Approximation with Introduced Randomness. To sidestep the above issues, Lotto introduces randomness to the selection process by incorporating secure random selection (§3.4) to *approximate* a given informed algorithm. The server first *refines* the population by excluding a fraction d of clients with the lowest utility, based on the original criteria employed in the algorithm. It then applies secure random selection to the refined population. For example, if the original algorithm prioritizes the fastest clients, Lotto approximates it by first excluding the slowest d of clients before random selection.

Effectiveness of Population Refinement. Consider the following single-metric scenario without loss of generality: the original algorithm selects the best s clients out of the initial population of size n_{init} based on a metric X (Case A). When employing Lotto, s clients are randomly selected from the refined population of size $n = n_{init}(1-d)$ (Case B).

The extent to which Lotto approximates the original algorithm relies on the disparity in participant quality, as measured by X, between Case A and Case B. This difference, in turn, depends on the distribution of X across the initial population. Intuitively, Lotto best approximates the original algorithm when X follows a long-tailed distribution (e.g., power-law distributions [20]), where the majority of the population is considered "good" and only a small fraction is deemed "bad". In this case, Lotto can exclude almost all the relatively few "bad" participants. For example, suppose that X is the smaller, the better, and it follows Zipf's distribution parameterized by p, such that the X value of the i-th worst client is proportional

(a) X follows Zipf's distribution. (b) Effectiveness of refinement.

Figure 4: Lotto excels in approximating the original algorithm when the majority of the initial population is "good".

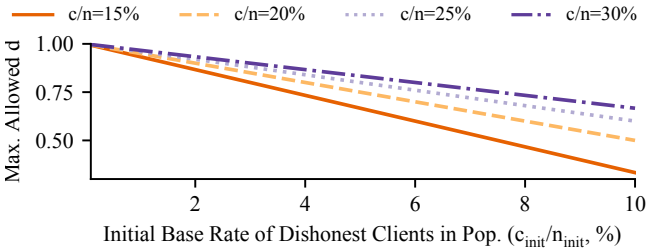

Figure 5: The maximum exclusion scale d that allows to achieve a target base rate of dishonest clients in the refined population (c/n) given various initial base rates (c_{init}/n_{init}).

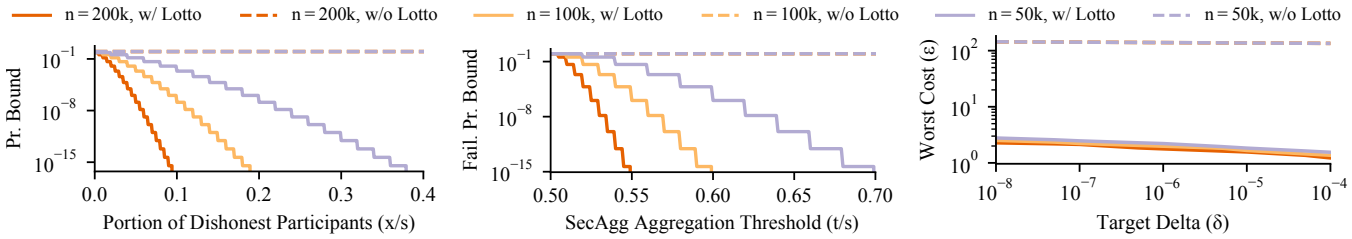
to i^{-p}. In this case, precluding the worst d of the initial population enhances the quality of the worst client in the refined population by a factor of $(1-d)^{-p}$, as shown in Figure 4.

At the other extreme, there could be a scenario where the majority of clients are "bad" while only the minority are "good." In this case, our approximation may not yield participants of quality comparable to the original algorithm. We acknowledge this limitation yet contend that this compromise is a necessary cost in order to secure the selection process.

Privacy-Utility Tradeoff under a Malicious Server. While excluding more "bad" clients helps create a better-refined population, it may also exclude more honest clients. When the server behaves honestly, this does not alter the base rate of dishonest clients in the refined population c/n, since they are equally excluded. However, a malicious server can grow this rate by intentionally excluding honest clients and/or more clients than planned. To limit the impact of such misbehaviors, Lotto first enables the enforcement of a specific d by having participants check the size of the refined population n against the minimum acceptable one n_{min} (§3.4).

Next, the selection of d involves a tradeoff between privacy and utility, where a smaller d provides enhanced privacy but also reduces the potential utility. We recommend utilizing the maximum permissible exclusion scale to attain a desired base rate of dishonest clients in the refined population, while minimizing the compromise on utility, as illustrated in Figure 5. For instance, if 5% of the initial client population consists of dishonest clients, using an exclusion scale no larger than 75% can ensure that the base rate of dishonest clients in the refined population does not exceed 20% in the worst case.

Handling Multiple-Metric Algorithms. In the cases where the original algorithm incorporates two or more independent metrics, a straightforward approach to conducting population refinement is the `Or` strategy which excludes the worst clients based on one of the metrics. Alternatively, we can also adopt the `And` strategy that excludes clients that perform poorly in all metrics simultaneously. Furthermore, if the original informed algorithm combines the information from the two metrics into a single comprehensive metric, such as what Oort defines as the utility score (§3.1), there further exists a `Joint` strategy which directly relies on this single metric for population refinement. We advocate the adoption of `Or` due to its superiority demonstrated in empirical experiments (§5.3).



3.6 Security Analysis

Secure Random Selection. Our primary objective is to limit the number of dishonest participants (§3.1). To assess how well Lotto's random selection achieves it, we focus on the properties exhibited by the finalized participant list P. Consider a population of size n, with c clients being dishonest. We denote by s the desired number of sampled clients, and x the number of clients that an adversary could manipulate among the selected participants. Let n_{min} be the population threshold, m the randomness range, and α the over-selection factor. Theorem 2 holds despite the adversary's misbehavior.

Theorem 2 (Security of Random Selection)**.** *If the protocol proceeds without abortion, for any $\eta > 1$, the probability that the proportion of dishonest participants, i.e., x/s, exceeds that in the population, i.e., c/n, is upper bounded as*

$$\Pr[\frac{x}{s} > \eta\frac{c}{n}] \leq 1 - \sum_{i=0}^{\lfloor \eta cs/n \rfloor} \binom{c}{i} \left(\frac{1}{m}\lfloor\frac{\alpha sm}{n_{min}}\rfloor\right)^{i} \left(1 - \frac{1}{m}\lfloor\frac{\alpha sm}{n_{min}}\rfloor\right)^{c-i}.$$

Intuitively, the larger the value of η, the smaller the right-hand side of the inequality mentioned above. This clearly demonstrates the effectiveness of Lotto as a secure selection framework for achieving the desired property (§3.1). While the proof is deferred to Appendix A, the significance of Theorem 2 in a practical scenario is visualized in Figure 6a. Here, we vary the population size n, while the number of colluding clients in the population set as $c = 10^3$, and the target number of participants as $s = n/1000$. We consider $\alpha = 1.3$, $m = 2^{256}$, and $n_{min} = n$. When the population size $n = 2 \times 10^5$, employing insecure random selection results in a probability of 1 for the event where the fraction of dishonest participants exceeds 5% (i.e., $\eta c/n$ with $\eta = 10$). However, with Lotto, this probability becomes negligible, approximately 1.3×10^{-7}.

(a) Direct implication. (b) End-to-end impact with SecAgg. (c) End-to-end impact with distributed DP.

Figure 6: Lotto's random selection effectively prevents arbitrary manipulation by the server in practical settings (§3.6).

We further use Theorem 2 to analyze the security of SecAgg and distributed DP (§2.2) when protected by Lotto. The related proof can also be found in Appendix A.

Corollary 1 (Bounded Failure Probability in SecAgg [12])**.** *Let t be the aggregation threshold of SecAgg (§2.2). With Lotto's random selection, the probability of the server being able to observe an individual update of an honest client, which indicates a failure of SecAgg, is upper bounded as*

$$\Pr[Fail] \leq 1 - \sum_{i=0}^{2t-s-1} \binom{c}{i} \left(\frac{1}{m}\lfloor\frac{\alpha sm}{n_{min}}\rfloor\right)^{i} \left(1 - \frac{1}{m}\lfloor\frac{\alpha sm}{n_{min}}\rfloor\right)^{c-i}.$$

Corollary 2 (Controlled Privacy Cost in Distributed DP, I)**.** *Let π be the distributed DP protocol parameterized by σ and built atop SecAgg with aggregation threshold t. Given target δ, an R-round FL training with π and Lotto's random selection (*`Client-Centric`*) achieves (ε, δ)-DP, where*

$$\varepsilon = \min_{\substack{0\leq k\leq \min\{c,2t-s-1\} \\ 0\leq r\leq R \\ p_k+q_r<\delta}} E_\pi(s,k,r,\sigma, 1-\frac{1-\delta}{1-p_k-q_r}),$$

$$p_k = 1 - \left(\sum_{i=0}^{k} \binom{c}{i} \left(\frac{1}{m}\lfloor\frac{\alpha sm}{n_{min}}\rfloor\right)^{i} \left(1 - \frac{1}{m}\lfloor\frac{\alpha sm}{n_{min}}\rfloor\right)^{c-i}\right)^{R},$$

with σ the noise multiplier used in π, and $E_\pi(\cdot)$ the privacy accounting method of π. In addition, $q_r = \phi_{R,r}$ with the recurrence definition of ϕ being $\phi_{j,r} = 1 - \gamma(j,r) + \gamma(j,r)\phi_{j-1,r}$ with boundary condition $\phi_{r,r} = 0$ and $\gamma(j,r) =$

$$\left(\sum_{i=0}^{r-1} \binom{j-1}{i} \left(\frac{1}{m}\lfloor\frac{\alpha sm}{n_{min}}\rfloor\right)^{i} \left(1 - \frac{1}{m}\lfloor\frac{\alpha sm}{n_{min}}\rfloor\right)^{j-1-i}\right)^{s}.$$

Corollary 1 provides insights into the robustness of Lotto in maintaining the security of SecAgg, while Corollary 2 outlines the end-to-end privacy guarantees offered by Lotto when integrated with existing distributed DP systems. In the specific case discussed above, when SecAgg is used with t set larger than $0.53s$[3], the probability of SecAgg's failure diminishes to less than 8.9×10^{-6} when employing Lotto. Otherwise, the probability is 1 (Figure 6b). Building upon SecAgg with $t = 0.7s$, if DSkellam [6] is implemented as the distributed DP protocol, with a target $\delta = 1/n$ and using a consistent noise multiplier, training over FEMNIST (refer to the related settings in §5.1), Lotto guarantees a moderate privacy cost of $\varepsilon = 1.8$. In contrast, insecure selection would result in a prohibitive cost of $\varepsilon = 265$ (Figure 6c).

Secure Informed Selection. Population refinement in Lotto's informed selection can be deemed as a preprocessing step that precedes its random selection (§3.5). Hence, the security guarantee provided can be inherited from the random selection. Assume that the initial population consists of n_{init} clients, with c being the number of dishonest clients. Denote by n the size of the refined population. As the server can act maliciously by deliberately excluding honest clients, in the worst case, all c dishonest clients remain in the refined population. Therefore, the security guarantee can be derived by *directly* applying Theorem 2.

4 Implementation

We have implemented Lotto as a library easily pluggable into existing FL systems with 1235 lines of Python code. It operates within the server and on each client.

System Workflow. Figure 7 shows how Lotto interacts with the FL execution framework during participant selection. ① *Pool Confirmation*: the framework forms a pool with clients meeting eligibility properties (e.g., battery level, §2.1) and forward their identities and characteristics (e.g., latency) to Lotto. In case of informed selection, the server end refines the pool by excluding worst-performing clients based on specific criteria. Lotto next proceeds to random selection and has two variants. ②a *Server-Centric Selection*: the server end selects participants from the pool as candidates using PRFs. ②b *Client-Centric Selection*: for each client in the pool, the server end informs its client end to self-sample with VRFs. Clients meeting the selection conditions report their results and become candidates. ③ *Mutual Verification*: the server selects the target number of clients from candidates as par-

[3]The feasible range of t SecAgg is $(0.5s, s]$ in the malicious settings [12].

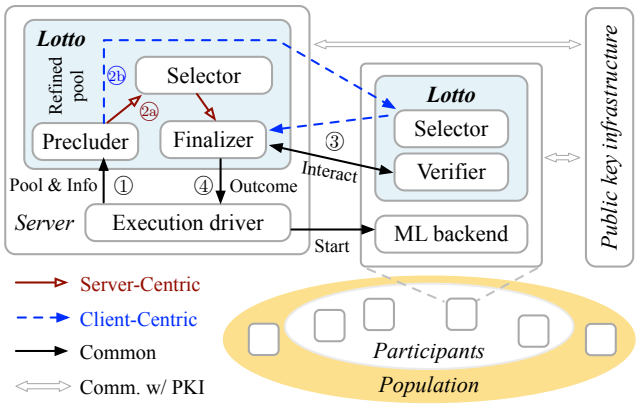


Figure 7: Lotto architecture.

ticipants. It then helps each participant verify the participant list. ④ *Finalization*: The FL framework proceeds with the participant list output by Lotto and starts FL training.

Cryptographic Instantiation. Secure PRFs can be implemented with a cryptographic hash function in conjunction with a secret key, and we use `HMAC-SHA-256`. For secure signature schemes, we utilize `Ed25519` [9], an elliptic-curve-based signature scheme. Both of the above choices are implemented leveraging the `cryptography` Python library [1]. We implement VRFs using `ECVRF-Ed25519-SHA512-Elligator2` as specified in [3] using the codebase provided by [5].

5 Evaluation

We evaluate Lotto's effectiveness in various FL training testbeds. The highlights of our evaluation are listed below.

1. Compared to insecure selection methods, Lotto introduces at most 10% runtime overhead and negligible extra network usage across different participation scales (§5.2).
2. In the case of informed selection, the adoption of Lotto achieves comparable or even superior training efficiency compared to that of insecure methods (§5.3).

5.1 Methodology

Datasets and Models. We run two common categories of applications with three real-world datasets of different scales.

- *Image Classification*: the FEMNIST [14] dataset, with 805k images classified into 62 classes, and a more complicated dataset OpenImage [2] with 1.5M images spanning 600 categories. We train a CNN [6,35], and MobileNet V2 [50] with 0.25 as width multiplier to classify the images in FEMNIST and OpenImage, respectively.
- *Language Modeling*: the large-scale Reddit dataset [4]. We train the Albert model [40] for next-word prediction.

Cluster Setup. We launch an AWS EC2 `r5n.8xlarge` instance (32 vCPUs, 256 GB memory, and 25 Gbps network) for the server and one `c5.xlarge` (4 vCPUs and 8 GB memory) instance for each client, aiming to match the computing power of mobile devices. We also throttle clients' bandwidth to fall at 44Mbps to match the average mobile bandwidth [19].

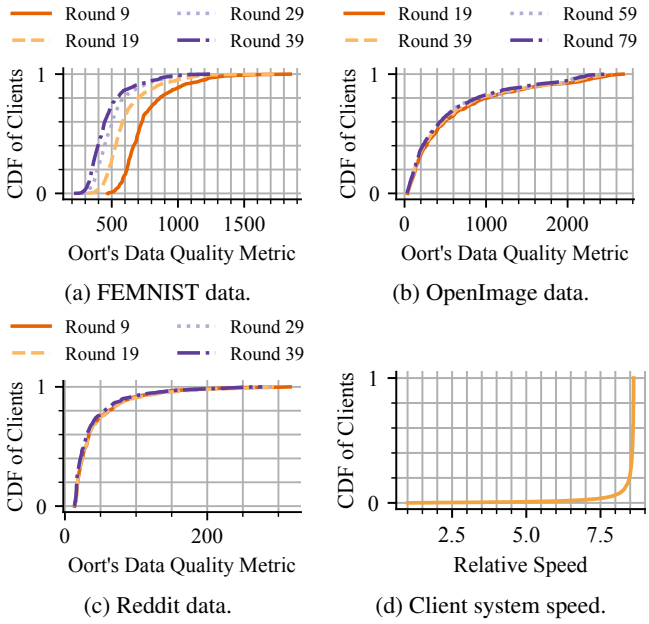
Hyperparameters. For local training, we use the mini-batch SGD for FEMNIST and OpenImage and AdamW [42] for Reddit, all with momentum set to 0.9. The number of training rounds and local epochs are 50 and 2 for both FEMNIST and Reddit and 100 and 3 for OpenImage, respectively. The batch size is consistently 20, while the learning rate is fixed at 0.01 for FEMNIST and 8e-5 for Reddit, respectively. For OpenImage, the initial learning rate is 0.05, and decreases by a factor of 0.98 after every 10 rounds. For model aggregation, we apply weighted averaging [44] protected by the SecAgg [12] protocol (§2.2).

Baselines. In evaluating random selection, we compare Lotto against Rand [44], the naive random selection protocol. As for informed selection, we compare Lotto against Oort [39], the state-of-the-art informed algorithm designed for maximum training efficiency. Both Oort and Rand are insecure as the server has the freedom to include dishonest clients. For Lotto, we primarily evaluate `Client-Centric`, while also demonstrating its similarity to `Server-Centric` (§3.4).

5.2 Execution Efficiency

We assess the time performance and network overhead of Lotto. To study the impact of the federation scale, we vary the population size from 100 to 400 to 700. The target sampled clients are proportionately set to 10, 40, and 70, respectively.

Lotto Induces Acceptable Overhead in Time. Table 2 reports the average round time measured at the server when random selection is deployed. Compared to Rand, training with `Client-Centric` incurs a time cost of less than 6%, 8%, and 10% for population sizes of 100, 400, and 700, respectively. Moreover, the overhead for `Server-Centric` is 1%, 4%, and 3%, respectively. Such acceptable overhead is expected as Lotto is built on lightweight security primitives (3.4). Table 2 also reports the time cost from the perspective of participants. In comparison to Rand, `Server-Centric` incurs less than 4% overhead at the participant side, again; whereas `Client-Centric` incurs an overhead of up to 40% due to the offloading of the client selection process to each client.[4] Regarding informed selection, the observed trends are similar to those reported in Table 2 (with Rand replaced by Oort) and are deferred to Appendix C.



[4] Such inflation barely affects the end-to-end latency (measured at the server end) as participants run in parallel with the server.

Table 2: Per-round training time and network transfer cost for the server and average participating client with random selection.

FL Application		FEMNIST@CNN				OpenImage@MobileNet				Reddit@Albert			
Population	Protocol	Time		Network		Time		Network		Time		Network	
		Server	Client	Server	Client	Server	Client	Server	Client	Server	Client	Server	Client
100	Rand	1.76min	0.97min	64.88MB	3.9MB	3.06min	2.28min	64.35MB	3.87MB	13.0min	6.67min	958.55MB	57.46MB

	Srv-Ctr	1.77min	0.97min	64.89MB	3.9MB	2.97min	2.17min	64.36MB	3.87MB	12.88min	6.58min	958.86MB	57.46MB
400	Rand	2.56min	1.4min	0.26GB	3.56MB	4.35min	3.36min	0.25GB	3.53MB	26.94min	15.65min	3.75GB	51.53MB
	Cli-Ctr	2.59min	1.83min	0.26GB	3.56MB	4.68min	3.89min	0.25GB	3.53MB	27.53min	21.95min	3.75GB	51.53MB
	Srv-Ctr	2.29min	1.3min	0.26GB	3.56MB	4.51min	3.49min	0.25GB	3.53MB	27.17min	15.76min	3.75GB	51.53MB
700	Rand	3.46min	2.01min	0.45GB	3.69MB	5.65min	4.1min	0.45GB	3.66MB	40.06min	24.77min	6.56GB	52.57MB
	Cli-Ctr	3.82min	2.82min	0.45GB	3.69MB	6.23min	5.06min	0.45GB	3.66MB	39.59min	33.91min	6.56GB	52.57MB
	Srv-Ctr	3.56min	2.02min	0.45GB	3.7MB	5.62min	4.06min	0.45GB	3.66MB	38.85min	23.84min	6.56GB	52.57MB

Lotto Induces Negligible Overhead in Network. Table 2 also provides the network footprint per round, measured at both the server end and the participant end. As one can see, Lotto consistently introduces less than 1% network overhead across all evaluated tasks and participation scales. This can be attributed to the fact that the predominant communication overhead in FL is the transmission of the model, rather than other auxiliary information. For example, when training over Reddit with 700 clients, model transfer in a round yields a network footprint of approximately 6.56 GB to the server. In contrast, the extra cost brought by `Client-Centric` and `Server-Centric` are merely 1.3 MB and 0.3 MB, respectively. As for informed selection, again, we defer the results to Appendix C given the similar implications.

Client-Centric v.s. Server-Centric. The preceding analysis emphasizes Lotto's minimal time and network costs, irrespective of whether it is implemented using a `Client-Centric` or `Server-Centric` approach. Given their comparable efficiency, we recommend adopting `Client-Centric`, as it ensures enhanced security (§3.4).

(a) FEMNIST data. (b) OpenImage data. (c) Reddit data. (d) Client system speed.

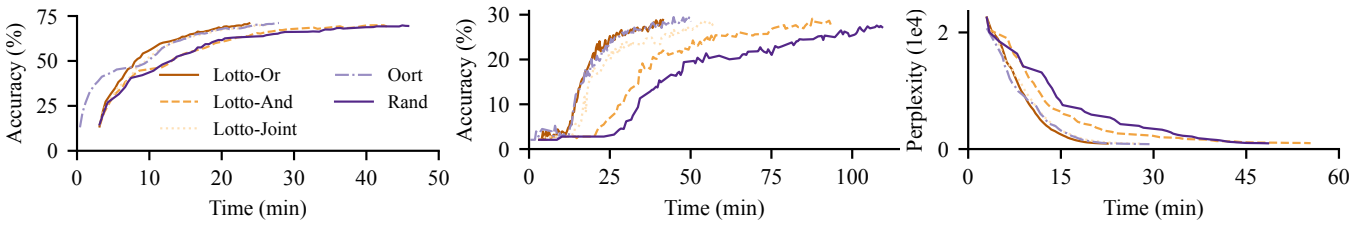

Figure 8: Visualization of the heterogeneous settings.

5.3 Effectiveness of Informed Selection

We next evaluate the effectiveness of Lotto's approximation strategies in achieving the objective of the target informed selection algorithm. We focus on the `Client-Centric` implementation of Lotto and use the 700-client testbed (§5.2).

Heterogeneous Environment. The realistic datasets we employ (§5.1) already demonstrate data heterogeneity, as they are partitioned by the original data owners. Figure 8a to 8c provides a visualization of the distribution of clients' data quality, as measured by Oort's definition (the first term in Equation (3)) without loss of generality. Snapshots are taken across different rounds of the training. For Oort's considerations on system speed to be relevant, we additionally emulate hardware heterogeneity. To this end, we set the response latencies of clients to consistently follow a Zipf distribution parameterized by $a = 1.2$ (moderately skewed), regardless of the specific FL task, as illustrated in Figure 8d.

The `Or` Strategy Outperforms Other Choices of Lotto. Lotto considers various strategies for population refinement when approximating the target informed algorithm (§3.5). Here, we compare them using a consistent exclusion threshold of 20%. Under this threshold, a client is excluded if it ranks in the bottom 20% in either system speed or data quality (`Or`); in both metrics (`And`); or in the comprehensive utility score (Equation (3)) defined by Oort (`Joint`). Additionally, we include the Rand method as a baseline reference. As illustrated in Figure 9, `Or` and `Joint` constantly outperform Rand, while `And` fails to surpass it in certain cases, e.g., FEMNIST (Fig. 9a). This can be attributed to the independent distributions of system speed and data quality across clients. As there are only a few clients that rank in the bottom 20% simultaneously for both metrics (observed to be $\leq$5% of the population), the number of clients that `And` excludes is inad-

(a) FEMNIST@CNN (b) OpenImage@MobileNet. (c) Reddit@Albert.

Figure 9: Lotto (with `Or` strategy) effectively approximates Oort and significantly outperforms Rand in training efficiency.

equate. Between `Or` and `Joint`, we advocate the use of the former due to its consistently superior performance and fix its use for the remaining analysis.

Lotto Achieves Comparable or Even Superior Performance to Oort. To examine the time-to-accuracy performance, we set the target accuracy at 69.8% and 27.6% for FEMNIST and OpenImage, respectively. For Reddit, we set the target perplexity (lower values are better) at 1010. As depicted in Figure 9, Lotto achieves nearly identical performance to Oort in OpenImage, and it even surpasses Oort by 1.1× for both FEMNIST and Reddit. In comparison to Rand, Lotto outperforms it by 2.1×, 3.0×, and 1.6× in FEMNIST, OpenImage, and Reddit, respectively. Note that we have accounted for the disparity in execution efficiency between Lotto and baselines (§5.2) for fairness of comparison. These results underscore the significant enhancement in the quality of selected clients through population refinement, specifically employing the `Or` strategy with a 20% exclusion factor, making the following random selection competitive with Oort which cherrypicks the best clients. Overall, the randomness introduced by Lotto for enhanced security does not compromise the training efficiency achieved by insecure methods.

6 Discussion and Future Work

Enhanced Support for SecAgg and Distributed DP. Lotto achieves a proportion of compromised participants close to the base rate of dishonest clients in the population, regardless of its magnitude (Theorem 2). Following this property, given an honest majority in the population, Lotto further ensures an honest majority among the participants. This entertains both secure aggregation (by tightening the bound in Corollary 1) and distributed differential privacy (by lowering the bound in Corollary 2). This condition can hold in practice, as simulating or compromising a large number of clients incurs prohibitive costs for the adversary given a vast client population in FL.[5] Specifically, it is expensive to register millions of identities to a PKI, which usually requires a unique, verifiable identifier for validation [8, 12]. For example, applying for Hong Kong Post eCert for individual PKI use mandates personal IDs [48]. Moreover, the costs involved in operating a client botnet at scale are also excessively high [52].

General Solutions for Inter-Stage Consistency. Lotto does not explicitly ensure consistent reference to a participant list throughout the entire FL workflow. This is because, for SecAgg this paper primarily focuses on, any inconsistent reference by the server offers no significant advantage in probing clients' data (§3.4). This applies to other secure aggregation protocols, such as SecAgg+ [8], the state-of-the-art follow-up work of SecAgg. Similar to SecAgg, SecAgg+ ensures that each participant will not share secrets with clients beyond its verified participant list, and also includes controllable dropout tolerance that can prevent the server from pretending the dropout of numerous honest participants. However, it would be beneficial to explore general solutions for achieving inter-stage consistency when combining Lotto with other potential privacy-enhancing techniques in the future.

7 Related Work

Privacy-Preserving Aggregation with Malicious Server. Numerous protocols have been proposed to enable a server to learn the sum of multiple inputs without gaining access to individual inputs. However, many of these protocols assume an honest-but-curious server [34, 54, 55] or a trusted third party [10, 18, 26], which has limited practicality. Only the commonly used SecAgg [12] and SecAgg+ [8] and a few other protocols [41, 43, 49] allow for a malicious server. To further control the information leakage through the sum, distributed DP protocols [6, 33, 35, 58] provide rigorous privacy guarantees by combining the DP noise addition with SecAgg. However, both secure aggregation and distributed DP are still vulnerable to the privacy risks posed by a dishonest majority among participants, while Lotto takes the initiative to tackle this issue by secure participant selection.

Secure Model Utility against Adversaries. Besides probing data privacy, an adversary may also compromise the global model performance [7, 27, 51, 62]. Several approaches have been proposed to mitigate these attacks, e.g., by employing certifiable techniques during local training [13, 15, 65] and

[5] If there are only tens or hundreds of clients, participant selection is no longer needed as all clients can be involved simultaneously [36].

model aggregation. These approaches back up Lotto with robust model utility, whereas Lotto enhances data privacy.

8 Conclusion

Several aggregation protocols have been developed in FL to enhance the privacy of clients' data. However, the participant selection mechanisms used in these protocols are vulnerable to manipulation by adversarial servers. We proposed Lotto to address this problem. Lotto offers two secure selection algorithms, random and informed, both of which effectively align the fraction of compromised participants with the base rate of dishonest clients in the population. Theoretical analysis and large-scale experiments demonstrate that Lotto not only provides enhanced security but also achieves time-to-accuracy performance comparable to insecure selection methods, while incurring minimal network cost.

Acknowledgments

A Proofs for Security Analysis Results (§3.6)

Theorem 2. *If the protocol proceeds without abortion, for any $\eta > 1$, the probability that the proportion of dishonest participants, i.e., x/s, exceeds that in the population, i.e., c/n, is upper bounded as*

$$\Pr[\frac{x}{s} > \eta\frac{c}{n}] \leq 1 - \sum_{i=0}^{\lfloor \eta cs/n \rfloor} \binom{c}{i} \left(\frac{1}{m}\lfloor\frac{\alpha sm}{n_{min}}\rfloor\right)^i \left(1 - \frac{1}{m}\lfloor\frac{\alpha sm}{n_{min}}\rfloor\right)^{c-i}.$$

Proof. The probability that x exceeds some value l is $\Pr[x > l] = 1 - \sum_{i=0}^{\lfloor l \rfloor} \binom{c}{i} p^i (1-p)^{c-i}$, where p is a dishonest client's chance of being selected into P. With client verification and consistency check enforced in Lotto, we have that $p = \frac{1}{m}\lfloor\frac{\alpha sm}{n}\rfloor \leq \frac{1}{m}\lfloor\frac{\alpha sm}{n_{min}}\rfloor$. The theorem follows when we combine the two arguments with $l = \lfloor \eta cs/n \rfloor$. □

Corollary 1. *Let t be the aggregation threshold of SecAgg. With Lotto's random selection, the probability of the server being able to observe an individual update of an honest client, which indicates a failure of SecAgg, is upper bounded as*

$$\Pr[Fail] \leq 1 - \sum_{i=0}^{2t-s-1} \binom{c}{i} \left(\frac{1}{m}\lfloor\frac{\alpha sm}{n_{min}}\rfloor\right)^i \left(1 - \frac{1}{m}\lfloor\frac{\alpha sm}{n_{min}}\rfloor\right)^{c-i}.$$

Proof. In SecAgg, the secrecy of an individual update is held only when the number of dishonest participants $x < 2t - s$ (see Theorem 6.5 in [12]). The corollary follows when we replace l with $2t - s - 1$ in the proof of Theorem 2. □

Corollary 2. *Let π be the distributed DP protocol parameterized by σ and built atop SecAgg with aggregation threshold t. Given target δ, an R-round FL training with π and Lotto's random selection (`Client-Centric`) achieves (ε, δ)-DP, where*

$$\varepsilon = \min_{\substack{0 \leq k \leq \min\{c, 2t-s-1\} \\ 0 \leq r \leq R \\ p_k + q_r < \delta}} E_\pi(s, k, r, \sigma, 1 - \frac{1-\delta}{1-p_k-q_r}),$$

$$p_k = 1 - \left(\sum_{i=0}^{k} \binom{c}{i} \left(\frac{1}{m}\lfloor\frac{\alpha sm}{n_{min}}\rfloor\right)^i \left(1 - \frac{1}{m}\lfloor\frac{\alpha sm}{n_{min}}\rfloor\right)^{c-i}\right)^R,$$

with σ the noise multiplier used in π, and $E_\pi(\cdot)$ the privacy accounting method of π. In addition, $q_r = \phi_{R,r}$ with the recurrence definition of ϕ being $\phi_{j,r} = 1 - \gamma(j,r) + \gamma(j,r)\phi_{j-1,r}$ with boundary condition $\phi_{r,r} = 0$ and $\gamma(j,r) =$

$$\left(\sum_{i=0}^{r-1} \binom{j-1}{i} \left(\frac{1}{m}\lfloor\frac{\alpha sm}{n_{min}}\rfloor\right)^i \left(1 - \frac{1}{m}\lfloor\frac{\alpha sm}{n_{min}}\rfloor\right)^{j-1-i}\right)^s.$$

Proof. In each round, each client flips a coin and becomes a candidate with probability $p = \frac{1}{m}\lfloor\frac{\alpha sm}{n_{min}}\rfloor$. The server then selects s participants from the candidates according to some selection policy. First, consider the event that in each round, there are at most k colluding participants in the candidate sets (Event A). The probability of A is

$$\Pr[A] = \left(\sum_{i=0}^{k} \binom{c}{i} p^i (1-p)^{c-i}\right)^R = 1 - p_k,$$

when the FL algorithm runs for R rounds, and $p = \frac{1}{m}\lfloor\frac{\alpha sm}{n_{min}}\rfloor$ given the use of Lotto (`Client-Centric`).

Next, consider the event that every client is selected in at most r rounds (Event B). We now derive a lower bound on its probability. Let $f_{n,R,r}$ be the maximum (among all possible policies) probability that at least one client is selected in at least $r+1$ rounds, given that the population has n clients and the training runs for R rounds. Consider the s clients selected by the server in the first round. Let E be the event that none of these s clients becomes a candidate in at least r rounds in the remaining $R-1$ rounds. Conditioning on E, all of them cannot be selected in at least $r+1$ rounds. Thus, if one client is selected in at least $r+1$ rounds, it must be either (i) one of the $n-s$ clients that are not selected in the first round, or (ii) selected in at least $r+1$ rounds among the rest $R-1$ rounds. We then have $f_{n,R,r} \leq \Pr[E] f_{n-s,R-1,r} + 1 - \Pr[E]$, where

$$\Pr[E] = \left(\sum_{i=0}^{r-1} \binom{R-1}{i} p^i (1-p)^{R-1-i}\right)^s.$$

By definition, $f_{n,r,r} = 0$, as no clients can be selected in $r+1$ rounds given only r rounds in total. When $n > sR$, we can see by induction that $f_{n,R,r} \leq \phi_{R,r}$, where $\phi_{R,r}$ is as defined in the corollary. For $n \leq sR$, since $f_{n,R,r}$ is non-decreasing in n (the server can simply ignore clients), we also have $f_{n,R,r} \leq f_{sR+1,R,r} \leq \phi_{R,r}$. Thus, $\Pr[B] \geq 1 - f_{n,R,r} \geq 1 - \phi_{R,r} = 1 - q_r$.

As SecAgg tolerates $2t - s - 1$ colluding clients, conditioning on the event $A \cap B$, the FL protocol is (ε', δ')-DP for $0 \leq k \leq \min\{c, 2t-s-1\}$, and $0 \leq r \leq R$, where $\varepsilon' = E_\pi(s, k, r, \sigma, \delta')$. Thus the overall FL training is $(\varepsilon', 1 - (1-\delta')\Pr[A \cap B])$-DP. The union bound implies that this happens with probability $\Pr[A \cap B] \geq 1 - p_k - q_r$. Thus for a target δ, we can set $\delta' = 1 - (1-\delta)/(1-p_k-q_r)$. Minimizing ε' over all valid k and r gives the desired results. □

B Client-Centric v.s. Server-Centric

We consider `Client-Centric` as the primary approach for Lotto's random selection as it offers superior security (§3.4). We illustrate this with multiple-round DP training, where the privacy cost is contingent upon the client selected for the maximum number of times, assuming a fixed noise multiplier. With `Client-Centric`, the server cannot predict which client will be self-sampled the most frequently until the training stops. Therefore, the server cannot reserve this specific client

Table 3: Per-round training time and network transfer cost for the server and average participating client with informed selection.

FL Application		FEMNIST@CNN				OpenImage@MobileNet				Reddit@Albert			
Population	Protocol	Time		Network		Time		Network		Time		Network

400	Oort	2.4min	1.33min	0.26GB	3.56MB	4.44min	3.34min	0.25GB	3.53MB	27.94min	16.46min	3.75GB	51.53MB
	Cli-Ctr	2.64min	1.87min	0.26GB	3.56MB	4.69min	3.89min	0.25GB	3.54MB	28.15min	22.67min	3.75GB	51.53MB
	Srv-Ctr	2.37min	1.34min	0.26GB	3.56MB	4.43min	3.38min	0.25GB	3.53MB	27.79min	16.51min	3.75GB	51.53MB
700	Oort	3.69min	2.09min	0.45GB	3.69MB	5.71min	4.12min	0.45GB	3.66MB	40.83min	25.22min	6.56GB	52.57MB
	Cli-Ctr	3.83min	2.79min	0.46GB	3.7MB	6.01min	4.98min	0.45GB	3.67MB	40.97min	34.83min	6.56GB	52.57MB
	Srv-Ctr	3.35min	1.95min	0.45GB	3.69MB	5.37min	3.98min	0.45GB	3.66MB	39.8min	24.73min	6.56GB	52.57MB

for each round it reports to join to construct the worst-case privacy leakage. However, with `Server-Centric`, the server can predict the selection outcomes and reserve this client with certainty. Hence, `Server-Centric` provides the adversary with less randomness, as implied by the following corollary:

Corollary 3 (Controlled Privacy Cost in Distributed DP, II)**.** *Let π be the distributed DP protocol parameterized by σ and built atop SecAgg with aggregation threshold t. Given target δ, an R-round FL training with π and Lotto's random selection (`Server-Centric`) achieves (ε,δ)-DP, where*

$$\varepsilon = \min_{\substack{0\le k\le \min\{c,2t-s-1\}\\ 0\le r\le R, p_k+q_r<\delta}} E_\pi(s,k,r,\sigma,1-\frac{1-\delta}{1-p_k-q_r}),$$

$$p_k = 1-\left(\sum_{i=0}^{k}\binom{c}{i}\left(\frac{1}{m}\lfloor\frac{\alpha sm}{n_{min}}\rfloor\right)^i\left(1-\frac{1}{m}\lfloor\frac{\alpha sm}{n_{min}}\rfloor\right)^{c-i}\right)^R,$$

$$q_r = 1-\left(\sum_{i=0}^{r}\binom{R}{i}\left(\frac{1}{m}\lfloor\frac{\alpha sm}{n_{min}}\rfloor\right)^i\left(1-\frac{1}{m}\lfloor\frac{\alpha sm}{n_{min}}\rfloor\right)^{R-i}\right)^{n_{max}},$$

with σ the noise multiplier and $E_\pi(\cdot)$ the privacy accounting method for π, and n_{max} the maximum possible size of the population.

Proof. The proof closely resembles that of Corollary 2, with the exception of the calculation of $1-q_r$, which represents a lower bound on the probability that all clients in the population are selected for at most r rounds (Event B). Considering the server's predictability, we could not get a bound as tight as that of `Client-Centric`. Instead, the bound is

$$\begin{aligned}\Pr[B] &= \left(\sum_{i=0}^{r}\binom{R}{i}\left(\frac{1}{m}\lfloor\frac{\alpha sm}{n_{min}}\rfloor\right)^i\left(1-\frac{1}{m}\lfloor\frac{\alpha sm}{n_{min}}\rfloor\right)^{R-i}\right)^{n}\\ &\ge \left(\sum_{i=0}^{r}\binom{R}{i}\left(\frac{1}{m}\lfloor\frac{\alpha sm}{n_{min}}\rfloor\right)^i\left(1-\frac{1}{m}\lfloor\frac{\alpha sm}{n_{min}}\rfloor\right)^{R-i}\right)^{n_{max}}\\ &= 1-q_r.\end{aligned}$$

The corollary follows when one substitutes this lower bound of $\Pr[B]$ with that used in the proof of Corollary 2 and follows the remainder of that proof. □

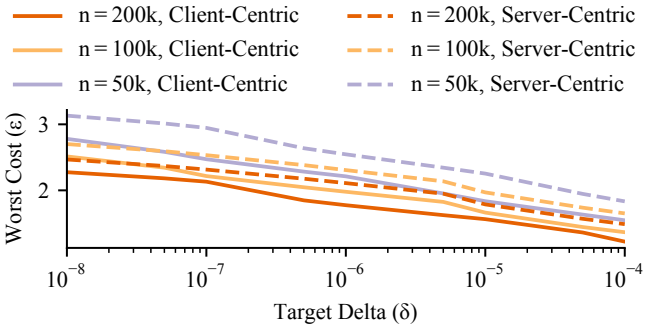

Figure 10: `Client-Centric` provides stronger DP privacy guarantees (lower ε) compared to `Server-Centric`.

To visualize the difference between the bounds presented in Corollary 2 and 3, we refer to the example discussed in §3.6. We set n_{max} to 10^9 for `Server-Centric`, which we consider to be the physical limit for the number of devices in the world. Figure 10 illustrates the gap in their privacy cost, demonstrating a slight disadvantage of `Server-Centric` across all scenarios. For instance, in the case of dealing with a population of size 2×10^5 when employing the same noise multiplier during training on FEMNIST, `Client-Centric` achieves $\varepsilon = 1.8$, whereas `Server-Centric` results in a higher cost of $\varepsilon = 2.3$.

C Execution Efficiency of Informed Selection

Table 3 presents the per-round time and network cost measured at both the server and average participant with informed selection. Compared to Oort, Lotto implemented with `Client-Centric` incurs a time cost of less than 5%, 10%, and 5% for population sizes of 100, 400, and 700, respectively. The overhead for `Server-Centric` is 2%, 0%, and 0%, respectively. Regarding the network footprint, Lotto consistently introduces less than 1% additional cost. In all, Lotto achieves an acceptable time cost and negligible network overhead in both random selection (§5.2) and informed selection.

Ahoy SAILR! There is No Need to DREAM of C: A Compiler-Aware Structuring Algorithm for Binary Decompilation

Abstract

Contrary to prevailing wisdom, we argue that the measure of binary decompiler success is not to eliminate all gotos or reduce the complexity of the decompiled code but to get as close as possible to the original source code. Many gotos exist in the original source code (the Linux kernel version 6.1 contains 3,754) and, therefore, should be preserved during decompilation, and only *spurious gotos* should be removed.

Fundamentally, decompilers insert spurious gotos in decompilation because structuring algorithms fail to recover C-style structures from binary code. Through a quantitative study, we find that the root cause of spurious gotos is compiler-induced optimizations that occur at all optimization levels (17% in non-optimized compilation). Therefore, we believe that to achieve high-quality decompilation, decompilers must be *compiler-aware* to mirror (and remove) the goto-inducing optimizations.

In this paper, we present a novel structuring algorithm called SAILR that mirrors the compilation pipeline of GCC and precisely inverts goto-inducing transformations. We build an open-source decompiler on `angr` (the ANGR DECOMPILER) and implement SAILR as well as otherwise-unavailable prior work (Phoenix, DREAM, and rev.ng's Combing) and evaluate them, using a new metric of how close the decompiled code structure is to the original source code, showing that SAILR markedly improves on prior work. In addition, we find that SAILR performs well on binaries compiled with non-GCC compilers, which suggests that compilers similarly implement goto-inducing transformations.

1 Introduction

Compiled programs called binaries power the devices that drive modern society. However, many of these binaries are shipped without accompanying source code, making their analysis arduous. To reduce this burden, decompilation techniques aim to recover source code from binary code. Security analysts use decompilation in reverse engineering [11, 31], malware analysis [19, 20, 33, 43], and vulnerability discovery and mitigation [32, 36].

Many applications of decompilation require *high-quality* decompiled source code. One important criterion of high-quality source code is meaningful control flow structures, such as `if-else` statements, `while` loops, and `do-while` loops in the C language. Unfortunately, the semantics of these control flow structures are lost during compilation, replaced by simple binary-level control flow transfers such as `jmp` instructions.

Decompilers leverage control flow *structuring* algorithms that analyze low-level constructs in the compiled binary and attempt to recover the high-level control flow. If compilers simply translated C code to assembly and pieced the assembly together with `jmp` instructions, the resulting code would be easily *structurable*, and decompilers would be able to produce high-quality decompiled source code. However, modern compilers optimize and distort code structures during compilation, making the result *unstructurable* and preventing current structuring algorithms from recovering the high-level control flow structure.

Structuring failures manifest as *goto* statements in the decompilation, stitching together portions of code where the decompiler failed to recover reasonable high-level structures [44]. The fact that it is specifically a goto that results from such failures has caused some semantic confusion between the Software Engineering and Decompilation research communities. In Software Engineering, *gotos are considered harmful*, with Dijkstra famously stating that "the quality of programmers is a decreasing function of the density of goto statements in the programs they produce" [18]. Treating decompilers as *software engineers*, and thus treating gotos as indicators of low-quality output, recent research into structuring algorithms has focused on extensively restructuring decompiled code to reduce or eliminate goto statements [9, 24, 44].

However, gotos *do* exist in popular C codebases, such as the Linux kernel, which, as of version 6.1, contains 3,754 gotos. Intuitively, previous work that removes all gotos will decrease the quality of decompiled code when it removes *intended, developer-written* gotos that are in the original source code, as

their elimination induces differences between the source code and the decompilation. Clearly, such gotos, *in the context of faithful decompilation*, are not harmful.

In fact, the lack of decompiler consideration for intended gotos is a symptom of a more general weakness in decompilation approaches. Existing techniques tackle the structure of binary code without a principled understanding of how this structure came to be. Our intuition is that an understanding of the differences between intended and spurious gotos in decompiled code will shed light on the binary constructs that hamper code structuring during decompilation.

This paper is the first work to investigate and identify the actual causes of spurious gotos. We systematically studied why spurious gotos appear in decompiled code, tracking them down to wide arrays of optimizations leveraged by the compiler. We investigated all compiler optimizations at level `O2` and below in GCC 9.5[1] on Coreutils and identified all optimizations that may introduce unstructurable code. To our surprise, some of these optimizations (responsible for around 17% of spurious gotos) are even enabled in *non-optimized* (`O0`) mode and cannot be easily disabled.

This investigation led us to a realization: To preserve the intended structure, including source-present gotos, and eliminate sources of gotos introduced by the compilation process, decompilers can leverage structuring algorithms informed by compiler-derived knowledge. Based on our findings, we created the first compiler-aware control flow structuring algorithm, SAILR[2], that uses compiler-derived knowledge to *deoptimize* binary code and make unstructurable code structurable. SAILR mirrors the compilation pipeline of GCC and precisely inverts goto-introducing transformations rather than using broad (and imprecise) goto-eliminating modifications leveraged by prior work.

SAILR generates decompilation that, compared to state-of-the-art techniques, contains significantly fewer spurious gotos while maintaining high structure similarity to the source code. For example, among other evaluations, we evaluated decompilers against 7,355 functions (containing 1,367 intended gotos) from 26 popular C Debian packages. The state-of-the-art Hex-Rays decompiler included in IDA Pro [3] emitted 6,115 gotos while achieving an average Graph Edit Distance (GED) of 22.52 between the decompilation and the source code. SAILR reduced the gotos count to 2,673 (we discuss the remaining gotos in Section 9) while maintaining an average GED of 22.64. DREAM, a state-of-the-art structuring technique that guarantees the elimination of *all* (including intended) gotos, emitted 0 gotos and significantly impacted the quality of the decompilation, achieving an average GED of 45.99. An optimal decompiler should have both the same number of gotos as the source and a GED score of zero.

Furthermore, while comparing SAILR against existing research, we realized that existing structuring techniques are either not open-sourced or have bit-rotted, hampering research in the field. To enable impartial comparative studies, we built a new decompiler for `angr`, which we refer to as the ANGR DECOMPILER hereinafter, and implemented SAILR as well as other previous structuring algorithms (namely, Phoenix [9], DREAM [44], and rev.ng's Combing [24]) in it. Due to its Python implementation, our decompiler can be significantly slower than other decompilers, however, we expect performance to improve as it is further developed. We hope the ANGR DECOMPILER will foster future decompilation research, improve the reproducibility of decompilation techniques, and make future work in this area easier to approach.

Contributions. This paper makes the following contributions:

- We identify the root causes of unstructurable code during the decompilation of C: compiler optimizations and knowledge gaps between the decompiler and the compiler.
- We design SAILR, a novel compiler-aware structuring algorithm that precisely inverts the root causes of goto-introducing compiler transformations to generate decompilation significantly closer to the original code.
- We build an open-source decompiler ANGR DECOMPILER, and then implement SAILR as well as three other structuring algorithms on our decompiler for an impartial evaluation.
- We design a new set of evaluation metrics to measure the quality of control flow structuring during decompilation by measuring how close it is to high-quality source code. Using our metrics, we evaluate SAILR and demonstrate its improved structuring performance over other structuring algorithms and state-of-the-art decompilers.

In the spirit of open science, we are *actively* developing the ANGR DECOMPILER and SAILR as open-source projects[3]. We have also open-sourced our evaluation framework, which includes the specific versions of `angr` and SAILR used in our evaluation[4].

2 Background & Motivation

Before diving into the technical details of SAILR, we introduce necessary background knowledge about compiling C programs (Section 2.1), decompiling C programs (Section 2.2), state-of-the-art control flow structuring algorithms (Section 2.3), and the motivation of our research (Section 2.4).

2.1 Modern C Compilation

Modern C compilation has two high-level phases relevant to the understanding of the decompilation process. First, the source code is "lifted" into an Intermediate Language (IL) as C is too high level to be operated on directly. In the case of GCC, C code is "lifted" into an IL called Gimple [2].

[1] We also analyzed LLVM and identified analogous optimizations.
[2] SAILR: Structured AIL Reverter.
[3] https://github.com/angr/angr
[4] https://github.com/mahaloz/sailr-eval

Once lifted, optimizations are applied to the IL. Optimizations that are specific to a program's control flow use *schemas* to identify optimization locations. Schemas are similar to puzzle pieces for a program's control flow. Once a schema is found to fit a certain control flow archetype, such as a while loop, the corresponding operation can be performed on the IL to manipulate it into an optimized form.

2.2 Modern Binary Decompilation

Modern binary decompilers generally perform three phases of analysis before generating C-style code.

Control flow graph recovery. A decompiler first disassembles machine code in a binary to recover assembly instructions, function boundaries, and execution flows. Control flow information is stored in a control flow graph (CFG), with basic blocks as vertices and execution flow as edges. Optionally, the decompiler may lift instructions into an IL to assist with architecture- and platform-agnostic analysis.

Type inference. After recovering a CFG, the decompiler uses parts of the graph to infer variable locations and their associated types. Prior research has explored various methodologies for inferring types, such as TIE [30], Howard [39], and retypd [34]. More recently, Osprey [46] and DIRTY [12] utilize machine learning techniques to predict types. Optionally, this inference phase may also recover prototypes and calling conventions for all functions.

Control flow structuring. In this last phase, the decompiler will transform assembly instructions or IL statements into C-style statements using patterns and flow information from the CFG. This phase will also simplify these statements and identify common compiler idioms to replace them with more human-friendly representations. In general, a CFG can be structured in many different, but semantically equivalent, forms, making choosing the right structure a difficult task.

2.3 Structuring in C Decompilation

Table 1 shows a taxonomy of existing control-flow structuring algorithms. We broadly categorize structuring algorithms into two groups:

Graph-schema-matching algorithms. These structuring algorithms attempt to match subgraphs of a CFG against known control-flow patterns for C control-flow structures. For example, a diamond-shaped subgraph commonly corresponds to an `if-else` construct when the two middle nodes have inverted edge conditions. Being condition-aware is critical to the correctness of these structuring algorithms [9].

A key challenge that these algorithms face is unknown graph schemas. Structuring algorithm authors usually hard-code graph schemas for common C control-flow constructs. However, because compiler optimizations create novel graph schemas, there are more graph schemas in real-world binaries than one can reasonably enumerate. As a result, these algorithms must virtualize edges (i.e., eliminating edges and replacing them with spurious gotos) to create more subgraphs that would match against known graph schemas, which significantly hampers the quality of decompiled code.

Goto-less algorithms. These structuring algorithms (used by DREAM and rev.ng) do not use edge virtualization to convert non-schema-matching subgraphs into schema-matching ones. Instead, they create new control-flow structures that are functionally equivalent to non-schema-matching subgraphs. These new structures often do not match the source's because they can introduce new or duplicated code. DREAM duplicates code found in conditions while moving around contained logic. rev.ng duplicates code found in incomplete structures to make them match known schemas. These algorithms rely heavily on block condition information to make goto-less structures.

Table 1: A taxonomy of control flow structuring algorithms in modern decompilers and decompilation literature. "Duplication Removal" refers to removing compiler-introduced code duplication. An optimal compiler will remove duplicates and have no redundant code/conditions. We observed that in rare cases Hex-Rays will remove exactly duplicate blocks.

Decompiler	Condition Aware	Emit Gotos	Duplication Removal	Open-source	Redundant Conditions	Redundant Code
Hex-Rays [3]	Yes	Yes	Rare	No	No	No
Ghidra [35]	Yes	Yes	No	Yes	No	No
mirtoc (extended) [21]	No	Yes	No	No	No	No
Phoenix [9]	Yes	Yes	No	No	No	No
DREAM [44]	Yes	No	No	Yes	Yes	No
rev.ng [24]	Yes	No	No	No	Yes	Yes
SAILR	Yes	Yes	Yes	Yes	No	No

```

21 }
```

Figure 1: (From left to right) the DREAM, Phoenix, and SAILR decompilation of Listing 1 (using GCC 9.5 -O2).

2.4 Motivation

At first glance, goto-less algorithms may appear superior to graph-schema-matching algorithms since they never generate spurious gotos. However, between the two structuring algorithms, goto-less approaches often differ more from the source's control flow structure. We assume that C source code in a popular and actively maintained codebase (such as code in GNU packages) is a high-quality implementation of program logic. Therefore, when decompiling binaries that are compiled from high-quality code, decompilation that is structurally close to the source is of high quality. Using source code structure as the ground truth, we manually evaluated modern structuring approaches and found their results to be significantly flawed.

Listing 1 shows a motivating example based on code found in the Linux kernel scheduler. Figure 1 shows the DREAM, Phoenix, and SAILR decompilation, respectively, for the compiled binary from Listing 1. While there are no spurious gotos in the DREAM decompilation, the `if` statements contain complex and irreducible conditions that make understanding execution flows difficult. DREAM decompilation contains duplicated conditions that did not exist in the source on Lines 13 and 15. Although this duplication decreases code complexity compared to Phoenix, it obfuscates the original programmer's intentions. It also makes the needed conditions at each line of code, like Line 16, harder to understand.

In the Phoenix decompilation, although it contains a goto found in the source code, it also contains two spurious gotos. The gotos targeting `LABEL_4012eb` are due to a lack of special-case `if`-statement schema in Phoenix. The goto targeting `LABEL_4012d3` is due to a lack of compiler-optimization knowledge. The compiler introduced extra code and created a path to skip an extra conditional instruction using the Jump Threading optimization (see Section 3.3). This optimization introduces an extra call to `refresh_jobs` in both the Phoenix and DREAM decompilation.

All the decompilers that we tested failed to remove the duplicated statements in this example. Additionally, any schema-based structuring algorithms, like those used in Ghidra and Hex-Rays, cannot remove the goto targeting `LABEL_4012d3`. This is because no schema exists to structure this goto edge. To generate high-quality decompiled code, we must develop a new structuring algorithm that can undo the compiler's transformations, remove the duplicated blocks, and generate high-quality decompilation that is close to the original source. The last code snippet in Figure 1 shows the decompilation result of such a new structuring algorithm.

3 Goto-Inducing Compiler Transformations

Without considering goto statements in source code, each C construct can be represented by a single-entry, single-exit (SESE) graph whose nodes are basic blocks in the construct [21]. Compilers rely on a finite number of graph schemas during the code generation phase (Section 2.1). If we split the binary CFG of a function into nested SESE graph regions, a graph-schema-matching structuring algorithm matches each graph region against a known schema as long as it knows *all* graph schemas that a compiler uses. This works for binaries built without *any* compiler optimizations.

Unfortunately, some compiler optimizations split, merge, or duplicate nodes on graphs without preserving graph schemas. These optimizations create new graph schemas and make it impossible for a structuring algorithm to exhaustively enumerate all possible graph schemas that an optimization compiler may generate. We find that there are three reasons for edge virtualization to happen during structuring:

- (Real) gotos that exist in the source code. An optimal structuring algorithm will want to preserve these gotos.

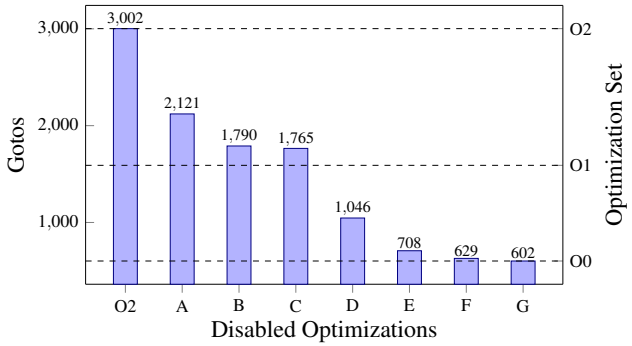

Figure 2: Gotos present in Hex-Rays decompilation as optimizations in Section 3.3 are disabled. Each optimization point disables itself and all optimizations to its left. Optimization sets `O2` through `O0` are shown for reference.

- Graph schemas that compilers use during code generation (without optimizations) but are not known to structuring algorithms. Because there are a finite number of these schemas, an optimal structuring algorithm should know all of them.
- New graph schemas that compiler optimizations create. An optimal structuring algorithm should remove all resulting gotos by reverting these optimizations.

We pick Coreutils 9.1 as the high-quality C codebase and GCC 9.5 as the compiler for our studies.

3.1 Enumerating Missing Graph Schemas

While one could read all of the source code of a compiler to find all unsupported graph schemas in a decompiler, this approach does not scale. We propose the following methodology to identify schemas missing in a decompiler.

First, we collect a set of binaries from high-quality codebases and compile them using GCC with optimizations (`O2`) while enabling the `save-temps` and `dump-tree-all` flags. These flags ask the compiler to save *intermediate files* that are generated during preprocessing and optimization passes. Next, we decompile all functions in all binaries and identify functions with gotos in the decompilation but not the source. For each function, we manually note the locations of the gotos in the function and perform a binary search on the intermediate files to identify which optimization pass changed the function to induce the goto. This identifies the GCC source for the optimization pass, and these passes are well-commented with information on the schema used.

3.2 Measuring Goto Introduction

Once we identify an optimization pass that causes an unstructurable subgraph, we attempt to understand the impact scale (i.e., how many gotos this optimization induces for binaries in Coreutils). We disable the optimization and repeat the steps in Section 3.1 until the goto disappears from the final decompilation. If the goto disappears, we count all the gotos in the decompilation before and after the optimization to measure its impact. We group all the disabled optimizations that are required to make the goto disappear as either one optimization algorithm or a set of tightly coupled algorithms.

This method worked surprisingly well for most optimizations in the GCC `O2` optimization set. It is worth mentioning that some optimizations did not disappear after disabling their frontend optimization option; These optimizations could only be entirely disabled by undocumented developer options.

