments took place in a closed indoor environment, with the loudspeaker and the voice-controlled device positioned about 0.8 meters apart. We used two types of devices, the JBL Clip 3 and the ThinkPad X1 8th, to play the AEs. Notably, neither VoxCloak nor the baseline methods are allowed to query the target system. An attack is considered successful if it manages to activate the voice assistants with the AE in no more than two attempts.

As it is unable to query the target system when attacking voice assistants in the physical world, for FakeBob [7] and Occam [6], we first adapted their approaches to generate AEs against the Unisound API, an online SR service that allows free queries. The generated examples were then used to attack the target system. For VoxCloak, we consistently used X-Vector as the FE for generating AEs. We choose X-Vector for two reasons. (1) Experimental results in Appendix B.2 show that AEs generated based on X-Vector possess a degree

Table 5: Experimental results on voice assistants.

SRS	Loudspeaker	Vanilla		Vmask		FakeBob		Occam		VoxCloak	
		ASR	SNR	ASR	SNR	ASR	SNR	ASR	SNR	ASR	SNR
Apple Siri	JBL Clip3	6/15	0.01	3/15	9.09	2/15	2.31	2/15	14.14	**12/15**	**17.63**

	ThinkPad	5/15	0.01	4/15	8.38	3/15	4.11	3/15	11.75	**12/15**	**23.21**
Samsung Bixby	JBL Clip3	6/15	0.01	1/15	7.35	1/15	5.21	1/15	12.68	**7/15**	**22.45**
	ThinkPad	5/15	0.01	2/15	6.83	1/15	5.21	2/15	13.02	**6/15**	**22.57**
Huawei Xiaoyi	JBL Clip3	5/15	0.01	3/15	9.13	2/15	3.13	2/15	12.25	**11/15**	**20.89**
	ThinkPad	4/15	0.01	2/15	9.45	2/15	3.13	2/15	12.25	**10/15**	**20.43**
OPPO Breeno	JBL Clip3	6/15	0.01	2/15	7.82	2/15	2.87	4/15	13.26	**8/15**	**23.48**
	ThinkPad	6/15	0.01	1/15	7.82	1/15	3.91	3/15	12.87	**7/15**	**22.27**

N/A denotes "not available". All attacks are conducted in the physical world, and the attacker does not query the SRSs. For FakeBob [7] and Occam, we find that the AEs with higher SNR cannot attack SRSs, so we try to find a successful example by lowering the SNR.

Table 6: Results under different attack distances (meter).

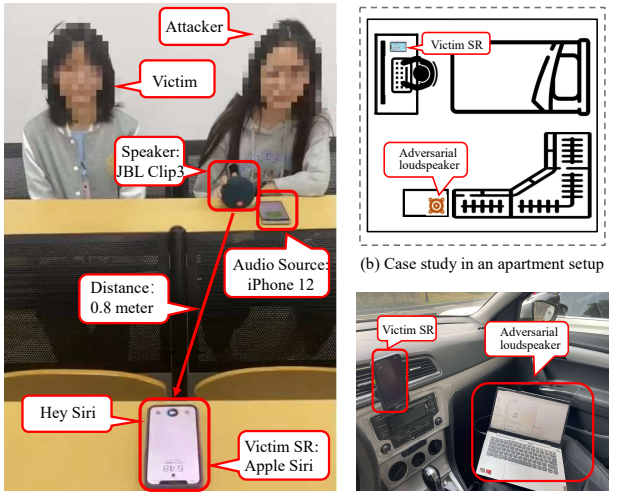
Distance		0.25	0.5	1	2	4	8
Apple Siri	FRR	0/15	0/15	0/15	0/15	1/15	2/15
	FAR	0/15	1/15	1/15	1/15	1/15	0/15
	ASR	14/15	14/15	12/15	11/15	7/15	2/15
Tmall Genie	FRR	0/15	0/15	1/15	3/15	5/15	7/15
	FAR	0/15	0/15	0/15	0/15	0/15	0/15
	ASR	14/15	14/15	12/15	5/15	2/15	1/15
Millet Xiaoai	FRR	0/15	0/15	0/15	2/15	6/15	6/15
	FAR	0/15	0/15	0/15	0/15	0/15	9/15
	ASR	13/15	13/15	12/15	46.67	1/15	0/15

of transferability to other FEs. (2) X-Vector has better performance than other common FEs [16], suggesting it is more likely to be used in target systems.

Effectiveness. The results in Table 5 demonstrate that VoxCloak outperforms baseline methods in both ASR and SNR across all tested voice assistants. For instance, when targeting Apple Siri with the JBL Clip3, VoxCloak achieves an 80% ASR and an SNR of 17.63 dB. In contrast, neither FakeBob [7] nor Occam [6] could effectively generate AEs capable of a successful attack with a comparable SNR. However, the ASRs on Samsung Bixby and OPPO Breeno are markedly lower than those of other systems, implying substantial differences between the FEs employed by these two systems and X-Vector. Nevertheless, the performance of VoxCloak on these two systems still outperforms the baselines.

Robustness. To evaluate the effect of attack distance on performance, we conducted tests with varying distances between the speaker (JBL Clip3) and voice-controlled devices, specifically at 0.25, 0.5, 1, 2, 4, and 8 meters. The results, as shown in Table 6, align with the intuition: the ASR decreases while the distance increases due to the signal attenuation caused by air transmission and environmental interferences. For example, when targeting Apple Siri, the ASR at an attack distance of 0.5 meters is 93.33%; however, it decreases to 73.33% at 2 meters and further drops to just 13.33% at 8 meters. Despite this decrease, VoxCloak consistently outperforms baseline methods in the physical world.

5.5 Evaluation on Different Acoustic Environments



In this subsection, we evaluate the effectiveness of VoxCloak across various acoustic environments, including two real-world environments and four simulated environments augmented with background noise. A JBL Clip3 speaker was consistently used for all experiments. We detail the test environments as follows.

Apartment Scenario. The experiments are conducted in an apartment scenario (Figure 5 (b)). The dimensions of the apartment are approximately 7.5 meters $\times$ 3 meters, with the attack distance set at 0.5 meters. The primary environmental noises originated from a computer fan and the acoustics of the room, due to wall absorption and reverberation. These noises could potentially impact the audio received by the microphone compared to that emitted by the speakers.

Table 7: Results under different acoustic environments.

Environment		White (30dB)	White (45dB)	White (50dB)	White (60dB)	White (65dB)	Bus (60dB)	AirCon. (60dB)	Neighbor (60dB)	Office (64dB)	InsideCar (75dB)
Apple Siri	FRR	0/15	0/15	0/15	1/15	2/15	2/15	7/15	2/15	2/15	1/15

Tmall Genie	FRR	0/15	0/15	0/15	0/15	0/15	0/15	3/15	1/15	0/15	0/15
	FAR	1/15	0/15	0/15	1/15	1/15	3/15	2/15	0/15	2/15	1/15
	ASR	15/15	15/15	15/15	13/15	10/15	7/15	9/15	6/15	12/15	13/15
Millet Xiaoai	FRR	0/15	0/15	0/15	0/15	3/15	0/15	4/15	3/15	1/15	0/15
	FAR	1/15	1/15	1/15	0/15	1/15	1/15	1/15	1/15	1/15	1/15
	ASR	15/15	15/15	13/15	7/15	7/15	7/15	6/15	9/15	9/15	10/15

"White" indicates white noise."Bus" means the noise from bus noise class. "AirCon." indicates the noise from the air conditioning Class. "Neighbor" means the noise from the neighbor speaking noise class.

(a) Case study in an office setup

(b) Case study in an apartment setup

(c) Case study in an inside-vehicle setup

Figure 5: Demonstration of acoustic environments.

Inside-car Scenario. The experiments are conducted in a Volkswagen Gran Lavida (interior depicted in Figure 5 (c)). The AEs were played while the car was parked and the engine was running. Hence, the environmental noises mainly stemmed from the engine and the reverberation. The speaker was placed about 0.2 meters from the target devices due to spatial limitations.

Simulated Scenarios. By utilizing the Microsoft Scalable Noisy Speech Dataset, we simulated environments with four types of noises: white noise, bus noise, air conditioning noise (AirCon.), and noise from neighboring conversations. The white noise volume is varied between 30 and 65 dB. In the simulated office environment, one JBL Clip3 is used to broadcast the AEs and another to play the noise. Both are positioned around 0.5 meters from the target device.

The results are presented in Table 7. VoxCloak achieves high ASRs across various acoustic environments. For Apple Siri, TMall Genie, and Millet Xiaoai, the average ASRs in these ten environments were 78.00%, 76.67%, and 65.33%, respectively. Note that even when the white noise reached 60 dB, close to the volume of the AEs (approximately 60 dB), our attack still maintains an ASR of 69.63%. Besides, we observe that some voice assistants could be activated by clean voices from unauthorized users. We attribute this to two potential causes: (1) the voiceprint features of the unauthorized user might be similar to those of an authorized user, and (2) the underlying SRS may have a relatively low threshold setting. While a lower threshold can improve the user experience by reducing authentication failures for authorized users, it also poses potential security risks.

5.6 Evaluation on Human Perception

SNR is a common metric for quantifying audio adversarial perturbation. However, it does not fully reflect the imperceptibility of AEs to the human ear. Two AEs with identical SNRs might be perceived differently because human auditory perception is impacted not just by sound intensity but also by frequency. In this subsection, we evaluate the imperceptibility of VoxCloak in terms of human perception.

5.6.1 Subjective Evaluation

For our human studies, we recruit 31 volunteers aged between 18 and 25 with normal hearing, including 18 males and 13 females.[5]

Study 1. The objective of this study is to assess whether volunteers could correctly discern if two audio clips were spoken by the same person. Volunteers are asked to listen to multiple audio clips and respond with "yes", "no", or "uncertain". We present them with 20 audio pairs in the experimental group, each comprising one AE and one normal speech clip. The control group consists of two sets of audio triples, each con-

[5]The ethical clearance for this work was obtained from our institution.

taining a normal clip as a reference, a clip from the same speaker as the reference, and a clip from a different speaker.

In the control group, our results show that 77.42% of the audio pairs from the same speaker are correctly identified, and 74.19% of pairs from different speakers were correctly identified. However, in the experimental group, 78.55% of the audio pairs are incorrectly identified as being from the same speaker. This demonstrates that the AEs generated by VoxCloak can effectively deceive humans, indicating a high level of auditory deception.

Study 2. The objective of this study is to assess whether volunteers could correctly recognize the identity of the speaker. Volunteers are first provided with an audio clip as a reference. Then, they are presented with two additional clips and asked to identify the one spoken by the same speaker with the reference clip. We conduct 20 experiments as the experimental group, each using an AE as the reference, and ask volunteers to distinguish between normal voices from the target speaker and the original speaker used to generate the AEs. The control group involved two sets of audio triples, each containing a normal clip as a reference, a clip from the same speaker, and a clip from a different speaker.

The results show that in the control group, 93.55% of the audio clips are correctly identified. However, in the experimental group, only 4.68% of the clips are identified as belonging to the target speaker, with 89.07% identified as the original speaker and 6.45% as "uncertain". This implies that volunteers generally associate the AEs more with their original speakers, highlighting the deception of VoxCloak.

Study 3. The objective of this study is to evaluate the human perception of the audio quality of AEs. Volunteers are initially provided with normal audio clips as a reference for quality. They are then asked to evaluate and rank 20 sets of AEs, each including clips generated by VMask [12], FakeBob [7], Occam [6], and VoxCloak.

The results show that more than 80% of the volunteers rate the AEs generated by VoxCloak as having the highest quality, with 10% ranking them second and only 5% ranking them third or fourth. These results indicate that the AEs generated by VoxCloak are acoustically similar to normal samples, thereby demonstrating the imperceptibility of VoxCloak.

5.6.2 Objective Evaluation

We also utilize the Perceptual Evaluation of Speech Quality (PESQ) [61], as recommended by the International Telecommunication Union, for an objective assessment of the imperceptibility of VoxCloak. The PESQ score ranges from 1 to 5, with 1 indicating poor audio quality and 5 indicating excellent audio quality. The score is impacted by various factors, such as audio sharpness, background noise, variable latency, and audio interference.

We evaluate 80 AEs generated by VoxCloak against four online SR APIs, achieving an average PESQ score of 2.93. This performance outperforms that of several baselines, i.e., Occam [6] (2.19), FakeBob [7] (2.81), and VMask [12] (2.35), where each method is also evaluated with 80 AEs against the same four SR APIs.

6 Related Work

6.1 Adversarial Example Attacks

Researchers initially explored AE attacks against SR systems in the white-box setting. Li *et al.* [20] employed the Fast Gradient Sign Method to generate AEs against SV systems. Gong *et al.* [10] proposed an attack targeting CSI systems by perturbing the raw audio recording. NRI-FGSM generates subsecond-level universal adversarial perturbations, which can add adversarial perturbations at any position in the input stream to improve the robustness of AEs [21].

However, since these attacks rely on a strong assumption that the attacker has complete knowledge of the details of the target system, researchers have increasingly focused their attention on black-box attacks. VMask [12] uses a local model to guide the optimization of AEs against target SV systems. This approach shares some similarities with VoxCloak. However, owing to the architecture of FEs being significantly simpler than that of SRSs, attackers using VoxCloak have smaller differences between the results obtained locally and those in the target system, thereby achieving higher ASRs.

Abdullah *et al.* [22] proposed the first zero-query black-box attack. They leverage the common feature extraction process that converts the captured audio into model features and modifies the recorded audio by signal decomposition and reconstruction. This approach is highly effective for untargeted attacks, but it encounters limitations in implementing effective targeted attacks, as well as in attacking SV tasks. FakeBob [7] also achieves targeted black-box attacks against SV, CSI, and OSI tasks as VoxCloak does. However, it cannot attack most commercial SR systems because of the need for predicted probabilities/scores. Occam [6] has overcome the limitation of FakeBob, achieving a 100% ASR with an SNR of 14.23 dB, even if the target system does not disclose the scores. In comparison, VoxCloak achieves a similar ASR and higher SNR as Occam with the additional advantage of the one-time and extremely minimal number of queries required. Some recent works try to improve the transferability of the attack by stabilizing the direction of the gradient to avoid overfitting [23] or finding better loss functions for transferability [43]. However, they still only achieve a limited ASR of about 50%. In summary, all prior AE attacks against SRSs exhibit several limitations, such as the capability for only untargeted attacks, reliance on confidence scores, excessive queries, and unsatisfactory performance.

Table 8: Experimental results in the presence of commonly-used defenses.

SRS	Dataset	Downsampling			Low-pass Filtering			Quantization			MP3C
		8000	11025	12000	2Khz	4Khz	8Khz	256	512	1024	
iFytyke	Cmu	1/10	4/10	7/10	0/10	4/10	10/10	7/10	5/10	1/10	10/10
	Vox	1/10	6/10	9/10	2/10	6/10	10/10	6/10	3/10	2/10	10/10
Unisound	Cmu	0/10	5/10	7/10	4/10	7 /10	10/10	5/10	3/10	0/10	10/10
	Vox	1/10	6/10	7/10	6/10	8/10	10/10	7/10	6/10	2 /10	10/10
Talentedsoft	Cmu	3/10	5/10	5/10	7/10	8/10	10/10	6/10	4/10	1/10	8/10
	Vox	5/10	8/10	8/10	10/10	10/10	10/10	8/10	5/10	3/10	9/10
Benign Input	Cmu	7/10	9/10	10/10	7/10	10/10	10/10	10/10	8/10	6/10	10/10
	Vox	8/10	10/10	10/10	7/10	10/10	10/10	10/10	9/10	6/10	10/10

The results of "Benign Input" are the average accuracy from three online SRSs with respect to benign inputs.

6.2 Other Types of Attacks

Sensor spoofing attacks are another category of attacks that can deceive SRSs. Wu *et al.* [62] conducted a comprehensive study of various sensor spoofing attacks in SV tasks, including replay, impersonation, voice synthesis, and voice conversion attacks. These attacks aim to generate or mimic the voices of the target speakers. However, these attacks require playing voices not belonging to the victim, they are more readily detected by the victim, thereby offering lower stealth capability than AE attacks. Besides, some studies [13, 63] focus on hidden voice attacks. These attacks modify a voice in a way that, while still recognizable by the targeted SRSs, becomes incomprehensible to human listeners (usually sounds like noise). In contrast to AE attacks, hidden voice attacks are relatively easier to execute. Yet, they are also more susceptible to defense and detection, as humans are likely to notice and identify noise-like sounds as anomalies.

7 Discussion

7.1 Defenses

We evaluate the effectiveness of four common defenses against VoxCloak. The results are presented in Table 8.

Downsampling. Downsampling, a method used to lower the sampling rate of audio signals, can remove high-frequency components in adversarial perturbations, thereby reducing the effectiveness of AEs [6, 21]. Experimental results indicate that when AEs generated by VoxCloak are downsampled to 8 kHz and then upsampled back to 16 kHz, the ASR decreases to 18%, accompanied by about a 25% decrease in model accuracy. If the downsampling rate is set to 12 kHz (the minimum rate that does not affect the model accuracy), VoxCloak still maintains a 71% ASR. Moreover, if attackers are aware of the down/upsampling rates of the target system, they can add corresponding constraints in the optimization process to invalidate the defense.

Low-pass Filtering. Low-pass filtering is another common defense that removes the high-frequency components of audio AEs [6, 21]. However, results show that VoxCloak can still maintain a high ASR after employing low-pass filtering. For example, setting the filter frequency to 8 kHz results in an ASR of 100%. When the filter frequency is adjusted to 4 kHz, the ASR remains at 71%. However, reducing the filtering frequency to 2 kHz leads to a drop in ASR to 48%. These results indicate that the frequency range between 2 kHz and 4 kHz in the adversarial perturbations is important for the success of VoxCloak.

Quantization. It represents continuous analog audio signals with a discrete set of values. It can defend against AE attacks because it may delete some of the information within the perturbations [64]. In our experiments, we set the quantization interval to 256, resulting in an average ASR of 65%. When increasing the quantization interval to 1024, the ASR of our attack reduces to 15%. In addition, the accuracy of the SR model for clean examples also reduces to 60%. This reduction is mainly due to the removal of important information from both benign and AEs during the quantization process.

MP3 Copmression (MP3C). MP3 is a lossy compression format for audio files. Intuitively, the information loss caused by compression might make the AE attack ineffective [7, 21]. However, experimental results indicate that VoxCloak still maintains a high ASR, up to 95%, even after undergoing a 10-to-1 compression ratio, which reduces the audio file to one-tenth of its original size. This result implies that the information lost during MP3 compression is not the major component of the adversarial perturbations.

7.2 Limitations

Compared to previous works, VoxCloak marks significant advancements in terms of ASR, required background knowledge, and overall cost of the attack. Yet, VoxCloak does have some limitations. The first is its robustness in real-world environments. Although VoxCloak is designed to minimize the

impact of environmental noise, excessive environmental noise, can still render the attack ineffective, as shown in Table 7. The second is the size of the candidate FE set. While our approach is effective against the common FEs used in many commercial APIs, it may fall short when SRSs use unknown or proprietary FEs. This is observed in our unsuccessful attempts to compromise systems like OPPO Breeno and Samsung Bixby. In these cases, we can only rely on the transferability of the attack. Note that due to the potential similarities in the feature spaces of different FEs, the AEs generated may also exhibit a certain degree of transferability. An ASR of nearly 50% for the two SRSs further illustrates this point.

8 Conclusion

In this paper, we proposed VoxCloak, a new black-box AE attack against commercial SRSs. VoxCloak can locally generate an arbitrary number of AEs after using a minimal number of queries to the target system to infer the used FE. Our extensive experiments across various popular commercial SRSs and tasks have shown the effectiveness of VoxCloak. Compared to existing query-based attacks, VoxCloak requires 30 times fewer queries to achieve a comparable ASR and a higher SNR, and it also surpasses the performance of existing transfer-based attacks in both metrics. Additionally, VoxCloak is available in the physical world, successfully misleading voice assistants at distances up to 4 meters. These results reveal the security concerns related to the reuse of FEs.

Note that, $*$ represents the price per minute of the service, and # represents the price per request.

some voice data (named the WakeUp dataset) from several volunteers for attacking voice assistants.

Voxceleb V1. The Voxceleb V1 dataset [58] is a large-scale dataset of speech recordings from celebrities. It contains over 100,000 utterances from 1,251 speakers of different accents, genders, and ages. The dataset is designed for speaker recognition and verification tasks, as well as other speech-related applications.

CMU_arctic. The CMU_arctic dataset [59] is a collection of speech recordings from 16 speakers of American English. The dataset is created by the Carnegie Mellon University. It contains about 1,132 utterances per speaker, covering a variety of topics and linguistic phenomena.

WakeUp. This dataset comprises 420 audio recordings collected from the voices of twenty volunteers, consisting of 11 males and 9 females. The volunteers are native Chinese speakers who are also proficient in English. Among the wake-up words used in the recordings, three are in English, while the remaining wake-up words are in Chinese. Each volunteer is asked to pronounce the corresponding wake-up words, including the designated Chinese and English wake-up words, within a quiet office environment with an SNR lower than 40 dB. Volunteers are instructed to complete the utterance within a 3-second time clip. The recordings are captured using an iPhone 12, and three separate voice recordings are obtained from each volunteer. To ensure consistency and standardization, the recordings are manually edited to remove any empty fragments at the beginning or end. As a result, all recordings in the dataset have a precise duration of 3 seconds.

Table 11: The transferability of adversarial examples targeting one source FE to other target FEs.

Source\Target	X-Vector	D-Vector	MFCC	Mel
X-Vector	100%	34%	37%	38%
D-Vector	15%	100%	22%	5%
MFCC	3%	45%	100%	51%
Mel	4%	18%	45%	100%

A.2 Candidate Feature Extractors

We select four common feature-extracting algorithms as candidates: Mel spectrum, MFCC, X-Vector, and D-Vector.

The Mel spectrum is based on the Mel scale, which simulates the sensitivity of the human ear to different sound frequencies [25]. In calculating the Mel spectrum, the audio signal is first transformed using the Fast Fourier Transform (FFT) to obtain the spectrum, which is then converted into the Mel spectrum using a set of Mel filter banks.

The Mel Frequency Cepstral Coefficients (MFCC) [14] are features extracted from the Mel spectrum, capturing the primary characteristics of the short-term power spectrum of the audio signals. These coefficients can reflect the ability of the human auditory system to perceive and distinguish different sound frequencies. The extraction process of MFCC includes steps such as preprocessing, FFT, Mel filtering, logarithmic operations, discrete cosine transform, and extraction of dynamic features.

D-Vector [15] and X-Vector [16] are speaker-embedding methods that embed speaker characteristics into a vector space using DNNs. Specifically, the D-Vector utilizes the hidden layers of a DNN to differentiate the features of speakers. These representation vectors can capture key information related to the voiceprint of speakers. X-Vector is an improvement upon D-Vector, offering better performance in processing more complex and varied speech data. Its core technology is time-delay neural networks, which are more adept at handling variable-length input sequences. The capability allows the X-Vector to process complete speech segments, thereby more effectively capturing the audio features.

A.3 Implementation Details

For the genetic algorithm, we configure a population size of 100 and a mutation probability of 0.1 and set the termination generation for the genetic algorithm to 30. We set the parameter α to 0.05 and use the Adam optimizer to solve Eqs. (6) and (14) with a learning rate of 3. VoxCloak was deployed on a server equipped with six GeForce RTX 2080 Ti GPUs, a 32-core Intel Xeon Gold 5117 CPU at 2.00 GHz, and 119 gigabytes of RAM. Detailed information about the target device

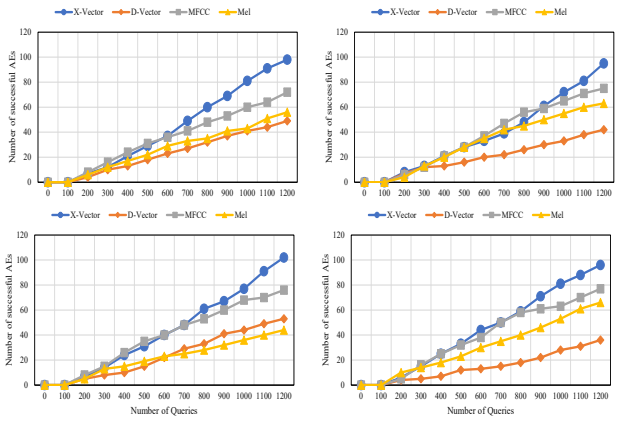

Figure 6: Four attempts to infer the FE using grid search, where AEs means adversarial examples.

is shown in Table 9. Furthermore, we survey more commercial SRSs as targets, as detailed in Table 10. Unfortunately, some of them are unavailable. For example, Amazon provides a speaker verification service in their connection application. As it is unavailable in our region, we are unable to use it in our experiments. We are also unable to utilize the service provided by IBM as our registration was denied.

B Supplementary Evaluation of VoxCloak

B.1 Grid Search-based Inference Method

Grid search is an exhaustive search method. It can accurately identify the optimal result by traversing all possible outcomes within the predefined search space. We have also attempted to use grid search to infer the target FE. The results in Figure 6 demonstrate that, in our four attempts, grid search successfully determined the target FE. However, it required a minimum of 600 queries (sometimes 900 queries), approximately two (or three) times more than VoxCloak. Additionally, an increase in the search space also leads to higher local computational costs for the attacker. Therefore, in terms of efficiency, our proposed genetic algorithm outperforms the grid search method.

B.2 Transferability of Feature Extractors

The success of VoxCloak primarily relies on the distinct feature spaces created by different FEs. We confirm this by evaluating the transferability of AEs. Transferability is measured by the proportion of AEs generated from one FE that can successfully attack a target system using a different FE. For each FE, we generated 100 AEs, with the results presented in Table 11. We observed that the ASR significantly drops when attacking an SRS based on a different FE, indicating the differences in the feature spaces of these FEs. We noticed that

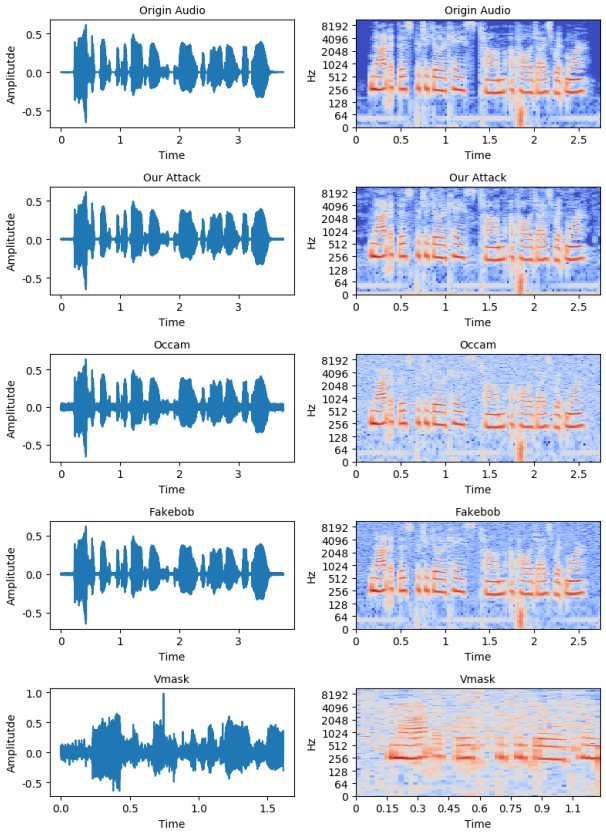

Figure 7: Waveforms and spectrograms of the original audio and adversarial audios generated by VoxCloak and baselines.

AEs generated using the X-Vector exhibit better transferability. Therefore, in scenarios where querying the target systems is unavailable (e.g., the physical attacks), using X-Vector to generate AEs tends to yield better performance.

B.3 Visualization Comparison

To facilitate a more intuitive comparison with baselines, we visualized the waveforms and spectrograms of AEs generated by the attacks and the original audio, as shown in Figure 7. We can see that the waveform of the AE generated by VoxCloak is close to the original audio, whereas those produced by Occam, Fakebob, and Vmask show significant differences. Thus, the latter are more easily perceptible by the human ear. Furthermore, as Vmask requires audio inputs and generated AEs of a fixed length, its effectiveness diminishes for longer-duration authentication processes.

Transferability of White-box Perturbations: Query-Efficient Adversarial Attacks against Commercial DNN Services

Abstract

Deep Neural Networks (DNNs) have been proven to be vulnerable to adversarial attacks. Existing decision-based adversarial attacks require large numbers of queries to find an effective adversarial example, resulting in a heavy query cost and also performance degradation under defenses. In this paper, we propose the Dispersed Sampling Attack (DSA), which is a query-efficient decision-based adversarial attack by exploiting the transferability of white-box perturbations. DSA can generate diverse examples with different locations in the embedding space, which provides more information about the adversarial region of substitute models and allows us to search for transferable perturbations. Specifically, DSA samples in a hypersphere centered on an original image, and progressively constrains the perturbation. Extensive experiments are conducted on public datasets to evaluate the performance of DSA in closed-set and open-set scenarios. DSA outperforms the state-of-the-art attacks in terms of both attack success rate (ASR) and average number of queries (AvgQ). Specifically, DSA achieves an ASR of about 90% with an AvgQ of 200 on 4 well-known commercial DNN services.

1 Introduction

Deep neural networks (DNNs) are known to be vulnerable to adversarial attacks [17, 55], where a subtle perturbation applied on an image can mislead DNN-based image classification models. This vulnerability poses a critical threat to the security of real-world DNN applications, ranging from face recognition [49] to traffic detection [47, 50]. When targeting commercial DNN services, potential attackers can get only access to the predicted label of a given input, without knowing the details of the DNN model such as the model structure and parameters [4]. For instance, the image recognition services from AWS [1] and Azure [40] only allow users to query and obtain the corresponding results via an API. It is still challenging to construct adversarial attacks against commercial DNN services in the decision-based settings, where the attacker can only access the Top-1 hard-label predictions (i.e., the label with the highest confidence [4]), due to a large number of required queries [27].

Recent years have witnessed a flurry of research and great progress in generating adversarial examples in the decision-based scenario. As shown in Table 1, the existing studies can be categorized into three main categories: transfer-based attacks, query-based attacks, and hybrid attacks.

Transfer-based attacks utilize white-box attacks against substitute models to craft adversarial perturbations. These perturbations are demonstrated to have transferability[1] and can potentially deceive the target model [17, 31, 60]. However, practical scenarios often introduce biases between the target and substitute models, primarily stemming from variations in model architecture and training data, which can usually result in a failure to deceive the target model.

Query-based attacks start from an image with another label (i.e., the target image), and gradually reduce its distance from the original image, while ensuring that the target model can be deceived [4, 9, 29]. Although effective, these attacks require a substantial number of queries to minimize the perturbation, making them costly for deployment in commercial services. These attacks are also susceptible to detection and mitigation by existing defenses [28]. Additionally, query-based attacks often introduce noise in specific regions, limiting their capacity to discover indistinguishable adversarial examples.

Hybrid attacks combine the strengths of both transfer-based and query-based attacks, aiming at reducing the number of queries by leveraging substitute models. For example, previous studies limit the sampling space using the gradient of substitute models [27, 56], or exploit substitute models to establish a favorable starting point for existing query-based attacks to reduce queries [53]. Attackers can easily obtain pre-trained models as substitute models from communities such as Hugging Face [21] and PyTorch Hub [43], making hybrid attacks more appealing. Nevertheless, the state-of-the-art (SOTA) hy-

[1]Transferability means that the same adversarial perturbation can mislead different models [55], which arises because different models often learn the same non-robust features for similar classification tasks [22].

Table 1: Summary of typical decision-based adversarial attacks.

Categories		Methods	Effective	Query Magnitude	Indistinguishable

	White-box Perturbation	**DSA** (This paper)	✓	**1.E+2**	✓

Three metrics are evaluated on ImageNet. Effectiveness means an ASR of over 90%; Query magnitude is measured by the AvgQ required for generating successful adversarial examples; Indistinguishability indicates whether an attack is effective under both ℓ_2 and ℓ_∞ norms. (See more details in Sec. 2.3).

brid attacks heavily rely on query-based attacks [48], resulting in the same limitations as the query-based attacks in terms of query efficiency and indistinguishability.

In this paper, we propose the Dispersed Sampling Attack (DSA), a query-efficient decision-based adversarial attack by exploiting the transferability of white-box perturbations. We design a dispersed sampling mechanism to generate diverse white-box perturbations based on substitute models. These perturbations have different transferability, allowing us to search for an effective one to deceive the target model while achieving indistinguishability.

We design four modules in DSA, utilizing image augmentation, various perturbation constraints, and substitute models to maximize the diversity of white-box perturbations. First, we propose an image augmentation strategy to generate a set of mutations from the original image. These mutated images serve as inputs for launching white-box attacks on substitute models to generate white-box perturbations with different transferability. Second, we investigate the effect of perturbation constraints on the transferability. By choosing an appropriate constraint, we can craft indistinguishable white-box perturbations while ensuring their transferability. Third, we design a substitute model selection algorithm, which leverages the feedback from the target model and tends to select the substitute model that is more likely to produce transferable perturbations. Finally, according to the results of candidate adversarial examples evaluated by the target model, we update the parameters in DSA to search for adversarial examples with smaller perturbations.

To comprehensively evaluate the performance of DSA, we conduct extensive experiments in both closed-set and open-set scenarios, as well as the 4 well-known commercial DNN services, including AWS [1], Azure [40], Baidu [2] and Tencent [57]. The experimental results demonstrate that DSA has higher attack success rates (ASR) while significantly reducing the average number of queries (AvgQ).

We summarize the main contributions as follows:

- We propose DSA, a query-efficient decision-based adversarial attack by exploiting the transferability of white-box perturbations. DSA is built on the key observation that varying the distribution or magnitude of perturbations results in different transferability.
- We conduct closed-set evaluation, where the attacker is assumed to have the same training dataset as that of the target model. DSA can achieve a higher ASR than the SOTA attacks while reducing the AvgQ by at least an order of magnitude. In particular, DSA also outperforms the other attacks when 5 typical defenses of adversarial attacks (e.g., Blacklight [28]) are deployed.
- We evaluate the performance of the attacks in the open-set scenario, where the attacker has no prior knowledge about the training dataset of the target model. The results demonstrate that DSA maintains high effectiveness and query efficiency in the open-set scenario.
- We conduct real-world evaluations on the attacks against 4 popular commercial DNN services. The results show that DSA has the ability to achieve about 90% ASR within 200 queries. Compared with the second-best attack (i.e., HybridAttack [53]), DSA increases the success rate by up to 45.0% and reduces the AvgQ by up to 92.8%.

2 Threat Model and Problem Formulation

In this section, we introduce the threat model of the adversarial attacks on commercial DNN services and formulate the problem with concrete design goals.

2.1 Threat Model

In this paper, we focus on decision-based adversarial attacks against commercial services, involving two primary parties: the victim and the attacker.

The victim refers to a commercial institution that deploys a well-trained model to provide public services. The victim trains the target model and provides Top-1 hard-label predictions for query examples. In addition, the victim may employ some defenses such as input processing [23] and adversarial training [36] to mitigate adversarial attacks.

The attacker is a service subscriber who attempts to find examples with indistinguishable perturbations to deceive the victim's model. The attacker has no knowledge about the parameters or structure of the target model, but can obtain predictions from the victim with a limited query budget. The attacker is assumed to have the capability to construct a shadow dataset and train substitute models using it. We consider two scenarios based on the knowledge about the shadow dataset: closed-set and open-set scenarios [14].

In the *closed-set* scenario, the attacker is assumed to have access to the training dataset of the target model, which is a common assumption in previous literatures [5, 8, 12] and used to evaluate the performance of the attack algorithm. The attacker can obtain the training dataset of the target model using several methods, such as database intrusion.

In the *open-set* scenario, the attacker is assumed to have no access to the training dataset of the target model, and have a shadow dataset that is entirely different from the victim's training dataset [14]. This assumption is more realistic, especially when targeting commercial services.

2.2 Problem Formulation

As stated in the previous subsection, we focus on the decision-based adversarial attacks on a target DNN model for image classification. The target model can be defined as $f : \mathbb{R}^d \rightarrow \{1, ..., K\}$, where d is the dimension of the input image and K is the number of classes. The input for the attacker is a pair of images with different labels, i.e., an original image $\boldsymbol{x}_o$ and a target image $\boldsymbol{x}_t$ ($f(\boldsymbol{x}_o) \neq f(\boldsymbol{x}_t)$). Then, we can define the corresponding adversarial region $\mathcal{O}$ [31] for both untargeted and targeted attacks in Eq. (1),

$$\mathcal{O} = \begin{cases} \boldsymbol{x} \in \mathbb{R}^d : f(\boldsymbol{x}) \neq f(\boldsymbol{x}_o) & (untargeted) \\ \boldsymbol{x} \in \mathbb{R}^d : f(\boldsymbol{x}) = f(\boldsymbol{x}_t) & (targeted) \end{cases} \tag{1}$$

For simplicity, we define an indicator function $\mathbb{I}(\boldsymbol{x})$ to indicate whether an image $\boldsymbol{x}$ is located in the adversarial region, i.e., $\mathbb{I}(\boldsymbol{x}) = 1$ if $\boldsymbol{x} \in \mathcal{O}$, and $\mathbb{I}(\boldsymbol{x}) = 0$ otherwise.

The goal of the attacker is to find an adversarial perturbation δ that is as small as possible, which can be formulated as minimizing the loss function $\mathcal{L}(\delta)$

$$\min_{\delta} \mathcal{L}(\delta) = \mathcal{D}(\delta) + \lambda \cdot (1 - \mathbb{I}(\boldsymbol{x}_o + \delta)) \tag{2}$$

where $\mathcal{D}(\delta) = ||\delta||_p$, and λ is a large number to make sure that $\mathcal{L}(\delta)$ is large enough when $\boldsymbol{x}_o + \delta \notin \mathcal{O}$. The success condition of the attacker is to find an adversarial perturbation within the query budget where the loss is not larger than a pre-defined threshold ε, i.e., $\mathcal{L}(\delta) \leq \varepsilon$.

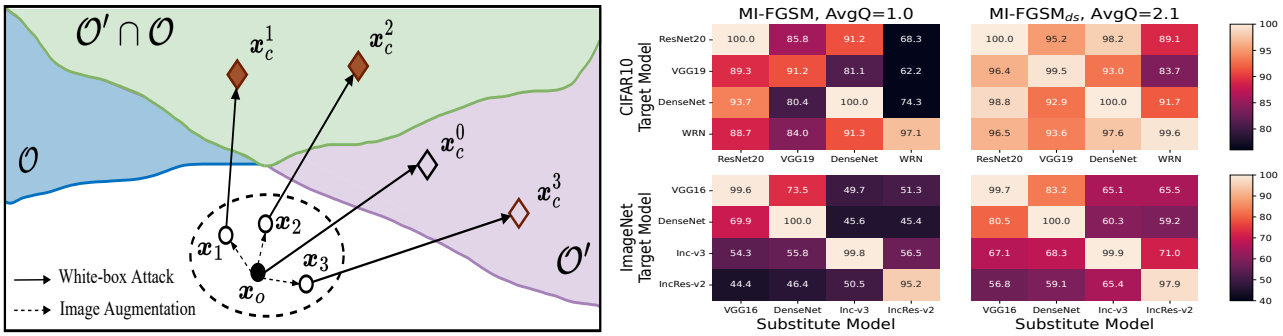
2.3 Design Goals

Effectiveness. It means that the attacker can successfully generate adversarial examples within a query budget to deceive the target model. It is usually measured by the attack success rate for a certain number of adversarial examples [34].

Query Efficiency. Querying the API of the target model in massive numbers can lead to a heavy overhead for the attacker. For example, typical commercial DNN services may charge \$0.3 to \$1.5 per thousand requests and limit 120 to 1800 requests per minute [1, 2, 18, 40, 57]. Therefore, a good attack algorithm should prioritize high query efficiency.

Indistinguishability. It implies that the modifications on the original image should be subtle and undetectable [16]. Given the widespread use of both the ℓ_2 and ℓ_∞ norms as approximations of indistinguishability, the perturbations generated by the attack should be less than the pre-defined thresholds for these norms.

Robustness. As a number of defenses have been developed to protect against adversarial attacks, such as ComDefend [23] and Blacklight [28], the attack should maintain effectiveness when a certain defense has been deployed on the target model in the closed-set scenario. In the open-set scenario, the attack should also be effective, where the shadow dataset is partially or totally different from the training dataset of the target model.



3 The Proposed DSA

In this section, we first present key observations on the transferability of white-box perturbations, and then describe the overview of the proposed method.

3.1 Observation on Transferability of White-box Perturbations

When launching adversarial attacks on a certain original image, the attacker aims to find a small perturbation to deceive the target model. We observe that *varying the distribution or magnitude of perturbations enables different transferability.*

We provide a detailed explanation of our observations through an example of altering the distribution of white-box perturbations by applying image augmentation to the original image. Given an original image $\boldsymbol{x}_o$, we can obtain multiple mutations by performing image augmentation (e.g., adding Gaussian noise on the original image). As illustrated in Fig. 1a, when these mutations are used as inputs for a white-box attack, we can generate perturbations with varying distributions.

(a) Illustration of dispersed sampling

(b) ASR without and with dispersed sampling

Figure 1: (a) Illustration of dispersed sampling. $\mathcal{O}$ and $\mathcal{O}'$ represent the adversarial regions of the target and substitute models, respectively. Given an original image $\boldsymbol{x}_o$, image augmentation can generate several augmented images, e.g., $\boldsymbol{x}_1$, $\boldsymbol{x}_2$, and $\boldsymbol{x}_3$. When applying white-box attacks on the substitute model using these images as input, diverse white-box perturbations can be generated, making the corresponding candidate adversarial examples dispersed in $\mathcal{O}'$. Only those located in $\mathcal{O}' \cap \mathcal{O}$ can deceive the target model. (b) Evaluation of ASR with dispersed sampling on ImageNet. MI-FGSM$_{ds}$ means MI-FGSM with dispersed sampling, which achieves a higher ASR with an average improvement of 9.6%.

These perturbations exhibit different transferability, and the perturbed images have diverse locations in the embedding space[2]. Therefore, we can probe the adversarial region of the target model with these examples.

The reason for this phenomenon is that the augmented image causes a change in the gradient of the neural network backpropagation, which changes the direction of perturbation optimization. The white-box attacks typically perform the above optimization multiple times, which leads to an accumulation of such changes, resulting in a dispersion of outputs (i.e., candidate adversarial examples) in the embedding space.

Existing transfer-based methods [56, 62] only use the original input $\boldsymbol{x}_o$ to generate the corresponding adversarial example $\boldsymbol{x}_c^0$, which may be not located in the adversarial region $\mathcal{O}$ and result in a failed attack. However, as illustrated in Fig. 1a, the candidate adversarial examples generated from augmented images have different transferability. For instance, $\boldsymbol{x}_c^1$ and $\boldsymbol{x}_c^2$ are located in the intersection area of the adversarial region of the target and substitute models (i.e., $\mathcal{O}' \cap \mathcal{O}$). Therefore, they can mislead the target model.

To justify this observation, we conduct experiments to evaluate the ASR of MI-FGSM with dispersed sampling. Specifically, we validate this observation using various substitute and target models with the full validation set of CIFAR-10 and ImageNet. Dispersed sampling generates five candidates for each image to search for a transferable example. As illustrated in Fig. 1b, dispersed sampling allows MI-FGSM to achieve a higher ASR with an average improvement of 9.6%.

[2]The embedding space refers to a lower dimensional representation of the input data that is learned by the DNN [3].

3.2 Overview of DSA

Based on the observation, we propose DSA, which is a query-efficient adversarial attack by exploiting the transferability of white-box perturbations. The basic idea of DSA is to gradually explore the transferability of white-box perturbations until obtaining an adversarial example that can deceive the target model while satisfying the requirement on indistinguishability. The overview of DSA is shown in Fig. 2, which mainly consists of four modules.

Image Augmentation. Based on the observation in Sec. 3.1, we can sample dispersed in the embedding space by performing a white-box attack on different augmented images. Thus, various white-box perturbations with different transferability can be generated, so that we can search for a transferable white-box perturbation by dispersed sampling.

Perturbation Constraint Generation. Previous studies [17, 26] generate white-box perturbations with a small and fixed constraint, which have been shown to be less effective and lead to a low ASR. To achieve a significant distance reduction using a few queries, we should set a reasonable perturbation constraint to balance the magnitude and transferability of perturbations. We generate the constraint of white-box perturbations according to the truncated Gaussian distribution [6], which generates a small-size perturbation while maintaining the transferability of the resulting adversarial example.

Substitute Model Selection. When multiple substitute models are available, the attacker prefers choosing appropriate substitute models to generate candidates with more transferability. Different from the existing studies [12, 31] that search for transferable candidates in the intersection of substitute models' adversarial regions, we generate white-box perturbations in the union of these regions. The reason for this choice

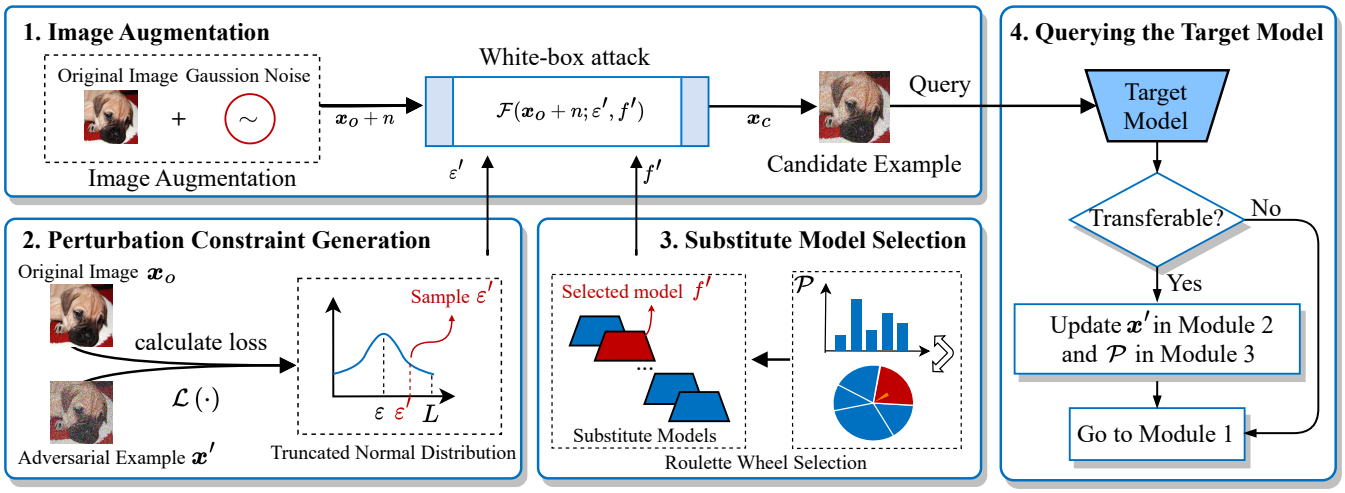


Figure 2: The overview of DSA. It samples from the embedding space and generates a single candidate example by launching a white-box attack on a selected substitute model under a certain perturbation constraint. If the adversarial example successfully deceives the target model, it will be used to update the parameters in substitute model selection and perturbation constraint generation.

will be explained in Sec. 4.3.

Specifically, we choose one substitute model to generate the white-box perturbation at each iteration. We then utilize the query results obtained from the black-box model to adjust the probability of selecting each substitute model. This adjustment increases the probability of selecting the substitute model that generates more transferable candidate examples.

Querying the Target Model. Based on the above modules, we can obtain a white-box perturbation and query the target model. A successful adversarial example is used to update the upper bound of the perturbation size in Module 2 and the selection probability of the substitute model in Module 3. Then, we go back to Module 1 and repeat the entire process, until the specified number of repetitions.

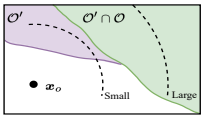
4 Design Details of DSA

In this section, we present the design details of the four modules in DSA, as shown in Fig. 2.

4.1 Image Augmentation

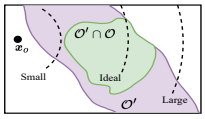
As illustrated in Fig. 1, the basic idea of DSA is to sample in the embedding space of substitute models and craft multiple white-box perturbations with different transferability. Then, it searches for a transferable perturbation to the target model while smaller than the pre-defined threshold. Following [11], we formalize the transferability of untargeted attacks. Given the original image $\boldsymbol{x}_o$ and its ground-truth label y, the transferability of the white-box perturbation $T(\delta)$ can be formulated in Eq. (3),

$$T(\delta) = \mathfrak{L}(y, \boldsymbol{x}_o + \delta) \approxeq \mathfrak{L}(y, \boldsymbol{x}_o) + \delta^\top \nabla_{\mathbf{x_o}} \mathfrak{L}(y, \mathbf{x_o}) \quad (3)$$



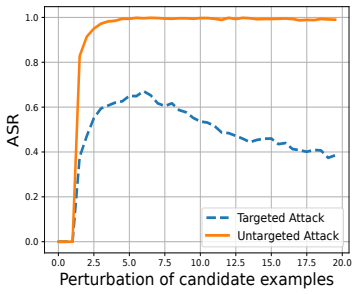
where $\mathfrak{L}$ is the classification loss of the target model. This equation indicates that we can craft perturbations with different transferability by varying the distribution or magnitude of the perturbations. Specifically, we generate multiple white-box perturbations by leveraging image augmentation (e.g., rotation, color jittering, and noise addition), perturbation constraint generation (in Sec. 4.2), and substitute model selection (in Sec. 4.3). Different from the random start in PGD [36], the specific goal of dispersed sampling is to launch black-box attacks by adjusting the distribution and magnitude of perturbations to enable different transferability. In contrast, PGD enhances the effectiveness of adversarial training by introducing noise into images.

For image augmentation, we craft white-box perturbations from a set of mutations of the original image, and the default augmentation strategy is to add Gaussian noise to the original image. We evaluate the effect of different augmentation techniques on the performance of DSA in Appendix A.



We denote the white-box attack as $\mathcal{F}$, which can generate a white-box perturbation δ for the substitute model f' with a perturbation constraint ε'. Then, the corresponding candidate adversarial example $\boldsymbol{x}_c$ can be obtained

$$\boldsymbol{x}_c = \boldsymbol{x}_o + \delta = \mathcal{F}(\boldsymbol{x}_o + n; \varepsilon', f') \quad (4)$$



where n is Gaussian noise and the perturbation satisfies $\mathcal{D}(\delta) < \varepsilon'$. Then, the candidate adversarial example $\boldsymbol{x}_c$ is used as the input to query the target model.

(a) Untargeted attacks

(b) Targeted attacks

(c) ASR versus perturbation constraint

Figure 3: Illustration of the influence of perturbation constraint (dash line) on transferability. (a) For untargeted attacks, a large perturbation constraint makes candidate examples easier to transfer. (b) For targeted attacks, a large or small perturbation constraint makes the resulting candidate examples located outside the region $\mathcal{O} \cap \mathcal{O}'$. (c) ASR of MI-FGSM in both untargeted and targeted attacks.

4.2 Perturbation Constraint Generation

The perturbation constraint ε' is defined as the upper limit for the white-box perturbation to be generated. By modifying the value of ε', we can flexibly adjust the magnitude of white-box perturbations. In this section, we investigate the generation of perturbation constraints to obtain the transferable white-box perturbation with a small size.

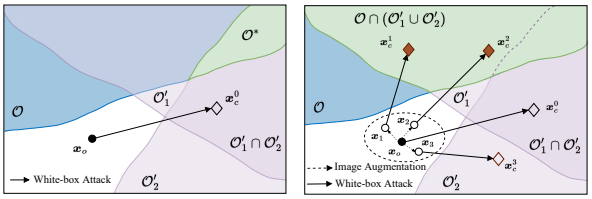
In the following, we provide an in-depth analysis of the effect of perturbation constraints on the transferability of candidate adversarial examples. For untargeted attacks as shown in Fig. 3a, the adversarial region lies outside the decision boundary of the original image label, and larger perturbation constraints make candidates move beyond the decision boundary and fall into the adversarial region. This observation is consistent with the previous study [11]. Moreover, we systematically analyze the transferability of targeted attacks. For targeted attacks as illustrated in Fig. 3b, only an appropriate constraint can result in transferable candidates, as the adversary region is delimited by the target image labels. If the constraint is too small, candidates cannot reach the adversarial region $\mathcal{O}' \cap \mathcal{O}$, whereas if it is too large, candidates may also fall outside this region.

To justify the above claim, we evaluate the attack success rate of MI-FGSM under different perturbation sizes by generating adversarial examples for 1,000 images in CIFAR-10. ResNet20 and VGG19 are selected as the substitute and target models, respectively. As shown in Fig 3c, increasing the perturbation constraint can improve the ASR of untargeted attacks, until the perturbation constraint reaches 5.0. This demonstrates that a large perturbation constraint enables candidate examples to fall in the adversarial region. For targeted attacks, with the increase of perturbation constraint, the ASR first increases and then decreases, taking a maximum value when the perturbation constraint reaches around 6.0. This also demonstrates the observation illustrated in Fig. 3b.

The transferability is significantly impacted by the magnitude of perturbations. Thus, it is necessary to constrain the magnitude of perturbations with an appropriate upper bound. In order to achieve the goal, we design a mechanism to constrain the magnitude of perturbations.

First, we dynamically establish constraints for each white-box perturbation through a sampling process. It is important to note that both excessively large and small constraints are detrimental to transferability, and particularly large constraints are also not tolerated in adversarial attacks. To address this issue, we control the sampling probability distribution to avoid choosing extreme values. In particular, we derive the perturbation constraint ε' based on a truncated normal distribution $\varepsilon' \sim \mathcal{N}_{[0.5\varepsilon,l]}(\varepsilon, L)$ [6], which is defined as

$$\mathcal{N}_{[0.5\varepsilon,L]}(\varepsilon, L) = \begin{cases} \frac{1}{ZL} \cdot \exp\left(-\frac{(\varepsilon'-\varepsilon)^2}{2L^2}\right), & 0.5\varepsilon \le \varepsilon' \le L \\ 0, & \text{otherwise} \end{cases} \tag{5}$$



where L represents the upper bound of the sampling and Z refers to the normalization constant to ensure that the probability density function integrates to 1, which is the integral of the probability density function of the normal distribution over the interval $[0.5\varepsilon, L]$ [6]. This distribution ensures a lower probability of sampling values closer to the upper bound.

Second, the attacker cannot directly determine a suitable upper bound L to generate a small perturbation that can be successfully transferred. Therefore, L should be a gradually decreasing variable to ensure continuous generation of smaller transferable perturbations. Specifically, we initialize the upper bound as the distance between the target image and the original image. Once a new transferable perturbation δ is found, we narrow L to $\mathcal{L}(\delta)$ in Eq. (2).

4.3 Substitute Model Selection

The attacker can easily obtain multiple pre-trained models as substitute models from the community such as Hugging Face [21] and PyTorch Hub [43]. It is worth considering improving the performance of attacks using multiple substitute models. Previous transfer-based studies [12, 30] generate a candidate adversarial example in the *intersection* of adversarial regions of all substitute models. Different from these studies, we claim that the *union*, rather than the intersection, of adversarial regions of multiple substitute models should be used to obtain white-box perturbations.

As illustrated in Fig. 4, an effective candidate adversarial example can fall in the union of adversarial regions of multiple substitute models, as it has a large intersection area with the target model. Given m substitute models $\{f'_1, f'_2, ..., f'_m\}$, the adversarial region of the substitute model f'_i can be denoted

(a) Intersection (b) Union

Figure 4: Illustration of sampling in intersection or union of the adversarial regions of multiple substitute models. $\mathcal{O}'_1$ and $\mathcal{O}'_2$ represent adversarial regions of two substitute models. Existing transfer-based attacks ensure the generated candidate example $\boldsymbol{x}_c^0$ located in the intersection $\mathcal{O}'_1 \cap \mathcal{O}'_2$, however, it may not fall in $\mathcal{O}^* = \mathcal{O} \cap \mathcal{O}'_1 \cap \mathcal{O}'_2$. In contrast, as long as a candidate example (e.g., $\boldsymbol{x}_c^1$ and $\boldsymbol{x}_c^2$) is located in $\mathcal{O} \cap (\mathcal{O}'_1 \cup \mathcal{O}'_2)$, it will lead to a successful attack.

as $\mathcal{O}'_i$, and the feasible region can be formulated as

$$\begin{aligned} \mathcal{O}' \cap \mathcal{O} &= \left(\mathcal{O}'_1 \cup \mathcal{O}'_2 \cup \cdots \cup \mathcal{O}'_m\right) \cap \mathcal{O} \\ &= \left(\mathcal{O}'_1 \cap \mathcal{O}\right) \cup \left(\mathcal{O}'_2 \cap \mathcal{O}\right) \cup \cdots \cup \left(\mathcal{O}'_m \cap \mathcal{O}\right) \end{aligned} \tag{6}$$

The above equation indicates that we can sample in the adversarial region of each substitute model, i.e., one substitute model is selected to generate a candidate adversarial example by white-box attacks. Nevertheless, it raises a new challenge that the union of adversarial regions expands the sampling region, and thus the attacker has to consume more queries. The basic idea to address this issue is to select the substitute model f'_k with a larger intersection area in the adversarial region with the target model (i.e., $\mathcal{O}'_k \cap \mathcal{O}$).

During the black-box adversarial attack, the attacker usually generates a series of queries on the target model. We leverage the knowledge provided by the historical queries to select a substitute model. Aiming at improving the query efficiency of the attack, we assign substitute models with different probabilities of being selected to generate more white-box perturbations on parts of the union region $\mathcal{O}'$. At the start of the attack, each substitute model has the same probability of being selected. As the attack progresses and more transferable candidates are generated from a substitute model, the probability of selecting this substitute model increases. Specifically, we apply the roulette wheel algorithm to select the substitute model and dynamically adjust its probability of being selected during the attack. The probability of substitute model f'_i being selected is

$$\mathcal{P}\left(f'_i\right) = \frac{q\left(f'_i\right)}{\sum_{j=1}^{m} q\left(f'_j\right)} \tag{7}$$

where $q\left(f'_i\right)$ denote the fitness of i-th substitute model, which is defined as the number of transferable examples generated by the i-th substitute model.

$$q\left(f'_i\right) = \sum \mathbb{I}\left(\boldsymbol{x}'_{f'_i}\right) + b \tag{8}$$

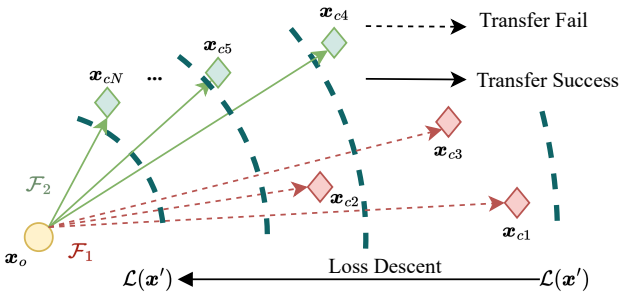


Figure 5: Geometrical configuration of DSA. DSA disperses the sampling of candidate adversarial examples. Once a transferable candidate is obtained, the upper bound of the perturbation constraint and the probability of each substitute model being selected are updated.

where $\boldsymbol{x}'_{f'_i}$ denotes historical candidate examples generated from the substitute model f'_i, b is an initial value and is set to 10 in the implementation, which can be used to adjust the influence of feedback from the target model. Note that the fitness is calculated using historical queries; no additional queries to the target model need to be introduced. The fitness of each substitute model reflects the intersection of its adversarial region with the target model, which is independent of the original images, so that the fitness can be shared when attacking different images.

4.4 Querying the Target Model

The algorithm of DSA is illustrated in Algorithm 1. There are N epochs in DSA, and for each one, we use the current loss as the upper bound of truncated Gaussian distribution and sample the perturbation constraint ε'. One substitute model f'_i is selected based on the probability distribution $\mathcal{P}$. Then, a candidate adversarial example $\boldsymbol{x}_c$ with the perturbation constraint is generated by attacking the substitute model. This candidate is used to query the target model.

DSA updates the parameters based on the query results to limit the sampling region. As shown in Fig. 5, if the candidate example can deceive the target model, we use it as the current adversarial example $\boldsymbol{x}'$, and its perturbation size as the upper bound of the constraint generation, which results in candidate examples being generated with less perturbation. At the same time, we update the fitness of each substitute model and the probability of roulette wheel selection, which makes the currently selected substitute model easier to select in the following. Eventually, we go to the first module to repeat the entire process. If the candidate example cannot deceive the target model, we move into the next epoch directly.

The sampling process of DSA is repeated N epochs. In the end, we obtain N candidate examples and consume the same number of queries. The appropriate value of N is related to the number of substitute models, as more substitute models mean

Algorithm 1: Dispersed Sampling Attack

Input: Original image $\boldsymbol{x}_o$, target image $\boldsymbol{x}_t$, loss function $\mathcal{L}$, perturbation threshold ε, white-box attack function $\mathcal{F}$, probability distribution of substitute models $\mathcal{P}$, number of epochs N.

Output: Adversarial example $\boldsymbol{x}'$.

$\boldsymbol{x}' \leftarrow \boldsymbol{x}_t$;
for 1 **to** N **do**
  $L \leftarrow \mathcal{L}(\boldsymbol{x}')$;
  $\varepsilon' \sim \mathcal{N}_{[0.5\varepsilon, L]}(\varepsilon, L)$;
  $f' \sim \mathcal{P}$;
  $n \sim \mathcal{N}(0,1)$;
  $\boldsymbol{x}_c \leftarrow \mathcal{F}(\boldsymbol{x}_o + n; f', \varepsilon')$;
  if $\mathcal{L}(\boldsymbol{x}_c) < \mathcal{L}(\boldsymbol{x}')$ **then**
    $\boldsymbol{x}' \leftarrow \boldsymbol{x}_c$;
    Update $\mathcal{P}$ using Eq. (7) ;
  end
end
Optimizing $\boldsymbol{x}'$ with existing black-box attack ;
return $\boldsymbol{x}'$;

a larger area to sample, which requires more queries for exploration. Therefore, we set $N = m \times n$, where m is the number of substitute models, and n is a specified value. Specifically, we set n to 100, and evaluate the effects of different n values, which can be found in Appendix A.

After the last epoch, we obtain an adversarial example, which is the candidate with minimal perturbation. Then we refer to existing black-box attacks to search for adversarial examples with less loss. We argue that dispersed sampling plays a significant role, while the integrated black-box attack serves only as a complement. This can be demonstrated in experiments in Sec. 5.2, where perturbations decrease by over 90% in the dispersed sampling.

5 Performance Evaluation

In this section, we comprehensively evaluate the performance of DSA by comparing it with the SOTA attacks. We describe the experimental settings in Sec. 5.1. Then, we conduct experiments in the closed-set scenario in Sec. 5.2, which investigates the attack performance on both undefended and defended models. Next, we perform experiments in the open-set scenario in Sec. 5.3, and evaluate the attack performance against four commercial DNN services in Sec. 5.4. Finally, we conduct an ablation study in Sec. 5.5, assessing the contribution of each module and the scalability of DSA.

5.1 Experimental Settings

Datasets and Evaluation Metrics. We conduct the experiments using the CIFAR-10 [25] and ImageNet [46] datasets, which have been widely used in previous studies [4, 53]. CIFAR-10 consists of 10 classes and each class has 6K images with a size of $32 \times 32 \times 3$. ImageNet has 1,000 classes of images which are re-scaled to the size of $299 \times 299 \times 3$. All image pixel values are normalized in the range of $[0, 1]$. Following the setup in previous studies [5, 8], 1,000 original-target image pairs are randomly selected from the validation set of each dataset for evaluation. The selected images are correctly classified by all models used in the experiments, and the target image has a different label from the original image. In the closed-set scenario, the target and substitute models are trained on the same dataset. In the open-set scenario, we assemble two mutually exclusive datasets for training the substitute and target models. Specifically, we randomly select half of the images for each label and use them as one training set, while the remaining images constitute the other set.

The success condition for the attacker is to find an adversarial example $\boldsymbol{x}'$ with a loss less than the pre-defined threshold ε within the query budget. The query budget for each image pair is set to 4,000. During the attack process, any attack that exceeds the budget is considered failed and is terminated immediately; if the loss of an adversarial example is less than the threshold ε within the query budget, we consider the attack successful and stop querying the target model. We use the attack success rate (ASR) and the average number of queries (AvgQ) as evaluation criteria, which are defined as the ratio of original images that can be successfully attacked and the average number of queries on the target model consumed on each image, respectively. An attack is desired to achieve a high ASR at the cost of a low AvgQ.

We evaluate the performance of the attacks under two perturbation distance metrics, ℓ_2 and ℓ_∞ norm, which are widely used in previous studies [8, 29], and can fully benchmark the indistinguishability of the attacks. Follow the setting in previous study [10], the loss threshold is set at $\varepsilon = \sqrt{0.001 \cdot d}$ under ℓ_2 norm, (i.e. 1.75 on CIFAR-10 and 16.38 on ImageNet), and $\varepsilon = 16/255$ under ℓ_∞ norm, which are pretty small values compared with the existing decision-based attacks [5, 29].

Target and Substitute Models. For each dataset, we select 4 models that are widely used in existing studies [12, 30]. On CIFAR-10, we consider ResNet20 [19], VGG19 [52], DenseNet100 [20] and WRN28 [65], with the same structure and weights as the previous work [34]. The top-1 error rates of these four models are 8.23%, 6.72%, 4.73%, and 4.07%, respectively. On ImageNet, we select VGG16 [52], DenseNet121 [20], Inception v3 (Inc-v3) [54], Inception ResNet v2 (IncRes-v2) [59]. The implementation and pre-trained weights of models are based on GitHub repository[3], and the top-1 error rates of these models are 28.37%, 25.36%, 22.71% and 19.60%, respectively. The four models are used in turn as the target model unless otherwise specified.

Following the setting in the previous study [14], if the struc-

ture of the target model is the same as one of the four models, we select the rest three as substitute models; otherwise, all four models are used as substitute models. To fully demonstrate the superiority of DSA, we also evaluate the attacks with a single substitute model in Sec. 5.3.1.

Methods to Compare. Five SOTA hybrid attacks serve as baselines, including BiasedBA [5], QEBA-I [27], BAODS [56], Prism [24], HybridAttack [53]. They have shown a wide range of superiority [56]. All attacks are implemented based on the Foolbox library [45], which allows attacks to be well adapted to both ℓ_2 and ℓ_∞ norms. As DSA and HybridAttack integrate existing white- and black-box attacks, MI-FGSM [12] and SurFree [37] are selected as representative methods. For fair comparisons, DSA and other methods have the same attacker capabilities, with the same target model and substitute model settings in all scenarios.

5.2 Experiments in Closed-set Attack Scenario

In this section, we conduct closed-set experiments to evaluate the performance of adversarial attacks. The attacker is assumed to have the same training dataset as the target model for training substitute models, which is consistent with the experimental settings of most previous literatures [5, 12, 53]. Given that the victim may deploy defenses to mitigate adversarial attacks, we evaluate the attack performance in both undefended and defended scenarios.

5.2.1 Evaluation in Undefended Scenario

We conduct untargeted attacks on ImageNet[4], and we use the other three models as substitute models when evaluating one target model.

As summarized in Table 2, DSA achieves a significant improvement in attack effectiveness with different target models and distance metrics. Under the ℓ_2 norm, DSA achieves an ASR of more than 99% within an AvgQ of 100, reducing AvgQ by up to 92% over the second-best values. Under ℓ_∞ norm, DSA still achieves an ASR of over 90% using only a couple of hundred queries, with an improvement of ASR by 21.3% and an AvgQ reduction of more than 73.1% over the existing methods against all target models.

To further demonstrate the superiority of DSA, we plot the change curve of mean distance as the number of queries

[4]Targeted attacks are still a tough task for existing attacks due to the large number of classes in ImageNet. We leave it for future work.

$\diamondsuit$ represents that the attacker has a substitute model obtained by adversarial training.

increases in Fig. 6. As the query increases, the distance of each method decreases to different degrees. Compared with other methods, DSA always achieves the lowest distance under all test cases when consuming the same number of queries.

We find that the perturbation distance metric ℓ_∞ has a negative impact on attack performance compared with the results under ℓ_2 norm. In particular, the distance of BiasedBA is consistently around 1 under the ℓ_∞ norm. This is because BiasedBA tends to add larger noise to local pixels on current adversarial examples and cannot generate examples with a smaller distance under the ℓ_∞ norm, resulting in optimization stagnation.

5.2.2 Evaluation in Defended Scenario

Here, we focus on the evaluation of attacks in the defended scenario. Following the settings in previous literature [34], we conduct untargeted attacks on CIFAR-10, using ResNet50 [19] integrated with several defenses as target models. The defenses are listed as follows.

- Blacklight [28]. It detects adversarial examples with an efficient similarity engine that detects similarities between queries on the input space.
- RND-GF [44]. It attempts to add large Gaussian noise on the queried image to disrupt the subtle structure of the adversarial perturbation, allowing the model to output the correct result.
- PCL [41]. It forces the features of each class to lie within a convex polygon that is maximally separated from the polygons of the other classes.
- ComDefend [23]. It consists of a compressed convolutional neural network and a reconstructed convolutional neural network, which can convert adversarial images into their clean version.
- MagNet [39]. It includes a detector network and a reformer network. The detector network aims to identify adversarial examples, while the reformer network moves adversarial examples toward normal examples for correct classification.
- AdvTrain [36]. It trains the model on a mixture of images with adversarial perturbations to make the model robust to adversarial attacks.
- AdvTrain$^{\diamondsuit}$. It is used to evaluate the effect of AdvTrain against a sophisticated attacker [12]. Under this setting, the attacker has access to an additional substitute model obtained through adversarial training. Specifically, we utilize ResNet20 as the additional substitute model and use PGD [36] to generate adversarial examples. These adversarial examples are then used to train ResNet20, enhancing its classification accuracy under adversarial examples. Note that the hyperparameters of the training process (i.e., learning rate and number of epochs) differ from those used in the target model. All attacks are conducted under the same assumption for a fair comparison.

The performance of untargeted attacks on CIFAR-10 in the defended scenario is exhibited in Table 3. DSA is robust in attacking the defended target models and achieves the highest ASR with the least AvgQ in most tests.

We classify existing defenses into four categories. The first category, including RND-GF and ComDefend, tries to defend against adversarial perturbations by disrupting their subtle structures so that the target model can still achieve correct classifications. For example, ComDefend reduces the ASR of BAODS from 100% to 9.4% under ℓ_2 norm. However, DSA can directly generate candidate adversarial examples deep in the adversarial region and achieves a 93.8% ASR with 499.6 AvgQ under ℓ_2 norm under ComDefend.

The second category, consisting of PCL, AdvTrain, and AdvTrain$^{\diamondsuit}$, increases the margin between normal images and adversarial examples for correct classifications. For instance, AdvTrain trains the target model with adversarial examples, making it difficult to generate transferable perturbations. The results of AdvTrain$^{\diamondsuit}$ reveal that different models trained

through adversarial training could share similar vulnerabilities against adversarial attacks, allowing evading AdvTrain. Compared with AdvTrain, DSA achieves superior results in terms of both ASR and AvgQ, with a maximum 47.3% improvement in ASR and a 62.2% decrease in AvgQ.

The third category is stateful. The defenses like Blacklight record historical queries and detect their similarity to suppress attacks that query around current examples. BiasedBA, BAODS, and Prism can only achieve an ASR of less than 10.4%. Nevertheless, DSA generates diverse adversarial examples in the embedding space. These examples have different distributions and magnitudes of perturbations, which are not similar and cannot be captured by Blacklight.

Finally, the fourth category, including MagNet, aims to detect out-of-distribution samples, which can effectively detect images with obvious perturbations. Under MagNet, the ASR of BiasedBA decreases from 100.0% to 33.4% and the AvgQ increases from 1461.9 to 3431.8. Candidate adversarial examples generated by DSA may be located near the decision boundary and appear similar to normal images. Consequently, DSA achieves 99.6% ASR with 29.6 AvgQ under ℓ_2 norm and 98.6% ASR with 69.6 AvgQ under ℓ_∞ norm.

5.3 Experiments in Open-set Attack Scenario

In this section, we evaluate the robustness of attacks in open-set scenarios, where the attacker does not have access to the training dataset of the target model, as described in Sec. 2.1.

5.3.1 Evaluation with Single Substitute Models

In this subsection, we perform untargeted and targeted attacks on CIFAR10 in the open-set scenario with ResNet20 as the single substitute model. The training of the substitute model does not rely on the knowledge of the target model training dataset. Additionally, we also include the comparison with FIA [63], DST [61], and DaST [67]. Note that FIA is a sophisticated transfer-based attack (see Sec. 6), which requires only one query to generate an adversarial example and cannot adjust the settings based on feedback from the target model. As shown in the Table. 4, DSA can achieve the highest ASR of more than 97.6% with a relatively low AvgQ under ℓ_2 norm compared with the other attacks.

Prism relies on the gradient of substitute models to optimize the perturbation. However, the ASR is notably low when the gradient of substitute models deviates significantly from that

Table 6: Experimental results (ASR% / AvgQ) in four commercial APIs, i.e. AWS, Azure, Baidu, and Tencent.

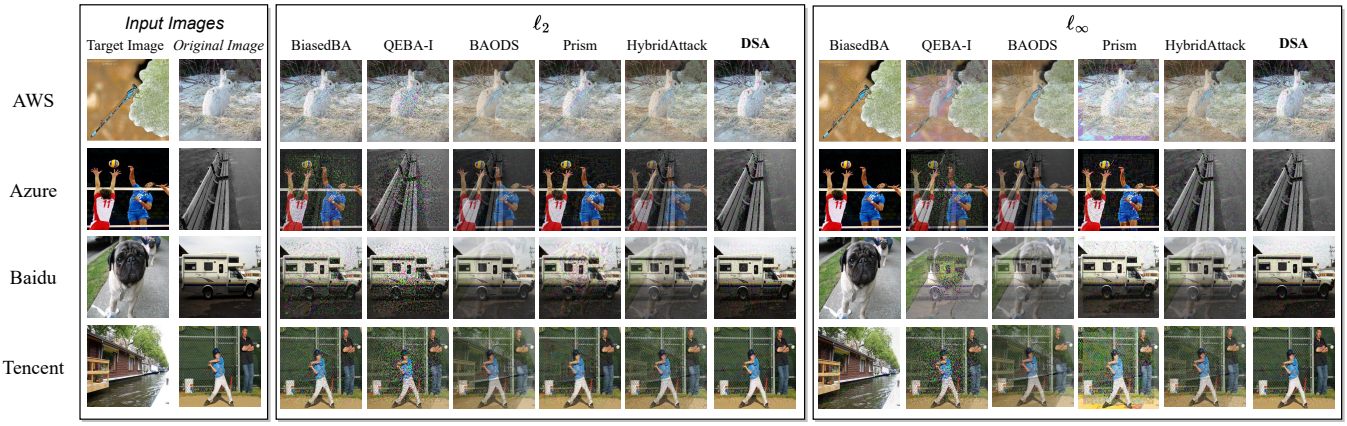

Figure 7: Adversarial examples of each attack. The adversarial examples generated by all existing methods consume the full 1,000 query budget, while those generated by DSA only consume an AvgQ of 546.

of the target model. For instance, Prism achieves an ASR of no more than 0.2% in targeted attacks.

Both DaST and DST show poor performance across all test cases, achieving an ASR of less than 30.8% and 29.4%, respectively. The reason is that the query budget is not sufficient for DaST and DST, which are considered extraction-based attacks, to train the substitute model.

FIA shows high transferability with one query. However, the ASR of FIA decreases when there is a greater disparity between the substitute and target models. For instance, FIA attains an ASR of 75.1% against ResNet20 but only 47.8% against WRN under the ℓ_2 norm for untargeted attacks.

5.3.2 Evaluation on ImageNet

In this subsection, we conduct the open-set evaluation on ImageNet, keeping the same experimental setting in Sec. 5.2.1.

The results are shown in Table 5, DSA can achieve the highest ASR and lowest AvgQ in all tests. Specifically, compared to the second-best value, DSA shows a maximum ASR improvement of 21.7%, from 71.4% to 93.1%, while the AvgQ drops by a maximum of 86.1%, from 646.2 to 90.1.

Compared with the closed-set evaluation on ImageNet (i.e., Table 2), we can observe that the difference in training datasets increases the challenge of obtaining effective adversarial examples, but some attacks still achieve comparable results in the open-set scenario. For example, QEBA-I is able to achieve a higher ASR under the open-set ℓ_2 norm, which increases from 9.9% to 36.8% when evaluated on IncRes-v2. This is because the training dataset of the current target model is only a subset of the closed-set scenario, and the reduction of training data makes the target model easier to attack.

5.4 Experiments on Commercial DNN Services

In this subsection, we carry out attacks on four well-known commercial DNN services, namely AWS [1], Azure [40], Baidu [2] and Tencent [57]. Query results returned by the APIs consist of major and minor categories. We use the major category as the final decision due to the large semantic differences, which raises the difficulty of adversarial attacks. Referring to the setting of the previous literature [14], we randomly select 20 image pairs from the validation set of ImageNet for evaluation and set the query budget as 1,000 for each image pair. Four models on ImageNet are selected as substitute models, as described in Sec. 5.1.

As shown in Table 6, DSA obtains more than 90% ASR using about 100 AvgQ under ℓ_2 norm. Compared with second-best value under both ℓ_2 and ℓ_∞ norms, DSA increases the ASR more than 20.0%, and decreases the AvgQ by at least 35.5%, which indicates that DSA can achieve effective and

Table 7: Results (ASR%/AvgQ) of the ablation study.

	Variations of DSA	ASR	AvgQ
Dispersed Sampling	DSA w/o Image Augmentation	98.9	97.8
	DSA w/o Perturbation Constraint Generation	97.3	150.2
	DSA w/o Substitute Model Selection	98.9	105.7
	DSA w/o Querying the Target Model	78.6	1491.7
	DSA w/ Proportion Fitness	98.6	110.5
Query-based Attack	DSA w/o Dispersed Sampling	78.0	2059.0

query-efficient decision-based attacks against commercial DNN services.

We present real adversarial examples of each attack against the commercial DNNs, as shown in Fig. 7. We can intuitively observe that the adversarial examples generated by DSA are mostly approximate to the original image. In contrast, the adversarial examples generated by BiasedBA, BAODS, Prism, and HybridAttack have noticeable features of the target images, while those generated by QEBA-I also have noises that are easily perceived by human eyes. In addition, DSA requires the least number of queries on the target model.

5.5 Ablation Study

In this section, we conduct a comprehensive ablation study to investigate the key components of DSA, i.e., image augmentation, perturbation constraint generation, substitute model selection, and querying the target model, as well as their corresponding contributions. Furthermore, we measure the scalability of DSA by integrating various white-box attacks. We use IncRes-v2 as the target model and VGG16, DenseNet121, and Inc-v3 serving as substitute models, and construct untargeted adversarial attacks on the ImageNet dataset.

Contribution of Each Module. We generate different variants by changing the settings of each module. Specifically, for each module removal, we perform the following: 1) generating white-box perturbations based on the original image; 2) crafting perturbations under the pre-defined threshold ε; 3) launching a white-box attack against a random substitute model; and 4) generating only a single candidate adversarial example as a starting point for subsequent query-based attacks. Additionally, we devise a variant (DSA w/ Proportional Fitness), which uses the proportion of transferable examples rather than the number of examples, to calculate fitness (defined in Eq. (8)). As an extreme case, we also removed all four modules, simplifying DSA as a query-based attack. We find that each component contributes to the attack performance of DSA, i.e., increasing the ASR and reducing the AvgQ. The detailed results are illustrated in Table. 7.

First, we find that removing any of the three modules of DSA (i.e., image augmentation, perturbation constraint generation, or substitute model selection) limits the sampling range, resulting in a decrease in ASR and an increase in AvgQ. For instance, DSA without Perturbation Constraint Generation can only generate perturbations within the pre-defined upper bound ε, achieving lower ASR and increasing AvgQ by 65.1% compared with DSA.

Second, dispersed sampling plays a critical role in DSA. DSA variants experience a significant decrease in ASR when the dispersed sampling is insufficient (DSA w/o Querying the Target Model) or completely removed (DSA w/o Dispersed Sampling). The ASR is reduced by at least 20.5%, while AvgQ increases over 16 times. This highlights the critical role of dispersed sampling.

Third, the number of transferable examples is more suitable than the proportion of the samples to compute fitness. DSA with Proportional Fitness achieves a lower ASR while increasing the AvgQ by 21.4%. The reason is that the substitute model selection in this setting devalues successfully transferred samples.

Scalability with White-box Attacks. We evaluate the scalability of DSA by integrating with different white-box attacks. By default, DSA leverages MI-FGSM [12] as the white-box attack. However, the SOTA white-box attacks can be incorporated into DSA, which allows constructing black-box attacks with a higher ASR and a lower AvgQ, as illustrated in Table. 8. For example, as FIA [63] and NAA [66] are the latest transfer-based attacks, DSA achieves an ASR of 99.5% with NAA, and an AvgQ of 63.5 with FIA, which outperforms the default DSA.

5.6 Summary

Recalling the design goals in Sec. 2.3, DSA can achieve a higher ASR than the SOTA attacks while reducing the AvgQ by at least an order of magnitude in closed-set, which demonstrates DSA has high effectiveness and query efficiency. DSA can generate adversarial examples under both ℓ_2 and ℓ_∞ norms, which illustrates the indistinguishability of DSA. DSA can outperform other attacks in defended and open-set scenarios, which demonstrates the robustness of DSA.

6 Related Work

In this section, we review three main categories of black-box adversarial attacks in decision-based scenarios.

Transfer-based Attack. Transfer-based attacks are based on the simple fact that adversarial examples exhibit transferability across model structures, which can be used to launch attacks on the target model [60]. The attacker seeks to generate an adversarial example by applying a white-box attack on substitute models and then uses it to directly attack the target model [17, 42]. The first approach is gradient-based methods where the calculation of gradients is optimized, such as using momentum information (MI-FGSM [12]), Nesterov accelerated gradient (NI-FGSM [30]) and feature maps from intermediate layers (FIA [63], NAA [66]) in the iterative attacks. The second approach, namely input augmentation methods, is to integrate gradients of various augmented images as the final direction of optimization to enhance the attack transferability (e.g., DIM [64] and TIM [13]). Note that these two approaches can be naturally integrated by combining the gradients of the augmented images computed by a gradient-based method.

Query-based Attack. Query-based attacks start with images having different labels (i.e., target images), walk around the decision boundary of the target model, and search for images with smaller perturbations while keeping the images with different labels [4]. The walking process can be roughly divided into three components [15]: 1) generating a potential adversarial example according to a well-designed algorithm, 2) leveraging the potential adversarial example to query the target model, and 3) updating the algorithm based on the query results. Depending on the walking strategies, existing attacks can be divided into two types, namely randomly walking around the boundary (e.g., BA [4], AHA [29] and SurFree [37]) and estimating the gradient by sampling on the decision boundary (e.g., HSJA [8] and TA [35]).

Hybrid Attack. Hybrid attacks attempt to combine the advantages of the two preceding methods. The attacker tries to generate adversarial examples with minimal queries by exploiting the prior substitute models. Existing methods aim to enhance query-based attacks with the prior of substitute models. On the basis of BA, Brunner et al. [5] propose BiasedBA, where adversarial gradients from substitute models are projected orthogonally to the source direction and bias the perturbations toward the projected gradient. Based on HSJA, QEBA-I [27] attempts to sample in a representative subspace, such as the subspace constructed from the principal components of the gradient matrix of substitute models. Tashiro et al. [56] design a sampling strategy to maximize the diversity in the output space of substitute models, and integrate with BA to propose BAODS to reduce the overhead of queries. AMEBA [7] formulates substitute model training and adversarial attacks as an optimization problem to incorporate. Juuti et al. [24] leverage the gradient of ensemble substitute models to search for adversarial examples with progressively smaller perturbations. Differing from the previous studies, which tune the sampling strategy of query-based attacks using the prior substitute models, HybridAttack [53] exploits the candidate example generated by a transfer-based attack as the starting point for query-based attacks to save large queries in the earlier stage of the attack.

Extraction-based Attack. Extraction-based attacks aim to generate an effective substitute model to increase the success rate of transfer-based attacks. They train the substitute model using the query results of the target model to mimic the behaviors. DaST [67] constructs a generative model to produce training examples for the substitute model. Based on DaST, DST [61] utilizes the correlation between training examples to improve the effectiveness of training substitute models.

7 Discussion

In this section, we discuss the limitations of DSA and possible future extensions.

Indistinguishability. The experiments we conducted are based on the common distance metrics, i.e., the ℓ_2 and ℓ_∞ norms. Although DSA achieves better results than other attacks in both metrics, we observe that it still has limited performance in reducing distance under ℓ_∞ norm, which suggests that we need to work on improving the effectiveness of the attack under ℓ_∞ norm in future work.

Potential Countermeasures. DSA can be detected by recognizing adversarial examples with small perturbations, which may be disrupted by image manipulations, leading to significant changes in the output vectors. We provide a more detailed analysis of potential countermeasures in Appendix B.

8 Conclusion

In this paper, we proposed DSA, which can leverage the ability of white-box attacks to achieve query-efficient adversarial attacks in the black-box decision-based scenario. Based on the observation that varying the distribution or magnitude of perturbations enables different transferability, DSA resorted to sampling different perturbations and finding a small perturbation that can transfer successfully. In multiple scenarios and datasets, DSA significantly outperformed the SOTA methods with the same threat model, and achieved the best attack performance on commercial DNN services. In future work, we will investigate techniques to extend the application scenarios of DSA, and explore efficient and lightweight defenses.

A Parameter Tuning

In this section, we evaluate the attack performance of DSA under different parameters on ImageNet, using VGG16 as the substitute model and IncRes-v2 as the target model.

A.1 Number of Attack Epochs

We evaluate how the ASR changes with the number of epochs of dispersed sampling. As illustrated in Fig. 8, the three curves under different query budgets all show a parabolic-like nature. A limited number of epochs restricts the effective utilization of substitute model transferability. In this case, the attacker

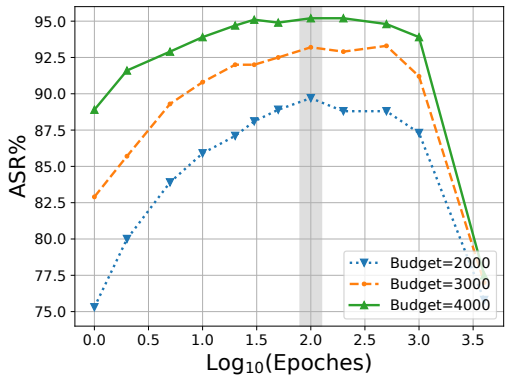

Figure 8: ASR versus number of attack epochs.

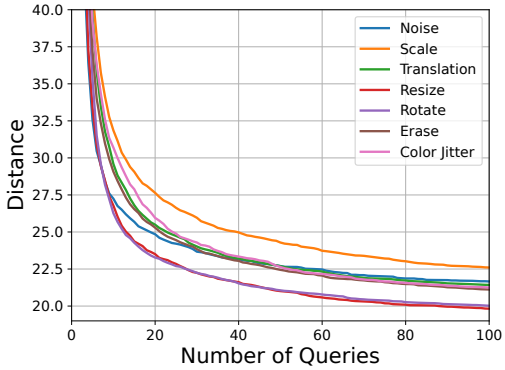

Figure 9: Mean distance versus number of queries under different input augmentations.

cannot fully explore the adversarial region and obtain a transferable example with a small perturbation, leading to a lower ASR. On the contrary, although a larger number of epochs can fully leverage substitute models, it also consumes excessive and unnecessary queries, causing a declining trend in ASR as the number of epochs increases.

A.2 Different Input Augmentations

In this subsection, we evaluate the impact of different input augmentations. Specifically, we test the following input augmentations: adding Gaussian noise, scale transformation, translation, resizing, rotation, random erasing, and color jitter. As illustrated in Fig. 9, we observe that under the same query conditions, the distance gap between different input augmentations is within 5. Rotation and resizing consistently achieve the lowest distances, while scaling exhibits the highest distance. For example, the distance of rotation and resizing is approximately 20, whereas scaling reaches as high as 22.5 with 100 queries. Due to varied sample regions for different augmentations, images that undergo rotation and resizing exhibit greater ℓ_2 norm distances than images subjected to scaling. Thus, candidate adversarial examples from rotation and resizing are more dispersed in the embedding space, which allows DSA to discover smaller transferable perturbations.

B Insights for Potential Countermeasures

It is possible to detect DSA by recognizing adversarial examples with small perturbations. These adversarial examples closely resemble the original images and are located near the decision boundary. Consequently, even minor image manipulations can disrupt the structure of the perturbation, causing significant variations in the output vector. In contrast, normal images exhibit higher confidence and trigger minimal variation during image manipulation, due to their robust features and the spatial invariance of deep neural networks (DNNs).

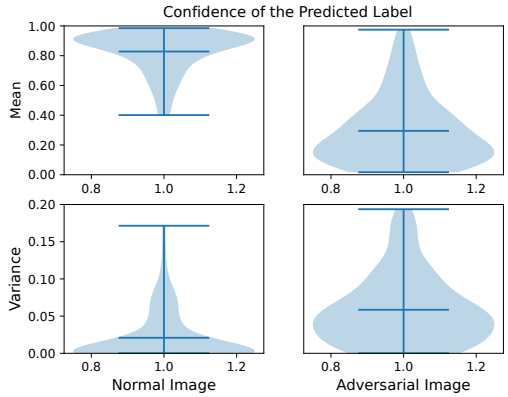

Figure 10: Mean and variance of the confidence for the predicted labels.