3.3 Goto-Inducing Transformations in GCC

In an analysis of 1,150 unique functions across 135 object files in Coreutils 9.1, we found the cause of every goto across the 3,002 gotos that are present in the decompilation of Hex-Rays 8.0. We compiled these object files with GCC 9.5 with optimization level `O2`, inlining disabled (for function tracking), debug symbols enabled, and intermediate file dumping. We filtered these functions for uniqueness by eliminating functions that shared the same name, with the exception of common symbols such as `main` and `usage`.

We associate every goto to a specific GCC transformation using the methodology in Section 3.2. These transformations include togglable optimizations, internal highly-coupled optimizations, and compiler knowledge exploitation.

Jump Threading (A). When one branch's conditions superset a future branch's conditions, the statements contained between the two may be duplicated into the first and end with a jump to avoid extra conditional instructions. Gotos appear between duplicated statements.

Common Subexpression Elimination (B). The compiler finds common statements among multiple blocks and reduces them into one use of the expression and a series of jumps to that expression. Gotos occur between condensed statements.

Switch Conversion (C). The compiler replaces simple assignments on switch statements in cases with assignments from scalars. Gotos can occur between cases that share a common expression for assignment.

Cross Jumping (D). Unifies equivalent code (e.g., repeated statements) across regions and replaces duplicates with a jump to the unification. A goto corresponds to the new jump.

Software Thread Cache Reordering (E). The compiler estimates the likelihood of executing a set of paths and clusters those frequently executed together through code duplication.

Loop Header Optimizations (F). The compiler moves branches that are always true or true only once to avoid executing a conditional instruction many times. The edge leaving the loop body (for the copied header) becomes a goto.

Builtin Inlining (G). The compiler replaces special built-in functions, e.g., `strcmp`, with optimized inlining and propagation. Gotos can occur when inlining happens inside a short-circuit Boolean expression.

Switch Lowering (H). A highly-coupled optimization that is non-disablable in GCC. The compiler optimizes switch

statements by breaking them into clusters and applying heuristics to avoid large jump tables. Gotos occur when the switch statement is fully transformed into a nested `if` statement.

Nonreturning Functions (I). Some functions, such as `exit` and `abort`, may not (always) return, and GCC uses this knowledge to transform the CFG. When the decompiler lacks knowledge of these functions' ability to not return, it can cause successors to be incorrectly added during CFG recovery, causing goto edges to those successors.

Figure 2 shows the number of gotos present in decompilation after disabling transformations in compounding order. In addition to associating the cause of every goto, we group the goto-inducing optimizations into two classes by effect. Both classes broadly transform *irreducible statements*, which we define as statements found in the source code that cannot be eliminated. Such statements must always exist for the *same path* they were found in the source, though the literal instructions that cause them may be condensed.

Irreducible Statement Duplication (ISD) converts a statement into many statements that are semantically equivalent to the original. This set includes optimizations A, E, and F.

Irreducible Statement Condensing (ISC) converts many statements into a condensed version with introduced graph edges. This set includes optimizations B, C, and D.

Optimizations G, H, and I do not fit well into either ISD or ISC optimizations and instead are classified as miscellaneous optimizations. These miscellaneous optimizations account for a minority of goto-inducing optimizations and require more specific algorithms to revert.

4 Overview of SAILR

We implemented our structuring algorithm, SAILR, and our decompiler, ANGR DECOMPILER, on top of the `angr` binary analysis platform [38]. As such, our decompiler supports any architecture `angr` supports. The ANGR DECOMPILER handles miscellaneous decompiler tasks such as program lifting while SAILR structures lifted Control Flow Graphs (CFG).

4.1 The Decompilation Pipeline

The ANGR DECOMPILER is similar in design to prior work [9, 44]. Using `angr`, we convert a binary into a lifted CFG. The lifted CFG contains VEX Intermediate Representation (IR) instructions, which is the IR `angr` uses. Figure 3 illustrates the high-level steps in the ANGR DECOMPILER after a VEX IR CFG is provided.

4.1.1 Lifting, Simplification, and Variable Recovery

The ANGR DECOMPILER takes a function-level VEX IR CFG as input. Because VEX IR cannot represent C-style expressions, we designed a more abstractable intermediate language called the ANGR INTERMEDIATE LANGUAGE (AIL). The ANGR DECOMPILER starts by lifting the VEX IR CFG into an AIL CFG. Multiple rounds of simplifications are run

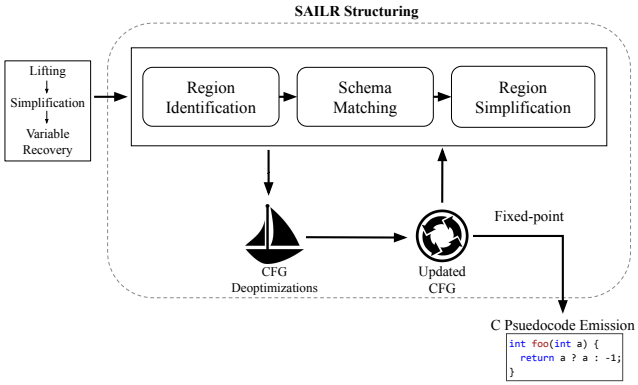

Figure 3: Overview of ANGR DECOMPILER's decompilation pipeline.

on the AIL CFG to eliminate redundancy. This lifting process is similar to GCC's simplification process while lifting C to Gimple. After lifting, the ANGR DECOMPILER recovers variable locations, function prototypes, and variable types using the AIL CFG.

4.1.2 SAILR Control Flow Structuring

After collecting an AIL CFG and variable information, the ANGR DECOMPILER uses the SAILR structuring algorithm to turn the AIL CFG into C pseudocode. The following four passes are run until a fixed point is reached. These passes together make up the core of the SAILR structuring algorithm.

Region identification. The region identification algorithm in the ANGR DECOMPILER is based on the algorithm that DREAM employs [44]. First, it identifies all single-entry, single-exit (SESE) regions in an AIL graph, following a reverse topological order of all nodes. As its name suggests, a SESE region refers to a group of AIL blocks and edges that contain one entry and one exit. A region may contain multiple regions.

Schema matching. The ANGR DECOMPILER then preliminarily structures each region using a graph-schema-matching algorithm built using concepts developed in Phoenix [9]. A major difference between SAILR and Phoenix is that Phoenix directly matches schemas against subgraphs on the full graph while SAILR matches schemas on a per-region basis. SAILR matches subgraphs in each region against known graph schemas.

When SAILR fails to match a region against any known graph schemas, it will virtualize an edge by removing it from the region and replacing the source jump statement with a goto. Then, SAILR condenses blocks that match a known graph schema into a C-style construct. Once the ANGR DECOMPILER finishes structuring a region, it replaces the region in its parent region with the structured node before continuing

to structure its parent region. Structuring terminates once the outermost region is structured.

Region simplification. Next, the ANGR DECOMPILER performs simplification and optimization on the AIL graph of each refined region to eliminate redundant edges and blocks that may not affect the control flow. This is also applied to the preliminarily schema-matched result.

Deoptimization. In the last step of SAILR structuring, the ANGR DECOMPILER performs deoptimizations directly on the AIL graph. The deoptimization phase relies on all knowledge previously collected in the pipeline, such as region information, goto locations, and reaching conditions. Each deoptimization described in Section 5 is run iteratively or until a limit is met.

4.1.3 C Pseudocode Emission

Finally, the ANGR DECOMPILER expands the structured regions into a C-style abstract syntax tree (AST) and pretty-prints it as a function with linear C-style statements. One novel aspect in the decompilation pipeline is that we stall optimizations on the lifted function CFG until the last point of the process. This allows CFG edits, which are the basis for SAILR, to have the most available knowledge.

4.2 Major Contributions of SAILR

Previous works in control flow structuring have focused on making decompilation more structured [9, 24, 44]. The Phoenix [9] decompiler identified this unstructurability through gotos. Phoenix focused on reducing these gotos through condition-aware graph schema matching. DREAM [44] eliminated gotos by duplicating conditions across the code to create bounded statements. rev.ng [24] also eliminated gotos through duplication, but instead duplicated executable code, not conditions on nodes. In the case of DREAM and rev.ng, these approaches generically eliminate all gotos regardless of their existence in the source.

In contrast, SAILR does not blindly eliminate gotos and instead treats the cause: compiler transformations. SAILR precisely reverts compiler transformations found to be the cause of unstructurable code, which manifest as gotos in decompilation. Of these transformations, certain compiler optimizations and the gap between the decompiler and the compiler play a significant role in unstructurability. SAILR approaches a solution to both of these problems by improving the knowledge of the decompiler and reverting certain optimizations.

Reverting compiler optimizations. SAILR's deoptimization passes revert the most impactful optimizations to control flow structure. At a high level, SAILR directly edits the AIL graph by condensing (Section 5.1), duplicating (Section 5.2), or moving (Section 5.3) nodes. In each case, SAILR uses information derived from GCC 9.5 to perform the reverse actions of these optimizations. For each deoptimization pass described in Section 5, the majority of computation time comes from searching for valid cases. This search phase is *goto-guided*. We assume all optimizations that SAILR wants to deoptimize are goto-inducing, so we only search the blocks around a goto edge when finding candidates. Although the understanding of these optimization techniques is based on GCC, we find that other compilers, such as Clang, implement the same optimizations in similar ways.

Closing the compiler-to-decompiler knowledge gap. We identified two critical knowledge gaps by studying the Hex-Rays decompilation of Coreutils `O2` binaries compiled by GCC 9.5. The first gap is the *returning* of a callee, i.e., whether a callee function returns or not. A compiler will not generate any return site for a call if it knows the callee never returns, for example, *_exit()*. The function CFG that any decompiler recovers will be different from the compiler's CFG if they are not aware of this fact, which may lead to unstructurable code. This problem is further complicated because the returning can be call-site specific: A callee function may be returning in one call site and non-returning in a different site, which we will detail in Section 6.1. The second gap is the decompiler's unawareness of all the graph schema the compiler uses. We discuss major ones in Section 6.2.

5 Deoptimizing Decompilation

In this section, we give an overview of novel algorithms to deoptimize decompilation. These algorithms revert three types of optimizations discussed in Section 3.3: ISD, ISC, and miscellaneous optimizations. In each deoptimization, there is a *search* and *transformation* phase that parallel the compiler's optimization process. The search phase is generally more computationally intensive.

5.1 ISD Optimizations

The main effect of ISD optimizations is the duplication of subgraphs found in the original source CFG. Most compilers will limit the number of statements that can be duplicated when performing optimizations in this class. During GCC's ISD optimization passes, reaching conditions are computed for each statement in the CFG. Reaching conditions determine what statements are accessible when a condition holds during execution. For each optimization, GCC further determines if a statement is duplicatable using other indicators. In the case of Jump Threading, the indicator is whether an ancestor statement shares an overlapping condition that guarantees the execution of the current statement. For optimizations such as Software Thread Cache Reordering, the duplication indicator can be as complicated as computing if a block has a higher execution probability over its neighbors.

Next, the compiler will duplicate both the marked statement and the graph found under that reaching condition. The duplication will be placed at another location in the graph that guarantees the same reaching conditions, guarded by either

```
void foo(int a, int b) {
  if (a && b) {
    puts("first print");
  }

  puts("second print");
  if (b) {
    puts("third print");
  }

  sleep(1);
  puts("leaving foo...");
}
```

```
void foo(int a, int b) {
  if (a && b) {
    puts("first print");
    puts("second print");
    goto label_1;
  }
  puts("second print");
  if (b) {
label_1:
    puts("third print");
  }
  sleep(1);
  puts("leaving foo...");
}
```

Figure 4: Example C code shown before and after transformation from Jump Threading, an ISD optimization. The second condition of the original code is always true if the first condition is true, causing the comparison to be subverted by a jump.

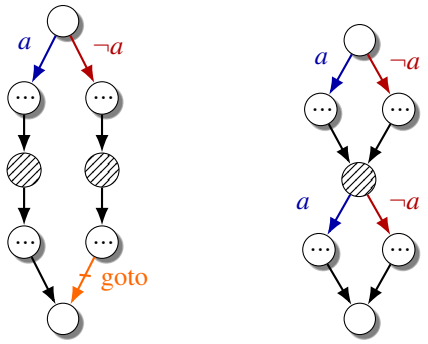

Figure 5: CFGs before and after deoptimizing an ISD optimization case. In order to identify an ISD case, the shaded node must be found to have a semantic duplicate, as well as post-dominating goto edge. The nodes are merged and then bounded by their previous conditions.

already present blocks or new conditional blocks. The duplicated subgraph may have other statements appended to the graph tail nodes. Finally, the duplicated subgraph tail nodes are connected to the original subgraph successors by an edge.

Figure 4 shows a C program that when compiled with GCC `O2` optimizations results in optimized output. The compiler computes the conditions for both the first `print` and the third `print`. Because the conditions overlap, the compiler determines that both scopes will execute if the first condition (a && b) holds true. The compiler then duplicates the code between the two conditions and creates a jump (a goto) from the first condition scope to the second condition scope. We next discuss how SAILR condenses ISD-duplicated blocks.

Finding duplicate statements. Given an AIL function CFG, SAILR starts by iterating through all combinations of two statements and creates an initial set of candidate statement pairs that exist in the same region and are *storage equivalent*. Two statements are storage equivalent when all their reads and writes to locations are the same. For a pair of call statements, storage equivalence means all arguments share the same storage locations and the function addresses are the same.

With the candidate set, we take all candidates and expand their similarity match by expanding the connected graph of the matching statements. We assume the first found statement of the pair is the head of each similar subgraph. Then we iteratively expand each subgraph using a Breadth-First Search (BFS) traversal and match the statements using the Knuth-Morris-Pratt (KMP) algorithm [28].

Finally, with each candidate expanded to its maximum graph similarity, we find the tail nodes of each duplicate graph. All of these nodes must share the same successor in each graph. At least one of the two graphs must have a goto edge, which was identified during structuring, that connects it to the common successor. In Figure 5 (left) the graph of a matching case is shown. Note, that any number of nodes can exist between the condition head and the duplicated node.

Condensing duplicates. The key to condensing a pair of candidate subgraphs while preserving the original semantics is maintaining the reaching conditions of every node in the graph after condensing. In Figure 5 (right), a graph shows the correct result of reverting an ISD case.

First, the duplicated node must be merged into one node by redirecting all predecessors to the newly merged node. Although shown as a single node in this example, the merged node can be a graph, which means the predecessors may go to multiple nodes. Next, the condition a must be used to correct the flow of execution before and after leaving the merged node. If there are multiple head nodes in the merged sub-graph, each head node must have the correct a condition blocking its path. In the case of a single node being the head of a merged graph, only the exits of the merged sub-graph need duplicated conditions. Finally, the graph is in the deoptimized state and should no longer have a goto. Depending on the conditions before and after the ISD case, we can simplify the exiting conditions on the merged sub-graph. Listing 3 in the Appendix shows the pseudocode of our ISD deoptimization algorithm.

5.2 ISC Optimizations

The main effect of ISC optimizations is the reduction of subgraphs found in the original source CFG through condensing. Condensing turns n equivalent statements into $n-m$ statements, where $m \geq 1$. Similar to ISD optimizations, ISC optimizations require knowledge of reaching conditions and statement semantics. ISC optimizations traverse the CFG for semantically equivalent pairs of statements (or subgraphs). Then, for each statement pair, ISC optimizations will eliminate one statement and connect the other with a jump to the remaining statement.

Figure 7 shows an example C program that exhibits gotos when optimized with Cross Jumping, an ISC optimization. The `return` statement is reused across many if-statements,

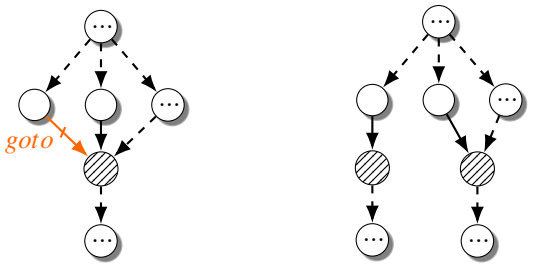

Figure 6: CFGs before and after deoptimizing an ISC optimization case. ISC cases contain a goto edge connecting one node to another node that has multiple predecessors. Duplication of the shaded node, and all its single-successor ancestors, revert this case.

```
int foo(int a, int b) {
  if(!a)
    return -1;
  puts("first print");
  if(!b) {
    return -1;
  }

  puts("leaving foo...");

  return 1;
}
```

```
int foo(int a, int b) {
  if(!a)
    goto label_1;
  puts("first print");
  if(!b) {
label_1:
    ret = -1;
    goto label_2;
  }
  puts("leaving foo...");
  ret = 1;
label_2:
  return ret;
}
```

Figure 7: Example C code shown before and after transformation from Cross Jumping, an ISC optimization. In the original code, the *return* statement, as well as its return value, are reused in the same execution pass resulting in statements being merged and connected with a goto.

which is a common programming pattern. In the resulting code output, all but one `return` is replaced with a goto. For the first `if`, Cross Jumping also eliminates the constant assignment to `ret`. We next discuss how SAILR duplicates ISC-condensed blocks to recover the original structure.

Finding condensed statements. Finding condensed statements requires finding the locations of goto edges (after structuring) in an AIL CFG. Similar to searching for ISD cases, this demands that a decompiler can iteratively perform graph optimizations and structuring. We can only know the locations of gotos in an AIL function CFG after structuring at least once. Figure 6 (left) shows a matched case of an ISC optimization.

Our algorithm considers any statement connected to another statement through a goto as an ISC deopimization candidate. ISC deoptimizations are a wide-catching net for gotos and may not always eliminate gotos. To avoid re-duplicating blocks that other passes condensed, this deoptimization must be run after all other goto-aware deoptimizations. As a special case, gotos to function-exit blocks, such as a return, are special-cased to reduce duplication. An arbitrary code duplication limit is set on jumps to these types of blocks to mimic the compiler. This allows the `goto cleanup` programming style to still exist in SAILR decompilation.

Reverting condensed statements. After locating all goto edges in the AIL graph, the destination nodes act as the head nodes for duplication. To revert an ISC optimization, the chain of single-successor nodes is copied beginning from the head node. Figure 6 (right) shows the effect of the duplication on an ISC case. For a node chain that ends in an exit node, or a node that leaves the current function, it is guaranteed to remove a goto. Listing 4 in the Appendix shows the pseudocode of our ISD deoptimization algorithm.

A common case we observe is that many functions have two exit nodes after a comparison of the stack canary. Therefore, we identify all the exit regions, or clusters of nodes, that end in an exit that has one entry. For stack canary comparison, there are three nodes in the cluster: the if statement, the return node, and the stack-check-fail node. This allows us to copy the entire region as the exit node.

In cases where the final node in the node chain is not an exit node, this deoptimization may not remove the goto. Instead, this deoptimization transforms the graph into a form that is easier to case match for other deoptimizations that run on the graph. This is important because during compilation, ISC optimizations are often stacked on top of other goto-inducing optimizations, similar to the ISD optimizations. SAILR must iteratively revert these optimizations one after another.

5.3 Miscellaneous Optimizations

Optimizations not deoptimized by ISD or ISC reverters require specific identification. Of the known miscellaneous optimization, only Switch Lowering may be identified using gotos.

Reverting switch lowering. To the best of our knowledge, depending on the density of switch case numbers, GCC may generate three forms of binary control-flow structures for switches: binary decision trees, jump tables, and bit-tests [4]. When fallthroughs between cases are in use, switches that are lowered into decision trees are usually unstructurable as cascading `if-else` constructs. To make such subgraphs structurable, we must transform them into normal switches. In SAILR, we implement a solution based on pattern and condition matching to revert lowered switches. Among all decompilers that we tested, only Hex-Rays has very limited support for reverting lowered switches. In Figure 8 a case of cascading `if-else` constructs is shown as well as its transformation into a switch node. A goto present in the cluster is optional but is a high-confidence indicator of a lowered switch.

Reverting switch clustering. Another common cause of switch-related unstructurable subgraphs is switch clustering [4], where a switch is broken into multiple disjoint subswitches (with different case numbers). Each sub-switch is transformed into its own binary representation (of the three

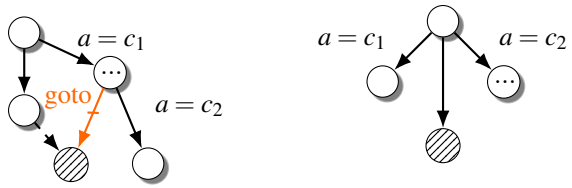

Figure 8: CFGs before and after Switch Lowering reversion. All nodes in a candidate switch region must hold a Boolean condition of $a = c$, where c is a constant. These condition nodes must cascade and either be post-dominated by a single node or exit early. A goto appearing in the region makes the case more likely to be a real Switch Lowering case.

forms). SAILR identifies and merges these sub-switches that are grouped together by conditions within the same region.

6 Narrowing Knowledge Gaps

When the decompiler and the compiler diverge in their views of the same binary, it may cause otherwise structurable code to be incorrectly regarded as unstructurable by the decompiler. Therefore, we must close or narrow the knowledge gaps between the decompiler and the original compiler to ensure they have the same view of all structuring-dependent artifacts. Our intuition is that decompilers must be *compiler-aware* to achieve high-quality decompilation. In this section, we summarize two significant sources of knowledge disparity that we identified (described in Section 3.3) on GCC-9.5-compiled Coreutils binaries: The returning of functions and missing graph schemas in decompilers.

6.1 Non-returning Functions

GCC does not generate edges or successors for function calls (e.g., `exit()`) that do not return. A decompiler that is not aware of these semantics may incorrectly add a spurious edge from the return site (that does not actually exist) to whatever block that follows the call. Unfortunately, fixing this problem requires more than just providing decompilers with a list of non-returning functions, because a function may be returning in some call sites and non-returning in other call sites.

The `error` function from glibc is an example: It returns when the first argument (`status`) is 0, and does not return in other cases. With the `error.h` header file, GCC determines that any call sites for `error` do not return if the first argument has a non-0 constant. To solve these, we augmented the ANGR DECOMPILER so that it determines the returning of `error` call by examining the value of its first argument at all its call sites.

6.2 Additional Graph Schemas

Schema-matching algorithms, as described in Section 2.3 match subgraphs against known graph schemas that correspond to C structures. By using the methodology outlined in Section 3.1, we identified three major missing graph schemas in most decompilers that we tested and added support for them in SAILR.

Short-circuited compound Boolean conditions. During the lifting of C to Gimple, GCC transforms compound Boolean conditions into control-flow constructs using specialized graph schemas to express the short-circuit condition. Both Hex-Rays and Ghidra support such graph schemas, but Phoenix does not and always generates gotos. Moreover, DREAM will generate a semantically equivalent graph where each node is guarded by much more complex conditions than what are in the source. We investigated and concluded that the root cause is DREAM's reliance on condition expression simplification. Simplification (or minimization) of Boolean expressions is an NP-hard problem, so it is too computationally expensive for DREAM to derive Boolean expressions that are as simple as in the source for non-trivial cases (e.g., Boolean expressions with more than six atoms).

Comma-separated multi-statement expressions. A not-that-uncommon usage in C is comma-separated multi-statement expressions, where the statements will be executed first before evaluating the expression at the end. Not supporting this expression type will prevent proper structuring of loops that use such expressions as loop conditions. Out of all decompilers that we test, only Hex-Rays supports such types of expressions. We add support for these expressions in SAILR.

Common condition while-loop exits. In some cases of structuring, the Phoenix algorithm can generate extra gotos that leave cyclic regions structured as `while-loops`. In a `while-loop`, if the loop contains a branch where both successors are inverted conditions of each other, like c and $!c$, this can be replaced by an `if` statement and a break out of the loop.

7 Measuring the Quality of Structuring

Measuring the structuring quality of decompilation is different from measuring its overall quality. Changes that improve readability, e.g., constant propagation or variable elimination, do not always impact the structure of the code. Previous work focused on evaluating the quality of structuring by relating it to structural complexity. They mainly used three metrics: Number of gotos (Gotos) [9, 24, 44], McCabe Cyclomatic Code Complexity (MCC) [24], and the Lines of Code (LoC) [44]. However, these metrics are flawed for evaluating structuring quality even when shown relatively similar source.

To understand these flaws, we evaluate previous metrics on our motivating example in Listing 1, with the decompilation results by Phoenix, DREAM, and SAILR shown in Figure 1

Table 2: Previous work's structuring metrics, GED, and CFGED measured on Figure 1 and Listing 1.

	Gotos	LoC	MCC	GED	CFGED
Source	1	19	4	0	0
SAILR	1	15	4	0	0
Phoenix	3	19	4	2	2
DREAM	0	16	9	21	38

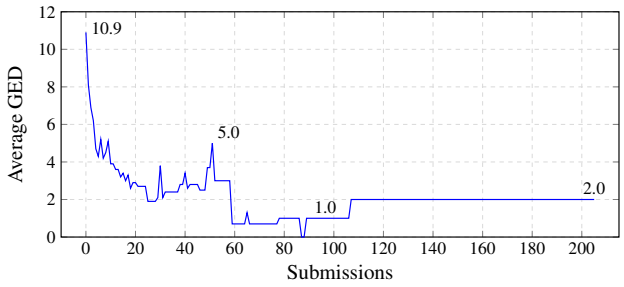

Figure 9: In the Decomperson study, a human participant's goal is to perfectly recover the source from only the assembly code of a binary. As human participants submit closer byte-matched decompilation, their average GED scores decrease.

(and measurements produced in Table 2). SAILR achieves perfectly structured decompilation, but its MCC is identical to Phoenix's result, despite the latter producing differently structured code from the source. This is because MCC only measures the number of independent paths without considering the resemblance of code structures. As a result, MCC can return significantly lower scores for decompiled code with spurious gotos rather than properly structured conditions because conditions add compounding edges in the CFG. For gotos, although Phoenix's decompilation was structurally closer to the source than DREAM's decompilation, Phoenix's score is worse than DREAM's score. Lastly, LoC rewards decompilers for non-structurally related optimizations, such as aggressive expression folding and constant propagation.

7.1 Graph Edit Distance

Conceptually, MCC is flawed because it does not consider edge and node locations relative to the source. Using this flaw as inspiration, we used the Graph Edit Distance (GED) relative to the source CFG to encode edge-node location differences into a metric. Prior work has used GED in binary similarity analysis by computing GED on binary-level CFGs [7, 42]. We run GED on the CFGs of the source and associated decompilation to estimate their structural closeness.

We associate lower GED-to-source scores with easier-to-understand decompilation. To study this association, we collected results from Decomperson, a study of human-written decompilation [11]. In Decomperson, participants manually create decompilation given assembly with the target of having the lowest assembly difference from the binary when compiled. With every submission, users attempt to get closer to the source code.

In Figure 9, we graph the average exact GED score of 30 participants as they submit results on the `winky` challenge. We could compute the exact GED scores because the functions in this challenge were sufficiently small. Each participant ended with a byte-match of 50% or higher. Their average GED scores decrease over time, indicating lower GED scores are likely associated with higher closeness to source, which means fewer structural differences.

7.2 Control-Flow Graph Edit Distance

Unfortunately, computing an exact GED is NP-hard [10]. In practice, we have found exact GED is usually too expensive to run on graphs with more than 12 nodes. When using upper-bound GED estimation algorithms, their estimations are significantly higher than the exact score, and, on exact match graphs, they rarely return zero. Therefore, we design a scalable algorithm, called Control-Flow Graph Edit Distance (CFGED), that uses CFG-specific characteristics to improve the scalability of GED estimations when applied to decompilation.

CFGED decomposes the GED problem using the identified SESE regions and uses exact GED when the region is small enough, and approximate GED if the region is too large (as the last resort). The CFGED between two CFGs is the sum of the GED of all regions. This often returns a score that is lower than the upper-bound GED approximation in the same or faster time. An example of CFGED computation on two graphs can be found in Appendix A.3.

To validate the accuracy of CFGED, we computed the exact GED, the maximum GED, and the CFGED of all functions with lower than 12 nodes in Coreutils 9.1. On all 506 samples, CFGED returns a score between the maximum and exact. CFGED gets the exact score on 64% of all samples. On average, CFGED introduces a 35% overhead to the percent difference score (the GED approximation divided by the max possible score).

8 Evaluation

We evaluate all structuring algorithms using two sets of C binaries: popular Debian packages and MSVC compilable packages. We attempt to answer the following research questions through experiments:

RQ1. How well does SAILR structure function CFGs during binary decompilation compared to state-of-the-art structuring algorithms?
RQ2. Given that SAILR is guided by findings on GCC 9.5, how does it perform on older and newer GCC versions?
RQ3. Given that SAILR is guided by findings on GCC 9.5, how does it perform on binaries generated by different C compilers?

Table 3: Structuring results on 7,355 functions across 26 popular Debian packages. The percent change relative to source is shown on each sum. The CFGED percent change is shown w.r.t. Hex-Rays.

Metric	Source			SAILR			Hex-Rays			Ghidra			Phoenix			DREAM			rev.ng		
	Sum	Avg	Med	Sum	Avg	Med	Sum	Avg	Med	Sum	Avg	Med	Sum	Avg	Med	Sum	Avg	Med	Sum	Avg	Med
Gotos	1,367	0.19	0.0	2,673 (95.5%)	0.36	0.0	6,115 (347.3%)	0.83	0.0	6,575 (380.9%)	0.89	0.0	8,497 (521.6%)	1.16	0	0 (100%)	0	0	0 (100%)	0	0
Bools	6,180	0.84	0.0	3,980 (35.6%)	0.54	0.0	4,279 (30.8%)	0.58	0.0	4,850 (21.5%)	0.66	0.0	2,685 (56.6%)	0.37	0.0	43,661 (600.5%)	5.94	0.0	2,003 (67.6%)	0.27	0.0
Calls	53,995	7.34	3.0	52,558 (2.6%)	7.15	3.0	52,508 (2.8%)	7.14	3.0	53,202 (1.5%)	7.23	3.0	51,167 (5.2%)	6.96	3.0	51,204 (5.2%)	6.96	3.0	166,798 (116.3%)	22.68	3.0
CFGED	0	0	0	166,468 (0.5%)	22.64	8.0	165,583 (0%)	22.52	8.0	187,509 (13.2%)	25.5	7.0	166,480 (0.5%)	22.64	8.0	338,231 (104.3%)	45.99	10.0	524,248 (216.6%)	71.29	8.0

Additionally, we explore tangentially related questions with an extended evaluation set in Appendix A.4.

8.1 Evaluation Methodology

All experiments are performed on an Ubuntu 22.04 server. During each experiment, we compile all .c files in a package and use the compiler to output intermediate source files that have been preprocessed. Next, we compile with debug symbols, no inlining, and saved object files. We then record the address-to-line mapping for each object file before stripping it of debug information. The mapping is recorded for evaluation with CFGED. Each object file has an associated intermediate (.i) file and address mapping.

After compiling, we decompile every object file, which is the non-linked version of the final executable, with every decompiler and parse the output with Joern [45]. We use Joern to collect metrics, as well as CFGs, from each decompiler to allow for decompilation that may not be recompilable. We evaluate Hex-Rays 8.0 (IDA Pro), Ghidra 10.1, and the ANGR DECOMPILER, which implements SAILR, Phoenix, DREAM, and rev.ng's Combing. Each structuring algorithm is evaluated on the metrics in Section 8.2. To assure a fair evaluation among all structuring algorithms, we only report metrics on functions that successfully decompiled on all decompilers and did not crash on our measuring pipeline.

Reimplementation of existing algorithms. For fair evaluation, we attempted to use prior work's decompilers. However, the Phoenix decompiler was not open-sourced, and the open-sourced DREAM decompiler does not build in their specified environment. We tried to use the rev.ng decompiler, but the alpha version crashed on most binaries in the Coreutils package, which prohibited us from evaluating it. We reimplemented all of them in the ANGR DECOMPILER.

8.2 Metrics

We evaluate the structuring algorithm of every decompiler using two metrics.

Structuredness. Structuredness measures how often a structuring algorithm creates C structures in the output. We follow prior work evaluations [44]: we measure structuredness by counting the number of gotos in the decompilation.

Faithfulness. Faithfulness measures how close the control flow structure is to the original source's. We use CFGED, function calls, and Booleans expressions to measure the similarity in flow, execution structure, and conditions to the source.

We further ensure the structuring correctness of each decompiler's output by manually sampling and verifying a small set of decompiler output. We do not measure the correctness by recompilability because the main contribution of our work is structuring, not recompilable decompilation.

Table 4: Structuring results on 433 functions across Coreutils compiled with various GCC versions and Clang.

	Most-Recent Release	Decompiler	Gotos	Bools	Calls	CFGED
Source	N/A		20	438	4,761	0
GCC 5	October 10, 2017	SAILR	152	295	4260	14499
		Hex-Rays	464	299	4199	14399
GCC 9	May 27, 2022	SAILR	169	284	4277	13462
		Hex-Rays	447	290	4353	13266
GCC 11	April 21, 2022	SAILR	170	280	4290	13445
		Hex-Rays	451	293	4353	13391
Clang 14	March 25, 2022	SAILR	167	292	4290	22879
		Hex-Rays	454	303	4335	22671

Table 5: Structuring metrics on 45 unique functions across Zlib compiled with MSVC.

	Gotos	Bools	Calls	CFGED
Source	0	70	158	0
SAILR	12	59	133	1813
Hex-Rays	14	52	133	1743

8.3 Structuring on Debian Packages

To answer RQ1, we focused on the effects of SAILR concerning programs compiled with GCC 9.5 on the `O2` optimization level, the compiler configuration we studied. We evaluate against all structuring algorithms on 26 popular Debian C packages [1], listed in full in Appendix A.1. Table 3 shows the results on each metric for every decompiler.

SAILR outperforms all algorithms in relative goto creation but loses to Hex-Rays in CFGED by 0.5%. Although SAILR loses in CFGED, the high reduction of gotos relative to Hex-Rays indicates SAILR is removing gotos in a non-structurally destructive way. In contrast, DREAM, which removes the most gotos, differs from Hex-Rays by 104.3% on CFGED.

8.4 Generalizability Across Compilers

To answer RQ2 and RQ3, we evaluated SAILR on various compiler versions and vendors. Building on the results of Table 3, we focus on the differences between the best structuring

algorithms of the Debian package evaluation: Hex-Rays and SAILR. In Table 4 we evaluate multiple versions of GCC as well as Clang on Coreutils, the defacto decompilation evaluation dataset [9, 24, 44]. Although Coreutils has a Windows variant, it does not natively compile with MSVC. In lieu of Coreutils, we chose Zlib since it was easily compilable. In Table 5 we evaluate Hex-Rays and SAILR on Zlib, compiled with MSVC 14.20.

Similar to the results in Table 3, SAILR marginally loses to Hex-Rays on CFGED (no more than 1.5%), but improves the gotos emitted across every compiler. Because the number of gotos, calls, and Boolean operators are all fairly consistent, we can conclude that the compiler-aware decompilation improvements that SAILR has on GCC 9 actually generalize to historical versions of GCC. However, in the highly different MSVC compiler, SAILR loses significantly more on CFGED, which may be due to hardcoded Windows-specific schema in Hex-Rays.

9 Discussion

To the best of our knowledge, this is the first effort for a complete investigation of goto-inducing compiler transformations and the significance of undoing such transformations in decompilers. We next discuss the limitations of SAILR.

The remaining gotos. While SAILR removes a lot of spurious gotos in decompilation, it does not remove all of them. Through a manual analysis of the remaining gotos, we find that they are caused by the following reasons: (a) Certain function calls not returning but angr is unaware, which leads to incorrect function-level CFGs; (b) The decompiler choosing the wrong edge among several candidates to virtualize, which prevents SAILR from applying deoptimization techniques at intended locations; and (c) SAILR condensing blocks that were not impacted by ISD optimizations in compilers. We believe (b) and (c) can be addressed by SAILR performing an iterative search when picking edges to virtualize and parts of code to deoptimize, which we leave as future work.

High CFGED between the best decompilation and source. We also investigated why the CFGED scores are still so high, even in cases where SAILR perfectly reverts every goto-inducing optimization that the compiler introduces. There are two main reasons. First, CFGED is still an approximation, which can significantly differ from the actual exact GED on larger CFGs. In a CFG with over 200 nodes and 100 edges, we observed that the exact GED between the decompilation and the source was as low as 4 while CFGED reported 306. We envision that future algorithmic improvements on GED computation will reduce GED scores in our measurement. Second, CFGED is extremely sensitive to structural differences, and many structuring choices that a decompiler makes (e.g., whether a node belongs to the loop body or not), while leading to high structural differences, are ultimately undecidable. We believe the use of statistical techniques, e.g., machine learning, will help immensely in these cases.

Architecture, platform, and compiler-specific study. Our investigation is specific to x86-64 Linux user-space executables that are compiled using GCC or Clang, and some MSVC-compiled Windows binaries. While it is likely to find new types of goto-inducing compiler transformations under other settings, decompiler authors can use the methodology we presented in Section 3.2 to find and address them.

Compounding ISC and ISD optimizations do not always cause gotos. In rare cases, compounding ISC and ISD optimizations may create subgraphs that happen to match against known graph schemas. As such, no unstructurable code regions will be created. A graph-schema-matching decompiler will generate a goto-free decompilation result, however it does not structurally match the source. Fundamentally, this is caused by the many-to-one mapping from legitimate C source to binary code. We believe a natural solution is using a machine-learning approach to predict the most suitable structuring result from the binary CFG and its context.

Using Hex-Rays to study gotos in Coreutils binaries. In the goto-origin study, we used Hex-Rays to investigate gotos in binary code with the assumption that Hex-Rays only performs basic graph-schema-matching and does not proactively remove gotos. We found that this assumption is false because Hex-Rays seems to have more graph schemas than other decompilers. Fortunately, we did not notice any cases where Hex-Rays would actively solve ISC- or ISD-optimizations. We believe using a naive graph-schema-matching decompiler can help increase accuracy of all goto sources.

10 Related Work

Control-flow Structuring. The two main methods for recovering control-flow structures from CFGs are *interval analysis* and *structural analysis*. Interval analysis [5, 16] partitions a CFG into nested regions called intervals. The nested nature ensures the data-flow analysis is not duplicating effort.

Structural analysis [37] is an extension of interval analysis, allowing a syntax-driven method of data-flow analysis that is normally reserved for abstract syntax trees to be applied on intermediate representations of low-level code such as AIL, VEX, and BIL. Structural analysis algorithms recover high-level control constructs from CFGs for use in decompilation.

Engel et al. [21] extended structural analysis to C-specific control statements, by proposing the SESS model. SESS accounts for statements in C that appear before control-flow changes induced by a `break` or `continue`. However, this approach relies on pre-defined schemas that occur in CFGs and introduces gotos that were not originally present in the source code. The SAILR approach focuses specifically on GCC-induced *gotos*.

A related area of research attempts to remove gotos at the source code level [22, 41] by defining AST transformations

that replace gotos with an equivalent semantic-preserving structure. This generally increases overall code size and complexity and also can insert unnecessary Boolean variables.

Decompilers. Cifuentes' PhD thesis [14] can be considered the academic foundation for many modern decompilers. The decompilation techniques, based on interval theory and expanded on in follow-up work [15], were implemented in the Intel 80286/DOS to C decompiler `dcc`.

Hex-Rays, a plugin for IDA, is the de facto commercial decompiler. There is no official source on the techniques Hex-Rays uses for decompilation. Schwartz et al. [9] noted that Hex-Rays uses some form of improved structural analysis.

The Phoenix [9] decompiler is built with the Binary Analysis Platform (BAP) [8]. Phoenix attempts to reduce the number of gotos in decompilation through *iterative refinement* which will replace an edge with a goto if the structural analysis algorithm cannot make forward progress. DREAM [44] builds upon the techniques in the Phoenix [9] decompiler to emit zero gotos by design. DREAM forcefully excludes gotos with the use of Boolean expressions and state variables. While it eliminates gotos, it can generate code with entangled execution paths [24]. rev.ng is a decompiler [17, 24] implementing the *Control Flow Combing* algorithm to remove gotos by aggressively duplicating code. These decompilers treat the symptom of the problem—gotos appearing in decompilation—but do not address the root of the problem. SAILR attempts to remedy this by following a simple idea: to achieve high-quality decompilation, decompilers must be compiler-aware.

Recent advances in deep learning techniques have led to progress in the field of decompilation. Researchers have used deep learning approaches to (1) enhance the quality of decompilation by predicting debug information [25], variable names [12, 13, 26, 29], types [12, 46] and function names [6], and (2) build an end-to-end, neural network-based decompiler [23]. These approaches open up exciting opportunities for future research aimed at developing a general-purpose end-to-end neural decompiler.

11 Conclusion

Decompilers seek the impossible—how to recover source code using only binary code. This act of divination requires a complex mix of binary analysis, graph analysis, and, fundamentally, engineering. We believe that the goal of a decompiler should be to get as close as possible to the original code and that the only way to accomplish this is to be compiler-aware. SAILR and the ANGR DECOMPILER represent the next steps in this direction toward perfect decompilation.

A Appendix

A.1 Popular Debian Packages for Evaluation

We evaluated SAILR on 26 randomly selected from the top 50 Debian packages collected from the Popcon [1] list: bash, libselinux, shadow, libedit, base-passwd, openssh-portable, dpkg, dash, grep, kmod, diffutils, findutils, gnutls, iproute2, gzip, sysvinit, bzip2, libacl, libexpat, libbsd, tar, rsyslog, cronie, zlib, e2fsprogs, and coreutils.

A.2 Case Study: Constant Depropagation

To better understand more complex cases of deoptimization, we document a case study involving constant depropagation in the Coreutils 9.1 package of compounding optimizations.

The binary `fmt` contains an ISD optimization in the function `main`, which causes a duplication of a subgraph shown in Listing 2. However, this case does not match any ISD deoptimization schema because the calls to `xdectoumax` are not the same, differing by a single argument value. The calls on Lines 7 and 11 originate from the same source line and are duplicates, but the constant which is assigned to `max_width` on Line 2 is constant-propagated, causing them to differ after the

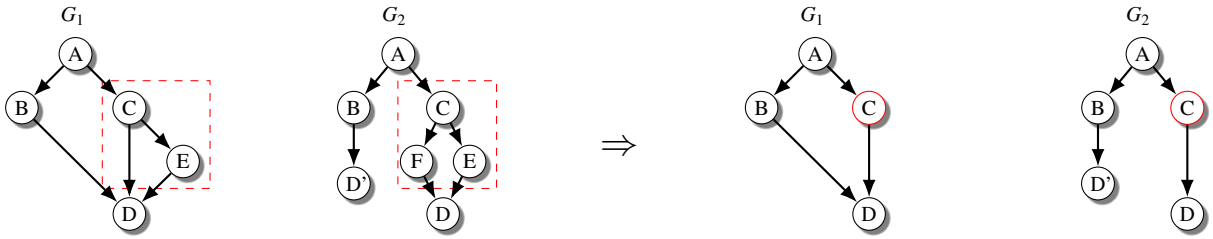

Figure 10: A single round of CFGED approximation and region collapsing. Every round, a region collapses after computing the GED inside the region. Additionally, the difference in the edges source and destination are added as edits.

ISD optimization. To revert this ISD case, the optimizations must be undone in reverse order.

SAILR first runs a KMP similarity matching algorithm to find arguments that may differ across calls. When these arguments are identified, SAILR checks to see if one argument is symbolic (such as a variable) and one is constant. If this is true, SAILR uses Reaching Definitions Analysis to find all the possible values of the symbolic argument on the path with the constant. If the symbolic argument can only equal the constant on that path, it is replaced by the symbolic variable.

In Listing 2 this makes both calls to `xdectoumax` an exact duplicate. Because both calls are duplicates, have a common successor to their blocks, and at least one is connected by a goto, this case matches the ISD algorithm. When this case is merged only one `xdectoumax` remains, with the assignment blocked by the reaching conditions of the two statements.

A.3 Computing CFGED

Figure 10 shows an example computation of CFGED between G_1 and G_2. CFGED starts by finding two tail regions that contain the same head node across graphs. In the decompilation-to-source comparison, the addresses associated with each decompilation line are used to map source lines to nodes. Because a tail region contains no nested regions, the size of these sub-graphs is often small when mapped correctly.

The highlighted regions in Figure 10 have a GED of 2. Because there are also edges leaving these regions, we must check the edit distance of the region's successor. There is a missing edge and node in G1 that should have an edge to the successor. Adding this node and edge constitutes an edit distance of 2. In practice, this can be computed by running GED on the region plus its successor node. In this example, round one has a total CFGED score of 4: 2 for the single edge and node conflict (F, D) and 2 for the GED of the regions.

Continuing, the next region collapsing round would have no more regions to collapse and would run GED on G_1 and G_2. The resulting GED is 3, with the total CFGED to 7, which is equal to the exact GED score of 7.

A.4 Extended Evaluations

Ablation Study. In this experiment, we measure the impact of deoptimization (discussed in Section 5) and knowledge expansion (Section 6). We use three structuring algorithm variants: Phoenix with improvements in Section 6.1, SAILR Lite (Phoenix with improvements in Section 6), and SAILR. We decompile 953 functions in Coreutils 9.1 compiled under optimization level `O2`. As shown in Table 6, both deoptimization and knowledge expansion are necessary for reducing gotos and CFGED scores. Deoptimization contributes more than knowledge expansion in terms of goto reduction.

Linux Kernel Study. To better understand how SAILR structures code highly saturated with gotos, we evaluate SAILR against other structuring algorithms on a subset of the Linux kernel [27]. We randomly picked 100 source files (and object files) from the core kernel code base, collected 802 functions, and ran decompilers against them. Table 7 shows the result: SAILR outperforms other solutions in terms of relative goto emittance to source but shows slightly worse CFGED scores.

```
1  max_width = 0x4b;
2  if (v0) {
3    max_width = xdectoumax(v0, 0x0, 0x9c4, &.LC11,
4        dcgettext(NULL, "invalid width", 0x5), 0x0);
5    if (!v1)
6      goto LABEL_40cd86;
7    goal_width = xdectoumax(v1, 0x0, max_width, &.LC11,
8        dcgettext(NULL, "invalid width", 0x5), 0x0);
9  } else {
10   if (v1) {
11     goal_width = xdectoumax(v1, 0x0, 0x4b, &.LC11,
12         dcgettext(NULL, "invalid width", 0x5), 0x0);
13     max_width = goal_width + 10;
14     goto LABEL_40ccc7;
15   }
16 Label_40cd86:
17   goal_width = (max_width * 187 >> 31
18                 CONCAT max_width * 187) /m 200;
19 }
20 Label_40ccc7:
21 v17 = optind;
```

Bools	17	15	17	8	33	1
LoC	1640	878	1881	1690	1681	2186

Malware Study. We also evaluated SAILR on a malware sample: the SpyEye malware on Windows [40]. In Table 8, we compare SAILR against other structuring algorithms on 54 functions. Because there is no source code to compare against, we use generic readability metrics, which may not reflect structural closeness.

Decompilation Times. In Table 9 we show the decompilation times across 1272 functions in Coreutils 9.1 compiled with GCC 9.5 `O2`. The ANGR DECOMPILER takes significantly longer to decompile due to its Python implementation. SAILR takes longer than our other structuring algorithms because of a naive implementation for the search phase for ISD deoptimization. In short, SAILR uses a shortest-path algorithm to find the head for deduplication, which we believe can eliminated with future engineering.

Table 9: Decompilation times (in seconds) across all functions in Coreutils.

	SAILR	Hex-Rays	Ghidra	Phoenix	DREAM	rev.ng
Median	1.16	0.01	0.05	0.82	0.8	0.71
Mean	5.24	0.03	0.07	2.15	2.08	2.33
Max	606.7	0.38	1.06	55.32	31.55	329.33
Sum	6670.0	31.84	91.43	2735.03	2647.14	2962.65

Compiler Configurations Study. To understand the full effect of different compiler optimizations on SAILR, we compiled the same 26 Debian packages in Section 8.3 on all optimization levels for GCC 9.5. In Table 10 we show a comparison against other structuring algorithms on 5,752 functions. The result shows that SAILR consistently yields the closest number of gotos (except `O0`) with CFGED scores being very close (within 6%) to the lowest CFGED scores (from Hex-Rays). We believe SAILR's poor results on gotos and CFGED compared to Hex-Rays is due to Hex-Rays maturity in schema for unoptimized binaries.

Expanded Multi-Compiler Study. We expanded our results from Table 4 in Table 11 to include all decompilers supported in our evaluation pipeline. Note, that there are fewer functions (392 total) in these results due to functions missing across more decompilers.

A Taxonomy of C Decompiler Fidelity Issues

Luke Dramko[*], Jeremy Lacomis[*], Edward J. Schwartz[†], Bogdan Vasilescu[*], Claire Le Goues[*]

Abstract

Decompilation is an important part of analyzing threats in computer security. Unfortunately, decompiled code contains less information than the corresponding original source code, which makes understanding it more difficult for the reverse engineers who manually perform threat analysis. Thus, the fidelity of decompiled code to the original source code matters, as it can influence reverse engineers' productivity. There is some existing work in predicting some of the missing information using statistical methods, but these focus largely on variable names and variable types. In this work, we more holistically evaluate decompiler output from C-language executables and use our findings to inform directions for future decompiler development. More specifically, we use open-coding techniques to identify defects in decompiled code beyond missing names and types. To ensure that our study is robust, we compare and evaluate four different decompilers. Using thematic analysis, we build a taxonomy of decompiler defects. Using this taxonomy to reason about classes of issues, we suggest specific approaches that can be used to mitigate fidelity issues in decompiled code.

1 Introduction

Decompilation—the process of analyzing a compiled program and recovering a source-code program that portrays the same behavior—is a crucial tool in computer security, as it allows security practitioners to more quickly gain a deep understanding of the behavior of compiled programs. This is particularly useful in security scenarios such as analyzing malware and commercial-off-the-shell software (COTS), where the source code may be unavailable. By converting executables into human-readable C-like code, decompilation allows security practitioners to more effectively understand and respond to the threats posed by malware [36]. An example of this can be seen in the study by Ďurfina et al. [43], where analysts employed a decompiler to analyze the `Psyb0t` worm, a piece of malware that infects routers to build a botnet.

Original

```
1  void cbor_encoder_init(CborEncoder *encoder, uint8_t
       *buffer, size_t size, int flags)
2  {
3    encoder->ptr = buffer;
4    encoder->end = buffer + size;
5    encoder->added = 0;
6    encoder->flags = flags;
7  }
```

Decompiled

```
1  long long cbor_encoder_init(long long a1, long long
       a2, long long a3, int a4)
2  {
3    long long result;
4    *((_QWORD *) a1) = a2;
5    *((_QWORD *) (a1 + 8)) = a3 + a2;
6    *((_QWORD *) (a1 + 16)) = 0LL;
7    result = a1;
8    *((_DWORD *) (a1 + 24)) = a4;
9    return result;
10 }
```

Figure 1: A decompiled function and its original source definition. Decompilers cannot recover many of the abstractions that make source code readily readable by human developers. Furthermore, they may incorrectly recover semantics, as demonstrated by the decompiled function's extra return statement.

Analyzing and understanding the behavior of executable code is significantly more difficult than analyzing source code due to information that is removed by the compilation process. Indeed, while high-level programming languages contain abstractions and constructs such as variable names, types, comments, and control-flow structures that make it easier for humans to write and understand code [34], executable programs do not. These abstractions are not necessary for an executable program to run, and thus they are discarded, simplified, or optimized away by compilers in the interest of minimizing executable size and maximizing execution speed.

This means that those useful abstractions are not present when it comes time to analyze an executable program, such as malware, without access to its source code.

Traditionally, security practitioners would reverse engineer executables by using a disassembler to represent the semantics of the program as assembly code. While better than nothing, assembly code is still far from readable. Decompilers fill this gap by analyzing an executable's behavior and attempting to recover a plausible source code representation of the behavior. Despite a great deal of work, decompilation is a notoriously difficult problem and even state-of-the-art decompilers emit source code that is a mere shell of its former self [18, 26, 33, 38, 39]. Despite this, decompilers are one of the most popular tools used by reverse engineers.

Figure 1 shows an example of a decompiled function and its original source code definition. Although the decompiled code is C source code,[1] it is arguably quite different from the original. We say that decompiled C code is not *idiomatic*; that is, though it is grammatically legal C code, it does not use common conventions for ensuring that source code is readable. Further, as Figure 1 also illustrates, decompiler output may be incorrect; that is, it may be semantically nonequivalent to the code in its executable form. We collectively call these readability and correctness issues *fidelity* issues because they do not faithfully represent the software as intended by its authors. (See Section 3.1 for a discussion of fidelity).

Fidelity issues are problematic because decompiled code is usually created to be *manually* read by reverse engineers. Reverse engineering is a painstaking process which involves much time spent rebuilding high-level program design as the reverse engineer develops an understanding of what the executable binary does [36]. Code that is more faithful to the original source contains more of the abstractions designed to assist with human comprehension of code. Thus, the fidelity of decompiled code to the original source matters, as it can significantly impact reverse engineers' productivity. Evaluating the products of decompilation based on fidelity to the original source is common in existing work [9, 11, 15, 21, 22, 24].

Improving the functionality and usability of decompilers has long been an active research area, with many contemporary efforts [7, 13, 14, 30, 37]. A recent trend in this direction is using statistical methods such as deep learning-based techniques to improve the process of decompilation [12, 15, 19, 21, 32, 42], or augment the output of traditional decompilers [2, 4, 11, 24, 31]. The latter strands of work have the potential benefit of building on top of mature tools like Hex-Rays and Ghidra instead of operating on binaries, and have already seen promising results for recovering missing variable names and types. Here, researchers have been developing models that *learn* to suggest meaningful information in a given context with high accuracy, after seeing many examples of original source code drawn from open-source repositories like the ones hosted on GitHub.

However, while variable names and types are certainly important for program comprehension, including in a reverse engineering context [7, 36, 40], there are many more fidelity issues in decompiled code, and there is relatively little knowledge of what they are, how they vary across decompilers, and what the implications are for learning-based approaches aiming to improve the fidelity of decompiled code to the original source.

We argue that before designing more advanced solutions, we first need a deeper understanding of the problem. Consequently, in this paper we set out with the **Research Goal** of developing a comprehensive taxonomy of fidelity issues in decompiled code. Concretely, we start by curating a sample of open-source functions decompiled with the Hex-Rays,[2] Ghidra,[3] retdec,[4] and angr[5] [35] decompilers. Next, we use thematic analysis, a qualitative research method for systematically identifying, organizing, and offering insights into patters of meaning (themes) across a dataset [6], to analyze the decompiled functions for fidelity defects, using those functions' original source code as an oracle. To minimize subjectivity, we develop a novel abstraction for determining correspondence between code pairs, which we call *alignment*. Using this abstraction, we define fidelity defects in decompiled code, creating a taxonomy consisting of 15 top-level issue categories with 52 in total. We then use our taxonomy to suggest how the issues could be addressed, framing our discussion around the role that deterministic static analysis and learning-based approaches could play.

In this study, we focus primarily on decompiled code from C-language binaries; that is, those that were built from C-language source. C is a common source language for malware and other binaries targeted by reverse engineering efforts. Further, most decompilers of machine-code executables generate output in terms of C pseudocode regardless of the language in which the source code for the executable was written. It is unclear what it would mean for a C decompiler to correctly decompile a Golang executable into C, for example, since Golang contains concepts and features without a direct equivalent in C.

We also examine Java decompilation. However, we find that decompiled Java code is of very high fidelity and thus there are few fidelity issues to classify.

Our results are robust both across different researchers as well as the four decompilers we considered.

In summary, we make the following contributions:

- A comprehensive, hierarchical taxonomy of fidelity issues in decompiled code beyond names and types.
- 235 coded decompiled/original function pairs, identify-

[1] Decompiled code is not always syntactically correct C code.

[3] https://ghidra-sre.org/

[4] https://github.com/avast/retdec

[5] https://angr.io/

ing over one thousand instances of issues in our taxonomy.

- A novel abstraction for assigning code correspondence in source code pairs and a framework built on this abstraction for rigorously applying open coding to those source code pairs.
- A comparison of four different modern decompilers.
- A thorough analysis describing classes of decompiler issues and suggestions for how to fix them.

2 Related Work

2.1 Decompilation

Significant efforts have been made in recent years to improve the performance of decompilers. A large portion of these efforts concentrate on addressing the core challenges in program analysis that are fundamental to decompilation, which mainly include type recovery and control flow structuring.

Type recovery is the process of identifying variables and assigning them reasonable types by analyzing the behavior of the executable. We refer readers to an excellent survey of type recovery systems [8], but also review some notable security-oriented work developed in recent years. This includes systems that operate on dynamic runtime traces, such as REWARDS [27], and follow-on systems that statically recover the types by analyzing the executable code at rest. TIE [26] is an exemplar static recovery system used in the academic Phoenix [33] and DREAM [38, 39] decompilers. The Hex-Rays decompiler uses its own static type recovery system [18].

Control flow structuring is the process of converting an unstructured control flow graph (CFG) into the structured control flow commands that are more common in source languages, such as if-then-else and while loops. The Phoenix [33] decompiler introduced a control flow structuring algorithm designed explicitly for decompilation in that it was semantics preserving, unlike other more general structuring algorithms. One of the main challenges of control flow structuring is how to handle code that cannot be completely structured, which can be caused by using non-structured language constructs such as gotos. Although the Phoenix algorithm preserved semantics, it emitted gotos for unstructured code, which could make the decompiled code hard to read. The subsequent DREAM [38] and DREAM++ [39] decompilers introduced a new control flow structuring algorithm and other changes that were intended to improve the usability of the decompiler. Notably, their structuring algorithm duplicated some code to avoid emitting gotos, which they found to improve readability. The RevEngE decompiler [5] provides the ability to do incremental, on-demand decompilation and is designed for human-in-the-loop decompilation.

Some researchers [9, 15, 21, 22] have focused on using machine learning to model the entire decompilation process. This approach, known as *neural decompilation*, attempts to map a low-level program representation, such as assembly, directly to the source code of a high-level language like C using a machine learning model, sometimes in multiple phases. Theoretically, these approaches are capable of generating decompiler output that is identical to the original source code. However, neural decompilation often fails to match the original source code.

2.2 Improving decompilation through learning

Recent work has studied whether it is possible to correct some of the limitations of current decompilers through learning-based methods. A popular focus of this work is recovering variable names for decompiled code, which is a problem that is not well-suited to traditional program analysis since the variable names are not explicitly stored in the executable. Lacomis et al. [24] and Nitin et al. [31] found that the generic variable names used in most decompilers (v1, v2, etc.), make it more difficult to read decompiled code than the original. In response, they propose machine-learning-based tools that propose meaningful variable names in decompiled code to help alleviate this issue. Chen et al. [11] also found that variable *types* are often recovered incorrectly by decompilers, especially composite types like C-language struct, array, and union types. They build a machine-learning-based tool to predict missing variable names and types at the same time, and note that variable names inform variable types and vice versa. However, while variable names and types are important fidelity defects, they represent only a subset of all readability defects in decompiled code. Our study develops a more complete taxonomy of readability defects in decompiled code.