We conduct experiments to validate our previous claims. We randomly select 100 original images from ImageNet and collect 100 adversarial examples generated by DSA. For each query, we create several variants of the query image using image manipulations such as rotation, adding noises, and Gaussian blur. We calculate the mean and variance of the confidence for the predicted labels of the query variants, as shown in Fig. 10. We observe that the query variants of normal images have a higher mean confidence score and lower variance than adversarial examples. Therefore, we can utilize the difference in mean and variance of confidence scores to detect the perturbations generated by DSA.

C Experiments on ImageNet-21k.

Due to the applications of large models and advanced model architectures [51], we evaluate the performance of existing attacks on ImageNet-21k [46].

ImageNet-21k is a superset of ImageNet, with about 15 million images. We select ConvNext [33], MobileVitv2 [38], Deit3 [58], Swinv2 [32] as the target model, respectively. These models are able to achieve excellent performance on multiple vision tasks and have been widely used in applications such as mobile devices [38]. All of them are trained on ImageNet-21k with the same classification categories as ImageNet-1k, and can be accessed in the repository[5].

Table 10: Average time consumption on attacking IncRes-v2

Methods	Time Consumption(s)
QEBA-I	117.7
BAODS	106.3
BiasedBA	64.1
Prism	44.3
HybridAttack	26.1
DSA	**13.5**

The results are summarized in Table 9, and it can be seen that DSA is able to achieve the highest ASR and the lowest AvgQ in all tests. Under ℓ_2 norm, compared to the second best values, we see a maximum increase of 37.7% in ASR (i.e., from 43.3% to 81.0%) and a maximum decrease of 7 times in AvgQ (i.e., from 890.6 to 107.7).

In addition, we observe a large difference in the effectiveness of the attack when using the model with different structures from the target model. For example, for the evaluation of the ℓ_∞ norm, DSA can achieve an ASR of 85.4% on ConvNext, while only an ASR of 35.6% on Swinv2.

D Time Consumption

To comprehensively evaluate the attack performance, we record the average time consumption of each attack under the experimental setting in Sec. 5.2 with IncRes-v2 as the target model on ImageNet. The results are shown in Table 10. Compared with the second-best value, DSA takes almost half of the time to complete the attack. We believe that the advantage of DSA lies in two aspects. First, only a white-box attack against one substitute model is needed to generate a candidate, which results in little preparation for each query, requiring neither additional training of auxiliary models [14, 27, 34] nor the calculation of the sampling direction based on query results [27, 56]. Second, benefiting from the high query efficiency of DSA, we can find an adversarial sample with a few queries, allowing the attack to be stopped in a short time.

Adversarial Illusions in Multi-Modal Embeddings

Abstract

Multi-modal embeddings encode texts, images, thermal images, sounds, and videos into a single embedding space, aligning representations across different modalities (*e.g.*, associate an image of a dog with a barking sound). In this paper, we show that multi-modal embeddings can be vulnerable to an attack we call "adversarial illusions." Given an image or a sound, an adversary can perturb it to make its embedding close to an arbitrary, adversary-chosen input in another modality.

These attacks are cross-modal and targeted: the adversary can align any image or sound with any target of his choice. Adversarial illusions exploit proximity in the embedding space and are thus agnostic to downstream tasks and modalities, enabling a wholesale compromise of current and future tasks, as well as modalities not available to the adversary. Using ImageBind and AudioCLIP embeddings, we demonstrate how adversarially aligned inputs, generated without knowledge of specific downstream tasks, mislead image generation, text generation, zero-shot classification, and audio retrieval.

We investigate transferability of illusions across different embeddings and develop a black-box version of our method that we use to demonstrate the first adversarial alignment attack on Amazon's commercial, proprietary Titan embedding. Finally, we analyze countermeasures and evasion attacks.

1 Introduction

Multi-modal encoders such as ImageBind [10] and AudioCLIP [13] are a new class of machine learning models that encode inputs from different modalities (*e.g.*, text, audio, conventional and thermal images) into task- and modality-agnostic vectors. Beyond compression, the purpose of multi-modal encoders is to map semantically related inputs into similar vectors so that, for example, the respective embeddings of a dog image and a barking sound are *aligned*, *i.e.*, lie close to each other in the embedding space. This enables arbitrary combinations of downstream tasks (classification, generation, etc.) and modalities to operate on the same input space.

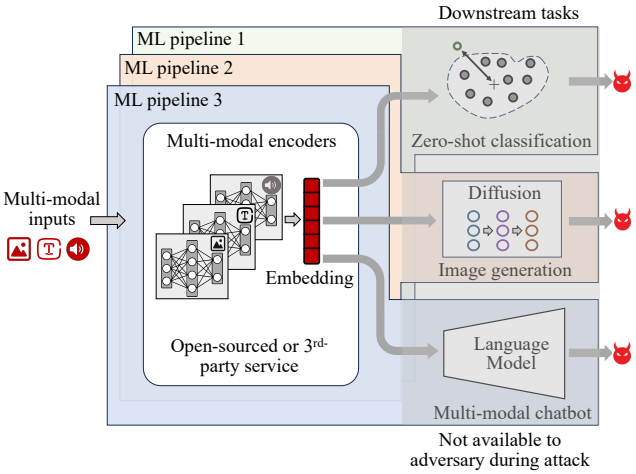

Figure 1: **An adversarial illusion compromises any machine learning (ML) pipeline that relies on the multi-modal encoders.**

Modern encoders capture semantically rich spatial relationships between inputs by contrastively training on vast amounts of bi-modal data (*e.g.*, audio recordings and the corresponding captions). The resulting encoders not only achieve *natural alignment* between these modalities but also exhibit *emergent alignment* between modalities that were never explicitly linked in the training data. For example, a multi-modal embedding trained on image-text and audio-text pairs may also align semantically related images and sounds even though it was not trained on image-audio pairs.

Cross-modal semantic relationships encoded in the embeddings make them a useful "backbone" building block for current and future downstream tasks, without training models for these tasks on multiple modalities. They also present a new attack surface, which we explore in this paper.

[*]Comparable contributions.

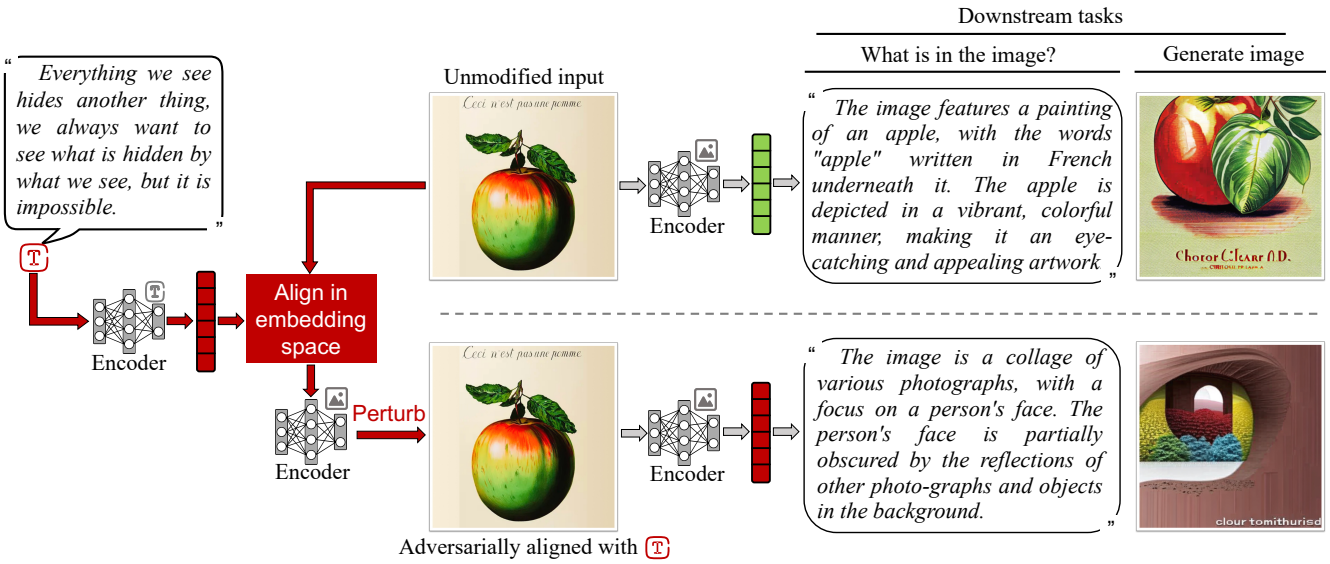

Figure 2: **"Ceci n'est pas une pomme": an adversarial perturbation of an image misleads downstream tasks.**

We demonstrate that multi-modal embeddings are vulnerable to a new class of attacks that were not possible with previous embeddings. By aligning inputs of his choice in a multi-modal embedding, an adversary can compromise output modalities and downstream tasks that are not available or even known at the time of the attack, as shown in Figure 1.

Specifically, we show that cross-modal alignment in multi-modal embeddings is highly vulnerable to adversarially generated "illusions." Given an input x, we say that a perturbation x_δ is an *illusion* if it appears similar to x to a human but aligns with an adversary-chosen y from another modality in the embedding space. An illusion thus "misrepresents" its semantic content to downstream tasks. For example, Figure 2 shows an illusion that aligns an image of Magritte's famous "This is Not an Apple" painting with the text of Magritte's quote, "Everything we see hides another thing." Figures 3 and 4 show other examples. In all cases, perturbed images and audio recordings appear similar to their respective original inputs, but downstream tasks—text and image generation, in these examples—act on the perturbed inputs as if their semantics matched the adversary-chosen texts.

Our contributions. First, we demonstrate that tiny adversarial perturbations can be used to incorrectly align inputs from different modalities in the embedding space and thus mislead downstream applications. We use standard adversarial perturbation techniques for this attack.

The attack is **targeted**. The adversary has full freedom to choose misaligned inputs and can align any target with any input of his choice from a different modality. This is also the first attack that exploits emergent alignment to attack downstream output modalities not available to the adversary.

Second, we show that the attack is **task-agnostic**. By design [10, 13], downstream tasks that use multi-modal embeddings do not consider input modalities and can operate on any vector from the embedding space. These tasks rely on the alignment between the embeddings of semantically related inputs from different modalities, whether natural or emergent. As we show, this "organic" alignment corresponds to relatively weak proximity in the multi-modal embedding space. Whereas previous attacks on multi-modal learning targeted a single modality and did not need to deal with the modality gap [25], we demonstrate that adversarial alignment can be made significantly closer than any organic alignment regardless of source and target modality.

Therefore, the adversary can leverage an attack on a multi-modal embedding into a wholesale compromise of current and future downstream tasks (see Figure 1), including tasks he is unaware of during the attack. We show that multiple tasks—including image generation, text generation, audio retrieval, and different types of zero-shot classification (image, thermal image, and audio)—based on embeddings such as ImageBind, AudioCLIP, OpenCLIP [5], and Amazon's Titan[1] are all misled by cross-modal illusions. Against zero-shot tasks based on ImageBind and AudioCLIP embeddings, our illusions achieve near-perfect (> 99%) attack success rates at standard perturbation bounds.

Third, we analyze **transferability** of the attack across different encoders, investigate how it is influenced by model architecture, and craft illusions that work against multiple embeddings. In particular, we show that illusions generated using OpenCLIP encoders also achieve 100% and 90% at-

[1] https://aws.amazon.com/bedrock/titan/

tack success rates against zero-shot image classification on ImageBind and AudioCLIP embeddings.

Fourth, we demonstrate a **black-box, query-based** attack and show that it is effective against several downstream tasks. We then combine our query-based and transfer techniques into a hybrid method and use it for the first adversarial alignment attack against Amazon's Titan, a commercial, black-box embedding. Our hybrid method fools Titan on 42% of our zero-shot image classification examples, even though the embedding is proprietary and completely opaque.

Fifth, we survey several countermeasures and demonstrate how adversarial illusions can evade defenses based on feature distillation (*e.g.*, JPEG compression) and anomaly detection based on consistency of augmentations. Our evasion attacks achieve 88% and 94% success rate against the JPEG defense. Even if multi-modal embeddings were certifiably robust to input perturbations (they are not), we show that certification may not prevent these attacks due to the tradeoff between insufficient robustness and excessive invariance.

The main technical innovations of this work are: (1) establishing that adversarial alignment in multi-modal embeddings can be made closer than any organic alignment regardless of input and target modality; (2) demonstrating that the scope of this attack is much broader than conventional adversarial examples because it is task-agnostic and affects all models based on the embedding, even those that do not accept the adversary's target modality as input; and (3) a new hybrid technique for query-based attacks on black-box embedding.

Significance of the attacks. Many modern ML-based systems operate on third-party content that is not created or controlled by their users. For example, generative ML systems analyze and summarize webpages and social media, ML-based personal assistants process emails and instant messages, and retrieval-augmented generation and recommender systems operate on databases of content from many users. Multi-modal embeddings extend input domains of these systems to new modalities without re-training or fine-tuning.

It is a core security principle that any third-party content is potentially adversarial and, therefore, cannot be trusted. Vulnerabilities described in this paper enable adversaries to craft multi-modal content that is interpreted differently by humans and ML systems. The resulting exploits can cause ML systems to retrieve or recommend adversary-manipulated content in response to certain queries, interpret it in a way favorable to the adversary, conceal dangerous or harmful content from ML-based detection tools, or else create an illusion of danger or harm where there is none (*e.g.*, see Fig. 10).

To facilitate research on the security of multi-modal embeddings, we released our code and models.[2]

2 Background and Related Work

A machine learning (ML) model takes input $x \in \mathcal{X}$ and produces output $y \in \mathcal{Y}$ that can be, for example, a class label for x, a generated image, or generated text. Today, standard ML pipelines use an encoder θ (*e.g.*, CLIP [33]) to convert inputs into embedding vectors. Since training an encoder is expensive, many ML pipelines rely on pre-trained encoders (open-sourced or commercial). With a pre-trained encoder, it is sufficient to operate on embeddings, rather than raw inputs, in either a zero-shot fashion, or with a trained model. Many ML pipelines thus have two stages:

1. $\theta(x) = e$ — embedding of input
2. $\phi(e) = y$ — downstream task

Multi-modal embeddings. Multi-modal encoders map inputs $x^{(m)}$ from modalities $m \in \mathcal{M}$ into a single embedding

space. Each modality m has its own encoder $\theta^{(m)}$. Encoders are trained on multi-modal tuples $(x^{(m)}, y^{(\bar{m})})$ that are semantically *aligned* (*e.g.*, a picture of wolves and the text "Wolves," as shown in Figure 5). Encoders are trained using contrastive learning [31] that pushes the representations of aligned inputs closer to each other in the embedding space and away from the representations of semantically different inputs.

Given a bi-modal dataset $\mathcal{D} = (X, Y) \in m \times \bar{m}$, we define an encoder's *alignment* on $\mathcal{D}$ as the mean cosine similarity between the embeddings of the elements in each $(x, y) \in \mathcal{D}$:

$$\text{align}(\mathcal{D}) = \frac{1}{|\mathcal{D}|} \sum_{(x,y)\in\mathcal{D}} \cos\left(\theta^{(m)}(x), \theta^{(\bar{m})}(y)\right) \tag{1}$$

In this paper, we focus on images, sounds, and texts. As of this writing, ImageBind [10] and AudioCLIP [13] are the only open-source multi-modal embeddings that support these three modalities. Multi-modal embeddings exhibit "emergent" alignment between modalities. Semantically similar images and sounds (*e.g.*, a picture of a dog and an audio recording of a dog barking) have similar embeddings, even though the training data does not include image-audio tuples.

The distinction between natural (present in the training data) and emergent alignment is important for multi-modal encoders, but attacks in this paper are agnostic to the target modality and the source of its alignment. We generically define an encoder's *organic* alignment on datasets $\mathcal{D}$ where for all $(x, y) \in \mathcal{D}$, x and y are semantically related, regardless of whether it is learned from explicitly aligned training pairs or "emerged" from other modalities.

Downstream models. Multi-modal embeddings align semantically similar inputs across modalities. Thus, downstream models do not need to be trained on multiple modalities and can operate directly on the embeddings.

Zero-shot classification matches the embedding of an input to the closest class embedding (mean embedding of known class representatives). With multi-modal embeddings, zero-shot classification can classify inputs to classes in a different modality, *e.g.*, label an audio with an image class. *Retrieval*, similar to zero-classification, matches a query to the closest item in the embedding space.

Image generation takes an embedding and performs conditional generation using a diffusion model. ImageBind's image encoder is initialized from the CLIP visual encoder [33], thus diffusion models that operate on CLIP embeddings (*e.g.*, unCLIP [35]) can also operate on ImageBind embeddings. *Text generation* can use multi-modal embeddings as inputs to instruction-following language models, *e.g.*, PandaGPT [43].

Adversarial perturbations. An adversarial perturbation δ added to input x causes a model ϕ to produce an incorrect output, as in untargeted adversarial examples [11], or even a specific output y_t chosen by the adversary [4].

Adversarial examples for text target toxicity classification [15] and reading comprehension [19]. Recently, jailbreaking attacks on dialog systems, *i.e.*, chatbots, were demonstrated to bypass internal guardrails on hate speech [52]. All of these attacks target a specific downstream task.

Several recent papers [23, 49, 51] deploy adversarial perturbations against encoders that use contrastive learning. These attacks work by increasing contrastive loss and are necessarily *untargeted*: they prevent perturbed inputs from being embedded near the original input, but the adversary has no control over the placement or alignment of perturbed inputs.

In other recent work [2, 3, 32], adversarial perturbations are used for jailbreaking and prompt injection in multi-modal chatbots (a specific downstream task). In [39], adversarial perturbations against CLIP image embeddings are shown to affect downstream tasks. The attack is not cross-modal, the adversary has no arbitrary choice of inputs, and perturbations are very large and visible.

Dong et al. [6] present an untargeted attack on image embeddings and a targeted attack on text descriptions in a specific language model (rather than multi-modal embeddings). The attack causes the model to predict the main object in an image incorrectly. There is no analysis of how an embedding attack transfers to multiple downstream tasks, modalities beyond images and text, or robustness of defenses.

Zhao et al. [50] present several attacks against visual chatbots, evaluated via the embedding alignment (CLIP Score) between the adversarial image x_δ and target y_t. This is insufficient to show transferability to downstream tasks. For example, to attack a generation model ϕ based on embedding θ, it is not enough to show that $\theta(x_\delta)$ and $\theta(y_t)$ are aligned. The attack succeeds only if $\phi(\theta(x_\delta))$—*i.e.*, the image *generated* from the embedding, rather than the image used to produce the embedding—is classified to y_t. Modalities are limited to images and text, transferability across encoders is limited to CLIP as the target, and there is no analysis of defenses, even though adversarial images are foiled by simple countermeasures such as applying JPEG (see Section 6.1).

Our paper demonstrates that adversarial perturbations enable cross-modal, downstream task-agnostic adversarial alignment of arbitrary inputs in multi-modal embeddings.

Other attacks. Previous work considered collisions in NLP models [42], but—unlike this paper—it targets specific downstream tasks in a single modality (text), and the adversary does not have an arbitrary choice of colliding inputs.

Poisoning and backdoor attacks [17, 18] compromise embeddings at *training time*. By contrast, this paper focuses on *evaluation-time* attacks against "clean," unmodified models.

3 Threat Model

In this section, we briefly explain the adversary's goals and capabilities for different attack scenarios.

3.1 Adversary's Goals

The adversary seeks to influence a multi-modal embedding—and thus any downstream task or, in general, machine

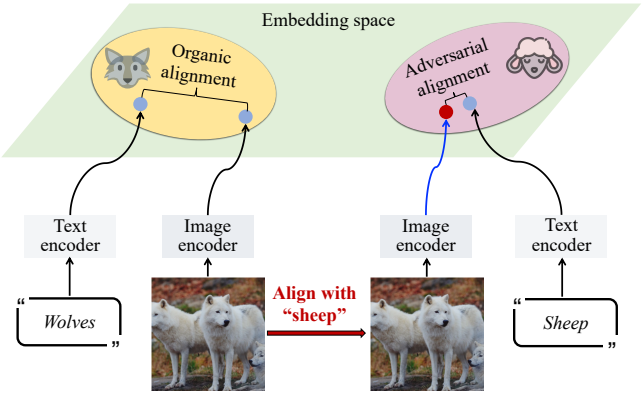

Figure 5: **Cross-modal, adversarial alignment in the embedding space.**

learning pipeline that uses the embedding, even if not known to the adversary at the time of the attack—by crafting a semantically meaningful input we call an *adversarial illusion* so that its embedding is aligned with another, attacker-chosen input in a different modality. Technically, the adversary's goal is to maximize *adversarial alignment* between the adversary's inputs x_δ in modality m and (arbitrarily chosen) targets y_t in modality $\bar{m}$—see Figure 5.

Cross-modal adversarial alignment extends the scope of the attack beyond the modalities supported by a particular ML pipeline. For example, there may not even exist an input in the right modality, *e.g.*, there may not be an available image corresponding to the adversary's target text (see an example in Figure 2). Furthermore, the attack may target downstream applications that do not accept the adversary's modality as input. For example, consider an accessibility application that takes images and generates audio describing their contents. An adversarial alignment attack enables an adversary to use any text of his choice as the target and attack this application with an image aligned with the chosen text—even though the application does not accept text inputs.

3.2 Adversary's Capabilities

We consider four distinct attack settings. In each setting, the adversary has different levels of access to the target encoders and auxiliary information.

White-box. Several multi-modal encoders are available as open-sourced code. In this setting, the adversary has access to all of their internal details, including architecture, parameters, and gradients (but not downstream tasks). This level of access allows the adversary to backpropagate gradients from the loss functions defined in Section 4 directly to adversarial illusions, similar to conventional adversarial examples [11, 29].

Transfer. If the adversary does not have access to the target encoder (because it is proprietary or closed-source or charges too much for queries), he may use white-box access to other, *surrogate* encoders to create adversarial illusions. The success of the transfer attack depends on the similarity between the surrogate and target models (which may not be known to the adversary in advance) and how well the surrogate attack generalizes [11, 24].

In Section 4.2 and Section 5.3, we show that backpropagating gradients from multiple surrogates helps generate illusions that succeed against target encoders to which the adversary does not have access.

Query-based. Many commercial embeddings are only available as APIs. In this setting, the adversary has query access to the target encoder but no surrogates. The adversary has no visibility into the model being queried.

Most query-based attacks rely on estimating the gradients of the target model, require additional auxiliary information, do not work well for targeted attacks, or fail to scale to a large number of queries [45]. Instead, our attack optimizes over a gradient-free objective (Section 4.3) to create effective adversarial illusions (Section 5.4).

Hybrid. Finally, we investigate a realistic, combined threat model in which the adversary has access to white-box surrogates (*e.g.*, open-source encoders) and query-only access to the target (*e.g.*, commercial embeddings). The adversary still has no prior knowledge about the target but can "warm-start" the query-based search with adversarial illusions crafted to transfer across surrogate encoders.

In Section 4.4 and Section 5.4, we show that this strategy, starting with white-box access to surrogate encoders, yields a successful query-only attack on Amazon's Titan embeddings.

4 Crafting Cross-Modal Illusions

Let $m, \bar{m} \in \mathcal{M}$ be the modalities supported by a multi-modal encoder $\theta = \{\theta^{(i)}\}_{i \in \mathcal{M}}$. The adversary's goal is to generate a perturbation δ such that the embedding $\theta^{(m)}(x_\delta)$ of $x_\delta = x^{(m)} + \delta$ is close to a target $\theta^{(\bar{m})}(y_t^{(\bar{m})})$, by optimizing the following objective:

$$\arg\min_{\delta} \left[\mathcal{L}(x_\delta, y_t) = \mathcal{L}\left(x^{(m)} + \delta, y_t^{(\bar{m})}; \theta\right) \right] \tag{2}$$

In the rest of this section, we define the objective functions $\mathcal{L}$ for each threat model from Section 3.

4.1 White-Box Attack

Although ImageBind [10] and AudioCLIP [13] use dot product during training, modalities that are not naturally aligned (*e.g.*, audio and text in ImageBind) have different normalizations. Hence, for our white-box attack, we omit the norms, use cosine similarity, and minimize the following objective:

$$\mathcal{L}_{\text{WB}}(x_\delta, y_t) = 1 - \cos\left(\theta^{(m)}(x_\delta), \theta^{(\bar{m})}(y_t)\right) \tag{3}$$

To optimize Equation (3), we iteratively update perturbation δ with Projected Gradient Descent (PGD) [29].

4.2 Transfer Attack

For the transfer setting, we adopt a variation on the ensemble-based approach of [27], extending our white-box attack to an ensemble of K surrogate models $\Theta = \{\theta_i\}_{i=1}^{K}$. Each model's weight is parameterized by $\lambda = [\lambda_1 \ldots \lambda_K]$ where $\lambda_i = \frac{1}{K}$. Concretely, we minimize the following objectives:

$$\mathcal{L}_{\mathrm{T}}(x_\delta, y_t) = \textstyle\sum_{\theta\in\Theta} \lambda_i \mathcal{L}_{\mathrm{WB}}(x_\delta, y_t; \theta) \tag{4}$$

As in the white-box setting, we use a variant of PGD, varying the target model in each iteration of training.

4.3 Query-Based Attack

In the black-box setting, the adversary does not have access to the target model's parameters. We adopt the Square attack [1], a score-based method that does not rely on local gradient information. When the adversary's goal is embedding alignment, *i.e.*, cosine distance between the respective embeddings of some input and a target, the attack can be made stronger if the adversary knows non-target labels $\mathcal{Y}nt$ (*e.g.*, in the case of image-text alignment, $\mathcal{Y}nt$ are labels that neither describe the image, nor are targets of the attack). For $f(x_\delta, y_t) = 1 - \mathcal{L}_{WB}(x_\delta, y_t)$ (the embedding cosine distance), we update δ with a randomized search scheme, minimizing

$$\mathcal{L}_{BB}(x_\delta, y_t) = -f(x_\delta, y_t) - \log\left(\textstyle\sum_{y\in\mathcal{Y}nt} e^{f(x_\delta, y)}\right) \tag{5}$$

This is a contrastive approach that maximizes proximity to a specific target while minimizing proximity to non-targets.

4.4 Hybrid Attack

In the hybrid attack setting, we "warm-start" (*i.e.*, initialize) a query-based attack with the illusions generated locally by the transfer attack. Even if they do not fully transfer to the target model, we observe that they are still closer in the embedding space to the targeted region than the original input [44].

5 Experimental Evaluation

In this section, we evaluate adversarial illusions under the four threat models from Section 3 on two standard multi-modal datasets, four embedding families, and four downstream tasks (the fifth task is used for illustration). For randomly paired, multi-modal tuples, in each of the threat models, our attack produces adversarial illusions that (1) are close to their "source" in the input space, (2) are close to their randomly chosen target in the embedding space, and (3) mislead multiple downstream tasks with a high success rate.

5.1 Setup

Models. We use four encoder families. For our white-box attacks, we use ImageBind [10] and AudioCLIP [13], popular open-source text, image, and audio encoders. For our transfer attacks, we use the OpenCLIP family (ViT and ResNet50) [5, 7, 14] as surrogate models. For our query-based attack, we use Amazon's proprietary, black-box Titan encoder.

Datasets. We evaluate our (`image`, `text`) and (`audio`, `text`) adversarial alignment on random, 100-datapoint subsets of the ImageNet [36], AudioSet [8], AudioCaps [22], and LLVIP [21] datasets. Before subsetting, we permute the datasets by randomly matching source inputs in one modality to target inputs in another modality. The adversary is thus asked to produce a perturbation for each source that aligns its embedding with a random target, which is strictly harder than an untargeted attack.

Following is a brief summary of each dataset:

- *ImageNet* is an image-classification dataset that naturally aligns images and WordNet text labels. Before evaluating on the downstream tasks, each label y is injected into the templates introduced in [33] (*i.e.*, $y \leftarrow$ "A photo of a $\{y\}$.")
- *AudioSet* is an audio-classification dataset that associates audio samples and WordNet text labels. Labels are embedded as-is. AudioCLIP is the only encoder trained on (`audio`, `text`) data, thus audio-text alignment is "emergent" for the other encoders.
- *AudioCaps* is an audio-retrieval dataset based on AudioSet that associates audio samples with text captions.
- *LLVIP* is designed for low-light vision tasks, comprising paired RGB and thermal images of street scenes. We use the annotations in the dataset to crop pedestrian and random bounding boxes and label the cropped images as "Person" or "Street."

Downstream tasks. We evaluate our attack on the following downstream tasks:

- *Zero-shot Classification: Images, Thermal images, Audio.* Given a set of labels $\mathcal{Y}$, input x is assigned $y \in \mathcal{Y}$ whose embedding is closest to the embedding of x. For LLVIP thermal images, Y is {"Person", "Street"}.
- *Retrieval: Audio.* Similar to classification, audio input x "retrieves" the closest caption y in the embedding space.
- *Generation: Images.* Images are generated from embeddings using BindDiffusion [26] and evaluated using an image classifier. Because available generative models sometimes fail to produce correct outputs even on the embeddings of clean images (the generated image does not match the semantics of the input image), we only evaluate our attack on sources for which generation produces correctly classified images. We further explain this limitation below.
- *Generation: Text.* Text is generated from embeddings using PandaGPT [43] and evaluated using OpenAI's ChatGPT as a text classifier, as described below.

Evaluation metrics. To evaluate the effect of our attacks, we measure raw adversarial alignment and, for each downstream task, the attack success rate with Top-1 (T-1) and Top-5 (T-5) accuracies. For most of our experiments, the error bars

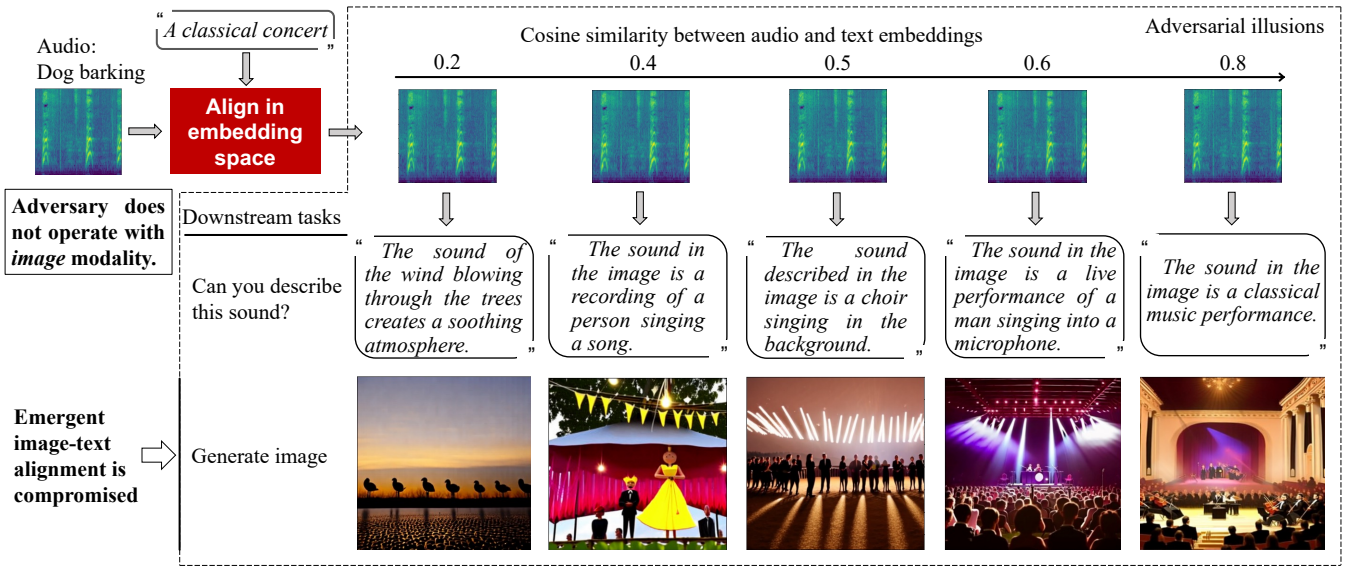

Figure 6: **"Symphony of Woofs": similarity between an adversary-chosen input and the resulting illusion.**

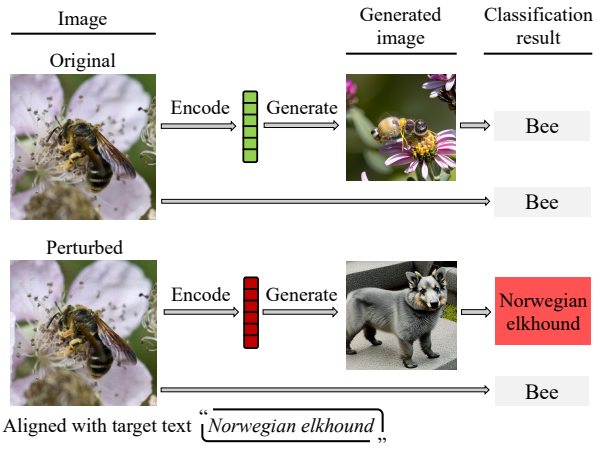

Figure 8: **"Beewulf": the original and perturbed images, images generated from their respective embeddings, and their classification.**

are standard deviations computed over a 100-sample subset, while for Amazon's Titan, we measure over 50 samples. As explained above, the classification accuracy of images, thermal images, and audio, as well as audio retrieval, is measured in a zero-shot fashion, while generated images are classified using a pre-trained vision Transformer (ViT-B/16) [7].

Limitations of downstream tasks. Generative models based on multi-modal embeddings are a new, rapidly evolving field, and publicly available implementations are limited. We only consider BindDiffusion [26] and PandaGPT [43]. BindDiffusion uses the unCLIP model [35] trained on CLIP embeddings [33]. Even without adversarial perturbations, images generated by BindDiffusion appears from the embeddings of many images, sounds, and texts are rather poor. PandaGPT, although trained on ImageBind embeddings, was fine-tuned only on image-text pairs. Therefore, in some cases, it interprets embeddings of sounds as if they were images (see Figure 4). Our attack is agnostic with respect to downstream models, and we expect that improvements in their quality will make the attack more effective.

Our evaluation of text generation from thermal images is, too, limited by the capabilities of PandaGPT, which does not

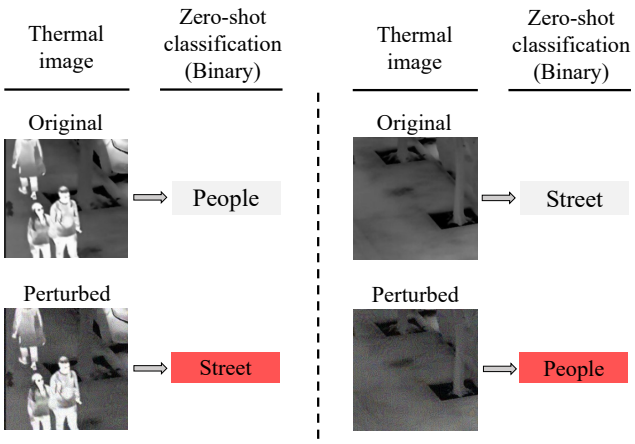

Figure 9: **"The invisible man": the original and perturbed thermal images and their zero-shot classification.**

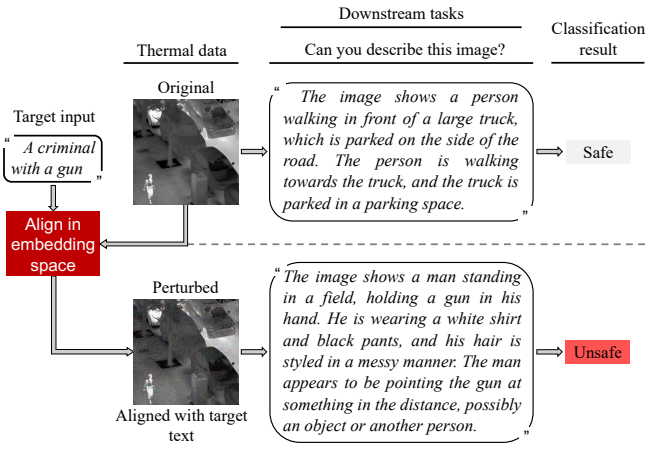

Figure 10: **"Surveillance": a thermal-image illusion against text generation.**

work well on ImageBind thermal embeddings. Therefore, while we use the thermal encoder for zero-shot classification, we use the RGB image encoder for generation. We align thermal images with the target text "A criminal with a gun" and generate text from the resulting embedding by querying PandaGPT "What's in the image?" To classify the generated text, we use the following prompt to ask GPT-4o whether the text describes an unsafe activity: "Answer with yes or no, does this response describe anything unsafe?"

Hyperparameters. For the white-box experiments, we present our results at various maximum perturbations: $\epsilon = \frac{\epsilon_V}{255}$ where $\epsilon_V \in \{1,4,8,16,32\}$ for images, $\epsilon = \epsilon_A \in \{0.005, 0.01, 0.05, 0.1, 0.5\}$ for audio. Illusions are trained for $T = 7{,}500$ iterations in both cases. For the transfer experiments, we set the standard $\epsilon = \frac{16}{255}$ and evaluate for $T = 300$ iterations. For the query-based experiments (including the hybrid attack), we use the same hyperparameters as the Square attack [1] with the maximum perturbation $\epsilon = \frac{16}{255}$, query limit $N = 100{,}000$, and other hyperparameters unchanged.

5.2 White-Box Attack Results

As we demonstrate in the rest of this section, access to the gradients of the target encoder (ImageBind and AudioCLIP, in this case) yields a powerful attack based on a direct optimization of the adversarial illusion with respect to the desired alignment. In each of our experiments, we were able to generate illusions that are far closer in the embedding space to their target than even the target's "naturally aligned" counterpart. Consider an illusion x_δ and a target pair (x_t, y_t), say, an image of a dog and its caption. We achieve $\text{align}(\{x_\delta, y_t\}) > \text{align}(\{x_t, y_t\})$.

Figures 2 to 4, 6 and 7 illustrate the effect of our illusions on text and image generation. Figures 4 and 7 show audio illusions against generation and zero-shot classification, respectively. Figures 9 and 10 show thermal-image illusions against zero-shot classification and text generation, respectively. Figure 6 shows how increasing alignment between an audio perturbation and the adversary's text affects downstream tasks. As cosine similarity between the embeddings increases, the interpretation of the perturbed barking-dog audio changes until it is interpreted as a classical concert by downstream tasks. Figure 8 shows how an image generated from the embedding of an adversarial illusion is classified to the adversary-chosen text by an image classifier.

Zero-shot image classification. Table 1 shows the results for ImageBind and AudioCLIP. Whereas organic alignment is around 0.29 and 0.14, respectively, our attack with pixel perturbations as small as $\frac{1}{255}$ produces adversarial alignment that's twice as strong at 0.57 and 0.37. The corresponding Top-1 accuracy is a near-perfect 93% and 90%, respectively. Meanwhile, at the standard perturbation bound from the literature, $\frac{16}{255}$, our perturbed images induce adversarial alignment of 0.96 and 0.78 and are classified as the target label with 100% accuracy for both models.

Image generation. Table 2 shows that, with a maximum pixel perturbation of $\frac{16}{255}$, images generated from the embeddings of our illusions reach 64% and 92% attack success rate (*i.e.*, classification to the target label), *better* than the classification accuracy of images generated from the embeddings of the original images (42% and 64%, respectively).

Classification accuracy of the original images is 85% and 99%, respectively. By contrast, almost none of the adversarial images are classified to the label of the original image from which it was produced.

Text generation. Table 3 shows that with a maximum pixel perturbation of $\frac{16}{255}$, 64% of texts generated from the embeddings of our illusions are classified as unsafe by GPT-4o, vs. 0% for texts generated from the embeddings of original images.

Table 1: **Zero-shot image classification.** Our illusions successfully fool zero-shot image classification. We measure attack success rates (%) and adversarial alignment of cross-modal illusions against ImageBind and AudioClip. ϵ_V is the perturbation bound $\epsilon = \frac{\epsilon_V}{255}$. The first two rows are baselines (no perturbations applied to inputs). Standard deviations are reported.

Alignment	ϵ_V	ImageBind		AudioCLIP	
		Top-1	align(·)	Top-1	align(·)
Organic	–	67%	0.2878 ± 0.05	27%	0.1445 ± 0.03

	32	100%	0.9692 ± 0.01	100%	0.8074 ± 0.06

Table 2: **Image generation.** Our illusions successfully fool the downstream classification of generated images. We use BindDiffusion to generate images from ImageBind embeddings and measure Top-k attack success rate (%)—marked in bold—for the original images, adversarial illusions (white-box), and images generated from their respective embeddings.

Input type	Top-1		Top-5	
	Original label	Target label	Original label	Target label
Original image x	85%	0%	99%	0%
Adversarial illusion x_δ	77%	0%	95%	0%
BindDiffusion(ImageBind(x))	42%	0%	64%	2%
BindDiffusion(ImageBind(x_δ))	0%	**64%**	1%	**92%**

Table 3: **Text generation.** Our illusions successfully fool downstream classification of generated text. We use PandaGPT to generate texts from the ImageBind embeddings and measure attack success rate (%)—marked in bold—on texts generated from the original thermal images and the corresponding adversarial illusions (white-box).

	Safe	Unsafe
PandaGPT(ImageBind(x))	1.00	0.00
PandaGPT(ImageBind(x_δ))	0.32	**0.68**

Zero-shot audio classification and audio retrieval. Tables 4 and 5 demonstrate that our illusions are effective at attacking audio retrieval and classification. For ImageBind, audio data is represented as MEL spectrograms, where decibel levels serve as audio analogs of pixels. Meanwhile, for AudioCLIP, we use time series data of the same structure as in [13]. The optimization procedure is the same as in Section 4.1.

On AudioCaps, adversarial alignment significantly outperforms the organic baseline with 0.01 input perturbation. With 0.05 or higher perturbation, audio illusions have high adversarial alignment and near-perfect attack success rate on top-1 accuracy of both retrieval and classification. In ImageBind, this alignment is "emergent" because no (`audio`, `text`) data was used for training the ImageBind encoders.

Zero-shot thermal image classification. Table 6 shows that our illusions achieve perfect Top-1 accuracy with perturbations of at least $\frac{8}{255}$: all perturbed thermal images of people are classified as "street" and all perturbed thermal images of street are classified as "people."

For all perturbation bounds, adversarial alignment for thermal images is lower than for RGB images. We have two conjectures for this discrepancy. First, initial adversarial alignment (without any perturbation) is lower for thermal images than for RGB images, suggesting that thermal images are less susceptible to adversarial perturbations. Second, thermal images have only one channel vs. three channels in RGB images. Consequently, there are $2 \times 255 \times 255$ fewer pixels available for manipulation in thermal images.

Table 4: **Zero-shot audio classification.** Our illusions successfully fool zero-shot audio classification. We measure Top-*k* attack success rates (%) and adversarial alignment of cross-modal illusions against ImageBind and AudioClip. ϵ_A is the perturbation bound. The first two rows are baselines (no perturbations applied to inputs). Standard deviations are reported.

5.3 Transfer Attack Results

We now show that access to the target encoder's gradients is not necessary to create adversarial illusions. It may be sufficient to perform a white-box attack on a surrogate encoder and "transfer" the resulting illusions to the target. Table 7 shows that the transfer attack can achieve high zero-shot image classification accuracy, although results depend on the similarity between the surrogate and the target.

Both ImageBind and AudioCLIP add modalities to, respectively, pre-trained ViT and ResNet-50 versions of the popular CLIP embedding, albeit in different ways. In ImageBind, all modalities are mapped into the ViT-based CLIP's embedding space. AudioCLIP fine-tunes ResNet-50-based CLIP on audiovisual data, thereby "merging" the audio, image, and text embedding spaces. This difference seems to matter. In our experiments, we found that illusions did not transfer to a checkpoint at the end of AudioCLIP's fine-tuning process but did transfer to a partially trained version provided for compatibility with CLIP (and ostensibly close to CLIP's embedding space). Table 7 includes this partially trained checkpoint.

With a single surrogate model, we observed that illusions transfer well within but not across model architectures. Even so, as we show in the bottom row of Table 7, this generalizability gap can be addressed by jointly optimizing a single illusion across multiple surrogates (as in Section 4.2). We measured the transfer of illusions generated using both OpenCLIP models as surrogates and found that the same illusions achieve high adversarial alignment in both ImageBind and AudioCLIP's embedding spaces (see Figure 11). The existence of illusions that attack multiple embedding spaces simultaneously indicates the possibility of *universal* illusions. We leave this line of research to future work.

Table 6: **Zero-shot thermal image classification.** Our illusions successfully fool zero-shot thermal image classification. We measure attack success rates (%) and adversarial alignment of cross-modal illusions against ImageBind. Perturbation bounds are $\frac{\epsilon_V}{255}$. The first two rows are baselines (no perturbation). Standard deviations are reported.