2.3 Taxonomy of decompilation defects

Liu and Wang [28] do provide a taxonomy of some defects in decompiled code, but their study is orthogonal to ours. They focus only on those defects that produce semantic differences in the source code, while we more broadly investigate the characteristics of decompiled code that cause it to differ from the original, including but not limited to semantic differences. Further, their taxonomy differentiates these semantic defects by the phases of decompilation in which they originate rather than by the nature of the defects themselves. In short, their study focuses on the decompiler itself while ours focuses on the fidelity of the decompiler output to the original source.

2.4 The Reverse Engineering Process

There is relatively little work examining how reverse engineers analyze a binary. Votipka et al. [36] conduct detailed

interview studies with 16 professional reverse engineers to develop a three-step process model for reverse engineering: overview, sub-component scanning, and focused experimentation. Burk et al. [7] corroborate these findings. Mantovani et al. [29] study how reverse engineers (both novices and experts) move through the flow graph of the binary. They find that while there is some variance in individuals' strategies, novice reverse engineers tend to move forward (from `main`) more and examine more of a binary, while experts move backwards and forwards through the flow graph as needed and more quickly dismiss irrelevant parts of the binary. Yong Wong et al. [40] investigate the workflows of malware analysts with an emphasis on dynamic analysis through interviews with 21 reverse engineering professionals. They build a taxonomy of reverse engineering processes each with its own unique interplay between static and dynamic analysis.

3 Methodology

To build our taxonomy of fidelity issues in decompiled code, we used open-coding techniques [23] followed by thematic analysis [6] to group these codes into hierarchical themes. In particular, we used pairs of function representations: a decompiled function and the corresponding original function. Open coding is typically used to systematically analyze textual data, such as interview data. Coding pairs of source code functions like this offered some unique challenges. First, we detail the philosophy we developed to help overcome those challenges. Next, we discuss practices we used to help guide the coding process. Finally, we discuss the process we used to code our examples and develop the codebook.

In open-coding techniques, features of the analyzed entity are assigned labels called "codes." Unfortunately, "code" is also a word used to describe text written in a programming language. In this paper, for clarity, we will use "label" to refer to open-coding codes and "code" or "source code" to refer to text written in a programming language. "Original code" and "decompiled code" are types of source code, the former (most likely) written by a human programmer and the latter generated by a decompiler from an executable program. We continue to use the term "codebook" to indicate the collection of all open-coding labels rather than the term "labelbook."

3.1 Fidelity

We seek to identify, characterize, and catalog the characteristics of decompiled code that make it differ from the corresponding original source code; the original source code is our oracle. Accordingly, the labels in our codebook are presented in terms of *differences relative to the original source code*. Henceforth, we use the term "difference" to refer to the difference between a piece of decompiled code and the corresponding piece of original code.

Broadly, we consider two ways in which decompiled code is not faithful to the original source code:

- *Correctness issues* occur when there is a semantic difference between the decompiled code and the corresponding original code.
- *Readability issues* occur when the code is semantically equivalent but is communicated using different language features that are difficult to interpret.

Our oracle is most suitable for diagnosing correctness issues. A human researcher can look at the decompiled code and, with sufficient effort, determine if it is semantically equivalent to the corresponding original code. It is less suitable for identifying readability issues. After all, there is no guarantee that the original source code is readable. Furthermore, readability itself is somewhat subjective. What some might consider readable others might not.

To shore up this source of subjectivity, we introduce a second test. To determine if a difference affects readability, we ask if the difference simply reflects a difference between two common idiomatic styles. For example, the decompiler may place opening curly-brackets on a new line after an if-statement conditional, while the original code might place them on the same line as the conditional. Both styles are common and idiomatic, so this does not constitute a readability issue. Each unique readability issue, along with each correctness issue, is assigned a label.

Unfortunately, our solution to the readability oracle problem does not eliminate subjectivity. Rather, it shifts the subjectivity to a different place—what styles are idiomatic? We estimate idiomaticity by asking if a given style is common in C-language source code. For example, some original code functions include extraneous code like a `do { ... } while(0);` loop. In each instance we observed this, the decompiled code does not include the extraneous code. We consider this difference to be benign. Another example is inverted conditional statements. The original code might have an if statement of the form `if (!a) b else c`, while the decompiled code might represent that if statement as `if (a) c else b`. One ordering of the clauses is not necessarily more idiomatic than the other. Missing `volatile` or `static` keywords in the decompiled code are also benign differences because they do not affect the computations the function performs. We provide a list of differences that we do not consider to be non-idiomatic, and thus not readability issues, in the supplementary material.

We treat borderline cases, as well as differences which only sometimes result in non-idiomatic code, as readability issues. A summary of the decision process we used to determine if a code should be added to the codebook is shown in Figure 2.

3.2 Coding Standards

Performing open-coding on our data presented some interesting challenges. We detail them and our solutions here.

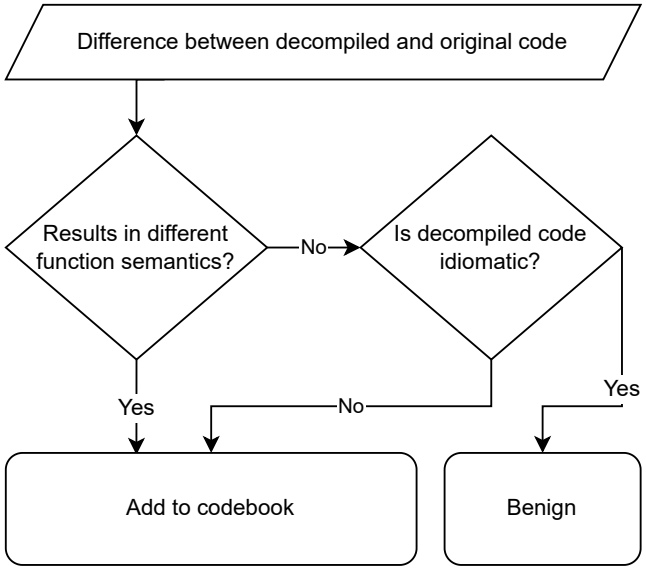

Figure 2: The process by which a difference between the decompiled code and corresponding original code was added to the codebook. Differences added to the codebook are considered meaningful defects, while others are considered benign differences in style. When in doubt, differences were added to the codebook.

3.2.1 Alignment

A critical assumption made in Section 3.1 was that differences between decompiled and original code could be easily identified. However, it is not immediately evident what precisely constitutes a "difference." Our goal is to determine if and how clearly the functionality present in the original code is communicated. Thus, we want to determine which pieces of the the code are supposed to represent the same functionality. We say two code fragments that perform the same functionality (or are intended to) are *aligned*. If the text of aligned code fragments is not identical, this constitutes a difference.

We found that it is often easy to align code by hand, though there are are some challenges to doing so. Figure 3 demonstrates several factors that can complicate determining an alignment. Decompilers may introduce extra statements, such as declarations and operations for variables that have no equivalent in the original source code (e.g., decompiled line 3 of Figure 3). Decompilers may also break complex expressions down into multiple statements, as happens when line 9 in the original code is broken into two statements in the decompiled code (lines 7 and 8). The opposite can be true as well—decompilers can inline expressions that are separate in the original code, and can even exclude code from the original function like redundant or extraneous assert statements. Thus, line numbers and other simple heuristics are generally unsuitable for aligning statements. In fact, many-to-one and one-to-many mappings between statements, like Figure 3's original line 9 and decompiled lines 7 and 8, means that alignment cannot even be thought of as a mapping between individual statements.

Despite this, in most cases, alignment is evident when coding an example. To ensure that our definitions are robust in corner cases, we provide a formal definition of alignment. The formal definition can be found in the supplementary material.

3.2.2 Multi-coding

Certain decompiler defects exhibit the characteristics of several different labels at once. In these cases, we allow for multiple labels to identify the same issue. We carefully select labels so that each fundamental issue receives its own label.

3.3 Dataset

We drew examples for our study from a large dataset derived from open-source projects on GitHub. This dataset was generated in an automated fashion by scraping GitHub through its API to collect majority-C language repositories. In total, our dataset contains functions from 81,137 repositories. A build of each project was attempted by looking for build scripts such as `Makefile`s and executing those to build executable binaries using a tool called GHCC.[6] All binaries generated by the build process were collected. Next, each binary was decompiled using the Hex-Rays decompiler, and all functions in the binaries were collected for a total of 8,857,873 across all projects. These functions were matched with the corresponding original function definitions in the original code. These functions were divided by size. Functions with more than 512 sub-words (which together make up an identifier name) and AST nodes were sorted into in the large function dataset (31% of the total); those with more were sorted into the smaller function dataset (69% of the total). We mostly used functions from the small function dataset, though we also coded ten functions from the large function dataset, as we discuss in the next section.

3.4 Coding Procedure

We selected a random sample of 200 decompiled/original function pairs from the small function dataset. We split the sample into two sets, which we refer to as the small function development set and small function test set. We coded in several phases.

1. **Collecting Differences.** We examined each example in the small function development set, building a set of differences without making judgement as to which semantics-preserving differences constituted readability

[6] https://github.com/huzecong/ghcc

Original

```
void help_object(obj_template_t *obj, help_mode_t mode)
{
  if (obj == 0)
  {
    set_error("help.c", 436, ERR_INTERNAL_PTR, 0);
    return;
  }

  obj_dump_template(obj, mode, get_nestlevel(mode), 0);
}
```

Decompiled

```
long long help_object(long long a1, unsigned int a2)
{
  unsigned int v3;
  if (!a1)
    return set_error("help.c", 436LL, 2LL, 0LL);

  v3 = get_nestlevel(a2);
  return obj_dump_template(a1, a2, v3, 0LL);
}
```

Figure 3: A decompiled function along with the corresponding original definition. Aligning decompiled code with the original is often easy to perform by hand, but even a relatively simple function like this one illustrates some of the challenges in defining alignment precisely. Except for return behavior, the decompiled function exhibits the same functionality as the original. However, the decompiled code uses a different, though equivalent, test in the `if` conditional, contains extra variables, reorganizes expressions, and uses a constant instead of the original code's macro.

differences. This also allowed us to get a sense of common, idiomatic practices from amongst the original code samples.

2. **Building the Codebook.** Next, we assembled a codebook from the differences. To do this, we first classified each semantics-preserving difference as either a readability issue or a benign difference. All readability issues and non-semantics-preserving differences (correctness issues) were assigned a label. Labels were organized hierarchically; higher-level labels generalizing several related labels were created when necessary.

3. **Coding Examples** With a complete codebook, we then labeled all 100 examples in the small function test set as well as 10 examples from the large dataset. This was an iterative process which ultimately involved refining the codebook and deriving precise definitions for each label. There was some interplay between this phase and the next. While missing variable names and types constitute readability issues, we did not label these issues on our examples because they are trivial and significantly clutter the coded examples.

4. **Generalization Across Decompilers** The process so far had been dependent on code that was decompiled by the popular Hex-Rays decompiler. However, we wanted to ensure that our results were representative of issues faced by decompilers in general and not specific to a certain tool. Thus, we randomly sampled 25 of the second 100 examples, decompiled the corresponding binaries using three other decompilers, Ghidra, retdec, and angr, and extracted the requisite functions. We then labeled those examples using the same codebook. Our codebook developed on Hex-Rays worked well, requiring one modification: differentiating between different types of incorrect return behavior. (As discussed in Sections 5.1.3 and 5.2, Hex-Rays exhibited only one type of incorrect return behavior.)

Table 1: Cohen's Kappa coefficient of intercoder agreement for each round of testing. After the first round of testing, we updated our codebook to make it more robust, which increased agreement. Cohen's kappa is usually interpreted as follows: > 0.4 indicates moderate > 0.6 indicates good, and > 0.8 indicates very good agreement. The bottom two rows are the mean and weighted mean of Cohen's kappa individually.

Measure	Round 1	Round 2
Lines researchers agreed had fidelity issues	0.67	0.78
Mean agreement across all labels	0.44	0.58
Weighted mean agreement across all labels	0.70	0.78

5. **Generalization Across Coders** To ensure that our codebook was robust, we performed several rounds of intercoder reliability testing [3]. We gave the completed codebook, along with thorough documentation and examples, to a researcher with reverse engineering experience. We randomly sampled 25 out of the second 100 examples, and gave these to him to code. We then computed interrater agreement using Cohen's kappa between his labels and the corresponding labels of the first author. Next, we measured the agreement and analyzed the results for any source of disagreement. We then updated the codebook and performed the process again with a different researcher, updating the codebook each time. Our evaluation of inter-coder agreement is shown in Table 1. The agreement is generally good, though worse for rare issues. Additionally, we found that some disagreement was not true disagreement but rather the result of mismatched assumptions about information external to the example function or simple fatigue.

6. **Generalization Across Languages** In steps 1–5, we focused exclusively on C code. We also wanted to determine if our taxonomy was applicable to other languages. We chose Java, which as an object-oriented and managed language, is significantly different from C and may offer different challenges to decompiler writers. We used the Defects4J dataset [20], which contains seventeen real-world Java projects and their corresponding build scripts. We built each project, randomly selected 25 non-unit-test functions from the dataset, then identified and decompiled the corresponding class files using the JD-GUI decompiler [1]. Finally, we applied our codebook to our sample of the dataset.

4 Taxonomy

Our study yielded a comprehensive codebook of defects in decompiled code. Our codebook is organized hierarchically, with broad, fundamental classes of issues at the top of the hierarchy and more specific instances at lower levels. There are 15 top-level labels, and 52 codes across all levels. In this section, we discuss each of the top-level labels in turn. Figure 4 contains several artificial example functions, composed of code fragments and specific issues observed in our dataset, which collectively illustrate all 15 top-level labels at least once. Figure 8 in the appendix shows the complete codebook.

C0. Incorrect identifier name: refers identifier names in the decompiled code, including variable names (C0.a), types (C0.b), and function names (C0.c), which do not match the corresponding identifier names in the original code. Compilers discard essential information about these abstractions: variable and some function names are discarded entirely, while type abstractions are reduced to memory offsets. In the examples we labeled, we did not explicitly label C0 issues because they vastly outnumber the other types of issues and because they have already been studied extensively in existing work [11, 19, 24, 31, 42].

C1. Non-idiomatic dereference: This occurs when a pointer variable in the decompiled code is used in a way that does not reflect its type in the original code. More precisely, it refers to a mismatch between aligned operator(s) where the operator in the original code is used to access value at or relative to a memory location. For example, in Figure 4, C1 labels what was a struct dereference in the original code (`current->next`) decompiled as a sequence of three operations: pointer arithmetic, a typecast, and a pointer dereference (`*((_QWORD *)(v5 + 8))`). The example in Figure 4 is in particular an instance of the sub-label C1.a.i. (Pointer arithmetic to access struct members) but there are others, including situations where `struct`s are accessed as if they are arrays (C1.a.ii.), and where arrays are accessed with pointer arithmetic (C1.b.ii.).

C2. Unaligned code: refers to situation where decompiled code does not align with any code in the original function; that is, the code is extra or missing relative to the original. Figure 4 illustrates an example where an extraneous variable, i.e., one that does not occur in the original source code, is itself initialized by an expression that does not occur in the original source code.

C3. Typecast issues: refers to extra or missing typecast operators relative to the original. We do not consider this to be a part of C2 because extra or missing typecasts are a consequence of decompilers' imprecise type recovery and in that sense could be considered to align with other operators to ensure that the decompiled code typechecks properly. Figure 4 illustrates an instance of an extra typecast added to a string literal, a pattern with some string literals in our dataset.

C4. Nonequivalent expression: refers to a collection of operators that align but that are not semantically equivalent to each other. Figure 4 illustrates one of several patterns found in our dataset, where a function call in the decompiled code receives an extra argument.

C5. Unaligned variable: This label refers to a situation where a variable in the decompiled code is missing or extra relative to the original code. We define alignment as a mapping between operators. Those operators can be connected in various ways by variables while still ensuring semantic equivalence. We define an alignment of variables as a mapping between sets of dataflow connections between operators. A good variable alignment minimizes the differences between sets. For example, in the `format_name` function in Figure 4, the decompiled code's variable `v1` aligns with `len`, and `v2` aligns with `buffer`. However, the variable `v3` in the decompiled code does not correspond to any variable in the original code; rather, it helps perform part of the functionality of an inlined function. Thus, it is extra relative to the original source code. Another example of a situation where extra variables can occur is when a multi-operator expression in the original code is broken up into two separate expressions with a variable storing the intermediate result. This occurs in Figure 3 where line 9 of the original code is split into lines 7 and 8 of the decompiled code.

C6. Non-idiomatic literal representation: This label is used to label literals used in nonstandard ways. For example, in Figure 4, the string literal `"}\n"` is replaced with the integer constant `2685`.

C7. Obfuscated control flow: This label is used when control flow is used in a way that is not idiomatic. In Figure 4, the `strcat` function is inlined. It may be harder to recognize what the decompiled code is doing relative to the original source code when a function definition is presented inline instead of the name which summarizes that functionality. Another example of C7 is a for-loop used in a non-idiomatic way as illustrated in Figure 5.

C8. Issues in representing global variables: Decompilers sometimes struggled to represent global variables correctly. In our examples, global variable names were not explicitly stripped out. Thus, in some cases, a reference to a global

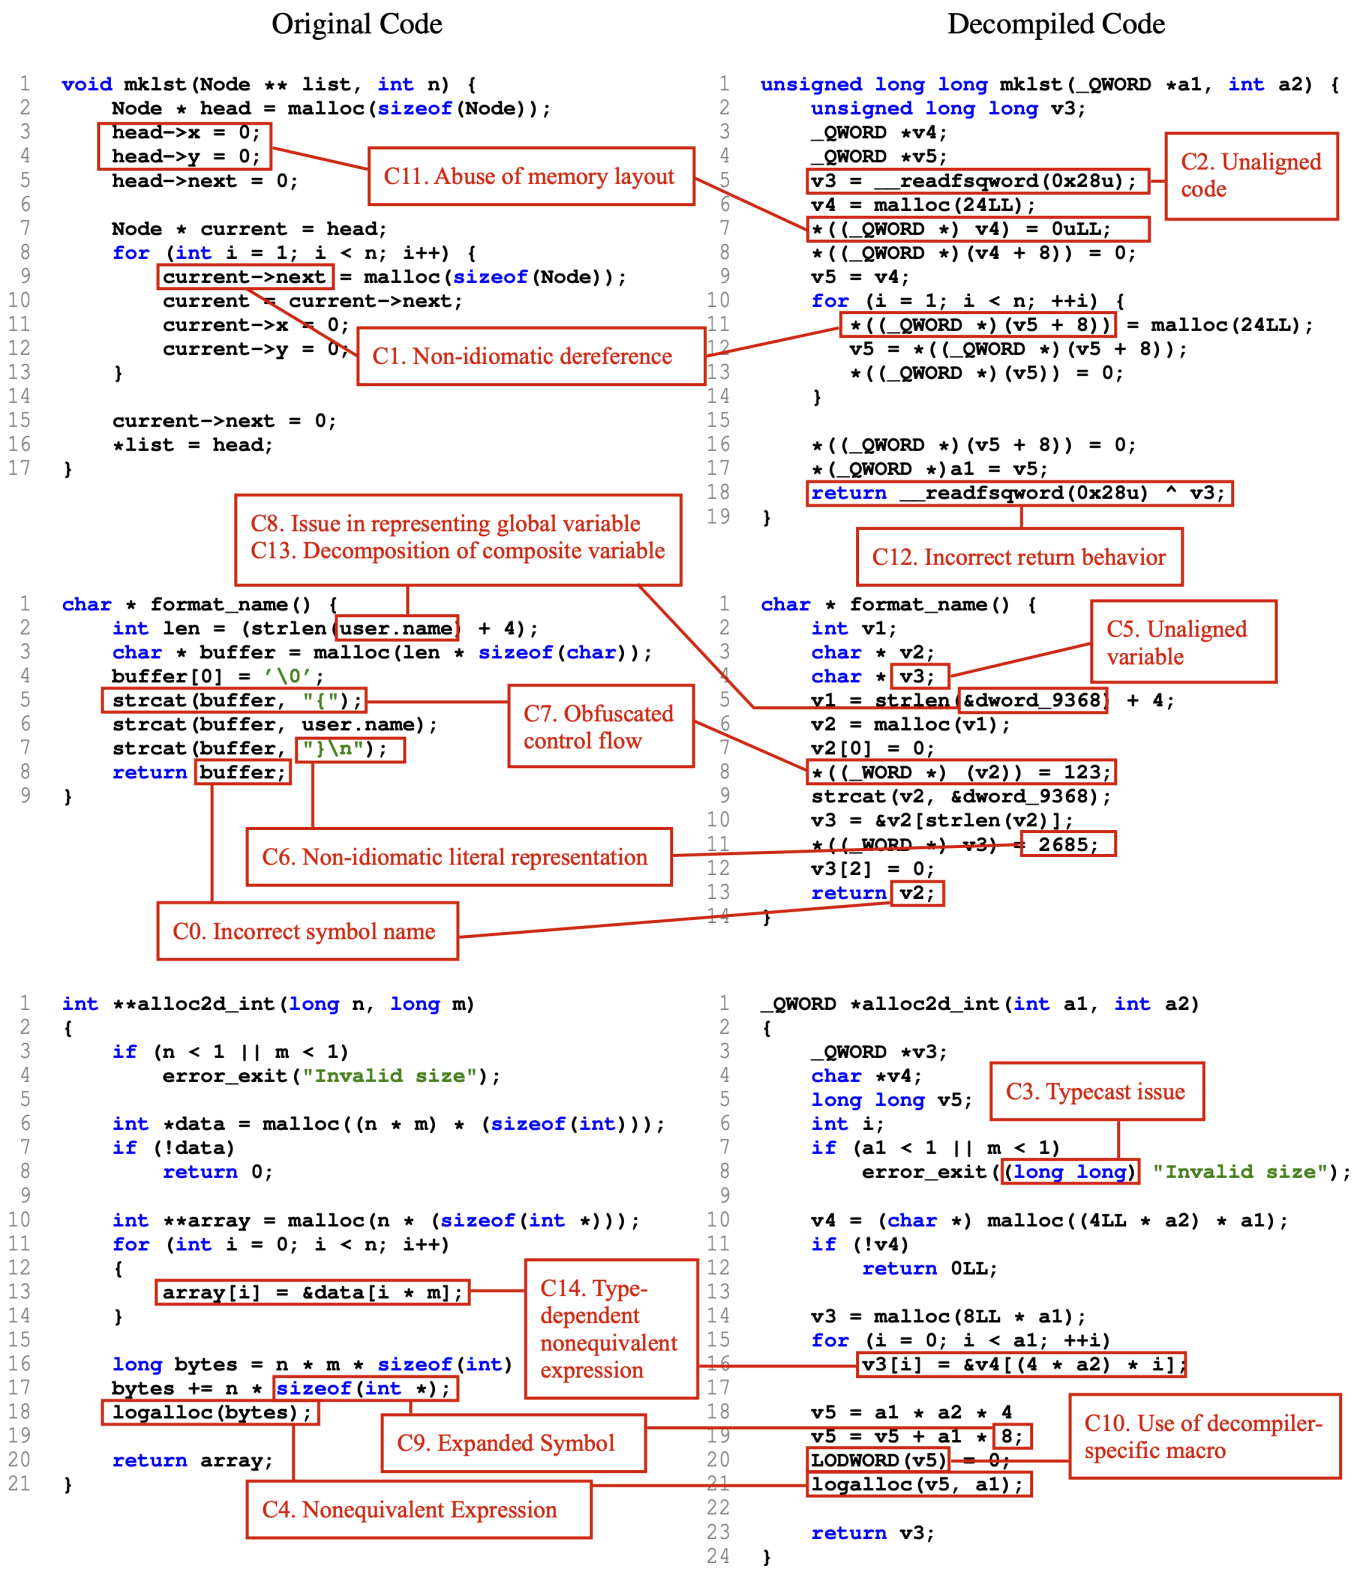

Figure 4: Examples of each of the top-level labels in our codebook. These examples have been artificially constructed by combining code fragments and common patterns from our sample in such a way that all fifteen top-level labels are represented at least once. For legibility, only one instance of each top level label is identified in the diagram, though there are multiple instances of certain issues present across each of the functions. In some cases, a subclass of the top-level label might apply; in this diagram, we identify issues only by their top-level labels for simplicity.

Original Code

```
while (pack->next_object != obj)
{
    pack = pack->next_object;
}
```

Decompiled

```
for (i = a2;
a1 != (*((_QWORD *) (i + 64)));
i = *((_QWORD *) (i + 64)));
```

Figure 5: A decompiled while loop that qualifies as an instance of label C7 (obfuscated control flow). This example also contains instances of C1 (non-idiomatic dereference), which also contribute to making it harder to read.

variable could occur by referencing the name of the global variable, just as occurred in the original source code. However, this was not always the case, especially with composite global variables. For example, Figure 4 illustrates an example of a pattern in our dataset where a global `struct` is broken up into multiple variables. The `.name` component of the struct is represented with a reference to a decompiler-generated global variable seemingly named after a memory location.

C9. Expanded symbol: refers to the situation where a macro or similar construct like `sizeof` is represented by its value rather than by the symbol itself. For example, Figure 4 shows an example of how a `sizeof` expression is replaced with a constant.

C10. Use of decompiler-specific macros: Some decompilers define and use macros in decompiled code. An example of this is the `LODWORD` macro shown in Figure 4 and similar macros used by the Hex-Rays decompiler, which are used in some situations involving type conversion and bitwise operators. As with any feature of decompiled code, these may become less problematic the more a reverse engineer becomes familiar with them, but they represent information a user must know to interpret decompiled code.

C11. Abuse of memory layout: This label refers to the situation where memory is used in a non-idiomatic while being semantically equivalent to the original code. For example, Figure 4 illustrates a situation where two consecutive elements of a struct are each initialized to 0. The decompiled code treats both struct members as a single entity and assigns 0 to the entire construct.

C12. Incorrect return behavior: Sometimes, a decompiled function returns a value while the original function does not or vice versa. In these scenarios, we code C12; there is one sub-label for each of the two situations. Figure 4 shows an instance of C12.a, where a function that is originally `void` has a return value.

C13. Decomposition of a composite variable: When composite variables like `struct`s or arrays are used directly in a function (as opposed to with a pointer), the decompiler may interpret the members of those composite variables as separate variables. Figure 4 illustrates this with a global variable.

C14. Type-dependent nonequivalent expression: This occurs as a by-product of the decompiler choosing an incorrect type. When the decompiler chooses an incorrect type, it may cause other expressions to become incorrect relative to the original code such that changing only the type does not fix the code. In Figure 4, the decompiler interprets what should be an `int` array as a `char` array. Accordingly, to ensure the behavior of the function remains the same, the decompiler uses the expression `(4 * a2) * i` as compared with the original code's `i * m` (where `a2` aligns with `m`). If the type in the decompiled code was corrected to `int *`, the resulting code would be incorrect without further changes.

5 Discussion

Our taxonomy can be used to reason about issues in decompiled code. In particular, we are interested in improving the fidelity of decompiler output. We use our taxonomy to reason about how certain classes of issues can be fixed. Next, we compare the four decompilers used in the study. We use the taxonomy to identify how each decompiler performs. Finally, we discuss how our taxonomy applies to Java.

5.1 Automatically Mitigating Issues

Our taxonomy classifies the types of defects that can be introduced when decompiling code. A natural question is then whether these differences can be automatically corrected. In this section, we analyze how some classes of defects might be automatically mitigated.

Many aspects of decompilation are fundamentally undecidable because multiple distinct source programs can compile to the same executable. Consequently, decompilers rely on approximation and heuristics to make decisions. Traditionally, decompiler researchers have approached the problem of constructing decompilers by creating sophisticated static analysis algorithms that examine a single executable in isolation. We call such approaches *deterministic* because they will always decompile an executable to the same code. More recently, researchers have been experimenting with *probabilistic* approaches such as machine learning [9, 11, 15, 21, 22, 24, 31]. In addition to examining the executable being decompiled, these approaches incorporate knowledge about the distribution of *other* programs.

Probabilistic approaches are attractive because they can leverage information about the distribution of programs to compute an answer that is—on average—most likely to be correct, even if it is not always correct. In some cases, this can allow predictions to be made that would be impossible using a deterministic approach. As an extreme example, a probabilistic approach can predict a variable's name by examining the context in which it is used, even though a vari-

able's name can be changed without affecting the executable form of the program [24]. The downside to probabilistic approaches is that they are inherently more difficult to understand, which can lead reverse engineers to mistrust them; this is a previously-identified problem in AI [41]. In contrast, as a reverse engineer who participated in Votipka et al.'s [36] study of the reverse engineering process said, "[...] Hex-Rays can be wrong [...] but [it] is only wrong in specific ways."

Thus, we prefer deterministic solutions when possible, because they are easier to understand, and thus to trust. In this vein, we differentiate between four different categories of determinism in our analysis:

- Deterministic: A deterministic function can be applied to the original decompiled code to repair the defect.
- Deterministic given types: Some defects are caused by inaccuracy during type recovery. Type prediction itself cannot be solved deterministically because multiple source programs with distinct types can be compiled to identical executables. However, if the decompiler is provided with accurate types—either by the user, or a system such as DIRTY [11]—then the issue can be fixed by a deterministic analysis.
- Deterministic heuristic: *Most* of these defects can be addressed using a deterministic heuristic—a heuristic that only examines the program being decompiled—but not always. The general case requires probabilistic reasoning.
- Probabilistic: These defects cannot be remedied by any function that only leverages information in the executable. Consequently, the best that can be hoped for is making *likely* decisions based on an expected distribution of programs.

In the following discussion, we make references to the relative frequencies of certain labels. We caution that our sample may not be representative of software in general, and that these relative frequencies may differ in other software.

5.1.1 Deterministic

Some types of defects can be repaired by applying a deterministic analysis. However, they are rare. It appears the sophisticated static analysis techniques used by modern decompilers already take advantage of most deterministic opportunities for improving fidelity.

One issue that can be deterministically repaired is C10.a (bitwise operators with decompiler-specific macro). Figure 6 shows an example of a C10.a issue that occurs in Hex-Rays, but not in the other three decompilers. This indicates by example that it is possible to decompile such operations without decompiler-specific macros. Some users of Hex-Rays may find these macros helpful because they help explicitly specify

Original Code

```
1  sreg |= 1 << 7;
```

Decompiled by Hex-Rays

```
1  LOBYTE(result) = sreg | 0x80;
2  sreg = result;
```

Decompiled by Ghidra

```
1  sreg = sreg | 0x80;
```

Figure 6: How an example bitwise operation is decompiled by Hex-Rays and Ghidra compared to the original source code. Wherever we identified code C10 for Hex-Rays, we did not identify it for Ghidra. Label C10 refers to decompiler-specific macros used with bitwise operators; `LOBYTE` here.

what is happening to specific bytes in an expression. However, in general, we do not know if they are more or less preferable to reverse engineers than the original code. In any case, C10 represents a barrier to entry for those unfamiliar with this aspect of the tool.

C6.d is another issue that can be repaired deterministically, and refers to situations where a string literal is replaced by a reference to another location in the binary, e.g. `fz_strlcpy(param_4,&DAT_00100cdf,param_5)` instead of `fz_strlcpy(buf, "CBZ", size)`. In this case, a rule that allows for the recovery of the string is to go to the location provided and replace the reference with the string at that location.

Finally, a subset of C5.a.i (extraneous variable duplicating another variable) issues can be addressed deterministically. This can happen when a duplicate variable:

- copies the value in another variable
- could be replaced with the variable they copied without altering function semantics. (In many cases, duplicate variables are never read from after initialization).

To fix these issues, replace the duplicate variable with the variable from which it takes its value.

Deterministic issues can be fixed such that they match the original code exactly.

5.1.2 Deterministic given types

We say some codes can be fixed by a function that is deterministic when given type information. Many codes fall into this category: C0.b, C1, C3, C8, C11, C13, and C14. Type prediction itself is undecidable in general. However, if some technique can correctly predict the type of the variables involved, then each code in this category can be resolved deterministically. Some decompilers, such as Hex-Rays, already feature an API to re-decompile a function when type information is given to correct these issues; that is, the deterministic piece is already built into these decompilers.

There is existing work on type prediction. Chen et al. [11] develop a probabilistic model, DIRTY, for predicting types in decompiled code. A key limitation of DIRTY, however, is that its prediction for a given variable is based on the memory layout of that variable on the stack and how that variable is used within a single given function. This is problematic in the case of a very common class of variables: pointers, especially pointers to composite types like `struct`s. The memory layout of a pointer variable on the stack is simply a single value representing the memory location of the data.

However, it is still possible to infer the composite types being pointed to based on how these types are accessed; different types may have different access patterns. For example, an array may be more likely to have its members accessed sequentially in a loop, while a struct may be more likely to have unordered accesses to arbitrarily-sized memory offsets. Accesses of different parts of a composite type are, in general, spread out throughout multiple functions. Therefore, it might be necessary to examine all functions in which a given composite data type is used to determine what that type is. We identify general type prediction as a major opportunity to significantly improve the output of decompilation.

Type prediction can also often help with better representing literals in certain situations. For example, the decompiler often represents character literals as small, positive integers (C6.a); when these integers are used in conjunction with `char` variables, it may be reasonable to convert each integer literal to the corresponding character literals (i.e., `65` to `'A'`).

If the type prediction mechanism is correct, these issues can be fixed so they match the original code exactly. However, probabilistic type prediction may make mistakes.

5.1.3 Deterministic heuristic

Most issues in this class can be fixed by applying a deterministic heuristic. However, the heuristic is known to be incorrect in some cases.

Unaligned Variables Unaligned variables (C5)—that is, those that are extra (C5.a) or missing (C5.b) relative to the original code—are examples of unaligned variables. Data can flow between operators in various ways. If the first argument to `bar` is the result of evaluating `foo`, we can represent this dataflow in source code by either inlining the two expressions (as in `bar(foo());`) or by assigning the result of `foo` to a variable and passing this to `bar` (as in `v1 = foo(); bar(v1);`).

In our observation, all four decompilers usually opt for the second approach. This results in many extra variables (C5.a) not present in the original source code, cluttering the code and, in our experience, making it harder to follow.

Of course, sometimes it makes sense to use variables to store intermediate values. When the result of an expression is used more than once, saving the value rather than recomputing it often makes sense or even may be necessary (in the case of functions with side-effects). Variables are often needed when their values are updated in a loop body. And in some cases, breaking a long expression down into smaller sub-expressions in a sensible way can help make those complicated expressions easier to understand. Finally, programmers will occasionally declare extraneous variables on purpose, often for type-related reasons, as occurs in this snippet from our dataset:

```
1  void FreeTextStream(void *ios)
2  {
3    TextStream *io = ios;
4    // other code using io but not ios ...
```

In general, though, for all four decompilers, extra variables greatly outnumbered missing ones, indicating that decompilers generally tend to err too much on the side of using intermediate variables, at least relative to what the authors of the original code had written. In many cases, extraneous variables can be eliminated by applying the following rule: if the variable is assigned to once then subsequently read from once, eliminate the variable and inline the two expressions. In fact, this rule applies to `v3` in Figure 3. It is possible that this may help reduce reverse engineers' mental strain because they have to track fewer variables in the decompiled code.

We empirically validate this heuristic by showing that the vast majority of variables written to and read from once are not present in the original source code. To do this, we use the DIRE dataset [24], a large dataset of decompiled functions wherein generic decompiled variable names are matched with the corresponding variable names in the original source code, if any. We search each function for non-parameter local variables that are written to and read from once. The percentage of these that are decompiler generated (i.e., are lacking a corresponding developer-provided name from the original source code) is 85.9%. In other words, the vast majority of variables that are written to and read a single time are fabrications of the decompiler. Cates et al. [10] evaluate how breaking down expressions into smaller expressions with intermediate variables affects comprehension. They found that breaking down expressions using extra variables impedes comprehension, which also suggests that our inlining heuristic may be reasonable. However, we caution against making strong conclusions due to the study's small number of participants ($n = 6$).

Extraneous Expressions C2.a.i is a common byproduct of C5.a (extra variable in the decompilation), which is discussed in the preceding section. C2.a.i refers to situations where an extraneous expression (i.e., one that does not align with anything in the original source code) is used to initialize an extraneous variable. Identifying extraneous variables cannot be done deterministically but can be done heuristically, as discussed above. If extraneous variables are identified and the extraneous expression has no side effects (which is usually the case), then the whole extraneous initialization statement can be removed.

Incorrect Return Behavior Incorrect return behavior (C12) is another instance of an issue that a heuristic can remedy. We consider two possible cases for incorrect return behavior: C12.a (return value for void function) and C12.b (no return value for non-void function). A deterministic heuristic that often fixes C12.a is to make a decompiled function return `void` if no function that calls it uses its return value. This rule does not work all of the time, however, in the case of functions that do have a return value that just so happens to be unused by all other functions in the program. Interestingly, it appears that Ghidra may follow this rule, while Hex-Rays, retdec and angr seemingly do not. Accordingly, our Ghidra sample has no C12.a labels but falls afoul of C12.b.

Thus, applying this rule incurs a trade-off. We endorse its use, however, because the code to prepare a return value that is never used can be thought of as extraneous from the perspective of the program as a whole. Eliminating it may in fact enhance clarity. Meanwhile, unnecessary extra code for returning values unnecessarily can clutter up decompiled functions, sometimes significantly. Additionally, C12.b also seems to be less common than C12.a, though we caution that this observation may be due to sample size.

We empirically evaluate this rule by measuring how often the return values of functions are used by other functions in the same project (i.e., GitHub repository) across all the projects and functions in the dataset from which we sampled our labeled examples. We perform this study on the original code so our results reflect the ground truth of how developers use return values. For each function in our dataset, we determine whether or not its return value is used in that project by scanning the body of each other function in the project and recording if a call to that function occurs in an expression that uses the function's return value. In addition, we record whether or not the function is void. There are thus four possible classes that a function can fall into:

1. `void` function, return value unused
2. non-`void` function, return value used
3. non-`void` function, return value unused
4. `void` function, return value used.

We count the first and second cases as rule successes, the third case as rule failures, and the fourth as undefined behavior. Undefined behavior was very rare (0.75% of the total). Excluding undefined behavior, our rule is successful 76.1% of the time across the projects in our dataset. To prevent very large projects from dominating the results, this number is calculated by computing the success rate in each project and averaging across projects.

Figure 7 shows the decompiled function from Figure 3 when both of these heuristics are applied. Applying the heuristics increases similarity to the original.

```
1  long long help_object(long long a1, unsigned int a2)
2  {
3    if (!a1)
4      return set_error("help.c", 436LL, 2LL, 0LL);
5
6    return obj_dump_template(a1, a2, get_nestlevel(a2),
         0LL);
7  }
```

Figure 7: The decompiled function from Figure 3 with the heuristics in Section 5.1.3 applied. Applying the heurisitics increases similarity to the original.

5.1.4 Probabilistic

Issues identified as probabilistic cannot be accurately remedied in general, because of the inherent undecidability in decompilation. However, these classes of issues can be improved in practice by techniques such as statistical modeling or machine learning.

Incorrect identifier names (C0) require nondeterminism because the information needed to reconstruct them is partially or completely discarded during compilation.

The label C2 refers to missing or extra code in the decompiled code relative to the original. In general, without access to the original source code, determining what is missing or extra is not possible. There are a few exceptions with C2.a (extra statement), however. As is discussed in Section 5.1.3, extra statements correlating with extraneous variables (C5.a) and extraneous return behavior (C12.a) can be eliminated. C2.b (missing code) issues are usually serious, and are discussed at the end of the section.

The label C7 refers to non-idiomatic control-flow representations. This is a good use case for function-level statistical modeling. In C7, the semantics of the code are presented correctly, but in a confusing manner, as illustrated in Figure 5. Because all of the correct semantics are present, the non-idiomatic code is reasonably predictive of the more idiomatic version.

C9 labeled issues (expanded macros and other symbols) generally require nondeterminism to address. This is especially true for user-defined macros, which in our sample overwhelmingly were used to "name" a constant (like `CRYPT_ERRTYPE_ATTR_ABSENT` representing `3`). These macros can be useful because they communicate information about the meaning of certain constants. Addressing C9 issues may require whole-program level information because it is often not clear from a single instance of a constant the meaning that the author assigned that constant. It may be possible, however, for these usage patterns to be teased from the program as a whole. The same is generally true for other macros, though some may be easier than others. Constant macros from common libraries may be guessable (e.g., `O_RDONLY` for C's `open` function).

C2.b issues occur when functionality is missing, and C4

Table 2: A comparison of the frequency at which selected labels occurred on a sample of 25 functions decompiled by four different decompilers. Note that these results may not generalize due to the relatively small sample size. The full table is given in the supplementary material (see Availability).

Label	Hex-Rays	Ghidra	Retdec	Angr
C1.a.i	20	22	20	0
C1.a.ii	8	4	0	20
C4	9	2	28	52
C4.a.i	2	0	3	21
C5.a.	14	16	24	16
C5.a.i	4	0	4	8
C12.a	11	0	12	5
C12.b	0	1	0	3

represents most types of semantic non-equivalence between two pieces of code. These are particularly difficult issues to handle. With most other issue classes, the semantics of the program as provided by the decompiler are predictive, sometimes in a roundabout way, of the target original code. However, with C2.b and C4, this is not the case. Thus, we would not generally expect a predictive model to be able to correctly fix them in general. It might be possible to infer the correct behavior if a nondeterministic technique is able correctly infer the purpose of the program as a whole. However, these issues might be best addressed by refining the rules decompilers use to generate source code.

Probabilistic techniques in the best case can fix issues so that they match the original code exactly. However, they are also capable of making arbitrary mistakes.

5.2 Comparison of Decompilers

To ensure the generality of our codebook, we randomly sampled 25 functions from the small function test set (Section 3.4) and decompiled them with the Hex-Rays, Ghidra, and retdec, and angr decompilers. We then coded the output from each decompiler using our codebook. We found that our codebook was applicable to all four decompilers, but that each decompiler tended to make different types of mistakes. In this section, we discuss the differences between the decompilers. The relative frequencies of selected issues across decompilers are show in Table 2.

5.2.1 Hex-Rays Decompiler

Hex-Rays is a popular commercial decompiler sold as an add-on to IDA, a popular, interactive disassembly tool. Compared to the original source code, Hex-Rays created many extraneous variables (C5.a). Hex-Rays also struggled with global composite variables, treating them as if they were separate global variables, with names derived from memory offsets (e.g. `dword_9368`) (C8 and C13). Hex-Rays also introduced a return value for many functions that did not have one (C12.a). However, we recorded no instances of C12.b (no return value for non-void functions). As a side effect of its tendency to create extraneous variables to store those extraneous return values and to favor a single return statement at the function's end rather than multiple throughout, Hex-Rays sometimes added many extra lines of code.

5.2.2 Ghidra

Ghidra is an open-source decompiler developed by the National Security Agency. Similar to Hex-Rays, Ghidra introduces many extraneous variables (C5.a). Unlike for Hex-Rays, we observed no instances of C5.a.i (extraneous variable duplicating another variable) for Ghidra. As with Hex-Rays, Ghidra struggled with global variables, though interestingly, not always on the same functions as Hex-Rays. In one case, Ghidra recognized an issue with overlapping symbols at the same address and provided a comment warning about it. As discussed in Section 5.1.3, Ghidra is conservative with return values; we observed no instances of C12.a (return value for void function) and only a single instance of C12.b (no return value for non-void function).

5.2.3 Retdec

Retdec, an open-source "retargetable decompiler", is a decompiler inspired by LLVM's retargetable nature. Like the other decompilers, retdec uses many extraneous variables (C5.a). However, retdec is also the only one of the four decompilers to create extraneous variables that represent individual `struct` members (C5.a). Retdec has many issues representing global variables (C8), and unlike the other decompilers, used generic placeholders instead of global variable names (e.g., `g2`) even when those global names were available from symbols in the binary. Perhaps most concerningly, retdec had many more instances of C4 (nonequivalent expression)—28—than Ghidra (2) or Hex-Rays (9), though fewer than angr (52). Retdec has a tendency to replace some expressions, especially string literals, with the constant 0.

5.2.4 Angr

Angr [35] is an open-source binary analysis framework with many features, including a decompiler. One notable feature of angr, unique among the decompilers we analyzed, is its generic structure suggestions, such as

```
1 typedef struct struct_1 {
2     char padding_0[8];
3     unsigned long long field_8;
4 } struct_1;
```

As expected, angr did not always correctly detect structs; it frequently decompiled structs as arrays, resulting in many instances of C1.a.ii (array access to access struct members).

Interestingly, unlike Hex-Rays and Ghidra, angr has instances of both C12.a (return value for void function) and C12.b (no return value for non-void function). More concerningly, angr frequently adds extra arguments to function calls that are not present in the original source (C4.a.i). Generally, angr's decompiler output is more frequently semantically incorrect than all three other decompilers (52 for angr as compared with 9, 2, and 28 for Hex-Rays, Ghidra, and retdec, respectively).

5.3 Applying the Taxonomy to Java

To determine how well our taxonomy applies to a language other than C, we sampled Java functions from the Defects4J dataset [20] and coded them as described in Section 3.4. We found that Java decompiler output has substantially fewer fidelity issues than C decompiled code. In particular, we only found instances of C3 (typecast issues) and C4 (correctness issues). The latter are mostly subtle, and we believe they are caused by decompiler bugs (rather than fundamental undecidability). For example, in one C4 issue we found, a variable in the decompiled code is declared inside an if-statement and used outside of it. This is semantically illegal in Java. In the original code, the variable is declared directly before the if statement. We believe that the additional information stored in Java bytecode makes the process of decompiling Java code substantially more tractable. We suspect this is true for decompiling other managed languages as well.

In summary, while all fidelity issues we discovered in Java decompilation fit within our taxonomy, the naturally high fidelity of Java decompilation meant that there were very few issues to classify.

6 Threats to Validity

There are several threats to validity resulting from the dataset's composition and construction. In some security applications, binaries may be obfuscated, making them more difficult to reverse engineer. The dataset we drew from did not include any obfuscated binaries. It also consisted largely of C projects from GitHub. It is unlikely that many of them are malware. It is possible that there are different fidelity issues that we did not consider that would be exposed had we performed this research on obfuscated binaries or malware, which may be disproportionately common in security settings.

Additionally, the dataset was constructed by attempting to compile projects found on GitHub. The sample is necessarily biased towards those projects that had recognizable build scripts and further, that built.

Finally, the dataset that we drew from performed a filtering step that removed grammatically invalid examples. Unfortunately, this filtering step filtered out some grammatically valid examples as well. This problem largely affected functions where `struct` type names were declared using the `struct` keyword in the function. Struct variables whose types were declared with `typedef`ed names were unaffected, and thus our data includes many struct-typed variables. It is possible, though unlikely, that this caused a certain type of decompiler issue to be excluded from our sample, though we found no evidence of this during spot-checks.

7 Future Work

Our study identifies nontrivial fidelity issues in decompiled code. It is probable, however, that not all of these issues have the same impact on the difficulty of reverse engineering. A challenge for future work is to determine which issues have the largest impact on reverse engineers' productivity.

Existing program comprehension literature, for the most part, does not cover issues in our taxonomy. This is because to our knowledge all existing program comprehension literature focuses on normal (original) source code. Decompiled code is fundamentally different from normal source and thus the issues identified by existing literature in program comprehension [16, 17, 25] differ from those in our taxonomy.

Our work may also be useful for evaluating decompilers. Our taxonomy is defined in terms of alignment. Determining alignment automatically in general is a hard problem; in our study, this was performed by human experts. However, given a suitable technique for determining alignment, our taxonomy could be used to automatically evaluate decompiler output or neural decompilation methods. In particular, numeric scores related to the frequency of each issue in the taxonomy could be reported. This would allow a detailed and nuanced quantitative measurement of the quality of decompiler output.

8 Conclusion

In this work, we build a taxonomy of fidelity issues in decompiled code. We analyze our taxonomy, identify patterns in our data, and suggest how different classes of defects could be addressed.

Based on our results, we identify several promising future directions for work on improving the output of decompilers. First, techniques with the ability to predict types in general, including the types of pointers, have the ability to help address a large class of issues. Second, decompilers themselves could adopt a collection of rule-based approaches which address some issue classes and minimize the impact of others. Finally, we see the opportunity for nondeterministic techniques, especially scaled to be multi-function or whole-program level, to broadly address many classes of errors including some of the most difficult issues and corner-cases that other techniques do not solve.

Abstract

Decompilers, one of the widely used security tools, transform low-level binary programs back into their high-level source representations, such as C/C++. While state-of-the-art decompilers try to generate more human-readable outputs, for instance, by eliminating `goto` statements in their decompiled code, the correctness of a decompilation process is largely ignored due to the complexity of decompilers, e.g., involving hundreds of heuristic rules. As a result, outputs from decompilers are often not accurate, which affects the effectiveness of downstream security tasks.

In this paper, we propose D-HELIX, a generic decompiler testing framework that can automatically vet the decompilation correctness on the function level. D-HELIX uses RECOMPILER to compile the decompiled code at the functional level. It then uses SYMDIFF to compare the symbolic model of the original binary with the one of the decompiled code, detecting potential errors introduced by the decompilation process. D-HELIX further provides TUNER to help debug the incorrect decompilation via toggling decompilation heuristic rules automatically. We evaluated D-HELIX on Ghidra and angr using 2,004 binaries and object files ending up with 93K decompiled functions in total. D-HELIX detected 4,515 incorrectly decompiled functions, reproduced 8 known bugs, found 17 distinct previously unknown bugs within these two decompilers, and fixed 7 bugs automatically.

1 Introduction

Widely applied in security, decompilation is a reverse engineering procedure that transforms a low-level binary program back to high-level source code representations such as C/C++. For example, Ghidra is such a decompilation tool "developed by NSA's Research Directorate in support of the Cybersecurity mission" [1]. The whole decompilation process can be divided into four stages: disassembly, lifting to Intermediate Representation (IR), higher-level semantics abstraction, and decompiled code generation [11]. Disassembly is the initial process that translates the machine code into assembly code. Then the lifter further converts it into IR (e.g., P-Code [6] or VEX [3]). Based on the IR, the decompiler recovers higher-level semantics (e.g., control flow graphs, variable types, or structures) and finally generates the decompiled code as output. In this paper, we refer *lifter* as the tool that can convert machine code into IR and define *decompiler* as the tool working on IR and finally generating the decompiled code.

Although decompilation techniques are expected to facilitate real-world reverse engineering, many engineers do not trust the output of decompilers. In fact, approximately 69% of reverse engineers (i.e., 11 out of 16) pay less attention to the decompilation output since they think the decompilation process is error-prone and the wrong result will mislead the analysis [50].

The hurdle of impeding security engineers from trusting decompilers, as we observe, is the essential trade-off between code readability and semantic accuracy. During the last two stages of the decompilation, a decompiler has to infer information (e.g., structural or type information) that has been discarded during compilation [60]. To tackle this, modern decompilers involve hundreds of heuristic rules, such as type reconstruction [38] and code structure recovery [12] to compensate for the missing information, and iteratively apply these rules to generate code that is progressively more and more readable. However, as shown in existing work [30], these heuristic rules might be unsound or even incorrect, introducing semantic inaccuracies in the decompiled code. Though security researchers have conducted numerous works [10, 12, 13, 16, 22, 54, 55, 60] to improve decompilers, most of them focus on improving the readability of the output, e.g., introducing heuristics to minimize `goto` statements. Consequently, as we will show later in Table 1, most of the state-of-the-art decompilers neglect the semantic accuracy of decompiled code when devising the heuristic rules. Meanwhile, not surprisingly, current decompilers [4, 5, 9, 29, 48, 51] have no mechanism to test their heuristic rules' soundness and implementation correctness, except basic unit testing. To the best of our knowledge, there is only

[1] https://ghidra-sre.org/

one existing study systematically investigating the correctness of decompilers [30]. However, its methodology has certain limitations, for instance, it fails to detect incorrect structure recovery. Furthermore, it can only identify bugs within the decompiled code, without identifying the root cause of the inaccuracy within decompilers.

In this paper, we propose D-HELIX, *a generic decompiler testing framework that can automatically vet the decompilation correctness.* Compared to the existing study, D-HELIX directly works on the binary code and thus does not require source code, thereby following a more realistic usage of decompilers and facilitating testing with a broader scope. Furthermore, D-HELIX is capable of identifying problematic heuristics within decompilers. Initially, D-HELIX performs a dedicated recompilation procedure to compile the decompiled code at the function level. Afterward, by performing symbolic execution, D-HELIX extracts symbolic models from the original binary and the recompiled decompiled output. These symbolic models are then compared to detect semantic discrepancies between the decompiled code and the original binary. Finally, D-HELIX applies a tuning algorithm to infer which decompiler's heuristic rule could be responsible for the detected decompilation inaccuracy by efficiently exploring the configuration space of the tested decompiler.

We have implemented D-HELIX and applied it to Ghidra [5] and angr [51]. In particular, we used Ghidra and angr to decompile a dataset of 2,004 real-world binaries from Github and obtained 93K decompiled functions in total. D-HELIX detected 4,515 incorrectly decompiled functions, reproduced 8 known bugs, found 17 distinct previously unknown bugs in these two widely used decompilers, and automatically located the root causes of 7 bugs. D-HELIX provides a powerful tool for both decompiler developers and security researchers to detect inaccurate decompilation results and debug decompilation processes.

In summary, our contributions are as follows:

- We design D-HELIX, a fully automatic decompiler testing framework using only binaries as the input, with three components:

  1) RECOMPILER, a best-effort recompiler enabling compilation of decompiled output at the function level.

  2) SYMDIFF, an automatic symbolic model checking tool supporting different symbolic execution engines and enabling the detection of inaccurate decompilation by capturing semantic discrepancies between the original binary code and decompiled outputs.

  3) TUNER, an automatic debugger to find potential culprit heuristic rules that lead to inaccurate decompilation by efficiently and effectively exploring different combinations of the heuristic rules available within a decompiler.

- We fully implement D-HELIX and apply it to Ghidra and angr. Besides reproducing 8 known bugs within these decompilers, D-HELIX found 17 distinct previously unknown bugs, 11 in Ghidra and 6 in angr, revealing intrinsic interactions among different heuristic rules that led to inaccurate decompilation.

We followed the disclosure practices and reported all the found bugs to the affected parties. The source code for D-HELIX is available at: https://github.com/purseclab/D-helix.

Table 1: Systematization of decompilers and their characteristics. SP = Semantic-Preserving, Heu = Heuristics, and OSS = Open Source Software.

Though decompilers are extensively used for security tasks [13, 15, 44, 50, 52–54], many people do not trust the output of decompilers because of the potential inaccuracy introduced during decompilation. To understand the inaccuracies in decompilers, we demonstrate the following observations.

Observation 1: *Decompilers tend to overlook the importance of ensuring the semantic preservation of their decompiled code.* We surveyed 15 state-of-the-art generic decompilers, including both open-source projects and commercial products. As shown in Table 1, we illustrate the systematization of the decompilers from four perspectives, which are semantic-preserving (SP), source lines of code (SLoC), the number of heuristic rules (Heu), and source code availability (OSS). For the semantic-preserving feature of decompilers, we check whether the terminology (e.g., preserving semantic accuracy) is mentioned as a feature in their papers or product descriptions. For open-source decompilers, we get SLoC from the entire codebase of the respective project and count the number of heuristic rules by exploring the projects ourselves.

We observe that most decompilers leave the semantic accuracy out of consideration, while only three decompilers include different semantic-preserving methods to build their decompilers. For instance, Phoenix [12] introduces semantic-preserving iterative refinements, attempting to ensure the control flow structure is correctly recovered. DREAM/DREAM++ [54,55]

provides semantic-preserving transformations focusing on data flow and control flow path recovery, such as `goto` removal, redundant variable removal, semantic-aware variable naming, etc. FoxDec [49] uses formal methods for semantic-preserving decompilation. However, except formally-verified decompilation, all these works focus on introducing semantic-preserving heuristics to address their corresponding task domains, such as `goto` statement elimination. Additionally, for FoxDec, the binaries it supports are constrained by certain assumptions, such as no global variables and no indirect branching. For the remaining decompilers, we observe that their decompiled outputs contain many semantic inaccuracies, e.g., type recovery errors, structure recovery errors, and function pointer type recovery errors. These inaccuracies arise due to the loss of critical information during the compilation process, that is, compilers translate variables and data structure fields to plain registers and memory locations without any structural or type information. Sometimes, decompilers use special symbols to represent the terms they cannot recover. For instance, Ghidra uses `undefined[16]` to represent the type of a 16-bit variable that it cannot recover. However, not every inaccuracy is labeled with special symbols. As we will show later in Section 6, there exists a certain amount of inaccuracies that can hardly be detected without testing.

To conclude, current decompilers define function semantics in different ways and conduct limited examinations of the decompiled code.

Observation 2: *There lacks a generic methodology, which can soundly examine the decompilers.* While existing works [25, 30–32, 34, 40] propose different methodologies to conduct code equivalence examinations, only one of them [30] focuses on the decompiled code. For the rest, as we will further discuss in Section 8, their methodologies are not sound enough to examine the decompiled code, e.g., these methods cannot detect incorrect recovery of function prototypes in the decompiled code. Meanwhile, the existing decompiled code equivalence examination [30] lacks generality and is not sound. Specifically, it uses Equivalence Modulo Inputs (EMI) testing [27] to mutate the original source code and compare it with the corresponding decompiled code under the same set of pre-defined inputs to find semantic inaccuracies. However, this method is not generic, since it cannot report inaccuracies in binaries without source code. For instance, it relies on Csmith [57] to generate the source code, which is devoid of undefined behavior (e.g., no uninitialized variables). Consequently, this approach cannot detect the semantic inaccuracy of decompilers on binaries containing undefined behavior. Furthermore, its methodology is not sound to thoroughly examine decompilers, as it does not support the decompiled code with C struct and union, thereby failing to detect any incorrect structure recovery bug in decompilers.

Observation 3: *It is hard to debug root causes of semantic inaccuracies in decompilers.* Based on our survey, we note that existing decompilers have a non-trivial codebase and employ a large number of heuristics (e.g., converting the `goto` statement to the while loop) to facilitate decompilation. As shown in the LoC and Heu columns of Table 1, decompilers have code base sizes from 12.9K (i.e., DREAM [55]) to 6.8M (i.e., Reko [48]) lines of code and can have as many as 151 heuristic rules (i.e, Ghidra [5]) applied during the decompilation process. One may think that debugging decompilers is similar to debugging compilers because they both apply heuristics/optimization passes to the code. However, in the case of compilers, developers can rely on the fact that compilers should always generate a correct binary when some optimization passes are applied. In our case, however, this assurance does not hold true. Specifically, because decompilation is a process of recovering the IR to the high-level language, decompilers heavily rely on heuristics to infer essential missing information. Therefore, when some heuristic rules are not applied, decompilers do not ensure semantic preservation in their generated code. In fact, when no heuristic rule is applied, decompilers may totally screw up the decompiled code.

Meanwhile, to correctly infer the missing information (e.g., the data type of a variable), decompilers usually look through the context of the whole binary (e.g., the data-flow of that variable) and iteratively apply heuristic rules to each instruction. For instance, Ghidra iteratively applies all heuristic rules to a single instruction before moving to the next one, while angr iteratively applies one heuristic rule at a time but to all instructions. Hence, it is common for decompilers to apply numerous heuristic rules on a single instruction hundreds of times, which yields thousands of distinct intermediate statuses. As a result, to debug a semantic inaccuracy, decompiler developers need to review these intermediate statuses to identify at which point the inaccuracy begins.

Our Approach: We propose our testing framework, which runs symbolic execution testing on the lifted IR level. Compared with previous work, it is more generic. Specifically, since every heuristic-based decompiler generates the decompiled code from the lifted IR, every piece of decompiled code has its corresponding lifted IR code. Therefore, as our testing framework runs symbolic execution testing on the lifted IR level, it allows any real-world binary as the input to test decompilers. Meanwhile, it is more complete compared with previous work. Since we use the lifted IR as the ground truth to compare with the decompiled code, our approach will not report inaccuracies introduced in the disassembling or lifting phase (i.e., lifter). Moreover, to help debug decompilers, we implement a dedicated heuristic rule tuning system on top of the symbolic execution testing approach that we use.

3 Design Challenges

Section 2 motivates the need for a novel decompiler testing framework, which can not only provide a more generic and sound semantic examination of the decompiled code but also automatically debug the root causes of different semantic in-

accuracies. In this section, we will summarize the challenges we need to solve to achieve our goal.

Challenge 1: *Recompilation.* To check the semantics of the decompiled code, existing work [12, 30] recompiles the decompiled code as a whole into a binary. However, as syntactical errors such as undefined global variables are common among the decompiled code [30], decompilers do not guarantee the recompilability of the code they produce. To address these errors, existing work [12, 30] needs the original source code for help. Specifically, they replace the component containing syntactical errors with their corresponding original source code during the recompilation. Nevertheless, many real-world binaries do not come with corresponding source code. Hence, recompiling the entire decompiled code of close-source binaries is challenging.

Observation: While recompiling decompiled code as a whole is usually challenging, an existing study indicates that recompiling at the function level is usually approachable [39], after proper adjustments.

Solution: To make sure one decompiled function that cannot be recompiled does not affect the evaluation of the other functions in the binary, we recompile each function independently. Specifically, we design RECOMPILER, an *iterative automatic recompiler* (details in Section 4.1) to revise and recompile the decompiled code at the function level.

Challenge 2: *Semantic error detection.* There is no universally accepted definition of function semantics in the existing work [12, 30, 49, 54, 55]. For instance, certain definitions consider two functions as equivalent in semantics if they both pass a unit test [12], whereas an alternative criterion checks equivalence in the sum of instrumented global variables [30]. Meanwhile, codes sharing the same function semantics can have syntactical differences in terms of control flows, data flows, and the used instructions. As a result, determining whether two functions are semantically equivalent is non-trivial.

Observation: Symbolic execution provides a sound approach to verify the semantic equivalences. However, it is known to suffer from poor scalability due to path explosions.

Solution: We define the semantic equivalence of two functions as a subset of observation equivalence focusing on their return values. To achieve this, we formally represent the semantics of each function as a symbolic model (refer to Section 4.2). Meanwhile, to examine the semantic equivalence of two functions, we propose *symbolic differentiator* (SYMDIFF), which first abstracts the semantics of each function into a symbolic model through symbolic execution and then employs an SMT solver to verify their equivalence. By focusing on comparing code at the function-level granularity and generating symbolic models from both binary and decompiled code, our symbolic model differentiator allows us to keep the scalability of the symbolic execution, while detecting bugs in decompilers.

Challenge 3: *Semantic errors debugging.* Modern decompilers typically have a complex codebase and employ a large number of heuristic rules. Due to this complexity, as we will later show in Section 6.4, we notice that even for their developers it is hard to trace and fix bugs in decompilers. For instance, as the time of writing, there are still over 850 issues open in Ghidra Github.

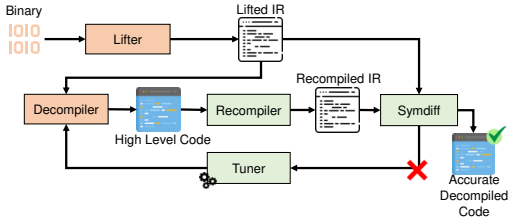

Figure 1: D-HELIX pipeline: D-HELIX extracts symbolic models for *Lifted IR* and *Recompiled IR*, and compares the symbolic models using a constraint solver. For semantically inequivalent models, D-HELIX uses the TUNER to fix the decompiled code.

Observation: Decompilers apply a set of heuristic rules while generating and simplifying the decompiled code. Typically, each heuristic rule has a dedicated goal (e.g., use debug information to help recover the function prototype) and the application of a specific heuristic rule (or a small subset of heuristic rules) is what causes a specific decompilation error, e.g., misordered function arguments due to incorrect debug information analysis.

Solution: To automatically find the root cause of the identified decompilation errors, we propose TUNER, which iteratively toggles decompilers' heuristic rules and compares the newly generated decompiled code with the original binary via the help of SYMDIFF. Since TUNER identifies the problematic heuristic rule(s) fully automatically, it can help decompilers' developers save manual efforts in locating the root cause of a given decompilation error.

4 Design

D-HELIX is a generic decompiler testing framework that can automatically vet the decompilation correctness. Figure 1 shows the pipeline for D-HELIX. D-HELIX takes a binary and a decompiler as its inputs. As a first step, D-HELIX translates the input binary to *Lifted IR* using the *lifter* of the analyzed decompiler. Then, D-HELIX performs the following operations for each function present in the analyzed binary. First, the *Lifted IR* is passed to the tested *decompiler* to generate the decompiled code. Then, RECOMPILER (Section 4.1) compiles the decompiled code to generate *Recompiled IR* with the help of the compiler. Next, D-HELIX checks the semantic equivalence of the *Lifted IR* and the *Recompiled IR* using the SYMDIFF (Section 4.2). If both IRs are equivalent, D-HELIX reports the decompiled code as accurate. Otherwise, D-HELIX uses TUNER to automatically identify the heuristic rule(s) within a decompiler that is(are) responsible for the detected

semantic inaccuracy (Section 4.3).

4.1 RECOMPILER

As mentioned, our approach is based on comparing the IR we obtain by lifting the original binary against the IR we compile from the recompiled decompiled code. To achieve this goal, we need to recompile the decompiled code output by the decompiler. Unfortunately, decompilers often output code that is not even syntactically valid and, for this reason, it cannot be directly recompiled.

A naive approach would just discard any non-recompilable function and consider it as a wrongly decompiled function. However, by doing so, a large amount of functions would be filtered out since decompilers do not guarantee recompilability, and the number of functions we can analyze using our symbolic differentiation approach would be significantly lower, hindering our ability to detect hard-to-find, semantic decompilers' errors.

To recompile as many functions as possible, we use RECOMPILER, a program mutation engine that uses the errors generated by the compiler as feedback to fix syntactic errors from the decompiled code. In particular, RECOMPILER uses an *Iterative Recompilation* process. Firstly, RECOMPILER places the decompiled source code of each function in a separate translation unit (i.e., file). Then, for each translation unit, RECOMPILER modifies the decompiled code iteratively. Specifically, during each iteration, RECOMPILER attempts to compile the code and counters the eventual error logs emitted by the compiler in the following way.

Undefined variables. RECOMPILER first tries to recover their initial values and types from the lifted IR code. Specifically, some decompilers (e.g., Ghidra) store the types and initial values of global variables in the IR code but do not define them in the decompiled code. In this case, RECOMPILER directly defines these variables using the information provided by the lifter. Otherwise, RECOMPILER follows the convention used by the VS compiler (i.e., C4430 [37]) to define these variables with a default type and value, e.g., *int x;*. Note that this approach can potentially introduce semantic inaccuracies into the code, as we will discuss further in Section 6.1.

Syntactic errors. RECOMPILER uses the syntactic error details to update the wrong type to the type expected by the compiler. For instance, RECOMPILER would help remove a pointer, when the compiler reports errors, such as *indirection requires pointer operand*.

RECOMPILER keeps fixing these errors until either the current translation unit is free of errors (i.e., can be recompiled) or a maximum iteration count (by default, 10) is reached. When the maximum iteration count is reached, RECOMPILER terminates and reports the failure to D-HELIX, which will ignore such a function in the later stages of the pipeline. Conversely, for each recompiled translation unit, RECOMPILER generates the corresponding IR for the next stage of D-HELIX pipeline.

4.2 SYMDIFF

To examine function-level semantics of the decompiled code, we design SYMDIFF, a dynamic symbolic execution engine that automatically verifies the semantic equivalence of two input functions. As RECOMPILER generates *Recompiled IR* at the function level, SYMDIFF first uses the function identifiers to map each function from the *Recompiled IR* to the corresponding function in the *Lifted IR* and then test their semantic equivalence using symbolic execution.

As shown in Figure 2, SYMDIFF constitutes two components: Generator and Comparator. Generator constructs a symbolic model of the input IR, whereas Comparator matches two models to determine if they are semantically equivalent. As the design of Generator aims to accommodate various IRs and symbolic engines, this design hides their potential differences.

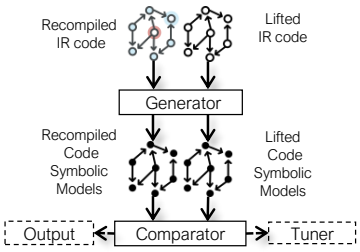

Figure 2: SYMDIFF: Comparator compares symbolic models, generated by Generator.

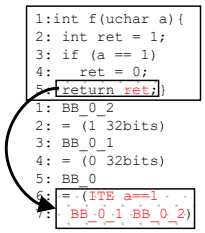

Figure 3: C code and its symbolic model.

4.2.1 Generator

For each input function, Generator generates a symbolic model to represent its function semantics. To do this, we build a symbolic model as a mathematical representation of the modeled function, such that the inputs of the formula are the input arguments of the modeled function and the output of the formula is the return value of the modeled function. For example, Figure 3 shows the symbolic model generated by Generator for a simple C function. The function takes one input argument and returns 0 if the value of the input variable is zero, otherwise, it returns one. Similarly, the corresponding symbolic model takes in one input argument and achieves the same behavior as the C code by using an If-Then-Else (ITE) expression that evaluates to zero if the value of the input variable is zero.

To generate these symbolic expressions, Generator performs symbolic execution on different IRs using different engines, exploring all possible paths leading to the function return instruction(s). More in detail, Generator first considers all functions' arguments as symbolic and then performs symbolic execution on the function through the modified symbolic execution engines. After that, Generator merges symbolic expressions related to different explored paths using appropriate ITE expression, in which the branch conditions (e.g., if condi-

tion) correspond to the path constraints of the merged paths. Finally, as exemplified in Figure 4, Generator creates a symbolic expression representing how the function's return value is computed based on its arguments.

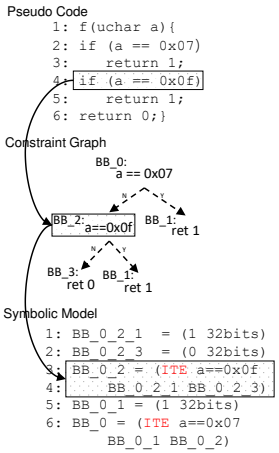

Figure 4: Sample function and its symbolic model.

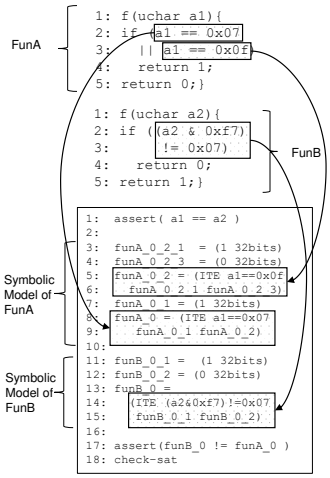

Figure 5: The bottom SMT query is generated by SYMDIFF to compare the two functions at the top.

Noted that to handle scalability problem [26], we designed specific strategies regarding how we handle external function calls, loops, and memory accesses, as we will explain next.

Loop Bounding: To limit the number of paths we need to explore, if a configurable timeout is reached during the symbolic execution of a function (as detailed in Section 5), we limit the number of times we execute each branch instruction. Specifically, if a branch instruction is about to be executed more than 2 times, we stop the symbolic exploration by executing a dummy `return` instruction. This ensures that we execute the loop body of each loop at least once. While this approach can introduce imprecision in our analysis, it is in line with HeapHopper [21] and FIE [18], which show that a single iteration of a loop can yield comparable code coverage to that of a hundred loop iterations.

Memory Model: To achieve a good trade-off between precision and scalability among existing ways to model symbolic memory accesses [42, 46], we follow the approach as outlined below. To universally accommodate the memory layouts and objects, we initialize all the memory to a default value of zero. In the case of a read operation, if a symbolic memory address is used in the read operation, SYMDIFF enumerates all of its possible values, up to a configurable upper bound. On the other hand, when handling a symbolic memory address used in a write operation, SYMDIFF queries an SMT solver to obtain its maximum possible value. To achieve a good trade-off between false positives and high memory usage overhead, for pointer-type input arguments, we make them point to an allocated symbolic space of 256 bytes. For other input arguments, we model their values as 8 symbolic bytes.

External Calls: Since RECOMPILER recompiles each function separately, SYMDIFF executes symbolically on a per-function basis. Hence, when an external function is called, Generator has no source code to directly execute it. A naive solution would be stubbing every function call with a `nop` instruction or with a dummy function returning a constant value. However, in this way, the symbolic execution would lose any information of the relationship between the arguments of a function call and its return value. Hence, SYMDIFF would be unable to detect the decompiler's errors caused by incorrect decompilation of an external function call.

While completely and precisely modeling each possible external function call is unfeasible, as a trade-off, we designed an approximation model in which every encountered external function call is modeled as returning a value that is the sum of the least significant byte of its arguments. Consequently, the resulting symbolic expression, although it does not model precisely the behavior of the external call, still keeps track of the relationship between the arguments of the external call and its return value. Specifically, Generator follows the calling convention recovered by the decompiler to extract the values of the arguments of the called function. Additionally, if an argument is of a pointer type, Generator extracts the content located at the address being pointed to by the pointer, rather than the pointer address itself. Finally, Generator generates the sum of the least significant bytes of the extracted values and signed extends this sum to generate the return value.

4.2.2 Comparator

We use Comparator to test the semantic equivalence of two symbolic models, corresponding to the function from the lifted IR and its recompiled version. To do this, Comparator uses two symbolic models to construct a mathematical formula and queries the SMT solvers whether there exists a path that has different return values, i.e., for the given symbolic models whether there is an input that causes the behavior of the symbolic models to diverge.

Specifically, Comparator first maps the arguments of the two functions from the symbolic models, if such arguments are present. If the mapping fails, Comparator reports semantic inequivalent directly. Otherwise, Comparator sets the corresponding function arguments with the same value, dumps the symbolic models of the two functions, makes an assertion that the return values of the two functions are different, and asks an SMT solver whether the assertion is satisfiable. If the SMT solver finds a path difference in these two symbolic models is satisfiable, Comparator reports two functions are not equivalent. Otherwise, Comparator reports two functions are semantic equivalent. Figure 5 provides an example of this procedure. As shown in line 1 of the SMT query, Comparator first maps two arguments and sets them as equal. After that, it dumps the symbolic models of two functions from line 3 to

line 15. Finally, it asserts return values are not the same and asks the SMT solver to check the satisfiability.

4.3 TUNER

As mentioned in Section 2, decompilers use heuristic rules to recover missing information regarding the original source code. During decompilation, we observed that these rules often lead to semantic inaccuracies. TUNER aims to automatically find a valid combination of rules that achieves semantic equivalence, by iteratively toggling different rules until SYMDIFF reports semantic equivalency.

In general, finding the right combination of rules can be time-consuming because of the large search space. In fact, if a decompiler provides n rules, there are 2^n possible combinations. We call the complete combinations of rules the *Configuration Space* (Γ) of a decompiler. Exhaustively finding the right configuration in the entire configuration space of a decompiler has $\mathcal{O}(2^n)$ complexity. To explore a large configuration space efficiently, we introduce two optimizations:
Binomial Search Optimization: We observe that semantic equivalence often can be achieved by toggling a small number of rules, because some rules are harder to implement correctly than others. Therefore, TUNER divides the configuration space of n rules into smaller subsets and chooses an unordered subset of x rules to toggle from the complete set of rules, i.e., $\binom{n}{x}$. For instance, TUNER creates a subset σ_1 by toggling only one rule at a time, i.e., $\binom{n}{1}$. While exploring the configuration space, TUNER starts from covering subset σ_0 until it reaches σ_n, thus evaluating the complete configuration as: $\bigcup_{i=0}^{n} |\sigma_i| = \Gamma$, where n is the number of rules in a decompiler.
Priority-Based Learning Optimization: During tuning, we observe that some combinations of rules repeatedly rectify semantic inaccuracies. After further research, we find that this phenomenon arises either due to bugs within the implementation of rules or incompatibility among rules. As a result, combinations of rules that have proven effective in the past are more likely to rectify semantic inaccuracies for upcoming input functions. For this reason, TUNER uses a *Pre-Learned Dictionary* to record existing effective combinations of rules, i.e., good configurations. The pre-learned dictionary is a map with configurations as keys and a priority number as a value. The priority of the combination of rules is the number of programs fixed by the combination of rules. While exploring the configuration space, TUNER first tries the configuration from the pre-learned dictionary, with a higher priority.

To apply the *Priority-Based Learning Optimization (PBLO)* and the *Binomial Search Optimization (BSO)*, TUNER uses a work queue to search the configuration space. Specifically, TUNER first inserts the configurations from the pre-learned rule dictionary in this work queue in the priority descending order. Next, it adds configuration to the work queue using the *BSO*. After that, TUNER iteratively consumes this work queue. For each iteration, TUNER dequeues the configuration and uses RECOMPILER and SYMDIFF to verify whether, by using the tested configuration, the decompiled code is semantically equivalent to *Lifted IR*. If the current configuration is able to achieve semantic equivalence between the recompiled and lifted IRs, TUNER increases the priority of the configuration if the current configuration already exists in the pre-learned rule dictionary. Otherwise, the configuration is added to the pre-learned rule map with a priority of one.

5 Implementation

We implement D-HELIX as a modular Python framework. Our implementation is designed to be flexible and allows for the easy integration of existing decompilers through the implementation of abstract interfaces. To better evaluate and understand the bugs found by D-HELIX, we choose to work with two popular and open-source decompilers: angr and Ghidra, by instantiating the abstract interface of these two decompilers. We utilize both decompilers in the headless mode, along with their respective lifters , to lift binary code to IR.
RECOMPILER is implemented as a Python front-end to Clang. RECOMPILER captures errors thrown by Clang and fixes them in the source code. Moreover, for pseudo instructions from different decompilers (e.g., CONCAT from Ghdira) RECOMPILER treats them as special function calls and integrates their implementation with the decompiled code at the function level. Specifically, instead of stubbing these instructions, RECOMPILER first implements them as function calls based on the definitions from the decompiler and then links them as a shared library with the decompiled code.
SYMDIFF is implemented as a Python package to provide an abstract interface to support the plugins of different symbolic engines. Currently, we symbolically execute LLVM IR using prompt [59] and symbolically execute both P-code and Vex IR using angr. Specifically, we run prompt with arguments *–posix-runtime* and *–search=bfs* and angr with arguments *auto_load_libs=False, load_debug_info=True,* and *CFGFast*. To run P-code on angr, the argument *engine=angr.engines.UberEnginePcode* is needed during the initialization.

To compare different IRs, we modify symbolic execution engines (i.e., angr and prompt) to generate function-level symbolic models and compare the generated symbolic models by querying SMT solver. Specifically, to generate the symbolic models for all explored paths, we profile the executions of two instructions (i.e., *return* and *conditional branch*). During the execution of *return* instructions (e.g., *RETURN* in P-code, *Ijk_Ret* in Vex IR, and *ret* in LLVM IR), we dump the constraints of return values following the smtlib format. During the executions of *conditional branch* instructions (e.g., *CBRANCH* in P-code, *Ijk_Boring* in Vex IR, and *br* in LLVM IR), we dump their condition constraints and jump targets using the If-Then-Else (ITE) expression format. Meanwhile, for each engine, we implement the handling for external func-

tion calls, loops, and memory accesses following the design specified in Section 4.2.1. We also implement a configurable timeout for all symbolic execution operations. Specifically, we set the timeout as two minutes by default, considering our server's running speed. Lastly, to compare the symbolic models, SYMDIFF utilizes Z3 [19] as the constraint solver.

TUNER is implemented as a Python package. To accommodate different decompilers, TUNER implements an abstraction layer, a Python class that is used for tuning all the rules within decompilers, to enable the search within the configuration space of any decompiler. The size of the configuration space is dependent on the decompiler as shown in Table 1. For our evaluated decompilers, Ghidra has 151 rules, out of which 124 are private rules, i.e., they are not accessible without modifying the source code. We modified 25 SLoC of Ghidra to expose a public interface for accessing every rule. Similarly, angr provides 41 rules, 11 of which are private. We modified 34 SLoC in angr to expose a public interface for these rules. Regarding the termination strategy, we halt TUNER, when it reaches a 2-week running time limitation, considering our server's running speed. This limit is established on the observations that toggling more than two rules (i.e., $\binom{n}{3}$) in Ghidra during the Binomial Search Optimization stage may introduce additional semantic errors. Meanwhile, we observe that TUNER typically completes toggling two rules within two weeks.

6 Evaluation

We apply D-HELIX to real-world decompilers to investigate the following research questions:

1. How effectively can D-HELIX find semantic inaccuracies between the binary and the decompiled code (Section 6.2)?
2. How effectively can TUNER debug the root causes of the detected semantic inaccuracies between the binary and the decompiled code? (Section 6.3)?

To address these questions, we use Ghidra [5] (version 10.0) and angr [1] (version v9.2.30) as the tested decompilers and evaluate D-HELIX on a 112-core Intel(R) Xeon(R) Gold with 1 TB of physical memory.

Our evaluation program set consists of 2,004 real-world binaries and object files from various open-source projects including binaries used in previous literature [12, 55] (i.e., coreutils and util-linux). Additionally, it contains actual binaries and object files from six Linux-based C language projects, selected from the most popular C language projects on GitHub in November 2021. [2] The selected applications include FFmpeg , skynet, masscan, libuv, curl, and openssl. We compile all projects with GCC (version 11.1.0) and Clang (version 16.0.0) using the default optimization settings specified by the projects. Table 4 in the Appendix shows an overview of our evaluation program set. It includes details on how the binaries were compiled, as well as the complexity of the input binaries at the function level. Using our program set, whose source codes contain 86.93k functions, Ghidra was able to decompile 55.4k functions, whereas angr could decompile 37.6k functions.

[2] We exclude non-Linux binaries from other trending projects, due to the limited support by the used upstream tools.

6.1 Findings

D-HELIX found a total of 25 (17 previously unknown) bugs in the two decompilers (Ghidra and angr). We categorize the bugs based on the semantics incorrectly recovered by the decompilers in 11 categories, listed in Table 2. As shown in the table, both decompilers have difficulties in the recovery of the function prototype, variable type, structure's member, and certain instructions. Moreover, Ghidra struggles with identifying boundaries of no-return functions and recovering some literal values. On the other hand, angr struggles with correctly recovering the CFG of the decompiled program. Note that, as mentioned in Section 4.1, SYMDIFF may detect semantic inaccuracies introduced by the RECOMPILER's approach of assigning default types and values to undefined variables. In Table 2, we categorize these inaccuracies, which arise from the absence of initialization, as missing instructions, i.e., rows #5 and #9.

We have reported all bugs discovered by D-HELIX to the relevant parties. As of this writing, 10 out of 17 previously unknown bugs have been acknowledged and resolved by the developers, while the remaining 7 bugs are still under review.

As shown in Table 2, D-HELIX *found a total of 25 bugs in the two decompilers (Ghidra and angr), and 7 of these bugs have been fixed by the developers.*

6.2 Semantic inaccuracies findings

To completely evaluate the effectiveness of semantic inaccuracies findings, we separate the evaluation into two parts, RECOMPILER and SYMDIFF.

6.2.1 RECOMPILER

To evaluate the effectiveness of RECOMPILER, we compile the decompiled functions in our evaluation program set using RECOMPILER and Clang. As shown in Figure 6, for Ghidra, Clang only compiles 24.9% (13,780) functions, whereas RECOMPILER recompiles 72.4% (40,129) functions. Similarly, for angr, Clang compiles 29.1% (10,953) functions, whereas RECOMPILER compiles 45.0% (16,910) functions. As shown above, RECOMPILER compiles 130.6% more functions than Clang, alleviating the challenges of the recompilation.

#	Category of Bugs	Decompiler	No. of distinct bugs	No. of funcs	Affected program set	Bug example:(GT *vs.* DC)
1	Function prototype recovery	Ghidra	7	63	P_1–P_5,P_7,P_8	`f(int a)` *vs.* `f(void)`
2	Literal value recovery	Ghidra	3	6	P_1,P_7,P_8	`x < 128` *vs.* `x < -128`
3	Type recovery	Ghidra	3	222	P_1–P_4,P_8	`-0x18` *vs.* `&DAT_ffffe8`
4	Structure recovery	Ghidra	1	130	P_1–P_4,P_8	`Struct{...}a; a+0x6` *vs.* `Struct{...}a; a+0x12`
5	Missing instructions	Ghidra	1	18	P_1,P_3,P_4,P_8	`int a = 23;` *vs.* `//a is not declared`
6	Function boundary recovery	Ghidra	1	4	P_3	`{f(); ...}` *vs.* `{f(); return;}`
7	Function prototype recovery	angr	4	132	P_1–P_8	`return a < 26;` *vs.* `return a;`
8	CFG recovery	angr	2	204	P_1–P_8	`while(){if...}` *vs.* `while(){...}`
9	Missing instructions	angr	2	8	P_1–P_3,P_4,P_8	`int a = 23;` *vs.* `//a is not declared`
10	Type recovery	angr	1	47	P_1–P_8	`char v1;` *vs.* `unsigned long long v1;`
11	Structure recovery	angr	1	121	P_1–P_8	`Struct{...}a; a+0x6` *vs.* `Struct{...}a; a+0x12`
Total			25	955	P_1–P_8	

Table 2: Summary of bugs discovered by SYMDIFF. Bugs are categorized into different rows according to their category. The fourth column refers to the number of bugs for each error category. The fifth column represents the number of incorrectly decompiled functions for each error category detected by SYMDIFF. The sixth column shows in which project D-HELIX found these bugs and the number corresponds to the projects listed in Table 4 in the Appendix. The last column shows how decompilers incorrectly decompile the GT (Ground Truth) as the DC (Decompiled Code).

We also analyzed the functions that RECOMPILER failed to compile. As shown in Figure 7, for both decompilers, two most common error types are type recovery and structure recovery. Besides these two error categories, RECOMPILER may fail to recover the function pointer, function prototype, etc. The distribution of errors for both decompilers is roughly the same.

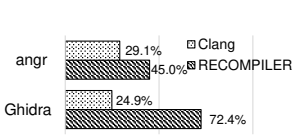

Figure 6: The percentage of functions that can be compiled after using RECOMPILER.

Figure 7: The distribution of different types of errors that cannot be fixed by RECOMPILER.

6.2.2 SYMDIFF

We evaluate the effectiveness of SYMDIFF by utilizing the decompiled functions recompiled by RECOMPILER. Specifically, our evaluation focuses on two metrics: the scalability and the accuracy of SYMDIFF analyses.

Scalability. Our evaluation shows that out of the functions that can be recompiled by RECOMPILER, SYMDIFF can successfully analyze 91.3% (36,628) functions for Ghidra and 93.9% (15,877) functions for angr. To understand the limitations of SYMDIFF, we manually analyze the cases where SYMDIFF fails. Figure 8 summarizes the errors thrown by SYMDIFF. The errors can be categorized into three categories, (1) error from the underlying tools, such as angr, prompt, etc., (2) timeout in the constraint solver due to the complexity of the collected constraints, and (3) unsupported instruction by

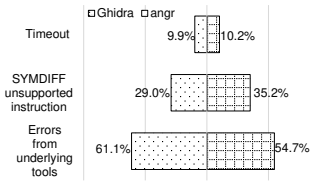

Figure 8: The percentage of decompiled functions that are not fully analyzed by SYMDIFF due to the listed errors.

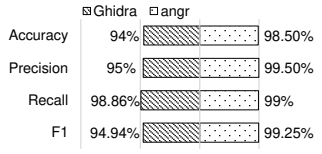

Figure 9: The accuracy, precision, recall, and F1 score of SYMDIFF on the tested decompilers.

SYMDIFF, such as floating point instruction. For the programs decompiled by Ghidra, 55% of the errors were caused by the tools used by our analysis such as angr, prompt, etc. Similarly, for angr, 61% of the errors are related to underlying tools. 29% of the errors are caused by unsupported instructions and 10% of failures are caused by constraint solver timeout.

Accuracy. To evaluate the accuracy of SYMDIFF, we calculate the false positives and false negatives generated by D-HELIX via manually comparing two symbolic models [3]. Since this evaluation requires extensive manual work, for each decompiler, we randomly sample a subset of 200 functions, 100 for examining false positives and 100 for examining false negatives. Figure 9 shows our evaluation result of SYMDIFF on Ghidra and angr, in the field of accuracy, precision, recall, and F1 score.

To understand the limitations of SYMDIFF, we investigate the root cause of false positives and false negatives. Based

[3] Ideally, we should manually examine the differences between IRs, which, however, requires significant human efforts. Hence, we compare the differences at the source code level. And if we observe an inaccuracy in the decompiled code that is not shown in its symbolic model, we claim a false negative.

#	Category	No. bugs	Related Rules	No. funcs	Root Cause
1	Incorrect function prototype recovery	3	DWARF	26	✓
2	Incorrect literal value recovery	1	RuleSubvarSext & RuleIntLessEqual	1	✓
3	Incorrect type recovery	2	Apply Data Archives	33	✓
			X86 Constant Reference Analyze	1	UR
4	Incorrect function prototype recovery	1	Decompiler Parameter ID	11	✓
Total		7		72	

Table 3: Summary of bugs in Ghidra that can be fixed by the TUNER. The last column shows whether the problematic rule found by TUNER is the root cause of this bug. UR illustrates that the bug is still under review.

on our findings, the false positives are all caused by the accuracy trade-offs employed by SYMDIFF to scale symbolic execution, as mentioned in Section 4.2.1. For instance, as shown in Figure 11 in the Appendix, the concretization strategy (e.g., using `malloc` to allocate memory for every symbolized pointer) causes the address of the symbolic pointers between the lifted and high-level source symbolic models varies and generates false positives. The false negatives were all caused by SYMDIFF's dependence on the function prototype recovered by the decompiler. Since the decompiler may fail to recover the correct function's prototype, as shown in Figure 12 in the Appendix, the generated symbolic models may have incorrect external call comparisons.

Hence, D-HELIX *works on the majority of the re-compiled functions (around 92% average of Ghidra and angr) and achieves high F1 scores (around 97% average of Ghidra and angr) in accuracy evaluation, overcoming the challenges of the formalization and semantic inaccuracy detection.*

6.3 Semantic inaccuracy debugging

To completely evaluate semantic inaccuracies debugging of D-HELIX, we separate the evaluation into two aspects, effectiveness (i.e, if TUNER can generate accurate decompiled code for the functions that are reported as inaccurately decompiled by SYMDIFF) and efficiency (i.e, the time required for tuning).

Effectiveness. We use the TUNER to analyze a set of inaccurately decompiled functions reported by SYMDIFF. Since TUNER depends on the heuristic rules provided by the decompiler, we evaluate TUNER for each decompiler separately.

Ghidra. For our program set, SYMDIFF identified 443 semantic inequivalent functions decompiled by Ghidra.

As shown in Table 3, out of these 443 functions, TUNER automatically fixed 16.3% (72) functions. Meanwhile, we identify 7 distinct bugs from these 72 functions. By observing how Ghidra developers fixed the reported bugs, we verified that TUNER correctly identified the root cause (i.e., bugs within the problematic rule) of 6 bugs, accounting for 98.4% (71) of the functions fixed by TUNER. For instance, in the first example of *Incorrect type recovery* (#3), Ghidra maintains a dictionary mapping the function names of well-known libraries (e.g., libcrypto) to their function prototype for faster decompilation. However, the function prototype information could be outdated, resulting in inaccuracies. TUNER fixes this bug by forcing Ghidra to avoid applying this rule (*Apply Data Archives*). For the rest cases that can be fixed by TUNER, we will further explore them in Section 6.4. For the second example of *Incorrect type recovery* (#3)) in Table 3, it is still under review by Ghidra developers as of this writing.

For the remaining 83.7% (371) functions out of 443 semantic inaccuracies, that TUNER could not fix, we manually investigated them. Based on our findings, TUNER fails to fix the inaccuracy if it is triggered by implementation bugs not in the rule but elsewhere, or if toggling all rules implemented by the decompilers is unable to fix the issue. For instance, one of the literal value recovery bugs was triggered by a bug in the code generation system of Ghidra, and hence TUNER was unable to fix it. Similarly, for one of the type recovery issues in Ghidra, TUNER was unable to generate the correct decompiled code, even after trying all permutations of rules related to type recovery. However, for these implementation bugs in Ghidra, TUNER can still help by, for example, ruling out some rule conjunctures, This will be further discussed in the last case of Section 6.4.

angr. For our program set, SYMDIFF identified 4,071 semantic inequivalent functions decompiled by angr. However, TUNER was unable to fix any semantic inequivalence for angr by tuning existing rules. We randomly sample 500 functions and conduct further analysis on them. We found that 30.2% functions have no instruction but a function prototype only (e.g., *int f(){}*), and the inaccuracies in the remaining 69.8% were caused by implementation bugs in angr. For instance, we found that, in angr, the decompilation handler of the `SETcc` instructions was not implemented. However, TUNER can still help, and we will demonstrate how TUNER helps in the second last case of Section 6.4.

D-HELIX *automatically fixes 16.3% detected inaccuracies and successfully identifies the problematic rule for 98% of these inaccuracies. Moreover, for the inaccuracies that cannot be automatically resolved,* TUNER *can still greatly aid developers in tracing their root causes.*

Efficiency. To evaluate the debugging efficiency of semantic inaccuracies, we show how the *Priority-Based Learning Optimization (PBLO)* boosts the efficiency of TUNER by presenting the time reduction achieved through its integration. Since tuning a function consumes considerable computing resources and may easily exceed the 2-week time limit, we select 5 different functions within 5 binaries, which contain the most inaccurate functions reported by SYMDIFF, to demonstrate this comparison. We use TUNER to fix the inaccuracy of these functions and show the time to fix them with and without the *PBLO*. As shown in Figure 10, the dashed bar represents the

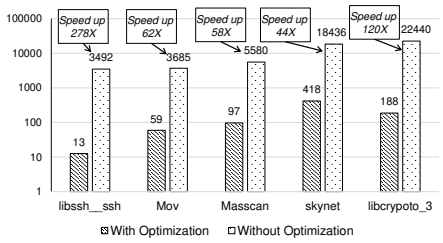

Figure 10: Time consumption in minutes with and without *Priority-Based Learning Optimization (PBLO)*, with annotations indicating the speedup achieved after applying *PBLO*. The y-axis is logarithmically scaled.

```
1://Original code                    1://Decompiled code
2:char temp3;                        2:int iVar1;
3:temp3 = getchar();                 3:iVar1 = getchar();
4:if (temp3 < 128){                  4:if ((char)iVar1<-0x80){
```

Listing 1: Sample code showing 128 incorrectly being decompiled as -128 (-0x80).

time used by TUNER to fix it using the *PBLO*, whereas the dotted bar represents the time used without the *PBLO*. Specifically, in resolving the function in the binary *libcrypoto_3*, *PBLO* accelerates TUNER by 120 times, resulting in a saving of approximately 15 days.

With the help of PBLO, D-HELIX *achieves notable time savings in resolving inaccuracies compared to scenarios without the optimization's assistance.*

6.4 Case studies

In this section, we describe a few interesting case studies highlighting different decompiler bugs discovered by D-HELIX.

6.4.1 Incorrect Literal Value Recovery

Sample Code: Listing 1 provides an example of this semantic inaccuracy that occurred according to D-HELIX. The original code(on the left) checks whether the output received from the `getchar` function is less than 128 (line 4). However, the decompiled code checks if the output from `getchar` is less than -128. As shown in Table 3 case 2, TUNER reveals that this inaccuracy is caused by the application of two specific rules in Ghidra, *RuleIntLessEqual* and *RuleSubvarSext*, and was able to fix this issue by disabling any of them.

Related rule explanation: Internally, Ghidra uses *RuleIntLessEqual* to convert all signed less-than-or-equal-to comparisons with one constant literal operand, e.g. $c <= V$, to a signed less-than comparisons by decrementing the constant literal by one, e.g., $c - 1 < V$. As the value of the constant involved in this step is changed (e.g., c to $c-1$) Ghidra uses another rule, *RuleSubvarSext*, to reduce the width of this constant's representation, if possible (e.g., reduce the width of constant $c-1$ from 32-bit to 8-bit if the value of $c-1$ can fit in an 8-bit sign integer).

Root cause explanation: Upon investigation, we found that the semantic inaccuracy was caused by the following events: ❶ The lifter generates the instruction `128 (0x80) <= iVar1`. ❷ Ghidra applies the rule *RuleIntLessEqual*, which converts `128(0x80) <= iVar1` to `127(0x7f) < iVar1`. ❸ This transformation triggers *RuleSubvarSext*, which changes the width of the constant literal from 32-bit to 8-bit losing signedness information. ❹ Ghidra's readability optimization pass (*ActionPreferComplement*) optimizes the cfg of this `if` branch and reverses the condition from `127(0x7f) < iVar1` to `iVar1 < 128(0x80)`. However, in doing so, the width of the constant literal is not extended from 8 bits back to 32 bits, resulting in a signed char compared to a value -0x80.

```
1:// Original code                  1:// Decompiled code
2:static int                        2:int decode_text_chunk
3: decode_text_chunk                3:  (void){
4: (PNGDecContext *s,
5:  GetByteContext *gb,
6:   int compressed){
```

Listing 2: Sample code shows the decompiled code does not generate any input arguments.

6.4.2 Incorrect Function Prototype Recovery

During our evaluation, we found 194 incorrect function prototype recovery bugs, with 62 of them found in Ghidra and 132 in angr, as listed in Table 2.

Depending on the project, TUNER can fix 47 semantic inequivalence related to three different rules: Debugging With Attributed Record Formats (*DWARF*), Decompiler Parameter ID, and Custom rule. Since the root causes of these inaccurate decompilations are different, we explain them separately as follows.

Debugging With Attributed Record Formats(DWARF):

Sample Code: In Listing 2, the decompiled source code of the function `decode_text_chunk` has the wrong input arguments.

Related rule explanation: Internally, Ghidra uses debug information, stored in the binary in the *DWARF* format, from binary to help recover the function prototype of the decompiled function. However, during the building of the binary, compilers can introduce bugs into the debug information, as shown by previous research [20, 28]. Hence, by disabling the rule *DWARF*, Ghidra will not use the debug information from the binary during decompilation. Disabling this rule allowed TUNER to successfully fix three types of function prototype inaccuracies, as shown in Table 3 case 1, fixing a total of 26 inaccuracies in Ghidra.

Root cause explanation: For these semantic inaccuracies that can be fixed by disabling the rule *DWARF*, our investigation discovered three distinct root causes, outlined as follows:

1) During the compilation of some binaries, compilers erroneously record the debugging information for one function as two distinct debug entities, each providing conflicting details about the function's arguments, e.g., different argument orders. Consequently, when decompiling such a binary, Ghidra's parser in rule *DWARF* struggles to resolve this conflict, leading to the generation of a decompiled function with incorrectly ordered function arguments.

2) For functions with the same name with different arguments (i.e., function overloading), compilers store multiple entities in *DWARF* sections. However, Ghidra may fail to match the correct entity for such a function. Consequently, Ghidra suspends the analysis of this function, which results in its decompiled function lacking arguments, i.e., `void`.

3) The third case arises when one of a function's input arguments is a structure, and this structure is passed from the callee to the caller using multiple registers. In such cases, there could be a mismatch between the number of registers used to pass a function's arguments and the number of function's arguments encoded in the *DWARF* debugging information. Consequently, when Ghidra decompiles this function, the structure will not be decompiled as an input argument but as a list of local variables.

Decompiler Parameter ID:

Sample Code: The decompiled source code has the incorrect function return type, e.g.,`long wvenc_wv_write` is incorrectly decompiled as `int wvenc_wv_write`.

Related rule explanation: In Ghidra, this rule will trigger an analysis that explores the call tree, a tree reduction of the call graph constructed by every function call, to determine the function prototype of the called function in a program. However, Ghidra disables this rule by default. Hence, TUNER automatically enables this analysis and effectively fixes the function prototypes of 11 semantic inaccuracies.

Root cause explanation: Upon investigation, we found Ghidra disables this rule by default since the analysis initiated by it requires a significant amount of time. For instance, during the decompilation of our program set, enabling the rule *Decompiler Parameter ID* results in an average increase of approximately threefold compared to when the rule is disabled.

Custom Rule:

Sample Code: The decompiled source code has the incorrect function return type.

Related rule explanation: In angr, as shown in Section 6.3, TUNER didn't achieve automatic fixes for any inaccuracies by toggling existing rules. Consequently, we developed *Custom rule* to ensure that the function return type matches the return value type. Specifically, we first identify the last return variable in a function and determine whether it is cast to a different type. If so, we set the function return type to the type specified in the cast. If not, we set the function return type to the type of the return variable as declared. As a result, TUNER was able to automatically fix 10 inaccuracies by applying *Custom rule*.

Root cause explanation: Further investigation of the 500 inaccuracies revealed that 121 of the inaccuracies were triggered due to incorrect function return type in the decompiled code. In the remaining 111 cases, where TUNER could not offer a resolution, the underlying problem was traced back to angr's inability to accurately recover the type of the return variable.

```
1:// Original code                  1:// Decompiled code
2:const char *                      2:long argmatch_to_argument(
3:argmatch_to_argument (            3: ...
4: ...                              4: while (true){
5: for (; arglist[i];)              5:  if (*(arglist[i]) != 0){
6:  if (!memcmp (...))              6:   v4 = memcmp(...);
7:   return arglist[i];             7:   return arglist[i];
8: return NULL;                     8:   return 0;
                                    9:  }
                                    10:}
```

Listing 3: Sample code showing how the CFG recovery of a if statement inside for loops is incorrect.

6.4.3 Incorrect CFG Recovery

Sample Code: As shown in Listing 3, the function `argmatch_to_argument` is decompiled with incorrect control flow semantics. Specifically, the check for the return value of the `memcmp` function call at line 6 in the original code (on the left) is not recovered in the decompiled code, resulting in dead code at line 8.

Related rule explanation: Upon reporting this issue, angr developers proposed disabling the rule *EagerReturnsSimplifier* to fix the inaccuracy. In angr, to improve the readability of the code, the rule *EagerReturnsSimplifier* adds additional return statements to the decompiled code, if the number of the "in edges" for the return node (i.e., in-degree of the return site) is less than a specified threshold.

Root cause explanation: Upon further investigation, we discovered that the inaccurate decompilation is caused by a bug in `SequenceWalker`, one of the core libraries used to traverse graphs by angr. Specifically, for each decompiled function, angr constructs a corresponding abstract syntax tree (AST). When angr modifies the CFG (e.g., applies *EagerReturnsSimplifier*), angr calls `SequenceWalker` to traverse the graph and modify nodes, e.g., insert additional return statements on the AST. However, a bug within the `SequenceWalker` causes the incorrect insertion of the node (e.g., return statement) into the AST. Consequently, the parent node (e.g., for loop node) fails to correctly link with the inserted node (e.g., return statement node) on the AST, which causes the return statement at line 8 in Listing 3 being decompiled as dead code.

```
1:// Original code              1:// Decompiled code
2:bool is_fatal(uint_8 code)    2:bool is_fatal(uint_8 code)
3: ...                          3: ...
4: if((1LL << (code & 0x3f)     4: if((1 << (code & 0x3f)
5:  & 0x1000000000000U)!= 0)    5:  & 0x1000000000000U)!= 0)
6:  ...                         6:  ...
7:  if(code < 0xff)             7:  if(code < -1)
```

Listing 4: Sample code shows the decompiled code does not generate correct constants.

6.4.4 Incorrect Constant Recovery

Sample Code: Listing 4 shows two incorrect constant recoveries in the decompiled code. Specifically, in line 4, the 64-bit constant (i.e., `1LL`) in the original code (on the left) is incorrectly decompiled as an `int` constant, i.e., `1`. Consequently, when `code` is `48`, the condition in the original code is true whereas the condition in the decompiled code is false, since the shift operation at line 4 of the decompiled code will be an undefined behavior. Moreover, in line 7, `0xff` in the original code is incorrectly decompiled as `-1`. Since the constant `-1` is treated as `int` type in C99 standard, as a result, the condition in line 7 of the decompiled code will always be false.

Root cause explanation: In Ghidra, constants are treated similarly to global variables, which means rules will be applied to infer their types (both their signedness and their sizes). However, since TUNER reports that no rule is related to these bugs, we infer the type information of these constants has been correctly recovered after the third stage of decompilation, i.e., higher-level semantic abstraction. Hence, we locate the varnodes that store the above two constants and find that their types have been correctly recovered by Ghidra. Since these two constants are correctly handled before the code generation, we, therefore, straightforwardly examine the code generation system of Ghidra and find the constant printing is not appropriately handled. Specifically, Ghidra cannot correctly print some 1-byte constants with edge values (e.g., 0x7f and 0xff) and constants with integer suffixes. We reported this issue within the code generation system to the Ghidra team. As of this writing, these issues have been resolved and included in Ghidra's 10.2 version release by the Ghidra team.

Takeaway: As we can see in the first two cases, D-HELIX can automatically identify the root causes of decompiler bugs and generate accurate decompiled code. Moreover, as shown in the last two cases, even when it's difficult to identify the exact root causes, TUNER proves valuable for decompiler developers during the debugging process, e.g., helps developers rule out some rule conjunctures. Hence, D-HELIX greatly simplifies the work for decompiler developers, saving them a significant amount of time.

7 Discussion and Limitation

Large binaries. As mentioned in Section 6, due to performance constraints, we decided to remove binaries larger than 30 MiB from our program set. In fact, experimentally, we have found that binaries larger than this size require multiple days to be fully analyzed. To this end, we plan to add optimizations such as constraint strength reduction, constraint independence, and constraint caching [14], to alleviate the runtime of SYMDIFF and D-HELIX in general.

Decompiler syntactic quirks. Currently, RECOMPILER can only tackle compilation issues in standard C code as mentioned in Section 6.2. However, some decompilers have their own syntactical quirks to emit code when their decompilation analyses cannot converge. For instance, when Ghidra cannot correctly resolve indirect addresses, it uses the notion of partially resolved address, as shown in this expression: "$var1$._x_y_ = $var2$". This expression means that only y bytes starting with offset x in $var1$ should become equal to $var2$. Currently, we only fix this syntax when $var1$ is an array. We plan to add support for such decompiler-specific syntactic quirks to increase the recompilation rate in future work.

Floating point operations. Currently, SYMDIFF lacks the support for parsing constraints related to floating point operations. However, during our evaluation, we observed that both Ghidra and angr struggle with recognizing floating point operations. Hence, this seems a promising avenue to find semantic bugs in decompilers. We will tackle this problem in our future work.

Memory model in SYMDIFF. D-HELIX currently does not model global variables and considers them as constant values (zero, in case they are not initialized). Additionally, although D-HELIX tries to make the memory model consistent between different symbolic execution engines, there are still some inconsistencies uncovered. For example, in angr, the value of `**param_1` would be set to zero while in prompt it would be set to a symbolic symbol such as `i8`. In future work, we will explore more accurate and consistent memory models.

Supporting a new decompiler. To evaluate a new decompiler with an IR that is not supported by the existing symbolic engine, such as FoxDec [49], D-HELIX requires extra engineering efforts to modify the symbolic execution engine to support a new IR. Specifically, this adaptation involves two steps. Firstly, the existing symbolic execution engine (e.g., angr) must accurately partition the new IR code (e.g., P-code code segment) into basic blocks, following the basic block convention of the supported IR (e.g., Vex IRSB). After that, the existing symbolic execution engine needs to properly handle each new IR instruction within each basic block by translating the new IRs to the supported IRs, thus enabling the use of existing handlers for the supported IRs on the new instructions, e.g., angr translates *cbranch* as *Ijk_Boring* to handle the conditional branch instruction. Overall, we estimate that supporting a new IR on an existing symbolic execution engine (e.g., angr) would require at least 40 days since it took angr

developers 41 days to support P-code [2].

8 Related Work

Existing work recompiles the incomplete C code using different techniques, such as unification-based heuristics [35, 36] and Large Language Models (LLMs) [23]. PsycheC [35, 36] uses unification-based heuristics to generate a well-typed program from an incomplete code. To achieve this, it deduces the missing types of terms by considering their context within the program's abstract syntax tree. However, this approach relies on the data-flow information within the incomplete code. Consequently, for variables in the decompiled code that remain undefined due to insufficient information, this method cannot provide a solution. Additionally, recent research [23] has begun to employ LLMs for the recompilation process. However, as its guiding criteria, i.e., reward function, relies solely on compiler error feedback and code similarity, this approach does not provide a guarantee of semantic preservation in its generated code. Hence, in D-HELIX, we design our own RECOMPILER to improve the recompilation rate, while maintaining semantic preservation as much as possible.

Using symbolic execution for equivalence checking has been explored in other domains [25, 31, 32, 40]. Alive [32] and Alive2 [31] use SMT to conduct code equivalence checks for LLVM IR, focusing on the bugs in LLVM optimizations when handling undefined behaviors. For each function, they encode the input arguments with three types: `undef`, `poison`, or `well-defined`, and determine whether the return value types from the optimized code and the source code are consistent. Since other function aspects (e.g., function prototypes, variable types, and constants) are not considered, their approach cannot detect common decompiler errors, such as the incorrect recovery of function prototypes detected by D-HELIX. MeanDiff [25], a testing tool for binary lifters, uses the symbolic formula to check the semantic equivalence between different IR representations obtained from a single binary instruction. As such, this technique is specifically designed to handle individual binary instruction rather than an entire function. Overall, D-HELIX brings symbolic differentiation into decompilers for the first time, and uses it to vet the whole decompilation process for semantic bugs.

A few research tunes optimizations in compilers for different purposes, such as binary diffing [45, 47] and problematic optimization identification [56]. For instance, Cornucopia [47] generates binaries by iteratively learning from the mutation of compiler optimizations. BinTuner [45] searches near-optimal optimization sequences to generate binaries that maximize the code differences. ODFL [56] differentiates finer-grained optimization to pinpoint problematic optimizations in compilers. However, since the purposes of optimizations in compilers and decompilers differ fundamentally, these approaches do not work properly for decompilers. Hence, in D-HELIX, we build our own TUNER to accurately and efficiently identify the problematic heuristic.

Equivalence checking [17, 33, 43, 58] at the source code level has been explored for different domains. DiffKemp [33] first applies semantics-preserving code transformations between different code patterns for refactoring, then maps variables between the source code and the refactored code, and finally checks the semantic differences between different versions of large-scale C projects by examining the memory states. Churchill et al. [17] first use the program alignment automaton to predict the behaviors of programs, then follow the prediction to align the compared source code, and finally verify the equivalence between different optimized binaries through the memory states. However, these two tools rely on source code availability. Hence, they could not be directly applied to IR code. UC-KLEE [43] automatically synthesizes inputs and runs symbolic execution on the LLVM IR to verify code equivalence between different implementations of the standardized interface with lazy initialization. Similarly, SEC [58] runs symbolic execution on Register Transfer Level (RTL) IRs and compares the terminal states between binaries with different optimizations. Nevertheless, both UC-KLEE and SEC operate on the same IRs, while D-HELIX faces the challenge of comparing different IRs.

9 Conclusion

In this paper, we design D-HELIX, a generic decompiler testing framework that can automatically vet the decompilation correctness. We have fully implemented D-HELIX and applied it to Ghidra and angr. D-HELIX managed to find 17 previously unknown decompilation bugs in Ghidra and angr and helped fix 7 of them automatically.

Table 4: Overview of our program set. The first eight columns show the info of the program set at the binary level, e.g., the number of binaries in each project [4] and how are they compiled. The rest columns show the complexity of the program set at the function level (e.g., the percentage of functions) that contains multiple return statements, pointer variables, or structure variables.

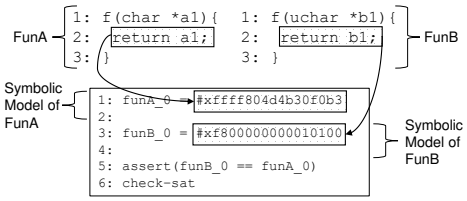

Figure 11: Sample code of a false positive of SYMDIFF.

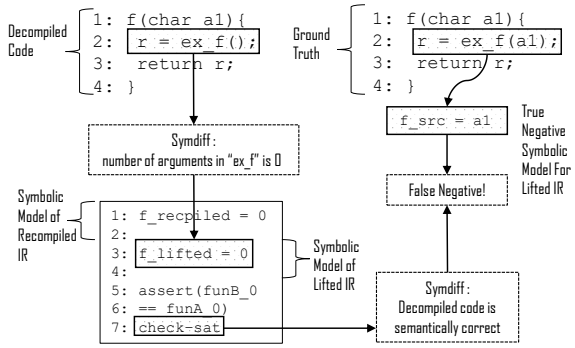

Figure 12: Sample Code of a false negative of SYMDIFF.

A Description of Program Set

Table 4 shows an overview of our program set. Specifically, `Archt.` refers to the architecture of the binary, `Comp. Optim.` refers to the compiler optimization levels of the binary, `No. of bins&objs` refers to the number of binaries and object files in this project, `Avg. size` refers to the average size of binary and object files, and `Pct. of funcs access structure variable` refers to the percentage of functions in this project that contain structure variables. Note that, since some binaries generated by the "ffmpeg" project are more than 30 MiB, directly applying D-HELIX on these large-size binaries significantly increases the running time, e.g., on average, it took SYMDIFF 14 days to finish the symbolic execution on one of the "ffmpeg" binary with size 100 MiB. Hence, we include the object files from "ffmpeg" project to test.

SYMFIT: Making the Common (Concrete) Case Fast for Binary-Code Concolic Execution

Abstract

Concolic execution is a powerful technique in software testing, as it can systematically explore the code paths and is capable of traversing complex branches. It combines concrete execution for environment modeling and symbolic execution for path exploration. While significant research efforts in concolic execution have been directed toward the improvement of symbolic execution and constraint solving, our study pivots toward the often overlooked yet most common aspect: concrete execution. Our analysis shows that state-of-the-art binary concolic executors have largely overlooked the overhead in the execution of concrete instructions. In light of this observation, we propose optimizations to make the common (concrete) case fast. To validate this idea, we develop the prototype, SYMFIT, and evaluate it on standard benchmarks and real-world applications. The results showed that the performance of pure concrete execution is much faster than the baseline SYMQEMU, and is comparable to the vanilla QEMU. Moreover, we showed that the fast symbolic tracing capability of SYMFIT can significantly improve the efficiency of crash deduplication.

1 Introduction

Symbolic execution [9, 13, 16, 26, 27] is a powerful technique for automated software testing that has gained significant attention in recent years. It has been widely used in finding security vulnerabilities due to its capability of effective code path exploration. Despite its effectiveness, symbolic execution is also known to be expensive. Recently, the efficiency of concolic execution has been greatly improved. SymCC [24] and SymSan [11] take a compile-time instrumentation approach to collect and solve path constraints and are several orders of magnitude faster than QSYM [31], which is based on dynamic binary instrumentation. SymSan [11] is even faster than SymCC [24] by utilizing the highly optimized shadow memory from data-flow sanitizer [30]. While SymCC and SymSan require the source code of the target program to perform concolic execution, QSYM [31] and SymQEMU [23] provide a binary-only solution by directly weaving the concolic execution logic into the dynamic binary translation process.

Essentially, concolic execution combines concrete and symbolic execution. While significant research efforts in concolic execution have been directed toward the improvement of symbolic execution and constraint solving [11, 12, 23, 31], our study pivots toward the often overlooked yet most common aspect, concrete execution. First, we review the design of existing binary concolic executors, focusing on how concrete and symbolic execution are mixed, and evaluate the overhead of handling concrete execution in the state-of-the-art binary concolic executor, SYMQEMU. We observed that even though SYMQEMU has significantly improved the performance of concolic execution on binary code over QSYM, it still exhibits a large overhead in handling the execution of concrete instructions. Our evaluation shows that when no symbolic inputs are introduced, the concrete execution in SYMQEMU is 35× slower than vanilla user-mode QEMU on SPEC CINT-2006 benchmarks.

"Optimize for the common case" is a principle in computer science and engineering that suggests designing and optimizing systems, algorithms, and software based on the most frequent or expected use cases, rather than focusing primarily on edge cases or rare scenarios. Inspired by this principle, we design an efficient concolic execution framework with optimization for the common case, concrete execution. We note that in concrete execution, only load and store instructions need to be checked as they can potentially access symbolic values in the shadow memory, the rest instructions can run natively without instrumentation. To reduce the latency of checking concrete shadow memory, we designed a Concrete Memory Lookaside Buffer (CMLB) that caches recent-accessed concrete memory pages. As a result, checking whether the address is concrete can be performed by a few instructions that look up CMLB. When loading a symbolic value in concrete mode, the execution should transit to symbolic mode, where instructions are monitored to collect their symbolic effects. More importantly, the concolic execution engine automatically switches between concrete mode and

symbolic mode to avoid unnecessary monitoring of concrete instructions.