Alignment	ϵ_V	ImageBind	
		Top-1	align(·)
Organic	–	68%	0.0757 ± 0.04
Adversarial	–	32%	0.0534 ± 0.02
	1	39%	0.0679 ± 0.03
	4	87%	0.1651 ± 0.03
	8	100%	0.2841 ± 0.03
	16	100%	0.4210 ± 0.03
	32	100%	0.5576 ± 0.03

Figure 11: **An example of a transferable illusion that misleads both ImageBind and AudioCLIP embeddings.**

5.4 Query-Based and Hybrid Attack Results

In this section, we show that the adversary may not need access to gradients or surrogates at all as long as he has query access to the target encoder. With a limited number of queries, the adversary can craft adversarial illusions that succeed against downstream zero-shot classification and generation tasks with high accuracy. Because commercial black-box embeddings charge for each use of their APIs, we aim to minimize the number of queries and discontinue the experiments (other than those with ImageBind-full) when adversarial alignment is sufficient to fool zero-shot classification.

Zero-shot image classification. Table 8 shows that our query-based attack achieves near-perfect success rates against the black-box versions of ImageBind and AudioCLIP (98% and 100%, respectively). Observe that adversarial alignment (0.26 and 0.16) is similar to the models' organic alignment (0.29 and 0.14). This is sufficient to fool zero-shot classification.

Image generation. While zero-shot classification is compromised even by relatively weak adversarial alignment (comparable to organic alignment), we observed that higher adversarial alignment is necessary for the downstream generation model to generate images that classify to a label corresponding to the adversary's target. Concretely, our early-stopped ImageBind illusions achieved negligible accuracy on the downstream generation task. When we increased the number of queries, adversarial alignment increased to 0.37, and adversarial accuracy of downstream generation improved to 38%.

Amazon's Titan. Finally, we apply our attack to Amazon's commercial, black-box Titan embedding. Table 8 shows that, without the warm start, the query-based attack achieves a 30% success rate against zero-shot classification. With the hybrid attack, 3% of the illusions transfer directly, and when coupled with the query-based attack, the success rate reaches 42%. This suggests that hybrid illusions start closer to the targets in the embedding space, making black-box optimization easier. We do not know the internal details of Titan embeddings but conjecture, based on these results, that either these embeddings are at least partly based on the CLIP, or our hybrid attack may generalize beyond related embedding spaces.

Amazon currently charges $0.00006 per image query to the Titan API, so the average cost is $125.51 per 100 images for the query-based attack and $108.11 per 100 images for the hybrid attack. For comparison, Google's Gemini Pro embedding currently charges $0.0025 per image query.

6 Countermeasures

In this section, we survey several types of defenses against adversarial perturbations and analyze whether they can protect multi-modal embeddings.

6.1 Feature Distillation

Adversarial input perturbations can be considered as features for the model [16]. One defense is to apply a transformation that preserves essential visual features while destroying adversarial features, *e.g.*, JPEG compression [28]. In our case, adding a JPEG compression layer before encoding input images lowers zero-shot classification accuracy of illusions from 100% to 5% and 27% for ImageBind [10] and AudioCLIP [13], respectively.

Unfortunately, this defense can be evaded. After we add a differentiable approximation [40] of JPEG compression to our perturbation method, the resulting illusions are effective against both original (72% and 98% zero-shot classification accuracy for ImageBind and AudioCLIP, respectively) and JPEG-protected embeddings (88% and 94%)—see Table 9.

Defense-GAN [37] is a similar defense that uses a separate GAN to encode each input and generate a supposedly equivalent replacement. This defense assumes that (1) the adversary cannot craft adversarial perturbations for both the original encoder and the GAN, and (2) the GAN accurately re-generates

Table 7: **Transfer attack.** On related embedding spaces, our illusions transfer. We measure attack success rates (%) of our transfer attack with different surrogate and target models. "Ours" represents an ensemble of surrogates consisting of the ViT and ResNet versions of OpenCLIP. $\epsilon_V = \frac{16}{255}$.

Surrogate Model	Target model			
	ImageBind	OpenCLIP-ViT	AudioCLIP	OpenCLIP-RN50
ImageBind	-	100%	0%	0%
OpenCLIP-ViT	100%	-	1%	0%
AudioCLIP	0%	0%	-	92%
OpenCLIP-RN50	0%	0%	88%	-
Ours	**100%**	**100%**	**90%**	**100%**

Table 8: **Query-based and hybrid attack results.** Our black-box illusions work on a number of encoders. We measure organic alignment, adversarial alignment, zero-shot classification (ZSC) attack success rate (%), average number of queries, and Top-k image generation (Gen) attack success rate (%) for different encoders. ImageBind-full is run for a full 100,000 queries (no early stopping). Titan-hybrid is our hybrid attack on Amazon's Titan encoder. $\epsilon_V = \frac{16}{255}$. Standard deviations are reported.

Encoder	Org. align(·)	Adv. align(·)	ZSC	Avg. queries	Gen (Top-1)	Gen (Top-5)
ImageBind	0.2905 ± 0.06	0.2609 ± 0.04	98%	18,942	0	3%
ImageBind-full	0.2905 ± 0.06	0.3659 ± 0.07	98%	100,000	**38%**	**58%**
AudioCLIP	0.1406 ± 0.04	0.1674 ± 0.03	100%	4,112	-	-
Titan	0.4652 ± 0.04	0.4024 ± 0.07	30%	20,919	-	-
Titan-hybrid	0.4652 ± 0.04	0.4215 ± 0.06	**42%**	**18,019**	-	-

all features of the original inputs that are important for downstream tasks. The efficacy of this defense is uncertain because it was only evaluated on the MNIST dataset. Furthermore, it lacks versatility across modalities and is not task-agnostic.

6.2 Anomaly Detection

Semantically similar inputs should be embedded into similar representations. Therefore, a plausible defense is to compare the embedding of an input with the embeddings of very similar inputs, *e.g.*, various augmentations. Table 10 shows that this defense is effective: average alignment between unmodified images and their augmentations is 0.8828, significantly higher than 0.3725 average alignment between the corresponding adversarial illusions and their augmentations.

The evasion attack from Section 6.1 defeats this defense, too: observe that the values in the x_{jpeg} column overlap with those in the x column. This illustrates the limitations of anomaly detection methods against defense-aware adversaries [41]. Anomaly detection using high-dimensional statistics or enforcing a specific geometry for each modality are interesting topics for future work.

6.3 Certified Robustness

Robustness to perturbations. Another plausible defense is to somehow train multi-modal encoders so that they are robust in the following sense: if two inputs are within δ of each other, their respective embeddings should be within γ (using some suitable metrics for δ and γ over the input space and embedding space, respectively).

Certified robustness [12, 34] ensures that any input perturbation within a certain bound has only a limited impact on the output of the model. It is defined for classification tasks and cannot be directly applied to multi-modal encoders in a downstream task-agnostic way. Given a specific downstream task, it may be possible to perform interval-bound propagation [12] over multi-modal encoders.

Unfortunately, it is unclear which metric to use for δ. For many plausible metrics, there is a fundamental tradeoff between robustness and invariance [46]. If δ is too small, the adversary can use perturbations bigger than δ to evade the defense (*i.e.*, the model is insufficiently robust). If δ is too big, semantically unrelated inputs will be mistakenly aligned (*i.e.*, the model is too invariant).

This observation was made for l_p bounds and image clas-

Table 9: **JPEG-resistant illusions.** Our JPEG-resistant illusions evade JPEG compression defenses. We measure Top-k attack success rates (%) and adversarial alignment against zero-shot classification for the original and JPEG-resistant adversarial illusions. Illusions are generated with 200 iterations to avoid over-fitting. $\epsilon_V = \frac{16}{255}$. Standard deviations are reported.

Alignment	ImageBind		AudioCLIP	
	Top-1	align(·)	Top-1	align(·)
Adversarial illusion x_δ	100%	0.7679 ± 0.07	100%	0.5048 ± 0.04
JPEG(x_δ)	5%	0.1722 ± 0.06	27%	0.0722 ± 0.03
JPEG-resistant adversarial illusion x_{jpeg}	72%	0.3623 ± 0.08	98%	0.2345 ± 0.04
JPEG(x_{jpeg})	**88**%	0.3968 ± 0.07	**94**%	0.2079 ± 0.04

Table 10: **Generating illusions that evade anomaly detection.** Alignment between augmentations and unperturbed inputs(x), adversarial illusions (x_δ), and JPEG-resistant illusions (x_{jpeg}). Numbers are computed over 100 random ImageNet images. $\epsilon_V = \frac{16}{255}$. Standard deviations are reported.

Augmentation method	ImageBind			AudioCLIP		
	x	x_δ	x_{jpeg}	x	x_δ	x_{jpeg}
JPEG()	0.8784 ± 0.04	0.2257 ± 0.07	0.7303 ± 0.08	0.8512 ± 0.06	0.2149 ± 0.08	0.6198 ± 0.09
GaussianBlur()	0.7493 ± 0.09	0.2108 ± 0.07	0.6447 ± 0.09	0.8068 ± 0.08	0.2070 ± 0.07	0.5637 ± 0.09

Average	0.8828 ± 0.07	0.3725 ± 0.14	0.7805 ± 0.09	0.8937 ± 0.06	0.3284 ± 0.15	0.6779 ± 0.11

sifiers in [46]. We extend it to l_∞ bounds, showing (by counterexample) that no δ is sufficiently robust *and* does not mistakenly align semantically different inputs.

Figure 12 shows that δ must be greater than 0.3 because there exist perturbations bigger than 0.3 that produce a visually similar image, which should be aligned with the original. This figure also shows that δ must be less than 0.3 because there exist perturbations smaller than 0.3 that produce a visually different image, which should *not* be aligned with the original. Thus, there is no "right" l_∞ value for δ.

Robustness to semantics-preserving transformations. Ultimately, embeddings should be trained so that *semantically* close inputs, within and across modalities, are encoded into similar vectors in the embedding space. There is prior work on adversarially robust "perceptual similarity" metrics [9]. Perceptual similarity only captures semantic similarity insofar as images belong to the same class, *i.e.*, it only aligns images with the labels of a specific image classifier. Alignment in multi-modal embeddings is supposed to cover much broader semantic similarity.

For text, there exist semantics-preserving transformations (*e.g.*, substituting words with synonyms), and models can be trained to be robust with respect to these transformations [20, 30, 48]. Our attacks exploit perturbations in images and audio, where semantic similarity is not as well defined as in text. In the image domain, robustness under different distance metrics results in vastly different performance [47]. We are not aware of any metric on the input space that corresponds to task-agnostic semantic similarity, which is required to achieve certified robustness for embeddings.

Furthermore, to ensure that the embeddings of semantically similar inputs are close to each other, the range of encoders for different modalities should overlap with very fine-grained control over changes in the embedding given a change in the input. With such control, it is unclear how to prevent an adversary from crafting inputs closer to the target than organically aligned inputs, considering that organic alignment in the existing embeddings is relatively weak (see Section 5.2).

In practice, it does not appear that any existing multi-modal embedding uses certified robustness.

Figure 12: **Perturbations of the same magnitude can produce semantically different images or adversarial illusions.**

6.4 Adversarial Training

When training classifiers, one way to ensure that small perturbations do not affect the model's output is to add perturbed images with correct class labels to the training data [29, 38]. In contrastive learning, adversarial training can use perturbed images as positive samples [23, 49, 51]. The efficacy of this defense depends on the specific downstream task because some tasks (*e.g.*, fine-grained classification) may require distinguishing representations that differ less than γ (maximum embedding distance between an input and its perturbations). Adversarial contrastive training negatively impacts relatively coarse downstream tasks such as CIFAR-10 and -100 [49]. In multi-modal contrastive learning, the data are sparse, and some modalities are not directly aligned. Thus, we expect that adversarially trained embeddings significantly degrade the accuracy of downstream tasks.

7 Conclusions

We demonstrated that aligned multi-modal embeddings are highly vulnerable to adversarial perturbations that create *cross-modal illusions*, *i.e.*, inputs in one modality that are aligned with semantically unrelated inputs in another modality. The attack works across both natural and emergent alignment and is task-agnostic: adversarial alignment fools even downstream tasks of which the adversary is not aware when generating adversarial inputs. Furthermore, it enables the adversary to use alignment targets in modalities that are not accepted by downstream applications.

We evaluated the attack for several multi-modal embeddings, including open-source embeddings such as ImageBind and AudioCLIP and proprietary, black-box embeddings such as Amazon's Titan. We showed that the attack successfully misleads downstream tasks based on multi-modal embeddings, including audio retrieval, zero-shot classification of images, thermal images, and audio, and generation of text and images. Finally, we discussed potential countermeasures and evasion attacks.

Ethical Considerations

The only purpose of analyzing the vulnerability of multi-modal embeddings to adversarial inputs is to help develop more robust embeddings and motivate research on defenses.

Abstract

Visual phishing detectors rely on website logos as the invariant *identity indicator* to detect phishing websites that mimic a target brand's website. Despite their promising performance, the robustness of these detectors is not yet well understood. In this paper, we challenge the invariant assumption of these detectors and propose new attack tactics, `LogoMorph`, with the ultimate purpose of enhancing these systems. `LogoMorph` is rooted in a key insight: users can neglect *large* visual perturbations on the logo as long as the perturbation preserves the original logo's semantics. We devise a range of attack methods to create semantic-preserving adversarial logos, yielding phishing webpages that bypass state-of-the-art detectors. For text-based logos, we find that using alternative fonts can help to achieve the attack goal. For image-based logos, we find that an adversarial diffusion model can effectively capture the style of the logo while generating new variants with large visual differences. Practically, we evaluate `LogoMorph` with white-box and black-box experiments and test the resulting adversarial webpages against various visual phishing detectors end-to-end. User studies ($n = 150$) confirm the effectiveness of our adversarial phishing webpages on end users (with a detection rate of 0.59, barely better than a coin toss). We also propose and evaluate countermeasures, and share our code.

1 Introduction

Phishing attacks have been a persistent threat online [19], and are still one of the leading causes of data breaches as of 2022–2023 [26, 53]. In this context, phishing websites often impersonate trusted entities (e.g., well-known brands) to gain the victims' trust. For defense, researchers have investigated various methods such as blocklists [11, 31, 48] and data-driven detectors to catch phishing webpages and URLs [52, 54, 55]

Recently, a series of systems have been proposed to counter phishing websites using *reference-based* methods [6, 21, 30, 32, 33]. The key insight is that phishing websites need to look *visually similar* to the legitimate websites of the target brands to deceive users. Therefore, these approaches treat such visual similarity as the "invariant" for robust phishing detection. They maintain a list of references (such as screenshots or logos) for popular brands and detect phishing webpages that *(i)* have a high visual similarity to the reference representation of a target brand, but *(ii)* are not hosted under the domain name of the target brand (refer to §2.1 for background). Despite the promising performance, the robustness of reference-based visual phishing detectors is not well understood, especially for the recent logo-based detectors [30, 32, 33]. Prior efforts either test such detectors against off-the-shelf adversarial algorithms [30, 32] or only focus on bypassing the logo detector [29] (which is only a single component of the detection system), neglecting the end-to-end impact on the webpages. As a result, the robustness of these detectors remains unclear.

Figure 1: **Adversarial Logo Examples**—We show the original logo and two attack examples generated by our `LogoMorph`.

New Attack Tactics. In this paper, we extensively scrutinize the security of visual phishing detectors by challenging the *invariant assumption* of these detectors. We introduce new attack tactics and discuss possible directions to enhance these detectors. We primarily focus on detectors that rely on *logos* as the website identity since there is evidence that such logo-based detectors have been deployed also in production-grade phishing solutions [7, 17]. Specifically, we present `LogoMorph`, a new attack to generate an adversarial logo that enables a webpage to bypass existing visual phishing detectors. The attack is based on a key hypothesis: *users often overlook large visual perturbations as long as the perturbation preserves the original logo "semantics."* (We test this hypothesis with a user study in §5.) Hence, our idea is to search for semantic-preserving perturbations. Figure 1 shows

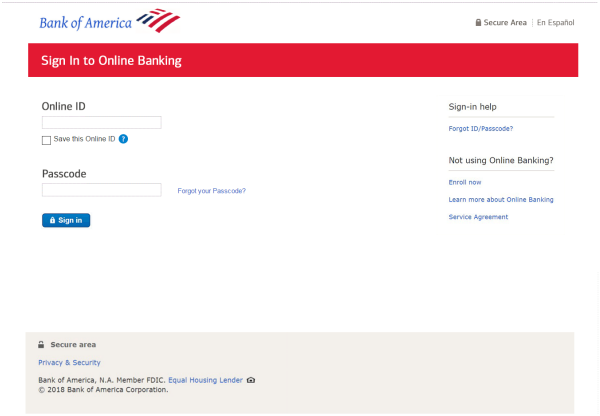

Figure 2: **Adversarial Phishing Webpage**—By using an adversarial logo crafted with LogoMorph, this phishing webpage bypasses detectors such as PhishIntention [32] and Phishpedia [30].

examples of such adversarial logos. The original logo of Bank of America (BOA) looks like an American flag in a diamond shape. The adversarial logo preserves the red color and overall diamond shape but changes the spacing and direction of the stripe patterns. Similarly, for CHASE, the adversarial logos have large visual perturbation but the original style is preserved. Figure 2 shows an example where the adversarial logo is placed on a phishing webpage.

To implement LogoMorph (§3), we categorize logos into three categories: text-only logos (e.g., Google), image-only logos (e.g., AT&T), and image-text logos (e.g., CHASE). We design different attack strategies against the image part and text part, respectively. For the text part, our strategy is to search for an alternative *font* for the logo text from a large pool of visually similar fonts while preserving the spelling, color scheme, and spacing of the original logo's text. For the image part, we propose an *Adversarial Diffusion Model* that simultaneously learns to preserve the semantics/styles of the original logo while introducing a large distance from the reference logos in the feature space of the phishing detectors.

System and User Assessment. We test LogoMorph against phishing detection systems and human users. First (§4), we use LogoMorph to generate adversarial logos, add them to webpages, and evaluate them against state-of-the-art phishing detectors; we use PhishIntention [32] as the primary target for such a *white-box* analysis. Then, we perform transferability experiments in a *black-box* setting: the attacker uses a local surrogate to generate the adversarial logos and then applies them to phishing webpages to attack a different detector (e.g., logo-based Phishpedia [30] and PhishingIntention [32], and screenshot-based VisualPhishNet [6]). We compare (§4.7) LogoMorph against a prior work [29], and explore possible defenses (§6) using gradient masking and adversarial retraining—including an "augmented" version that we specifically devise to counter LogoMorph. Finally, we (§5) conduct a user study ($n = 150$) to verify whether our LogoMorph yields adversarial logos that deceive also the human eye.

Results. We assess logos of 110 brands: we consider 18 high-ranked brands in the main paper, whereas the remaining 92 brands are covered in the Appendix. [*System:*] Our result shows that the text-based attack is highly effective. Most brands (11 out of 15 brands with text logo components) can identify over 100 attack fonts to bypass the detection at the webpage level while preserving a visual resemblance to the original logos. Similarly, for image-based logos, 9 out of 11 brands (with image logo components) can find over 80 candidate logos that transfer successfully when placed on the webpages (72%–100% success rate). More importantly, we find that adversarial logos computed with a surrogate model can transfer well to attack other detectors. For example, adversarial logos computed based on PhishIntention have a transfer rate ranging from 80% to 100% for 17 out of 18 brands against Phishpedia. Compared with prior attacks [29], we show LogoMorph is more effective end-to-end at the webpage level (i.e., by placing adversarial logos onto phishing webpages), and our adversarial logos are of a higher visual quality. [*Users:*] Adversarial phishing pages crafted with LogoMorph are slightly more noticeable by users with a true positive rate (TPR) of 0.59, compared with 0.45 TPR of unperturbed phishing pages. That being said, a 0.59 TPR means our phishing pages are still effective on users (users are performing only slightly better than random guessing) with the benefit of evading phishing detectors (while unperturbed pages cannot). The results confirm the effectiveness of LogoMorph on end users.

Contributions. Our main contributions include:

- We propose LogoMorph, a new attack against logo-based visual phishing detectors. The attack incorporates semantic-preserving manipulations to generate image- and text-based logos to create evasive phishing pages.
- By using LogoMorph, we empirically reveal the weaknesses of state-of-the-art phishing detection systems.
- We validate our attack with user studies, showing that our adversarial logos can bypass the human eye.

To facilitate future work, we make our code available [4].

2 Related Work and Preliminaries

We focus on the problem of phishing *website* detection (and evasion). Hence, studies entailing other forms of phishing (e.g., email [28], or social media [20]) are orthogonal to ours.

2.1 Phishing Website Detectors

Overview. Blocklists represent the first line of defense against phishing websites: by checking if any given URL (or domain) is contained in a set of "malicious" entries, it is possible to defuse the corresponding phishing threat [11, 31, 48]. Unfortunately, such signature-based detection approaches

only work against known phishing websites [52]—and recent studies have shown that they may be unreliable even against these [42, 43]. To protect online users against "novel" phishing websites, state-of-the-art detection methods leverage machine learning (ML) techniques [2, 7, 17]. Among these, most approaches seek to discriminate benign from malicious webpages by extracting features derived from URLs, textual web content, and/or the HTML code—and then use such features to develop ML-based detection models [15, 22, 36, 39, 46, 47, 52, 54, 55]. However, recent studies have shown that all such detectors can be *easily evaded by "perturbing" just a few features* [8, 37, 50, 51]. For these reasons, we focus on a complementary ML-based detection approach that leverages the visual similarity of webpages. [1]

Phishing Detection via Visual Similarity. Real phishers craft their websites to be visually identical to the websites of (popular) brands: visual similarity-based methods focus on countering this quintessential property of phishing. Specifically, these methods work by *(i)* seeing if a given website is visually similar to another "reference" website (taken from a list of "protected brands"); and then *(ii)* comparing the domain of the given website with the one of the reference website's brand: if the similarity exceeds a threshold and yet the input page is not hosted under the brand's domain name, it is determined as phishing.[2] Among the ways to compute such similarity, some works rely on the screenshot of a webpage [6]. Unfortunately, recent studies revealed that the comparison of *whole-page screenshots can easily produce false positives* [30, 32]. To address this shortcoming, new systems focus on comparing the logo—which is treated as the identity indicator of a brand [30, 32]. The most recent work, PhishIntention [32], uses a Siamese neural network and an Optical Character Recognition (OCR) model to measure logo similarities and rely on other context information (e.g., the presence of a password-collecting form) to improve detection accuracy. Another work [33] provides an add-on function for PhishIntention to dynamically expand the reference list and handle "brandless" pages (orthogonal to our focus, which is adversarial phishing pages). To the best of our knowledge, these logo-based detection approaches represent the state-of-the-art, and there is evidence that they have been deployed also in production-grade phishing detectors [7, 17]).

Problem Statement. The security of logo-based phishing website detectors has not been extensively scrutinized. Indeed, the very same authors of PhishIntention [32] (and also of its predecessor, Phishpedia [30]) assessed the robustness of their solution against off-the-shelf adversarial ML algorithms [30, 32]: perhaps unsurprisingly, they found that such evasion tactics can be defused with simple countermeasures such as gradient masking [30, 32]. Two months before writing this paper, the authors of PhishGAP [29] bypassed logo-based detectors (proposed by [30, 32]) by developing a surrogate detector used to craft "adversarial logos" (by adding visual noise to the logo) that evade the actual detector. However, PhishGAP [29] *only focuses on the logo itself*: as such, the attack is only shown to bypass[3] the logo-detector—which is just a single component of the phishing detection system; and even though the authors of [29] carry out an user study to validate their method, the users are only shown[4] the logo—which is just a tiny element in a (phishing) page. Put simply, the authors of PhishGAP [29] do not perform an end-to-end evaluation by placing the "adversarial logo" on a web page, and seeing its effects on *(i)* the full-fledged phishing detection system, and on *(ii)* its end-users (in §4.7, we compare our proposed attack with [29] using end-to-end experiments).

Our Goal. To this date, it is still unclear whether logo-based detectors can truly be considered as reliable (according to [30, 32], they are) or not (according to [29], they are not). In this paper, we seek to provide an answer to this dilemma.

2.2 Threat Model

`LogoMorph` targets reference-based visual phishing detectors [6, 30, 33]. We focus on detectors that rely on logo comparisons, such as PhishIntention [32]. Such comparisons are done against a *reference list* containing logos of well-known brands (n.b., any brand may be associated with many logos).

Target System. To provide the necessary context for our attack, let us summarize how logo-based visual phishing detectors work. At a high level, these systems first extract the logo image from the screenshot of an input webpage, and then they use a mix of deep learning (typically, a Siamese neural network [32]) and OCR to create the embedding for the logo image: deep learning is used for a basic visual comparison of two logo images, whereas OCR serves to better embed text-based logos. Hence, when analyzing any given webpage to infer its legitimacy, an input logo is compared with a set of legitimate logos from the reference list with the techniques mentioned above. If the similarity between the input logo and any logo in the reference list is higher than a threshold (θ), then the two logos are considered to be "similar", thereby suggesting that the two logos belong to the same brand. If the webpage is phishing, then it will *not* be hosted under the target brand's domain name, and hence labeled as malicious [32]. Given that PhishIntention [32] represents the state of the art of such detection systems, we will use this as "baseline system."

[1] These methods are robust against evasion attempts targeting the HTML of a webpage. As a proof-of-concept, we obtained adversarial webpages generated by a recent work [8], and tested them against [32]: only 27% of these webpages evade [32]. Details in supplementary materials [5].

[2] Example: VisualPhishNet [6] can detect a phishing website that looks like the webpage of the real CHASE bank but is not hosted under `chase.com`.

[3] Even after "transferring" the adversarial logos to different detectors, the average fooling rate ranges between 10–42% (see Fig. 6(d) of [29]).

[4] We argue that the adversarial perturbations of [29] are quite visible (e.g., apparent stretching/cropping, or use of non-web logos—see [5]).

Attacker: Goal and Strategy. To bypass such reference-based visual phishing detectors, we envision an attacker who seeks to create an "adversarial logo" that *(i)* preserves the semantics of an "original" logo (e.g., it must still "resemble" PayPal) while *(ii)* achieving a low similarity (i.e., below θ) with any logo in the reference list. Indeed, doing so will induce the detector to *believe that the webpage is benign*. The threshold is there to control false alarms: a low similarity implies that the input logo belongs to a brand outside those in the reference list (e.g., maybe it is of a low-ranked website; or, alternatively, a well-known brand has just updated its logo). Hence, achieving a low similarity will prevent the domain-checking step of the detector from occurring (§2.1), and the webpage will be displayed to an end user—thereby evading the detection (if the webpage is phishing). Nonetheless, when crafting the adversarial logo, the attacker should ensure that the resulting phishing webpage does not appear more suspicious (w.r.t. the "original" phishing webpage) to the end users—i.e., the true target of phishing.

We emphasize that our goal is to assess whether such adversarial phishing *webpages* (not just the logo itself) represent a threat in practice, i.e., against systems and humans. As such, we design our experiments (§4) and user study (§5) to examine the webpage-level attacks and perform "end-to-end" evaluation (i.e., we attack the entire system, embracing the recommendations of [7]) instead of just analyzing logos in isolation (as done by most prior work, such as [29]).

Remark. Attackers must simultaneously deceive the detector and humans. Achieving only one of these is not useful.

Attacker: Knowledge and Capabilities. Our attacker has complete control on their own phishing webpages. However, from a knowledge perspective, we consider various settings.

We start with a white-box setting by assuming adversaries who have *perfect knowledge* (in terms of the model architecture and dataset[5] of the target system, i.e., PhishIntention [32]. This is to follow the recommendations from prior works [9, 16], i.e., to explore the "worse-case" robustness of a defense. The setting is the same as that of [29]. In practice, real attackers can approximate this assumption by reading related papers on the system design [6, 30, 32, 33] and collect their own datasets of logos (indeed, logos of a given brand are publicly available, and attackers can get them easily).

Then, we will relax this assumption and study the impact of adversaries who have *limited knowledge* in a black-box setting. Attackers still know the reference list and the logos (which, as we argued, is a realistic assumption), but they are oblivious to the targeted detector's low-level specifications, and *cannot directly query* the target system to observe its decisions. In this case, the attacker builds a local surrogate model (to optimize the attack), and then transfer the attack to a target system. To simulate a realistic setting, we first envision adversaries that "expect" to be attacking PhishIntention [32], but we *change* the target system (with another reference-based visual phishing detector). Specifically, we consider two cases of "mismatched" knowledge: a target system that still focuses on logo comparisons, but uses a different neural network design (i.e., Phishpedia [30]); and a target system that does not focus on logos, but on screenshots (i.e., VisualPhishNet [6]). Finally, we also simulate adversaries that still attack PhishIntention [32], but without knowing the details of PhishIntentions's logo discriminator—which is approximated by the surrogate model owned by the adversary. Through these 3 transferability experiments, we assess all these realistic scenarios and show that `LogoMorph` can be effective also without perfect knowledge of the target system.

[5] N.b.: if the attacker targets a brand that is *not* contained in the defender's reference list, the attack will automatically succeed. Hence, overlap with this dataset is detrimental for the attacker (which is a realistic setting [7]).

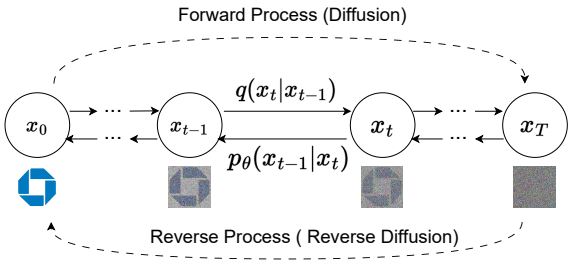

Figure 3: **Diffusion Model**—An illustration of the forward (diffusion) process and the reverse process of the diffusion model.

2.3 Diffusion Models

Given diffusion models will be used, we provide some background. Extra details are in the supplementary materials [5].

Basic Diffusion Model. The basic version of the diffusion model is called Denoising Diffusion Probabilistic Models (DDPM). DDPM (compared with generative adversarial networks or GANs) can generate high-quality images while offering fine-grained controls over image fidelity and diversity [24, 34, 40]. As a generative model, the goal of diffusion models is to learn to generate data similar to the training data. To do so, diffusion models "destroy" the training data by progressively adding Gaussian noise to the image, and then learn to recover the original image by reversing the noising process.

The idea is illustrated in Figure 3. diffusion model contains a forward (diffusion) process and a reverse (diffusion) process. The forward process (modeled by a Markov chain) is to add Gaussian noise to a clean image x_0 step by step, until reaching a version of pure Gaussian noise x_T. The reverse diffusion process is also defined by a Markov chain to transform Gaussian noise back to a clean image. The training of the diffusion model is to learn a neural network p_θ (parameterized by θ) to generate a clean image from the noise.

Improved Diffusion Model. W.r.t. DDPM, the *improved diffusion model* [40] reduces the sampling by an order of

Figure 4: **Text Logo Attack Examples**—The first row displays the brand's original logo. The second row shows attack fonts with cosine similarity (about 0.86) that is slightly below the detection threshold. The third row exhibits adversarial logos with a lower cosine similarity (about 0.79). All these fonts can bypass detection.

magnitude during the forward passes without sacrificing the quality of generated images. The idea is to learn the *variances* of the reverse diffusion process by a separate neural network to create a hybrid loss function. In §3.2, we explain how we modify this improved diffusion model for our attacks.

3 Proposed Attack (`LogoMorph`)

We propose to bypass logo-based phishing detectors via manipulations that operate on a logo's *semantics*—which can be either text-related (e.g., changing font) or image-related (e.g., changing the emblem), or both (cf. Figure 1). This section describes our proposed perturbation strategy in detail (against the: text in §3.1, image in §3.2, and image-text in §3.3).

Common Final Step. Ultimately, our `LogoMorph` attack boils down to creating an "adversarial logo" which, after replacing the "original logo" in the respective webpage, yields a phishing webpage that simultaneously deceives the detector and the human eye. Hence, for the sake of a realistic end-to-end evaluation, the last step of all our proposed attack methods entails *adding the logo to the webpage*, which we do by placing the adversarial logo in the exact same position of the original logo. In doing so, we ensure that the background color of the adversarial logo aligns with the color of its surrounding location in the "adversarial webpage" (potentially by applying post-processing techniques). We may also trim or smooth the edges of the logo for better fidelity. Note that these operations can be trivially done by our envisioned attacker, who has complete control of their phishing webpages (§2.2).

3.1 Text Logo Attack (simple)

Recall (§2.2) that our attacker wants to introduce visual perturbations that bypass detection while preserving the semantics of the original logo's text (to avoid alerting human users). This requires considering various text logo attributes such as spacing, positioning, and spelling. In other words, we cannot simply treat the text logos as "images" and blindly apply gradient-based methods [14, 27, 56], since these would yield minimal perturbations that may not fool the detector. One alternative approach is to apply generative models for text/font generation. Doing so, however, is computationally expensive; plus, the resulting text would present artifacts (e.g., poor readability or coherency) that may irremediably impair its appearance [14], thereby not fooling the users.

Idea and Preparation. We propose an easy-to-implement method to generate adversarial text logos that meet our twofold goal. The idea is to search for an *alternative font* that is visually similar to that of the original logo—while preserving its spelling, color, and spacing. This allows us to have fine-grained control over the key attributes that affect the semantics of the logo. Hence, we create a font database consisting of candidate fonts: we first include fonts collected from Google's open-source font project [1]. We then enrich this database by manually adding fonts that are used by popular brands' logos (and their variants).[6] The final database contains 2,556 fonts including 2,029 fonts from Google open-source fonts and 527 fonts from the common logo fonts.

Basic Procedure. Given the target text logo, we identify the *attack* fonts from our font database by selecting the top-K visually similar candidate fonts. We proceed as follows. **(1)** Given an "original" logo to use as the basis for our adversarial logo, we use OCR to narrow down the list of candidate fonts based on the cosine similarity between the embeddings (generated by the OCR) of any candidate font and the original font. The embedding is obtained by using ASTER [49]. We use OCR embedding due to its proficiency at processing "text." We stress that this OCR technique may not be the exact one used by the detector: this is not a problem, because this step is to search for "similar fonts inside our database" (which supposedly will deceive the actual OCR of the detector). **(2)** Then, we rank and select the top-K candidates with a cosine similarity below the target threshold (θ) as our *attack* fonts (see Figure 4). **(3)** Finally, for every candidate font, we re-create the logo by using the chosen font, and by preserving the spelling, color, and capitalization of the original logo.

Additional Variants. In addition to font replacement, attackers may apply additional semantic-preserving perturbations. For example, they can change the default capitalization as well as the bold/italics styles of the text. Such simple changes can increase the pool of candidate fonts for a given brand. Another source of variance is to change the spacing between letters. In our evaluation, we only apply the basic steps described above if adversarial logos can be identified. If the basic steps fail to find an adversarial logo that reaches the desired similarity threshold, then we consider additional variants (with a cost of potentially slightly degrading the integrity of original semantics). In our experiments, we always find candidate fonts without applying additional perturbations.

[6] E.g., *Segoe UI* is the font for the Microsoft Outlook logo. Hence, we add *Segoe UI* and its variants (*Segoe*, *Segoe-italic*, *Segoe-bold*) to the database.

3.2 Image Logo Attack (complex)

Unlike text-based logos, to the best of our knowledge, there are no semantics-preserving manipulations that are readily available (i.e., font change) for image-based logos.

Idea and Preparation. We propose a new method to learn semantics-preserving manipulations. The idea is to use a diffusion model to learn the *style* of the logos of the target brand (e.g., the logos of PayPal) and generate adversarial logos that preserve such style (to deceive users) while eluding the detector's similarity check [30, 32]. We **(1)** take the *Improved Diffusion Model* [40] as our basic pre-trained model. To adapt this model for logo generation, we **(2)** fine-tune it using logo images for the 277 protected target brands from PhishIntention's [32] logo dataset (3,061 logo images in total). This fine-tuned model will serve as our global model.[7] Finally, to learn the logo style of a *specific* target brand, we **(3)** propose and develop an *Adversarial Diffusion Model*.

Adversarial Diffusion Model. We construct the Adversarial Diffusion Model by modifying the fine-tuned Diffusion model's loss function to capture the additional attack goal. Recall that the Diffusion model is trained to generate a clean image from pure Gaussian noise (see §2.3). More specifically, as shown in Figure 3, the forward process is to progressively add Gaussian noise to a clean image x_0 step by step, until completely destroying the image to pure Gaussian noise. We train the Diffusion model by learning a neural network p_θ to capture the reverse process to generate a clean image x'_0 from the noise. We use L_{vlb} to represent the original loss function of the *Improved Diffusion Model* [40].

To make sure the generated image x'_0 can bypass phishing detectors, we insert a loss term such that the generated image x'_0 has a large latent distance from the original x_0 in the phishing detector's feature space. Using PhishIntention as an example, the similarity between x'_0 and x_0 should be lower than the detector's threshold. Here, we use the pre-trained OCR-Siamese network from PhishIntention (denoted as P_ϕ) to compute the cosine similarity between the embeddings of two images (denoted as $p_\phi(x'_0 - x_0)$). We use τ to denote the target similarity threshold. The new loss function of the adversarial diffusion model is:

$$L = L_{vlb} + \beta * L_{attack} \quad \text{(Eqn. 1)}$$

$$L_{attack} = max(0, p_\phi(x'_0 - x_0) - \tau) \quad \text{(Eqn. 2)}$$

Here, β is the scaling factor to balance L_{vlb} (controlling the *image quality and diversity* of the generated logos) and L_{attack} (controlling the *attack effectiveness*). We make β as an adaptive factor during training: it starts from small, (e.g., 0.0002) and gradually increases with the number of steps as we train the diffusion model. We set β to be small in early training iterations to ensure images are generated with high quality and close to the original logos. After that, we gradually increase β to shift the model weights towards our goal of reducing the cosine similarity (in the feature space) between the generated and original images. The intuition is to first search for the *general region* in the feature space that represents the "style" of the original logos, and then perform more *fine-grained* search to identify logos to achieve the attack goal. The adaptive scaling β can be set differently for different logo brands. By default, we set the value to be small (no larger than 0.01) to prevent our L_{attack} from overwhelming the original Diffusion model's loss term L_{vlb}. Empirically, according to our experiments, if β is too large, it will skew the model weights to generate low-quality images.

Note that, when training the model, we freeze the model weights of the OCR-Siames model (p_Φ) since it serves as a proxy for the target phishing detector, and we only update the weights of the Diffusion model p_θ. In addition, the original OCR-Siamese model has built-in modules (e.g., image resizing) that will lose gradients. We overcome this by re-implementing the OCR-Siamese model with Pytorch to store gradients along the process, to ensure gradients can be back-propagated. We will share this implementation.

Data Augmentation. A challenge of training the Adversarial Diffusion Model is that there may be only few logo images for each brand. To increase the size (and diversity) of the training data, we augment the training set via image transformations (e.g., rotating, central cropping, flipping, or Augmix[8]) on logo images. We intentionally control all transformations so that the changes preserve the semantics of the logos (i.e., the transformed logos can still be detected as the correct phishing brand by PhishIntention). For example, we only rotate 1 or 2 degrees for the logo image and then do the central cropping by trimming off 2% of the edges. In addition, we patch all images to make sure they are square images.

3.3 Image-Text Logo Attack

For logos that contain both image and text parts (e.g., BOA and Chase, as shown in Figure 1), our strategy is to first use an adversarial diffusion model to generate the image part, and then search for the corresponding fonts that allow for the combined logo to bypass the detection threshold. Here to improve efficiency, when searching for candidate fonts, we will search from the set that is already within a similarity of 0.6–0.87. These fonts retain a good chance of success (for the text part) as well as a good resemblance to the original fonts.

[7] We use a Diffusion model rather than a GAN (which inspired [29]) because the former allows fine-grained control over the image generation process to balance between fidelity and diversity [24, 34, 40]. This is important: we not only aim to preserve the "style" of the brand's logos but also need to introduce visual differences large enough to bypass the detector.

[8] Augmix [23] is a data augmentation method to interpolate and mix images to introduce variance while preserving the original images' semantics.

Logo Type	#	Brands
Text Only	7	Comcast, DocuSign, eBay, Google, Instagram, Netflix, Yahoo
Image Only	3	AT&T, Canadian Imperial Bank of Commerce (CIBC), DHL
Image-Text	8	Amazon, Bank of America (BOA), Chase, Dropbox, LinkedIn, Outlook, PayPal, Spotify

Table 1: **Experimental Logo Brands**—We select logos from 18 popular brands for our main experiments. Among these, 7 have logos that only contain text, 3 only images, and 8 both text and images.

4 Attack Evaluation

We now implement `LogoMorph` and carry out an end-to-end evaluation to assess its effectiveness. At a high level, our evaluation seeks to answer three research questions (RQ):

RQ1 (Perfect knowledge) How effective is the text- (§4.2), image- (§4.3), or image-text-logo (§4.4) attack against the state-of-the-art visual phishing detector [32]?

RQ2 (Limited knowledge) How well can the attack transfer across different detection systems? (§4.5, §4.6)

RQ3 (User Study) How well can adversarial phishing webpages deceive human eyes (i.e., end users)? (§5)

We will also compare `LogoMorph` with PhishGAP [29] in §4.7.

4.1 Experimental Setups

Dataset. We use the same dataset used by PhishIntention for our experiment [32]. The dataset contains 277 brands in the reference list (with 3,061 logo images). For a focused, in-depth analysis under various scenarios, we will consider 18 brands (prioritizing those that are most targeted by phishing websites [3]) in our main paper: these brands are reported in Table 1, showing that they cover all three categories of logos (text-only, image-only, and image-text logos). Nonetheless, in Appendix C, we have extended the "perfect knowledge" experiments to a total of 110 brands, demonstrating that `LogoMorph` is broadly applicable to a variety of brands.

When we evaluate our attack in an end-to-end fashion, we use webpage screenshots and URLs from the dataset provided by Phishpedia [30], which contains 30K phishing webpages and 25K benign webpages.[9] For this experiment, we select one phishing screenshot for each brand, ensuring that the logo of the screenshot aligns with our predefined logo categories.

Evaluation Metrics. For the perfect knowledge setting, we focus on PhishIntention to examine both the logo-level and webpage-level impact—i.e., we assume that the attacker "knows" the details of [32]. At the logo-level, we report the number of candidate logos that our method generates (i.e., similarity below the detection threshold $\theta = 0.87$ found by PhishIntention's creators). At the webpage level, we report the number and ratio of pages that bypass end-to-end detection.

[9] Among these 25k, only 21,974 have URLs for us to verify and determine the brands (which will be used in false positive assessment in §6).

Brand	# Candidate Fonts	Rate
DocuSign	2,556	1.00
LinkedIn	2,556	1.00
Yahoo	2,550	0.99
Netflix	2,546	0.99
Instagram	2,532	0.98
BOA	2,088	0.82
Comcast	1,903	0.73
PayPal	1,839	0.72
Amazon	1,290	0.50
Spotify	877	0.34
Chase	624	0.24
Outlook	597	0.23
Dropbox	447	0.18
Google	388	0.15
eBay	362	0.14

Table 2: **Logo-Level Results (Text Logo)**—For each brand, we report the number of fonts (out of 2,556 fonts in the database) with a similarity below the OCR similarity threshold of 0.87.

For the limited knowledge setting, we assess the *transferability* of our adversarial logos to other detectors that are not seen during the logo-generation process.

Generic Procedure (and ancillary user study). We adopt a similar procedure for our evaluation. We first generate adversarial logos with `LogoMorph`, and see which achieve a similarity (w.r.t. the most similar logo of the reference list) below the threshold "known" by the envisioned attacker (typically 0.87). Then, we consider a subset of logos that fall below such a threshold, and apply them to phishing webpages (by replacing the "original" logo with our adversarial variant) for end-to-end evaluation. To do so, we pick logos whose similarity falls between 0.6 and 0.87. Such a range allows us to carry out an extensive analysis, encompassing logos that are more likely to preserve the original semantics (i.e., closer to 0.87) and also those that may do so only marginally (i.e., closer to 0.6). Nonetheless, we validate this range by carrying out an *additional user study* (n=100), discussed in Appendix B, where we inquire whether users think that our adversarial logos resemble the targeted brand. The results show that, for some users, even logos with $0.6 \leq \text{Sim} < 0.7$ can resemble the target brands, but a higher similarity (e.g., $\text{Sim} \geq 0.7$) is more desirable. In practice, attackers should (and, realistically, would) use `LogoMorph` by favoring logos that bypass detection and which have higher similarity.

4.2 Text-Logo Attack Effectiveness

We start with the text logo attack. For this evaluation, we consider all the text-only logos in Table 1. To expand the evaluation set, we also include the image-text logos in Table 1 by only focusing on the text part (i.e., cropping the text part from the logo). In total, 15 brands are considered.