We build our prototype, SYMFIT, on top of user-mode QEMU, with our optimizations for the common (concrete) cases. For the frontend, we follow the instrumentation strategy in SYMQEMU to propagate and collect symbolic constraints. For the backend, we adopt the ideas in SymSan [11] for its efficient symbolic state and shadow memory management.

We compared SYMFIT with its baseline SYMQEMU, and found that the overhead in concrete execution is greatly reduced on standard benchmarks (SPEC CINT-2006 [5] and Linux/Unix nbench [3]) and real-world applications (Google's Fuzzbench [2] and Unibench, the real-world benchmark presented in UniFuzz [20]). The evaluation results showed that compared to SYMQEMU, SYMFIT achieved 13× and 20× speedup on SPEC CINT and nbench for pure concrete execution. When the overhead of constraint solving is excluded, SYMFIT is 12.03× faster than SYMQEMU on Fuzzbench programs. When solving is enabled, SYMFIT can still enjoy a 6.67× speedup over SYMQEMU. In the end-to-end hybrid fuzzing experiment, SYMFIT can achieve similar edge coverage faster than SYMQEMU and sometimes achieve higher edge coverage. Moreover, the fast symbolic tracing capability of SYMFIT can significantly improve the efficiency of bug detection and crash deduplication.

Contributions. In summary, we make the following contributions:

- We review the system designs of existing binary concolic executors, with respect to how they combine concrete and symbolic executions. We make an observation that these designs incur significant overhead for concrete execution, which is the common case.
- We propose two key optimizations, lightweight concrete mode and concrete memory lookaside buffer, which significantly reduce the concrete execution overhead.
- We build a prototype, SYMFIT, and evaluate it on standard benchmarks (SPEC-CINT and nbench), real-world applications (Fuzzbench and Unifuzz), and security applications (crash deduplication). Moreover, we make SYMFIT publicly available to foster future research in the area.

2 Background and Motivation

Symbolic execution is a technique that can explore all possible execution paths in software using symbolic values instead of concrete inputs. It tracks the values of symbolic inputs as they are propagated by the program, and maintains a map from program variables (including registers and memory) to their symbolic expressions. When the engine encounters a branch statement with symbolic operands, it constructs a boolean formula based on collected symbolic expressions and checks the feasibility using an SMT solver. To generate a concrete input that follows the same execution path, the engine queries the SMT solver for feasible assignments to symbolic values.

Concolic Execution. One challenge of classic symbolic execution is that it fails to explore the execution path when the path constraints are too complex for the SMT solver to solve within a limited time. To alleviate this issue, researchers have proposed concolic execution, where the symbolic path exploration is guided by the execution of the program with concrete inputs. To explore executions that deviate from the current concrete execution path, the concolic execution engine checks the feasibility of the opposite branch by querying the SMT solver and generates concrete inputs leading to that direction if feasible.

2.1 Source-Code Concolic Execution

In order to trace the execution of the target program, symbolic execution engines need to understand the underlying instruction set. Classic symbolic execution engines [9,13,28] perform the analysis on the intermediate representation (IR) lifted from the program. At the core of such engines, an interpreter runs the IR symbolically and keeps a record of how symbolic values are computed in the program. While IR interpretation-based approaches are portable and architecture-agnostic, they all face scalability issues. Recently, a line of research works has shown that compiling or instrumenting the symbolic execution logic into the program can benefit from the native execution of the program, thus much faster than IR interpretation-based approaches. For example, SymCC [24] and SymSan [11] compile symbolic execution logic into the target program at LLVM IR level. They hook into the compiler and inject library function calls that interact with the symbolic execution backend. Such approaches also benefit from compiler optimizations, and instrumentation only needs to be done once for each program. However, compilation-based approaches fundamentally require a compiler, thus not applicable when the source code of the program or third-party libraries are not accessible.

2.2 Binary-Code Concolic Execution

While source-code concolic execution (such as SymCC [24] and SymSan [11]) is highly efficient, it has drawbacks too. The source code of the target program as well as all the dependent libraries must be available for compiler instrumentation. This assumption does not hold for proprietary software and library components. Even if the source code of all the software components is available, one may still encounter various compatibility issues when compiling these components with the compilers that come with these concolic execution engines. If for any reason a component cannot be properly compiled, function summaries must be provided for the functions exported by this component. Otherwise, constraint collection

might be incomplete or incorrect. However, writing function summaries can be a tedious and error-prone process by itself. Therefore, concolic execution that can directly work on binary code is desirable.

In essence, concolic execution combines symbolic execution and concrete execution to explore program execution space. In this subsection, we review the system designs of existing binary-code concolic executors, with respect to how they combine concrete and symbolic executions, as illustrated in Figure 1.

Angr. Angr [17, 28] is a binary concolic executor that utilizes the Unicorn engine [25] (i.e. user-mode QEMU) for concrete execution and the Valgrind framework for symbolic interpretation. To avoid heavyweight symbolic interpretation, Angr provides APIs for users to select functions or code regions for symbolic exploration (Figure 1). Initially, Angr executes the target binary concretely via the Unicorn engine to aggregate a concrete environment model, i.e., concrete values for registers and memory. Upon reaching a user-defined *Point of Interest (PoI)*, a symbolic state is initialized, replicating the concrete states and setting user-selected states (register or memory) as symbolic. Then symbolic execution is performed with initialized symbolic states. Once the symbolic exploration converges on the *Target Point (TP)*, symbolic execution terminates and each symbolic variable is assigned a concrete value that satisfies collected symbolic constraints and synchronized with concrete states to drive the concrete execution.

S2E. S2E [13] runs the entire operating system in the whole-system emulator QEMU and connects to KLEE [9] to symbolically execute selected code regions (Figure 1). Similar to Angr's strategy, it minimizes symbolic emulation overhead by letting users pinpoint functions or code regions to explore symbolically. Specifically, it provides two plugins, *Annotation*, and *CodeSelector*, allowing users to annotate variables as symbolic and specify code ranges to perform symbolic execution.

Mayhem. Instead of manually selecting boundaries between symbolic and concrete executions, Mayhem [10] provides a different strategy to reduce unnecessary emulation for concrete instructions with taint tracking. Specifically, the concrete execution engine instruments the target binary and performs dynamic taint analysis to track attacker-controlled input from environment variables, files, and networks. During the concrete execution, tainted instruction traces are streamed to the symbolic executor (KLEE) for symbolic exploration and exploit generation.

Problem 1: Concolic executors like Angr and S2E determine boundaries between concrete execution and symbolic execution upon user selection. This strategy effectively reduces the total overhead of symbolic emulation, as only selected code regions are executed symbolically. However, this strategy is coarse-grained. First, it requires preliminary reverse engineering efforts to first identify target functions or relevant code ranges, and designate which values should be treated as symbolic. Second, even within code segments selected for symbolic execution, many instructions that do not operate on symbolic values should be executed concretely. Third, selected code regions might overlook instructions outside of the selected range that require symbolic emulation. Mayhem performs dynamic taint analysis to ensure tainted instructions are subject to symbolic emulation, while untainted ones are spared. However, dynamic taint analysis introduces additional overhead at runtime, which becomes particularly problematic for whole-system emulation.

Problem 2: Notably, the above approaches all perform symbolic and concrete executions in two processes. As a result, Angr and S2E inevitably need to perform context switches between two engines and non-trivial synchronization between the symbolic and concrete environment, while Mayhem has to lift the target binary twice, one in Pin to perform dynamic taint tracking, another one in BAP for symbolic emulation.

QSYM and SymQEMU. Instrumentation-based approaches, such as QSYM and SymQEMU, were proposed to obviate the need for context switches and synchronization between the symbolic and concrete environment. This is achieved by injecting symbolic emulation logic directly into the target program, which enables running concrete code and symbolic emulation within one process, rendering mode switches extremely lightweight - essentially, a mere function call. Moreover, symbolic emulation logic is instrumented and executed together with the target binary on CPU, yielding a much higher performance compared to interpretation-based symbolic emulation like Angr, S2E, and Mayhem.

To avoid symbolic emulation overhead for concrete instructions, QSYM employs dynamic taint tracking to identify instructions that need symbolic emulation (Figure 1). Specifically, QSYM has to disassemble each instruction at run time and check each operand to determine if this instruction needs to be executed concretely or symbolically. The disassembling and taint checking inevitably introduce additional overhead. Notably, symbolic emulation intrinsically propagates symbolic data. Therefore, SYMQEMU (Figure 1), rather than relying on additional taint tracking, evaluates the need for symbolic emulation for an instruction by checking if its operand(s) (variables or memory addresses) are symbolic. This method enables it to bypass symbolic emulation for concrete instructions while eliminating the need for dynamic taint tracking and shows better efficiency than QSYM.

2.3 The Common Case Overhead

Our study pivots towards the often overlooked yet most common aspect: concrete execution, rather than symbolic execution and constraint solving methodologies, where significant research efforts have been directed towards [11, 12, 23, 31].

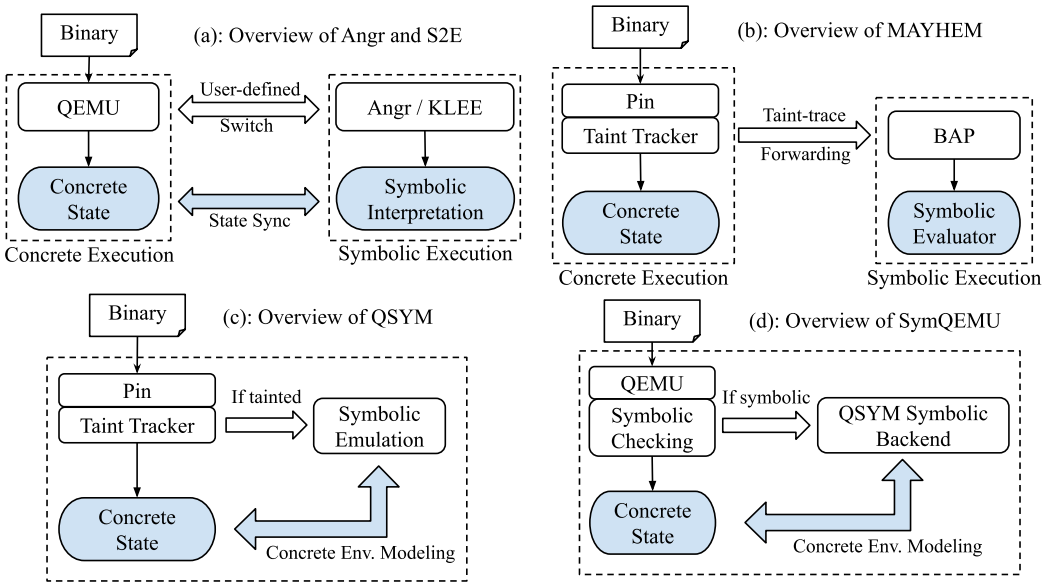

Figure 1: How concrete execution and symbolic execution are combined in binary-code concolic execution

Table 1: SymQEMU on CINT-2006 w/ concrete inputs

CINT-2006	QEMU (s)	SymQEMU (s)	Overhead (×)
hmmer	8.00	293.39	36.63
libquantum	541.78	17035.43	31.44
bzip2	179.81	4625.94	25.73
mcf	244.83	3072.34	12.55
sjeng	978.06	29495.09	30.16
gcc	71.82	1749.03	24.35
xalancbmk	308.25	68874.56	223.44
Geo. Mean			34.74

Notably, within the mix of concolic execution, concrete execution often emerges as the "common case". In this section, we want to gain insights into how good SymQEMU, the state-of-the-art binary concolic, handles the common case, concrete execution. We conducted a preliminary evaluation using the SPEC CINT-2006 benchmark programs. Since QEMU fails to run new versions of SPEC CINT benchmarks due to unsupported instructions, only a few benchmarks were selected from SPEC CINT-2006 as motivating examples. By comparing the execution time of pure concrete inputs, we were able to identify the overhead introduced by SymQEMU in handling concrete execution, in which it only needs to perform concreteness checks on shadow variables and memory. The results (Table 1) indicate an overhead of up to 223× and an average of 35×. According to the evaluation in Mayhem [10] and our observation, the majority of instructions (90%) are executed concretely. Therefore, the room for further performance improvement is still large.

We further analyzed SymQEMU to understand the overhead of handling the common case, concrete execution. First, to determine whether an instruction should be executed concretely or symbolically, SymQEMU inserts a helper function call before each instruction (except for `mov`-like instructions) to check whether operands are concrete. If so, the symbolic emulation of this instruction can be skipped. As an example shown in Listing 1, a helper function is added (at line 5) when generating the IR for the `add` instruction. This helper function (at line 8) checks the concreteness (line 11) of operands and builds symbolic expression (line 17) if needed. While checking the concreteness of operands is necessary, doing so by checking every instruction incurs a non-negligible over-

```
1  static inline void tcg_gen_add_i64(TCGv_i64 ret,
2          TCGv_i64 arg1, TCGv_i64 arg2)
3  {
4    // Add a helper function call to IR.
5    tcg_gen_helper_sym_add(ret_expr, arg1_expr, arg2_expr);
6    tcg_gen_op3_i64(INDEX_op_add_i64, ret, arg1, arg2);
7  }
8  void *helper_sym_add(ret_expr, arg1_expr, arg2_expr)
9  {
10   // Concreteness checking.
11   if (arg1_expr == NULL && arg2_expr == NULL) {
12     // Return if both expressions are concrete.
13     return NULL;
14   }
15   ......
16   // Build symbolic expression for add.
17   return _sym_build_add_i64(arg1_expr, arg2_expr);
18 }
```

Listing 1: An example of SymQEMU's instrumentation using helper functions.

head. Secondly, shadow memory checking in SYMQEMU is expensive. To check the concreteness of an address, the virtual address is first translated to its corresponding shadow address using a two-level mapping. Then, the shadow address is accessed to determine if it is concrete. As memory accesses are frequent, such overhead can be significant when analyzing real-world applications.

Scope. In this work, we follow the system design principle of "optimize for the common case" to design a concolic executor with optimized concrete execution. While this principle is generic to be applied to different solutions of concolic executors, such as QSYM, our concolic executor follows the design of SYMQEMU, as the underlying framework, QEMU, is open-sourced, allowing us to implement our optimization strategies at the system level. We have made key observations of SYMQEMU that guide our approach:

- The concrete execution exhibits non-negligible overhead due to concreteness checking at the instruction level. We argue that, in concrete execution, only load and store need to be monitored as they may potentially access shadow memory from memory. No concreteness checking is necessary for the rest instructions to keep concrete execution fast. The transition to symbolic execution happens as soon as a symbolic value is loaded from shadow memory to ensure the correctness of symbolic emulation. In symbolic execution, the engine should switch back to concrete execution as soon as no symbolic emulation is needed.
- (Concrete) shadow memory access can be frequent and imposes significant overhead. Checking for shadow memory can be optimized by caching recent-accessed concrete memory pages. By doing so, the overhead of shadow address translation and shadow memory access can be avoided if the cache hits.

3 System Overview

Essentially, the design of concolic executors consists of the front end for symbolic state collection and the back end for symbolic state management. SYMFIT follows the front-end design of SYMQEMU, which adopts user-mode QEMU for its reasonable performance and multi-architecture support. Instead of reusing the symbolic backend from QYSM as SYMQEMU does, we adopt the symbolic state management from SymSan [11], a recent work that shows efficient symbolic expression and shadow memory management. While SymSan requires the source code of target programs, we introduce more details about how we apply SymSan's ideas for binary concolic execution in §3.2.

More importantly, SYMFIT is designed to optimize for the common (concrete) case. It features a lightweight concrete execution and the ability to efficiently discern the boundary between symbolic and concrete execution. To optimize for the common (concrete) case, it only monitors load and store instructions in concrete execution. When a symbolic load is detected, SYMFIT switches to the symbolic mode with full instrumentation. When symbolic emulation is no longer necessary, it transitions back to the concrete mode. To determine when to switch, SYMFIT evaluates the concreteness of CPU registers at the end of each basic block, instead of checking every instruction which has a non-negligible overhead.

Figure 2 illustrates the architecture of SYMFIT. It is built atop a dynamic binary translator, QEMU, and takes a binary as input. The concolic execution logic is instrumented into the binary dynamically, allowing it to switch between lightweight concrete mode and symbolic execution mode at runtime. The latency of shadow memory access is improved by the Concrete Memory Lookaside Buffer (CMLB) lookup, which is done by a few instructions inlined into native code during translation. SYMFIT utilizes a symbolic backend to construct symbolic path constraints, query the SMT solver, and generate new test inputs for path exploration.

Lightweight Concrete Execution. As shown in Table 1, even with no symbolic inputs, SYMQEMU still incurs a 35 times slowdown compared to the vanilla QEMU. This overhead comes solely from instrumented helper function calls (as shown in Listing 1) that check whether shadow variables or memory are concrete. In fact, when no symbolic value is involved, there is no need for such instrumentation and the program can be analyzed in concrete mode. In concrete mode, no symbolic emulation will be added to the original code, except for the load and store instructions that may potentially access symbolic values from the shadow memory. Therefore, only the memory access instructions are instrumented to monitor whether the source is symbolic, if so, the execution should switch to the symbolic mode. Section §3.1 introduces how SYMFIT efficiently performs this check for load and store instructions. For memory stores, the shadow memory of the destination operand will be cleaned since the source operand is always concrete.

Mode Switch. While concrete mode is efficient, instructions that need symbolic emulation should be instrumented to ensure correct symbolic state propagation and constraint collection. Also, SYMFIT should transition back to concrete mode as soon as symbolic emulation is not necessary. The key challenge is to decide when and how the transition between the two modes should occur. To ensure the proper propagation of symbolic states, the execution should switch to the symbolic mode immediately upon loading symbolic data from the shadow memory. To minimize the instrumentation overhead, the execution should switch to the concrete mode whenever no symbolic values are involved. Moreover, the transition between the two modes should be seamless without disrupting the program's execution. SYMQEMU [23] is built on top of the dynamic binary translator QEMU (user mode) [7]. It

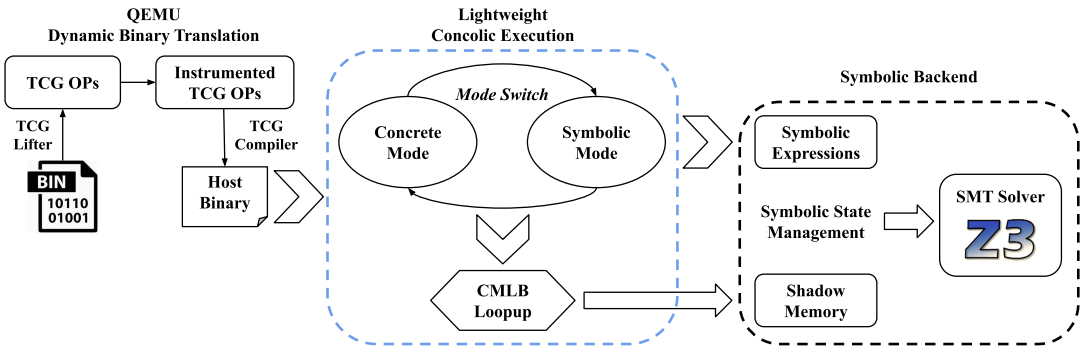

Figure 2: Overview of SYMFIT

translates and executes the target binary at the basic block level. Before executing a basic block, it first checks whether this block has been translated before, if so, it directly fetches the generated machine code from the code cache and if not, it translates this block of code and stores the generated code into the code cache. To avoid the repeated translation overhead, we designed two code caches for two execution modes correspondingly such that each mode only fetches from or stores to its own code cache.

Transition from Concrete Mode. In the concrete mode, all vCPU registers are concrete, and only the shadow memory may contain symbolic values. Therefore, SYMFIT only instruments memory loads and stores to detect if a symbolic value is loaded from memory or overwritten by a concrete value. If so, SYMFIT will automatically switch to the symbolic mode. This switch is triggered by a custom exception: `EXCP_SYM_SWITCH` defined in QEMU's vCPU data structure. When a load from symbolic shadow memory occurs, the exception is raised, forcing the execution to jump back to the main execution loop of QEMU. In the execution loop, this exception is captured and handled by changing the mode flag that instructs how QEMU should instrument the target binary and select the code cache.

Transition from Symbolic Mode. In the symbolic mode, SYMFIT inserts the full symbolic execution logic into the program. We use the vCPU register states as an indicator to switch from the symbolic mode to the concrete mode. Right before QEMU executes the target basic block in symbolic mode, SYMFIT checks if all vCPU registers are concrete. If so, no symbolic value is involved in this basic block, and SYMFIT can safely switch back to the concrete mode for better efficiency.

3.1 Efficient Shadow Memory Checking

SYMFIT adopts a lightweight concrete execution by only monitoring memory accesses (i.e., load and store). As presented in Table 2, the concrete execution mode results in an average of 3× speedup over SYMQEMU on SPEC-CINT benchmarks. However, shadow memory checking still has about an 11× slowdown compared to the vanilla QEMU.

Table 2: Speedup of lightweight concrete mode over SYMQEMU on SPEC CINT-2006 with all concrete inputs and overhead of mode switch compared to vanilla QEMU. SYMFIT-M represents SYMFIT with only the optimization of mode switching between lightweight concrete mode and symbolic mode.

CINT-2006	SYMQEMU	SYMFIT-M	Speedup	Overhead
hmmer	293.39s	107.85s	2.72×	13.46×
libquantum	17035.43s	4155.04s	4.01×	7.66×
bzip2	4625.94s	1109.15s	4.17×	6.16×
mcf	3072.34s	883.54s	3.48×	3.61×
sjeng	29495.09s	6634.13s	4.45×	6.78×
gcc	1749.03s	518.36s	3.38×	7.21×
xalancbmk	68874.56s	63293.54s	1.09×	205.34×
Geo. Mean			3.08×	11.27×

In SYMQEMU, load and store instructions are instrumented with helper function calls to first check whether the destination address is concrete. To optimize for the common case of concrete shadow memory access, SYMFIT maintains a buffer that stores recently accessed concrete pages. It is inspired by how the system-mode QEMU accelerates the address translation. In the system-mode QEMU, each memory access must go through an address translation from its guest virtual address to its host virtual address. A naïve implementation would also involve a helper function call and the complex address translation logic inside the helper call. To speed up this address translation, the system-mode QEMU adopts software TLB (Translation Lookaside Buffer). It checks this TLB for a quick translation and only goes through the page table traversal when there is a TLB miss. Furthermore, it inlines this TLB lookup logic into the generated code block (the code that is finally executed natively on the host machine), to eliminate the overhead of a helper call. Similarly, we maintain a lookaside buffer for recently accessed concrete memory blocks (in

```
#define CPU_TLB_ENTRY_BITS 3
#define CPU_TLB_DYN_DEFAULT_BITS 10
typedef struct CPUTLBDescFast {
  /* (n_entries - 1) << CPU_TLB_ENTRY_BITS */
  uintptr_t mask;
  /* The array of TLB entries itself. */
  CPUTLBEntry *table;
} CPUTLBDescFast QEMU_ALIGNED(2 * sizeof(void *));

typedef struct CPUTLBEntry {
  target_ulong page_addr;
} CPUTLBEntry;
static void user_tlb_dyn_init(CPUArchState *env) {
  for (int i = 0; i < NB_MMU_MODES; i++) {
    size_t n_entries = 1 << CPU_TLB_DYN_DEFAULT_BITS;
    env_tlb(env)->f[i].mask =
          (n_entries - 1) << CPU_TLB_ENTRY_BITS;
    env_tlb(env)->f[i].table =
          g_new(CPUTLBEntry, n_entries);
  }
}
```

Listing 2: The design and configuration of the Concrete Memory Lookaside Buffer.

which all memory bytes are concrete). We refer to this buffer as Concrete Memory Lookaside Buffer (CMLB). The CMLB lookup logic is inlined in the native code to avoid the helper call overhead. In this way, since most memory blocks are concrete, we expect the majority of memory accesses will result in CMLB hits and no further actions are needed. Occasionally, if a memory access results in a CMLB miss, meaning at least one byte in that block is symbolic, SYMFIT goes through the slow path by making a helper call as in SYMQEMU.

We follow the design of QEMU's software TLB and reuse some of the TLB data structures for the Concrete Memory Lookaside Buffer. As shown in Listing 2, the buffer is initialized with 1024 (1 << `CPU_TLB_DYN_DEFAULT_BTIS`) entries and is associated with the `CPUArchState` data structure per vCPU. Each entry contains an 8-byte address of a concrete memory block. For load and store instructions in concrete mode, SYMFIT first looks up the CMLB to check if the target address is concrete. If so, it can safely continue in the concrete mode. If not, a helper function is called to read the shadow memory. Note that a store in the concrete mode will write the destination shadow memory as concrete. For load instructions in symbolic mode, if CMLB hits, the shadow variable of the destination operand will be marked as concrete, and the function call to read shadow memory is skipped. For store instructions in the symbolic mode, SYMFIT only goes to the fast path when CMLB hits and the source variable is also concrete. The entries in CMLB will be filled with a new block if it is concrete, or evicted if the cached concrete blocks become symbolic.

The granularity of the cached memory blocks in CMLB impacts both the hit rate and overall performance. The original TLB design in QEMU holds the starting address of a 4096-byte page in each entry. However, this level of granularity is inefficient for buffering concrete memory blocks as a small amount of symbolic data would mark the whole page as symbolic. To address this, we evaluated various granularity levels ranging from 32-byte to 2048-byte and selected 512-byte which demonstrated the best hit rate in our evaluation. More details can be found in §5.5.

As presented in Table 3, lightweight concrete mode and shadow memory access (dubbed SYMFIT-MC) together can achieve an average speedup of over 13 times compared to SYMQEMU. The overhead compared to the vanilla QEMU is only 2.65 times.

Table 3: Speedup of the optimizations for concrete instructions and shadow memory access over SYMQEMU on SPEC CINT-2006 with all concrete inputs and overhead of mode switch compared to vanilla QEMU. SYMFIT-MC represents the combination of mode switch and shadow memory access.

CINT-2006	SYMQEMU	SYMFIT-MC	Speedup	Overhead
hmmer	293.39s	19.09s	15.37×	2.38×
libquantum	17,035.43s	907.43s	18.77×	1.67×

Geo. Mean			13.10×	2.65×

3.2 Symbolic State Management

SYMQEMU utilizes the same backend with QSYM [31] to manage symbolic expressions and shadow memory. Recently, SymSan [11] proposed a novel approach that extends the dynamic data-flow analysis framework, DFSan [30], to optimize the management of symbolic expressions and shadow memory. Unfortunately, SymSan requires source code, so it cannot be used directly with binary concolic executors. In this subsection, we explain how we apply the ideas of SymSan to enhance existing binary concolic executors.

Symbolic Expression Management. State-of-the-art concolic executors, such as SymCC [24], SYMQEMU [23] and QSYM [31], utilize Abstract Syntax Trees (ASTs) to represent symbolic expressions and their dependencies. When a new symbolic expression is created, an AST node is allocated on the heap to store the new symbolic expression populated based on the source operand(s) and instruction. At a symbolic branch, QSYM looks up the AST tree and unfolds the dependencies to build a Z3 expression for path negation. According to the performance profiling in SymSan, QSYM spends 3% of execution time on AST node allocation and 28% on AST node tracking. To reduce the overhead of allocating and tracking symbolic expressions, SymSan modifies the taint labels in DFSan [30] to represent symbolic expressions and preserves a

large, consecutive address space for forward allocation of new labels. As a result, tracking symbolic expressions is a simple look-up of the label array (constant time), and allocating new labels is done by performing an `atomic_fetch_add` to update the last allocated index. Interested readers can refer to SymSan [11] for more technical details. To adopt the design of SymSan, we add helper functions at TCG IR level that interact with SymSan's backend for symbolic state management.

Shadow Memory Management. For variables stored in memory, SYMQEMU uses QSYM to model the shadow memory to store their expressions. In QSYM, the shadow memory mapping is maintained in a red-black tree (`std::map`). To calculate the shadow address for a given application address, the page-level application address is first used as an index to retrieve the target shadow page, then the page offset is added to it to get the shadow address. As a result, the mapping complexity is *O(log(n))*.

```
// Calculate shadow address in QSYM.
std::map<uintptr_t, SymExpr *> g_shadow_pages;
static SymExpr *getShadow(uintptr_t address) {
  shadowPageIt =
            g_shadow_pages.find(pageStart(address));
  if (shadowPageIt != g_shadow_pages.end())
    return shadowPageIt->second + pageOffset(address);

  return nullptr;
}
// SymSan direct shadow memory mapping.
void *shadow_for(uptr addr) {
  return (addr & ShadowMask()) << 2;
}
```

Listing 3: The shadow memory design in QSYM and SymSan

As designed in SymSan [11] and other dynamic taint analysis (DTA) tools [30], direct mapping is the most time-efficient way to maintain shadow memory, which offers constant time (*O(1)*) lookup. SYMFIT employs the direct mapping from SymSan's symbolic backend. Listing 3 shows the shadow memory address translation in SymSan. Despite the fast shadow memory mapping, the shadow memory access still suffers from poor memory access locality. As presented in Table 4, the application memory and shadow memory exhibit a significant distance between them. Therefore, CMLB is still useful in terms of reducing shadow memory access latency.

In conclusion, we improve the performance in symbolic mode by adopting the faster symbolic backend from the source code-based concolic executor SymSan to SYMFIT.

4 Implementation

SYMFIT utilizes the user-mode emulator QEMU [7] to build the front-end and follows the design of SymSan to build the symbolic backend. In this section, we reveal some implementation details of SYMFIT.

TCG Instrumentation. Fundamentally, SYMFIT utilizes the Tiny Code Generator (TCG) of QEMU to perform the instrumentation. TCG first lifts basic blocks of the target binary to an intermediate representation called TCG ops, then compiles TCG ops to machine code that runs on the target architecture. During the dynamic binary translation, additional TCG ops are emitted to invoke library functions from the symbolic execution backend. For each TCG op, the symbolic handler function is added to build corresponding symbolic expressions. Unlike source code-based instrumentation that benefits from compiler optimizations, TCG instrumentation has a limited view of instructions and renders advanced static analysis infeasible. As a result, it is difficult for SYMQEMU to statically determine if a variable is concrete, and remove the inserted symbolic execution logic. SYMQEMU settled for a solution that performs concreteness checks at the cost of library function calls. In SYMFIT, we use vCPU registers to indicate whether TCG variables are concrete in the target basic block. Specifically, in symbolic mode, we add one helper function per basic block to check the states of all registers. If they turn out to be concrete, we can safely avoid the cost of concreteness checks for every instruction in this block.

Symbolic State Management. SYMFIT uses runtime library functions from SymSan's symbolic backend to construct symbolic expressions and send solving queries to the SMT solver. At the core of SymSan, a special form of dynamic data-flow analysis is performed to collect taint labels of program variables and their dependencies. When encountering a symbolic (i.e., tainted) branch, a symbolic expression is reconstructed based on collected taint labels. While SymSan works on LLVM IRs, we instrument TCG IRs to achieve the equivalent functionalities.

SYMFIT supports symbolic data from input files and `stdin`. To achieve this, we hook the syscall wrappers in QEMU (e.g., open, openat, read, and lseek) and assign corresponding labels to the buffer that receives the read bytes. Symbolic data from network interfaces is not supported yet but can be easily extended.

Symbolic Address. SYMFIT uses the same strategy to handle symbolic address as SYMQEMU. Specifically, for a symbolic address, new test inputs are generated to reach other possible addresses. A symbolic address is also associated with the concrete value of the address to ensure correctness.

Memory Layout. SymSan uses direct shadow memory mapping and forward allocation of symbolic expressions. As a result, heap memory regions are preserved in advance to program execution, and a specific memory layout is enforced. To benefit from this design, SYMFIT follows the same memory layout and reserves designated memory regions when QEMU starts. To make sure QEMU-related data structures (i.e., vCPU states) are mapped into the shadow memory, we also modify QEMU's customized memory allocator to allocate these data

structures at preserved regions. Listing 3 depicts the memory layout.

Table 4: Memory layout designed for SymSan's backend

Start	End	Desription
0x700000050000	0x800000000000	application memory
0x700000040000	0x700000050000	QEMU's object
0x400010000000	0x700000020000	AST array
0x400000000000	0x400010000000	hash table
0x000000020000	0x400000000000	shadow memory
0x000000000000	0x000000010000	reserved by kernel

Hybrid Fuzzer. In the end-to-end hybrid fuzzing experiment, we reuse the same hybrid fuzzer from SYMQEMU and SymCC [24]. Specifically, the concolic executor takes seeds from fuzzer's seed queue as input and generates new seeds for fuzzer to synchronize periodically. It also maintains a global coverage bitmap for branch filtering. For a fair comparison, we implemented the same branch filters as in SYMQEMU.

5 Evaluation

In this section, we evaluate the performance of SYMFIT, a prototype implementing our proposed optimization schemes atop SYMQEMU. We demonstrate the effectiveness of SYMFIT by answering the following research questions:

- **RQ1: Efficiency.** We investigate the extent to which SYMFIT improves efficiency compared to SYMQEMU under different settings. Additionally, we analyze the individual contributions of each design choice to the overall efficiency improvement.
- **RQ2: Effectiveness.** We evaluate whether SYMFIT can achieve the same level of effectiveness as SYMQEMU in terms of generating new test cases and achieving increased code coverage. In other words, we want to ensure that the efficiency improvement does not come at the cost of compromising the quality of generated test cases and the growth of code coverage.
- **RQ3: End-to-end Hybrid Fuzzing.** We evaluate the contribution of SYMFIT to the end-to-end hybrid fuzzing with respect to code coverage growth and bug-finding performance.
- **RQ4: Security Applications.** We assess the contribution of SYMFIT's efficient symbolic tracing capability on one security application, crash seed deduplication.

5.1 Evaluation Plan

To answer the aforementioned research questions, we evaluate the following configurations:

- **SYMQEMU.** The original SYMQEMU with QSYM backend obtained from the public repository [6].
- **SYMFIT-M.** SYMFIT (QSYM backend) with only mode switch enabled.
- **SYMFIT-MC.** SYMFIT (QSYM backend) with both mode switch and CMLB enabled.
- **SYMFIT-MS.** SYMFIT with only mode switch enabled and SymSan backend.
- **SYMFIT.** Full-fledged SYMFIT with the mode switch, CMLB and new symbolic backend from SymSan.

These configurations allow us to discern the enhancements brought about by each design choice, both individually and collectively. For instance:

- The comparison between SYMFIT-M and SYMQEMU illustrates the gains from the lightweight concrete mode.
- Comparing SYMFIT-MC with SYMFIT-M reveals the advancements due to efficient shadow memory access via CMLB.
- By comparing SYMFIT-MS and SYMFIT-MC, we discern the improvements from the fast symbolic backend.
- Ultimately, comparing SYMFIT and SYMQEMU provides insight into the overall benefits of our concolic executor.

Dataset. We evaluate SYMFIT on several benchmarks, including standard benchmarks (SPEC CINT-2006 [5] and Linux/Unix nbench [3]), and real-world programs (Google's Fuzzbench [2] and unibench, the real-world benchmark presented in UniFuzz [20]). Since QEMU cannot run new versions of SPEC CINT benchmarks due to unsupported instructions, we only selected a few benchmarks from SPEC CINT-2006 as motivating results presented in §2.3. In the evaluation, we use nbench to show the concrete mode overhead of SYMFIT and the baseline concolic executor SYMQEMU.

To answer **RQ1**, we conduct experiments on the standard benchmark nbench to evaluate the speedup of SYMFIT over SYMQEMU in two settings: 1) pure concrete execution and 2) concolic execution without solving. Additionally, we evaluate SYMFIT's performance on real-world programs from Fuzzbench to demonstrate the improvements on practical applications. For **RQ2**, we compare the total execution time and basic block coverage achieved by SYMQEMU and SYMFIT on Fuzzbench programs, using the same input seeds. To answer **RQ3**, we pair SYMQEMU and SYMFIT each with two AFL-2.56 instances, one main instance (in -M mode) and one secondary instance (in -S mode) and evaluate the 24h coverage gain and bug detection capability on unibench programs. For **RQ4**, we use symbolic constraints to cluster PoCs that share the same constraints and evaluate the efficiency in symbolic constraint collection of SYMFIT and SYMQEMU.

Experiment Setup. All evaluations were conducted on a workstation with 96-core Intel Xeon Platinum 8260 processors.

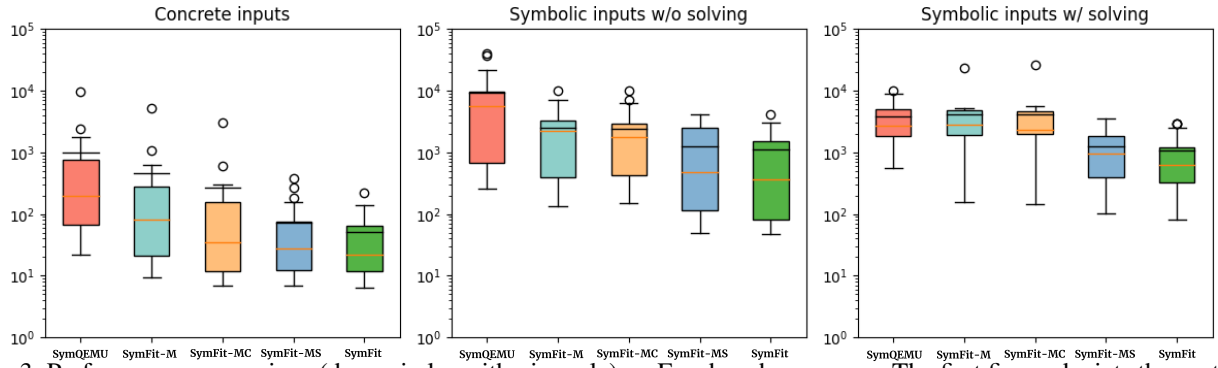

Figure 3: Performance comparison (drawn in logarithmic scale) on Fuzzbench programs. The first figure depicts the runtime of executions with concrete inputs, the middle shows the runtime of executions with symbolic inputs but no constraint solving. The last figure shows the runtime with symbolic input and constraint solving enabled. More statistic details can be found in Appendix Table 8 and Table 9.

The workstation has 1.45T memory with Ubuntu 18.04 operating system and kernel 5.4.0. To ensure a fair comparison, we run each trial in a docker container with one dedicated core assigned. All the evaluation results are averaged across ten experimental trials to reduce the impact caused by randomness from hardware and constraint solver.

Input Selection. To generate test cases for Fuzzbench programs, we used AFL++ to fuzz the target programs for 24 hours and obtained the generated seeds. To avoid bias toward repetitively executed code paths, we used the utility CMIN from AFL++ to prune the seed corpus. For unibench programs, we used the publicly available seed corpus from [20] for better reproducibility.

5.2 RQ1: Efficiency

To evaluate the performance gain in the concrete mode, we run nbench without any symbolic inputs. Consequently, the symbolic backend is not invoked and the only runtime overhead of SYMQEMU comes from instrumentation for concrete code blocks, such as helper function calls that check the concreteness of shadow variables and shadow memory. As shown in Table 5, this overhead results in a significant 22× slowdown on SYMQEMU compared to the vanilla QEMU. Such overhead in SYMFIT can be optimized by the lightweight concrete mode and shadow memory access. We evaluate these two strategies individually and show performance improvement from each optimization.

Speedup of Lightweight Concrete Execution. In the first experiment, we evaluated SYMFIT to understand the performance improvement achieved through the lightweight concrete mode. As all inputs were concrete, all basic blocks were executed in concrete mode. Table 5 presents the results. Compared to vanilla QEMU, SYMQEMU exhibited a 21.6× slowdown on the memory index, a 16× slowdown on the integer index, and a 6× slowdown on the floating-point index.

Table 5: Performance of concrete execution on NBENCH

Iterations/sec.	Native	QEMU	SYMQEMU	SYMFIT-M	SYMFIT-MC	SYMFIT

This slowdown was primarily attributed to the instrumentation required for symbolic emulation in SYMQEMU, even when handling concrete inputs. In contrast, SYMFIT was able to avoid much of the overhead caused by symbolic emulation since all inputs were concrete. The primary overhead in SYMFIT arose from memory load/store monitoring and shadow register checking at the basic block level. As presented in Table 5, SYMFIT-M is 3.9× faster on the memory index, 4.97× faster on the integer index, and 2.84× faster on the floating-point index.

Speedup of Efficient Shadow Memory Access. In this experiment, we evaluated SYMFIT to understand the performance improvement achieved through efficient shadow memory access. In this configuration, recently accessed concrete pages are stored in the Concrete Memory Lookaside Buffer (CMLB), and the cache lookup logic is inlined into the generated code, allowing it to run directly on the host machine. As presented in Table 5, SYMFIT-MC shows faster execution time than SYMFIT-M. Compared to SYMQEMU, SYMFIT-MC is 7.4× faster on the memory index, 7.5× faster on the integer index, and 4.7× faster on the floating-point index. We also observed that SYMFIT shows better performance (1.5×) than SYMFIT-MC alone. This is attributed to the di-

rect shadow memory mapping mechanism that accelerates the shadow memory lookup when the CMLB misses.

Real-world Applications. We then extended the pure concrete execution evaluation to real-world applications. In this evaluation, we ran Fuzzbench programs with the same seed corpus obtained from 24h fuzzing. Results are presented in Figure 3. Compared to SYMQEMU, SYMFIT-M is 3.65× faster, SYMFIT-MC is 4.68× faster and SYMFIT is 8.86× faster.

Concolic Execution without Solving. In this experiment, we evaluated the performance of concolic executors without solving. Compared to pure concrete execution, the overhead in this setting comes from concreteness checking of shadow variables and memory and symbolic state management. According to the result presented in Figure 3, SYMFIT-M, SYMFIT-MC, SYMFIT-MS and SYMFIT are 3.26×, 3.86×, 9.73× and 12.03× faster than SYMQEMU respectively.

Overall, these results demonstrate that SYMFIT, incorporating both lightweight concrete mode and efficient shadow memory access, outperforms SYMQEMU on standard benchmarks and real-world scenarios.

5.3 RQ2: Effectiveness

In this experiment, we enabled constraint solving for each concolic executor. For each target program, we used the coverage bitmap collected from afl for branch filtering to avoid flipping every encountered symbolic branch and placed a 100-second timeout for each execution. Otherwise, the experiment cannot be completed within a reasonable time. The execution times for inputs that did not reach the timeout are shown in Figure 3. Additionally, the basic block coverage was measured using SanitizerCoverage [4] to verify the correctness of constraint solving.

Table 9 shows the coverage achieved by SYMQEMU and SYMFIT. We noticed that SYMQEMU reached the timeout on more inputs than SYMFIT. This observation suggests that SYMFIT can explore more basic blocks, resulting in higher coverage on certain programs (e.g., freetype + 17.09%, woff2 +17.31%) when provided with the same seed corpus. Overall, the results indicate that SYMFIT improves the efficiency of concolic execution without compromising correctness.

Based on the results depicted in Figure 3, when solving is enabled, SYMFIT can still achieve a 6.67× performance speedup over the baseline SYMQEMU. Furthermore, even without SymSan's symbolic backend, SYMFIT-M and SYMFIT-MC independently achieve an approximate 2× performance speedup, showcasing the contribution of lightweight mode switch and shadow memory access. With the integration of the new backend from SymSan, the performance significantly boosts up to 6.67×, as symbolic state management proves to be heavyweight in SYMQEMU's symbolic backend.

5.4 RQ3: End-to-end Hybrid Fuzzing

In this experiment, we pair SYMQEMU and SYMFIT each with two AFL-2.56 instances and evaluate coverage growth and bug detection efficiency of the hybrid fuzzers on unibench, a real-world program benchmark. To ensure a fair comparison, we run each fuzzer/concolic executor in a docker container with one physical CPU-core assigned. The results are obtained by averaging 10 repetitions of 24h fuzzing campaigns to reduce the randomness.

5.4.1 Coverage Efficiency

The coverage growth over time is shown in Figure 4. SYMFIT achieved faster coverage growth on seven applications (wav2swf, pdftotext, infotocap, mp42aac, objdump, tcpdump, and nm-new) and showed similar performance with SYMQEMU on the rest programs. This result indicates that a faster concolic executor can indeed expedite the exploration process during hybrid fuzzing. By achieving faster coverage growth, SYMFIT is able to explore more paths and execute a broader range of code segments within the same amount of time, potentially leading to the discovery of new vulnerabilities or bugs earlier. However, it is essential to note that in a hybrid fuzzing setting, the fuzzer operates with much higher throughput and actively drives the path exploration process. As a result, the speedup achieved by SYMFIT is less obvious than the improvement observed in the pure concolic execution evaluations.

5.4.2 Bug Detection Efficiency

To further understand the benefit of having a faster concolic executor, we evaluated the bug detection efficiency of SYMFIT-HF and SYMQEMU-HF. At the end of each hybrid fuzzing run, the crashes are triaged into unique bugs using the same method implemented in unibench: we use ASan [1] to produce the stack trace for each crash and then use three stack frames to de-duplicate the bugs. In this experiment, we compare the time it took to trigger mutual bugs found by both SYMFIT and SYMQEMU. We only counted the first time a bug was triggered. Among evaluated unifuzz benchmarks, seven programs produced crashes but no bug ID was assigned by unibench. There were four programs where both SYMFIT and SYMQEMU did not generate any crash. The results for the rest six programs where mutual bugs were found are presented in Figure 5. As shown, for the same group of mutual bugs found by SYMFIT and SYMQEMU, SYMFIT spent less time to trigger these bugs. This outcome indicates that SYMFIT demonstrates improved efficiency in detecting bugs during hybrid fuzzing. By being faster in its execution, SYMFIT can discover bugs with reduced time-to-trigger, making it an effective tool for detecting vulnerabilities or crashes in real-world applications.

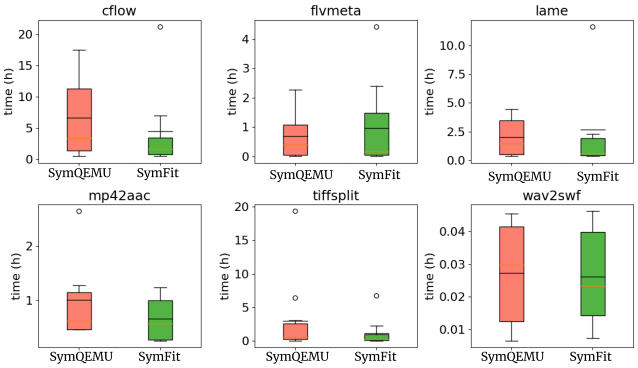

Figure 5: Mutual Bug Time-to-Trigger(h) Result

5.5 Ablation Study

In §5.2, we have assessed the improvement brought by the primary components in SYMFIT, namely the mode switch, Concrete Memory Lookaside Buffer (CMLB), and the integration of the SymSan backend. Here we conducted ablation study to quantify the contribution of each component.

SymSan Backend. Compared to the QSYM backend used in SYMQEMU, SymSan is more efficient in symbolic state management. Specifically, SymSan allocates labels for symbolic variables and preserves a large, consecutive address space for forward allocation of new labels. As a result, allocating new labels is done by performing an `atomic_fetch_add` to update the last allocated index, and label look-up when constructing symbolic expressions occurs in constant time. For variables stored in memory, SymSan utilizes a direct mapping of application memory to maintain the shadow memory, enabling constant time (*O(1)*) shadow memory lookup. In contrast, SYMQEMU employs a red-black tree (`std::map`) for shadow memory mapping, which incurs a logarithmic complexity *O(log(n))*. The performance gains from integrating SymSan's backend are evident by comparing SYMFIT-M (mode switch only) and SYMFIT-MS (mode switch plus SymSan backend), with a 3x speedup, as shown in Table 8.

Mode Switch. SYMFIT features a lightweight execution mode for concrete code blocks and switches between lightweight concrete mode and symbolic mode to minimize unnecessary overhead. As evidenced in Table 6, symbolic blocks constitute only a small percentage of the total execution blocks (9.49% on average) for Fuzzbench benchmarks, demonstrating the significance of maintaining minimal overhead in concrete execution. In the evaluation, we have shown that this optimization alone can bring a 3.26x speedup, as indicated in Table 8 under the SYMFIT-M (mode switch only) configuration.

CMLB. The Concrete Memory Lookaside Buffer (CMLB) is designed to optimize the latency of shadow memory access by buffering recently accessed concrete pages. In this section, we conducted an ablation analysis to measure the CMLB hit rate and explore different levels of granularity. The granularity refers to the size of concrete memory stored in a CMLB entry. The original TLB design in QEMU holds the starting address of a 4096-byte page in each entry. However, this level of granularity is inefficient for buffering concrete shadow memory blocks, as even a small amount of symbolic data

within a page would mark the entire page as symbolic. To address this, we experimented with finer granularity levels and compared the hit rates across different granularity, the results of which are presented in Table 6.

Overall, CMLB can achieve a high hit rate, indicating that the cache is frequently accessed instead of the shadow memory. It is important to note that, due to the presence of symbolic memory, the hit rate is lower than the typical TLB hit rate (around 99%), as accessing symbolic shadow memory consistently results in a CMLB miss. As presented in Table 6, the hit rate varied across different levels of granularity and there is no one-size-fit-all configuration. Therefore, we selected a granularity of 512 for our evaluation, as it yielded the highest average hit rate. As presented in Table 8 under the SYMFIT-MC configuration, the CMLB brings an additional 20% improvement on top of the mode switch.

Table 6: Ablation study for mode switch and CMLB. % of sym blocks represents the percentage of symbolic basic blocks during execution. CMLB hit rate is measured with different granularity, ranging from 32 to 2048. The configuration with the best hit rate is marked as bold.

6 Case Study: Crash Deduplication

At its core, SYMFIT stands as an efficient symbolic constraint tracer for binary code. In this section, we demonstrate the benefit of SYMFIT's efficiency in one security application, crash deduplication.

Fuzzers typically output a large set of proof-of-concept (PoC) test cases. These raw findings and crash dumps are often directly submitted to maintainers. Large fuzzing farms, such as ClusterFuzz and OSS-Fuzz, produce a large amount of crash seeds, which exacerbate this problem. An efficient and automated approach is needed to filter out redundant and duplicated crash test cases and cluster them by the root cause. Given a large number of crash seeds produced by fuzzers, a symbolic tracer can examine these crash seeds, and collect symbolic constraints at the last branch before the crash site that is controlled by certain input bytes. This symbolic constraint signature can be used to cluster crash seeds and filter out duplicates and redundancies. The intuition is that the PoCs that trigger identical bugs are likely to follow identical execute paths, therefore sharing the same path constraints.

The above security application highlights the need for efficiency. In this case, the timeout strategy of SymQEMU is no longer valid: without the timeout, SymQEMU could take hours or days to process crash seeds from large fuzzing farms or respond to new exploits, highlighting the need for a more efficient tool.

To trace symbolic constraints for crash deduplication, it is imperative to disable certain features within SYMQEMU. namely the timeout strategy and the global branch filter. SYMQEMU sets a 90-second timeout on each execution during hybrid fuzzing and adopts a global branch filter to avoid collecting and solving constraints for "uninteresting" branches across executions [23, 24]. While these measures enhance the efficiency in hybrid fuzzing by trading off completeness, crash deduplication demands a more thorough and efficient approach. It requires the tracking of a Proof of Concept (PoC) execution up to the crash site, along with the tracing of all necessary constraints associated with each unique PoC.

To demonstrate the efficacy and efficiency of SYMFIT in crash deduplication, we evaluated SYMQEMU and SYMFIT on the Magma dataset [18], which contains PoCs and ground truth for grouping PoCs. Specifically, we run each PoC and collect symbolic constraints at the last symbolic branch before the crashing site and back-tracing nested constraints that share the same input dependency, i.e., all precedent branches whose input bytes overlap with the last branch. Then we normalize the variable names in constraints since Z3 might use different names to represent sub-constraints across executions. After this, we compare and group together PoCs that have the same normalized symbolic constraints. Then we measured the efficiency by comparing the total runtime and efficacy by comparing the F1 score [29] of deduplication results, following the calculation in Igor [19]. For the ground truth of PoC grouping, we utilize the ground truth data from the magma dataset to identify and categorize PoCs that reach or trigger identical bugs as belonging to the same group. We excluded benchmarks with no crash seeds provided. As presented in Table 7, the number of PoCs is greatly reduced after deduplication, with an average of 80% F1 score. Note that we used a relatively simply method by grouping identical symbolic constraints. While there are rooms for improving the accuracy of crash analysis, SYMFIT shows significant better runtime performance as an efficient symbolic tracer; the constraint collection time is greatly reduced from 19 hours to 2.5 hours

on average, compared to SYMQEMU.

Table 7: Results of crash seed analysis on Magma benchmarks. The column labeled "after dedup." shows the number of PoC clusters grouped using symbolic constraints produced by SYMFIT

Magma	# of PoC	After dedup.	F1 (%)	Execution Time (h)

Average	866	42	80	19.34	2.54

7 Discussion

Comparison of Symbolic Backends. In SYMFIT, we ported the symbolic backend from SymSan and compared it with SymQEMU with QSYM backend. While these two backends are similar in path constraint collection and solving, as they can achieve similar coverage when given the same seed corpus, we observed some differences in branch and basic block filtering. As presented in QSYM [31], basic block pruning is employed to reduce constraints that are repeatedly generated from the same code paths, while SymSan is not shipped with such strategies. Therefore, in the hybrid fuzzing experiments, we observed less coverage growth for some programs.

Overhead of Concolic Executors. In general, the overhead of concolic executors comes from instrumentation, symbolic state management, and constraint solving. In this work, we have brought down the overhead of instrumentation and symbolic state management to near-optimal. Nevertheless, we still observed a significant overhead of constraint solving and dynamic binary translation itself, which overshadow our improvement to some extent. The dynamic binary translator, QEMU, translates the target binary at runtime, and the translated code blocks are cached for a single execution. We believe that in a hybrid fuzzing setting, the performance of dynamic binary translation can be improved by sharing the translation cache among every execution. Moreover, with the recent progress in improving the performance of constraint solving [8, 12, 21, 22], more efficient and scalable concolic execution engines can be achieved.

8 Related Work

Compilation-based Concolic Execution. Recent advances in compilation-based concolic execution (e.g., SymCC [24], SymSan [11]) have been shown to improve the performance of concolic execution significantly. When source code is available, compilation-based instrumentation can benefit from compiler optimizations and high-level semantic information (e.g., type) from the source code. While such approaches are sufficient for testing software with source code available, many real-world scenarios require binary-only testing methods, such as firmware, COTS software, shared libraries, etc. SYMFIT focuses on advancing the state-of-the-art binary concolic executor.

Hybrid Instrumentation for Concolic Execution. SymFusion [14] proposed a hybrid instrumentation strategy to minimize the analysis overhead. In particular, this hybrid instrumentation allows users to perform compilation-based instrumentation on selected components of the application and performs dynamic binary instrumentation for the rest of the application at execution time. As such, it can benefit from the high efficiency of compiler-generated code. However, unlike SYMFIT which automatically determines the instrumentation strategies, SymFusion users have to manually decide which components need what instrumentation strategies.

Alternating Execution Modes. To mitigate performance overhead, some previous works proposed to alternate the execution between heavy-weight and light-weight modes. For example, Firm-AFL [32] boots up the IoT firmware in whole-system emulation and ensure the program to be fuzzed runs properly, then it switches to user-level emulation to gain fast execution speed. Only on rare occasions, the execution is migrated back to the system-mode emulation to ensure the correctness of execution. DECAF++ [15] adopts a similar strategy to speed up whole-system taint tracking. It alternates between a lightweight check mode with minimal instrumentation overhead and a track mode with full taint propagation capability. To avoid memory exhaustion, Mayhem [10] introduces hybrid symbolic execution to actively manage memory usage without constantly re-executing the same instructions. When the system reaches a memory cap, it switches to offline execution mode and produces checkpoints to start new online execution tasks later on.

9 Conclusion

In this work, we propose an efficient concolic execution framework with optimizations for the common case, concrete execution. The evaluation showed that SYMFIT can achieve much better performance compared to state-of-the-art binary concolic executor, SYMQEMU. The fast execution speed translates to faster coverage growth and improved efficiency in security applications such as bug detection and crash deduplication.

Abstract

The Signal protocol and its X3DH key exchange core are regularly used by billions of people in applications like WhatsApp but are unfortunately not quantum-secure. Thus, designing an efficient and post-quantum secure X3DH alternative is paramount. Notably, X3DH supports *asynchronicity*, as parties can immediately derive keys after uploading them to a central server, and *deniability*, allowing parties to plausibly deny having completed key exchange. To satisfy these constraints, existing post-quantum X3DH proposals use ring signatures (or equivalently a form of designated-verifier signatures) to provide authentication without compromising deniability as regular signatures would. Existing ring signature schemes, however, have some drawbacks. Notably, they are not generally proven secure in the quantum random oracle model (QROM) and so the quantum security of parameters that are proposed is unclear and likely weaker than claimed. In addition, they are generally slower than standard primitives like KEMs.

In this work, we propose an efficient, deniable and post-quantum X3DH-like protocol that we call K-Waay, that does *not* rely on ring signatures. At its core, K-Waay uses a split-KEM, a primitive introduced by Brendel et al. [SAC 2020], to provide Diffie-Hellman-like implicit authentication and secrecy guarantees. Along the way, we revisit the formalism of Brendel et al. and identify that additional security properties are required to prove a split-KEM-based protocol secure. We instantiate split-KEM by building a protocol based on the Frodo key exchange protocol relying on the *plain* LWE assumption: our proofs might be of independent interest as we show it satisfies our novel unforgeability and deniability security notions. Finally, we complement our theoretical results by thoroughly benchmarking both K-Waay and existing X3DH protocols. Our results show even when using plain LWE and a conservative choice of parameters that K-Waay is significantly faster than previous work.