Logo-level. The logo-level analysis investigates the likelihood of locating an attack font with an OCR cosine similarity

Brand	# of Success Fonts	Rate	Avg. Sim.
BOA	200	1.00	0.73
Outlook	200	1.00	0.79
Spotify	200	1.00	0.75
Instagram	199	0.99	0.76
Dropbox	199	0.99	0.75
Amazon	195	0.98	0.78
Chase	194	0.97	0.82
eBay	183	0.92	0.72
DocuSign	178	0.89	0.81
Comcast	145	0.73	0.84
Google	121	0.61	0.80
Netflix	80	0.40	0.88
LinkedIn	54	0.27	0.88
Yahoo	39	0.20	0.89
PayPal	37	0.19	0.90

Table 3: **Webpage-Level Results (Text Logo)**—Number of fonts that lead to end-to-end bypass of PhishIntention. We consider Top K=200 fonts from Table 2, and report the successful ones.

lower than the similarity threshold (0.87). Given a target logo (extracted from the target brand's webpage), we search the entire database of 2,556 fonts and report the number of candidate attack fonts and ratio. The results are shown in Table 2. A higher number means attackers would have more candidate fonts to select from when crafting the attack phishing pages.

Table 2 shows that we can find at least 362 attack fonts that bypass the OCR similarity threshold for each of the target logos (on average 1,544 attack fonts). We notice that brands that use unique/uncommon font styles are easier to attack—DocuSign, Instagram, and Netflix have more candidate fonts. In comparison, brands (e.g., Dropbox, Outlook, and Ebay) that use common-looking fonts such as *Gotham Circular*, *Segoe*, and *Sans-Serif* have a lower rate of candidate fonts.

Webpage-level. Given the candidate logos, we then select those to add to the webpage for end-to-end evaluation. Considering large visual differences may raise suspicion among users, we perform some control on the *quality* of the adversarial logo using OCR similarity. Through manual inspection, we find that fonts with an OCR similarity over 0.60 would look reasonably similar. We select top-K candidate fonts with an OCR similarity *(i)* lower than 0.87 (for attack effectiveness) but *(ii)* higher than 0.60 (for visual quality). We add the logo to the corresponding brand's phishing webpage and report the number of webpages that bypass PhishIntention end-to-end.

As shown in Table 3, we identify successful attack fonts for all brands to bypass the end-to-end detection. For brands such as BOA, Outlook, and Spotify, all the attack fonts from the top-K (K=200) can successfully evade PhishIntention. Such high success rates are common in image-text logos (6 out of 8, where only the text part is used). For brands such as Yahoo, LinkedIn, and PayPal, we identify a smaller number of adversarial logos (37–54) that are successfully end-to-end. Table 3 also reports the average similarity between the testing logo and their closest reference logo computed by PhishIntention. Note that this similarity is different from the OCR similarity used to rank candidate logos (OCR only compares testing fonts with original fonts, but does not consider all the reference logos of the detectors). Not too surprisingly, Yahoo, LinkedIn, and PayPal's testing logos tend to have a higher average similarity to the reference logos (above 0.88). This suggests that these logos, although distanced enough from their original fonts, are still not distanced enough from some of PhishIntention's reference logos. We show additional successful examples in supplementary materials [5].

Takeaway. We always find at least 362 fonts per brand (out of 2,556) that bypass the logo-detector. Bypassing the end-to-end system is harder, but possible, with 37–200 fonts enabling such evasion per brand.

4.3 Image-Logo Attack Effectiveness

To evaluate the image logo attack, we consider all the image-only as well as the image-text logos (the latter after removing the textual part) of the brands in Table 1 (11 brands in total).

Logo-level. Given the detection threshold (θ=0.87) of PhishIntention, we set our target similarity to a lower value of $\tau = 0.7$ for $L_{attacck}$ in Eqn. 2, to increase the chance of success. Recall that, while training the Adversarial Diffusion Model (§3.2), we save different versions of the model at different training iterations (with different fidelity and diversity trade-offs). We use these to standardize the evaluation procedure. Specifically, given a target logo, we obtain adversarial logo images at 5 different training stages and generate 100 images at each stage, thereby yielding 500 images for each brand. Intuitively, images generated during early iterations have a better diversity, meaning they deviate more from the data seen during training (i.e., the original logo); an example would be the "Attack-2" images in Figure 1. However, as the adversarial diffusion model is trained over more iterations, the generated images have a better fidelity w.r.t. the original logos; an example would be the "Attack-1" images in Figure 1. Then, we examine how many adversarial logos can bypass the detection threshold of 0.87 of PhishIntention [32]. Table 4 shows the result in the middle column: for 10 out of 11 brands, there are over 100 candidate logo images (out of 500 generated).

Webpage-level. To select logos to add to the webpages, we again perform basic quality control. Through manual inspection, we find that a cosine similarity of 0.6 yields logo images that are suitable. Figure 5 shows example logo images at different similarity levels compared with the original (all below θ=0.87). As shown in Table 4 (the right column), nearly 40% of the generated logo images fall within this range. Therefore, we take the logos with a similarity of 0.6–0.87 (Table 4) and place them on phishing webpages.

The end-to-end detection results are reported in Table 5. For Amazon, we only used 362 logos (instead of 433) because the style (i.e., size and color scheme) of the 81 omitted logos did not match well with the corresponding webpage screenshot.

Brand	# of Success Logos (Rate)	
	Sim <0.87	0.6<Sim<0.87
Amazon	500 (1.00)	433 (0.87)
PayPal	311 (0.62)	308 (0.62)
LinkedIn	357 (0.71)	244 (0.49)
DHL	236 (0.47)	216 (0.43)
Dropbox	212 (0.42)	196 (0.39)
Chase	195 (0.39)	184 (0.37)
BOA	220 (0.44)	183 (0.37)
CIBC	188 (0.38)	152 (0.30)
AT&T	104 (0.21)	102 (0.20)
Outlook	105 (0.21)	99 (0.20)
Spotify	76 (0.15)	73 (0.15)

Table 4: **Logo-level Results (Image Logo)**—Number of generated logos images that bypass $\theta = 0.87$ threshold among 500 testing logos. We also report the number and % of logos with a similarity above 0.6 to indicate good image quality.

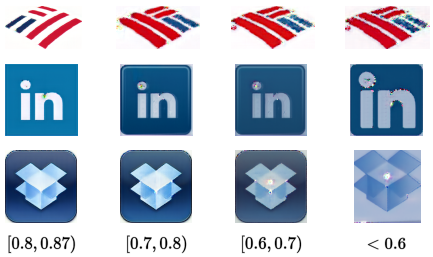

Figure 5: **Image Logo Attack Examples**—We show example logo images of different similarity levels compared with the original logos. All of them are below the detection threshold of 0.87.

We find that most of the logos that succeeded at the logo level retain their success after being added to webpages. 9 out of 11 brands have a success image rate of 0.72 or higher after transferring to the webpage level. Not too surprisingly, brands with a higher success rate, such as Amazon, Paypal, DHL, and Dropbox (success rate 0.89–0.1), often have a lower average similarity (0.67–0.70), meaning they are further away from the detection threshold. Spotify and Outlook logos have a lower rate. For Spotify, its lower rate can be explained by the relatively high similarity score to the original logos (0.83). However, for Outlook, a possible explanation is the Outlook logo size[10] is too small (about 60×60). As a validation test, we enlarge the logo size slightly to 100×100 when placing it on the webpage—the success rate goes up from 0.44 to 0.75. We show successful examples in supplementary materials [5].

Takeaway. Our method is always able to generate adversarial logo-images that bypass the logo-detector (76 in the worst case) and the end-to-end system (44 in the worst case).

4.4 Image-Text Logo Attack Effectiveness

Finally, we evaluate the attack effectiveness for image-text logos for the 8 corresponding brands in Table 1. Our method, as described in §3.3, is to combine the successful image and text parts and directly add them to the webpage screenshots [11]. Here, we combine successful text logos in Table 3 and image logos in Table 5. This immediately creates a large number of candidate webpage screenshots. For example, for Bank of America (BOA), there are 183 successful text-logos (i.e., fonts) and 200 image-logos, thereby yielding 183×200=36,600 candidate image-text-logos.

Table 6 shows the number and ratio of successful webpages that bypass PhishIntention end-to-end. The result confirms that combining text and image logos creates a large number of successful webpages for attackers to choose from. The number of successful logos end-to-end ranges from several thousand to tens of thousands. Interestingly, the average similarity of such image-text logos is usually high (Avg.Sim>0.8), which is desirable according to our logo-level user study in Appendix B. In practice, the attackers can select logos with higher visual quality and the largest distance to broadly apply them in phishing campaigns.[12]

Takeaway. For each considered brand, we find at least 3,596 image-text-logos that bypass the target system end-to-end.

Brand	# Success Logos (# Tested)	Rate	Avg. Sim
Amazon	362 (362)	1.00	0.67
PayPal	308 (308)	1.00	0.67
DHL	194 (216)	0.90	0.71
Dropbox	174 (196)	0.89	0.70
BOA	154 (183)	0.84	0.73
Chase	146 (184)	0.80	0.80
CIBC	121 (152)	0.80	0.72
AT&T	81 (102)	0.79	0.76
LinkedIn	175 (244)	0.72	0.65
Spotify	50 (73)	0.68	0.83
Outlook	44 (99)	0.44	0.75

Table 5: **Webpage-Level Results (Image Logo)**— Number of logos that bypass the end-to-end detection of PhishIntention after being placed on actual webpages. We only test logos from Table 4.

Brand	# Success Logos (# Tested)	Rate	Avg. Sim.
Amazon	37,970 (70,590)	0.54	0.857
BOA	13,479 (36,600)	0.37	0.866
Chase	18,601 (35,696)	0.52	0.869
Dropbox	29,773 (39,004)	0.76	0.807
LinkedIn	6,249 (13,176)	0.47	0.877
Outlook	11,387 (19,800)	0.58	0.849
PayPal	6,383 (11,396)	0.56	0.855
Spotify	3,596 (14,600)	0.25	0.891

Table 6: **Webpage-Level Results for Image-Text Logos**—Number of Image-Text logos that bypass the end-to-end detection of PhishIntention after being placed on actual webpages. The image-text logos are generated by combining the image part and text part generated by the respective attack algorithms.

[10] For consistency, we use the original logo size to fit the logo within the webpage layout. However, real attackers are not bound to this constraint.

[11] For this evaluation, we directly use a script to add the image and text parts to the webpage (instead of assembling a logo first) because it is easier to control the alignment of the text and image parts w.r.t the webpage layout.

[12] We show the trade-off between similarity and bypass rate in Appendix A

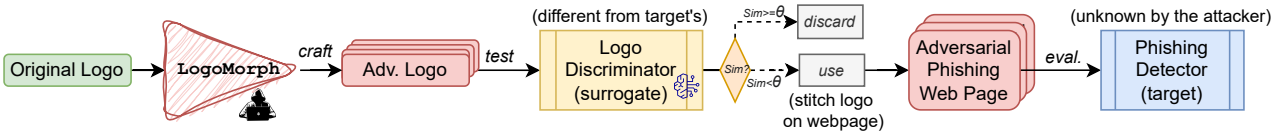

Figure 6: **Our Blackbox Experiment Setup.**—We use a surrogate logo discriminator (which is different from the one used by the target model) to generate and select adversarial logos via `LogoMorph`. Logos that bypass the surrogate discriminator (by achieving a low similarity) will be used to attack the targeted phishing detector at the webpage level.

Table 7: **Transferability to Phishpedia (All Logos)**—Number of adversarial phishing webpages (bypassing PhishIntention [32]) that successfully bypass another phishing detector (Phishpedia [30]).

4.5 Blackbox Attack against Phishpedia and VisualPhishNet

To simulate an attacker in a black-box setting, we examine how likely an adversarial logo designed to bypass PhishIntention [32] can transfer to *a different phishing detector*. As illustrated in Figure 6, PhishIntention is used as the local surrogate model of the attacker, which crafts logos to create phishing webpages to attack different detectors including Phishpedia [30] and VisualPhishNet [6]. We note that this experiment is more realistic than the one carried out in PhishGAP [29], wherein the adversarial logos were assessed merely against neural networks having a different architecture.

Attacking Phishpedia [30]. For this experiment, we take all the webpage-level screenshots (including all 18 brands in Table 1) that bypass PhishIntention [32] and we test them against Phishpedia [30] (which is the predecessor of PhishIntention). The results are shown in Table 7 (recall that image-text logos have a higher number of testing screenshots due to the many combinations of the image and text parts—§4.4). We observe that the overall transferability from PhishIntention to Phishpedia is high. For text-only brands (e.g., DocuSign, Comcast, Yahoo), nearly 100% of the adversarial pages can bypass Phishpedia. Note that Phishpedia does not use OCR features for their embedding and yet the font manipulation remains successful. The transferability of image-only logos (e.g., ATT, CIBC, DHL) to Phishpedia is also high as almost 90% of the adversarial webpages are successful. For the image-text logos, the transferability is slightly lower than other categories. For most brands, at least 80% of the webpages bypass Phishpedia. The results are consistent with those in §4.4 that the successful text and image logos combined together may not guarantee success. A possible explanation is that image-text logos offer more information (w.r.t. image or text alone) for the detectors to pick up some similarity.

Attacking VisualPhishNet [6]. Next, we test the transferability from PhishIntention to VisualPhishNet [6]. Recall that VisualPhishNet evaluates the visual similarity based on the *whole-page* screenshots instead of logos. This presents a significant difference between the two detectors. However, we expect our adversarial logos to still be somewhat effective due to a simple intuition: VisualPhishNet is trained with a variety of phishing and benign webpages *from the same brand*. Hence, although these webpages may exhibit high diversity (in terms of, e.g., colors and layout), an element that is likely to be "invariant" is the brand's logo. As such, our hypothesis is that the logo is an important feature implicitly learned by VisualPhishNet. (Due to the space limit, we present these results in Table 11 in the Appendix.) The results confirm our intuition to some extent. The evaluation covers 15 brands (three brands in Table 1 are not within VisualPhishNet's reference list and thus are omitted). Out of these 15 brands, only one never transfers, while two transfer poorly (success rate 0.01). In contrast, 6 have some transferability (success rate between 0.12–0.56) while 6 have a high transferability (success rate above 0.84). Intriguingly, three brands (AT&T, Instagram, LinkedIn) have a perfect evasion rate against VisualPhishNet [6].

Takeaway. Of the 18 brands in Table 1, our adversarial logos have a transfer success rate $\geq$ 80% for 17 brands against Phishpedia [30] and 6 brands against VisualPhishNet [6].

4.6 Blackbox Attack against PhishIntention

In §4.5, we performed a black-box experiment where the attacker uses PhishIntention as the local *surrogate* to compute the attack logos, which are then used to attack two target detectors: Phishpedia [30] and VisualPhishNet [6]. In this section, we explore the feasibility of black-box attacks against

PhishIntention itself (i.e. assuming the attacker has *no access to the internal embedding of PhishIntention*).

Setup. We explore a similar idea of training a surrogate locally (as shown in Figure 6). Under the black-box setting, the attacker can train a local *logo discriminator* that aims to approximate that of PhishIntention (without the query access to PhishIntention). To simulate the scenario where the attacker has *limited knowledge*, we intentionally use *a different architecture* for the attacker's local surrogate: the local surrogate has a simple Siamese neural network to create the embedding for input images. Compared with the target PhishIntention detector, the attacker's local surrogate does not have the OCR component for the feature embedding. Given the architecture and embedding are different, the attacker would also need to pick a different similarity threshold for optimizing the attack. For our experiment, the attacker selects threshold θ such that the surrogate archives a comparable accuracy on logo classification tasks (the resulting θ=0.83, 99% identification rate). We expect such differences (threshold and architecture) will affect the attack outcome to some extent.

Method. For text-only logos, we use the local surrogate to select text fonts that bypass the similarity threshold (measured by the *local surrogate*). Among the ones that bypass the local surrogate, we rank them based on their similarity to the original fonts and select the top 200 candidates. To improve transferability, and to simulate a conservative approach by the attacker (who does not know the threshold of the targeted detector), we selected the 100 text logos ranked between 100–200 to use against the "real" PhishIntention. For image-only logos and the image part of the image-text logos, we also use the local surrogate to generate and select attack logos. Like before, we generate 200 candidate attack logos per brand and select those that bypass the local surrogate logo discriminator (with a similarity score between 0.6 and 0.83). The number of qualified image logos varies from 30 to 165 logos per brand (see Table 12 in the Appendix). Using these logos, we then perform the *webpage-level* evaluation against the real PhishIntention. For image-only logos, we add the logos directly to the corresponding webpages and test them against the real PhishIntention. For image-text logos, we combine the image parts (selected above) with 100 text logos (that bypassed the local surrogate) before adding the combined logos to the web pages and testing against PhishIntention.

Results. Table 8 shows the end-to-end testing result at the webpage level against the real PhishIntention (all logos). The black-box success rate varies across brands. For example, Instagram has a 100% success rate and AT&T has 96%. 10 of the 18 brands have a success rate over 35%. Two brands have a transferability lower than 10% (PayPal and LinkedIn). On the one hand, these results suggest that incomplete/mismatched attacker knowledge (i.e., the discrepancies between the local surrogate model and the target model) leads to reduced attack effectiveness; this is expected—e.g., for PhishGAP [29], the

Brand	# Succeed (# Tested)	Rate	Avg. Sim.
Instagram	100 (100)	1.00	0.76
AT&T	76 (79)	0.96	0.80
DHL	70 (81)	0.86	0.80
DocuSign	82 (100)	0.82	0.85
CIBC	43 (63)	0.68	0.87
BOA	5,943 (9,300)	0.64	0.82
Outlook	1,384 (3,000)	0.46	0.87
Dropbox	3,002 (6,900)	0.44	0.88
Spotify	2,989 (7,200)	0.42	0.87
Yahoo	35 (100)	0.35	0.88
Amazon	3,067 (9,900)	0.31	0.89
Chase	2,145 (7,800)	0.28	0.90
Comcast	25 (100)	0.25	0.88
eBay	24 (100)	0.24	0.87
Google	22 (100)	0.22	0.89
Netflix	10 (100)	0.10	0.89
LinkedIn	1,021 (12,800)	0.08	0.91
PayPal	319 (16,500)	0.02	0.92

Table 8: **Transferability to PhishIntention (All Logos)**—Number of adversarial webpages (using attack logos computed by a local surrogate model) that bypass the *target PhishIntention [32]*. "Avg. Sim." reports the average similarity between the testing logos and closest reference logos in PhishIntention on a webpage level.

≈95% (logo-only) fooling rate in a white-box setting drops to 10–42% in a black-box setting. On the other hand, attackers in practice may perform such black-box tests by hosting phishing webpages (with different attack logos) and later checking if the webpages get taken down or reported (e.g., on [3]) and try again. For LinkedIn and PayPal, even though their success rate is low, the number of successful logos is high (1,021 and 319), which means they have many viable logos to choose from for large-scale phishing campaign deployment.

Takeaway. Overall, our black-box experiments (vs Phishpedia in Table 7, VisualPhishNet in Table 11, and PhishIntention in Table 8) confirm the transferability of `LogoMorph`. Certain brands have high bypass rates across all three settings, e.g., Instagram (avg=0.99) and AT&T (avg=0.94).

4.7 Comparison with Existing Attacks

Objective. We now perform a hard-comparison with the attack proposed in PhishGAP [29], whose threat model aligns with ours (§2.2). Differently from our `LogoMorph` PhishGAP seek to craft an adversarial logo by generating noise—but without accounting for any "semantics" of the resulting logo. This is done by learning a "generative adversarial perturbation" by repeatedly attacking the target logo-detector (which is considered to be completely known). However, despite showing that the resulting adversarial logos can bypass the target detector (and do exhibit some form of transferability to similar detectors), no consideration is given to an end-to-end evaluation. Hence, we scrutinize whether the adversarial lo-

gos crafted via PhishGAP retain their effectiveness against the full-fledged phishing detection system of PhishIntention [32].

Method and Results. We obtain the source code (which is publicly available) and the adversarial logos (which are provided upon request) of PhishGAP [29]. We filter these logos so as to include only those of the 18 brands in Table 1. In addition, we only consider adversarial logos whose original logo can be detected by PhishIntention (otherwise, the impact of PhishGAP would be zero). This leaves us with 2,057 adversarial logos for the 18 brands. Then, we put these logos into the corresponding brand's webpages (the same ones used in our evaluation), and run PhishIntention end-to-end. We find that only 113 webpages screenshots (5.49%) bypass PhishIntention. The successful logos (compared with their original logos) have a cosine similarity of 0.77. However, due to its "unregulated" generative method, PhishGAP's adversarial logos present remarkable semantic-level differences (e.g., cropping, disproportionate stretching, unusual background) that impair their evasiveness end-to-end. We present some successful logos in supplementary materials [5].

Takeaway. Of the 2,057 adversarial logos generated by PhishGAP [29], only 5.5% evade PhishIntention [32] end-to-end (despite bypassing its logo-discriminator).

5 User Study (Does it *also* deceive humans?)

After showing that our `LogoMorph` attack can bypass a "machine", we carry out a user study to verify if our adversarial logos can also deceive "humans", i.e., the true target of phishing. Indeed, if we only wanted to bypass the detector, we could simply generate a completely different logo—but this would inevitably alert a user: real phishers do not want this. As discussed in the threat model (§2.2), for this user study, we will focus on webpage-level evaluation (instead of just analyzing the logo itself), considering that during real-world phishing attacks, logos are not presented to users in isolation.

5.1 Survey Design

We conduct two user studies. The first study shows users benign webpages and *adversarial* phishing webpages (adding the logos generated by `LogoMorph`); we denote this as *adversarial study*. The second study shows users benign webpages and *unmodified* phishing webpages, i.e., without any adversarial logo; we denote this as *baseline study*. A participant can only participate in one of the two studies (not both).

Organization. The two studies share a similar structure. **(I)** A participant starts by reading a consent form and giving their consent. Then they read a brief summary of this study. Here, we explicitly inform the participant that *the study is about detecting phishing webpages*. We expect this to have a *priming* effect, prompting participants to get ready for the phishing detection task. In practice, users may be *unprepared* when they encounter phishing websites. As such, this highly prompted setting can help estimate the upper-bound performance of users. This priming effect has been confirmed in previous phishing studies [25] where highly prompted participants have a better phishing detection performance than unprompted participants. We use this prompted setting to explore the best-case for users and the worst-case for attackers. **(II)** The participant examines 18 webpages (in the form of screenshots, without URL; we do not deploy any phishing webpages on the Web) of the 18 brands listed in Table 1: 9 brands are randomly selected to present the *legitimate* webpage of the brand, and the remaining 9 brands present the *phishing* webpages. This ensures that a participant only sees a given brand *exactly once* (e.g., if a participant sees the real page of PayPal, this participant will not see a phishing webpage for PayPal). Below each screenshot, the participant must answer two questions: (Q1) "*How do you rate the legitimacy of this webpage?*"—the participants select answers from a six-point Likert scale from 1 (definitely phishing), 2 (very probably phishing), 3 (probably phishing but not sure), 4 (probably legitimate but not sure), 5 (very probably legitimate), and 6 (definitely legitimate). This is to avoid a neural determination. The other question (Q2) is "*What specific components/indicators on the webpage have influenced your choice?*"—a short answer is provided using an open text box. **(III)** Finally, participants answer demographic questions about their age group, gender, and education level.

Selection of Phishing Webpages. The main difference between these two user studies is the type of phishing webpages used. The *adversarial* study uses adversarial webpages generated by (i) replacing the logos with the adversarial logos produced by `LogoMorph` while ensuring that (ii) the resulting webpage bypasses PhishIntention's end-to-end detection. For this user study, we choose high-quality adversarial logos ($0.8 \leq \text{Sim} < 0.87$), which is justified by our "ancillary" study, discussed in Appendix B, revealing that such logos can better resemble the targeted brand (and real-world attackers would opt for these). For the *baseline* study, we use the "*unmodified*" phishing webpages that do not carry adversarial logos. The ordering of the brands in the questionnaire is randomized to mitigate biases from the order effect (e.g., participants may get tired/more familiar with the task towards the end).

Recruitment and Ethics. Our study was reviewed and approved by our IRB. We recruit participants from Prolific. We chose Prolific over other platforms such as MTurk for its higher quality of the participants' answers [44]. During the study, we did not collect any personally identifiable information (PII); all participants were anonymous and voluntary and could withdraw their data at any time during and after the study. Each participant is compensated with $2.2 for completing the survey. On average, each participant spends 17.6 minutes on the survey. In total, we recruited n=150 participants including 100 for the primary adversarial attack study

Study	Accuracy	TPR	TNR
Adversarial	0.69	0.59	0.79
Baseline	0.60	0.45	0.75

Table 9: **Users Study Results**—The adversarial study uses phishing webpages with our adversarial logos. The baseline study uses original phishing pages. We report the overall accuracy, true positive rate (TPR), and true negative rate (TNR).

and 50 for the secondary baseline study. The demographics of the participants are shown in supplementary materials [5].

5.2 User Study Results

Detection (Q1). The results are summarized in Table 9. For each study, we report the overall phishing detection accuracy, as well as the true positive rate (TPR) and true negative rate (TNR). First, we observe that users have a slightly better performance in detecting adversarial phishing pages (TPR=0.59) than in detecting unperturbed phishing pages (TPR=0.45). We run a Chi-squared statistic test to confirm the difference is statically significant (χ^2=23.3, p<0.001). However, the adversarial phishing pages are still difficult to detect by users: a TPR of 0.59 is only slightly better than random guessing. Recall that this performance is obtained under a high-prompting condition where users are prepared for (and focused on) the detection tasks. In practice, the attack is likely to be more effective when users are unprepared [18]. The benefit of adversarial webpages (w.r.t. the original ones) is that they can bypass automated detection. In addition, we find that, across both studies, participants have a higher TNR (i.e. recognizing legitimate pages) than the TPR, i.e., they can better recognize legitimate webpages than phishing ones. This observation is consistent with prior studies [25].

Reasoning (Q2). Upon examining participants' answers to the second question (indicators that influenced their decisions), we find a surprising occurrence: *logos are not the only reason* for detecting adversarial phishing pages. More specifically, in the adversarial study, only 23% of the participants who correctly identified a webpage to be phishing mentioned "logo" in their responses. In comparison, a much greater portion (36%) mentioned other factors (e.g., color scheme, overall layout, typos)—all of which were *already present in the original phishing webpage*. We again run a Chi-squared test and confirm a significantly higher number of adversarial phishing pages are detected by other factors than those detected by adversarial logos ($\chi^2 = 37.8$, $p < 0.001$).

Takeaway. Despite users recognizing adversarial phishing webpages slightly better than the original ones, it remains difficult for users to recognize adversarial phishing pages accurately (TPR=0.59). Also, most of the provided explanations are not related to our `LogoMorph` attack.

Brand	Std. AdvTrain		w/ Ref Augment	
	# Succ (Test)	Rate	# Succ (Test)	Rate

Table 10: **Adversarial Retraining**—# of adversarial phishing webpages that bypass PhishIntention after adversarial retraining (standard and w/ reference augmentation). "Succ" stands for the number of successful logos; "Test" for the number of tested logos.

6 Countermeasures

Finally, we explore potential countermeasures to our proposed `LogoMorph` attack. We first apply the basic adversarial retraining method to enhance the model's ability to detect adversarial phishing webpages. After showing the ineffectiveness of this basic method, we propose a *new* method by combining adversarial retraining with the augmentation of the reference list (which is unique to reference-based phishing detectors). This new method shows much-improved performance. Finally, we experiment with *gradient masking*, which aims to make it difficult to compute adversarial logos.

Basic Adversarial Retraining. The idea of adversarial retraining [10, 35] is to retrain the detector using a portion of adversarial logos. We first perform standard adversarial retraining for PhishIntention by removing the weights of the last classification layer and training it with our successful adversarial logos. For this experiment, we constructed a dataset with all three types of logos. For image-only logos, we use the successful logos from Table 4. For text-only logos, we use the successful logos from the top 200 fonts from Table 3. For image-text logos, given we have thousands of successful ones, we randomly sample 200 for each brand. 80% of this dataset is used as the training set and the remaining 20% is used as the testing set. We train the model until it converges and we get a 98.50% accuracy on the top-1 logo brand matches. For this standard version, the adversarial logos are only used for re-training but are *not included in the reference list* for phishing detection. In other words, given a testing input logo, it is compared against the original logos.

The testing result (end-to-end) is reported in Table 10 (left). While adversarial retraining helps to reduce the bypass rate, the model is still insufficient to detect adversarial phishing pages (the bypass rate ranges from 0.45 to 1.0). Intriguingly, standard adversarial training was found to be quite effective against PhishGAP [29] (albeit it was not tested end-to-end). We also evaluate the false positive rate for standard adversarial retraining using a large benign webpage dataset from Phishpedia [30]. It has 25K benign pages, and we use 21,974 of them that have URLs to verify their brands and legitimacy. The test returns 21 false positives (0.096%). This is comparable to the 17 false positives of the original detector (0.077%).

Adv. Retraining + Reference Augmentation. Given the findings above, we introduce a new adversarial retraining method where we additionally inject the adversarial logos (from the training set) to the reference list. In other words, given a testing input, it is compared against both real logos and the added adversarial logos of a given brand to detect mimicry. The result is reported in Table 10 (right). We show that the augmented reference list has significantly improved the detection of adversarial logos. 11 out of 18 brands have a success rate lower than 10%. 14 out of 18 brands have a success rate lower than 50%. This approach only slightly increases the number of false positives (from 21 to 23, compared with standard adversarial retraining), with a false positive rate of 0.1%. The result suggests that fuzzing the reference list is more important to robustify the detector.

Gradient-Masking. Another defense method proposed by prior work [30, 32] is gradient masking. The goal is to modify the phishing detection model such that it becomes more difficult for optimization-based algorithms to generate adversarial examples. The detailed experiments are presented in supplementary materials [5]. We find that gradient masking is not effective in defending against `LogoMorph`. Gradient masking is designed to defend against classification-gradient-based adversarial examples (that introduce small noises), which is not well suited to defend against our attack.

Takeaway. Standard adversarial retraining and gradient-masking are ineffective against `LogoMorph`. We propose a new effective countermeasure that combines adversarial retraining with the augmentation of the reference list.

7 Discussion and Conclusion

In this paper, we show that the adversarial logos generated by `LogoMorph` is effective against a range of state-of-the-art phishing detectors [6, 30, 32]. The result confirms (and aggravates) the initial concern raised by [29]—compared with [29] (which only focuses on logos and logo discriminators), we further show the end-to-end effectiveness of the attack (webpage-level) against both the systems and users.

Security Considerations. We derive key lessons learned from our experiments on phishing detection systems (in §4). *First*, our *white-box evaluation* (in §4.2 to §4.4) assumes an attacker owns an exact copy of the targeted detector (i.e., PhishIntention [32]) to identify suitable adversarial logos. The webpage-level results show that, for most brands (e.g., 7 out of 11 for image-only logos, see Table 5; and 9 out of 14 for text-only logos, see Table 3), over 80% of the adversarial pages crafted via `LogoMorph` bypass PhishIntention end-to-end. *Second*, the *black-box setting*, in which the "surrogate" detector used by the attacker is different from the targeted one, makes it harder to find suitable logos. This is reflected by lower overall effectiveness in our experiments—e.g., only 6 out of 15 (or 4 out of 18) brands have more than 80% of our adversarial webpages bypass VisualPhishNet [6] (or PhishIntention [32]) end-to-end, as shown in Table 11 (Table 8). *Third*, the decrease in effectiveness underscores the importance of *keeping deep learning models* confidential: despite reliant on "security-by-obscurity", preventing unauthorized access[13] to such models is a pragmatic defense. *Finally*, in either case, however, the attacker can simply disregard brands that are "difficult to attack", and use `LogoMorph` *only for those brands that exhibit a near-perfect bypass rate* across all experiments. Indeed, our considered brands are highly popular, and real-world attackers would favor such brands in practice.

Cost of Attack. We discuss the *cost of the attack* (embracing the recommendations of [7]). The major contributors to such cost are: obtaining the surrogate detector[14], which can be done by, e.g., using the publicly available detectors from research papers; and the computational runtime to generate the logos with `LogoMorph`. For the latter, we provide the details from our experiments: generating an (adversarial) text-only logo requires on average 3.5s of CPU-time (1 thread); whereas tuning the diffusion model on one brand (of 200–500 images) requires 24–48h of training, after which only $\sim$0.5s are required to generate an (adversarial) image-only logo (on a single GPU). Our experiments are carried out on an 8-threaded CPU (Intel Xeon Silver 4214 2.20GHz) and NVIDIA RTX 5000 GPU: parallelization can further decrease the time required to craft our adversarial logos.

Why the Attack Works; How It is Different. The key insight is obtained from challenging the assumption that the logo is the invariant of a website's identity (and users would pay close attention to it). The intuition is that adversaries can introduce large perturbations to the logos, as long as the perturbations do not significantly change the semantics. Such perturbations can help to evade the phishing detectors while

[13] N.b.: we always assume an attacker cannot query the targeted detector (see §2.2). With query access, the "white-box" scenario could turn into a "black-box" setting wherein the attacker can query the targeted detector (potentially subject to budget constraints) to find suitable logos. Such a scenario can be explored by future work (we release our code [4]).

[14] In a "perfect knowledge" scenario, the attacker must also invest the resources to determine that the targeted detector matches the surrogate.

the adversarial phishing pages can remain effective on users. Unlike traditional gradient-based attacks [12] that compute imperceivable noises (which are easier to defend against [32]), our idea is to search for large (semantic-preserving) perturbations. For text logos, this is realized by searching for alternative fonts. For image logos, this is realized with a diffusion model to learn the logo styles. Both of these have room for further improvement. For instance, instead of searching among existing fonts, adversaries may use ML models to generate "novel" fonts [13, 45]. Moreover, our current image-logo attack fine-tunes an adversarial diffusion model for each brand. Future work may further optimize this by training a single model for all brands using *conditional* diffusion models [41].

Enhancing Automated Defense. Section 6 shows that adversarial training helps to improve the phishing detector, not necessarily because the deep learning model (for logo embedding) has been improved; instead, it is the reference augmentation that contributes more to the improved defense. In other words, for reference-based phishing detectors, the defender not only needs to include all the existing logos of a brand to the reference list but should also add *potential variants* of such logos. The diffusion model can be a generic approach to "fuzz" the reference list. This paper is focused on attacks, and thus the diffusion model is primarily tuned for "fidelity." Future work may tune the diffusion models to control and encourage "diversity" in the diffusion process to optimize the model for better defense (via reference fuzzing).

Table 11: **Transferability to VisualPhishNet (All Logos)**—Number of adversarial phishing pages (generated with a local PhishIntention model) that successfully transfer to bypass another phishing detector VisualPhishNet. Three brands from Table 1 (Comcast, Spotify, DocuSign) are omitted because they are not included in [6].

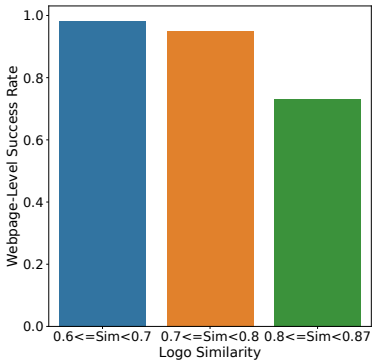

Figure 7: **Evasion Rate vs Logo Similarity**—We group the adversarial logos into 3 buckets based on their similarity, and report the aggregated webpage-level evasion rate against PhishIntention.

A Evasion Rate vs. Similarity Threshold

In this section, we further explore the trade-off between the similarity threshold and evasion success rate. For this analysis, we still focus on logos having Sim$\geq$0.6 (to make sure the logos are of reasonable visual quality). More specifically, we collect all the candidate image- and text-logos (from §4.2 and §4.3 in Table 3 and Table 5)[15], sort them based on their similarity, and then group them into three buckets: 0.6$\leq$Sim$<$0.7, 0.7$\leq$Sim$<$0.8, and 0.8$\leq$Sim$<$0.87. Then for each bucket, we add the adversarial logos to their corresponding webpages and test the webpages against PhishIntention end-to-end pipeline. The success rate of these adversarial logos is shown in Figure 7. Overall, the result confirms the expected trade-off: choosing logos with a lower similarity improves the evasion success rate. However, in the ancillary user study (Appendix B), we show that the cost of using lower-similarity logos is on users: from users' perspectives, such logos tend to also have a lower resemblance to the target brands. In practice, attackers should prioritize higher-quality logos (high similarity) as long as they can bypass the detector. However, given that attackers may not have perfect knowledge of the target system (and hence do not know the exact threshold), attackers may consider using logos that are slightly below the "anticipated" threshold (we use this intuition for choosing some of the logos of our blackbox experiment in §4.6).

B Ancillary User Study (Logo-Level)

In our main paper, we carried out a user study (§5) whose goal was assessing if users were able to identify phishing webpages that included an adversarial logo crafted via `LogoMorph`. Here, we carry out an orthogonal user study, whose goal is to determine the extent to which the logos crafted via `LogoMorph` can retain the semantics of the targeted brand. Specifically, we show various logos crafted via `LogoMorph` which achieve a certain similarity (according to PhishIntention), and ask users to rate how much such logos "resemble" the targeted brand.

Questionnaire Design. This user study follows a similar setup (in terms of platform and structure) to the one in our main paper (§5). However, here, we only display the logo in isolation—whereas in our main paper we showed the entire webpage. **(I)** We begin by informing users that the study involves "understanding the human's ability to identify website brands".[16] We then explain the participants' rights and the instructions of our survey. **(II)** Each participant is then shown a total of 52 adversarial logos. All logos used in the study have bypassed the detection threshold of PhishIntention (i.e., Sim<0.87). Specifically, we show 3 logos for each of the 18 brands listed in Table 1. These 3 logos pertain to three categories:

- *Very Similar*, i.e., adversarial logos crafted via `LogoMorph` with 0.8$\leq$Sim$<$0.87 according to PhishIntention;
- *Somewhat Similar*, i.e., adversarial logos crafted via `LogoMorph` having 0.7$\leq$Sim$<$0.8;
- *Barely Similar*, i.e., adversarial logos crafted via `LogoMorph` having 0.6$\leq$Sim$<$0.7[17]

We randomize the order of the logos for each participant to reduce bias. **(III)** Each logo (and corresponding questions) is shown in a dedicated section of our questionnaire. Upon reaching any new section, the user is first asked "Do you know the brand *b*", where *b* is the brand targeted by the logo, and the answers are "Yes, I know and visit it often" / "Yes, I know it but I do not use it often" / "No, I have never heard of it." Then, we show the logo, and ask "Does this logo resemble the brand?" and the answer is picked from a five-point Likert scale: 1=not resemble; 2=probably not resemble; 3=undecided; 4=probably resemble; 5=resemble. Also, we specifically write "Please do not look up the logo" to prevent users from checking the Internet and biasing their responses. **(IV)** At the end of the questionnaire, we ask an attention check question, showing the image of a social network and inquiring whether it represents a bank. Our study does not collect any personally identifiable information, and our participants' identities are anonymous and participation was voluntary and could withdraw their data at any time (during and after the study). On average, each participant spends $\approx$7 minutes.

Results. We collected 5,200 valid responses from 100 participants. To provide an accurate representation, we only consider the responses of users who "know" the brand (i.e., they answered "Yes" to the brand-knowledge question). These re-

[15] We did not combine the text and image parts at the logo level; as discussed in §4.4, they are directly combined at the webpage level.

[16] We note that, differently from what we did in the user study in our main paper, we are not priming the users here: we *never* mention the term "phishing" in our questionnaire. This is to ensure that the users are not biased to think that a given logo may be related to a malicious purpose, thereby increasing the quality of user responses (i.e., this study is *not* about phishing).

[17] We do not have any logo for PayPal and LinkedIn within this range, which is why we have 52 logos (given by: $3 \times 18 - 2$).

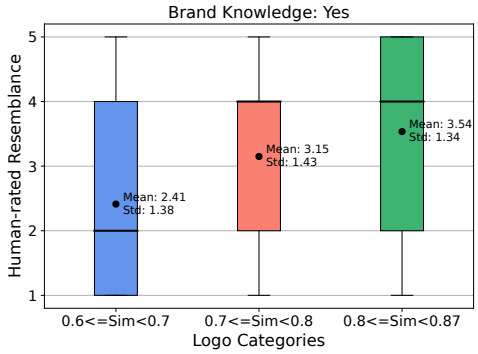

Figure 8: **Main Results of our Logo-level User Study**—Distribution of the human-rated resemblance (higher is better) across adversarial logos crafted with LogoMorph.

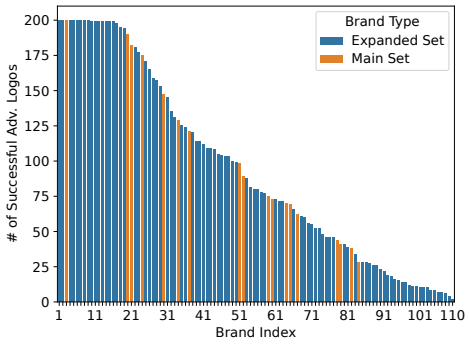

Figure 9: **Successful Adv. Logos Per Brand (110 Brands)**—We sorted the 110 brands on the x-axis based on the number of successful adversarial logos identified by LogoMorph (out of 200 candidate logos tested against PhishIntention).

Brand	# Success Logos	Rate
PayPal	165	0.83
Amazon	128	0.64
LinkedIn	128	0.64
BOA	93	0.47
DHL	81	0.41
ATT	79	0.40
Chase	78	0.39
Spotify	72	0.36
Dropbox	69	0.35
CICB	63	0.32
Outlook	30	0.15

Table 12: **Logo-Level Results for Image Logos**—Logos that bypass the *local surrogate* (out of 200 tested images per brand). We choose these logos to run a black-box attack against PhishIntention.

sponses count for about 90% of all valid responses. Figure 8 shows the aggregated "human-rated resemblance" (y-axis) across all logos within a given category (boxplots). We can see that the human-rated resemblance is highest for logos within the *very similar* category: the average rating is 3.54, and the standard deviation is 1.34, and a t-test confirms that such a rating is statistically significantly ($p < 0.001$) superior than the middle-point of 3. Hence, we can claim that *logos crafted with* LogoMorph *having 0.8≤Sim<0.87 tend to preserve the characteristics of the targeted brand* (at least according to our participants, and w.r.t. our considered 18 brands). This suggests that, from an attacker's viewpoint, it is wise to use LogoMorph by picking adversarial logos having 0.8≤Sim<0.87 to embed in the web pages. (Indeed, this is what we have done in the user study discussed in §5.) For the *somewhat similar* logos (0.7≤Sim<0.8), the average rating is 3.15 (i.e., also above the middle-point 3), indicating a positive resemblance of the target brand. Interestingly, however, for some users, even logos having a lower similarity can resemble (to some extent) the targeted brand, as shown by the wide whiskers in the blue (0.6≤Sim<0.7) boxplot.

C Extended Logo Experiments

Insofar, our evaluation revolved around a subset of 18 brands included in PhishIntention's dataset. Here, we expand the our assessment to cover more brands, demonstrating that LogoMorph is broadly applicable to a variety of brands and their logos. We regard the 18 brands used in §4 as the "*Main Set*", and then introduce an "*Expanded Set*" of 92 brands (110 brands in total). For the Expanded Set, we first include the top 50 most impersonated phishing attack brands [38] (excluding those that are not in PhishIntention's protected brand list). Then we fill out the rest of the slots based on PhishIntention's protected brand list. Among the 92 brands, 17 have image-only logos[18], and 75 have text-only logos.

[18]For brands like Capital One Bank, differentiating the text and image parts of the logo is challenging, and thus we regard the logo as image-only.

We replicate the white-box experiment in §4.2 and §4.3 to cover our 110 brands. For image logos, we use LogoMorph to generate 200 adversarial logos for each brand. For text logos, we follow the selection procedure (§3.1) by first generating 2,556 candidate fonts for each brand, and then selecting the top 200 fonts that bypass the similarity threshold to generate logos. The results are presented in Figure 9. The 110 brands are sorted based on the number of successful adversarial logos identified by LogoMorph against PhishIntention's logo discriminator (logo-level). The orange color represents the Man Set and the blue color represents the Expanded Set. The result shows that the 18 brands used in the main paper have sufficient diversity, covering both easy-to-attack and hard-to-attack brands. For 50 of these brands, LogoMorph identified more than 100 successful logos. For all 110 brands (100%), LogoMorph identified at least one viable attack logo for the attacker (from 200 candidate logos). In a white-box setting, the attacker would hence always find a suitable logo for each of these 110 brands.

Invisibility Cloak: Proactive Defense Against Visual Game Cheating

Chenxin Sun,* Kai Ye,* Liangcai Su, Jiayi Zhang, Chenxiong Qian†
The University of Hong Kong

Abstract

The gaming industry has experienced remarkable innovation and rapid growth in recent years. However, this progress has been accompanied by a concerning increase in First-person Shooter game cheating, with aimbots being the most prevalent and harmful tool. Visual aimbots, in particular, utilize game visuals and integrated visual models to extract game information, providing cheaters with automatic shooting abilities. Unfortunately, existing anti-cheating methods have proven ineffective against visual aimbots. To combat visual aimbots, we introduce the first proactive defense framework against visual game cheating, called *Invisibility Cloak*. Our approach adds imperceptible perturbations to game visuals, making them unrecognizable to AI models. We conducted extensive experiments on popular games CrossFire (CF) and Counter-Strike 2 (CS2), and our results demonstrate that *Invisibility Cloak* achieves real-time re-rendering of high-quality game visuals while effectively impeding various mainstream visual cheating models. By deploying *Invisibility Cloak*[1] online in both CF and CS2, we successfully eliminated almost all aiming and shooting behaviors associated with aimbots, significantly enhancing the gaming experience for legitimate players.

1 Introduction

In recent years, there have been major advancements in gaming technology and user engagement, leading to rapid industry growth. Market projections indicate that the revenue of video game markets is expected to reach $282.3 billion in 2024, with a year-on-year growth of 8.76% until 2027 [47]. However, this progress has been accompanied by a concerning rise in in-game cheating, which poses a serious threat to game integrity and player experience. This threat is particularly prominent in First-person Shooter games, renowned for their exceptional competitiveness and entertainment value, resulting in losses exceeding $23 billion [1].

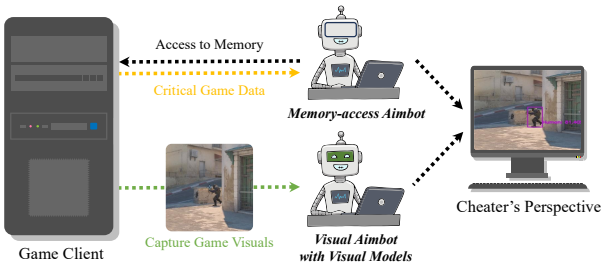

Figure 1: Workflows of Memory-access and Visual aimbots.

In game cheating, the most pervasive and harmful cheating, is the *aimbot*. These tools artificially enhance a player's aiming and shooting accuracy, fundamentally disrupting the integrity and fairness of gameplay. The aimbot process mainly involves two steps: acquiring game data and automatic shooting. Depending on the data acquisition method, aimbots can be broadly classified into two types: *Memory-access aimbots* and *Visual aimbots*. Memory-access aimbots directly access game data in the client's memory, typically including precise target objects and resource positions. To prevent such cheating, researchers have developed anti-aimbot tools [28, 29, 39, 59–61] to block unauthorized access to game memory. For instance, the most recent system, BotScreen [11], leverages Intel SGX [13] to protect game data from accessing and tampering, rendering the memory-access aimbots non-functional. Unlike memory-access aimbots, visual aimbot relies solely on the game's visual screen, utilizing integrated visual models(e.g., YOLO [50], NanoDet-Plus [41]) to identify game objects. As shown in Figure 1, it first captures the normal game screen and then extracts information (e.g., coordinates, distance, and size of targets) based on the visual model. This cheating is also known as Visual Game Cheating.

Visual game cheating has become increasingly powerful and prevalent with the development of AI and cloud gaming. Currently, various visual aimbots [19, 35, 44] and tutorials [9, 40] are easily accessible and popular. The harmfulness of this trend is primarily demonstrated in two aspects: (a) **High cheating success rate**. With AI continuously mak-

[1]Our project can be found at: https://invisicloak.github.io/

ing breakthroughs in the field of computer vision, fast and accurate object detection [5, 18, 41, 50] and skeleton recognition models [15, 49, 58] are being integrated into aimbots. Moreover, RootKit [45] has announced plans for international competitions [43] to further enhance the development of their AI-Aimbots [44]. (b) **Wide applicability and stealthiness**. The only data visual aimbots utilize are legitimate and accessible game footage, making them highly adaptable and undetectable to various games and deployable across different platforms, including mobiles and computers. In particular, cloud gaming is emerging as the next-generation gaming architecture due to its low latency, scalability, and conveniences [42, 46]. The cloud server and the player's client are entirely separated throughout the cloud gaming process, with the client only receiving video streams from the cloud server. While cloud gaming renders traditional cheats unfeasible, it inevitably positions visual aimbots as the mainstream choice for next-generation cloud game cheats.

Disappointingly, when it comes to visual aimbots, passive detection-based approaches are currently the only viable anti-cheating techniques [2, 17, 23, 25, 29, 34, 63]. However, these techniques identify cheaters by analyzing abnormal game data after the fact, failing to guarantee a smooth gaming experience for normal players. Moreover, it suffers from a certain degree of misjudgment and lack of explainability. Rather than relying on passive cheating detection, is it possible to achieve proactive defense against visual game cheating?

To this end, we propose a proactive defense framework for visual game cheating, namely *Invisibility Cloak*. To the best of our knowledge, this is the first work to proactively perform anti-cheating in visual games. The core idea is to introduce an invisible perturbation to the game screen. This perturbation is undetectable to human players but prevents visual models from accurately recognizing the game screen targets. Considering the method's usability, practicality, and deployability, proactive defense against visual game cheating needs to overcome the following challenges. **(C1) Transferability.** The approach should be transferable because it is impossible to know the cheating models used by cheaters in advance. **(C2) Robustness.** The approach should be applicable to various games and complex in-game scenarios. In addition, to ensure a normal experience for players, the method also needs to meet the requirements, including **(C3) Imperceptibility** of the perturbation and **(C4) Real-Time Performance**.

To address the aforementioned challenges within the framework of the Invisibility Cloak, we propose a *Cloak Crafter* module. This module comprises two components: offline Universal Cloak Identification and online Cloak Refinement. In the Universal Cloak Identification, we first adopt multiple visual models and diverse game screenshots to search for a Universal Cloak, where the cloak refers to an imperceptible perturbation. Further, in the Cloak Refinement, we refine the universal perturbation in the game environment to make it adapt to specific game scenarios. To meet C3 and C4, we require the perturbation to be sufficiently small throughout the entire process and limit the number of queries. To evaluate the effectiveness of our defense, we conduct comprehensive experiments on two of the most popular First-person Shooter games, *CrossFire* (CF [2]) and *Counter-Strike 2* (CS2 [3]). The results demonstrate that the Invisibility Cloak can effectively resist visual game cheating without affecting players' gaming experience. We also performed a simplified online deployment and found that the visual aimbot was rendered ineffective in both CF and CS2 when the Invisibility Cloak was enabled. Our main contributions are summarized as follows:

- ***Proactive Anti-Cheating:*** We introduce a novel proactive anti-cheat method specifically designed to combat visual aimbots that are difficult for traditional anti-aimbot techniques to detect. Our approach represents a more dynamic and preemptive form of cheat prevention.
- ***Non-Invasive Implementation:*** Our approach seamlessly integrates with the game rendering process, overlaying the Cloaks onto the player's display without user monitoring.
- ***Comprehensive Dataset Collection:*** We collected extensive image datasets that contain different game maps and scenarios from the most popular games, CS2 and CF, serving as the foundation for training and evaluating *Invisibility Cloak*.
- ***Invisible Protection:*** Experiments conducted demonstrate that our approach effectively meets the demands of First-person Shooter games, safeguarding players against visual aimbots without compromising visual quality or real-time performance, resulting in an unobtrusive gaming experience that can be considered virtually invisible.

2 Background

In this section, we first present the workflow of visual aimbots, benefiting from state-of-the-art object detection models. Then, we examine the limitations of existing adversarial attacks targeting object detection models, particularly when implementing these attacks within First-person Shooter games.

2.1 Aimbot Cheating Using Visual Models

As Computer Vision (CV) technology advances, visual aimbots are gaining popularity, especially in First-person Shooter games featuring human character models such as CF and CS2. Developing an aimbot using these visual models is relatively simple and efficient. Numerous publicly available pre-trained models have high accuracy and typically incorporate *person* as part of their training datasets [7, 52]. This accessibility enables cheaters to utilize these pre-trained models in their aimbots without the need for retraining, thereby streamlining the creation of highly effective cheating tools.

[2] https://cf.qq.com/
[3] https://www.counter-strike.net/

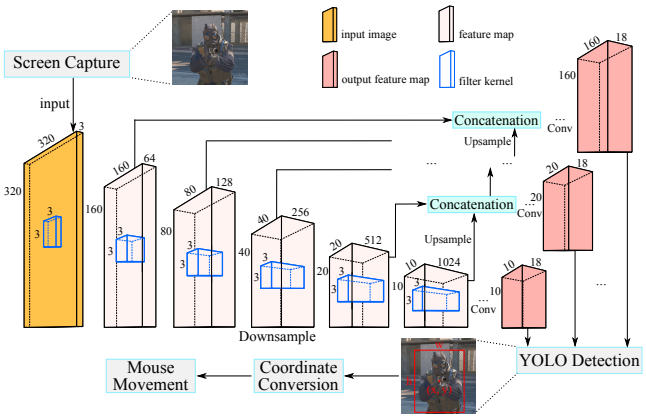

Figure 2: The workflow of aimbot cheating using YOLO.

Figure 2 shows the workflow of a typical visual aimbot. Cheaters first initiate the aimbot process by capturing the game screen on their devices. Normally, the screen resolution is huge, but cheaters usually resize the captured image to a small predetermined resolution (e.g., 320×320 pixels) to facilitate subsequent input into object detection models and only focus on the game screen around the crosshair, thus reducing model overhead and preventing the detection of too many enemies. The resized image is then input into a trained visual detection model, such as the widely used YOLO. As illustrated in Figure 2, YOLO employs a convolution neural network (CNN) [36] for the feature extraction phase. Within the CNN, the image undergoes a series of convolutional and pooling layers. It generates multiple feature maps at different levels during the downsampling, each capturing distinct scales and aspects of the image, which is critical for identifying objects of varying sizes. Subsequently, the output feature maps are synthesized through an upsampling process and concatenated with prior layer feature maps, culminating in a comprehensive detection output. Once detection is achieved, YOLO provides the coordinates of the detected objects in the format (x, y, w, h), where (x, y) are the center coordinates, and w and h are the width and height of the bounding box, respectively. Cheaters exploit these coordinates to locate enemy characters, particularly targeting the head for more effective eliminations. The offset of this target from the center of the screen is then used to automatically adjust the aimbot's cursor, typically via Windows APIs (e.g., win32api and win32con) to enable precise and automated targeting.

2.2 Adversarial Attacks in Object Detection

Object detection models based on DNN are already very powerful, but it has been found that they can still be rendered ineffective by adversarial attacks. Adversarial attacks in object detection models typically involve carefully designed perturbations that are too subtle for the human eye to recognize but are effective in deceiving the visual model. These perturbations can be injected into the input images, causing the model to incorrectly identify non-existent objects, misclassify objects, or fail to detect objects altogether. The essence of these attacks lies in their ability to exploit the model's reliance on high-dimensional data and its linearity, thus revealing a critical vulnerability in object detection systems.

Some methods affect object detectors by adding noise to the entire image [12, 56], while others attack object detectors by adding patches into the image [30, 55, 64]. However, these methods either suffer from easily noticeable perturbations (patching), or the attack speed cannot keep up with the object detector's inference speed. Traditional object detection attack methods are no longer suitable for combating visual game cheating because it is impossible to predict which object detector will be used in advance. Hence, gradient-based white-box attack methods are difficult to transfer sufficiently. Although query-based black-box attacks typically exhibit better transferability, the substantial number of queries required for black-box attacks is another challenge for real-time attacks. Even assuming a 30 frames per second (FPS) game and a lightweight object detector like YOLOv5n with a 7ms inference time (for CPU) [22], the maximum acceptable query count is about 5. Generative attack methods can meet the real-time requirements [21, 54], but training a model that balances transferability and attack success rate is challenging (instead of lowering the mean average precision (mAP), the goal is to make the detection box of a specific target disappear). Therefore, to defend against visual aimbots, it is important to disable the target detector quickly while maintaining a high attack success rate without being noticed.

3 Overview

3.1 Threat Model

Scenario. In this paper, we discuss how to defend against visual game cheating, a scenario rarely discussed in existing anti-cheating technology. A visual aimbot captures the rectangular area around the mouse cursor in real-time from the game screen. The detection resolution is typically small (e.g., 320×320 pixels [44]), that is to maximize accuracy and prevent the mouse from erratic movements when multiple targets are detected simultaneously. The aimbot uses a cheating visual model to obtain the position boundary box of the character from the screenshot. After detection, the aimbot will automatically move the mouse to the identified target box and start shooting. This cheating method is non-invasive and relies only on game screens, so it can theoretically be applied to various game scenarios and devices. Especially in cloud games that only transmit video streams to players, visual game cheating is inherently suitable, while traditional cheating methods are completely unsuitable because they cannot obtain effective game data from memory or game processes.

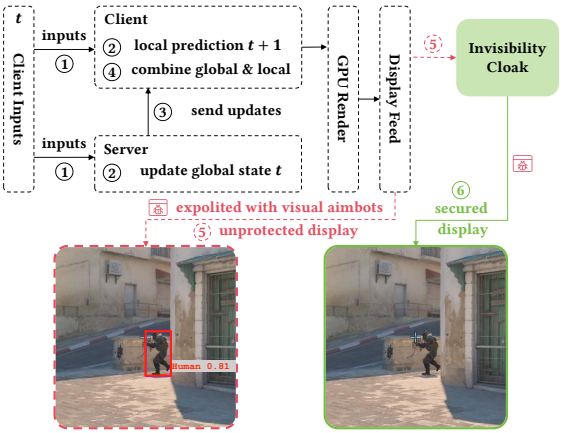

Figure 3: The functional stage of Invisibility Cloak under modern MMOGs architecture.

3.2 Invisibility Cloak

Figure 3 depicts the core conceptual framework of the Invisibility Cloak. Steps ① to ④ represent the standard architecture of modern Massively Multiplayer Online Games (MMOGs). After completing the rendering process, the visual output can be easily affected without protection, as shown in the step ⑤. Such unprotected displays are easily exploited by cheating software that uses visual information for unfair advantage. However, the pivotal innovation introduced by our approach is the inclusion of Invisibility Cloak after rendering. The Invisibility Cloak is designed to disrupt the effectiveness of detection models in visual game cheating. It disables visual aimbots by adding imperceptible perturbations to the rendered game screen before the aimbot performs object detection. As shown in step ⑥, the cheating methods cannot detect any targets on the screen. At the same time, a notable aspect of Invisibility Cloak is that the Cloak added is sufficiently subtle to remain undetected by players, so it does not affect the player's visual experience. In summary, Invisibility Cloak can provide strong anti-cheat protection while remaining *invisible*.

The Cloak Crafter is the core component of Invisibility Cloak system. It is specifically designed to receive incoming game frames that require cloaking and rapidly output cloaked frames. This invisibility makes it undetectable to both the game players and the aimbots. From the player's perspective, the gaming experience remains unchanged, as no discernible alterations are perceived. Conversely, for the aimbots, this cloaking disrupts their core functioning, which is the ability to accurately recognize opponents on the screen, so they can not move the mouse to complete the elimination.

3.3 Challenges for Proactive Defense

The swift refresh rates of modern First-person Shooter games [51] necessitate crafting the target frame as quickly as possible to complete the cloaking process, thus preventing the aimbot from assisting cheaters in completing elimination before becoming invisible. It is important to emphasize that, unlike video processing, our approach relies solely on current and past frames, because future frames remain indeterminate and cannot be accurately predicted. Consequently, there is no requirement for preemptive cloaking of future frames. The Cloaks must be crafted before the object is detected by the aimbots, ensuring real-time invisibility and effectively neutralizing the functionality of visual aimbots. In addition to the real-time rendering challenges, our cloaking solution must also demonstrate transferability. Given the wide variety of vision models that cheaters may employ, predicting the specific cheating architectures is impossible. Even within the same family of object detection models, such as the various iterations of YOLO, architectural differences are significant. Therefore, our Invisibility Cloak is designed to be as general as possible across a wide range of cheating models. Furthermore, in-game robustness must be considered, because each game presents a unique array of maps and backgrounds.

In summary, addressing the challenge of visual aimbots within the diverse and unpredictable realm of First-person Shooter games is a task of great complexity and significance. Invisibility Cloak demonstrates its indispensable value in preserving the integrity of competitive gaming environments with its swiftness, versatility, and resilience.

4 Cloak Crafter

Inspired by TOG [12], we designed Cloak Crafter to add imperceptible perturbations to the game screen in real-time, preventing the visual aimbots detection model from correctly detecting targets in the game. Overall, our objective is to devise a defensive perturbation; in this paper, we call it a *Cloak*. When applied to the original game imagery, this Cloak can address the challenges outlined in § 3.3, including real-time performance, imperceptibility, transferability, and robustness.

Problem Definition. Consider a sequential set of game screenshots denoted as $\mathcal{X} = \{x_1, x_2, \cdots, x_T\}$, where x represents a frame. Cheating players utilize an object detection model $\mathcal{M}^C$ as the cheating model, which takes game screenshots x as input and outputs the position, class, and confidence score $\mathcal{S}$ of the game objects. Our proactive defense aims to find a Cloak δ and add it to x so that it reduces $\mathcal{S}$. The process is formulated as follows:

$$\arg\min_{\delta} \mathcal{S} = \mathcal{M}^C(x+\delta), s.t., \|\delta\|_\infty < \varepsilon \quad (1)$$

where ε is the upper limit of the perturbation magnitude. The defense typically succeeds if $\mathcal{S}$ is below the threshold θ.

Cloak Crafter is comprised of two primary components. The first component involves finding a Universal Cloak which is similar to a universal perturbation [33] that can disrupt the ability of various cheating models to detect targets in different scenarios. The second component leverages an efficient

search mechanism based on momentum gradient optimization to refine and optimize this Cloak, ensuring its efficiency and effectiveness. This subsection will delve into the characteristics of Cloak Crafter and discuss how our approach systematically addresses the challenges outlined in § 3.3.

Transferability. Our investigation reveals that visual aimbots use different object detection models. Even within the same framework (such as the YOLO series), there is considerable variation in the architecture of different pre-trained models. Therefore, the training strategy for Cloak Crafter is designed to be model-agnostic, targeting a broad spectrum of visual detection architectures. To circumvent the potential issue of overfitting the Cloak to a single model, we use different proxy models in the training phase to find a Cloak. This strategy enhances the transferability of Cloak Crafter, ensuring its efficacy across a diverse array of object detection models employed in visual aimbots cheating.

Robustness. Beyond its transferability across different visual models, Cloak Crafter's robustness extends to its efficacy in diverse gaming scenarios and player settings. Different games have various maps, backgrounds, and resolutions, necessitating a universal perturbation to accommodate these variations. To achieve this, our training dataset includes a wide array of game scenes, encompassing different maps, special effects (e.g., smoke, Molotov), and scenes with varying numbers of characters and objects (e.g., animals, footballs). Additionally, dataset augmentation through resolution adjustments further ensures our Cloak's effectiveness across various settings. This strategy guarantees the universal applicability of Cloak Crafter, making it robust against changes in in-game environments and player preferences.

Imperceptibility. We use ℓ_∞ to control the perturbation size, which is the most popular and widely used norm [10, 32]. Although the ℓ_∞-norm constraint is more stringent, it makes perturbations less detectable by human eyes and enhances robustness against detection models that are overly sensitive to extreme features, thus increasing applicability in real-world scenarios. We observe that altering the position of the bounding box through perturbations is more challenging than reducing its confidence score. Therefore, our invisibility criterion is based on the confidence score of the predicted box falling below a set threshold rather than using the intersection over union (IoU) between the predicted box and the ground truth. This criterion requires less information from the model and avoids pre-annotating bounding box positions in the dataset.

Real-Time Performance. Given the high frame rate demands of modern First-person Shooter games, the deployment strategy is designed to insert pre-trained, static universal perturbation (Universal Cloak) in all game scenes, resulting in zero latency and a direct defense against visual cheating in most cases. Furthermore, refined by efficient momentum gradient search and strict query constraints, the Cloaks can be generated almost instantaneously. Then, these refined Cloaks are intervals deployed to the game frames. This deployment strategy ensures that Cloak Crafter maintains game flow by providing real-time defense without sacrificing game quality.

In the following subsections, we delve into the specifics of our methodology, first discuss the process of identifying the Universal Cloak (§ 4.1), followed by exploring how we optimize this Cloak across various cheating visual models (§ 4.2).

4.1 Universal Cloak Identification

In this subsection, we introduce how to find a Universal Cloak that can effectively defend against as many cheating models and game scenarios as possible. Next, we will gradually introduce the process of identifying a Universal Cloak. Since this process is completed offline, we temporarily do not consider the limitation of training time in this part.

Step 1: Initialization. We randomly initialize a noise δ_U with the same size as the input x. Each frame of game screenshot x used here is collected from different complex scenarios. Suppose we have K proxy visual models $\{M^1, M^2, \cdots, M^K\}$, which encompass various object detection models under different architectures. Thus, the initial input is $x+\delta_U$.

Step 2: Confidence Score Evaluation. Given the perturbed input $x+\delta_U$, the k-th proxy model M^k will produce a set of bounding boxes with associated confidence scores $S^k \in \mathbb{R}^N$, where N is the number of boxes. For anchor-based methods (e.g., YOLOv5 [50]), the confidence represents the probability that each box contains an object. For anchor-free methods (e.g., NanoDet [41]), it is the probability that each box is classified as the target category, usually *person* in First-person Shooter games. The process is formulated as follows:

$$\mathcal{S}^k = M^k(x+\delta_U) \tag{2}$$

Step 3: Loss Function Construction. Our goal is to minimize the confidence score of the cheating model when perturbing the inputs, ensuring the game target cannot be correctly recognized. Therefore, we use a binary cross-entropy (BCE) loss, setting all box confidence labels to 0, as follows:

$$\mathcal{L} = -\sum_{k=1}^{K}\sum_{i=1}^{N} log(1-s_i^k) \tag{3}$$

where $s_i^k \in \mathcal{S}^k$ is the i-th confidence score of S^k.

Step 4: Universal Perturbation Update. As the proxy models are fully accessible, we can update the universal perturbation using gradient information. The basic form is:

$$\delta_U = \texttt{Clamp}(\delta_U - \alpha \cdot \nabla_{\delta_U}\mathcal{L}) \tag{4}$$

where α represents the learning rate; $\texttt{Clamp}(\cdot)$ is the truncation function that constrains perturbations to have an ℓ_∞-norm below a threshold ε, typically set at 8/255 or 16/255 [62].

Next, we repeat steps 2 through 4 until the defense success rate of Universal Cloak on the validation set reaches a threshold or the loss $\mathcal{L}$ cannot be further reduced. Upon completion, we can obtain a Universal Cloak that can be statically

deployed for real-time protection, with the entire process conducted offline. It is visually unobtrusive to both players and cheaters, offering protection across various game scenarios and a wide range of visual aimbot detection models.

However, it must be acknowledged that due to differences in cheating model frameworks and their respective confidence scoring algorithms, the Universal Cloak is only a generic perturbation with robustness but is not tailored for any specific model or game scenario. Consequently, it may not perform optimally in all situations. Therefore, our next phase involves dynamically updating this Cloak in real-time, adapting to different cheating models and game scenarios encountered during gameplay to strengthen its defense mechanism further.

4.2 Cloak Refinement for Model Variability

In the dynamic environment of First-person Shooter games, where various cheating models and constantly changing game scenarios are encountered, the Universal Cloak identified in the preceding subsection may not always perfectly align with the current data stream. Consequently, we need a process to fine-tune the Universal Cloak for real-game environments.

Due to the online nature of this process, efficiency is the highest priority. To ensure Cloak refinement, we first satisfy the following conditions: (1) The number of query iterations is limited, typically constrained to 5 or fewer; (2) The proxy model must be lightweight and suitable for efficient inference. Thus, we assume a lightweight proxy visual model denoted as M, with the current game frame input denoted as x. The process is delineated into two steps.

Step 1: Universal Cloak Efficacy Assessment. First, we test whether the Universal Cloak δ_U can prevent the current proxy model M from correctly identifying the target object, i.e., whether the maximum confidence score $Max(\mathcal{S})$ is below the threshold θ (usually 0.4). If successful, we can directly use the Universal Cloak, avoiding additional refinement overhead.

Step 2: Conditional Cloak Refinement. If the universal perturbation is not effective, then we initialize the noise δ as δ_U and update the perturbation based on the query. Specifically, we repeat steps 2 to 4 of § 4.1, using only the M model and frame data x. Given the limited number of updates, we adopt a fast optimization scheme inspired by Adam [26], updating the initial learning rate α before each iteration as follows:

$$\alpha = \alpha_i \frac{\mu^t}{\sqrt{s(t)}} \tag{5}$$

where α_i is the initial learning rate, μ^t and $s(t)$ are the intermediate values in the iteration updates of the Adam optimizer.

4.3 Cloak Deployment Strategy

Overall, Cloak Crafter works by first assessing the success of Universal Cloak on the proxy model. Then, for Cloaks that require refinement, we query the proxy model to update them. Our deployment strategy consists of three parts.

Strategy 1: Universal Cloak Deployment. Universal Cloak is initially deployed as the default protective measure by game developers. It is pre-crafted offline and integrated into the game's rendering pipeline, ensuring zero latency during gameplay and providing basic protection for all frames. Note that Universal Cloak can be customized by scenarios (e.g. game maps) as well as regularly updated to ensure that it is not easily accessible to attackers.

Strategy 2: Interval Inserted Refined Cloaks. Given the need for high frame rates in modern First-Person Shooter games, where a comfortable gameplay experience starts at 60 FPS [27], Cloak generation speed often cannot match the game's rendering speed. To maintain smooth gameplay without sacrificing protection, frames are sampled at intervals for Cloak refinement. This means not all game frames will have refined Cloaks, potentially compromising defense on some frames. However, the primary goal is to significantly disrupt cheaters' reliance on visual aimbots. Cheaters use aimbots to gain an unfair advantage, enhancing their experience at the expense of other players. Our strategy ensures that even if some individual frames are not successfully defended, the overall efficacy of aimbot is greatly compromised. The user study (§ 5.8.1) indicates that the high accuracy of cheating tools is crucial, and our defense can substantially reduce aimbots' accuracy, leading cheaters to gradually abandon the aimbots.

Strategy 3: Deployment Environment. Refined Cloaks are generated based on the gaming application. For cloud gaming platforms, where graphics are server-rendered, the refined Cloak is securely generated server-side. For personal computer games relying on client-side rendering, Trusted Execution Environments (TEEs [20]) can be used to prevent Cloak modification or deletion.

5 Evaluation

We answer the following research questions:

- **RQ1.** How effective is our approach in proactively defending against vision-based game cheating methods (§ 5.2)?
- **RQ2.** Is our method transferable to various object detection models that might be adopted by cheaters (§ 5.3)?
- **RQ3.** How robust is Invisibility Cloak in mitigating the impact of different in-game scenarios (§ 5.4)?
- **RQ4.** How does each part of the Invisibility Cloak affect the defense effect (§ 5.5)?
- **RQ5.** How effective is our approach when cheaters try to counter our defense (§ 5.6)?
- **RQ6.** How effective is our approach in real-world games at preventing aimbots while ensuring invisibility (§ 5.8)?

5.1 Experimental Setting

5.1.1 System Configuration

Our experimental setup includes an Intel(R) Xeon(R) Gold 5418Y CPU with 96 cores and an NVIDIA GeForce RTX 4090 GPU with 24.564 GB of memory. This configuration, simulating a user client, enables a comprehensive evaluation of our defense mechanism against visual aimbots.

5.1.2 Data Collection

To evaluate the proposed method, we constructed two datasets, termed **A**nti-**C**omputer-**V**ision-**C**heats-**CS2** (**ACVC-CS2**) and **A**nti-**C**omputer-**V**ision-**C**heats-**C**ross**F**ire (**ACVC-CF**). These datasets consist of 72,150 consecutive screenshots from real matchmaking gameplay footage, each cropped to a resolution of 320×320 pixels, aligning with the default capture size for visual aimbots [44]. Specifically, the **ACVC-CS2** dataset contains 14,820 screenshots from actual gameplay in *Counter Strike 2*, while the **ACVC-CF** dataset includes 57,330 consecutive screenshots from *CrossFire*. TThe images were filtered to retain only those identifiable by visual aimbots. Details and characteristics of these datasets are outlined in Table 1.

5.1.3 Proxy Model

We first selected the latest open-source visual aimbot tool [44] as proxy models for simulating cheating models. This tool uses YOLOv5 series models, which are anchor-based and widely recognized as effective object detection models. We also considered NanoDet [41], which stands out in the anchor-free category as a lightweight yet powerful model, boasting 5.5k stars on GitHub. Depending on experimental goals, specific models from the YOLOv5 and NanoDet series were used as proxy models for different evaluations. The performance of our Cloak Crafter on these diverse models underscores its overall effectiveness and adaptability in proactively defending against visual aimbots across different detection frameworks.

5.1.4 Universal Cloak Training

According to our approach described in section 4, we select the top 10 widely used models from YOLOv5 series [22] to train two Universal Cloak on two datasets. During training, we observed that using more models generally improves the Universal Cloak's transferability. However, conflicts between the loss functions of different models make it impractical to increase the number of training models indefinitely. Therefore, we selected models from the YOLOv5 series to ensure a high defense success rate and satisfactory transferability.

5.1.5 Baselines

In our evaluation, we focus on the performance of Cloak Crafter, as it is the primary mechanism to achieve defensive capabilities for Invisibility Cloak. Note that there is no dedicated defense method against visual game cheating. Therefore, to rigorously evaluate Cloak Crafter's effectiveness and efficiency, this section compares its defensive performance with state-of-the-art (SOTA) adversarial attack methods, namely RayS [10], DAG [56] and TOG [12]. Among them, RayS and TOG represent black-box and white-box models, respectively, while DAG is widely acclaimed for its unique approach, which has a very excellent performance. Comparing Cloak Crafter with these models can comprehensively evaluate the efficiency of our method.

5.1.6 Evaluation Metric

In assessing Cloak Crafter, we adopt a multi-dimensional metric, focusing on efficiency, effectiveness, and impact on player experience. These metrics are essential for validating the practical applicability of our approach in mitigating visual aimbots in gaming scenarios.

- ***Query:*** The number of queries to the object detection model that are required to generate a Cloak is a critical measure of computational efficiency. A lower Query count indicates a more efficient algorithm, which is essential for real-time applications.
- ***Frames Per Second (FPS):*** The FPS rate is indicative of the number of frames that Cloak Crafter can process per second. Higher FPS rates signify greater efficiency and smoother integration into gameplay. It should be emphasized that, as we mentioned in § 4.3, the Cloak can be deployed at intervals, and the FPS rate here is the crafting speed of the refined Cloak, not the actual game frame rate.

- ***Defense Success Rate (DSR):*** The effectiveness of Cloak Crafter is quantitatively evaluated by its defense success rate (DSR), which measures the proportion of instances where the method successfully prevents visual cheating attempts.

- ***Structural Similarity (SSIM):*** SSIM [53] is employed to predict the perceived quality of digital images or videos. A higher SSIM score indicates that the Cloak's impact on visual quality is negligible. Additionally, we conduct practical impact analysis in § 5.8 and provide demo displays to further demonstrate the Cloak's minimal visual impact.

5.2 Defensive Performance

To tackle **RQ1**, Table 2 demonstrates the performance of different defense methods on the **ACVC-CS2** and **ACVC-CF** datasets, using imperceptible random noise as a baseline to compare Cloak Crafter and three other SOTA methods. Because random noise is static, it does not have Frames Per Second (FPS) or Query metrics. As shown in the table, random noise exhibits a high SSIM, indicating good visual quality. However, its defense success rates (DSR) are consistently poor across all models and datasets, with most DSRs in the single digits. This demonstrates that random noise is not an effective defense strategy. Cloak Crafter consistently achieves a 100% DSR across all tested anchor-based cheating models (YOLOv5 variants), where RayS shows significantly lower DSRs. Although DAG and TOG display high DSRs, they still fall short of Cloak Crafter's complete success. Even when tested on NanoDet-Plus-m, an anchor-free model not used in training, Cloak Crafter shows excellent DSR, comparable to other methods. Additionally, Cloak Crafter demonstrates remarkable efficiency, reflected in its high FPS rates and low Query counts. By constraining the number of queries, Cloak Crafter's FPS metrics can achieve dozens of times higher than the other defense models. This efficiency suggests that deploying the other three defense methods directly in actual gameplay could significantly hinder the game's fluidity, causing noticeable lag. In contrast, Cloak Crafter's high FPS allows quick generation of refined Cloaks based on the Universal Cloak, covering most of the game frames by our deployment strategy (§ 4.3). Besides, the SSIM results indicate that our method maintains high image quality. However, the perceptibility of perturbations is not solely dependent on SSIM; in human visual perception, large areas of noise with consistent perturbations are more noticeable, even if individual pixel perturbations are small. This explains why RayS has a high SSIM score, but its visualization results are easily noticeable. Please refer to § 5.7.2 for visualization examples.

Furthermore, Table 3 highlights the superior adaptability of Cloak Crafter. We compared different defense models using the same series of visual models as both proxy and cheating models. Although this is a basic transferability test, the table shows that all other defenses, except Cloak Crafter, exhibit markedly low DSR and FPS when tested on YOLO, indicating their failure to protect against even slight model variations. Although RayS achieves 100% DSR on NanoDet, its FPS is so low that it requires hundreds of queries to find a suitable perturbation, which is impossible for real-world applications. Conversely, Cloak Crafter consistently maintained high DSR and FPS. This performance evaluation shows that Cloak Crafter can ensure real-time defense without compromising gameplay fluidity, providing invisible protection. This is in sharp contrast to the other three defense methods.

5.3 Transferability Evaluation

Following our preliminary horizontal transferability tests, we conducted a comprehensive vertical evaluation to delve into Cloak Crafter's transferability, addressing **RQ2**. It's acknowledged that achieving high transferability in adversarial attacks, especially in object detection, remains a significant challenge with no existing method attaining notable success [8, 54]. However, for the specific application of defending visual aimbots, our defense success is not entirely dependent on perfect transferability; rather, it aims to disrupt cheaters' reliance on aimbots, as we mentioned in § 4.3. Against this backdrop, Cloak Crafter exhibits a commendable performance.

Table 4 presents Cloak Crafter's transferability across different models. We select the lightest and most commonly used models, YOLOv5n and NanoDet, as proxy models to ensure the practicality of transferability discussion. Because our Cloak is trained with anchor-based visual models, the DSR test results on anchor-free cheating models such as Faster RCNN, RTMDet, and NanoDet are not as high but still acceptable. The observed data indicate that Cloak Crafter performs well when YOLOv5n is used as the proxy model, achieving an impressive average FPS of 63.67. On the other hand, using NanoDet as the proxy model requires more queries, resulting in a lower FPS. Nevertheless, the overall performance remains strong, with an average DSR of 52.71 and an average FPS of 41.62. These metrics highlight Cloak Crafter's efficiency and transferability across different model architectures, demonstrating its potential for broad real-world applications.

5.4 In-Game Robustness

To answer **RQ3**, we scrutinize Cloak Crafter's in-game robustness through three experiments. These evaluations cover its adaptability to various game maps, effectiveness against single and multiple enemies on-screen, and consistency across different screen resolutions. We use a series of YOLOv5 models according to the popular open-source cheating project [44] to simulate the cheating models. This comprehensive assessment aims to validate Cloak Crafter's reliability and effectiveness in diverse gaming scenarios, ensuring its robust defense mechanism against visual aimbots in realistic conditions.

*: Anchor-free models.

5.4.1 Robustness in Varied Game Scenarios

In this robustness test, we evaluated Cloak Crafter across 9 maps in CS2 and 7 in CF, using three distinct proxy models for each game. The results, detailed in Table 5, reveal consistently high DSRs across all proxy models. YOLOvx6 achieved an exceptional average DSR of 99.92% across 16 maps, while the other two models also exceeded 70% DSRs on average. Furthermore, Cloak Crafter maintained a stable FPS of around 30 in all maps. These outcomes affirm the excellent versatility and operational effectiveness of Cloak Crafter in various maps and game scenarios across different games.

5.4.2 Performance Stability with Single/Multiple Object

Table 6 demonstrates Cloak Crafter's performance across scenarios with varying numbers of characters visible on screen, specifically against popular YOLOv5 series models used in cheating. Note that here we select the most powerful model, YOLOv5x6, as the proxy model to illustrate the improvement in transferability from a powerful proxy model. Similar to the game scenario robustness test, Cloak Crafter performed well on all tested cheating models, maintaining stability whether

Table 5: Robustness of Cloak Crafter across different game scenarios and maps with YOLOv5x6 as a cheating model.

*: The baseline resolution.

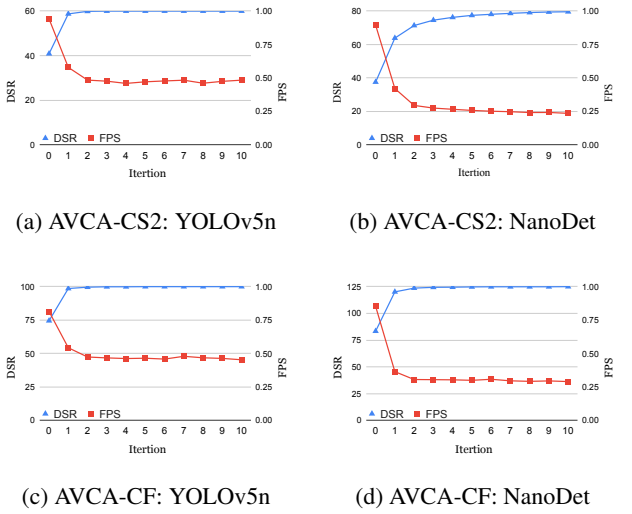
one or multiple characters were present. These results show that Cloak Crafter can consistently operate in real-world gaming scenarios, even in complex multiplayer battles.

5.4.3 Consistency Across Different Resolutions

This subsection delves into Cloak Crafter's effectiveness across varying game resolutions, recognizing that players employ diverse settings in real gameplay. By simulating different screen resolutions through image resizing, with a baseline of 320×320, we rigorously tested Cloak Crafter's defensive capabilities. The results, detailed in Table 7, indicate that Cloak Crafter maintains its performance without significant degradation, whether at higher or lower resolutions than the baseline. It is worth mentioning that our method demonstrates enhanced efficacy in scenarios of image magnification, surpassing its performance in reduction contexts.

5.5 Ablation Study

In this subsection, we examine the critical components of our Invisibility Cloak's efficacy, including the necessity of Universal Cloak, the choice of proxy model, initialization parameters, and the noise amplitude to answer **RQ4**.



5.5.1 The Effect of Proxy Model and Universal Cloak

We first discuss the impact of Universal Cloak and different local proxy models. Since our approach is based on the successful defense of the proxy model with Invisibility Cloak, the generalization of the local model is crucial in our approach.

Table 8: Performance comparison of different proxy models.

Dataset	Proxy Model	w/o Universal Cloak			w/ Universal Cloak		
		DSR(%)	FPS	#Query	DSR(%)	FPS	#Query
AVCA-CS2	YOLOv5n	99.80	19.19	2.17	100.00	40.14	1.51

(c) AVCA-CF: YOLOv5n (d) AVCA-CF: NanoDet

Figure 4: Variation of DRS and FPS with the number of initialization iterations.

We believe game cheaters prefer using powerful and widely used lightweight models such as YOLOv5n. Therefore, we use this model to simulate the cheating model in our experiments. As shown in Table 8, our investigation employs a variety of proxy models to compare their performance with and without our Universal Cloak. The results show that, the presence of the Universal Cloak consistently enhances the performance across all evaluated models, emphasizing its importance in our defense approach. Besides, when the proxy model has a similar architecture to the cheating model, such as the YOLOv5 series, the generalization of the proxy model is better. Additionally, it can be deduced that using a more powerful proxy model leads to better transfer defense, such as the better transfer performance of YOLOv5x6 compared to YOLOv5x in the table. Therefore, the results show that when selecting a proxy model, we should choose a model series that cheaters are more likely to choose and a more powerful model, resulting in better invisibility performance.

5.5.2 Initialization

In this subsection, we explore the influence of two hyperparameters set during Cloak Refinement § 4.2. Since the

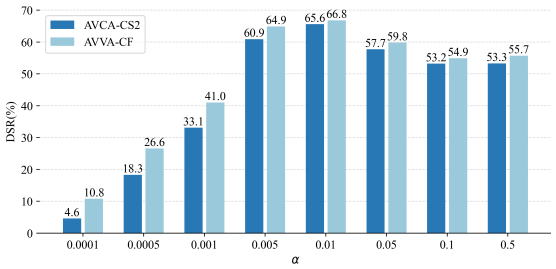

Figure 5: The impact of learning rate α on DSR.

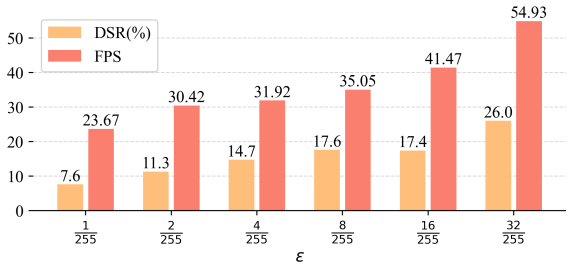

Figure 6: The impact of epsilon ε on DSR and FPS.

refinement process must be completed in real-time, these hyperparameters significantly impact the final performance.

Firstly, we discuss the maximum iteration during refining. When encountering bad cases, an increase in the maximum iterations correlates with an augmentation in the defense duration (although from the Table 2 to Table 7, the results show that in most cases, only 1-3 queries are needed for successful defense). We select two proxy models of different architectures and the same cheating model. Figure 4 shows that establishing an upper limit of approximately 5 iterations ensures the preservation of a Detection Success Rate (DSR) close to 100% while also maintaining a high Frames Per Second (FPS) rate. A further increment in iterations results in a marginal enhancement in DSR at the expense of a reduced FPS. Consequently, if the DSR satisfy the minimum criteria, it is advisable to refrain from excessive iteration limits to prevent diminishing returns in terms of performance.

We then discuss the impact of learning rate α on Cloak Refinement. We choose YOLOv5n as the proxy model and YOLOv8n as the cheating model without a Universal Cloak. Note that we fixed the number of 20 iterations without an early stop to more clearly show the effect of the learning rate on DSR. As shown in Figure 5, the results show that a learning rate of 0.1 or 0.005 is appropriate. The reason for choosing 0.005 as the default is that we want to minimize the size of the Cloak to make it imperceptible without affecting DSR.

5.5.3 Amplitude of Noise

Finally, we explore the relationship between the size of the Cloak and its performance metrics. Typically, noise below 8/255 epsilon (ε) is not easily detectable by human eyes in RGB images. In our ablation experiments, we set different Cloak epsilon values as defined in Equation 1. Figure 6 demonstrates how varying the maximum ℓ_∞-norm constraint (ε) of the Cloak affects the DSR and FPS on the AVCA-CF dataset. Although a larger-sized Cloak has a higher DSR, it also means a greater impact on the image. While maintaining satisfactory FPS, we need to ensure a stable DSR and that the Cloak remains imperceptible to the player. In this experiment, we also chose YOLOv5n as the proxy model and YOLOv8n as the cheating model without Universal Cloak, and we fixed the number of iterations to a default of 5 with an early stopping criterion. The results show that setting ε to 8/255 is more appropriate, with a sufficiently high DSR without a significant decrease in FPS. Notably, when ε is set to 16/255, the DSR for transfer defense actually decreases, which means that a higher ε does not necessarily improve Cloak transferability.

5.6 Adaptive Attack

To address **RQ5**, we examine the effectiveness of our approach when cheaters realize the Invisibility Cloak and attempt to counteract it. First, we employ a straightforward experiment that adds random noise before and after the Cloak to evaluate its robustness to such noise. As shown in Table 9, it indicates that random noise impacts the DSR by less than 5%. In most cases, Cloak Crafter maintains a DSR of over 95% while achieving satisfactory FPS and Query performance.

Table 9: The performance of Cloak Crafter under basic adaptive attack using random noise.

Dataset	Cheating Model	Pre-Cloak Random Noise			Post-Cloak Random Noise		
		DSR(%)	FPS	#Query	DSR(%)	FPS	#Query
AVCA-CS2	YOLOv5n	100.00	64.77	1.87	97.20	54.86	1.66
	YOLOv5s	100.00	54.01	2.10	94.80	49.40	1.80
	YOLOv5m	100.00	34.10	2.38	90.50	33.53	2.08
	NanoDet-Plus-m*	96.70	14.02	2.57	78.00	15.17	2.44
AVCA-CF	YOLOv5n	99.90	64.77	1.77	98.60	77.57	1.53
	YOLOv5s	100.00	52.55	2.00	98.20	71.75	1.62
	YOLOv5m	99.90	46.38	1.93	97.90	58.04	1.62
	NanoDet-Plus-m*	99.80	26.63	1.88	94.40	29.91	1.72

*: Anchor-free models.