1 Introduction

Researchers for several years now have sought to build cryptographic primitives and protocols that are resistant to efficient quantum attacks [58]. This is highly evidenced with the NIST Post-Quantum Cryptography competition for standardising quantum-safe key encapsulation mechanisms (KEM) and signatures, organised by the United States National Institute of Standards and Technology (NIST). Recently, four schemes were selected by NIST for standardisation, out of which three rely on algebraic lattices. Indeed, with the US National Security Agency releasing their new CNSA 2.0 Suite [62], which says that CRYSTALS-Kyber [13] and CRYSTALS-Dilithium [32] should be the main cryptographic force for communication security beginning from 2030, lattices are a natural candidate for building more advanced cryptographic primitives, such as secure messaging.

The widely used Signal protocol for secure messaging as currently deployed is not quantum-safe since it is based on Diffie-Hellman key exchange [30]. The protocol, used in applications like Signal and WhatsApp, comprises two components, namely 1) the X3DH key exchange [50] which is used to bootstrap sessions of 2) the Double Ratchet messaging protocol [54]. The Double Ratchet has been investigated in a line of recent works [4, 10, 18] that each neatly abstract the protocol into primitives like so-called *continuous key agreement*. Fortunately, these primitives have post-quantum (PQ) instantiations that leaves the core structure and resulting security guarantees of the Double Ratchet in place.

In standard X3DH, parties use a mixture of ephemeral (one-time), semi-static (many-time but temporary) and long-term keys. First, parties upload their keying material to a central server or public key infrastructure in a so-called prekey bundle. A party can then derive a session key by downloading their partner's bundle and performing three (or four) Diffie-Hellman key exchanges with a mixture of ephemeral and long-term (resp. plus semi-static) keys, ensuring at least confidentiality if the ephemeral *or* long-term key of each party is corrupted.

Observe that X3DH does not use signatures after signed prekeys are uploaded: at that point, the DH exchanges provide (implicit) authentication guarantees. Consequently, the protocol provides a level of *deniability* [33, 55, 60] as was formalized by Vatandas et al. [63]: informally, a participant can deny having performed key exchange with its counterpart. This is an important privacy guarantee that prevents (at least on a cryptographic level) a conversation transcript from incriminating an unsuspecting party, which is especially pertinent in situations like whistleblowing and protesting.

In May 2023, Signal published code corresponding to their initial *hybrid* post-quantum key exchange solution, namely the "PQXDH protocol".[1] Like in X3DH, several Diffie-Hellman key exchanges are performed at once, but in PQXDH, parties upload prekey bundles that also contain a Kyber-1024 public key that the initiator additionally encapsulates to the responder with. Moreover, prekey bundles are still signed with the same signature scheme as regular X3DH based on Curve25519 [8]. Although PQXDH appears to provide post-quantum confidentiality, which is an important first step towards post-quantum security as it prevents "store-now-decrypt-later" kind of attacks, it does not provide post-quantum *authentication* as an active quantum attacker can trivially forge pre-key bundles. It is thus prudent to design a suitable X3DH alternative that is *fully* post-quantum secure.

A natural direction for building such a protocol is to emulate X3DH's structure by replacing Diffie-Hellman key exchange with a cryptographic group action, such as CSIDH [21]. In order to broadly capture this protocol structure, Brendel et al. [17] introduce a primitive called *split-KEM* that captures the symmetry of e.g. Diffie-Hellman. In a split-KEM, a party A encapsulates to their partner B by using their own secret sk_A and their partner's public key pk_B to produce a ciphertext; B then decapsulates it using sk_B and pk_A. The authors define indistinguishability-based security notions and notice that Frodo [12] lattice-based key-exchange fulfills the split-KEM syntax and the weakest notion of indistinguishability they define.[2] Although they present a X3DH-like protocol, they do not define a security model, and, looking ahead, their split-KEM security notions do not suffice to construct X3DH-like key exchange with authenticity and deniability.

In two recent works, Hashimoto et al. [37, 38] and Brendel et al. [16] concurrently proposed instead to construct X3DH-like key exchange using KEMs directly. Since a core feature of X3DH is its *asynchronicity*, a challenge-response protocol cannot be employed using KEMs alone to provide authentication [57]. Thus to ensure deniability, two seemingly different approaches were proposed: Hashimoto et al. [37] apply ring signatures while Brendel et al. [16] use a flavour of designated verifier signatures; these primitives were later shown to be equivalent [38].

[1] https://signal.org/docs/specifications/pqxdh.

[2] The construction can conceptually be seen as instantiating the lattice-based cryptographic group action from [9].

As described in the aforementioned works, the currently most efficient post-quantum ring signatures [9, 34, 44, 48, 64] are proven to be secure in the random oracle model [7] and can enjoy signatures that are a handful of kilobytes large. Often, however, the constructions do not come with a security proof in the quantum random oracle model (QROM) [11]. In this vein, parameters are generally optimistically chosen as the security loss incurred by proofs in the ROM is not taken into account when setting these, without even mentioning QROM loss, which is usually much larger. Further, security notions can differ between papers, making it less clear exactly when they are appropriate for use.

More generally, it is of interest to determine the cost (or overhead) that deniability incurs in (X3DH-like) key exchange. Towards this goal, Hashimoto et al. [38] provide benchmarks for their baseline, non-deniable X3DH-like protocol based on signatures and KEMs, and Brendel et al. [16] consider parameter sizes for (but do not benchmark) existing ring and designated verifier signatures. As such, a more fine-grained and detailed evaluation will help inform practitioners on the overhead incurred by deniability in the post-quantum setting.

While the use of ring signatures to build PQ and deniable X3DH is at least theoretically understood, this far from exhausts the protocol design space. Motivated by this and the above discussion, we therefore first ask: Can we design a provably-secure, efficient and deniable post-quantum X3DH alternative that does *not* require ring signatures?

1.1 Our Results

In this work, we propose an efficient, deniable and post-quantum X3DH-like protocol without ring signatures that we call K-Waay. To summarise our contributions:

- Towards building our protocol, we revisit the split-KEM formalism proposed by Brendel et al. [17] and deduce that several additional properties, namely notions of authenticity and deniability, are needed to construct a secure X3DH-like deniable authenticated key exchange protocol (DAKE).
- We propose K-Waay, a X3DH-like DAKE that uses deniable and unforgeable split-KEM at its core. Our protocol uses signatures to sign prekeys, and then uses ephemeral KEM, long-term KEM and split-KEM for the final key exchange step.
- The main drawback of a naive version of our protocol is that parties can run out of ephemeral keys, thus making the protocol synchronous if this happens (e.g. Alice needs to wait for Bob's fresh ephemeral key before sending a message). While such a problem would rarely occur in practice, given enough keys are uploaded on the server, we propose a simple trick that makes the

reuse of ephemeral keys possible on the receiver's side for messages they received while offline. We think this trick could be of independent interest as it – perhaps surprisingly – allows for a specific kind of key reuse for a split-KEM that is *not* IND-CCA secure.

- We prove key indistinguishability in our model that captures ephemeral key reuse and session state exposure, and prove a variant of deniability that strengthens the notion of Brendel et al. [16] by additionally leaking the victim's session state to the adversary in the security game.
- We instantiate a post-quantum split-KEM secure under our new security notions derived from the Frodo key exchange protocol (FrodoKEX) [12] based on the plain LWE assumption. We then use a transform in the (Q)ROM to prove it UNF-1KMA (i.e. our new unforgeability definition for split-KEM). This construction incurs a security loss as usual in the (Q)ROM, and we pick conservative parameters such that our split-KEM has 128 (resp. 64) bits of classical (resp. quantum) security if the adversary is limited to $\approx 2^{64}$ queries (resp. $2^{64}/d$ quantum queries) to the random oracle, where d represents the maximal number of distinct participants that can send a message to a given receiver while the latter is offline. In other words, our parameters take into account the loss due to the (Q)ROM proof.
- We benchmark our protocol K-Waay using our modified version of FrodoKEX (which we call FrodoKEX+) as the split-KEM, along with standard X3DH and the two previous proposals for PQ X3DH-like AKE [16, 38]. We find that while K-Waay has larger prekeys, it is 6× faster compared to these. In addition, the only non-standard primitive we use in K-Waay (i.e. FrodoKEX+) is based on both an assumption (i.e. LWE) and a scheme (FrodoKEM) that have been thoroughly scrutinized by the cryptographic community. Overall, we believe our protocol more mature for short to medium-term integration compared to previous work based on ring signatures.

1.2 Technical Overview

1.2.1 X3DH-like key exchange.

A quantum-secure X3DH-like protocol should satisfy certain properties. Apart from satisfying standard authenticated key exchange (AKE) properties like secrecy and authentication, it should also be *asynchronous*. That is, parties should be able to upload keying material to a central server, after which an initiating party can derive a session key immediately with their counterpart who may be offline. This also entails *receiver-obliviousness*, using the language of Hashimoto et al. [38], as the initial key upload should not depend on the keys of any other party. Another is *deniability*, allowing parties to claim that they plausibly did not participate in the key exchange. Note that we cannot possibly ensure that parties can claim that they never uploaded prekeys as they are signed (and using ring signatures, e.g., would violate receiver-obliviousness). Finally, a DAKE should, like X3DH, provides security guarantees even if the session state of a party is leaked.

1.2.2 Revisiting split-KEM.

In an attempt to model the primitive central to X3DH-like AKE, Brendel et al. [17] introduced *split-KEM*, which is similar to a standard KEM except the encapsulator can contribute to the derived key. However, we discovered that the accompanying security definitions were not sufficient to use such a primitive as the main component of a KE. The reason being that their notions ensure that an encapsulated ciphertext will not leak information on its encapsulated key, but not that only the sender can send a "legitimate" ciphertext to the sender (or that only the sender and receiver can derive a common key). In other words, there is no guarantee of implicit authentication. Therefore, we introduce the notion of unforgeability against one known-message attacks for split-KEM (UNF-1KMA), which states that if Bob receives a message allegedly sent by Alice, either Alice really sent it or the decapsulation will fail. Jumping ahead, this will be used in the security proof of the protocol to argue that either the adversary relayed a legit split-KEM ciphertext to the receiver that the adversary cannot learn the decapsulation of, or the sender aborts as the ciphertext is forged.

We also introduce an intermediary notion of decaps-OW-CPA, which says that an adversary should not be able to recover a key *decapsulated* by some party without knowing the sender's or the receiver's secret key. We will prove that our lattice-based split-KEM satisfies such a definition, then we will apply some transform in the (Q)ROM to obtain a UNF-1KMA split-KEM.

Finally, we also define the notion of deniability for split-KEM, which states that no party J can be convinced that a party A sent a given ciphertext to B, even knowing B's secret key but assuming both parties did not deviate from the protocol. This models a setting where B communicates with A and later tries to frame the latter by giving the transcript and their own secret key to J.

1.2.3 Construction.

As any X3DH-like protocol, our construction works in 4 phases: long-term key generation, prekey generation, send and receive. The first observation we make is that in X3DH implementation, prekey bundles are signed with a long-term signing key before being uploaded to the server. This fact is often abstracted away in formal analysis as it hurts the claims one can make about the deniability of X3DH: as a signature is undeniable by definition, users cannot deny they *participated*

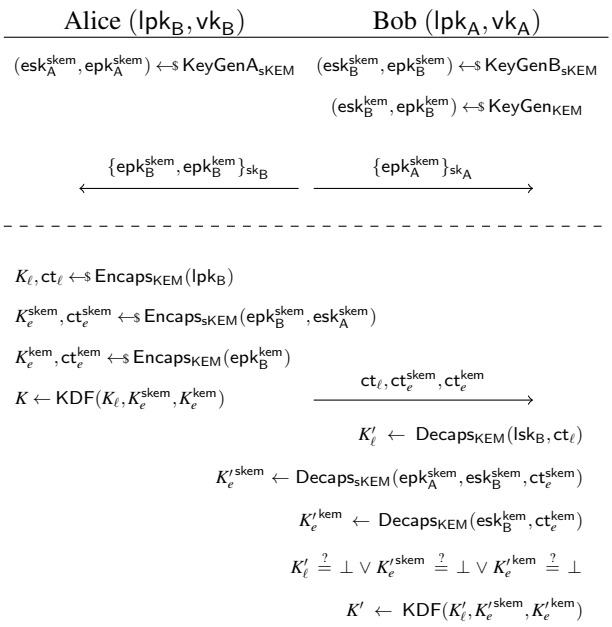

Figure 1: High-level overview of the K-Waay protocol. Values in brackets $\{\cdot\}_{\mathsf{sk}}$ are signed with sk and the signature is verified upon reception. For clarity, we omit the calculation and addition of session identifier sid to KDF.

in the protocol. Based on this, our goal was to achieve some level of peer-deniability [26], where parties can deny they communicated with someone in particular, and to leverage the fact that we use signatures to authenticate the prekeys. Our protocol works then as follows (see Figure 1 for a high-level overview). The long-term key pair consists of a KEM and signature key pair, the latter being used to sign the prekey, which comprises an ephemeral KEM key pair and ephemeral split-KEM key pair. The former is used for forward secrecy while the second is used for the implicit authentication of the sender. Although usually ephemeral keys cannot be used for authentication as they are dynamic, in our case we can since they are authenticated (i.e. signed) by their owner. Then, the sender encapsulates against both KEM public keys of the receiver, and uses their own split-KEM secret key and the receiver's public key to derive a split-KEM ciphertext. Upon decapsulation, the receiver recovers the three keys and combines them using a PRF to derive the shared key.

Ephemeral split-KEM key reuse. The way our protocol is described above works perfectly well if the split-KEM satisfies the UNF-1KMA unforgeability notion introduced above. However, in practice, it could happen that some party (e.g. Bob) is offline for too long and all their ephemeral split-KEM keys have been used. If that occurs, another sender would have to wait for Bob to come online and upload new keys before they can send him a message.

We fix this issue by modifying the protocol as follows: when Bob's ephemeral public keys have run out on the server, a sender can simply reuse one of them. Then, when Bob is back online, he groups the ciphertexts corresponding to the same public-key and decrypts all ciphertexts in a group *at once*. If one or more of the decapsulations in a group fails, Bob outputs $\perp$ for *all* ciphertexts and e.g., restarts the protocol. Otherwise, Bob proceeds as before (and *never* decapsulates again using the same split-KEM key). We formally model this key reuse with an algorithm BatchReceive that takes as input a given session state and one or more messages to be received.

Security. We show this version of the protocol is secure assuming the split-KEM satisfies a stronger notion than IND-CPA that we call IND-1BatchCCA. This definition is the same as traditional IND-CPA (adapted to the split-KEM syntax), except the adversary can query a decapsulation oracle *once* with multiple public keys and ciphertexts, and the oracle returns $\perp$ if *one or more* of the decapsulations failed, and the resulting keys otherwise. We show that one can easily build an IND-1BatchCCA split-KEM out of a CPA secure one in the (Q)ROM, conveniently using the same transform mentioned above that builds a UNF-1KMA scheme out of a decaps-OW-CPA one.

As in previous protocols [16, 38], the long-term KEM provides implicit authentication of the receiver as only they can decrypt. As mentioned above, the ephemeral KEM provides forward secrecy, and the UNF-1KMA/IND-1BatchCCA split-KEM provides implicit authentication of the sender, as it guarantees that only the sender could have sent a ciphertext that correctly decapsulates (unforgeability), and no adversary knows what is inside that ciphertext (indistinguishability), even after seeing the decapsulation of one batch of ciphertexts encapsulated against the same public-key (if all decapsulated correctly). We note that the sender-to-receiver authentication depends both on a long-term key (i.e. the signing key) and an ephemeral one (the split-KEM key). Consequently, our model (that allows session state exposure) is more restrictive than that of Hashimoto et al. [38], since in particular it suffices for the adversary to learn a receiver's ephemeral state during key exchange to forge a message that the receiver accepts. Intuitively, this is because split-KEM is effectively a symmetric primitive. Nevertheless, the security that we achieve is stronger than weak forward security without session state exposure.

Deniable split-KEM from lattices. We provide the first lattice-based split-KEM which satisfies both deniability and UNF-1KMA security. Our starting point is the Frodo key-exchange (FrodoKEX) [12], which was identified (among other schemes) as a split-KEM by Brendel et al. [17], the security of which relies on the well-known Learning with Errors (LWE) problem [56]. We highlight that the vanilla

construction of FrodoKEX does not enjoy the aforementioned properties. Indeed, when looking closely at the security games of deniability and UNF-1KMA, partial information about the secret keys are revealed - thus making a reduction to LWE completely non-trivial[3]. We circumvent this problem in two ways.

First, we reduce deniability of our scheme to a so-called Extended-LWE problem [2], where in addition to a standard LWE instance, the adversary is given a short random combination of the secret coefficients. We show that deniability of our scheme reduces straightforwardly to Extended-LWE, and then follow the methodology of Alperin-Sheriff and Peikert [2] to reduce it further to plain LWE.

Towards UNF-1KMA security, we slightly modify the Frodo split-KEM by introducing masking terms. As the name suggests, they are used to hide the partial information about secret keys. Consequently, this enables us to simulate the decapsulation mechanism via rejection sampling [47]. In Section 5.2 we discuss the necessity of these (seemingly artificial) changes.

1.3 Additional Related Work

The security of X3DH has been modelled in detail by Cohn-Gordon et al. [22]. Vatandas et al. [63] investigate the deniability of X3DH and similar key exchange protocols under the deniability notion of Di Raimondo et al. [55], requiring strong knowledge-of-exponent-type assumptions to prove X3DH secure. Dobson and Galbraith [31] propose a SIDH-based X3DH-like protocol which is unfortunately now broken [20]. Very recently, [40] prove X3DH tightly-secure in the generic group model under a new multi-user assumption although do not allow the adversary to expose parties' session states.

Unger and Goldberg build a number of different DAKEs [60, 61]. However, the protocols do not provide post-quantum guarantees: only in their later paper [61] is it suggested to add a PQ KEM for post-quantum *confidentiality* and the authors do not propose a more comprehensive hybrid protocol. Nevertheless, the protocols provide relatively strong online deniability (i.e. where a judge and a party can communicate while trying to frame another party) at the expense of stronger primitives like dual-receiver encryption and non-committing encryption.

Alwen et al. [3] define the notion of authenticated key encapsulation mechanism (AKEM) and some security definitions. AKEM captures the same primitive as a split-KEM, but we opted for the syntax and language of the latter as it was meant to be used in a X3DH-like protocol.

Cremers and Feltz [26] introduce peer deniability, which captures the kind of participation deniability property we are after in this paper, namely that a party cannot deny using a system but can deny communicating with a particular party. However, their security notion does not require the simulator to output the session key and the adversary to distinguish between the real and simulated key, and so composability issues may arise from using it.

[3] Nevertheless, we found no deniability/UNF-1KMA attack on [17].

2 Preliminaries

In this work, we denote by *efficient* adversary a probabilistic polynomial-time or quantum polynomial-time algorithm unless otherwise specified. Let $[n] = \{1, \ldots, n\}$, i.e. the set of integers between 1 and n.

2.1 Triple PRF

We first define the notion of a triple PRF, a natural generalisation of a dual PRF:

Definition 2.1 (Triple PRF)**.** *Let $F : \mathcal{K} \times \mathcal{K} \times \mathcal{K} \times D \to R$ be a function. We consider the game shown in Figure 2. We say that F is* 3PRF *if for all efficient adversaries, we have:*

$$\mathsf{Adv}^{\mathrm{3prf}}_{F}(\mathcal{A}) := \max_{i \in \{1,2,3\}} \left| \Pr\left[\mathrm{PRF}_{F_i}(\mathcal{A}) \Rightarrow 1\right] - \frac{1}{2} \right| = \mathsf{negl}\,.$$

where F_i denotes F keyed in its i-th argument for $i \in \{1,2,3\}$.

Note that the notion of a triple PRF generalises the now common notion of a *dual PRF* [6]. A triple PRF F_{triple} can be trivially constructed in the random oracle model, or from a dual PRF F_{dual} as $F_{triple}(k_1,k_2,k_3,x) = F_{dual}(k_1, F_{dual}(k_2,k_3,x),x)$.

$\mathrm{PRF}_F(\mathcal{A})$	$\mathrm{PRF}(a,b,c)$
Sample random function G	**if** $b = 0$
$k \leftarrow\$ \mathcal{K}$	**return** $F_k(a,b,c)$
$b \leftarrow\$ \{0,1\}$	**else**
$b' \leftarrow\$ \mathcal{A}^{\mathrm{PRF}}(1^\lambda)$	**return** $G(a,b,c)$
return $1_{b'=b}$	

Figure 2: PRF game for function F_k taking three arguments as input.

2.2 Split-KEM

We next define split-KEM, which was introduced by Brendel et al. [17].

Definition 2.2 (Split-KEM)**.** *A split-KEM* sKEM *is a tuple of four efficient algorithms* $(\mathsf{KeyGenA}, \mathsf{KeyGenB}, \mathsf{Encaps}, \mathsf{Decaps})$ *defined as follows:*

- $(\mathsf{pk_A}, \mathsf{sk_A}) \leftarrow\$ \mathsf{KeyGenA}(1^\lambda)$ *(resp.* $(\mathsf{pk_B}, \mathsf{sk_B}) \leftarrow\$ \mathsf{KeyGenB}(1^\lambda)$*): The key generation function of the first/second party takes the security parameter λ as input, and outputs a pair of public/secret keys* $(\mathsf{pk_A}, \mathsf{sk_A})$ *(resp.* $(\mathsf{pk_B}, \mathsf{sk_B})$*).*

- $K, \mathsf{ct} \leftarrow\!\$\ \mathsf{Encaps}(\mathsf{pk}_{\mathcal{P}}, \mathsf{sk}_{\overline{\mathcal{P}}})$*: The encapsulation function takes the public key* $\mathsf{pk}_{\mathcal{P}}$ *of a party* $\mathcal{P} \in \{\mathsf{A}, \mathsf{B}\}$ *and the other party's secret key* $\mathsf{sk}_{\overline{\mathcal{P}}}$ *as inputs, and outputs a ciphertext* ct *and a key* K*.*
- $K/\perp \leftarrow \mathsf{Decaps}(\mathsf{pk}_{\overline{\mathcal{P}}}, \mathsf{sk}_{\mathcal{P}}, \mathsf{ct})$*: The decapsulation function takes the secret key* $\mathsf{sk}_{\mathcal{P}}$ *of a party* $\mathcal{P} \in \{\mathsf{A}, \mathsf{B}\}$*, the other party's public key* $\mathsf{pk}_{\overline{\mathcal{P}}}$ *and a ciphertext* ct *as inputs, and outputs a key* K *or the error symbol* $\perp$*.*

Finally, we say a split-KEM is $(1-\delta)$*-correct if*

$$\Pr\left[K \neq K' : \begin{array}{c}(\mathsf{pk}_\mathsf{A}, \mathsf{sk}_\mathsf{A}) \leftarrow\!\$\ \mathsf{KeyGenA}(1^\lambda);\\ (\mathsf{pk}_\mathsf{B}, \mathsf{sk}_\mathsf{B}) \leftarrow\!\$\ \mathsf{KeyGenB}(1^\lambda);\\ K, \mathsf{ct} \leftarrow\!\$\ \mathsf{Encaps}(\mathsf{pk}_\mathsf{B}, \mathsf{sk}_\mathsf{A});\\ K' \leftarrow \mathsf{Decaps}(\mathsf{pk}_\mathsf{A}, \mathsf{sk}_\mathsf{B}, \mathsf{ct})\end{array}\right] \leq \delta\,.$$

Intuitively, a split-KEM is similar to a normal KEM except material from both participants is used for encapsulation (i.e. the final key will depend on both parties' secret/public keys). In a X3DH-like protocol, it can be used to implicitly authenticate the party encapsulating. For security, we first define one-wayness (OW-CPA) for sKEM, which is very similar to the usual one for KEM and another new notion called IND-1BatchCCA. Looking ahead, we will show that any OW-CPA split-KEM can easily be transformed into a IND-1BatchCCA one.

Definition 2.3 (split-KEM OW-CPA)**.** *We consider the* OW-CPA *game defined in Fig. 3. A split-KEM scheme* $\mathsf{sKEM} = (\mathsf{KeyGen}_\mathsf{A}, \mathsf{KeyGenB}, \mathsf{Encaps}, \mathsf{Decaps})$ *is* OW-CPA *if for any efficient adversary* $\mathcal{A}$ *we have*

$$\mathsf{Adv}^{\text{ow-cpa}}_{\mathsf{sKEM}}(\mathcal{A}) = \Pr\left[\text{OW-CPA}_{\mathsf{sKEM}}(\mathcal{A}) \Rightarrow 1\right] = \mathsf{negl}\,.$$

A split-KEM scheme over* $\mathcal{K}$ $\mathsf{sKEM} = (\mathsf{KeyGen}_\mathsf{A}, \mathsf{KeyGenB}, \mathsf{Encaps}, \mathsf{Decaps})$ *is* IND-1BatchCCA *if for any efficient adversary* $\mathcal{A}$ *we have*

$$\mathsf{Adv}^{\text{ind-1batchcca}}_{\mathsf{sKEM}}(\mathcal{A}) := \left|\Pr\left[\text{IND-1BatchCCA}_{\mathsf{sKEM}}(\mathcal{A}) \Rightarrow 1\right] - \tfrac{1}{2}\right| = \mathsf{negl}\,.$$

On the original split-KEM security. In the original work on split-KEM by Brendel et al. [17], the authors defined several indistinguishability notions meant to capture which level of security a split-KEM should achieve in order to be used as part of a X3DH-like key exchange. This goes from nn-IND-CCA security, which is the same as IND-CPA security for split-KEM, to mm-IND-CCA security (equivalent to some kind of IND-CCA security). Many intermediary notions of the form xy-IND-CCA, $\mathrm{x}, \mathrm{y} \in \{\mathrm{n}, \mathrm{s}, \mathrm{m}\}$ were also defined, where x (resp. y) specifies the number of queries an adversary can make to the decapsulation (resp. encapsulation) oracle (i.e. none, single, or many). We refer the reader to the original work on split-KEM [17] or the full version of this paper [25] for the formal definitions.

return $1_{K'=K^*}$

Figure 3: IND-1BatchCCA and OW-CPA games.

We recall that the advantage of split-KEMs over normal KEMs is that they capture the fact that the party encapsulating can contribute towards the shared key, whereas it is not the case with KEMs, as the encapsulation function only takes the receiving party's public key as input. In particular, this means that KEMs cannot be used for implicit authentication of the encapsulator, unlike split-KEMs. However, we argue that the original xy-IND-CCA definitions for split-KEMs [17] do not capture implicit authentication either and thus are not suited for their purpose (i.e. building an asynchronous DAKE). In fact, any IND-CPA (resp. IND-CCA) KEM can be seen as an (asymmetric) split-KEM satisfying IND-CPA (resp. mm-IND-CCA), where the sender's pair of key is set to $(\perp, \perp)$ and encapsulation is done using only the receiver's public key.

More formally, imagine a setting where Alice and Bob know each other's public key, and Alice wants to implicitly authenticate to Bob using a split-KEM. In addition, we assume a mm-IND-CCA split-KEM sKEM_0 exists (note mm-IND-CCA security is the strongest so this holds for all weaker notions). We first modify sKEM_0 s.t. on a special ciphertext $\mathsf{ct}^\star$ not in the original ciphertext space, Decaps returns a constant key $K^\star$. Let's call this modified scheme sKEM. We observe that sKEM is still mm-IND-CCA secure as no adversary can break an honestly-generated challenge ciphertext. Now, implicit authentication means that if Bob decapsulates a ciphertext and obtains a key K, then only Alice knows K. However, in our case, any adversary can send $\mathsf{ct}^\star$ to Bob and set their own key to $K^\star$. Both the adversary and Bob will share the same key and implicit authentication does not hold. In a way, xy-IND-CCA security does not prevent forgery.

This leads us to define our notion of UNF-1KMA security for split-KEMs below which, along with OW-CPA (which can be turned into IND-1BatchCCA), guarantees that only

$\underline{\text{UNF-1KMA}_{\mathsf{sKEM}}(\mathcal{A})}$

return b

Figure 5: Deniability game (we assume w.l.o.g. that B encapsulates and A simulates).

Alice (and obviously Bob) can know the result of Bob's decapsulation on some ciphertext. More precisely, UNF-1KMA ensures that no adversary can forge a valid split-KEM ciphertext when knowing a (distinct) legitimate one. We also define a security notion called decaps-OW-CPA that will serve as a building block to build UNF-1KMA. This notion ensures that it is hard for an adversary knowing one legitimate ciphertext ct to come up with a ciphertext ct' (possibly equal to ct) and a key K' s.t. the decapsulation of ct' returns K'.

Definition 2.5 (split-KEM UNF-1KMA)**.** *We consider the* UNF-1KMA *game defined in Fig. 4. A split-KEM scheme* $\mathsf{sKEM} = (\mathsf{KeyGen_A}, \mathsf{KeyGenB}, \mathsf{Encaps}, \mathsf{Decaps})$ *is* UNF-1KMA *if for any efficient adversary* $\mathcal{A}$ *we have*

$$\mathsf{Adv}^{\text{unf-1kma}}_{\mathsf{sKEM}}(\mathcal{A}) := \Pr\left[\text{UNF-1KMA}_{\mathsf{sKEM}}(\mathcal{A}) \Rightarrow 1\right] = \mathsf{negl}\ .$$

Definition 2.6 (split-KEM decaps-OW-CPA)**.** *We consider the* decaps-OW-CPA *game defined in Fig. 4. A split-KEM scheme* $\mathsf{sKEM} = (\mathsf{KeyGen_A}, \mathsf{KeyGenB}, \mathsf{Encaps}, \mathsf{Decaps})$ *is* decaps-OW-CPA *if for any efficient adversary* $\mathcal{A}$ *we have*

$$\mathsf{Adv}^{\text{decaps-ow-cpa}}_{\mathsf{sKEM}}(\mathcal{A}) := \left|\Pr\left[\text{decaps-OW-CPA}_{\mathsf{sKEM}}(\mathcal{A}) \Rightarrow 1\right] - \tfrac{1}{2}\right| = \mathsf{negl}\ .$$

2.3 Deniability

We state here the notion of split-KEM deniability we would like to achieve.

Definition 2.7 (Deniability)**.** *We consider the game shown in Figure 5. We say a split-KEM* sKEM *is* DENY *if there exists a simulator* Sim *s.t. for all efficient adversaries* $\mathcal{A}$*, we have*

$$\mathsf{Adv}^{\text{deny}}_{\mathsf{sKEM},\mathsf{Sim}}(\mathcal{A}) := \Big|\Pr\left[\text{DENY}^{\mathsf{REAL}}_{\mathsf{sKEM},\mathsf{Sim}}(\mathcal{A}) \Rightarrow 1\right] - \Pr\left[\text{DENY}^{\mathsf{SIM}}_{\mathsf{sKEM},\mathsf{Sim}}(\mathcal{A}) \Rightarrow 1\right]\Big| = \mathsf{negl}\ .$$

Note that for the sake of simplicity, we define deniability with respect to B *encapsulating. The other case (i.e.* A *encapsulates) follows by symmetry.*

Informally, the setting considered is the following. Alice and Bob use the split-KEM to establish a shared key (we assume the public keys are only used for this one exchange), and Alice (while following the protocol) wants to frame Bob and prove that he did communicate with her. Therefore, after receiving Bob's ciphertext and deriving the key, Alice gives both public keys, the derived key, the ciphertext and her own secret key to a judge (i.e. the adversary) that must decide whether Bob actually sent the ciphertext that was used to derive the key or not. The scheme is deniable if there is a simulator that, given Alice's view, outputs a ciphertext and a key indistinguishable from the ones output by Bob.

2.4 Model for DAKE

We next describe our model for deniable authenticated key exchange (DAKE) that we tailor to the semantics and flow of X3DH.

Syntax. A DAKE DAKE is a tuple of four efficient algorithms $(\mathsf{KeyGen}, \mathsf{Init}, \mathsf{Send}, \mathsf{BatchReceive})$ defined as follows:

- $(\mathsf{pk}, \mathsf{sk}) \leftarrow\!\$\ \mathsf{KeyGen}(1^\lambda)$. This function takes as input the security parameter λ and outputs the long-term public/secret key pair of the caller.
- $(\mathsf{st}_i, \mathsf{prek}_i) \leftarrow\!\$\ \mathsf{Init}(\mathsf{sk}_i, \mathsf{role})$. This function takes as input a long-term secret key sk_i and a role $\mathsf{role} \in \{\mathsf{sender}, \mathsf{receiver}\}$ and outputs a session state st_i and a prekey bundle prek_i. This function models the creation of key material that will be uploaded to the public key infrastructure by both parties (e.g. the prekey bundle in X3DH). The output values depend only on the public key of party i executing the function.
- $(\mathsf{k}, m) \leftarrow\!\$\ \mathsf{Send}(\mathsf{sk}_i, \mathsf{pk}_j, \mathsf{st}_i, \mathsf{prek}_j)$. This function takes as inputs the secret key of the executing party i, the public key of the intended recipient pk_j, party i's session state st_i and the (claimed) prekey bundle of the intended recipient prek_j, and outputs a key k and a message m.
- $\{k_s\}_s \leftarrow\!\$\ \mathsf{BatchReceive}(\mathsf{sk}_i, \mathsf{st}_i, \{\mathsf{pk}_j, \mathsf{prek}_j, m_j\}_j)$. This function takes as inputs the secret key of the executing party i, an ephemeral state of party i st_i and a vector of size $d \geq 1$ of the form $(\mathsf{pk}_j, \mathsf{prek}_j, m_j)$ for party i's session with the public key of the (claimed) sender pk_j,

party i's session state st_i, the (claimed) prekey bundle of party j prek_j and a message m_j, and outputs a vector of d keys $(\mathsf{k}_1,\ldots,\mathsf{k}_d)$, some or all of which can be $\perp$.

Init explicitly captures parties uploading ephemeral keys to a central server in the first protocol step. This contrasts with the formal modelling in some previous works on X3DH-like key exchange [16, 38] that formally model a three-move key exchange with a single initiator. As Init is independent of keying material from the caller's counterpart, our definition captures so-called *receiver obliviousness* [38] (sometimes *post-specified peers* [19]), corresponding to some, but not all, key exchange protocols in the literature.

The most novel part of our primitive is BatchReceive which in particular captures ephemeral key reuse when uploaded ephemeral keys are exhausted. In the case of key exhaustion, when a party comes back online, they execute BatchReceive several times, where the number of inputs of the form $(\mathsf{pk}_j,\mathsf{prek}_j,m_j)$ in a given BatchReceive call corresponds to how many times ephemeral state st_i is re-used. Otherwise, BatchReceive can be used as one would expect with a single value $(\mathsf{pk}_j,\mathsf{prek}_j,m_j)$ as input.

Security. Due to space limitations and its similarity with previous work [16, 38], we defer a formal description of our key indistinguishability game and some discussion to the full version [25]. We nevertheless define security and discuss its core features below.

Definition 2.8 (DAKE key indistinguishability)**.** *We consider the KIND game described below. We say a DAKE* DAKE *is* KIND *if for all efficient adversaries $\mathcal{A}$ and polynomially-bounded n (the total number of parties), we have*

$$\mathsf{Adv}^{\mathrm{kind}}_{\mathsf{DAKE},n}(\mathcal{A}) := \left|\Pr[\mathrm{KIND}^{n}_{\mathsf{DAKE}}(\mathcal{A}) \Rightarrow 1] - \frac{1}{2}\right| = \mathsf{negl}\,.$$

The KIND game proceeds in two phases in which the adversary drives the execution of several parties, each of which can be executing several concurrent instances of the DAKE. In the first phase, the adversary $\mathcal{A}$ is given access to several oracles, including EXEC (driving protocol execution and including message injection), LTK (for long-term key reveals), REGISTER (for adversarial public key registration), STATE (for ephemeral state exposure) and KEY (for session key exposure). At the end of the first phase, $\mathcal{A}$ makes a TEST query with respect to some session key output by either the sender or receiver, which outputs either the correct session key or a key uniformly sampled by the challenger. In the second phase, the adversary continues to make oracle queries, and finally outputs a guess as to whether the key is real or random.

Apart from the fact we make several extensions to typical AKE modelling to capture BatchReceive, the game is closest to that of Hashimoto et al. [38] except that we additionally enforce correctness checks as done by Brendel et al. [16]. To capture partnering, we consider partner and key identifiers that may be *vectors* for a receiver, such that several sender sessions may be partnered with a receiver session if, for a given sender session, it partners with a part or component of the receiver session. We do not capture semi-static keys explicitly as Brendel et al. [16] do, although in principle they could be captured in Init. We note in particular that our model captures session state exposure, unlike that of Brendel et al. Note that for BatchReceive which can output several keys, just one of the output keys are tested.

$\mathrm{DENY}^{exp}_{\mathsf{DAKE},n,\mathsf{Sim}}(\mathcal{A})$

$b \leftarrow\$ \{0,1\}$
$L \leftarrow \emptyset$
for $i \in [n]$
  $(\mathsf{pk}_i,\mathsf{sk}_i) \leftarrow\$ \mathsf{KeyGen}(1^\lambda)$
  $L \leftarrow L \cup \{(\mathsf{pk}_i,\mathsf{sk}_i)\}$
$b' \leftarrow\$ \mathcal{A}^{\mathrm{CHAL}}(L)$
return $1_{b'=b}$

$\mathrm{CHAL}(s,r)$

require $s \in [n] \wedge r \in [n]$
$(k,m) \leftarrow (\perp,\perp)$
$(\mathsf{st}_s,\mathsf{prek}_s) \leftarrow\$ \mathsf{Init}(\mathsf{sk}_s,\mathsf{sender})$
$(\mathsf{st}_r,\mathsf{prek}_r) \leftarrow\$ \mathsf{Init}(\mathsf{sk}_r,\mathsf{receiver})$
if $b=0$: $(\mathsf{k},m) \leftarrow\$ \mathsf{Send}(\mathsf{sk}_s,\mathsf{pk}_r,\mathsf{st}_s,\mathsf{prek}_r)$
else : $(\mathsf{k},m) \leftarrow\$ \mathsf{Sim}(\mathsf{sk}_r,\mathsf{pk}_s,\mathsf{st}_r,\mathsf{prek}_s,\mathsf{prek}_r)$
$T \leftarrow (\mathsf{prek}_s,\mathsf{prek}_r,m)$
if $exp = \mathsf{true}$: **return** $(\mathsf{k},T,\mathsf{st}_r)$
else return (k,T)

Figure 6: Deniability game.

Trivial attacks. We restrict the adversary's behaviour to prevent 'trivial' attacks (e.g. directly revealing the challenge key) by defining *freshness* predicates. Due to our protocol's design, our notion restricts more than the full forward security notion under session state exposure defined by Hashimoto et al. [38]. Our freshness predicates imply weak forward secrecy and implicit authentication given session state exposure is not allowed (enforced in some recent works [5, 23]). Brendel et al.'s model provide these guarantees but additionally protect against randomness exposure [16]: the standard NAXOS trick [42] can be applied to our protocol to mitigate this attack vector.

2.5 Deniability

We next introduce our security notion for a deniable DAKE. To this end, we introduce security game $\mathrm{DENY}^{exp}_{\mathsf{DAKE},\mathsf{Sim}}$ in Figure 6.

Definition 2.9 (DAKE deniability)**.** *We consider the game shown in Figure 6. We say a DAKE* DAKE *is* DENY^{exp} *for $exp \in \{\mathsf{true},\mathsf{false}\}$ if there exists an efficient simulator* Sim *s.t. for all efficient adversaries $\mathcal{A}$ and polynomially-bounded n, we have*

$$\mathsf{Adv}^{\mathrm{deny}}_{\mathsf{DAKE},\mathsf{Sim},\mathsf{exp}}(\mathcal{A}) := \left|\Pr[\mathrm{DENY}^{exp}_{\mathsf{DAKE},n,\mathsf{Sim}}(\mathcal{A}) \Rightarrow 1] - \frac{1}{2}\right| = \mathsf{negl}\,.$$

Our definition captures the following deniability property. Initially, the judge $\mathcal{A}$ is given the long-term keys of all parties.

$\mathcal{A}$ then observes honest protocol runs between pairs of parties (via CHAL). Depending on the challenge bit b, either Send or a simulator Sim that takes as input the secret keying material of the receiver trying to frame the sender is executed in each run. Moreover, $\mathcal{A}$ is given the prekey messages independent of b and, if the parameter exp is set to true, also the session state of the receiver in each protocol run. The goal of the adversary is to distinguish whether Send or Sim is being called.

Our notion DENY$^{\mathsf{false}}$ corresponds most closely with that of Brendel et al. [16] which was also adopted by Cremers and Zhao [27]. Due to their AKE syntax, they also consider semi-static key pairs which are also given to the adversary. DENY$^{\mathsf{true}}$ provides stronger deniability, corresponding in practice to a receiver who co-operates with a judge by handing over the entire contents of e.g. their phone. Although incomparable formally, our DAKE would not be considered deniable under a notion like that of Brendel et al. [16] since their protocols do not formally model long-term signatures. Finally, note that our definition, like Brendel et al.'s, can be straightforwardly converted to a 'simulation-based' notion like Definition 2.7.

3 K-Waay: Post-Quantum X3DH from Split-KEM

We present our DAKE K-Waay (Key-exchange With asynchrony, authentication and peer-deniability) in Figure 7.

Each party is associated with a long-term public/secret key pair which in K-Waay comprises of a signature and KEM key pair generated in KeyGen. In Init, ephemeral KEM and split-KEM keys for both parties are generated and the public keys are signed with the long-term signature key.

After initialisation, the sender P_i (sometimes initiator) invokes Send that takes the prekey prek_j output by the receiver P_j's Init call as input. After verifying the signature in prek_j, P_i encapsulates to 1) the long-term KEM key of P_j; 2) the ephemeral KEM key contained in prek_j; and 3) the ephemeral split-KEM key contained in prek_j. Note that the split-KEM provides implicit authentication (without it, Send could be simulated without secrets). P_i then combines the keys using a KDF and outputs the key and its message for P_j consisting of the three encapsulation ciphertexts. Receiving is analogous: receiver P_i verifies P_j's prekey, decapsulates using its three respective secret keys and derives the session key. If P_i's prekeys have run out, it is possible that multiple P_j's have sent using the same prekey prek_i. In that case, P_i decapsulates for all sessions using the same secret keys but aborts if *any* split-KEM decapsulation failed in *any* of the session.

3.1 Security

Theorem 1. *Consider* $(1-\delta_{\mathsf{EKEM}})$*-correct* IND-CCA KEM EKEM, $(1-\delta_{\mathsf{LKEM}})$*-correct* IND-CCA *KEM* LKEM, $(1-\delta_{\mathsf{Sig}})$*-correct* SUF-CMA *signature scheme* Sig *and* $(1-\delta_{\mathsf{sKEM}})$*-correct* IND-1BatchCCA, UNF-1KMA *split-KEM* sKEM *and* 3PRF KDF *used to build K-Waay (Figure 7). Then, we have that for every efficient adversary* $\mathcal{A}$ *that makes at most* q *oracle queries, one can build an adversary* $\mathcal{B}$ *such that*

$$\mathsf{Adv}^{\mathsf{kind}}_{\mathsf{K\text{-}Waay}}(\mathcal{A}) \leq \frac{q}{4}\cdot\left(\delta_{\mathsf{Sig}}+\delta_{\mathsf{LKEM}}+\delta_{\mathsf{EKEM}}+\delta_{\mathsf{sKEM}}\right) + q^2\cdot\left(\varepsilon_{\mathsf{EKEM}}+\varepsilon_{\mathsf{LKEM}}+2\varepsilon_{\mathsf{KDF}}+2\varepsilon_{\mathsf{Sig}}\right) + q^3\cdot\left(\varepsilon_{\mathsf{EKEM}}+\varepsilon_{\mathsf{LKEM}}+\varepsilon_{\mathsf{sKEM}}+3\varepsilon_{\mathsf{KDF}}\right),$$

where $\varepsilon_{\mathsf{EKEM}} = \mathsf{Adv}^{\text{ind-cca}}_{\mathsf{EKEM}}(\mathcal{B})$, $\varepsilon_{\mathsf{LKEM}} = \mathsf{Adv}^{\text{ind-cca}}_{\mathsf{LKEM}}(\mathcal{B})$, $\varepsilon_{\mathsf{Sig}} = \mathsf{Adv}^{\text{suf-cma}}_{\mathsf{Sig}}(\mathcal{B})$, $\varepsilon_{\mathsf{sKEM}} = \mathsf{Adv}^{\text{ind-1batchcca}}_{\mathsf{sKEM}}(\mathcal{B}) + \mathsf{Adv}^{\text{unf-1kma}}_{\mathsf{sKEM}}(\mathcal{B})$ *and* $\varepsilon_{\mathsf{KDF}} = \mathsf{Adv}^{\text{3prf}}_{\mathsf{KDF}}(\mathcal{B})$.

Proof. We defer the proof to the full version [25]. At a high level, we first argue protocol correctness by invoking the correctness of the underlying primitives. Then, we partition the adversary's behaviour into three classes, depending on whether 1) the test session is partnered; 2) it is unpartnered

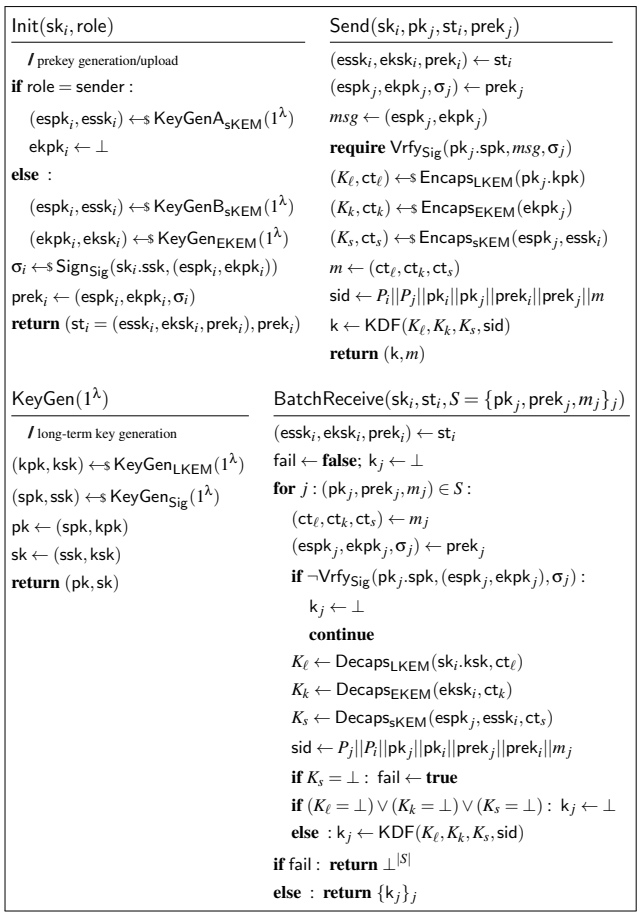

Figure 7: K-Waay: X3DH-like DAKE from IND-CCA KEMs EKEM and LKEM, SUF-CMA signature scheme Sig and IND-1BatchCCA and UNF-1KMA split-KEM sKEM.

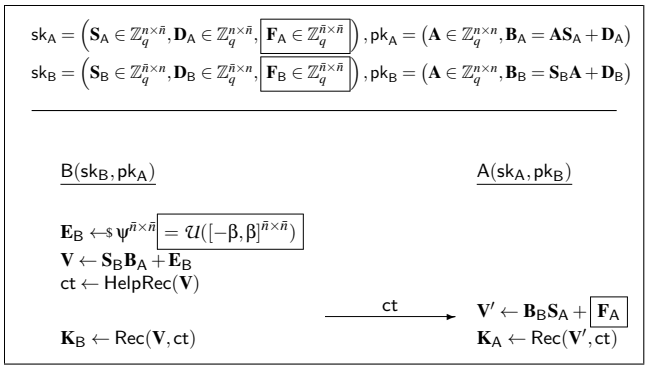

Figure 8: The modified FrodoKEX [12] as a split-KEM. Boxed terms correspond to the changes made to the original construction [12]. Here, Rec and HelpRec are the reconciliation mechanisms [53] used to derive the same key (see the full version [25] for details).

and the tester is a sender and 3) it is a receiver, and, depending on the combination of corruptions/reveals the adversary makes, reduce to the security of a primitive that the adversary does not have access to the secrets of. □

Theorem 2. *Consider deniable split-KEM* sKEM *with simulator* $\mathsf{Sim}_{\mathsf{sKEM}}$ *used to build K-Waay (Figure 7). Then, we have that for every efficient adversary* $\mathcal{A}$ *that makes at most* q *oracle queries, there exists an efficient* Sim *s.t. one can build an adversary* $\mathcal{B}$ *such that for* $\mathsf{exp} \in \{\mathsf{true}, \mathsf{false}\}$ *we have:*

$$\mathsf{Adv}^{\mathsf{deny}}_{\mathsf{K\text{-}Waay},\mathsf{Sim},\mathsf{exp}}(\mathcal{A}) \leq q \cdot \mathsf{Adv}^{\mathsf{deny}}_{\mathsf{sKEM},\mathsf{Sim}_{\mathsf{sKEM}}}(\mathcal{B}) \ .$$

Proof. We defer the proof to the full version [25], noting we construct Sim using split-KEM simulator $\mathsf{Sim}_{\mathsf{sKEM}}$ then apply a standard hybrid argument that replaces Send calls in CHAL queries with calls to $\mathsf{Sim}_{\mathsf{sKEM}}$. □

4 Deniable Split-KEM from Lattices

In this section, we give a technical overview of our new lattice-based split-KEM. More formal treatment of the construction can be found in the full version [25].

4.1 Overview

We start with the Frodo key-exchange by Bos et al. [12], which corresponds to the informal description in Fig. 8 where (i) the boxed terms are ignored, and (ii) the coefficients of all the secret matrices come from a distribution χ.

In this setting, the deniability property says that one can efficiently simulate the key $\mathbf{K}_\mathsf{B}$ and the ciphertext ct, given only the public key pk_B of B and the secret key sk_A of A. This means that no efficient adversary $\mathcal{A}(\mathsf{pk}_\mathsf{A}, \mathsf{pk}_\mathsf{B}, \mathsf{sk}_\mathsf{A})$, which has the public key as well as the secret key sk_A, can distinguish between the honestly computed $(\mathbf{K}_\mathsf{B}, \mathsf{ct})$ and the simulated one. By construction, if one can simulate $\mathbf{V}$, then ct and $\mathbf{K}_\mathsf{B}$ come for free, hence we focus on the latter task. Now, in order to prove deniability, we first observe that:

$$\begin{aligned}\mathbf{V} = \mathbf{S}_\mathsf{B}\mathbf{B}_\mathsf{A} + \mathbf{E}_\mathsf{B} &= \mathbf{S}_\mathsf{B}\mathbf{D}_\mathsf{A} + \mathbf{S}_\mathsf{B}\mathbf{A}\mathbf{S}_\mathsf{A} + \mathbf{E}_\mathsf{B} \\ &= \mathbf{S}_\mathsf{B}\mathbf{D}_\mathsf{A} - \mathbf{D}_\mathsf{B}\mathbf{S}_\mathsf{A} + \mathbf{B}_\mathsf{B}\mathbf{S}_\mathsf{A} + \mathbf{E}_\mathsf{B}.\end{aligned}$$

Since we are already given pk_B and sk_A, we only need to find a way to simulate the term $\mathbf{S}_\mathsf{B}\mathbf{D}_\mathsf{A} - \mathbf{D}_\mathsf{B}\mathbf{S}_\mathsf{A}$. A naive approach would be to simulate the secret key of B. That is, simply sample $\mathbf{S}_\mathsf{sim}, \mathbf{D}_\mathsf{sim} \leftarrow\$ \chi^{\bar{n}\times n}$ and set

$$\mathbf{V}_\mathsf{sim} := \mathbf{S}_\mathsf{sim}\mathbf{D}_\mathsf{A} - \mathbf{D}_\mathsf{sim}\mathbf{S}_\mathsf{A} + \mathbf{B}_\mathsf{B}\mathbf{S}_\mathsf{A} + \mathbf{E}_\mathsf{B}. \tag{1}$$

We formally show that this approach is a valid simulation under the LWE assumption. To this end, we define a (matrix-version) Extended-LWE (ELWE) problem which can be described as follows: distinguish between

$$(\mathbf{A}, \mathbf{S}\mathbf{A}+\mathbf{D}, \mathbf{Z}, \mathbf{W}, \mathbf{S}\mathbf{Z}+\mathbf{D}\mathbf{W}) \quad \text{and} \quad (\mathbf{A}, \mathbf{T}, \mathbf{Z}, \mathbf{W}, \mathbf{S}\mathbf{Z}+\mathbf{D}\mathbf{W}) \tag{2}$$

where $\mathbf{S}, \mathbf{D} \leftarrow\$ \chi^{n\times\bar{n}}, \mathbf{Z}, \mathbf{W} \leftarrow\$ \chi^{\bar{n}\times n}$ and $\mathbf{T}$ is uniformly random in $\mathbb{Z}_q^{\bar{n}\times n}$. We call $\mathbf{S}\mathbf{Z}+\mathbf{D}\mathbf{W}$ the hint matrix, and its height the number of hints. Now, the proof consists of two main steps which we sketch out below:

1. First, we argue that if we consider a hybrid Game_1, where we swap the public key $\mathbf{B}_\mathsf{B} := \mathbf{S}_\mathsf{B}\mathbf{A} + \mathbf{D}_\mathsf{B}$ with a uniformly random matrix over $\mathbb{Z}_q$, then no efficient adversary can distinguish between the two experiments under the ELWE assumption. Indeed, given the ELWE tuple $(\mathbf{A}, \mathbf{T}, \mathbf{Z}, \mathbf{H})$, the reduction $\mathcal{B}$ can set $\mathbf{T} := \mathbf{B}_\mathsf{B}$, $\mathbf{Z} := -\mathbf{D}_\mathsf{A}$, $\mathbf{W} := \mathbf{S}_\mathsf{A}$ and $\mathbf{V} := \mathbf{H} + \mathbf{B}_\mathsf{B}\mathbf{S}_\mathsf{A} + \mathbf{E}_\mathsf{B}$, where $\mathbf{E}_\mathsf{B}$ is sampled by $\mathcal{B}$ as in the protocol. Then, either $\mathbf{T} = \mathbf{S}_\mathsf{B}\mathbf{A} + \mathbf{D}_\mathsf{B}$ or $\mathbf{T}$ is uniformly random. However, in both cases we have $\mathbf{V} = \mathbf{H} + \mathbf{B}_\mathsf{B}\mathbf{S}_\mathsf{A} + \mathbf{E}_\mathsf{B} = \mathbf{S}_\mathsf{B}\mathbf{D}_\mathsf{A} - \mathbf{D}_\mathsf{B}\mathbf{S}_\mathsf{A} + \mathbf{B}_\mathsf{B}\mathbf{S}_\mathsf{A} + \mathbf{E}_\mathsf{B}$. Therefore, if $\mathbf{T}$ is a true LWE instance then the reduction can simulate the deniability game. Otherwise, $\mathbf{T}$ is uniformly random and thus $\mathcal{B}$ simulates Game_1. For notational convenience, in Game_1 we denote the secret key matrices for B as $(\mathbf{S}_\mathsf{sim}, \mathbf{D}_\mathsf{sim})$ rather than $(\mathbf{S}_\mathsf{B}, \mathbf{D}_\mathsf{B})$, which are *only* used to compute $\mathbf{V}$.

2. The next step is to introduce the next Game_2, where the public key is now computed as $\mathbf{B}_\mathsf{B} := \mathbf{S}_\mathsf{B}\mathbf{A} + \mathbf{D}_\mathsf{B}$, for $\mathbf{S}_\mathsf{B}, \mathbf{D}_\mathsf{B} \leftarrow\$ \chi^{\bar{n}\times n}$, instead of being sampled uniformly at random. Since $\mathbf{S}_\mathsf{B}, \mathbf{D}_\mathsf{B}$ are only used to compute $\mathbf{B}_\mathsf{B}$, computational indistinguishability of the last two games comes from the hardness of plain LWE. We highlight that Game_2 is not just reversing Game_1, since $\mathbf{V}$ is still computed as $\mathbf{V}_\mathsf{sim} = \mathbf{S}_\mathsf{sim}\mathbf{D}_\mathsf{A} - \mathbf{D}_\mathsf{sim}\mathbf{S}_\mathsf{A} + \mathbf{B}_\mathsf{B}\mathbf{S}_\mathsf{A} + \mathbf{E}_\mathsf{B}$.

Finally, one observes that the matrix $\mathbf{V}_\mathsf{sim}$ from (1) is computed exactly as in Game_2. Hence, the indistinguishability of $\mathbf{V}$ and $\mathbf{V}_\mathsf{sim}$ follows from both ELWE and LWE assumptions via the hybrid argument.

4.2 Achieving Stronger Security Properties

As discussed above, for the main applications in this paper we need our split-KEM to satisfy stronger security notion than e.g. IND-CPA [17]. It turns out that split-KEM deniability, which is a useful feature on its own, can be used as a building block to prove more advanced properties. We showcase this by giving an intuition on how to build a "decaps-OW-CPA" split-KEM.

In the decaps-OW-CPA game, the challenger generates the secret and public keys for both parties, applies the encapsulation for B to obtain $(\mathbf{K}^*, \mathsf{ct}^*) \leftarrow \mathsf{Encaps}(\mathsf{pk}_\mathsf{A}, \mathsf{sk}_\mathsf{B})$, and outputs $(\mathsf{pk}_\mathsf{A}, \mathsf{pk}_\mathsf{B}, \mathsf{ct}^*)$ to the adversary $\mathcal{A}$, which then returns a new ciphertext-key pair $(\mathsf{ct}', \mathbf{K}'_\mathsf{A})$. The adversary's goal is to guess the key $\mathbf{K}_\mathsf{A}$ which is output by $\mathsf{Decaps}(\mathsf{pk}_\mathsf{B}, \mathsf{sk}_\mathsf{A}, \mathsf{ct}')$. Note that by definition of deniability, we can use the simulator $\mathsf{Sim}(\mathsf{pk}_\mathsf{B}, \mathsf{sk}_\mathsf{A})$ from before to simulate the encapsulation output $(\mathbf{K}^*, \mathsf{ct}^*)$ instead. After the substitution, the only place, where the secret key sk_B of B is actually used, is when computing $\mathbf{B}_\mathsf{B} = \mathbf{S}_\mathsf{B}\mathbf{A} + \mathbf{D}_\mathsf{B}$. Hence, under the LWE assumption, we can swap $\mathbf{B}_\mathsf{B}$ with a uniformly random matrix. After all these changes, the modified decaps-OW-CPA experiment, which we call decaps-OW-CPA*, can be explicitly summarised below (ignoring the boxed items for now).

decaps-OW-CPA*

$\mathbf{S}_\mathsf{A}, \mathbf{D}_\mathsf{A} \leftarrow\!\$\ \chi^{n\times\bar{n}}; \mathbf{F}_\mathsf{A} \leftarrow\!\$\ \chi^{\bar{n}\times\bar{n}};\ \mathbf{B}_\mathsf{A} \leftarrow \mathbf{A}\mathbf{S}_\mathsf{A} + \mathbf{D}_\mathsf{A}$

$\mathbf{E}_\mathsf{B} \leftarrow\!\$\ \Psi^{\bar{n}\times\bar{n}};\ \mathbf{S}_\mathsf{sim}, \mathbf{D}_\mathsf{sim} \leftarrow\!\$\ \chi^{\bar{n}\times n}$

$\mathbf{V}_\mathsf{sim} \leftarrow \mathbf{S}_\mathsf{sim}\mathbf{D}_\mathsf{A} - \mathbf{D}_\mathsf{sim}\mathbf{S}_\mathsf{A} + \mathbf{B}_\mathsf{B}\mathbf{S}_\mathsf{A} + \mathbf{E}_\mathsf{B}$

$\mathsf{ct} \leftarrow \mathsf{HelpRec}(\mathbf{V}_\mathsf{sim})$

$\mathbf{K}'_\mathsf{A}, \mathsf{ct}' \leftarrow\!\$\ \mathcal{A}(\mathsf{pk}_\mathsf{A}, \mathsf{pk}_\mathsf{B}, \mathsf{ct})$

$\mathbf{V}' \leftarrow \mathbf{B}_\mathsf{B}\mathbf{S}_\mathsf{A} + \mathbf{F}_\mathsf{A}; \mathbf{K}_\mathsf{A} \leftarrow \mathsf{Rec}(\mathbf{V}', \mathsf{ct}')$

Our main goal is to make sure that after a certain number of hybrid games, $\mathbf{V}'$ is uniformly random. If this is the case, then using a high min-entropy argument on the reconciliation mechanism Rec, we could show that the probability of guessing $\mathbf{K}_\mathsf{A}$ is negligible.

By looking at how $\mathbf{V}' = \mathbf{B}_\mathsf{B}\mathbf{S}_\mathsf{A}$ is currently defined, the intuition is to somehow rely on the LWE problem. The first issue with this idea is that the expression for $\mathbf{V}'$ lacks an "error term". We can easily patch this by adding a short $\bar{n}\times\bar{n}$ matrix $\mathbf{F}_\mathsf{A} \leftarrow\!\$\ \chi^{\bar{n}\times\bar{n}}$ as a part of the secret of sk_A, which is used only for decapsulation. Then, by defining $\mathbf{V}'$ exactly as in the figure above, we have:

$$\begin{bmatrix}\mathbf{B}_\mathsf{A}\\ \mathbf{V}'\end{bmatrix} = \begin{bmatrix}\mathbf{A}\\ \mathbf{B}_\mathsf{B}\end{bmatrix}\mathbf{S}_\mathsf{A} + \begin{bmatrix}\mathbf{D}_\mathsf{A}\\ \mathbf{F}_\mathsf{A}\end{bmatrix}$$

which is exactly a LWE instance. The reason why we cannot swap $(\mathbf{B}_\mathsf{A}, \mathbf{V}')$ with random matrices is that we still need to simulate $\mathbf{V}_\mathsf{sim}$ which depends on the secret key sk_A. We solve this issue using the following approach. By rearranging, we first compute $\mathbf{V}'$ and then $\mathbf{V}$. Next, we can alternatively compute $\mathbf{V}$ as $\mathbf{V} = \mathbf{S}_\mathsf{sim}\mathbf{D}_\mathsf{A} - \mathbf{D}_\mathsf{sim}\mathbf{S}_\mathsf{A} + \mathbf{V}' + \mathbf{E}'$ where $\mathbf{E}' = \mathbf{E}_\mathsf{B} - \mathbf{F}_\mathsf{A}$. Here, our key idea is to apply *rejection sampling* [47]. Namely, if we allow to pick coefficients of $\mathbf{E}_\mathsf{B}$ uniformly at random from much larger interval $[-\beta, \beta]$ than for χ, i.e. $\psi := \mathcal{U}([-\beta, \beta]^{\bar{n}\times\bar{n}})$, then conditioned on $\|\mathbf{E}_\mathsf{B} + \mathbf{F}_\mathsf{A}\|_\infty \le \beta - \gamma$, where $\|\mathbf{F}_\mathsf{A}\|_\infty \le \gamma$, the matrix $\mathbf{E}' = \mathbf{E}_\mathsf{B} - \mathbf{F}_\mathsf{A}$ is uniformly random with coefficients between $[-\beta+\gamma, \beta-\gamma]$. This allows us to simply substitute the term $\mathbf{E}_\mathsf{B} - \mathbf{F}_\mathsf{A}$ with a uniformly random matrix $\mathbf{E}'$, which in particular is independent of $\mathbf{F}_\mathsf{A}$.

After all these modifications, we show that under a slightly modified Extended-LWE assumption, we can swap $(\mathbf{B}_\mathsf{A}, \mathbf{V}')$ with uniformly random matrices which finishes the proof. Here, the main change from (2) is that we now allow the error terms in the LWE sample not to be included in the hint. That is, this time the adversary has to distinguish between

$$\left(\begin{bmatrix}\mathbf{A}\\ \mathbf{B}\end{bmatrix}, \begin{bmatrix}\mathbf{A}\\ \mathbf{B}\end{bmatrix}\mathbf{S} + \begin{bmatrix}\mathbf{D}\\ \mathbf{F}\end{bmatrix}, \mathbf{Z}, \mathbf{W}, \mathbf{Z}\mathbf{S} + \mathbf{W}\mathbf{D}\right) \quad \text{and}$$
$$\left(\begin{bmatrix}\mathbf{A}\\ \mathbf{B}\end{bmatrix}, \mathbf{T}, \mathbf{Z}, \mathbf{W}, \mathbf{Z}\mathbf{S} + \mathbf{W}\mathbf{D}\right).$$

The modified scheme we use (with added noise in decapsulation) is given in Figure 8 with boxed instructions.

Hardness of Extended-LWE. We provide a formal reduction from the newly defined Extended-LWE problem to plain LWE. The reduction is similar to the one presented by Alperin-Sheriff and Peikert [2], albeit not a straightforward adaptation. The issue is that in [2], the ELWE problem outputs hints of size only a single $\mathbb{Z}_q$ element. Here, we have to deal with $\bar{n}$ many $\mathbb{Z}_q$-hints, which becomes problematic when arguing about invertibility of certain matrices when following the original reduction. We circumvent this by first reducing our ELWE to the corresponding knapsack-type version [52], then applying the reduction from [2] to reduce to plain knapsack-LWE, and finally going back to plain LWE using [52].

UNF-1KMA and IND-1BatchCCA. We have informally proven so far that the modified version of FrodoKEX given above is decaps-OW-CPA and OW-CPA. In the full version [25] we show that any scheme satisfying both these properties can easily be transformed into a UNF-1KMA and IND-1BatchCCA split-KEM in the ROM and QROM using the T_CH transform of Huguenin-Dumittan and Vaudenay [39] adapted to the split-KEM setting.

4.3 Concrete Instantiation

In Table 1 we propose the parameter set where we aim for 128-bit classical security. We detail in the full version [25] the calculations that lead to these numbers.

n	$\bar{n}$	q	B	χ	β	$\lvert pk \rvert$	$\lvert ct \rvert$
1452	8	31751	4	$\mathcal{U}(\{-1,1\})$	2^6	21.3KB	64B

Table 1: Concrete parameters for our lattice-based split-KEM. B is the number of bits that can be extracted per coefficient. We note that in practice, we do not need to include the whole matrix $\mathbf{A}$ in the public key, but rather the seed for the pseudo-random function to generate it.

5 Benchmarks, Comparison and Discussion

Hereafter, we refer to the scheme by Brendel et al. [16] as SPQR, and we refer to the deniable (i.e. with ring signatures) scheme by Hashimoto et al. [38] as HKKP.

5.1 Benchmarks

Security of non-standard primitive. As K-Waay, SPQR and HKKP can each be implemented using, except for a single primitive in each case, only (soon to be) standardised primitives, we wish to compare the security of the non-standard primitives. In the case of K-Waay it is a split-KEM, here implemented using a variant of FrodoKEX passed through the T_{CH} transform (that we call FrodoKEX+), and in the case of both HKKP and SPQR it is a ring signature (or a DVS derived from a ring signature). The authors of both SPQR and HKKP proposed possible implementations for the RS without picking one in particular. The most efficient one for a ring of size 2 that has an existing C implementation is Raptor [45] which we use for the benchmarks below. Other candidates would be Falafl [9] or DualRing-LB [64].

We present in Table 2 a summary of the security claims, approximate leading factor in the bounds in the (Q)ROM, and assumptions for these non-standard primitives. We note that none of these primitives are proven secure in the standard model and all are based on lattices.

First, we note that parameters for these RS schemes are picked *before* the reduction in the ROM. That is, a primitive P based on lattices is built, parameters are chosen such that P satisfies the security claim, then P is used to build a RS in the ROM, which incurs a loss factor that usually depends on the number of queries to the random oracle q_H. In particular, it is common to have at least a q_H factor in the security bound (e.g. if the adversary can make 2^{32} queries to the RO, the security level is reduced by 32 bits). Therefore, the claimed security level does not match the *provable* security level. In the QROM, the security loss is usually greater: square root and q_H^2 or q_H^3 losses are quite common, however these schemes are not proven secure in this model.

We chose the opposite approach in designing a split-KEM with a conservative assumption (i.e., plain LWE) and parameters. Therefore, FrodoKEX+ with our proposed parameters achieve 128 (resp. 64) bits of classical (resp. quantum) security *after* the (Q)ROM proof. We put the (approximate) highest terms of both the ROM and QROM security bounds in Table 2. These satisfy our security claims as long as $q_H \leq 2^{64}$ in the ROM and $q_H \cdot d \leq 2^{64}$ in the QROM, where d is the number of public key/ciphertext tuples allowed in the IND-1BatchCCA game. We note that in K-Waay, d corresponds to the number of distinct users trying to communicate with an offline receiver after all prekeys have run out, thus should typically be small. We note that the leading coefficients in all our bounds are always related to the (Q)ROM security (e.g. finding a collision) and not to the underlying hardness assumptions. Therefore, one can easily make these coefficients smaller by picking a larger digest size n, e.g. 512 bits.

The reason behind the approximations and lack of QROM proofs for PQ ring signatures is likely the youth of the field and the speed at which it is evolving. Still, we believe it is worth noting as it makes any comparison between our protocol and previous ones quite difficult.

Benchmarking. The protocols we benchmarked are: our own implementation of the current X3DH protocol, a witness protocol made only with PQ KEMs and a signature scheme similar to the *non-deniable* variant of HKKP, Brendel et al.'s [16] construction SPQR using PQ KEMs, a signature scheme and a DVS, Hashimoto et al.'s [37, 38] construction HKKP using PQ KEMs, a signature scheme and a RS, and our scheme K-Waay with FrodoKEX+ using PQ split-KEM, KEMs and a signature scheme.

We picked Kyber512 as the KEM, both Falcon-512 and Dilithium2 as signatures, and Raptor as the ring signature. We implemented both HKKP and SPQR with signed prekeys as is the case in Signal's implementation of X3DH. That is, a PQ signature key pair is part of the long-term key, and ephemeral keys uploaded to server are signed with it. Note that this is make explicit in K-Waay as the ephemeral keys are signed with the long-term one. The authors of HKKP show that this is not necessary in their protocol, however not doing so weakens perfect forward secrecy.

We built the different protocols in C using the `liboqs` library[4] for Kyber, Falcon, and Dilithium, the Raptor implementation provided by the authors[5], and a modified version of the `lwe-frodo` library[6] with scaled parameters to properly simulate FrodoKEX+. More precisely, the modulus was set to the first power of 2 larger than the modulus in FrodoKEX+, the addition of the noise during decapsulation was also added, and the noise distributions were modified to match the ones of FrodoKEX+. We did not optimise the scheme in any way (e.g. by using AVX instructions or parallelisation) and we leave this as future work. For the sake of completeness, we also provide a reference implementation of FrodoKEX+ in Rust[7] for the interested reader. All benchmarks were run on a

Scheme	Cl. (C)	Cl. (Q)	ROM bnd	QROM bnd	Assumption
FrodoKEX+	128	64	$q_H^2/2^{256}$	$q_H \cdot d/2^{128}$	LWE
Raptor [45]	114	103	?	✗	NTRU
DualRing-LB [64]	(128)	(64)	?	✗	MSIS, MLWE
Falafl [9]	128	64	?	✗	MSIS, MLWE

Table 2: Security comparison between FrodoKEX+ and several post-quantum RS. 'Cl.' stands for claimed number of security bits. DualRing-LB's authors do not seem to make a clear security claim, we thus assume NIST level I. '?' indicates that no bound is explicitly given for the security, '✗' indicates that no proof is provided in the QROM.

virtual machine running Ubuntu 22.04 with 2 cores of an Intel i7-9750H running at 2.60GHz and 4GB of RAM allocated.

Speed. For the speed benchmark, we measured how many cycles each protocol takes in one execution. We summarise our results in a logarithmic graph on Figure 9 (note that the internal division of the bars is linear).

Fixing the choice of KEM and signature scheme, our protocol K-Waay, depending on the choice of KEM and signature scheme, is between 3 and 6 times faster than the previous proposals even with our relatively conservative parameter choice. In our protocol K-Waay using Dilithium2, most cycles are spent in the ephemeral key generation, while using Falcon makes the static key generation as expensive as the ephemeral key one. Overall, one can see that Falcon, while more compact than Dilithium2, has a great impact on efficiency. For instance, K-Waay with Dilithium2 is faster than the non-deniable scheme using Kyber and Falcon.

Apart from Falcon, we see that the most time-consuming primitives are the non-standard ones, i.e., ring signatures and split-KEM. Hence, we see that the KEM+SIG protocol (HKKP's baseline proposal) performs even better than X3DH, which shows once again that lattice-based schemes can be faster than their classical counterparts. However, we recall that it does not provide deniability. At last, we note that X3DH is the only construction that spends more time in sending and receiving than generating keys. Our protocol's Send and Receive (i.e. BatchReceive with a single input message) procedures are very fast.

Data size. In Table 3, we provide for each scheme the size of the long-term keys, the prekeys (output by Init in our DAKE syntax), and the ciphertext output by the sender. We computed for both HKKP and SPQR the size with and without long-term signatures. We see that K-Waay compares well in term of long-term public key and ciphertext size as both are smaller than signed HKKP and SPQR. However, the prekeys are much larger as one could expect from a LWE-based scheme and due to our conservative choice of parameters.

Scheme	|lpk|	|prek|	|ct|
K-Waay + Dilithium	2112	24520	1632
K-Waay + Falcon	1697	22790	1632
HKKP [38]	1700	1700	4056
HKKP [38] + Dilithium2	3012	4120	4056
HKKP [38] + Falcon	2597	2390	4056
SPQR [16]	3400	1632	4824
SPQR [16] + Dilithium2	4712	4052	4824
SPQR [16] + Falcon	4297	2322	4824

Table 3: Size comparison in bytes between K-Waay instantiated with FrodoKEX+, HKKP [38] and SPQR [16]. We also computed the sizes for both HKKP and SPQR implemented with signed prekey bundles.

5.2 Advantages, Limitations and Discussion

Running out of ephemeral keys. The main disadvantage of our protocol is that running out of ephemeral keys requires the receiver to abort if *any* of the sessions that used the same prekey is bogus. If this happens, then a malicious party could mount some kind of denial of service (DoS) attack against the user that was offline for too long by sending a bogus split-KEM ciphertext. There is an obvious trade-off between the risk of such an attack happening and the number of ephemeral keys uploaded on the server, thus the storage required on the server. We leave the analysis and the mitigation of such a threat as future work, but we believe that if a reasonable amount of prekeys are uploaded, creating fake accounts is difficult (e.g. by requiring a phone number as in Signal), and/or users are online often enough, such an attack would be difficult to mount. Furthermore, several practical mitigations are possible. For instance, if the receiver (i.e. the victim) received a bogus ciphertext among the n ciphertexts sent for the same prekey while offline, they can restart K-Waay with the n parties but as the initiator, which will probably succeed. The victim could also send n new prekeys to the n initiators directly, making sure the protocol will succeed at the next iteration. This would make the attack less useful as it could only *delay* communication and not prevent it.

We also think it is worth mentioning that the trick we propose might be easy to misimplement. In particular, it is crucial that no information about which split-KEM ciphertext

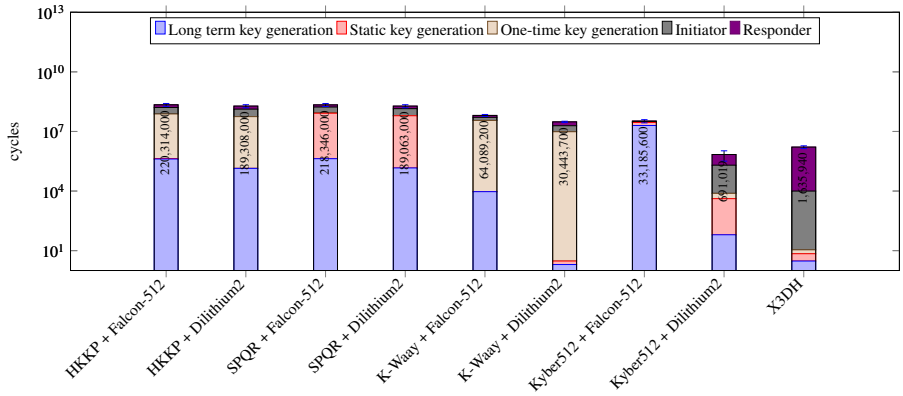

Figure 9: Speed benchmark for X3DH protocols

failed leaks if such a situation occurs. That is, all precautions should be taken such that such leakage via side-channels is prevented.

split-KEM instead of Ring Signatures. The first advantage of using our protocol over existing ones is the use of an ephemeral primitive instead of a long-term one, the former being often more efficient as the security requirements are less strict. In addition, the use of a primitive similar to a post-quantum KEM allows us to leverage the extensive literature on the topic and existing safe/optimised implementations. This also gives good security guarantees as post-quantum KEMs have been heavily scrutinised as part of the NIST standardisation process. For example, as mentioned above, our proposed lattice-based implementation is based on a key-exchange variant of FrodoKEM, which is itself the PQ KEM recommended by the German Federal Office for Information Security (BSI) [35]. Overall we think that a split-KEM such as FrodoKEX+ is more mature and closer to being usable in practice than ring signatures.

On the necessity of modifying FrodoKEX. Currently, our split-KEM significantly differs from the original FrodoKEX in two aspects: (i) the modulus for our construction has to be prime in order for our reduction from Extended-LWE to LWE to hold[8], and (ii) we have to introduce additional masking terms to prove UNF-1KMA security. However, we believe that both changes are artefacts of the security proofs, and the original FrodoKEX split-KEM should be (up to a reasonable security loss) deniable.

There are alternative reduction techniques from Extended-LWE to LWE in the literature [14, 15], which do not rely on having an odd modulus at the cost of using discrete Gaussian error distributions with large parameters. It is thus an interesting research problem to efficiently reduce Extended-LWE to LWE for even modulus with small reduction loss. In practice, the most efficient LWE attacks do not consider the structure of the modulus, so intuitively this should translate to the Extended-LWE setting[9].

As for our second main modification, it is unclear how to argue UNF-1KMA security without the additional masking terms and rejection sampling, even though the latter could potentially be removed using very recent techniques [1, 41]. Hence, we leave deniability and UNF-1KMA security of the original FrodoKEX construction as exciting future work.

Deniability. While the signature on the ephemeral public keys might give the impression that our protocol is less deniable than X3DH or previous PQ alternatives, this is actually not the case. The reason is that prekey bundles in these protocols are signed as well, but this detail is abstracted away in the analysis (i.e. it is assumed that all parties have received and authenticated all public-keys before the protocol actually starts). While this kind of analysis allows for strong deniability claims, in practice these protocols do not satisfy something stronger than some kind of peer-deniability. The exception is the ring signature based variant by Hashimoto et al. [38], where the prekey bundle is not necessarily signed. However, in this variant, the authors can only prove the security of their protocol in a weaker model (i.e. it satisfies a weaker notion of forward secrecy). Overall, if deniability should not come at the price of security, peer-deniability seems like the best notion one can achieve in these DAKEs.

We wished to provide a transparent model for peer-deniability, where the upload of signed ephemeral keys is made explicit. We also strengthen the deniability definition of Brendel et al. [16] by allowing the exposure of one of the parties (i.e. the receiving one, which would be the malicious party trying to frame the sender). While our protocol satisfies our stronger (in term of key exposure) notion of deniability, we believe both previous PQ X3DH alternatives satisfy it as

[8] Recall FrodoKEX [12] uses a power-of-two modulus for efficiency.

[9] Recently, various frameworks have been developed [28, 29], which measure concrete hardness of LWE given hints of specific form, such as linear combination of secrets with short random coefficients.

well. Indeed, in these schemes, the ephemeral keys are KEM and RS keys only, which are deniable. Hence, exposing these should not harm deniability.

Hashimoto et al. [38] consider a strong notion of deniability where the adversary is malicious (i.e. can arbitrarily deviate from the protocol) and show how to modify HKKP s.t. it is secure against such a threat. However, such deniability comes at the expense of NIZKs, which are complex, expensive and are not always proven secure in the QROM when random oracles are used. Moreover, as in other deniable systems against malicious adversaries, non-falsifiable assumptions (i.e. knowledge-type assumptions) are required to prove the security. In addition, it seems difficult to defend against adversaries actively trying to frame a given user in messaging in practice [24, 36]; for example, an adversary could also simply ask questions that would identify the victim with good probability. Because of these reasons, we do not consider such a notion of deniability here.

To contextualise our results, we remark here that cryptographic deniability, which is targeted by this work and all previous work on deniable X3DH key exchange, translates to deniability on a *system* level only if the application preserves deniability. For example, Collins et al. [24] observe that Signal as currently deployed does not provide this kind of 'practical' deniability for ordinary users. Suppose Bob is trying to frame Alice and hands over their phone, that contains a transcript of communication between Alice and Bob, to a judge. Because Signal authenticates users (either directly or indirectly through Signal sealed sender [46]), unless Bob was able to modify their phone (which depends on the technical expertise of Bob), the judge can deduce that the conversation plausibly took place as in the transcript, regardless of the cryptographic protocols employed underneath. It is interesting future work to further explore deniability on the broader system level.

An optimisation. As presented in Section 3, the K-Waay protocol generates a signature for each ephemeral public-key uploaded. This can easily be optimised by signing the whole prekey bundle containing several ephemeral keys. This way, the server needs to store only one PQ signature for each user. The downside is that now each user needs to download the whole bundle to verify the signature. This offers a trade-off between data stored at the server and sent to clients.

Strengthening protocol security. Note that we proved K-Waay key indistinguishable in a model that considers state exposures like Hashimoto et al.'s [38] but is nonetheless weaker (our protocol is provably-secure under a notion similar to that of Brendel et al. [16]). This is mainly since our protocol only uses ephemeral split-KEM keys. As noted by Brendel et al. [17], however, it seems much more difficult to construct split-KEM secure under several encapsulation/decapsulation queries, which we leave again as important future work.

Future work. An interesting line of research would be to try to build other unforgeable IND-1BatchCCA split-KEMs that are more efficient (mostly in key and ciphertext size). One obvious direction would be to work over structured lattices [43, 49, 59]. Indeed, Ring/Module-LWE with hints (similar to our Extended-LWE problem) have already been analysed from a theoretical point of view [14, 51]. We also believe that our techniques can also be applied in the ring setting. However, for security purposes one needs to take a ring dimension d to be at least linear in the security parameter λ which becomes problematic when proving deniability. Indeed, the leaked hint is informally the product of secret keys of both parties. Thus, in the ring setting the hint would be at least a single polynomial, which contains $d = O(\lambda)$ coefficients. We predict that this would result with much larger reduction loss than what we have now. However, the concrete analysis is left as future work.

Finally, on a more practical side, it would be informative to benchmark our protocol and others in a real-life scenario or something close to it, and to implement other ring signatures schemes to have a more complete comparison. Different parameter sets to achieve higher level of security could also be provided and benchmarked.

Abstract

Voice over Wi-Fi (VoWiFi) uses a series of IPsec tunnels to deliver IP-based telephony from the subscriber's phone (User Equipment, UE) into the Mobile Network Operator's (MNO) core network via an Internet-facing endpoint, the Evolved Packet Data Gateway (ePDG). IPsec tunnels are set up in phases. The first phase negotiates the cryptographic algorithm and parameters and performs a key exchange via the Internet Key Exchange protocol, while the second phase (protected by the above-established encryption) performs the authentication. An insecure key exchange would jeopardize the later stages and the data's security and confidentiality.

In this paper, we analyze the *phase 1* settings and implementations as they are found in phones as well as in commercially deployed networks worldwide. On the UE side, we identified a recent 5G baseband chipset from a major manufacturer that allows for fallback to weak, unannounced modes and verified it experimentally. On the MNO side –among others– we identified 13 operators (totaling an estimated 140 million subscribers) on three continents that all use the same globally static set of ten private keys, serving them at random. Those *not-so*-private keys allow the decryption of the shared keys of every VoWiFi user of all those operators. All these operators deployed their core network from one common manufacturer.

1 Introduction

The term *non-3GPP Access Networks* refers to the method of accessing cellular network core services without the use of a GSM/GPRS/UMTS/LTE/NR radio access network. This technique has been around since the times of GSM and has been updated multiple times since then. Some operators in the U.S. and Japan have used it to offload traffic via unlicensed Wi-Fi bands.

There are two types of non-3GPP access networks: *trusted networks* (e.g., provider-operated Wi-Fi access points) and *untrusted networks* (third-party Wi-Fi and Internet connections). In recent years, the latter variant started enjoying massive adoption as *Voice over Wi-Fi* (VoWiFi), also called *Wi-Fi Calling* or *Voice over WLAN* (VoWLAN). For the end user, it often provides better coverage, and for the operator, it provides a way to externalize the last mile's costs while keeping the full revenue.

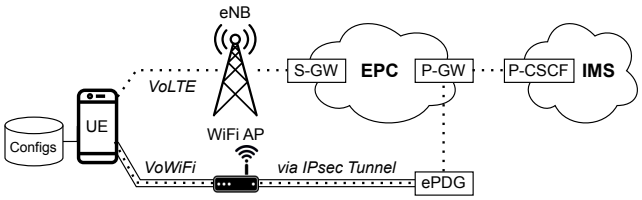

Figure 1: VoLTE compared to VoWiFi over an untrusted Internet connection – as relevant for this paper

On iPhone and Android, by default, VoWiFi is the preferred call termination channel when available.

At its core, *untrusted non-3GPP access* works by setting up at least one IPsec tunnel to the operator's Evolved Packet Data Gateway (ePDG). It uses the Internet Key Exchange (IKE) protocol [34] and relies heavily on predefined Diffie-Hellman (DH) groups, some of which are known to be weak. For example, since 2015 [15], $DH1^{768\text{ bits}}$ is assumed to be breakable by motivated academic actors, while $DH2^{1024}$ is within reach of nation-states.

Within the IPsec tunnel, all core network access is handled like regular Voice over LTE (VoLTE). Because of its recently massively increased popularity and its security perimeter function to many Evolved Packet Core (EPC) services, we investigated its specified as well as practical security from different vantage points. We facilitate static configuration analysis, active measurements of real-world implementations in network operators, as well as active measurements of handset implementations to answer the following research questions.

RQ1 What VoWiFi key exchange methods and security parameters are preset in phones for their Mobile Network Operator (MNO)?

RQ2 What key exchange methods do operators actually sup-

port on their ePDG, and will they always prefer the strongest one?

RQ3 How strong are VoWiFi connections in the real world, and how realistic is it to downgrade to weaker, breakable key exchange methods?

We found that most operators are non-compliant with 3GPP's specifications, by still announcing and supporting deprecated DH groups weaker than 2048 bits. Furthermore, only 42% will take the extra step to request an upgrade if the client chooses a weaker group, but both parties actually support stronger groups. We also found one handset manufacturer that will silently support the much weaker DH1^{768} group, albeit not proposing it in the handshake. DH1^{768} was never part of a 3GPP specification, making those handsets susceptible to man-in-the-middle attacks. We simulate such an attack by intercepting and rewriting actual VoWiFi traffic.

More abstractly, our findings illustrate that functional overprovisioning and missing predefined procedures for deprecating cryptographic algorithms create a massive technical debt. Last but not least, we uncovered at least 13 operators[1] that used the same private keys on three continents.

The paper is structured as follows. In Section 2, we give the necessary background of how IPsec with IKE is used and embedded within the 3GPP structure. The threat model and the methodology are outlined in Sections 3 and 4, the latter of which also includes ethical considerations. Sections 5 to 7 describe our implementation and report the findings, followed by an outline on how to put those findings to work for a full stack VoWiFi attack. A related work section, a discussion, and recommendations round up the picture in Sections 8 through 10. The paper ends with a conclusion in Section 11 and an Appendix for supplementary material.

2 Background

VoWiFi is a technology that transfers voice traffic over non-3GPP access networks, typically unsecured Wi-Fi networks. It effectively routes VoLTE traffic to the EPC (and ultimately to the IMS) by encapsulating it in an IPsec tunnel over the public Internet, as shown in Figure 1. This basic technique has been around since the GSM era for network traffic off-loading and is now experiencing a resurgence due to the popularity of VoWiFi.

[1] 12 during our initial scan and one more during responsible disclosure.

2.1 The IKE/IPsec/SIP Stack

The complete stack consists of a nested stack of tunnels (Figure 2). The outer (or *Phase 1*) IKEv2 layer (L1 in Figure 2) is responsible for securing the inner layers (e.g., negotiating security parameters and creating key material for the nested tunnels via IKEv2 [21]). Within this layer, the client (UE) authenticates the user via the (U)SIM card and creates a CHILD_SA (*Phase 2*), that allocates an IPsec tunnel into the EPC via the Packet Gateway (P-GW). Via this tunnel (L2 in Figure 2), the UE is assigned a dedicated IP address and can reach internal endpoints within the EPC. This level of access (and also the assigned IP address) is functionally identical to connecting to the `IMS` APN over the regular radio access network (VoLTE). Lastly, to be able to terminate voice calls, the UE uses the created CHILD_SA (IPSec tunnel) to talk to the P-CSCF (Proxy Call Session Control Function) and establish a SIP (Session Initiation Protocol) and an RTP (Real-time Transport Protocol) connection over *ipsec-3gpp* [17], secured via IPsec in transport mode. The encryption on this final layer (L3 in Figure 2) is, however, often optional and not enforced by many clients or servers.

2.2 Creating the ePDG Connection L1

In the first step, the phone connects to the Internet-facing side of the ePDG server of the appropriate MNO using its Fully Qualified Domain Name (FQDN), standardized in ETSI/3GPP TS 23.003 [24]:

`epdg.epc.mnc`⟨*id*⟩`.mcc`⟨*id*⟩`.pub.3gppnetwork.org`,

where the Mobile Country Code (MCC) and the Mobile Network Code (MNC) are globally unique for each operator. The IKE protocol (nowadays IKEv2 [21, 33, 34] or, more precisely, its slightly modified 3GPP variant [22]) is used to negotiate a session key using the Diffie-Hellman key exchange mechanism. Hereby, the client proposes its supported

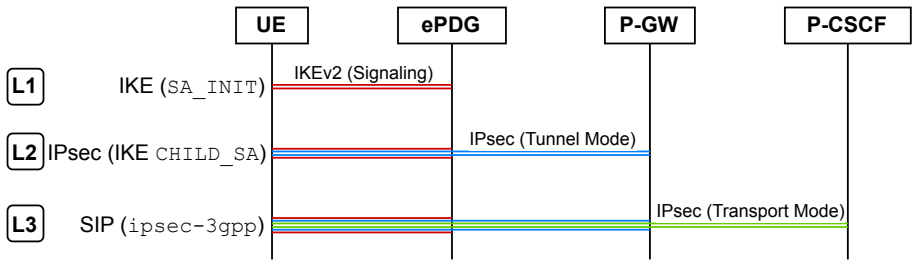

Figure 2: VoWiFi uses multiple tunnels to ensure security: L1 provides a trusted channel and manages the subsequent connections, L2 acts as a gateway to the internal infrastructure and L3 is used for the actual voice and messaging functionalities.

Security Associations (SAs), i.e., the available encryption, integrity, and key exchange algorithms (DH groups) and its preferred DH group. The ePDG chooses a subset of the proposed SAs and either accepts the favored DH group or indicates its preference toward a different DH group from the proposal. After this initial `SA_INIT` phase, all subsequent messages are encrypted and integrity-protected.

2.3 IPSec Tunnel Mode (CHILD_SA) L2

After establishing the encryption on the outer IKE layer, both endpoints (i.e., the UE and the ePDG) authenticate using EAP-AKA using credentials from the (U)SIM. Furthermore, the AKA procedure provides both parties with secret keys for the first CHILD_SA (i.e., the IPSec tunnel into the EPC). Note that the secret keys (and other SA parameters) used by the parent (i.e., the outer IKE) and child SAs are regularly renewed via repeated DH key exchanges and thus only valid for a certain period. However, the authentication of both endpoints is not renewed. Thus, cracking the outer key exchange is enough to gain stealth rewriting capabilities within the first two layers.

2.4 Session Initiation Protocol (SIP) Layer

The *ipsec-3gpp* protocol that secures this layer can ensure the confidentiality and integrity of the SIP and RTP traffic. The first two packets before establishing the encrypted channel are transmitted in plaintext (a *SIP REGISTER* that is usually answered by a *SIP Unauthorized* packet with the AKA challenge). In the past, some implementations were vulnerable on the SIP layer, e.g., Exynos [13].

However, in practice, not many operators enforce encryption and integrity on this layer. In Appendix A , we verify this experimentally. In such cases, an attacker who cracked the outer IKEv2 key exchange and is thus able to take over the first two layers could subsequently also hijack the third layer after the SIP authenticated between UE and P-CSCF is finished, effectively seizing control of all three communication layers.

Table 1: Relevant DH groups for this work, as named/numbered by IANA [32]

Name	Bits	Type
DH1[1]	768	MODP
DH2	1024	MODP
DH5[1]	1536	MODP
DH14	2048	MODP
DH15	3072	MODP
DH16	4096	MODP
DH17	6144	MODP
DH18	8192	MODP

Name	Bits	Type
DH25	192	ECP
DH26	224	ECP
DH19	256	ECP
DH20	384	ECP
DH21	512	ECP
DH31	Curve25519	

[1] never specified for 3GPP usage deprecated [23]

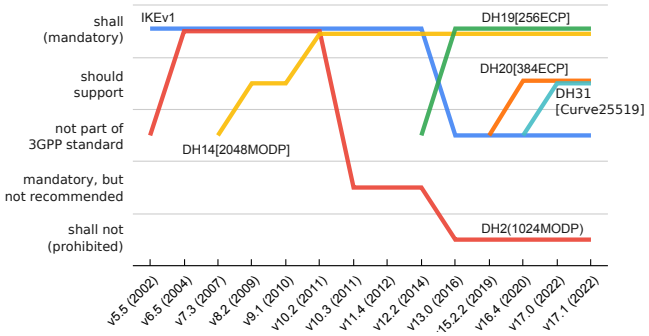

Figure 3: Development of the IPsec IKE Profile as defined in IETF TS 133.210 (IKE_SA_INIT) [23] Note: LTE started with v8, and IKEv1 has been phased out since v12.

2.5 IPsec/IKE Diffie-Hellmann Key Exchange in the 3GPP's VoWiFi ecosystem

For most of the paper, we only look at the first-stage IKE handshake, i.e., the outermost layer L1. All subsequent operations rely on the confidentiality and integrity of the negotiated encryption with the negotiated shared session key.

In contrast to much of the VoLTE/VoWiFi world (see Section 2.7), IKE itself offers an automatic negotiation for key exchange mechanisms via capabilities announcements and the selection of different Diffie-Hellman (DH) groups. A DH group defines an algorithm, a key length, and a set of public parameters. The relevant DH groups for VoWiFi (and this paper) are listed in Table 1. In 2015, researchers estimated that cracking $DH1^{768}$ is within the capabilities of a determined academic group, while $DH2^{1024}$ is within reach for nation-states [15].

Accordingly, ETSI/3GPP changed its recommendations and requirements over the years. The results of our requirement analysis for the IKE profile in TS 133 210 [23] are depicted in Figure 3. While $DH1^{768}$ was never part of the standard, $DH2^{1024}$ was recommended until 2011, then demoted to *required but not recommended* and finally prohibited (*shall not use*) in 2016. At the same time, new ECP^2-based DH groups were added as recommendations (our results show that they are rarely used).

2.6 Modular Exponential (MODP) Diffie-Hellman Key Exchange in IKE

After the client and the server agree on the key parameters, including the DH group, the server initiates a DH exchange.

Let a and A be the private and the public key of the server, and likewise b and B the private and public key of the client. Further, let p be a publicly known prime and g an integer smaller than p. p and g are predefined by the chosen DH

[2] Elliptic Curve Groups modulo a Prime

group.

The server provides the client with its public key $A = g^a \bmod p$ along with the chosen DH group. With that information, the client can compute its public key $B = g^b \bmod p$ and transmit it to the server. Both parties can now compute a shared session key using $K = B^a \bmod p$ (on the server side) and $K = A^b \bmod p$ (on the client side).

Only A, B, and the DH group (defining p, g) are transmitted in clear over the wire. Ultimately, both parties know the secret symmetric session key K. If at least one of the private keys (or the nonce) is a fresh random integer, the generated session key K will not repeat.

2.6.1 Optimization through Precomputation

A server can precompute A from a (temporarily) fixed private key a for each DH group, as it is independent of the client. This is a valid approach if the rekeying period is considerably less time than it takes a potent attacker to crack those keys, and if the client doesn't follow a similar strategy.

However, as pointed out by Flesh et al. [25], those a keys should not be shared between different DH groups. Otherwise, an attacker could crack a on a weak DH group and use it for stronger ones.

2.7 VoWiFi Provisioning Ecosystem

The 3GPP VoLTE/VoWiFi ecosystem lacks a comprehensive autoconfiguration or provisioning protocol (similar to USIM files or MIB/SIB announcements used for other cellular parameters). This has caused (and still causes) massive compatibility problems for operating VoLTE on handsets [40]. The modem and mobile OS vendors help themselves by preloading configuration databases for known MNOs in their firmware and OS images. Those configurations define a multitude of properties, from the bearer and tunnel settings down to IMS/SIP codec parameters. Some operators use an app with operator privileges to push a configuration onto the device.

The GSM Association (GSMA) approaches the problem in three ways. First, it created a database[3] as a paid service for use by manufacturers. Second, it created a small set of standard configurations (e.g., to ease VoLTE roaming). Third, they recently started a new Internet-based configuration service under `aes.mnc⟨id⟩.mcc⟨id⟩.pub.3gppnetwork.org`. At the time of writing, only 66 operators registered that domain.

2.7.1 Apple iOS

Independent of the used modem chipset (i.e., Qualcomm or Intel), Apple organizes country-specific and operator-specific configurations into `.ipcc` files (called Country Bundles and Carrier Bundles, respectively). They can be distributed via the iOS system image and system updates as well as via itunes.com. *ipcc-downloader*[4] extracts them from latter source.

2.7.2 Qualcomm: Xiaomi, Oppo

Qualcomm uses proprietary encoded binary `.mbn` files to load carrier-specific modem configurations (also called `MCFGs`) into their modems. These configuration files can be extracted from the modem image (often named `NON-HLOS.bin`) that is part of the smartphone ROM.

There have been efforts from the open source community towards providing tools to inspect the loaded configuration settings of a smartphone (e.g., *EfsTools*[5]) and to sideload configurations from other smartphones with similar chipsets (e.g., to enable VoLTE support on non-carrier-branded devices). The VoWiFi-related settings are located within the `/data/iwlan_s2b_config.xml` file of the unpacked configuration tree.

2.7.3 Samsung

The VoWiFi configuration on Samsung devices can be found within the `/system/etc/epdg_apns_conf.xml` file on the smartphone. We believe these settings are also used with other modem chipsets on Samsung devices since the file also exists in ROMs for MediaTek- and Qualcomm-equipped models. In contrast to the OEMs mentioned above (e.g., Xiaomi), the Qualcomm-based Samsung devices do not contain additional `.mbn` modem configurations in their modem image.

2.7.4 Google Pixel

Google Pixel generations up to the Pixel 5 used a Qualcomm chipset, utilizing the Qualcomm configuration approach described above. Starting with the Pixel 6, Google introduced its own Tensor-based SoCs, where VoWiFi-specific configuration parameters are consolidated into Android-generic *Carrier Configuration* settings[6]. However, inspecting the publicly accessible operator-specific configuration files[7] shows that the responsible `iwlan` settings are not used in practice. Besides shipping *Carrier Configurations* via the Android-wide presetting, operators can change these settings via their own carrier app (to gain *Carrier Privileges*, an app needs to be signed with a specific certificate that is saved on the SIM card). In practice, many modern Pixel phones fall back to the default values (defined in the Android source code[8]).

3 Threat and Attacker Model

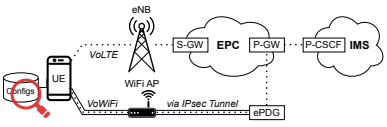
Goals From an adversary's perspective, three main goals motivate an attack:

- G1 Eavesdropping on private communications (e.g., extracting the signaling or voice channel of realized calls or spying on sent SMS messages).
- G2 Using the trusted communication channel as an attack vector towards the phone (e.g., by injecting maliciously formed SIP messages as seen in the recent Exynos vulnerabilities [13]).
- G3 Injecting actions towards the provider (e.g., spoofing SMS messages to impersonate the user or monetizing the exploit by calling value-added numbers) or EPC access in general.

Capabilities Traffic interception and modification can happen at any point over the Wi-Fi (e.g., via ARP/RA spoofing, the Wi-Fi access point (e.g., from a hotspot operator), or while on Internet transit.

For some of the presented attacks, we further assume a determined attacker with the capability to break DH1^{768} or even DH2^{1024}, according to Adrian et al. [15].

Criteria If both the server and client support those weak DH groups and actually use them (either by tricking them or by default config), those VoWiFi tunnels into the EPC would be vulnerable.



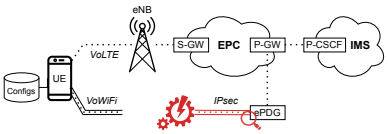
Further, any divergence from the privateness (secrecy) of a *private key* constitutes a broken encryption.

4 Methodology

To explore the VoWiFi landscape and answer RQ1-3, we had to approach it from multiple vantage points: a) We examine the different client-stored operator configurations. b) We test the configuration of commercial network operators worldwide and their corner cases. c) We examine real UE-operator interaction by observing and modifying traffic. In the Discussion in Secion 9, we then contrast those results.

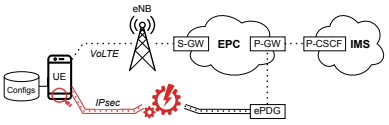
4.1 Static Client-Side Configuration Analysis

To approach RQ1, we chose a static configuration analysis since otherwise, we would need a valid SIM card for each operator.



As stated in Section 2, critical information about the VoLTE and VoWiFi data bearer (or tunnels), as well as the IMS settings, need to be known to the UE in advance for each MNO. In lieu of a 3GPP autoconfigure protocol, a database of known settings for each operator is preloaded to the device. Due to different VoLTE and VoWiFi implementations – depending on the OS, OEM, and modem chipset manufacturer – there is no standardized way to access these settings. Thus, we extract those settings from Apple, Qualcomm-based, Tensor-based (Pixel), and Exyonos-based (Samsung) phones separately, roughly following the market share [14].

We identified the following interesting parameters: 1) the key exchange methods (e.g., Diffie–Hellmann groups), 2) rekeying timers, and 3) encryption, integrity algorithms & pseudo-random function (PRF).



4.2 Active MNO-Side ePDG Scanning

To answer RQ2, we have to analyze operators' IKE handshakes and probe different key exchange methods. First, we query all possible DNS names (described in Section 2), resolving DNS requests in an iterative manner (i.e., getting all the IP addresses from authoritative servers). For each operator, we try to negotiate an IKE phase 1 key with every key exchange method from Table 1 separately – i.e., we pretend to support only one method at a time. For all operators, we record how their servers react and whether they propose a different DH group (if so, which one) or accept the client's choice for a stronger one. Additionally, we test if the server tolerates the client's choice for a weaker DH group, even if both parties announce support for a stronger one. This would ease downgrade attacks to an attackable bit length.

4.3 Testing Implementations and Composition

To answer RQ3, we need to combine multiple results from the client and the server side to form a view of the complete system and its security properties.

4.3.1 Downgrading Possibilities

We examine if phones from different manufacturers accept weaker DH groups even if higher ones are available, with an active test against the phone. We also want to know if phones support any undocumented DH groups. To this end, we redirect real traffic between our phone and the ePDG to a script that allows us to intercept and rewrite data.

Further, we test if networks would accept a weaker DH group despite both parties indicating support for higher groups. To this end, we probe each operator's ePDG but announce multiple methods at once.

4.3.2 Interception Opportunity

When attacking the key, the attacker has to outrace the rekeying period of connections, i.e., crack the key before it loses

validity. We extract those settings from the phones. Putting both sides together, we also consider key value re-usage and undocumented DH groups.

4.4 Limitations

4.4.1 Limited MCC-MNC mapping

One operator can have multiple MCC-MNC designations, for example, because of past mergers. Likewise, one MCC-MNC tuple can (but does not have to) be shared between multiple virtual network operators. This depends on whether the MVNO operates its own Home Subscriber Server (HSS). MVNOs can also contract services, i.e., share the same physical servers with another operator.

We refrained from error-prone manual disambiguation. Thus, unless otherwise stated (for a very particular vulnerability), results operate on a one-⟨MCC-MNC⟩-tuple-per-operator approximation.

4.4.2 Consistent Configuration

For resilience and load balancing, operators could either explicitly or invisibly operate multiple servers/gateways, some of which could have diverging configurations. Explicit load balancing is externally visible, e.g., via DNS round robin, while a dedicated load balancer would conceal load balancing from the outside world (it has only one IP address). Unless otherwise stated, we assume consistent configurations within an operator for our measurements and results.

4.5 Ethical Considerations

Since some parts of this paper include measurements on real-world production provider infrastructure, we assessed its necessity and the least invasive method to perform the investigation.

Invasiveness. We always measured properties with our devices or in sandboxes unless the research subject required real-world data.

Traffic and Server Load. Connections to production systems were of low volume and with the minimum number of connections necessary for the task. Since those systems (e.g., ePDG) are made to handle traffic for (millions) of customers, we are confident that our attempts did no harm.

Traffic Abnormality. Our handshake attempts for the ePDG always confirmed the appropriate RFC format and never contained illegal data or malformed structures.

Confidentiality and Integrity. Our handshake attempts never contained real credentials and, therefore, should never have access to any privileged functions of confidential data.

5 Static Client-Side Configuration

To cover a considerable share of real-world client configurations, we analyzed different implementations and extracted the corresponding settings for the available operators out of smartphones and smartphone firmware images that reflect the current market situation [14]. While not part of our threat model, we additionally extract encryption, integrity and pseudo-random function (PRF) algorithms alongside DH groups and rekey timers for the IKEv2 security association parameters and evaluate their prevalence.

5.1 Implementation

After downloading and extracting the available **Apple iOS** carrier bundles (Section 2.7.1), we filter for iPhones (discarding other device types such as Apple watches) and group them by operator. For our statistical analysis, we select the latest VoWiFi configuration for each operator.

Configurations for **Qualcomm**-based phones, such as Xiaomi and Oppo, use the Qualcomm `.mbn` mechanism as described in Section 2.7.2. Leveraging the information from other open-source projects, we implemented a parsing tool[9] to unpack and parse the modem configuration files. We analyzed configuration files from the Xiaomi 13 Pro (2023-08-22) and the Oppo X6 Pro (2023-12-06).

In the category of **Samsung**'s VoWiFi configurations (see Section 2.7.3), we analyzed the most recent (2023-12-29) configuration file from the Exynos-based Galaxy S24+.

As **Google Pixel** phones have multiple ways to receive carrier configurations, we used them primarily to extract Android 14 default values.

IKEv2 Default Values We focused our client-side analysis on operator-specific settings, overriding the default state. However, operators may also refrain from providing specific values, leading to a fallback to a predefined default. Additionally, these default settings are also used for operators that are not part of the preloaded configuration files at all (e.g., smaller mobile virtual network operators, MVNOs).

In our static analysis, we were able to recover the default settings for Samsung devices (cf. Section 2.7.3) and for newer Pixel phones (cf. Section 2.7.4).

5.2 Results

Table 3 compares the presence of operator-specific VoWiFi settings in our analyzed client configuration files. The percentage column shows the share of operators that actually provide dedicated VoWiFi settings. Figure 4 shows the prevalence of the different DH groups in the analyzed client configurations. We see that on the client side, DH groups with larger key sizes have not reached widespread support yet. Within all analyzed

	PRF	219 (29%)	120 (44%)	203 (54%)	0 (0%)
Total MNO Configs		745	270	377	319

device groups, only a single operator (T-Mobile Germany) on Samsung devices signals support for an elliptic curve group (i.e., $DH19^{256}_{ECP}$).

5.2.1 Apple iOS

Of a total of 745 operator-specific `.ipcc`-configurations for iPhone devices, 219 specify VoWiFi-related settings. The remaining 526 operators either do not support VoWiFi yet or rely on the device's default configuration.

Analyzing the operator-specific VoWiFi settings for iPhones, we discover two properties:

1. While other vendors (e.g., Qualcomm, Samsung) usually define a broad set of supported security parameters, Apple, with the exception of three MNO configs, only defines a single algorithm setting for each VoWiFi-related attribute. Thus, on the network, it just signals support for one single DH group. The same holds true for the other configuration settings (e.g., rekeying or encryption and integrity algorithms).
2. Whenever one IKEv2-related parameter is set for an operator, the configuration also contains all the other parameters. (i.e., the `.ipcc`-configurations always contain complete settings). This can be seen in Table 3, as all columns contain the same percentage values (i.e., 29%).

Due to these properties, Figure 4 shows that iPhones exclusively support (never 3GPP-standardized) $DH1^{768}$ to connect to 9% of the analyzed operators.

5.2.2 Android

Qualcomm `.mbn` files can be deployed and adjusted both by the chipset vendor and OEMs, leading to a different number of `.mbn` files for Xiaomi and Oppo. Our analyzed Xiaomi device includes 270 `.mbn` files, compared to 377 for the selected

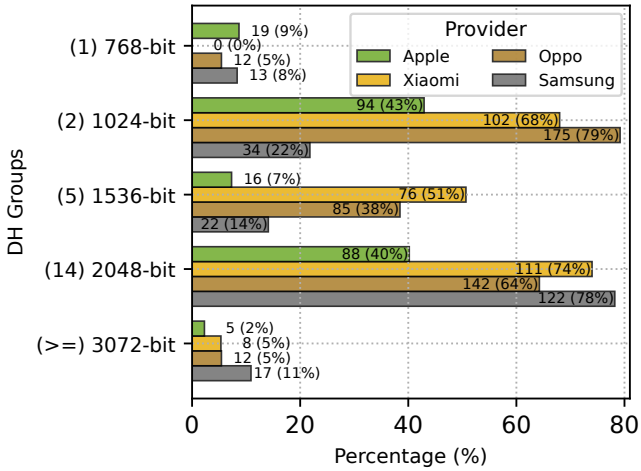

Figure 4: Number of MNOs per supported DH group (client side, grouped by device type).

Oppo smartphone. While MBN files are more likely to include VoWiFi-specific settings, they do not always specify all parameters (as opposed to Apple, Section 5.2.1). Nearly every `.mbn` file includes a rekey timer and differentiates between soft and hard timers. The soft timer specifies the number of seconds until the client tries to renew the corresponding SA. The hard timer states the maximum lifetime of an IKEv2 SA. If only one timer is specified, as is the case for Samsung, it represents the hard timer, thus the total lifetime of the SA. In contrast to the rekey timer only half of the `.mbn` files include SA parameters such as the DH groups, encryption, integrity, or PRF algorithms.

5.2.3 Default (Fallback) Values

As described in Section 5.1, we extracted the default values for Samsung devices and recent Google Pixel phones. Since there were no IKEv2-specific SA parameters available within our default Qualcomm `.mbn` profiles, the used settings are taken from the modem's default (defined in even deeper layers of the modem firmware). To gain comparable settings for Qualcomm, we thus extracted the proposed values from an active capturing of our lab's Qualcomm-based Xiaomi device (the Xiaomi Poco X3 NFC, using the Snapdragon 732G) when no specific carrier `.mbn` file was loaded. We list the default values in Table 2. As the table shows, Samsung only sets

Table 2: Default parameters for IKEv2 if no MNO-specific configuration is present.

Vendor		Qualcomm (Xiaomi†)	Samsung	Google Pixel
Defaults	DH Group	$DH2^{1024}$, $DH5^{1536}$, $DH14^{2048}$	$DH2^{1024}$	$DH2^{1024}$, $DH5^{1536}$, $DH14^{2048}$
	Rekey Timer	64,800s (soft), 64,900s (hard)	86,400s	7,200s (soft); 14,400s (hard)
	Encryption	$AES\_CBC^{128,256}$, 3DES	AES_CBC^{128}	$AES\_CBC^{128,192,256}$
	Integrity	$SHA1^{96}$, AES_XCBC^{96}, $MD5^{96}$	$SHA1^{96}$	$XCBC^{96}$, $SHA1^{96}$, $SHA2^{256,384,512}$
	PRF	$SHA2^{256}$, SHA1, AES^{128}	*	SHA1, AES_XCBC^{128}, $SHA2^{256,384,512}$

* If no PRF is set, the PRF can be derived from the integrity algorithms. † Xiaomi Poco X3 NFC deprecated DH [23]

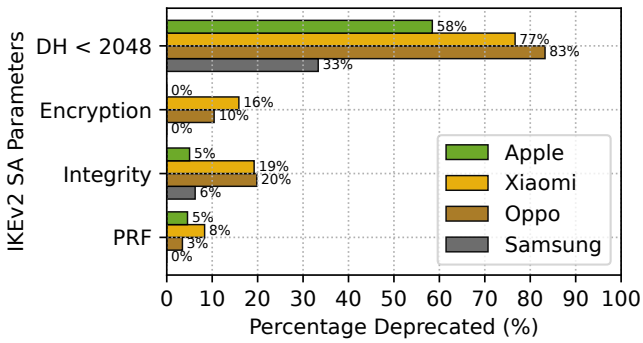

Figure 5: Share of deprecated IKEv2 parameters within all operator-specific VoWiFi settings, i.e., 83% of Oppo's configured DH settings include a deprecated DH group.

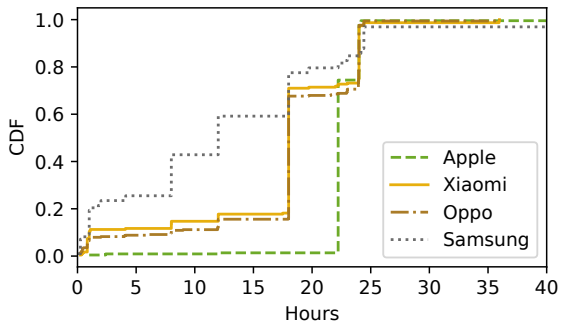

Figure 6: Operator-specific configuration of rekey timings. The majority of Apple devices is configured to renew the keys after 22 hours. For Xiaomi and Oppo, the graph represents the configured soft timers (peaking at 18 hours).

one specific value for each IKEv2 parameter category (similar to the operator-specific behavior observed for iPhones). In contrast, our Xiaomi and Google Pixel devices propose various settings to the server endpoint.

Both Xiaomi and the Pixel phone default to the first (and weakest) setting and propose a DH2^{1024} key exchange within the first `SA_INIT` handshake packet. Note that the initial DH client preference is not relevant for active attackers, because it can be arbitrarily switched by sending an IKEv2 protocol extension packet to the client (as described in Section 7.3 towards the end of the paper).

In the first packet (`SA_INIT`), the UE has to choose a DH group from the list. During our test, the first and weakest DH group DH2^{1024} was chosen.

5.2.4 Deprecated IKE Parameters

Our static analysis of IKEv2 security parameters on the client side shows an alarming share of deprecated algorithms. Figure 5 shows the deprecation share by each IKEv2 security algorithm group and device type.

DH2^{1024} is the most dominant group among the deprecated groups, but also among all measured groups in total for many devices (e.g., Apple, Xiaomi, and Oppo). It is also the go-to fallback value for many configurations (cf. Table 2).

Regarding encryption and integrity, many clients still support the deprecated DES and MD5 algorithms. Table 4 in the Appendix lists decrepated IKEv2 SA algorithms.

Note that Figure 5 only shows the results of the operator-specific settings, not considering default values. For example, Samsung only shows a DH group deprecation of 33%. However, only 49% of the operators override the default value (cf. Table 3); thus, in practice, the deprecated DH2^{1024} group is used as a fallback in many real life scenarios.

5.2.5 Key Lifetimes

The key lifetime on the IKEv2 layer essentially defines the available timeframe for cracking the key. From a security perspective, shorter lifetimes (and, obviously, strong DH groups) are recommended to extend the time and resources needed to crack the key.

Figure 6 shows the rekey intervals set by each vendor. In almost all cases, re-keying takes place within a 24-hour time frame. 40% of Samsung devices tried to rekey in the first 10 hours, while most iPhones rekey after 22 hours, which should leave enough time to be in reach for nation-state attackers. We observed three outliers inside Samsung's MNO configurations that specify a key lifetime of a year. The 3GPP specification [23] does not give recommendations for rekey timers, which ultimately delegates the decision to the operators.