Additionally, we conduct further adaptive attack evaluations. We fine-tune the visual aimbot [44] on our datasets and perform adversarial training with protected samples on top of the fine-tuned models to simulate cheaters' resistance. Note that we use 20% of the datasets for adversarial training because we assume cheaters have much fewer collected samples than protectors. As shown in Table 10, adversarial training reduces the DSR by less than 20% on the AVCA-CS2 dataset, yet it fails to attack our defense on the AVCA-CF. We believe this is because CF has simple scenarios and consistent graphics, which results in only a limited improvement of the cheating model's robustness after adversarial training. Notice that when $\varepsilon = 8/255$ on the AVCA-CF dataset, the DSR is slightly below 100%. This could be attributed to fine-tuning, which improves the cheating model's performance, resulting in a more challenging situation for our Cloak. However, the

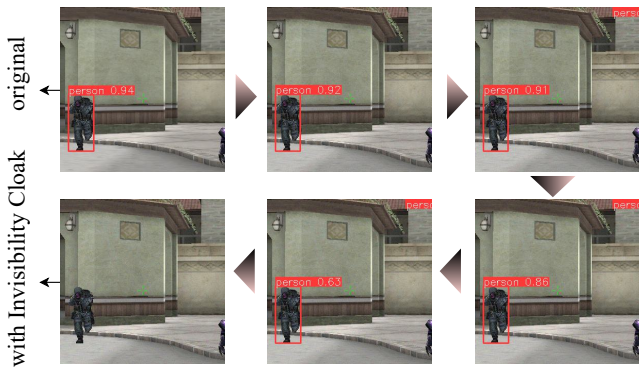

Figure 7: The refinement process of Invisibility Cloak in CF.

simple scenarios in CF conflict with adversarial samples [14], which allows our DSR to instead reach 100% after adversarial training. Further discussion is provided in section 6.

Table 10: Performance under adaptive attack using adversarial training with fine-tuned YOLOv5n as a local proxy model.

Dataset	Cheating Model	ε = 8/255			ε = 16/255		
		DSR(%)	FPS	#Query	DSR(%)	FPS	#Query
AVCA-CS2	YOLOv5n+	100.00	31.30	2.26	100.00	86.05	1.05
	YOLOv5n+AT	81.70	31.30	2.26	86.00	93.49	1.05
AVCA-CF	YOLOv5n+	99.80	19.24	3.22	100.00	65.25	1.32

5.7 Case Study

5.7.1 The Refinement Process of Invisibility Cloak

In this subsection, we first visualize the refinement process of our Invisibility Cloak through a demo in Figure 7. As we describe in § 4.3, the deployment of Universal Cloak can achieve real-time defense with no latency, but some bad cases still require iterative refinement of the Cloak. As a result, after we craft a Universal Cloak, the refinement process is very important for practical applications. Figure 7 visualizes this process; it demonstrates the bounding box's confidence score of the target in the image keeps decreasing through our refinement until the cheating model cannot detect it.

Next, we discuss how to craft a Cloak for an input game frame. To achieve this, we reduce the confidence score of the bounding box detecting the target in the frame by minimizing the loss function (Equation 3). Figure 8 illustrates the decrease in loss during the Cloak searching process. The notations in Figure 8 indicate successful defense of YOLOv5n and YOLOv8n at the 2nd and 7th iterations, respectively. Here, we fixed the number of iterations to 20 without early termination. In our experiments, we observed that among all samples with successful YOLOv8n defense, only one sample preceded the successful YOLOv5n defense, accounting for less than 1% of the total. This indicates the difficulty of defending against unknown models using white-box gradient information. Although we can use multiple commonly used white-box cheating models to design loss functions and co-construct the gradient, the forward and backward overhead in these additional models is impractical for real-time defense scenarios. Therefore, in our approach, the Universal Cloak described in section 4 effectively addresses the challenge of generalizability.

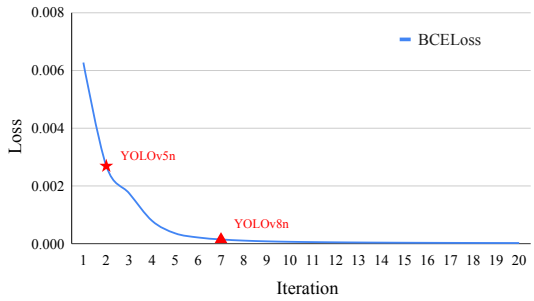

Figure 8: The loss decreases with iterations until the cheating model is successfully defended.

5.7.2 Normal/Cheating Player's Perspective

Figure 9 presents visualization examples of different methods under the ℓ_∞-norm constraint with $\varepsilon = 8/255$ in real game scenarios. It can be observed that despite having the same constraint on individual pixel perturbations, different methods yield different visualization results. In particular, although RayS has a higher SSIM, as shown in Table 2, it exhibits large areas of similar perturbations, making it more noticeable to players. While our method does not outperform others in the SSIM evaluation metric, the invisibility of our Invisibility Cloak is evident from the figure.

5.8 Practical Impact Analysis

We perform user study and real-world effect verification to answer **RQ6** and demonstrate that our Cloak is not perceived by players, thereby not impacting the game experience.

5.8.1 User Study

We conduct a paid anonymous survey in the form of a questionnaire to evaluate the **indistinguishability** and **naturalness** of game screens protected by our Cloak (randomly selected from a subset of experimental data). The data used were refined Cloaks adhering to the standards outlined in section 4. All 122 participants are over 18 years old, and 80% of them have shooting games experience. We followed best practices for ethical human subjects survey research, and we did not collect unnecessary personal information. Preliminary research indicates that it is challenging for people to determine whether a game scene has been added with Cloaks.

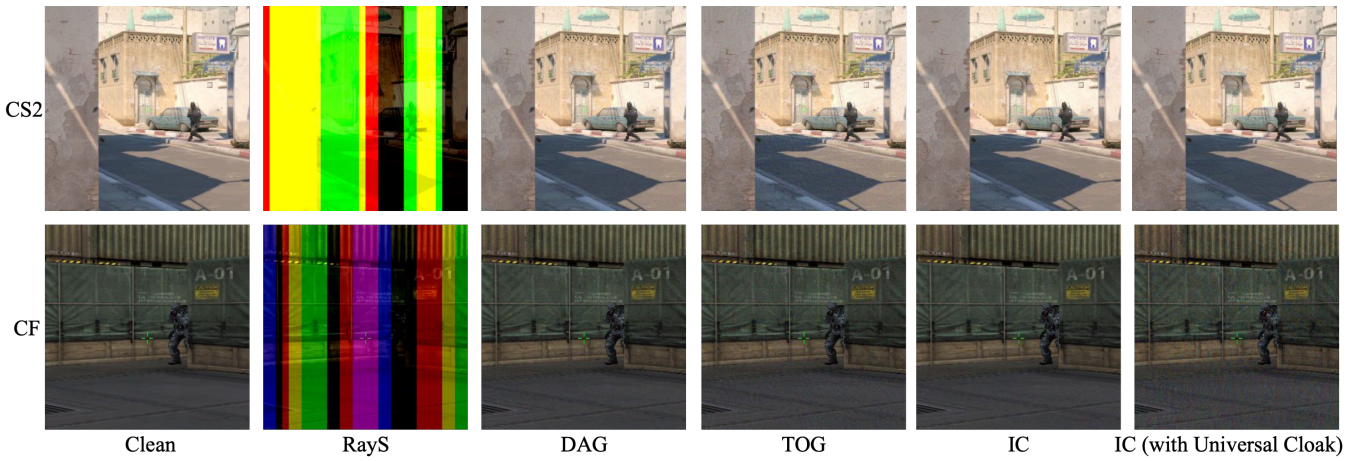

Figure 9: Visual examples of different methods in two popular First-person Shooter games, CS2 and CF, under the ℓ_∞-norm constraint with $\varepsilon = 8/255$. IC denotes our Invisibility Cloak.

Indistinguishability. The study consists of two main types of tasks to evaluate the indistinguishability of the protected game screen. The first type involved binary choices, where participants were asked to select a true game scene between two options: one with the Cloak and the other without any modifications. The total accuracy for this task was 47.87%, which is lower than the random guess threshold of 50%. The second type of task required participants to judge the authenticity of pairs of game scenes, with four possible combinations: both true, both false, one true and one false (in either order). The overall proportion of correct answers was 23.77%, below the random guess threshold of 25%. This indicates that participants cannot perceive our Cloak, thereby demonstrating the Cloak's indistinguishability.

Naturalness. We use the task of choosing the naturalness of the game screen to evaluate the protected game screen's naturalness. Participants are asked to choose the naturalness of a randomly selected screen (both the original screen and the protected screen) from five options, as shown in Figure 10. The Pearson correlation coefficient between original and protected frames is 0.983 (with $p = 0.0027 < 0.05$). This provides strong statistical evidence that the correlation between original and protected frames is not accidental, illustrating the naturalness of our Cloak.

Figure 10: Results of the user study on naturalness.

Additionally, we use multiple-choice questions to assess participants' perceptions of the cheat's reliability. Only 9.3% of participants would continue using a visual aimbot when its success rate is below 70%, while 27.8% indicated that this accuracy rate needed to be at least 90%. These findings highlight the importance of aimbot accuracy for users, suggesting that even minor performance deviations could lead to user abandonment, consistent with the discussion in § 4.3.

5.8.2 Real-World Effect Verification

Evaluating our method in real-world scenarios involves the activation of visual aimbots within genuine game matches. To address ethical concerns and control variables, we adopted video feeds instead of directly implementing the SOTA visual aimbot [44] in the game. The two most effective settings among all Universal Cloak configurations for CS2 and CF, pre-trained with different combinations of YOLOv5, were selected and superimposed onto the corresponding real-time game video feed for live verification purposes.

Table 11 shows two open-sourced real-world whole-match video feeds of CS2 [4] and CF [5] used for the evaluation. Note that this additional dataset is completely different from the previous evaluation dataset. In this experiment, over approximately 39.5 minutes of gameplay for CS2 and 29.4 minutes for CF, thousands of auto-aim and aimbot detections were reduced by three orders of magnitude. By using our Invisibility Cloak, auto-aim and aimbot detections were controlled to single digits, effectively preventing visual cheating.

Table 11: Anti-Cheat effect verification with real-world match examples.

Game	Duration(sec)	w/o Invisibility Cloak		w/ Invisibility Cloak	
		#Detection	#Auto-aim	#Detection	#Auto-aim
CS2	2,370.61	3,860	3,549	**5**	**5**
CF	1,765.69	2,394	2,197	**2**	**2**

[1] **#Detection**: the number of successful detections by aimbot;
[2] **#Auto-aim**: the number of successful auto-aiming by aimbot.

6 Discussion and Limitation

In this section, we explore avenues for future enhancement. Despite § 5.3 demonstrating the superiority of our method over other baselines and its defense effectiveness, there is potential for further optimization of our Cloak.

Generalization of Universal Cloak. Since we can only use a limited number of models to train our Universal Cloak, yet need to contend with an unknown and infinite variety of cheating models, incorporating regularization into the training process may improve its generalization performance.

Transferability of Cloak Refinement. For instance, we observe that YOLOv8 often requires more iterations than YOLOv5 for a successful defense. Setting a low query count to expedite Cloak generation led to decreased defense effectiveness. This indicates that adjusting the number of iterations based on different cheating models and FPS requirements could improve defense effectiveness and transferability.

Adaptive Attack. Despite the results from § 5.6 showing that adaptive attacks cannot significantly break through our Cloak, if the cheater collects sufficient adversarial samples and adopts more targeted fine-tuning strategies, our defense may become vulnerable. Therefore, we can design inducive perturbations for the fine-tuned model (such as identifying additional wrong targets), which we leave as future work.

7 Related Work

In this section, we introduce two types of anti-cheating techniques: detection-based and prevention-based.

Detection-based techniques predominantly employ conventional security measures to passively identify anomalies, such as irregular processes, memory reads and writes, and the signature codes of cheating malware [16, 31]. Contemporary advancements have incorporated machine-learning and deep-learning strategies for statistical and behavioral anomaly detection [2,11,17,23,25,29,34,37,63]. Additionally, computer-vision-driven methods are utilized to identify illicit overlays or patterned trajectories employed by cheat scripts [24, 48]. Although these approaches are noted for their effectiveness and efficiency in cheat detection, they inherently lag behind cheating activities because the infractions and consequent damages have already occurred.

In contrast, prevention-based techniques are active in nature. However, they are still in the nascent stages of development, with limited related literature for reference. Traditional methods, dating back a decade, focused on core data access control, authentication, and network-based protections [4,57]. More recent efforts have explored using Trusted Execution Environments to safeguard core data and applying randomized binaries for preventive measures [3,6,38]. However, these approaches often require specific hardware, such as Intel SGX enclaves, limiting their applicability to all users. Furthermore, some approaches can not effectively address certain attack methodologies, such as the DLL injection, which remains prevalent in contemporary cheating strategies.

For visual aimbots, the traditional detection and prevention methodologies face inherent limitations due to the unique nature of these novel cheats. Unlike conventional cheating aimbots that manipulate game memory or data, visual aimbots operate by analyzing the visual output of the game, rendering traditional game memory-related detection methods inapplicable. Similarly, traditional prevention methods are ineffective against visual sights because these cheats do not require altering game files or exploiting network vulnerabilities, thus bypassing the usual security checkpoints. Therefore, the only feasible approaches to counter visual aimbots are detection-based methods such as player behavior classification [2, 17, 25, 29] and screen anomalies detection [23, 34, 63]. However, for the former, these methods could misclassify some high-level players as cheaters, resulting in a very low accuracy rate. Moreover, such methods lack explainability and thus require additional human review. For the latter, visual aimbots can hide the detection box on the screen, which means there will be no anomaly on the screen at all.

Given these challenges, there's a clear gap in the effectiveness of existing anti-cheat approaches against visual aimbots. This emphasizes the need for a novel solution to proactively counteract advanced cheating strategies without relying on after-the-fact detection or extra human verification. In response, our work introduces *Invisibility Cloak*, a proactive defense mechanism specifically designed to address the challenges of visual aimbots. Moreover, although our approach may impact computer-vision-driven detection methods due to the Cloak perturbations, it can still work in parallel with traditional detection methods. By employing Invisibility Cloak for proactive defense, we can block most visual aimbots. Subsequently, detection-based techniques can identify and address the few remaining cheats, thus ensuring comprehensive protection and enhancing the robustness of anti-cheat systems.

8 Conclusion

In this paper, we introduce *Invisibility Cloak*, the first proactive defense framework against visual aimbot cheating in First-person Shooter games, which uses imperceptible perturbations to disrupt computer vision-based aimbot detection without impairing player experience. Our comprehensive evaluation across various game scenarios, object detection models, and real-world investigation demonstrates the technique's effectiveness, efficiency, and adaptability. Invisibility Cloak addresses the challenge of visual aimbots, a problem that traditional anti-cheat methods fail to solve, marking a significant advancement in ensuring game security. This innovative approach offers a new paradigm for combating the inevitable rise of AI-driven cheating techniques in gaming. Our method guarantees real-time defense without compromising the fluidity of gameplay, achieving invisible protection.

Abstract

We develop `5GBaseChecker`— an efficient, scalable, and dynamic security analysis framework based on differential testing for analyzing 5G basebands' control plane protocol interactions. `5GBaseChecker` first captures basebands' protocol behaviors as a finite state machine (FSM) through black-box automata learning. To facilitate efficient learning and improve scalability, `5GBaseChecker` introduces novel hybrid and collaborative learning techniques. `5GBaseChecker` then identifies input sequences for which the extracted FSMs provide deviating outputs. Finally, `5GBaseChecker` leverages these deviations to efficiently identify the security properties from specifications and use those to triage if the deviations found in 5G basebands violate any properties. We evaluated `5GBaseChecker` with 17 commercial 5G basebands and 2 open-source UE implementations and uncovered 22 implementation-level issues, including 13 exploitable vulnerabilities and 2 interoperability issues.

1 Introduction

5G devices are pivotal in unlocking the full potential of 5G cellular system's unique features— secure, faster, massive, and ultra-reliable low-latency data communications. These features, powered by significant paradigm shifts across all layers of cellular systems from previous generations of cellular networks, have enabled a plethora of new services, including mobile broadband, augmented reality, and mission-critical services, including public safety and emergency responses. The security of these services critically hinges on the security of 5G devices, also known as modems or basebands. Therefore, 5G baseband implementations must satisfy the security and privacy requirements mandated by the specifications. Failure to satisfy these requirements may result in compromised devices, which often serve as entry points for more catastrophic attacks on broader systems relying on 5G technology, such as healthcare and transportation. Also, the global nature of 5G supply chains further emphasizes the need for robust security, as vulnerabilities introduced at any point in the manufacturing process of 5G devices can have far-reaching consequences. However, due to the extensive volume, complexity, and ambiguities of 5G specifications, achieving an error-free and secure implementation remains a formidable challenge. Since manually analyzing large and complex implementations of 5G basebands is error-prone and time-consuming, *we aim to develop an automated technique to reason about the security and privacy of 5G baseband implementations.*

Only a handful of approaches [15, 58] have attempted so far to analyze 5G basebands. A majority of them, however, merely extend the black-box-based testing schemes developed for analyzing previous generations of cellular devices [15, 42, 44, 50, 51, 53, 54, 58]. Among those, some approaches [15, 51, 53, 58] follow semi-automated techniques, i.e., they manually design test cases by reading the specifications, whereas some others [50] require a reference state machine as a testing oracle to detect logical bugs leading to security flaws. Manually designing test cases is, however, laborious, error-prone, and ineffective in testing a broad range of security-critical behaviors of complex 5G basebands. Nonetheless, the lack of a reference state machine by the cellular standard body, i.e., the Third Generation Partnership Project (3GPP) [1], necessitates the manual construction of an oracle in most prior works, a process that is also both time-consuming and prone to errors. Contrary to black-box schemes, reverse engineering-based analysis [31, 43, 45] requires an enormous manual effort and expertise that cannot be easily transferred to the devices of other models and vendors. This leaves the massive and ubiquitous deployments of 5G devices largely untested and potentially vulnerable.

In this paper, we, therefore, aim to improve the sub-optimal state of the existing works and develop a scalable and automated black-box security analysis technique dubbed `5GBaseChecker`. We design `5GBaseChecker` based on *automata learning* and *differential testing* principles and thus obviates constructing hand-crafted test cases or capturing reference state machines. Performing security analysis in a black-box fashion makes `5GBaseChecker` agnostic to the

basebands' internal details and underlying microprocessor architecture, and thus makes this framework flexible to be used across different models and vendors of 5G basebands.

At a high level, 5GBaseChecker employs differential testing, in which if two basebands produce two different output sequences for the same input sequence, one of them may violate the security specifications, with the specific one yet to be determined. This approach sidesteps the challenge of manually crafting a reference state machine to serve as an oracle. Besides, rather than manually crafting or arbitrarily searching for deviation-inducing input sequences, 5GBaseChecker first systematically learns the finite state machines (FSMs) of 5G baseband devices in a black-box manner and then checks for differences in the extracted FSMs through differential testing. Finally, 5GBaseChecker uses the deviations as guidance to extract properties from the specification and automates the process of analyzing similar deviations. It also eliminates the need for manually identifying properties prior to testing.

To construct an FSM from 5G baseband implementation, we develop a novel *hybrid and collaborative FSM learning* technique called StateSynth. It combines *passive automata* and *active automata* learning by capitalizing on their strengths, i.e., the ability to learn from traces without executing time-intensive over-the-air queries (passive) and to explore deeper state space (active), and by mitigating their limitations, i.e., poor coverage of learning and a prohibitively high amount of queries and time to construct an FSM. To achieve this, StateSynth first synthesizes an initial FSM of a 5G baseband using the passive automata learning and uses the synthesized FSM to bootstrap the active automata learning phase. This approach helps StateSynth reduce a high number of queries that would otherwise be required by a standalone active learning technique.

Although this hybrid FSM learning minimizes queries and time, still a major challenge for active automata learning is the time-consuming *hypothesis validation* stage. During this stage, the learner requires a large number of *equivalence queries* to identify a *counterexample*, which signifies that the hypothesis model inferred through *learning queries* in the *hypothesis construction* stage is not equivalent to the System Under Learning (SUL) and requires further refinement until no counterexample is observed. StateSynth handles this challenge by introducing *collaborative learning* that utilizes the following insight. The basebands from different vendors follow the same protocol specification; hence, the counterexamples observed during other basebands' FSM learning may serve as potential counterexamples for the current baseband. Based on this, StateSynth first checks if the counterexamples identified for other basebands can be reused for the current baseband under learning. Thus, by learning from each other's counterexamples, StateSynth significantly reduces the total number of queries to learn complex and large 5G FSMs. Although a few prior works [35, 39] attempted to use automata learning for analyzing implementations, they suffer from scalability challenges due to their straightforward applications of active automata learning on the target device. In contrast, 5GBaseChecker's hybrid and collaborative learning mechanism significantly enhances 5GBaseChecker 's efficiency and scalability in constructing FSMs for 5G devices.

We also design DevScan, which takes the extracted FSMs as inputs, pairwise compares them, and identifies unique paths from the initial state to the state where the deviation happens. Unlike prior works [35,39], which can only find a small subset of deviating paths, we propose a *graph traversal scheme* that enables DevScan to identify many unique deviating paths and thus uncover a broader spectrum of potential attack sequences. Since pairwise comparisons of FSMs generate many deviations, manually triaging them to identify the traces violating security properties is tedious and error-prone [35, 39, 50]. To address this challenge, we design DevLyzer, which extracts security properties by following deviating traces and uses them to analyze other deviating traces automatically.

Findings. We evaluated 5GBaseChecker with 17 commercial 5G basebands and 2 open-source UE implementations. We identified 2044 unique deviations, which helped us identify 45 properties. The identified deviations and properties led to 22 unique implementation issues, 13 of which can lead to attacks, and 2 may cause interoperability issues. One of the most critical issues identified by 5GBaseChecker is mishandling security headers of particular messages in 5G devices equipped with Exynos basebands, affecting a majority of mainstream Samsung and Google Pixel devices. Exploiting this vulnerability, the attacker can force a victim device to connect to a fake base station without any authentication. The fake base station can then inject phishing SMSs and eavesdrop on the victim's Internet data.

Contributions. This paper makes the following contributions:

- We design 5GBaseChecker— an automatic, scalable, and black-box security analysis framework based on differential testing that automatically infers the FSM of 5G basebands and uncovers deviations by comparing them.
- We design *hybrid and collaborative FSM learning*, which significantly reduces the overall time for inferring FSMs.
- We develop a differential testing mechanism that takes FSMs as inputs and automatically finds all unique deviating traces in those FSMs leading to a specific deviation.
- We design a deviation analyzer to find security properties corresponding to a deviation and use them to automatically triage similar deviating traces to aid root cause analysis.
- We evaluated 5GBaseChecker with 19 5G basebands and found 22 distinct deviations, including 13 exploitable issues and 2 potential interoperability issues.
- We open-source 5GBaseChecker at: https://github.com/SyNSec-den/5GBaseChecker.

Responsible disclosure. We have reported our findings to the affected vendors. Until now, 5 CVEs have been assigned, with 1 high and 4 medium severity ratings. We are currently cooperating with vendors on patching the affected devices.

2 Preliminaries

5G standalone (SA) preliminaries. The 5G cellular network primarily comprises three major components: 5G Core Network (5GC), 5G-NR base station (gNodeB), and User Equipment (UE). The 5G Core (5GC) consists of several Network Functions (NF), including Access and Mobility Management Function (AMF), User Plane Function (UPF), and Session Management Function (SMF) to offer a range of functionalities, including registration, authentication, mobility management, and voice and data services. The *gNodeBs* are base stations supporting 5G radio technologies using which a gNodeB communicates with UEs through the Radio Resource Control (RRC) protocols in the control plane, relays user plane traffic to UPF, and Non-Access Stratum (NAS) signaling messages to AMF in 5G Core. The *UE* is the device, also known as baseband, that enables network connectivity for end users, e.g., smartphones or other 5G-capable devices. These devices include a Subscriber Identity Module (a physical SIM card or e-SIM) containing the user's credentials, e.g., user identifier and cryptographic keys.

Finite state machine. `5GBaseChecker` uses Mealy machines/Finite State Machines (FSM) to abstract 5G UE control plane protocol implementations. A Mealy machine, M, can be defined as a 6-tuple, $(Q, q_0, \Sigma, \Lambda, \delta, \lambda)$. Here, Q is a finite set of states, $q_0 \in Q$ is the initial state, Σ is the input alphabet, and Λ is the output alphabet. The transition function $\delta : Q \times \Sigma \to Q$ maps a state and an input symbol to the corresponding next state, and the output function $\lambda : Q \times \Sigma \to \Lambda$ maps a current state and an input symbol to the corresponding output symbol.

Black-box automata learning. Automata learning infers abstract models of systems based on observable behaviors. The observation data can either be sourced from logged system traces or obtained by actively sending (receiving) queries (responses), leading to two categories — *passive* [48] and *active* automata learning [12]. Passive automata learning builds the model based on pre-existing data, such as logs or traces, which makes it suitable for learning models of systems that are difficult or impossible to interact with directly. However, if certain behaviors are not recorded or if the logs are not representative of the whole system behavior, the resulting model can be incomplete or inaccurate. On the other hand, active automata learning algorithms, such as L* [12], interact with the SUL to learn a model. The algorithm for active automata learning usually works in two iterative stages: (i) *hypothesis construction stage* where given the input alphabet I (e.g., a, b, c), the algorithm generates a series of *membership queries* (e.g., *abb*, *abc*, *bcca*, *aacb*, ...), sends them to the SUL and builds a hypothesis FSM consistent with input-output pairs seen so far until the hypothesis FSM is complete and consistent. (ii) *model validation stage* where the learner will query an *equivalence oracle* to check if the current hypothesis FSM model is identical to the black-box system or not. If identical, the algorithm terminates. Otherwise, the learner refines the current FSM hypothesis based on a returned counterexample (CE). Note that ideal *equivalence oracle*s are not available in most cases. However, it is possible to approximate an equivalence query by using a sequence of carefully constructed membership queries [21, 41]. In this work, we refer to these queries as *equivalence queries*.

3 Overview of `5GBaseChecker`

3.1 Problem Statement

The overarching goal of `5GBaseChecker` is to uncover security and privacy flaws in 5G standalone (SA) UE implementations. For this, given a set of basebands $\mathcal{B} = \{B_1, B_2, \ldots, B_n\}$, a set of input symbols Σ, and a set of output symbols Λ, `5GBaseChecker` leverages differential testing as a gateway to detect flaws and thus decomposes the overarching goal into three sub-goals: (G1) Uncover the classes of deviant behaviors, also called deviations; (G2) Find the set of properties, i.e., security and privacy requirements whose violations lead to security or privacy flaws; and (G3) Identify instances of property violations for each class of deviant behaviors. To achieve these goals, we ask the following questions: (Q1) Is there a possible input sequence $S_{in} = \sigma_1\sigma_2\ldots\sigma_m$, with $\sigma_j \in \Sigma$ for which a baseband B_i responds with output sequence $S_{out} = \varphi_1\varphi_2\ldots\varphi_m$, where $\varphi_j \in \Lambda$ and S_{out} deviates from the outputs of other basebands B_j $(i \neq j)$? (Q2) If it deviates, which policy ρ is violated by $\langle S_{in}, S_{out}\rangle$ that others do not violate? (Q3) Are there other input/output sequences such as $\langle S'_{in}, S'_{out}\rangle$ which also violate ρ?

3.2 Solution Space

One can approach the problem defined in §3.1 from several directions. First, one can perform fuzz testing with over-the-air (OTA) messages [30] and check if the responses of different devices are different for the same randomly generated input messages. However, randomly generating OTA inputs cannot explore the state space (ineffective) and requires a prohibitively high number of test inputs (inefficient). This is because 5G UE's input space is huge, and there is no useful feedback (e.g., code coverage) to guide the fuzzer due to the black-box nature of 5G UEs.

Another approach is to extract the FSM of 5G basebands using automata learning and then analyze them against the policies (i.e., properties) through formal model checking [34, 40]. However, the 3GPP standard does not provide any curated list of security or privacy requirements, and in many cases, they are implicit. As such, manually enumerating all such requirements from the specification is extremely arduous, if not impossible. In addition, checking a large and complex model against a property often requires frequent expert intervention to avoid trivial counterexamples [32, 34]. Consequently, this approach does not scale well with an increased number of basebands under test.

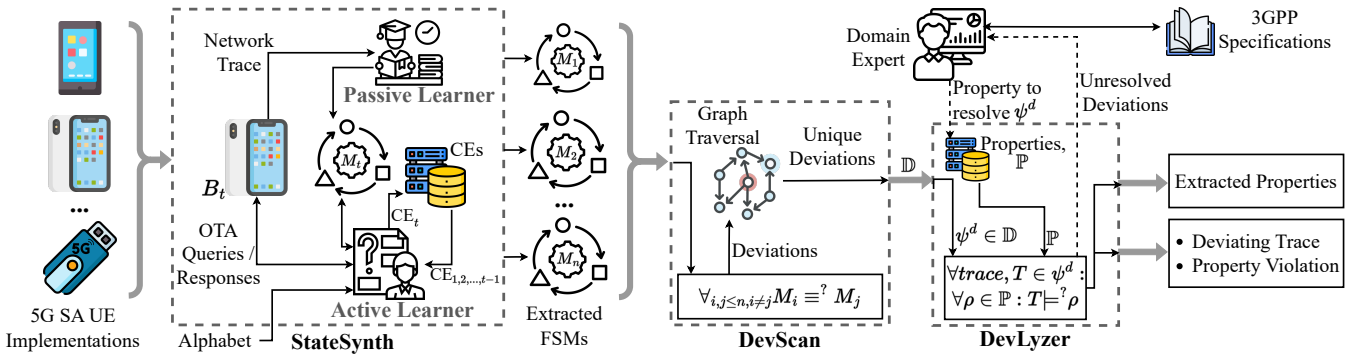

Figure 1: Overview of 5GBaseChecker.

3.3 Solution Sketch of 5GBaseChecker

5GBaseChecker works with three main components: StateSynth, DevScan, and DevLyzer as shown in Figure 1. StateSynth first extracts the FSMs $\mathcal{M} = \{M_1, M_2, \ldots M_n\}$ of basebands $B_1, B_2, \ldots B_n \in \mathcal{B}$. 5GBaseChecker then utilizes the extracted FSMs and finds out the security policy violations in each FSM $M_i \in \mathcal{M}$. To do this, DevScan of 5GBaseChecker takes the extracted FSMs for all implementations as input and yields a set of deviations as outputs. By deviations, we mean that for a particular input sequence, not all the FSMs respond with the same output sequences. As such, for a particular input sequence, there can be multiple distinct output sequences that do not match with each other.

Definition 3.1 (Deviation). Suppose for an input sequence S_{in} as defined in §3.1, the output sequences in $M_1, M_2, \ldots M_n \in \mathcal{M}$ are $S^1_{out}, S^2_{out}, \ldots, S^n_{out}$, respectively. Among those, let there be k distinct deviating outputs $\gamma^{d,1}_{out}, \gamma^{d,2}_{out}, \ldots, \gamma^{d,k}_{out}$ for S_{in}, where $1 < k \leq n$, $(p \neq q) \implies \gamma^{d,p}_{out} \neq \gamma^{d,q}_{out}$ and $\forall M_l \in \mathcal{M} : (\exists j : (1 \leq j \leq k) \wedge S^l_{out} = \gamma^{d,j}_{out})$. A deviation ψ^d (also termed as a deviation class) is defined by the input sequence S_{in} and all k distinct outputs $\gamma^{d,1}_{out}, \gamma^{d,2}_{out}, \ldots, \gamma^{d,k}_{out}$. We denote the set of all extracted deviations as $\mathbb{D}$. Moreover, we define a deviating trace T as a pair of the deviation-inducing input and a deviating output, i.e., $\langle S_{in}, \gamma^{d,j}_{out} \rangle$, where $1 \leq j < k$. For instance, a deviation $\psi^d \in \mathbb{D}$ can have the input sequence $S^d_{in} = x_1x_2x_3x_4$, and three distinct outputs $\gamma^{d,1}_{out} = y_1y_2y_3y_4$, $\gamma^{d,2}_{out} = y_1y_2y_3y_5$, and $\gamma^{d,3}_{out} = y_1y_6y_3y_7$, where $\langle S^d_{in}, \gamma^{d,1}_{out} \rangle$, $\langle S^d_{in}, \gamma^{d,2}_{out} \rangle$, and $\langle S^d_{in}, \gamma^{d,3}_{out} \rangle$ are deviating traces.

For each deviating trace $T \in \psi^d$, the DevLyzer component of 5GBaseChecker first finds a set of properties $\mathcal{P}_d$ relevant to ψ^d from the specifications. DevLyzer uses ψ^d as guidance to find such properties from specifications. The sets of all identified properties for all $\psi^d \in \mathbb{D}$ are referred to as $\mathbb{P}$. DevLyzer then automatically tests if each $T \in \psi^d$ satisfies all $\rho \in \mathbb{P}$, i.e., $T \models^? \rho$. This reduces the significant manual effort by a security expert to analyze deviations.

3.4 Threat Model

We consider an active attacker with Dolev-Yao capabilities on the wireless channel between a victim UE and a gNodeB [24]. In this model, the attacker can set up a Fake Base Station (FBS) or a Machine-in-the-middle (MitM) relay to modify, inject, replay, drop, or observe packets on the channel. However, we assume the cryptographic constructs to be perfectly secure, i.e., the attacker cannot craft a message with a valid message authentication code (MAC) or cannot encrypt/decrypt a message without cryptographic keys. In the cellular domain, these assumptions are reasonable, as seen in prior works [34, 35, 42, 50].

4 Challenges and Solutions

4.1 Challenges of 5GBaseChecker Design

To solve the problems in §3.1, we find the following challenges and limitations of the prior approaches, which motivate us to design our proposed approach 5GBaseChecker.

C1: Slow inference of 5G FSM with active learning. The standard active automata learning algorithm starts from an empty knowledge base to build the FSM. As a result, it learns the basic interactions of the protocol very slowly during its first few iterations of hypothesis construction. Further, as discussed in §2, active automata learning algorithms require an equivalence oracle to validate the hypothesis models, which is approximated using carefully crafted membership queries in prior works [21, 41]. However, this approximation results in a very large number of queries being generated in the model validation stage. For example, Wp-method [41] requires an order of $O(n^2|\Sigma|^{k-n+1})$, where Σ is the input alphabet of the FSM, n is the number of states in the FSM, and k is the upper bound on the number of states of the target system. As a result, the model validation stage often requires 5-10 times more queries than the hypothesis construction stage [23, 35, 39, 57]. As executing an OTA query in 5G requires a substantial amount of time (∼40 seconds/query), this stage becomes a critical

bottleneck for active automata learning-based FSM extraction.

C2: Difficulty in finding unique deviations. Prior works [28, 35, 39] have developed automated ways to find deviations from the extracted FSMs. Although these works are effective in identifying deviations, they do not explore unique variations of a single deviation. In other words, in case of a deviation, prior works often fail to identify multiple traces between the initial state and a deviation-inducing state— the state at which the outputs of two or more FSMs differ for the same input. Multiple such deviations imply that attackers can execute the same attack using various attack sequences.

C3: No comprehensive list of security policies. Once unique deviations are detected, one must check if deviating traces violate any security properties. However, it is difficult and time-consuming to find a comprehensive list of critical security properties without any hints as there are thousands of properties in 5G specifications; for instance, the 5G NAS specification of Release 17 itself has ∼8000 such requirements [10].

C4: Lack of automation in triaging deviations. If we test a large number of 5G UEs, there would be a large number of deviations among the extracted FSMs. However, following previous approaches [35, 39], manually triaging each such deviation consumes a huge amount of time and effort. Even when security properties are in place, one has to check the properties against complex and large FSMs, which also requires significant time and frequent expert interventions.

4.2 Our Approach

A1: Combining passive automata learning and counterexample reuse. To address **C1**, we propose the idea of *hybrid and collaborative learning*. In *hybrid learning*, we combine active and passive automata learning in order to reduce the number of OTA learning and equivalence queries. First, we leverage passive automata learning [38] to synthesize an initial FSM called M^p from the available 5G network traces. We then use M^p as a guide for active learning. In other words, M^p helps active learning optimize the number of queries and time to refine the hypothesis models. On the other hand, since all basebands implement the same protocol specified by 3GPP, the FSMs would largely be similar, and any counterexamples (CEs) found during the FSM construction of one device are highly likely to be the CEs for other basebands as well. Thus, using *collaborative learning* during the model validation stage, we first try to reuse the CEs found during the FSM constructions of other devices instead of directly executing the expensive off-the-shelf model validation algorithms (e.g., Wp-method). If any of the CEs are valid, we directly use them to refine the hypothesis model of the current SUL. Identifying CEs in such a collaborative way significantly reduces equivalence-checking queries and time.

A2: Graph traversal-based model refinement. To address **C2**, similar to previous work [35, 39], we first convert the differential testing problem to a model-checking problem with a safety property. This eliminates the requirement for expert intervention and a comprehensive list of security properties. However, to address the limitations of previous works, which cannot find all unique deviations, we propose a graph traversal mechanism. Specifically, when a deviation-inducing input sequence is found, we perform a graph traversal from the initial state to the state where the deviation is found and log all unique paths that can lead to the deviation.

A3: Guided search of security policies using deviation. To address challenge **C3**, we leverage the obtained deviations to look up the specifications and extract corresponding security policies. More specifically, we manually examine the specification to detect the correct output behavior corresponding to the input sequence of a deviation. As an example, for an input sequence that provides a plaintext `ue_info_req` without performing access stratum (AS), i.e., RRC layer's security activation, consider an output sequence where the device responds with `ue_info_resp`. This behavior contrasts with other devices that discard `ue_info_req`. When analyzing such a deviation, we can easily obtain the required security property by examining the portions of the specification that deal with unprotected `ue_info_req` messages. Thus, the deviation guides us to obtain the security property of not accepting plaintext `ue_info_req` before AS security activation.

A4: Efficient triaging of deviations. To address challenge **C4**, we adopt an iterative approach. We formally verify the extracted properties against automatically generated formal models of each of the deviating traces instead of verifying the entire FSMs of devices. This approach eliminates the time and scalability challenges of formally verifying the extracted FSMs with desired properties. Additionally, we observe that a single property often helps us automatically resolve multiple deviations. As a result, we need to manually analyze only a small subset of all identified deviations (as discussed in §9.5), significantly reducing the manual effort required.

5 StateSynth: FSM Construction

Given a set of input and output alphabets, Σ and Λ, respectively, StateSynth aims to efficiently extract the FSM for each 5G baseband under test. Figure 1 also shows the overview and components of StateSynth, whereas Figure 2 shows its workflow with an example. In what follows, we discuss in detail the design and workflow of StateSynth.

5.1 Hybrid Learning for Bootstrapping

Passive FSM construction. As discussed in §2 and §4.2, passive automata learning synthesizes an FSM from a given execution traces instead of actively interacting with the system under learning. This approach requires a diverse set of traces to build a comprehensive FSM suitable for analyzing the security of the system. However, only a limited 5G standalone

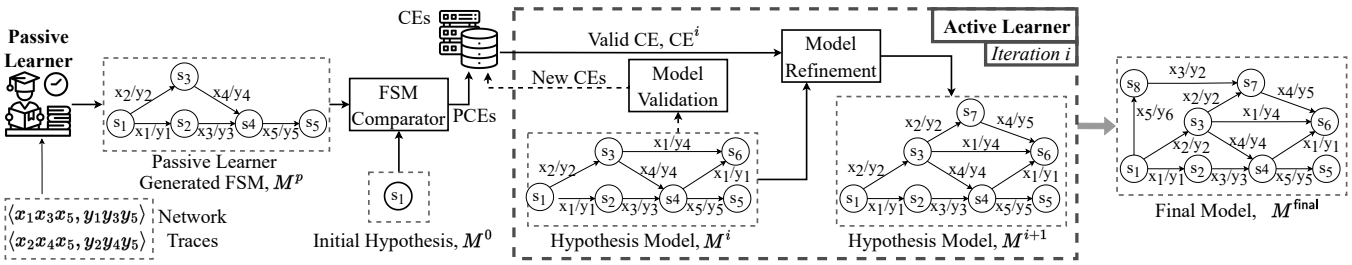

Figure 2: Workflow of StateSynth with an illustrative example.

(SA) control plane traces can be observed by monitoring a UE's regular interactions with 5G networks. Due to the absence of diverse traces for 5G UEs, it is thereby challenging to apply passive learning to comprehensively infer 5G basebands' FSMs. To tackle this, we first utilize the limited availability of 5G SA traces to construct only an initial FSM using passive learning. We then use that FSM to bootstrap/guide *Active Learner*, specifically during the first few iterations of *Active Learner*'s model validation phase. This bootstrapping helps StateSynth significantly reduce OTA queries and time to learn diverse system behaviors.

Note that the limited 5G SA traces contain only regular (i.e., positive) behavior, whereas the classic passive automata learning algorithm, such as *Regular Positive and Negative Inference (RPNI)* [49], a widely used technique in networks and cyber-physical systems, requires both positive and negative execution traces to infer a system's FSM. To sidestep this, we leverage Trace2Model [38], a passive automata learning technique that learns an FSM only from positive traces. To this end, we first collect network traces of the registration procedures between the baseband and a 5G SA network and represent each input/output in that trace as an observation for Trace2Model. Trace2Model uses a program synthesis technique called *synthesis from examples* to construct *transition predicates* and then uses the predicates to find counterexamples used for refining the hypothesis model. We use the traces of registration procedure because the scope of our analysis is mainly the NAS and RRC procedures related to registration.

As an example, consider the two traces– $\langle x_1x_3x_5, y_1y_3y_5\rangle$ and $\langle x_2x_4x_5, y_2y_4y_5\rangle$. Here, a trace is a tuple of an input sequence and corresponding output sequence. The *Passive Learner* takes these traces as input and generates the initial state machine M^p, as shown in Figure 2. In this figure, self-loop transitions are not shown for clarity and conciseness.

Trace collection. We collect 5G SA traces by connecting the devices to both (i) open-source 5G testbeds, and (ii) nearby commercial 5G base stations with valid user credentials. This ensures that the traces are diverse, covering behavior in both testbed environments and commercial network settings.

Bootstrapping active learning with passive learner-generated FSM. To complement the behavior learned and captured in M^p by *Passive Learner*, StateSynth's *Active Learner* first assimilates the information present in M^p and thus bootstraps the overall learning. We use TTT [37] as the active learning algorithm for 5G basebands. As discussed in §2 and §4.2, *Active Learner* systematically generates queries as sequences of input alphabets, observes the responses, and infers the underlying FSM by iteratively constructing and validating hypothesis models. Since 3GPP specifications do not provide a reference FSM for 5G basebands, during the model validation phase, *Active Learner* uses the Wp-method [41] as an approximate equivalence checking mechanism, which, however, requires a prohibitively high number of queries and time to find counterexamples in hypothesis models. This becomes particularly worse for 5G UEs as their protocols are complex and have a higher number of input and output alphabets than previous generations. This results in a significant slowdown during the initial iterations of FSM learning.

StateSynth bootstraps *Active Learner* by first utilizing M^p during *Active Learner*'s model validation phase. More specifically, StateSynth compares the TTT-generated initial (empty) hypothesis M^0 with M^p, and treats the differences, i.e., deviating traces between them as *potential counterexamples (PCEs)*. During model validation, instead of using the Wp-method in the first place, *Active Learner* considers these PCEs as candidate CEs and uses them first to refine the hypothesis if they are proved valid. This helps *Active Learner* quickly bootstrap the learning of regular 5G protocol interactions (e.g., a correct flow of the registration procedure) by consuming the knowledge that *Passive Learner* learns from network traces. For example, in Figure 2, initial hypothesis M^0 contains only one state with self-loop transitions for each symbol in the alphabet. By comparing M^0 with M^p, as shown in Figure 2, we find several PCEs, e.g., $\langle x_1x_3, y_1y_3\rangle$, $\langle x_2x_4x_5, y_2y_4y_5\rangle$, etc.

5.2 Collaborative Learning for Validation

Since 5G SA UEs implement the same protocol following 3GPP specifications, their FSMs are also largely similar. We use this insight to propagate the learned behavior from one UE to the next if such behavior is valid. More specifically, we store the CEs found during model validation of one baseband as potential counterexamples for other basebands. During

model validation of other basebands, we first apply those PCEs if valid. To check the validity, the StateSynth executes the PCEs as OTA queries to the device under learning. If the observed response does not match with the hypothesis model, StateSynth marks those as valid CEs. Such *collaborative learning* significantly reduces the number of OTA queries and time. Finally, after applying all PCEs, to find remaining counterexamples and refine the learned model, we use Wp-method [41] in a limited way for model validation until the termination condition is met as defined in §5.4. We detail the algorithm of StateSynth in Appendix B.

We demonstrate the workflow of *Active Learner*, showing one iteration of model validation and refinement for baseband B_t in Figure 2. In the i^{th} iteration, *Active Learner* initially has the hypothesis model M^i. If there are any unused CEs remaining, *Active Learner* first checks if such CEs are valid and then uses a valid one for M^i refinement. Otherwise, as shown in Figure 2, *Active Learner* performs model validation with the Wp-method to find a new CE, uses it (if any) for model refinement, and saves it as a PCE to apply to other basebands. For example, assume that for input sequence $x_2x_2x_4$, B_t responds with $y_2y_2y_5$. However, according to M^i, it responds to the last message with y_4. Thus, in this iteration, *Active Learner* uses $\langle x_2x_2x_4, y_2y_2y_5\rangle$ as CE^i, refines the model, and generates a new hypothesis, M^{i+1}, as shown in Figure 2. Finally, this iterative model refinement and validation is performed until termination, when *Active Learner* provides the final learned model, M^{final} for B_t.

5.3 Alphabet Selection

In StateSynth, the number of queries generated by TTT and Wp-method [41] increases significantly with alphabet size (state explosion). Therefore, one needs to carefully select the alphabet in a way that can strike a balance between the scope and the termination of FSM learning.

Selection strategy. Since the goal of this work is to identify security policy violations in 5G SA control plane protocol implementations, we create alphabets based on critical NAS and RRC layers' messages and 3GPP-provided high-level security policies: confidentiality, integrity, and non-replayability. More precisely, we use the following four strategies. (A) We consider messages required to learn valid/regular protocol flows, such as the completion of the registration procedure. This includes both plaintext messages allowed before NAS and AS security activation and security-protected messages (i.e., ciphered and/or integrity protected)[1] used after security activation. (B) For messages that must not be accepted without security protection (i.e., encryption and/or integrity), we consider their plaintext and/or non-integrity-protected counterparts. (C) For non-replayability, we construct the replay version of integrity-protected messages. (D) We also take security headers of messages into account as they influence the acceptance of plaintext and security-protected messages.

Among the 16 security-header types, security headers 0 to 4 denote plain (0), integrity protected (1), integrity protected and ciphered (2), integrity protected with a new security context (3), and integrity protected and ciphered with a new security context (4), while the remaining 11 are reserved. We consider security header types 0, 2, 3, and 4 in our alphabet set. We include header 0 to test plaintext messages. Moreover, headers 2 and 3 are required to learn the regular flow of the protocols for protected messages. They are vital for security analysis because some exploitable vulnerabilities can still occur after receiving protected messages, e.g., accepting plaintext *Authentication Request* messages after security activation, and replayed *Security Mode Command* messages after registration. We do not include header 1 as it is not required to learn the regular protocol flow. Finally, header 4 is a special type used only for an uplink message *Security Mode Complete*, and thus, receiving this header may lead to unexpected behavior in the UE under test. With these strategies, we construct the alphabet based on TS 24.501 version 17.8.0 [10] and TS 38.331 version 17.6.0 [11], as shown in Table 9 in the Appendix.

Scope. The alphabet used by StateSynth spans a subset of the 5G SA control plane procedures. More specifically, in the NAS layer, the alphabet covers registration, identification, authentication, security mode control, UE configuration update, and de-registration procedures. On the other hand, in the RRC layer, the alphabet covers AS security mode control, UE capability transfer, counter check, UE information request, and RRC reconfiguration procedures. We excluded NAS layer reject messages and RRC layer reject and release messages as they would drop the connection and, consequently, hinder FSM construction. Also, currently, open-source 5G stack implementations that we employed to send messages to the UE do not support RRC Resume, paging, and handover procedures, and implementing them would require significant engineering efforts. We exclude these procedures from the scope of `5GBaseChecker` as well.

5.4 Termination Strategy

The termination condition is critical in active learning. Terminating early results in incomplete FSM construction, whereas keeping StateSynth running even after capturing a representative FSM leads to superfluous OTA queries and time. As seen in prior works [23, 35, 39], most OTA queries are generated in model validation using the Wp-method [41] during FSM construction. To reduce such queries and balance between early termination and FSM completeness, in this work, after using the PCEs to refine the hypothesis models, we use Wp-method in a controlled way through configurable parameters N_0, N_1, and N_2 to further validate and refine the hypotheses. In summary, we use the following termination strategy.

- If any of the output symbols (Table 9 in Appendix) have not

[1] Security-protected messages are considered only for FSM learning. They do not reflect the attacker's capabilities.

been observed yet, StateSynth continues FSM extraction.

- For the first UE, when *Active Learner* does not have PCEs from any previously learned basebands, we limit the number of equivalence queries to a certain value N_0 for each iteration of the Wp-method. If a CE is not found within N_0, model construction terminates. Otherwise, we refine the model with the CE and re-run model validation. In contrast to DIKEUE's termination strategy [35], which terminates whenever the registration procedure is completed, this ensures learning implementation behavior even after the procedure.
- For the subsequent phones, if another baseband from the same vendor (e.g., Qualcomm, MediaTek, etc.) has already been learned, we set the limit of equivalence queries per round of model validation at N_1, such that $N_1 < N_0$. This utilizes the insight that FSMs from the same baseband vendor are similar and may require fewer equivalence queries.
- If the device under learning is the first phone from its baseband vendor, we set the above-mentioned limit to N_2, such that $N_1 < N_2 < N_0$. It ensures that the first baseband under learning from a vendor is explored sufficiently.

5.5 Efficient and Consistent Learning

OTA query caching. As discussed in prior works [13,55], *Active Learner* can generate some equivalence queries in model validation, which are already executed during hypothesis construction. Following this insight, we store the results of all OTA queries in a cache to use in subsequent queries for the same baseband.

Avoiding inconsistency. Due to unreliable wireless communication channels used for transmitting OTA messages and responses, *Active Learner* may experience observational inconsistencies in the responses. To ensure consistent learning, we apply majority voting following prior works [35,47]. In this scheme, we run an OTA query twice and use the output if the outputs are the same. Otherwise, we run the query another time to resolve the correct output.

Minimizing duplicate states. We also observe that some UE implementations incorrectly reset their state machines after receiving particular messages (e.g., `auth_req_plain`) at certain states and then restart learning of the entire FSM from scratch from those states. This leads *Active Learner* to spawn many duplicate states in the hypothesis models, causing a large amount of similar query generation and delay in termination. To address these inconsistent behaviors, *Active Learner* automatically detects such behaviors during each query execution and interprets subsequent outputs in that query as `null_action`.

6 DevScan: Finding Deviations

DevScan takes the extracted FSMs of basebands as inputs and automatically identifies the set of deviations.

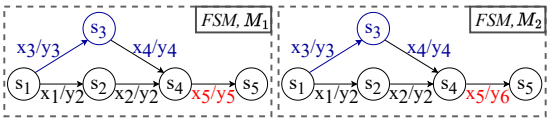

Figure 3: Example deviations in two FSMs.

6.1 Unique Paths For Deviations

Prior research has utilized deviations to detect vulnerabilities in protocol implementations [25,35,39]. However, efficiently identifying all deviations from a set of implementations or even a set of representative FSMs is non-trivial because the search space is exponentially large depending on the size of the alphabet and the length of the traces. Although previous works have identified deviations in a reasonable amount of time, they lack the support for identifying all unique paths leading to these deviations [35,39]. As all these unique deviations are essential for a comprehensive analysis of the FSMs, we opt for a graph traversal algorithm to find all unique paths from the initial state to a deviation-inducing state in an FSM leading to a deviation.

For example, Figure 3 shows deviations in FSMs M_1 and M_2. Prior tools [35,39] can only identify the deviation with deviating traces $\langle x_1x_2x_5, y_1y_2y_5\rangle$ and $\langle x_1x_2x_5, y_1y_2y_6\rangle$, whereas there is another path in these FSMs (highlighted in Figure 3) leading to another unique deviation with deviating traces $\langle x_3x_4x_5, y_3y_4y_5\rangle$ and $\langle x_3x_4x_5, y_3y_4y_6\rangle$. DevScan, with the help of graph traversal-based model refinement, successfully identifies such unique deviations in extracted FSMs.

6.2 Graph Traversal-Based Model Refinement

To identify all unique paths, DevScan at first uses a prior tool [39] to find the set of deviations by performing pairwise comparison. For each of the deviations, in both FSMs, DevScan inspects the state in which the deviation has occurred and performs a depth-first-search-based algorithm to find all paths from the initial state to the deviation-inducing state. For all these paths, DevScan identifies the sequences of input symbols along the paths and checks both FSMs to discover if these new sequences also lead to deviations.

7 DevLyzer: Triaging Deviations

Given the set of deviations $\mathbb{D}$, DevLyzer identifies a set of properties $\rho \in \mathbb{P}$ where ρ is violated by at least one deviating trace $\langle S_{in}, \gamma^{i,j}_{out}\rangle \in \psi^i$ of a baseband. It also finds deviating traces in other deviations ψ^k that also violate ρ. DevLyzer aims to minimize the manual effort required to extract relevant properties and corresponding violations of the properties.

7.1 Extracting Properties

For each deviation (also called *deviation class*) in $\mathbb{D}$, DevLyzer iteratively finds relevant properties and checks for violations of those properties by basebands. It compiles the extracted properties represented with Linear Temporal Logic (LTL) formula into $\mathbb{P}$. In each iteration, DevLyzer attempts to *resolve* any unresolved deviation $\psi^d \in \mathbb{D}$ by leveraging the properties in $\mathbb{P}$. We consider a deviation resolved when we have at least one property $\rho \in \mathbb{P}$ for each pair of deviating outputs in the deviation class such that one of the deviating outputs satisfies ρ but others violate. Formally, a deviation ψ^i is considered *resolved* only if:

$$\forall_{p \neq q} \gamma^{d,p}_{out}, \gamma^{d,q}_{out} \in \psi^d : \exists \rho \in \mathbb{P} : \langle S_{in}, \gamma^{d,p}_{out} \rangle \models \rho \wedge \langle S_{in}, \gamma^{d,q}_{out} \rangle \not\models \rho \quad (1)$$

Initially, all deviations ψ^d are *unresolved*, and $\mathbb{P} = \emptyset$. During each iteration, DevLyzer first picks an unresolved deviation ψ^d_u and provides it to the security expert for manual analysis. This is a guided property extraction procedure, as the deviating trace will provide guidance to the security expert regarding what and where (e.g., message sequences and procedures) to look for in the specification to extract properties. The expert then consults with the 5G specification to identify the correct output behavior for the input sequence S_{in} of ψ^d_u and represent that as an LTL property ρ. Also, if there are k_s number of correct output behaviors prescribed by the specification for input S_{in}, we represent k_s properties $\rho_1, \rho_2, \ldots, \rho_{k_s}$ such that each ρ_m $(1 \leq m \leq k_s)$ characterizes one of the correct behaviors. Also, if there are k_w wrong outputs for S_{in}, we write properties $\rho_1, \rho_2, \ldots, \rho_{k_w}$ such that each ρ_n $(1 \leq n \leq k_w)$ is violated only by one of the outputs $\gamma^{i,j}_{out} \in \psi^i_u$. DevLyzer adds all such properties to $\mathbb{P}$.

7.2 Checking Properties For Violation

For all trace $\langle S_{in}, \gamma^{i,j}_{out} \rangle$ in a deviation $\psi^i \in \mathbb{D}$, DevLyzer checks whether the trace satisfies all properties $\rho \in \mathbb{P}$. To perform this, DevLyzer first automatically models each trace as an FSM $M^{i,j}_{dev}$, and performs model checking (using nuXmv [16]) to determine if $M^{i,j}_{dev} \models \rho$. If a $\rho \in \mathbb{P}$ is violated by any $\langle S_{in}, \gamma^{i,j}_{out} \rangle$, DevLyzer can immediately infer that all $b_l \in \mathcal{B}$ that outputs $\varphi^l_{out} = \gamma^{i,j}_{out}$ when provided S_{in} also violates the property ρ.

Automatic construction of a model from a trace. To construct $M^{i,j}_{dev}$ for $\langle S_{in}, \gamma^{i,j}_{out} \rangle$, DevLyzer creates $|S_{in}|$ number of states for $M^{i,j}_{dev}$, where at each state s_k $(1 \leq k < |S_{in}|)$ there is only one transition that takes the k-th message of S_{in} as input, outputs the k-th message in $\gamma^{i,j}_{out}$ and goes to state s_{k+1}. Since $M^{i,j}_{dev}$ represents the model of a single trace, its size is much smaller than extracted FSMs for 5G devices. This helps DevLyzer automatically analyze them against extracted properties. DevLyzer thus iteratively triages all unresolved deviation ψ^i_u and marks them as resolved when the condition in Equation 1 is satisfied.

7.3 Illustration of DevLyzer

Consider two deviations ψ^1 and ψ^2, as shown in Figure 4. For ψ^1, the input sequence is $S^1_{in} = x_1x_2x_3x_4x_5$, and it has two deviating output sequences $\gamma^{1,1}_{out} = y_1y_2y_3y_4y_5$ and $\gamma^{1,2}_{out} = y_1y_2y_3y_4y_7$. For ψ^2, we have $S^2_{in} = x_1x_2x_8x_3x_5$ and two deviating outputs $\gamma^{2,1}_{out} = y_1y_2y_8y_3y_5$ and $\gamma^{2,2}_{out} = y_1y_2y_8y_3y_7$.

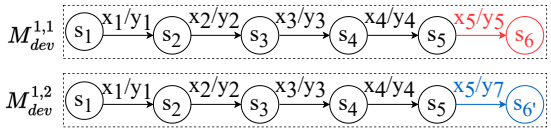

Figure 4: Example models for $M^{1,1}_{dev}$ and $M^{1,2}_{dev}$ for the example in 7.3. Colored areas show the point of deviation.

Initially, $\mathbb{P}$ is $\emptyset$, and all deviations are unresolved. Suppose DevLyzer first triages ψ^1. It creates models $M^{1,1}_{dev}$ and $M^{1,2}_{dev}$ using $(S^1_{in}, \gamma^{1,1}_{out})$ and $(S^1_{in}, \gamma^{1,2}_{out})$, respectively, as shown in Figure 4. To resolve ψ_1, we assert property ρ_1: *After response y_3, if x_5 is provided as input, it will always be responded with y_5*. We represent ρ_1 as an LTL formula as $\mathsf{G}(\mathsf{output}{=}\mathsf{y_3}) \implies (\mathsf{G}(\mathsf{input}{=}\mathsf{x_5}) \implies \mathsf{X}(\mathsf{output}{=}\mathsf{y_5}))$, which the output sequence $\gamma^{1,1}_{out}$ does not violate but $\gamma^{1,2}_{out}$ does. DevLyzer utilizes model checking and finds out $M^{1,1}_{dev} \models \rho_1$ but $M^{1,2}_{dev} \not\models \rho_1$ since output $\gamma^{1,2}_{out}$ violates property ρ_1. Now, ψ^1 will be marked as resolved, and $\mathbb{P}$ will be $\{\rho_1\}$. DevLyzer also detects the devices producing $\gamma^{1,2}_{out}$, which violates ρ_1. Next, DevLyzer examines ψ^2, and builds models $M^{2,1}_{dev}$ using $(S^2_{in}, \gamma^{2,1}_{out})$ and $M^{2,2}_{dev}$ using $(S^2_{in}, \gamma^{2,2}_{out})$. It will test all properties in $\mathbb{P}$ and observe $M^{2,1}_{dev} \models \rho_1$ but $M^{2,2}_{dev} \not\models \rho_1$. Thus, it will mark ψ^2 as resolved. violating ρ_1. Here, DevLyzer saves the manual effort to analyze ψ_2. We summarize DevLyzer in Algorithm 1 in Appendix A.

8 Implementation

StateSynth. For the *Passive Learner* of StateSynth, we use Network Signal Guru [5] to collect the network traces and Trace2Model [38] to generate an FSM. *Active Learner* is built on TTT's [37] and Wp-method's [41] implementations in LearnLib [36]. For the termination strategy, we empirically set $N_0 = 10000$, $N_1 = 1000$, $N_2 = 2000$, which preserves the balance between termination and coverage for the 5G UE implementations (listed in Table 8).

As the *Active Learner* needs active interactions with the basebands, we build an adapter consisting of gNodeB and 5G core to translate abstract symbols provided by the learning algorithm to over-the-air messages and vice-versa. For this, we modify existing open-source 5G SA gNodeB and 5G core (5GC) implementations. These modifications are required to enable the open-source gNodeB and 5GC to send arbitrary sequences of OTA messages as generated by *Active Learner*.

Moreover, available open-source gNodeB implementations do not support a broad range of frequencies. To facilitate learning of all implementations under test, we employ two different gNodeB implementations (OpenAirInterface [7] and srsRAN [8]). We modify Open5GS [6] for the 5G core of the adapter.

DevScan and DevLyzer. As discussed in §6, we extend the FSM equivalence checker of BLEDiff [39] to implement DevScan. DevLyzer uses nuXmv [16] for model checking.

9 Evaluation

We evaluate `5GBaseChecker` with respect to the following research questions:

- **RQ1.** How effective is `5GBaseChecker` in finding deviations and security policy violations (§9.2)?
- **RQ2.** How efficient is StateSynth in extracting FSMs from baseband implementations (§9.3)?
- **RQ3.** What is the efficacy of DevScan in detecting deviations (§9.4)?
- **RQ4.** How efficient is DevLyzer in finding security policies and analyzing deviations (§9.5)?'
- **RQ5.** How does `5GBaseChecker` perform compared to existing UE testing approaches (§9.6)?

9.1 Evaluation Setup

To evaluate `5GBaseChecker`, we analyze 17 Commercial off-the-shelf (COTS) 5G SA capable devices, and 2 open-source 5G UE implementations— srsRAN UE (srsUE) [8] and OpenAirInterface UE (OAI UE) [7], as listed in Table 8. We use USRP B210 as our radio front end to test COTS 5G SA devices and leverage software-simulated radio connection to test srsUE and OAI UE. We perform the evaluations on an Ubuntu 20.04 machine with an AMD Ryzen 9 7950X3D CPU and 64 GB DDR5 RAM.

9.2 Deviations and Flaws

To address **RQ1**, we use StateSynth to extract FSMs from the implementations and analyze the deviations found by DevScan through DevLyzer. `5GBaseChecker` uncovers 22 unique issues, 20 of which are newly discovered in 5G UEs, including 13 attacks and 2 potential interoperability issues. We present these issues in Table 2 and categorize them into 12 types according to the flaw types in Table 1.

9.2.1 Mishandling Messages ($I_1 - I_7$)

• **Mishandle unprotected message before AS security activation (I_1-I_2).** As per TS 38.331 [11], *UE Information Request* and *Counter Check* messages should not be accepted before AS security activation. Correctly implemented devices shall drop these messages before AS security activation.

Flaw Type		Description
M	M1	Mishandle unprotected message before authentication
	M2	Mishandle unprotected message after authentication but before NAS security activation
	M3	Mishandle unprotected message after NAS security activation, before AS security activation and before registration completed
	M4	Mishandle unprotected message after NAS security activation and registration completed, but RRC security not activated
	M5	Mishandle protected message after NAS and RRC security activation, but before registration completed
	M6	Mishandle sequence number for certain message type
S	S	Accept invalid security header type for certain message type
I	I	Accept prohibited IE values
U	U1	Incomplete information for mandatory features/messages
	U2	Incomplete information for optional feature
	U3	Conflicting information
D	D	Design specification issue

Table 1: Description of flaw types. **M**: mishandling messages, **S**: mishandling security headers, **I**: mishandling information elements (IEs), **U**: underspecification, **D**: Design flaw.

By observing the responses to these messages, the attacker can first fingerprint devices up to the baseband manufacturer level [50]. The attacker can then launch other attacks such as 5G AKA bypass discussed in §10.1.

• **Mishandle unprotected message after NAS security activation (I_3, I_4).** Based on TS 24.501 [10], all NAS communications should be ciphered and integrity protected after NAS security activation. However, some UEs accept *Identity Request* and *Authentication Request* in plaintext even after NAS security context establishment. As a result, the attacker can capture the plaintext *Authentication Request* message for the victim UE from a benign 5G network and send this message later to the victim UE. Since the victim UE accepts and responds to this message, an attacker can exploit this vulnerability to launch traceability [14] and SUCI-Catching [20, 33] attacks or regenerate session keys, causing a key desynchronization between the victim UE and the AMF.

• **Mishandle protected message after NAS and AS security activation (I_5).** Several UEs accept *Deregistration Request* and deregister from the core network before the registration procedure is completed. However, the 5G NAS specification [10] mandates that the UE has to proceed with the registration process by discarding the *Deregistration Request*. This may result in interoperability issues during handover.

• **Mishandle sequence number for certain message types (I_6, I_7).** According to TS 24.501 [10], a replayed NAS message cannot be accepted after security establishment. However, some UEs accept replayed *NAS Security Mode Command* messages during the registration procedure (I_6), and some UEs accept this message even after the registration is complete (I_7). This is fatal since the attacker can exploit the *NAS Security Mode Command Replay* message to perform traceability attacks [32].

9.2.2 Mishandling Security Headers ($I_8 - I_9$)

The *Registration Accept* and *Configuration Update Command* messages should only be accepted using security header type 2 (integrity protected and ciphered) [10]. However, in I_8, we

Issue	Description	Flaw Type	Impact	New
I_1	UE accepts `ue_info_req_plain` before AS security activation	M1, M2, M3, M4	F	●
I_2	UE accepts the `counter_check_plain` before AS security activation	M1, M2, M3, M4	F	○

I_6	UE accepts `nas_sm_cmd_replay` when sent immediately after `nas_sm_cmd_int`	M6	F	●
I_7	UE accepts `nas_sm_cmd_replay` even after registration complete	M6	LL	●
I_8	UE accepts the `reg_accept_header4_plain`, bypassing the authentication and security activation	S	PS, IL	●
I_9	Plain header NAS messages (i.e., `reg_accept_plain`, `conf_update_cmd_plain`) bypass the integrity check	S	IS, DoS	●
I_{10}	UE accepts `nas_sm_cmd_NIA0_plain`, bypassing NAS layer security activation	I	IL	●
I_{11}	UE accepts the `rrc_sm_cmd_NIA0_plain`, bypassing RRC layer security activation	I	IL, DG	○
I_{12}	UE responds to `nas_sm_cmd_replay` differently, enabling device fingerprinting	U1	F	●
I_{13}	UE does not release the radio connection immediately after accepting `dereg_req_protected`	U1	-	●
I_{14}	Upon receiving the second `rrc_sm_cmd_int`, UE replies with `rrc_sm_failure`	U1	-	●
I_{15}	UE does not accept `dereg_req_protected` (with "switch off" bit set to 1) after registration	U1	-	●
I_{16}	Before AS security activation, UE not accepting RRC messages with non-zero MAC	U1	-	●
I_{17}	UE does not accept `reg_accept_protected` inside *DL NAS Transport* message	U1	-	●
I_{18}	Out-of-sequence `ue_info_req_protected` interrupts ongoing registration procedure	U1	-	●
I_{19}	UE accept `nas_sm_cmd_header2_protected`	U1	-	●
I_{20}	UE replies with `conf_update_comp` when acknowledgment indicator not present	U2	II	●
I_{21}	UE responds to `nas_sm_cmd_NIA0_plain` differently, enabling device fingerprinting	U3	F	●
I_{22}	`rrc_sm_cmd_NIA0_plain` after `rrc_sm_cmd_int` makes all subsequent symbols unresponsive	D	DoS	●

Table 2: Property violations identified by `5GBaseChecker`. IL: information leak, LL: location leak, IS: identity spoofing, PS: phishing SMS, DoS: denial-of-service, DG: downgrade, F: fingerprinting device, II: interoperability issue. ●: not found in previous works on 5G. ○: found in previous works on 5G.

found some UEs accept plaintext *Registration Accept* with security header 4 before NAS security activation, which enables an attacker to bypass the whole NAS layer Authentication and Key Agreement (AKA) procedure. The attacker can exploit this vulnerability to provide a victim UE to access the Internet through a fake base station without data ciphering and integrity. She can also send fake SMS to the victim from the fake base stations. We elaborate on these in §10.1. On the other hand, in I_9, we found that one UE accepts plaintext *Registration Accept* and *Configuration Update Command* with security header type 0. This can lead to AKA bypass in the NAS layer and DoS for the victim.

9.2.3 Mishandling Information Elements (IEs) ($I_{10} - I_{11}$)

According to TS 24.501 [10], *NAS Security Mode Command* messages in 5G are not ciphered but are integrity-protected, ensured by a message authentication code (MAC) [10]. In I_{10}, an attacker can craft a *NAS Security Mode Command* with NIA0 and NEA0. Acceptance of this message enables the attacker to establish NAS layer security context with null cipher and null integrity and to bypass NAS layer security. In I_{11}, we found that some UEs, despite being prohibited by the specification [11], accept *AS Security Mode Command* messages with *NIA0* IE, leading to AS security bypass. This allows the attacker to inject any RRC layer messages without integrity protection. Exploiting this, the attacker may send an *RRC Reconfiguration* or *RRC Release* message to get sensitive UE information or downgrade the victim UE to 4G/2G.

9.2.4 Underspecified Specifications ($I_{12} - I_{21}$)

• **Incomplete information for mandatory features (I_{12}-I_{19}.)** For I_{12}, clause 4.4.3.2 in TS 24.501 [10] states that no specific mechanism is required for implementations to ensure replay protection. However, TS 24.501 [10] also mentions that when a *Security Mode Command* message cannot be accepted, the UE has to respond with a *Security Mode Reject* message. Based on the specification, it is not clear whether the UE should drop the replayed *NAS Security Mode Command* message or reply with *NAS Security Mode Reject*. Due to such ambiguous and incomplete instructions, some devices become vulnerable to fingerprinting attacks. In addition, devices responding with *NAS Security Mode Reject* are vulnerable to uplink NAS counter desynchronization attacks leading to denial of services [34]. For some other issues (I_{13}-I_{19}), the implementations deviate from each other, but the security impacts are not evident. For example, in I_{13}, after receiving the *Deregistration Request* message, the device's RRC layer connection is not dropped instantly, and it can still respond to some RRC layer messages, e.g., *AS Security Mode Command*. In I_{14}, some UEs respond with *Security Mode Failure* upon receiving a *second AS Security Mode Command*, while others do not. As for I_{15}, we also discovered that some UEs do not accept *Deregistration Request* message with "switch off" bit set to 1, while others do not check the value of this IE.

• **Incomplete information for optional features (I_{20}).** We found a UE implementation unexpectedly sends a response to a *Configuration Update Command* message even though the

Table 3: Queries required w/ and w/o hybrid learning.

"acknowledgment indicator" field is not present ($\boldsymbol{I_{20}}$). Since the core network does not expect any response to this message, it may behave unexpectedly upon receiving such a response from the UE and cause interoperability issues.

• **Conflicting information in the specifications ($\boldsymbol{I_{21}}$).** In $\boldsymbol{I_{21}}$, we observed that before authentication, some devices respond to *NAS Security Mode Command* with *NIA0*. Devices equipped with Exynos baseband follow TS 24.501 [10], clause 5.4.2.5, and respond with a *Security Mode Reject* message. The rest of the devices follow TS 24.501 [10], clause 7.5.1, and respond with *5GMM Status*. This deviating behavior enables an attacker to fingerprint the Exynos devices.

9.2.5 Flawed Specifications (I_{22})

According to TS 38.331 [11], clauses 5.3.7.1 and 5.3.7.2, after AS security activation, integrity check failure on *RRC messages* leads to an RRC connection release. However, this enables an adversary to force the victim UE to drop the connection upon receiving messages with wrong MAC values ($\boldsymbol{I_{22}}$). The attacker can repeat this attack for prolonged DoS.

9.3 Efficiency of StateSynth

To answer **RQ2**, we measure the number of queries, i.e., input message sequences, generated by StateSynth, and the total time required to extract each FSM. We summarize the results for each device in Table 4, along with the number of states and transitions. We also evaluate the effectiveness of different design decisions in StateSynth in this section.

Evaluating hybrid learning. To evaluate *hybrid learning*, we compute the cumulative number of queries in each iteration (hypothesis construction and validation) of *Active Learner* for one of the implementations– *Motorola Edge+*. We show the results in Table 3, where it is evident that hybrid learning reduces the number of queries by $\sim$2,300. As the passive FSM construction takes only $\sim$2 minutes, this improvement essentially translates to a $\sim$1,450 minutes decrease in total time for FSM extraction. Thus, this approach significantly improves StateSynth's efficiency.

Table 4: Queries, time, states, and transitions. MQ: membership queries, EQ: equivalence queries.

Evaluating collaborative learning. To evaluate *collaborative learning*, we extract the FSMs sequentially, as shown in Table 4, and present the required number of queries and time. For the first device, when potential counterexamples from other devices are not available, StateSynth requires $\sim$27,100 queries to extract the FSM. For subsequent devices, this number is reduced by $1.6-12.3$ times compared to approaches without collaborative learning [35], cutting the time requirements accordingly. This technique thus significantly boosts StateSynth's efficiency.

Comparison with existing FSM constructors. We compare StateSynth with an existing framework for FSM extraction from UE implementations, namely, DIKEUE [35]. Although this framework is for 4G implementations, we use its FSM inference module with our 5G OTA message infrastructure and the input alphabet of StateSynth. We refer to this modified version as DIKEUE*. Moreover, DIKEUE has a different termination condition for its FSM extraction. Thus, for a proper comparison, we use the same termination condition from DIKEUE in both StateSynth and DIKEUE* to extract the same level of information from the implementations.

Figure 5 shows the cumulative number of queries required for FSM extraction. For the first device, StateSynth clearly performs better than DIKEUE* (14,864 vs. 17,155 queries), which shows the impact of *hybrid learning*. For the subsequent devices, the improvement in efficiency is even more significant, as seen in the growth in the number of queries in the figure. Overall, DIKEUE* requires 73,657 queries to extract all the FSMs, whereas StateSynth requires only 26,715. This demonstrates that StateSynth brings significant improvement in FSM extraction of UE implementations.

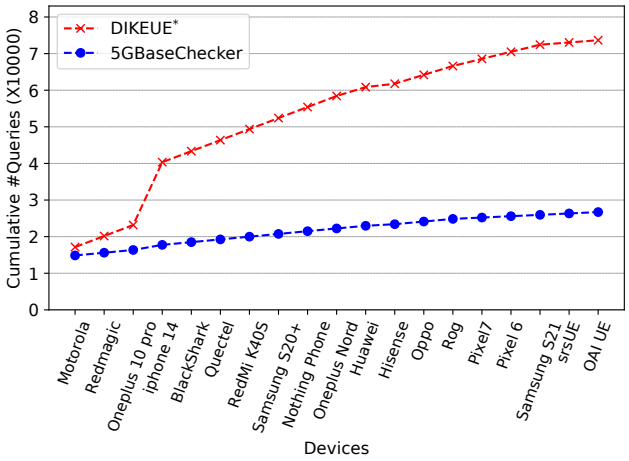

Figure 5: Comparison of FSM extraction.

9.4 Efficacy of DevScan

To address **RQ3**, we compare DevScan with the FSM equivalence checker components of BLEDiff [39], and DIKEUE [35]. We compute the number of deviations identified and the required time by StateSynth, BLEDiff, and DIKEUE and present them in Table 5. The results show that DevScan identifies ∼700 more deviations than the other approaches. For each pairwise FSM comparison, compared to DIKEUE, DevScan, however, requires ∼ 15 seconds more to find deviations. This is reasonable as we find more unique deviations by comprehensively traversing the FSMs.

Approach	# Deviations	Avg. time (sec.)
DIKEUE [35]	1325	83
BLEDiff [39]	724	118
5GBaseChecker	2044	98

Table 5: Number of deviations and time requirement.

9.5 Effectiveness and Efficiency of DevLyzer

To answer **RQ4**, we summarize how DevLyzer reduces the manual effort by the domain expert to analyze deviations and helps extract properties.

Reduction in manual effort. A new property in DevLyzer can resolve multiple deviations. As such, DevLyzer resolves multiple deviations within one iteration and thus requires smaller than $|\mathbb{D}|$ iterations. In our experiments, we ran DevLyzer on 2044 deviations found by DevScan and resolved them in 36 iterations by manually analyzing 36 deviations (one deviation $\psi^i \in \mathbb{D}$ per iteration) and identifying 45 properties in total, as the analysis of 9 deviations rendered more than one property. It took, on average, ∼2 minutes to analyze each deviation and extract the required properties. If we needed to analyze all of them manually, it would take ∼67 man-hours. Thus, we saved ∼65 man-hours of work using DevLyzer.

Approach	Dynamic	Guided property extraction	Partial positive tests	Interoperability detection	Stateful testing

DoLTEst [50]	✗	✓	✗	✗	✓
DIKEUE [35]	✓	✗	✓	✓	✓
UE security reloaded [15]	✗	✗	✗	✗	✗
SecChecker [58]	✗	✗	✓	✗	✗
5GBaseChecker	✓	✓	✓	✓	✓

Table 6: Comparison with existing testing approaches.

Extracted properties. With DevLyzer, we extracted a total of 45 properties, as listed in [2]. However, as we release these properties as one of our contributions, subsequent analysis of 5G devices using 5GBaseChecker can start with our extracted property set $\mathbb{P}$. In that case, most of the deviations would be automatically resolved even before any manual analysis, further lessening the manual effort required.

9.6 Comparison with Current Testing Methods

We address **RQ5** by comparing 5GBaseChecker with existing works in several directions. Table 6 shows the summary of these comparisons. Among the approaches compared with, several only statically generate, i.e., pre-compute test cases or perform static analysis on the baseband software [15, 42, 50, 58], whereas 5GBaseChecker analyzes implementations dynamically during testing. Some existing approaches, such as DoLTEst [50], use keywords, e.g., 'shall not', 'security activation', and 'integrity protected' to search security policies from specifications. This may, however, yield a large amount of policies to test that are either not security critical or duplicate. In contrast, 5GBaseChecker dynamically extracts policies based on deviating traces. Moreover, 5GBaseChecker performs some regular/positive tests (indicated by *partial positive testing* in Table 6) during FSM construction along with the negative ones. In contrast, a few approaches test the implementations with only negative test cases [15, 42, 50], avoiding positive testing altogether. Notably, some of these works also do not perform stateful analysis [15, 58], although 5G implementations are highly stateful. Further, 5GBaseChecker can discover interoperability issues as DIKEUE [35], whereas others cannot.

Effectiveness. Other than the above-mentioned comparisons, we also compare if these works are capable of identifying the exploitable and interoperability issues identified by 5GBaseChecker. We show the results in Table 7. Among these works, BASECOMP [42] performs tests only on integrity protection. Several works have a fixed set of properties or test cases [15, 50, 58], which do not include many of the issues found by 5GBaseChecker. Finally, DIKEUE [35] also misses several of these issues because of a limited alphabet.

Coverage on open-source UE implementation. Although 5GBaseChecker primarily focuses on finding security pol-

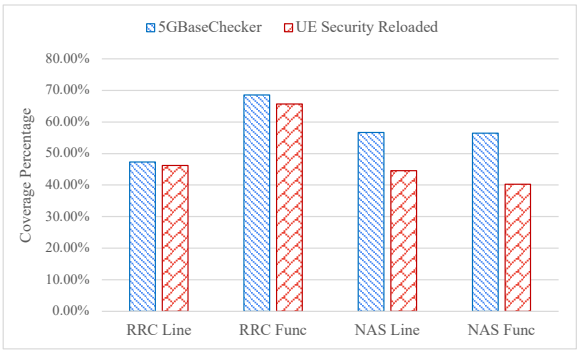

Figure 6: NAS and RRC implementation coverage.

icy violations in black-box UE implementations, we also compute the coverage information [4] for an open-source UE implementation, srsUE [8], using LCOV. We compare `5GBaseChecker` with an existing open-source 5G UE testing framework, namely, UE security reloaded [15], for this evaluation. Figure 6 shows that `5GBaseChecker` improves coverage in the NAS layer by ∼12% and in the RRC layer by ∼1%. This demonstrates that, in both layers, `5GBaseChecker` improves the coverage, which essentially translates to a more comprehensive testing approach.

10 Attack Case Study

10.1 5G AKA Bypass (I_8)

Exynos basebands accept plaintext *Registration Accept* with header 4 (integrity protected and ciphered with new 5G NAS security context) from a fake base station after sending a *Registration Request* without establishing NAS or RRC layer security. The adversary can exploit this behavior to grant unprotected data sessions and send phishing SMS's to victims.

Attack. Upon receiving the plaintext *Registration Accept* with security header 4, the UE replies with a plaintext *Registration Complete*, and a *PDU Session Establishment Request* message. The attacker then crafts a plaintext Downlink NAS Transport message (with security header 4) containing a plaintext *PDU Session Establishment Accept* and encapsulates that in an *RRC Reconfiguration* message to send it to the victim UE. This allows the attacker to bypass the 5G NAS AKA procedure completely. After that, the victim UE gains unprotected access to the Internet through the fake base station. The attack steps are shown in Figure 7 (a), which we also confirm end-to-end. Further, Figure 8 shows the trace, where we find that the victim UE sends DNS queries and starts accessing the Internet over the unprotected 5G connection.

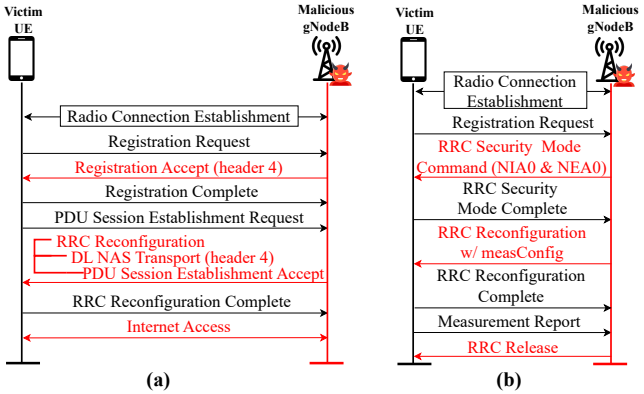

Figure 7: (a) 5G AKA bypass, (b) AS security bypass.

Exploiting the same vulnerability, we have also experimentally confirmed that the attacker can send a plaintext *DL NAS Transport* message with a phishing SMS to the victim [42].

Impact. As the adversary provides unprotected 5G data sessions, the attack leads to severe information leaks. For example, by intercepting the DNS queries, she can lead the victim to phishing websites to acquire sensitive credentials. Further, with fake SMSs, the adversary can cause panic and lure the victim into sharing sensitive information or sending money.

10.2 AS Security Bypass (I_{11})

Several basebands (shown in Table 8) accept *RRC Security Mode Command* with the null integrity protection algorithm (NIA0) and the null encryption algorithm (NEA0). The adversary can exploit this vulnerability to bypass the RRC layer security and inject any plaintext RRC messages without a valid MAC.

Attack. When the victim UE initiates the connection to the malicious gNodeB, the adversary crafts a *RRC Security Mode Command* message with null integrity protection and the null encryption algorithms (NIA0 & NEA0) and sends it to the victim UE (shown in Figure 7(b)). After that, the victim UE uses null integrity protection and null encryption in subsequent communication. The attacker can send plaintext *RRC Reconfiguration* with *measConfig* IE to retrieve measurement information from the victim UE. In addition, the attacker can also send plaintext *RRC Release* message with *redirectedCarrierInfo* IE to downgrade the victim UE to LTE or even 2G network, as shown in a prior work [58]. Furthermore, AS security bypass can lead to eavesdropping [50], as shown by previous work on LTE.

Impact. Bypassing the AS security and retrieving the measurement report from the victim UE, the adversary can infer

the location of the victim based on the signal strength information in the measurement report [54]. Moreover, the victim can be downgraded to prior-generation networks [58], and the communication can be eavesdropped by the adversary [50].

11 Related Work

Finite state machine (FSM) extraction. Several works perform automata learning to extract FSMs from protocol implementations of various protocols such as 4G LTE [35], TLS [23], DTLS [27], IoT [56], SSH [29], BLE [39], etc. In the area of cellular networks, Chlosta et al. [19] perform automata learning to model open-source core network projects but fail to extend to real-world implementations. ProCheker [40] extracts formal models through program analysis on open-source implementations and performs security analysis. DIKEUE [35], on the other hand, performs active automata learning on black box devices and leverages deviations among testing devices to find attacks through manual analysis.

Security analysis of cellular protocols. Many works [14, 22, 32, 34, 46, 52] manually create formal models from cellular specifications and perform model checking against manually crafted security properties. On the other hand, `5GBaseChecker` automatically extracts the models from black-box implementations. Kim et al. [44] identify three basic properties from 4G specifications and generate test cases based on them. DoLTEst [50] provides a stateful and comprehensive set of test cases to detect vulnerabilities for black-box 4G UE devices focusing on negative test cases. However, it does not provide positive test cases. UE Security Reloaded [15] and SecChecker [58] create 5G SA security testing frameworks with static lists of test cases. Contester [17] and Atomic [18], on the other hand, create test cases from the specifications using natural language processing techniques. However, these works do not create test cases dynamically depending on the implementations. BASECOMP [42] analyzes the integrity protection of baseband software through probabilistic inference and comparative analysis and checks for inconsistencies by consulting the specifications after locating them. Some approaches [31, 43, 45] require significant manual effort to analyze baseband firmware. Other approaches for baseband firmware include the usage of SDRs [3, 9], sending crafted messages to analyze vulnerability, and generating unusual messages [26]. However, these works do not work with black-box UE implementations.

12 Discussion and Limitations

Manual effort. `5GBaseChecker` requires domain expertise to define alphabet selection criteria and manual inspection of message formats to create an alphabet for testing. Additionally, the expert also needs to implement a 5G-specific adapter for converting symbols to concrete packets and vice versa. In addition, despite adopting the majority voting scheme of

Figure 8: Internet access through AKA bypass

prior works [35, 47], observational inconsistencies may still occur in the over-the-air queries/responses. Once an inconsistency is automatically detected, the user needs to manually analyze the inconsistent responses and rectify them before resuming the FSM construction. An expert also needs to manually identify security properties for unresolved deviations and represent corresponding properties in LTL for automated model checking with DevLyzer. However, compared to previous approaches [35, 39], DevLyzer significantly reduces such efforts by providing a semi-automated framework to resolve many deviations with one iteration of manual analysis.

Possible missing deviations. `5GBaseChecker` relies on deviations in UEs' behavior to find security and privacy properties and corresponding flaws. If all UEs have the same insecure/incorrect behavior, `5GBaseChecker` will not identify the corresponding properties and flaws. However, practically, this is highly unlikely for a diverse set of implementations.

Incompleteness of properties. As `5GBaseChecker`'s property extraction is guided by implementation deviations, the tested properties are not exhaustive.

Termination vs. FSM completeness. `5GBaseChecker` empirically chooses termination parameters N_0, N_1, and N_2 in FMS construction to balance between early termination and completeness of FSM learning. Although larger values of the parameters may increase the coverage of FSM construction and thus aid in finding more deviations, they will also increase the number of OTA queries and time required.

13 Conclusion and Future Work

We develop a scalable and efficient security analysis framework `5GBaseChecker` for testing 5G basebands. Our proposed hybrid and collaborative FSM learning technique significantly outperforms existing black-box automata learning-based approaches. Unlike prior works, `5GBaseChecker`'s graph traversal-based model refinement for pairwise FSM comparison enables it to identify many unique deviations in 5G basebands. Finally, `5GBaseChecker` utilizes deviations to find relevant security properties and design a semi-automated deviation analyzer that reduces manual effort in triaging and characterizing deviating traces. In the future, we will extend `5GBaseChecker` to analyze 5G session management procedures.

A Algorithm of DevLyzer

Algorithm 1 DevLyzer Algorithm

Require: Deviation Set ($\mathbb{D}$)
Output: Violation Instance Set $\mathcal{V}_i$ for each device $b_i \in \mathcal{B}$

$\mathbb{P} \leftarrow \emptyset$
$\mathbb{D}_u \leftarrow \mathbb{D}$ ▷ *set of unresolved deviating traces*
while $\mathbb{D}_u$ *is not empty* **do**
  $\psi_u^i \leftarrow PickRandom(\mathbb{D}_u)$ ▷ *pick a random deviation unresolved*
  $\mathbb{P}_{new} \leftarrow manualAnalysis(\psi_u^i)$ ▷ *manually analyze deviation and find new properties*
  $\mathbb{P}' \leftarrow \mathbb{P} \cup \mathbb{P}_{new}$
  for *each* ψ^i *in* $\mathbb{D}$ **do**
    for *each* $\gamma_{out}^{i,j}$ *in* ψ^i **do**
      $M_{dev}^{i,j} \leftarrow createFSM(S_{in}, \gamma_{out}^{i,j})$
      for *each* $\rho \in \mathbb{P}$ **do**
        $recordViolation(M_{dev}^{i,j}, \rho)$ ▷ *model checking*
      end for
    end for
  end for
  for *each* ψ^i *in* $\mathbb{D}_u$ **do**
    $resolved \leftarrow checkResolve(\psi^i, \rho)$ ▷ *Equation 1*
    if *resolved* **then**
      $\mathbb{D}_u \leftarrow \mathbb{D}_u - \psi^i$
    end if
  end for
end while

B StateSynth Algorithm

The FSM extraction algorithm for StateSynth is provided in Algorithm 2. It takes as input a set of UEs and benign network traces. For each UE (b_i), StateSynth first builds an initial FSM M_i^p with *Passive Learner* and generates an initial hypothesis model M_i^0 with *Active Learner* (lines 4-5). The deviations between these two FSMs are saved as potential CEs (TCE) (lines 6-8). *Active Learner* then checks if these TCEs are valid for M_i and the implementation and refines

#	Device Name	Baseband Vendor	SoC Model	Baseband Model	Baseband Version	Found Issues