5.2.6 Client Side Validation (Sanity Check)

We used a random sample (n=12) of available smartphone devices (i.e., all testing devices from our lab and some additional models from volunteers that allowed us to record the IKEv2 handshake from their regular smartphone) to do a sanity check and verify whether the obtained results from our static analysis are feasible. Our selection covers every device group from our static analysis with at least one model (i.e., using iPhones, Qualcomm-based devices, Samsung models, Google Pixel, and additionally, several MediaTek-based devices). Although the extracted IKEv2 proposals from our captures are biased towards operators from our home country Austria, we used them as a sanity check to verify the results from our static analysis. For all devices that matched the exact models from the configuration file analysis (i.e., iPhone and Google Pixel), we were able to verify the obtained results, i.e., the proposals were identical to the settings in the configuration files. Moreover, the residual devices from our sample also showed a similar distribution (e.g., DH2^{1024} being the most popular DH group).

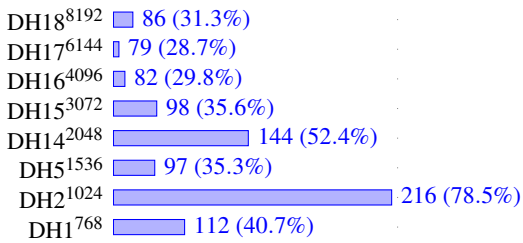

Figure 7: Number of MNOs per supported DH group

6 Active MNO-side ePDG Scanning

6.1 Implementation

To analyze operators' IKE handshakes and probe different key exchange methods we operated as follows. First, we queried all possible ePDG DNS names (Section 2.2) with *massdns*[10], delegating all queries to a local *unbound*[11] instance, iteratively resolving DNS requests (i.e., getting the IP addresses from the authoritative server). Afterward, our Python-based IKEv2 implementation tried to negotiate a key with each of the methods from Table 1 with every operator. Our implementation[12] is based on predefined packet structures from *scapy*[13] and was verified against a self-hosted *strongSwan* server. For each tested operator, we recorded the server's answer, including any optional DH group suggestions, the public key value, and additionally the whole interaction as a PCAP file. Additionally, we tested if the server tolerates a client's choice of a weaker DH group, even if both parties announce support for a stronger one. This would ease downgrade attacks to a feasibly attackable bit length.

6.2 ePDG Supported Key Exchange Methods

As of Q4 2023, operators maintained 423 ePDG domain names (minimum one A record, of which 16 additionally provided `AAAA` records). Of these 423 operators, 275 responded to our handshake, of which 33 rejected all of our proposed key exchange methods. We suspect that some might have geoblocked their VoWiFi services to prevent roaming evasion or for increased security.

6.2.1 MODP Groups

275 ePDG servers responded to our handshake attempts. By offering only one DH group, we tested the servers' capabilities. Some servers tend to ignore requests with unsupported groups, while most reported a handshake error; none proposed a downgrade. As depicted in Figure 7, 79% support DH2^{1024}, followed by DH14^{2048} with 52%, and DH1^{768} with 41%.

[10] https://github.com/blechschmidt/massdns
[11] https://github.com/NLnetLabs/unbound
[12] https://github.com/sbaresearch/vowifi-ke-scanning
[13] https://github.com/secdev/scapy/blob/master/scapy/contrib/ikev2.py

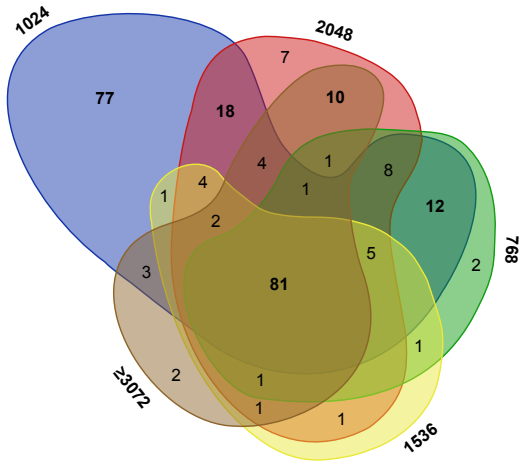

Figure 8: Number of MNOs that support a specific combination of DH key exchange groups. 3072-8192 bit groups are combined because of their low diversity.

Figure 8 shows the combinations of supported methods per operator. Only two operators solely support DH1^{768}, and 77 only support DH2^{1024}. The former was never proposed by the 3GPP for usage [23]. 12 and 18 operators support combinations of DH1^{768}+DH2^{1024} and DH2^{1024}+DH14^{2048}, respectively. Once an operator chooses to support DH15^{3072}, it usually supports most of the groups up to DH18^{8192}. 65 operators supported all groups from DH1^{768} up to DH18^{8192}.

6.2.2 ECP Groups

Except for one private operator, there is no support for elliptic curve groups. 13 operators proposed a downgrade to DH1^{768} in their response, even though all of them support up to DH18^{8192}. Two operators proposed a downgrade to DH14^{2048}. All others (including T-Mobile Germany, which signals ECP support in the client-side config on Samsung devices) either ignored the handshake, returned a negative answer, or reported an error. Thus, in practice, ECP appears to be rarely used for real-world VoWiFi connections.

6.3 Tolerating Weak DH Preferences

We want to know if ePDGs tolerate weaker DH groups than their common set of supported methods allows for. In this test, our client connected, indicating support for all DH groups, but chose DH2^{1024} as the preferred one.

41% of the operators accepted the proposed less secure method, 12% returned an error without indicating which group to choose instead, but 42% desired an upgrade by the client. Roughly half of them chose DH18^{8192}, most of the others DH14^{2048}, with a few single-digit outliers requesting DH15^{3072}, DH16^{4096}, and DH5^{1536} (in descending order).

Curiously, 4% seemed to indicate a desired downgrade to DH1^{768}. However, as all those networks actually support our

proposed DH2[1024], this probably represents a generic *make it work at all costs* error message (e.g., if some of the higher groups are not recognized, similar to what we have seen with ECP groups).

6.4 Inter-MNO Static Key Sharing

In our scans, initially[14], 14 ePDG servers (12 operators, based on IP addresses and background story, see Appendix C) showed a very peculiar behavior: They repeatedly served the same keys. A repeated scan with apx. 500 DH2[1024] handshakes on those MNOs revealed a globally shared set of exactly ten static public keys randomly used on each connection attempt by every one of those operators.

However, this, in return, means that those 12(+1) operators all use the same ten private keys. Violating the secrecy requirement of the *private key* allows any of those operators (or anyone else who seizes the keys from them legally or through other means), as well as the originator of those keys, to decrypt any other operators' shared session secrets instantly.

Using the notation from Section 2.6, if an attacker can read the plaintext DH group and B from the wire and knows one of the private keys (in our case a), the secret session key can be reconstructed using $K = B^a \bmod p$.

In a smaller sample, we also confirmed that similar sets exist for other DH groups on the same operators. As the key a is independent of the DH group, an attacker who does not know the private key A can crack the weakest group DH1[768] and then use it to reconstruct K generated for the stronger groups.

Using passive banner analysis with Shodan[15], we confirmed that at least three of those ePDGs are from ZTE (the others were firewalled). For all MNOs (except for one), press releases show contracts with, winning bids by, or strategic cooperation with ZTE to build an LTE or 5G network. Eight of those networks are located in Asia, three in central Europe, and two in South America.

Without knowledge about how those operators arrived at using the same static set of then non-randomized keys, we initiated a responsible disclosure with the GSMA. The process, the manufacturer's response, and a list of key hashes are to be found in Appendix D.2. We later found that the same ten keys are also used for the phase 2 (L2) key exchange.

6.5 Intra-MNO Key Reusage

We also encountered MNOs that reused keys between handshakes. If handled carefully, this can be a valid optimization on the server side as described in Section 2.6.1.

We have also encountered rare instances of nonce reuse, which violates the IKEv2 specification and also defies the common definition of *number used once*.

[14] After the manufacturer provided a fix, a 15th ePDG/13th MNO appeared.

[15] https://www.shodan.io/

7 Downgrading Vulnerabilities

Based on the results from the above sections, we devise experiments to assess and test the resilience against downgrade attacks. As per our threat model from Section 3, a downgrade to a sufficiently weak key exchange method is considered a successful attack.

7.1 Implementation

As described in the threat model in Section 3, a user's traffic can be intercepted locally (e.g., by a malicious WiFi operator), anywhere on the path, or on a large scale (e.g., by a nation-state monitoring an IXPs traffic). To simulate these threats, we set up a Wi-Fi AP (monitoring the occurring traffic with `tcpdump`) and use it as an Internet uplink for off-the-shelf smartphones equipped with SIM cards of commercial operators within our home country.

For invasive traffic-altering attacks, we devised `iptable` rules that forward the corresponding packets to our MitM (Monster in the Middle) script. For the traffic rewriting we reused the Scapy-based implementation of our server-side scanning solution.

7.2 Outdated Software

While preparing the exploit chain and testing the setup described above, we identified that Samsung and (some) MediaTek-based devices use strongSwan[16] as a foundation for their VoWiFi support.

While Samsung uses a recent version of strongSwan (i.e., version 5.9.8 for the Galaxy S24+), the `charon` binary of our MediaTek device (i.e., the Xiaomi Redmi A1) identifies itself to be part of strongSwan 5.1.2, released in March 2014.

7.3 Pivoting DH Groups via `INVALID_KE`

Whenever a client connects to an IKEv2 server, it has to communicate its supported SA (Security Association) parameters within the `SA_INIT` packet. While it has to decide on a specific key exchange method (i.e., DH group), it can also signal support for other groups within its proposal. The server can then either accept the proposed key exchange method or switch to another offered group by sending an `INVALID_KE` (invalid key exchange) message. This message can carry the server's proposed method. The client then retries and sends a fresh `SA_INIT` packet with the chosen key exchange, as shown in Figure 9. While the proposed SAs within the `SA_INIT` packet are normally protected against rewriting attacks by subsequent integrity checks, downgrading by the `INVALID_KE` message is possible because the client discards its current state and starts from scratch with the indicated key exchange.

[16] https://github.com/strongswan/strongswan

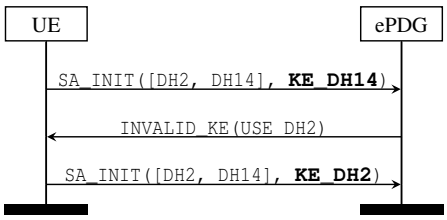

Figure 9: An ePDG server can switch from the initially selected DH group ($DH14^{2048}$) to a different group that is offered by the client within the proposal ($DH2^{1024}$).

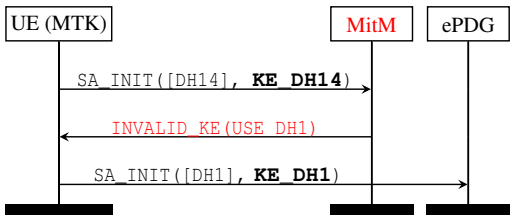

Figure 10: Some of MediaTek's Dimensity basebands are vulnerable to severe downgrade attacks, allowing the selection of DH groups that are known to be weak and were never part of the initial IKE_INIT-proposal nor 3GPP specification.

Thus, an active attacker can suppress the first SA_INIT message and send the client a spoofed INVALID_KE packet proposing a lower DH group and effectively, downgrading the key length. Clients supporting weak DH groups and servers tolerating insecure proposals (without demanding the client to switch to a stronger group if available) facilitate this kind of downgrade attack.

7.3.1 Results

Properly implemented clients that propose multiple SAs are prone to this attack. For example, since Apple devices only announce a single DH group within their client-side proposal, they are not vulnerable to this kind of downgrade attack. The same holds true for other scenarios where the client explicitly uses a single DH group (e.g., devices using Samsung's default configuration that is shown in Table 2). However, as our client-side analysis showed, most devices are overprovisioned with multiple DH groups, and their settings include deprecated groups. For all those devices in our sample, we successfully switched the used key exchange to the weakest offered group using the attack described above – if they were not already making the weakest selection their default anyway.

In context with our results probing the ePDGs, where we have seen that at least 41% of the operators tolerate weak client preferences over stronger available DH groups, we can conclude that it is feasible to execute this attack under real-world circumstances.

7.4 MediaTek Implementation Bug

Besides testing our available UEs for (maliciously played) *protocol-conform* downgrade attacks (as described above), we also tested whether the INVALID_KE message is properly implemented. Specifically, we test how the client will react to the server's (or spoofed) request to switch to a DH group not part of the preloaded configuration.

7.4.1 Results

While all devices behaved as expected (rejection of the offer), some MediaTek-based devices stood out.

We found that there are at least two different IPsec implementations for VoWiFi support on MediaTek devices. The first one (presumably older devices with a Helio chipset) uses strongSwan (based on strongSwan-related configurations in the firmware images). In contrast, newer Dimensity-based devices lack the necessary strongSwan files and thus presumably use a different IPsec/VoWiFi stack.

Our active measurements on multiple models reveal that the latter MediaTek devices are not only *vulnerable* to the attack described above, but also accept INVALID_KE fixations to any DH group (i.e., also to a group that was not part of the UE's proposal). In practice, an attacker can thus downgrade to the weakest $DH1^{768}$, as shown in Figure 10. According to our threat model and Adrian et al. [15], we consider this breakable by well-funded academic researchers and certainly within reach of resourceful (not necessarily nation-state) actors. We want to emphasize that the two downgrade attacks described above work on unmodified, unrooted smartphones within commercial networks.

7.5 Responsible Disclosure

We disclosed those vulnerabilities to MediaTek and a fix is available (Appendix D.1).

7.6 Escalating L1 Attacks

This Section gives some context, on how L1 attacks can be facilitated to gain control over the full IKE/IPSec/SIP stack. The key observations are:

L1 downgrading drastically eases key recovery Even a downgrade to $DH1^{768}$ (Section 7.4) still needs massive computing power to be cracked, but is considered in reach for several years now [15].

Regular Rekeying without Reauthentication IKE's keys are regularly regenerated using a DH exchange based on the selected lifetime (see key lifetime analysis in Section 5.2.5). An attacker can hijack the rekeying as shown in our experiment in Appendix B. However, no authentication is performed

on (L2) making it roll over into the next session key.

(L2) Child SA has no integrity protection It relies on (L1) for providing all of the integrity protection. Since there is no subsequent reauthentication, cracking the outer key exchange is enough to gain stealth rewriting capabilities within the first two layers.

(L3) SIP encryption is optional and not enforced As shown in Experiment Appendix A, SIP encryption is considered optional by most providers.

7.6.1 Full Attack Outline

1. An active attacker inhibits the first `INIT_SA` message from the client to the server and proposes a weak DH group (as described in Section 7).
2. From now on, the attacker lets the client and server handshake the weaker DH group, authenticate the connection (via EAP-AKA), and create a session key for (L2).
3. The attacker can now race to crack the outer key exchange and thus gain rewriting capabilities on (L1) – before the key lifetime expires and a rekeying is triggered. Note: the attacker does not have (L2)'s session key yet.
4. If or when the time comes[17] (Section 5.2.5) for a rekeying of (L1), the attacker can handshake both sides independently and inject themselves in between.
5. Similarly, when (L2) is rekeyed, the attacker can handshake both sides independently and inject themselves in between without needing authenticating. Note: The attacker now has also control over (L2).
6. As encryption of the SIP connection (L3) is optional (Appendix A), an attacker also likely gains control over the client' authenticated IMS session.

8 Related Work

Encryption in Cellular Networks Cryptographic problems have plagued cellular networks from the start. More recently, Yomna et al. [37] presented Android's approach to combat so-called *null ciphers*. Null ciphers are mock ciphers that can be inserted into the encryption stack in case no actual encryption is desired. Cholesta et al. [18] put European networks to the test - many of them still accepted null ciphers on the radio layer. Tsay and Mjølsnes [44] found impersonation vulnerabilities in the Authentication and Key Agreement Protocols (AKA) in UMTS and LTE. Rupprecht et al. [41] categorized past cellular network vulnerabilities to identify classes of errors and how to combat them.

[17] The standard allows both peers to trigger a rekeying prematurely, but we have not tested that.

Diffie-Hellmann Groups and IKE In *Imperfect Forward Secrecy*, Adrian et al. [15] show all the little ways in which DH implementations fail in practice. Bhargavan et al. [16] try to answer the question of how to support reconfigurability while at the same time guaranteeing the preferred mode is negotiated. Felsch et al. [25] reports on Bleichenbacher attacks on IKEv1 and IKEv2.

Evaluating Real-World Security Configurations Hue et al. [31] evaluated both client- and server-side WPA2-enterprise configurations for education institutes (e.g., eduroam), uncovering deprecated settings and suspected private key sharing across different institutes. Valenta et al. [46, 47] performed Internet-wide scans for TLS, SSH, and IPsec, surveying their elliptic curve usage and improper curve validation. Heninger et al. [30] analyzed the occurrence of weak (factorable) keys in the wild.

Evaluation of VPN Servers Maghsoudlou et al. [36] executed Internet-wide scans to discover and fingerprint VPNs, finding over 7 million IPsec servers. Kahn et al. [35] and Ramesh et al. [39] made large-scale measurements in the commercial VPN ecosystem exposing leaked user traffic. Wu et al. [49] investigated academic VPNs, which have become an integral part of the home office life.

Roaming Experiments and Large-Scale Cellular Measurements Sahin and Francillon [42] observed hijacked and thus monetized voice calls being redirected to over-the-top (OTT) services (e.g., WhatsApp, Viber). Gegenhuber et al. [28, 29] introduced a measurement platform enabling scalable cellular measurements by tunneling the communication between SIM card and modem over the Internet. Besides measurements on the radio layer, Gegenhuber et al. [26, 27] also evaluated global VoWiFi deployments, exposing geoblocking practices at VoWiFi by simulating clients from different countries.

SIP in VoLTE and RCS Tu et al. [45] uncovered spoofing and injection vulnerabilities at VoLTE's SIP layer. Similarly, Yang et al. [50] exposed weaknesses in real-world RCS deployments. In 2023, the Google Project Zero team discovered four severe Exynos vulnerabilities, including a remote code execution on the most recent Pixel and many Samsung baseband processors by injecting malicious SIP messages [13] into the VoLTE/VoWiFi traffic.

9 Discussion

This paper set out to cartograph the state of VoWiFi on the UE and MNO side. Little did we know what awaited us. The ecosystem is haunted by multiple structural and standardization problems:

a) an inadequate and slow process of provisioning provider settings to the UEs, with too many middlemen,

b) structural disincentives for phasing out deprecated cryptography and a naïve standardization approach,

c) optional encryption in certain parts of the ecosystem and the prevalence of the dumb client paradigm,

d) critical bugs on the UE and MNO side.

9.1 Provisioning and Configuration

The missing VoLTE/VoWiFi autoconfiguration feature inspired handset manufacturers to find (non-interoperable) ways to preload known settings and curate their own databases (RQ1). It is a painful, tedious task for the operators and the handset manufacturers alike, with multiple middlemen that do not inspire quick, painless updates to new settings, disincentivizing updates.

This is represented in the very inconsistent settings among the different vendors (Section 5) and the large adoption of deprecated DH groups in provider-specific settings (Section 6) as well as default settings, as seen in Figures 4 and 5.

Ultimately, MNOs should have the power to make configuration changes, including removing deprecated cryptographic algorithms without impairing service, if they wish to.

9.2 Structural Hurdles of Deprecation

The MNOs have little to no incentive to phase out older insecure key exchange methods (RQ2). On the one hand, (anticipated) compatibility issues with legacy devices and the slow update process might stoke sentiments against changes. In our sample, only 7% of operators ditched all the insecure DH groups below 2048 bits.

On the other hand, 3GPP/ETSI lacks a defined depreciation path. Just removing it from the standard does not actually remove the method from the world nor the affected devices.

In standards, there is no room to be stingy on the number of key bits. If anything, it is the place to be bold and visionary. If shorter lengths are required at the start, a stringent phase-out plan/process should be defined with it. The development of computing power turned out to be somewhat predictable, and the same can be expected for the deprecation of key lengths.

9.3 Optionality and Strict Configurations

The *dumb client* paradigm, often found in large infrastructure, envisions the majority of decisions to be made by the network and not the client.

Using SIP encryption? If the network does not mandate it, the client will definitely not object.

However, the VoWiFi ecosystem, which is built upon many Internet technologies, has the infrastructure and protocolary means for clients to request better settings at their discretion. UE chipset and operating system manufacturers should take this chance.

Furthermore, the data suggest the importance of those preloaded configurations might also be simply overestimated - as seemingly conflicting carrier configurations from different handset vendors still work, and 42% of the operators request an upgrade of the key exchange method if a common higher group is available. 3GPP, the operators, and handset/baseband manufacturers should trust more in autoconfiguration measures (or enforce their own minimum standards), even at the expense of slightly longer connection times.

9.4 Downgrades, Bugs, and Vulnerabilities

Attacks (Section 7.6.1) against $DH1^{768}$ still require heavy lifting for cracking the key exchange within the key lifetime, but it is assumed to be within reach for resourceful attackers. This is not for everyone, and nation-state actors would, therefore, likely choose a legal approach for domestic key seizure.

However, downgrading to a weaker DH group alone should already be considered a serious vulnerability. Otherwise, selecting different key lengths would be pointless.

Recovered (downgrade attack) and leaked static keys do not always have to be used to attack higher layers up to the SIP/IMS connection (snooping conversations or spoofing commands). (L1) decryption alone can be used as a type of IMSI Catcher [19] on VoWiFi by sniffing EAP-AKA identifiers.

9.4.1 IPsec Rekeying Problems

We see a number of downgrade attacks against the IKE phase 1 manifesting in the 3GPP VoWiFi ecosystem (RQ3). An attacker should not be able to force an exchange method and bit length upon the parties.

Attacks on (L1) and the rekeying system gain impact because they inherit a previous EAP-AKA authentication on (L2). And since (L3) SIP Encryption is optional in many cases (Experiment see Appendix A), this gives an attacker control over all three signal and user data panes.

9.4.2 Accepting Undocumented and Unoffered Algorithms or Key Lengths

The MediaTek vulnerability of accepting unproposed and non-complaint key exchange methods is an *insecure implementation* by over-fulfilling the specification, as described by Rupprecht et al. [41]. In this type of implementation error, the attack surface is unnecessarily enlarged (the client accepts a larger input language than required or even advertised) by including extra functionality outside of the specification. The weak key exchange method was likely inherited from a general-purpose IKE implementation or library. The developer removed it from the advertised methods but never checked the received selection. Ideally, unsupported methods should also be removed from the code.

9.4.3 Not-so-private Private Keys

As the manufacturer was identified as the source of the global static set of ten round-robin keys, they can not be considered *private* for a number of reasons:

a) All of the affected operators are in possession of the same keys and can decode each other's traffic.

b) The manufacturer (and any demo or test customer) are also in possession of those keys.

c) Security or private actors could seize the opportunity to get those keys from an institution under their jurisdiction or other control.

d) Used telco equipment finds its way to second-hand hardware marketplaces [43] and might leak those keys into the public.

10 Evasive Recommendations

10.1 Default to Strongest DH Group

Operator configurations that are preloaded to clients are updated only irregularly and thus often outdated. In practice, supported DH groups within those configs are often comparatively weaker than on the server side. To counter this, clients should treat the preloaded options as a lower bound, and always signal (and prefer) stronger DH groups in their proposal. In the worst case, this adds another roundtrip where the server indicates that it does not support that mode. To save that on subsequent connections, server capabilities could be temporarily cached.

Failure mode. A rejected VoWiFi handshake on security grounds does usually not lead to loss of service for the customer, as the phone falls back to cellular service.

10.2 Not-so-private Private Keys

Leakage or re-usage of private keys can happen for a number of reasons - but from the perspective of a phone that most of the time connects to a single operator's ePDG, only the intra-operator reusage is detectable, not the inter-operator reusage.

UE-local freshness tests. In lieu of a cryptographically ensured freshness, the client can detect key intra-operator reusage with a history mechanism. However, based on the observation time frame and the network volatility, this history might grow large. A constant size and complexity key history could employ a temporal ring of Bloom Filters [20].

Distributed methods. Inter-operator key re-usage detection would require cooperation between a (vast) number of phones either with a common infrastructure (e.g. like DNS blocklists) or in peer-to-peer mode.

Failure Mode. A security-rejected handshake is tolerable, as the user would not experience a loss of service due to fallback to cellular service.

10.3 Fallback to an Unannounced Mode

Do not roll your own crypto! is valuable advise. However, if a standard library is used, unsupported methods and ciphers should be removed not only from the negotiations but also from the code base. A missing test coverage for a particular piece of code could either hint at a missing test or a removable over-implementation.

10.4 Defined Upgrade Path in Standardization

As discussed in Section 9.2, standards of cryptographic applications should define an upgrade timeline for minimum supported security features, such as key length.

11 Conclusion

The VoWifi ecosystem relies on IKE and IPsec to set up secure tunnels into the operator's EPC. However, multiple factors lead to a delayed adoption of up-to-date key exchange mechanisms. Deprecated DH groups (by 2015 standard) and other dated cryptographic primitives are the norm on the client and the operator sides in 2024 – and computing power only got cheaper in that time frame.

Furthermore, we encountered client implementation issues with a major smartphone SoC vendor, facilitating downgrade attacks to weak, non-compliant key exchange methods.

The biggest surprise was the operator side, as at least 13 operators serving 140 million customers apparently used the same global set of static private keys. In both cases, we helped to remove those vulnerabilities through responsible disclosure programs and tracked their progress.

	22	1024 Bit MODP 160 Prime

stock MTK EngineerMode app), we were still able to connect to the home operator successfully.

In such cases, an attacker that cracked the outer IKEv2 key exchange and is thus able to take over the first two layers can subsequently also hijack the third layer after the SIP authenticated between UE and P-CSCF is finished, effectively dominating all three communication layers and reaching all available goals (G1-3).

B Experiment: No Integrity Protection in Regular Rekeying

As described in Section 7.3, downgrade attacks via the `INVALID_KE` message are not integrity protected and work as a stepping stone to taking over the full (L1-L3) stack.

In this experiment, we verify that the same is true for the regular rekeying of (L1).

In this instance only, to simulate the capability of breaking the key exchange, we used a rooted phone. We inject Frida[18] into the process responsible for the IKEv2-related communication and extract the used encryption and authentication keys by intercepting the corresponding library functions.

Thus, we were able to manipulate the rekeying interval and observe it in vivo.

The results confirm that regular rekeying lacks integrity protection similar to `INVALID_KE`-triggered rekeying.

C Static Key Re-usage: Mapping MCC-MNC to Operators

As mentioned in Section 4.4.1, an MCC-MNC tuple does not necessarily constitute an operator. Old MCC-MNCs are often kept alive for historical reasons.

In our set of 15 ePDGs using static keys (Table 5), three pairs had identical IP addresses. *Hutchison Drei* actively maintains 232-05 and 232-10 after merging *Orange* and *One*. The case is very similar for *Smartfren* and their 510-09 and 510-28 designations. In contrast, Malaysia's *U Mobile* and *DiGi* cooperate by maintaining a common 5G infrastructure but are otherwise (mostly) independent operators. Thus, the latter ones are counted as two operators.

Pakistan's Telenor newly showed up in our scans on April 2nd, 2024, over a month after we started the responsible disclosure, and several operators had already rolled out the patch.

D Responsible Disclosure and Remediation

D.1 MediaTek Unannounced DH Group and Downgrade

MediaTek confirmed our findings and issued CVE-2024-20069[19] (severity: high) for the described downgrade attack. The affected basebands[20] with the NR15 modem are from the Dimensity product line.

They released patches to all affected customers. All Android devices with a Security Patch Level (SPL) of 2024-06-05[21] or later are protected from the downgrade attack.

D.2 Globally Static Set of DH Exchange Keys

After the experience with the few and slow responses from the operators themselves [29], this time we reached out to the GSMA's Coordinated Vulnerability Disclosure (CVD) program to timely contact the affected operators and the manufacturer on 2024-02-13. We further reached out to Apple and Google to consider countermeasures for their mobile operating systems.

The GSMA has issued CVD-2024-0089 to track our findings and further helped to communicate them with the affected manufacturers and operators.

ZTE confirmed our findings and issued CVE-2024-22064[22] (severity: high). The software component responsible is ZXUN-ePDG from their CCN (Computing and Core Network) product line. According to ZTE, the bug has been present in all versions before V5.20.20. The issue was caused by incorrectly shipping integration test keys in the production release, they explained. Besides a fixed version, ZTE also offers a volatile runtime-only fix for MNOs that can not currently be updated; it must be reapplied after each restart.

[a] Vulnerability introduced April 2nd 2024. [b] Cut-off date: May 31th 2024

D.2.1 Remediation Timeline

To track the progress of the update, we ran scans hourly. In mid-March 2023, one operator confirmed to us that they received a patch and were testing it. Shortly thereafter, most operators started rolling out the patch into production. Figure 11 and Table 5 note the last time for each operator, we recorded an ePDG server using one of those static keys.

Interestingly, Pakistan's Telenor first started showing up as vulnerable on April 2nd in the scans well after a fix was available. We were later informed, that this is a test site not ready for commercial use and will be upgraded before it is open to customers.

D.2.2 Key Hashes

We include the SHA256 hashes of the found globally-used non-random public keys (bytes in network order) to facilitate blacklisting of those keys. Because of space constraints, we only include DH1^{768} through DH15^{3072}.

[1]Cryspen
[2]Inria Nancy Grand-Est, Université de Lorraine, LORIA, France
[3]Signal Messenger

Abstract

The Signal Messenger recently introduced a new asynchronous key agreement protocol called PQXDH (Post-Quantum Extended Diffie-Hellman) that seeks to provide post-quantum forward secrecy, in addition to the authentication and confidentiality guarantees already provided by the previous X3DH (Extended Diffie-Hellman) protocol. More precisely, PQXDH seeks to protect the confidentiality of messages against harvest-now-decrypt-later attacks.

In this work, we formally specify the PQXDH protocol and analyze its security using two formal verification tools, PROVERIF and CRYPTOVERIF. In particular, we ask whether PQXDH preserves the guarantees of X3DH, whether it provides post-quantum forward secrecy, and whether it can be securely deployed alongside X3DH. Our analysis identifies several flaws and potential vulnerabilities in the PQXDH specification, although these vulnerabilities are not exploitable in the Signal application, thanks to specific implementation choices which we describe in this paper. To prove the security of the current implementation, our analysis notably highlighted the need for an additional binding property of the KEM, which we formally define and prove for Kyber.

We collaborated with the protocol designers to develop an updated protocol specification based on our findings, where each change was formally verified and validated with a security proof. This work identifies some pitfalls that the community should be aware of when upgrading protocols to be post-quantum secure. It also demonstrates the utility of using formal verification hand-in-hand with protocol design.

1 Introduction

The impending advent of large-scale quantum computers poses an existential threat to the security of modern cryptography. As quantum algorithms can efficiently break all widely used asymmetric cryptographic schemes, a paradigm shift towards post-quantum cryptography (PQC) is required to ensure the confidentiality, integrity, and authenticity of sensitive data and communications.

The Signal messenger uses two protocols: X3DH [32] and Double Ratchet [33] (DR) to provide mutual authentication, forward secrecy, post-compromise security, and a form of deniability. These protocols are widely considered as the benchmark for end-to-end encrypted messaging and are also used in other messengers like WhatsApp, Facebook Messenger, and Skype. Both X3DH and DR rely heavily on the Diffie-Hellman (DH) construction, instantiated in the implementation using the Curve25519 elliptic curve [31]. However, this construction can be broken by a quantum computer that uses Shor's algorithm [36] to compute discrete logarithms. Consequently, any message sent using Signal today could be eventually decrypted using a quantum computer, significantly reducing the expected forward secrecy threshold.

To mitigate this risk, Signal proposed a new protocol, called PQXDH (Post-Quantum Extended Diffie-Hellman) as a first step in the post-quantum transition of the Signal messenger. The protocol uses a post-quantum key encapsulation mechanism (PQ-KEM) to fortify X3DH against future quantum adversaries. In the Signal implementation, the PQ-KEM is instantiated using Kyber [17], which is currently undergoing standardization as ML-KEM [2]. The goal of the protocol is to preserve the existing security of X3DH while also providing forward secrecy against harvest-now-decrypt-later (HNDL) adversaries who collect encrypted messages sent today with a view to decrypting them later using a quantum computer.

PQXDH is already deployed, alongside X3DH, in the Signal messenger and is used by tens of millions of users. It is one of the first post-quantum secure channel protocols to be deployed at this scale and serves as an early case study of how to integrate post-quantum crypto in real-world systems.

In this paper, we formally specify and analyze the security of the PQXDH protocol against both classical and quantum adversaries. The security properties we consider are mutual authentication and forward secrecy, but we do not analyze deniability. We use the automated symbolic protocol analysis tool PROVERIF [14] to find flaws and potential attacks in the first version of PQXDH. We suggest fixes to the protocol and then develop a security proof for the updated protocol

using the CryptoVerif prover [15]. In collaboration with Signal developers and designers, we helped incorporate these changes into the now published second version of PQXDH.

Contributions. We provide the first formal security analysis of the PQXDH [29] protocol deployed in Signal, uncovering a public key confusion attack, a KEM re-encapsulation attack, and two additional weaknesses in the protocol. We propose fixes for these attacks, resulting in a second version of the PQXDH specification [30], and we present formal security theorems for this updated version.

As a side contribution, our re-encapsulation attack also brings additional light to the current discussion over the correct security definitions for KEMs [6, 22].To prove that the instantiation of PQXDH in the current Signal implementation is secure, we needed an extra security property for KEMs, which we prove is met by Kyber, and under which PQXDH is secure. This definition is of independent interest.

To the best of our knowledge, this paper provides the first machine-checked security analysis for a real-world post-quantum cryptographic protocol. Our work identifies pitfalls in transitioning cryptographic protocols to post-quantum secure versions, and demonstrates how they can be avoided by the use of formal analysis tools during protocol design, and by deeper collaborations between verification researchers in academia and cryptographic developers in industry.

Models and reproducibility. Our formal models are available online at [12]. Standard versions of the CryptoVerif and Proverif tools are sufficient and not provided at [12].

2 PQXDH: Post-Quantum Extended Diffie-Hellman Key Agreement Protocol

The classic Signal Protocol is the composition of the X3DH handshake protocol [32] with the Double Ratchet protocol [33] for continuous key agreement. In 2023, the X3DH protocol was replaced by PQXDH [29], which we detail in this section, along with the security properties expected from the protocol. Our description is based on the standalone specifications for X3DH and PQXDH.

2.1 X3DH: Extended Triple Diffie-Hellman

We begin with a brief description of the legacy X3DH protocol before detailing the changes made by PQXDH.

The Signal Protocol is designed for asynchronous communication between agents who upload their public keys to a key distribution server. For simplicity, we present X3DH as a synchronous key exchange between two agents Alex and Blake, where Blake may be refered to as the initiator of the exchange, even though in practice, it is the key distribution server that prepares the initial protocol message.

Key Generation Each agent generates multiple key pairs:

- A long term identity key IK.
- A medium term key, called a "Signed PreKey", SPK. This key will be signed when used in the protocol and will be regularly rotated, e.g. every two days.
- A short term "One Time Prekey", OPK, that is deleted after each use, and short term ephemeral keys, EK, used within each session.

For each key pair K, we use K^{sk} to refer to the private key and K^{pk} for the public key. For the agents Alex and Blake, let IK_A and IK_B respectively denote their long term identity key pairs; Similarly, for all other keys, the subscript A denotes a key controlled by Alex and the subscript B denotes a key controlled by Blake. We assume a public-key infrastructure (PKI) so that all identity keys are known by all parties.[1]

Initiation To initiate the protocol, Blake prepares a Pre-key bundle message containing $\mathsf{SPK}_B^{\mathsf{pk}}, \mathtt{sign}(\mathsf{SPK}_B^{\mathsf{pk}}, \mathsf{IK}_B^{\mathsf{sk}})$ and optionally some One-Time Prekey $\mathsf{OPK}_B^{\mathsf{pk}}$.

Session Secret Generation After receiving those pre-keys, Alex verifies the signatures, generates their own ephemeral DH key pair EK_A, and computes some DH shared secrets:

$$DH_1 = (\mathsf{SPK}_B^{\mathsf{pk}})^{\mathsf{IK}_A^{\mathsf{sk}}} \qquad DH_2 = (\mathsf{IK}_B^{\mathsf{pk}})^{\mathsf{EK}_A^{\mathsf{sk}}}$$
$$DH_3 = (\mathsf{SPK}_B^{\mathsf{pk}})^{\mathsf{EK}_A^{\mathsf{sk}}} \qquad DH_4 = (\mathsf{OPK}_B^{\mathsf{pk}})^{\mathsf{EK}_A^{\mathsf{sk}}}$$

DH_4 is optional, and only computed if $\mathsf{OPK}_B^{\mathsf{pk}}$ was provided. Intuitively, DH_1 will authenticate Alex to Blake, and the rest are for increasing levels of confidentiality towards Blake. These three or four DH values are then concatenated and used inside a Key Derivation Function (KDF) to obtain a session key SK_A, used to encrypt a first message with an Authenticated Encryption with Additional Data (AEAD), where the associated data includes an encoding of $\mathsf{IK}_A^{\mathsf{pk}}, \mathsf{IK}_B^{\mathsf{pk}}$. Alex then sends their ephemeral DH public key $\mathsf{EK}_A^{\mathsf{pk}}$, along with the AEAD ciphertext, back to Blake.

Completing the Handshake Upon receiving Alex's message, Blake performs the symmetric DH computations, mutatis mutandis, and passes the concatenated values to the KDF to obtain the final secret, SK_B. Blake then uses this to decrypt the AEAD ciphertext. This decryption is successful if $\mathsf{SK}_A = \mathsf{SK}_B$, and the protocol session is complete.

2.2 PQXDH Design Rationale

The X3DH protocol becomes entirely insecure in the presence of an adversary with a quantum computer or an improved classical algorithm capable of computing discrete logarithms in the underlying group. Because of this, the engineers at Signal Messenger designed an update to X3DH, called PQXDH, with the following design goals:

[1] In practice, this assumption is met if we either trust the server to distribute correct identity keys, or if agents check key fingerprints out-of-band.

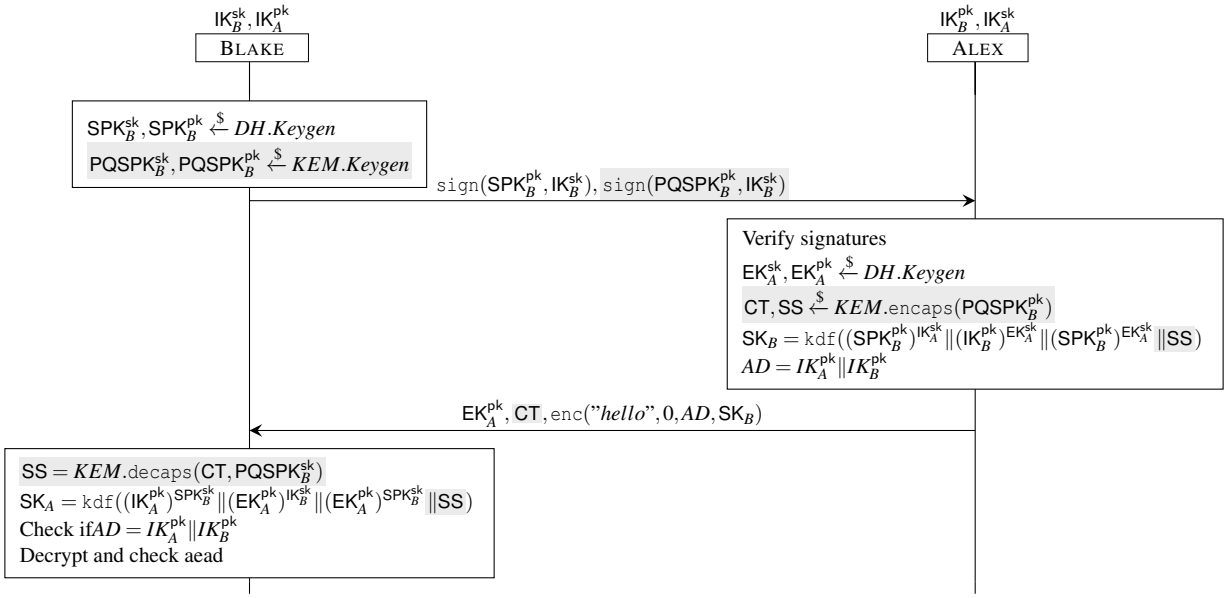

Figure 1: The PQXDH protocol (simplified).
It behaves like the X3DH protocol, with additional (PQ-)KEM computations, highlighted with a light gray background.

1. **Passive quantum adversary.** The protocol must provide security against passive attackers capable of computing discrete logarithms in the underlying group. In particular, it must prevent HNDL attacks.
2. **No security loss.** The protocol must not remove any security guarantees. In particular, the protocol must provide the same DH-based confidentiality and authentication guarantees as X3DH so that even if attacks are found on post-quantum primitives in the protocol, Signal users are no less secure.
3. **Efficient.** When the above security requirements are met, a more efficient protocol for Signal Messenger's usage patterns is preferred. This is a soft design goal, since when performance is reasonable, Signal will trade some efficiency for a security level that exceeds the design goals.

We emphasize that protection against active quantum adversaries is not a goal for PQXDH, although Signal engineers intend to provide this in a future protocol version. Also, since the Signal Protocol and Signal Messenger's implementation of it have seen extensive scrutiny they add to these a fourth, informal guideline: the new protocol should minimize changes to the existing X3DH protocol and its codebase.

Fully Post-quantum Handshake Protocols There is a growing body of research into fully post-quantum replacements for X3DH [19, 20, 25], but these protocols do both more and less than what Signal Messenger requires. They offer more by providing full post quantum security against active quantum adversaries. They offer less since they rely on entirely different cryptographic assumptions and lose all DH-based security guarantees, so these protocols do not meet the requirements without some modification.

Hybrid Protocols One way to reclaim the DH-based security would be to design a hybrid protocol that mixes DH operations into a fully post-quantum handshake protocol. While this is an interesting area of research, the costs of the post-quantum handshake protocols are significant. Since security against active quantum adversaries is not a requirement, any protocol that gives this up in exchange for more lightweight communication and computation will be preferred.

Post-quantum Primitive Selection As seen in Section 2.3, PQXDH uses a PQ-KEM to add post-quantum secure entropy into the classical protocol. While the specification does not require a particular PQ-KEM, Signal selected Kyber1024 [17] for deployment. The Kyber family of KEMs was selected because its standards-track status has both put it under extensive scrutiny and leads them to expect high quality library support in the future. In the Kyber family, the 1024-bit variant was selected as the most conservative option. Since PQXDH is designed to provide security decades into the future, they judged that a marginal additional cost in message size and client computation is a worthwhile hedge against future advances in lattice algorithms.

2.3 Protocol outline

Signal chose an approach that made minimal changes to the X3DH protocol and to their existing codebase. At a high level, PQXDH can be seen as injecting a post-quantum secure shared key into the classical X3DH protocol using a PQ-KEM. In Fig. 1 we present a simplified execution of PQXDH, where we highlight the additions to X3DH. The changes are as follows:

1. Agents also generate a KEM key pair, PQSPK.
2. In the initial message to Alex, Blake includes $\mathsf{PQSPK}_B^{\mathsf{pk}}$ and $\mathtt{sign}(\mathsf{PQSPK}_B^{\mathsf{pk}}, \mathsf{IK}_B^{\mathsf{sk}})$.
3. When computing the session secret, Alex also computes $\mathsf{CT}, \mathsf{SS} \xleftarrow{\$} \mathit{KEM}.\mathtt{encaps}(\mathsf{PQSPK}_B^{\mathsf{pk}})$ and concatenates SS to the X3DH Key Derivation Function input.
4. Alex includes the KEM ciphertext, CT, in its message.
5. Blake uses their private key to compute $\mathsf{SS} = \mathit{KEM}.\mathtt{decaps}(\mathsf{CT}, \mathsf{PQSPK}_B^{\mathsf{sk}})$ and also concatenates it to the X3DH Key Derivation Function input.

Simplifications For clarity we made several simplifications to our description of PQXDH. We provide a full version in Appendix with Fig. 4. In particular, Fig. 1 omits:

- the asynchronous behaviour of the protocol and its untrusted key distribution server;
- the encoding functions for public keys;
- the key identifiers sent in Alex's final message of the asynchronous protocol;
- the DH_4 computation based on the optional OPK;
- the distinction between short-term (or "one time") KEM keys PQOPK and medium-term (or "last resort") KEM keys PQSPK.

However, our formal models of PQXDH include all of the above except the last, and we discuss their security impact. For one-time KEM keys, we note that in the PQXDH specification, Alex has no way to distinguish between a short-term or medium-term KEM key, and an untrusted server can always choose to send medium-term keys and hold back the short-term ones. Thus, in our models and analysis we assume that all KEM keys are medium term.

2.4 Desired Security Properties

The specification does not formally define which security guarantees are meant to be provided by the protocol. However, it provides a high-level discussion on security considerations, including authentication, secrecy, identity binding, deniability, and post-quantum resistance.

We of course would like to prove resistance to harvest-now-decrypt-later (HNDL) adversaries, as it is the main design goal of PQXDH. However, since we expect that PQXDH must attain the same level of security as X3DH against classical adversaries, we also consider traditional authenticated key exchange security properties in our analysis:

- **Mutual Authentication**: if a party completes the protocol with a given public key, it is indeed communicating with the owner of this public key.
- **Forward secrecy**: keys computed between honest participants are secret, unless the long term secrets of a party were compromised before the exchange took place.
- **Resistance to key compromise impersonation**: even if the long term keys of an agent are leaked, sessions initiated by this agent are still secure.
- **Session independence**: the compromise of the short-term material of a session does not affect the security of other sessions and the compromise of medium-term material does not affect the security of sessions using different medium-term keys.
- **HNDL protection**: if an attacker suddenly has access to a quantum computer, all previously completed key exchange are still secure.

Note that we in fact consider a slightly stronger notion of HNDL protection than the one discussed in the "passive quantum adversaries" consideration of [29, Section 4.7]. Indeed, rather than a fully passive quantum attacker, we consider the security against an active attacker that at some point gets access to a quantum computer, and can then try to break the security of previously completed key-exchanges.

The PQXDH security considerations explicitly give some compromise cases leading to insecurity, while stating incompleteness. In our work, we will strive to capture precisely under which conditions the security holds.

2.5 Threat Model and Crypto Assumptions

We consider an active attacker that can intercept and modify all messages sent over the network. The security of PQXDH is expected to hold under a set of standard cryptographic assumptions about the algorithms used in the protocol:

1.A) Either gapDH is intractable for the elliptic curve X25519, which typically implies that any of the DH_x value computed in X3DH cannot be computed if the attacker as only seen the corresponding public shares;

1.B) Or the PQ-KEM (Kyber1024) is IND-CCA [16], which means that only Alex and Blake can derive the shared secret computed by the KEM;

2) And the signature Sig (XEdDSA), is EUF-CMA [18], which means that signatures are unforgeable, and ensures the authentication of the pre-key bundle, which in turn ensures that Blake knows that only Alex will be able to compute the same SK;

3) And the final AEAD (AES256 in CBC mode with HMAC and Encrypt-Then-Mac) is IND-CPA (plaintexts are secrets) and IND-CTXT (ciphertexts are integrity protected) [35], which is of course needed to ensure the secrecy of the first sent message, and is also used to authenticate Alex and Blake together;

4) And the KDF function (HKDF) is a Random Oracle;

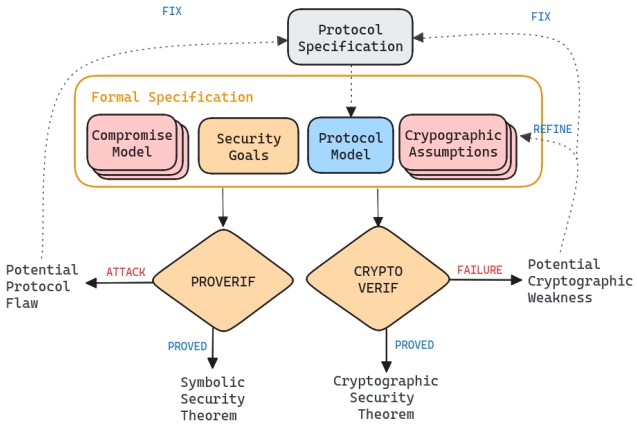

Figure 2: Protocol Verification Workflow

which ensures that if any part of the input is secret, the final key is a strong secret that is indistinguishable from a fresh random bitstring.

We also consider that the attacker may compromise some short, medium and long term keys, depending on the scenario and security property under consideration.

Assumptions 1.A) and 2) must hold against classical attackers, while 1.B), 3) and 4) are also for quantum attackers. Hence, the intuition behind the hybrid design is that 1.A+2+3+4 implies classical security today, and 1.B+2+3+4 implies long term security against future quantum attackers.

We choose the gapDH and ROM assumptions above following prior formal analyzes of X3DH [21]. However, in the quantum setting, we will not rely on the ROM, but rather on the simpler Pseudo Random Function (PRF) assumption.

3 Formal Verification Methodology

To formally analyze whether PQXDH meets its security goals, we employ a multi-faceted approach using both a symbolic protocol analysis tool and a computational proof framework. Our workflow is depicted in Figure 2. We describe each step of this workflow in sequence.

3.1 Modeling the Protocol

We begin by taking the English-language protocol specification document [29] and formalizing it in a protocol description language. Different verification tools accept different input languages. For example, the ProVerif and CryptoVerif tools accepts protocols specified in the applied pi calculus, where each role of the protocol is specified as a *process* that communicates with other protocol participants and the adversary over public *channels*. CryptoVerif also accepts protocols specified using an *oracle* syntax that is more similar to pen-and-paper cryptographic proofs.

For PQXDH, we model two roles (Alex and Blake) and specify how they process and construct the two messages in the protocol using a library of cryptographic constructions. Once the protocol messages are modeled, we define the overall scenario including the public key infrastructure, and the servers that hold the pre-keys. For PQXDH, we model:

- an arbitrary number of agents communicating together;
- a trusted PKI that provides the identity keys of clients to each other (modeled as a public database with tables);
- each device uploads Curve and KEM keys to a server which is fully untrusted (modeled as a public channel);
- each connection consists of one encrypted message from the Alex to Blake (with no follow-up messages);
- each connection can optionally use an OPK;
- we consider that all KEM keys are medium-term keys.

3.2 Threat Model

We add processes to the model that allow for certain keys to be compromised. In our model, identity keys IK may be compromised (dynamically, adaptively) at any time, allowing the adversary to then maliciously sign other keys like SPK and PQSPK and upload them to servers. For certain security goals, we also consider the compromise of short- and medium-term secrets such as OPK, EK, PQSPK, and SPK.

We also model the quantum adversary, which is done by:

- explicitly giving the attacker the power to break the non post-quantum secure primitives (i.e., allow it to compute discrete logarithms and signatures);
- or equivalently, leaking the secrets used by non post-quantum secure primitives;
- or even stronger, not making any cryptographic assumption about the elliptic curve or signature at all.

Essentially, we mark the timestamp for each compromise or quantum attack, and then consider the security for key exchanges completed before this point in time.

Note that depending on the tool and the complexity of the analysis, adding more compromise scenarios may make the analysis infeasible. For example, in CryptoVerif, we only consider the dynamic compromise of the long term identity keys. In ProVerif, thanks to its high level of automation, we are able to consider the dynamic compromise of any cryptographic material of any agent.

3.3 Security Goals

To state the security goals of the protocol we annotate the protocol model with *events* that indicate the current protocol status of each participant. Events do not affect the concrete execution of the trace and are only used to reason about it. For instance the process for Blake triggers the event:

```
event(BlakeDone(A,B,spk,pqpk,sk))
```

to indicate that an agent `B` (playing the role of Blake) has completed a PQXDH session with `A` (playing Alex), where it

used the keys corresponding to the public keys `spk` ($\mathsf{SPK}_B^{\mathsf{pk}}$) and `pqspk` ($\mathsf{PQSPK}_B^{\mathsf{pk}}$) to compute the session key `sk` (SK_B).

Mutual Authentication For authentication, we state that whenever Alex completes the protocol, Blake must also have completed the protocol with matching parameters, which is expressed in PROVERIF (simplified) as:

```
query A,B,spk,pqpk,sk,i,j;
  event(BlakeDone(A,B,spk,pqpk,sk))@i
    ⟹ event(AlexDone(A,B,spk,pqpk,sk))@j & j<i
```

This read as, for all values of the given variables, whenever the event `BlakeDone` was raised with the corresponding values at some point in time `i`, then another agent concluded with the event `AlexDone` with the same parameters and at some time point `j` before `i`. Note that in a query of this form, the variables occurring before the implication are universally quantified, and the other ones are existentially quantified. We state a similar authentication goal in the reverse direction to get mutual authentication.

Confidentiality We can state a range of confidentiality properties for PQXDH. The weakest property is that the attacker should not be able to compute the session key. Since we allow the compromise of long term keys, this query would be trivially false on our models. We then typically write a stronger query corresponding to forward secrecy, covering the fact that the session key is secret unless we compromised the long-term key *before* the session was completed. Then, also taking into account the fact that the attacker may at some point have access to a quantum computer, the post-quantum forward secrecy query is written in PROVERIF as:

```
query A,B,spk,pqpk,sk,i,j;
  event(BlakeDone(A,B,spk,pqpk,sk))@i
          ⟹ not(attacker(sk))
             | (event(LongTermComp(A))@j & j<i)
             | (event(QuantumComp)@j & j<i)
```

Here, the time point `j` represents either the compromise of the long term key of `A`, or the arrival of quantum computers. And this read as, if any agent Blake completed a session and computed key `sk`, then either the attacker cannot compute the key, or the long term key of `A` was compromised before, or the attacker had access to a quantum computer before. If the query is true, it implies that at least one of the cases must be true, which in turn implies forward secrecy, as all session keys computed before the compromise at time `j` is secret.

We can also state an even stronger property that the session key is indistinguishable from a freshly generated random key, which is what we typically prove in CRYPTOVERIF.

3.4 Symbolic Verification using PROVERIF

PROVERIF is a fully automated tool in the symbolic model, where after specifying a protocol and some security properties, it either gives back an attack or a security claim. The attacker model is weaker than the computational model, as the cryptography is assumed to be perfect. PROVERIF does attack finding, and also allows the analyst to quickly explore a set of possible scenarios or protocol variants, as well as scale better to bigger protocols, or more complex compromise scenarios.

Symbolic Cryptographic Model In the symbolic setting for PROVERIF, cryptographic primitives are assumed to be perfect by default. However, we can explicitly give additional capabilities to the attacker. To model the arrival of a sufficiently powerful quantum computer or major advances in classical algorithms, we include in our models the fact that an attacker may at some point be able to compute discrete logarithms. Likewise, to model that advances in cryptanalysis may render a KEM insecure, we include in our models the fact that an attacker may at some point be able to decapsulate KEM ciphertexts without access to the secret key. In PROVERIF, we will thus have a single monolithic attacker model, that may at some point have access to quantum computers, or may at some point be able to compromise the KEM. We will then prove security properties stating the security unless some bad case happens, either a compromise of some keys, or the compromise of one of the primitive.

Finding Attacks with PROVERIF Consider the post-quantum forward secrecy confidentiality query we stated above. If we drop the second and third cases in the disjunction, it just models a basic form of confidentiality.

In our models, this property is of course false: typically, the identity of `A` may be compromised, and in fact fully controlled by the attacker. That is, if we ask PROVERIF to prove this query, it will come up with an attack trace against it where `A` was compromised. As this is a normal and expected insecure case, we then adapt and fix the property we are trying to prove by adding this normal case to the insecure case disjunctions.

Our methodology is to rely on the high automation level of PROVERIF to iteratively do this process, and add the possible compromises that are "normal" cases, until we reach a point where either PROVERIF proves the security by validating the query, or we find an attack that does not correspond to a normal compromise case, and in fact invalidate the security.

By following this informal methodology, one can obtain a query where the disjunction of compromise cases are all independent, and where removing a single one of the cases falsifies the query. When such a query is true, it can be seen as a correct and maximal formulation of the security property: it is correct in the sense that it is met by the protocol, and maximal in the sense that removing any part of the security

property yields an attack and it thus captures that maximal variant of this security property. Note that in our methodology, one has to indeed manually check that all the cases in the disjunction are indeed independent, and that removing a single one leads to an attack. This maximality notion is not a notion of completeness with respect to the real world or the computational model, but it is one with respect to our models and the Dolev-Yao attacker. As our models do include the possible dynamic compromise of any cryptographic material used by any party, this gives us a high level of confidence in the analysis, and in the end we obtain security properties that give us an exhaustive understanding of in which cases security holds.

Interestingly, formulating this kind of property captures at once multiple flavours of the previously mentioned classical security properties for key exchanged. We typically cover in a single query the forward secrecy, session independence and HNDL resistance.

We will detail attacks found when doing this iterative process of query definition, as well as the final queries we proved on the fixed version of the protocol, in the next sections.

3.5 Cryptographic Proofs in CryptoVerif

CryptoVerif is used to make cryptographic proofs of protocols in the computational model. Such proofs are closer to the reasoning used by cryptographers, and model attackers more precisely by considering that they can be any computer running in a reasonable time. It thus gives guarantees similar to cryptographic proofs under common assumptions such as gapDH, IND-CCA or EUF-CMA. It allows an analyst to specify the original protocol as a cryptographic game as well as security properties, and then tries to automatically apply a set of valid game transformations in order to obtain a proof. It supports manual guidance of the proof, which is often needed in complex applications. Importantly, CryptoVerif was recently updated to be post-quantum sound [15], and we can use it to provide valid computational guarantees for post-quantum attackers. Overall, CryptoVerif has a stronger attacker model than ProVerif, it is less automated and does not do attack finding. Further, while the security guarantees of CryptoVerif are stronger, as they correspond to the computational model, making proofs in this model is more difficult. We sometimes have to consider fewer compromise scenarios than is possible in the highly automated ProVerif. All those elements highlight the value of combining the two approaches.

Cryptographic Assumptions In CryptoVerif, the goal is to carry out the proofs under the cryptographic assumptions from Section 2.5, one in the classical setting and another in the post-quantum one. Importantly, in the post-quantum proof, we simply do not make any assumption over the curve which is thus completely insecure, and conversely for the classical proof, no assumption is made over the KEM.

The first proof under the classical security assumptions of gapDH for the curve, EUF-CMA for Sig, IND-CPA+INT-CTXT for the AEAD and the ROM for the KDF should ensure that PQXDH is as secure as X3DH was.

The second proof, this time under classical EUF-CMA for Sig, and post-quantum IND-CCA for the KEM, and post-quantum PRF for the KDF, ensures that PQXDH does bring a new post-quantum resistance. We rely on the PRF assumption for the KDF, both because the post-quantum soundness of CryptoVerif does not capture the quantum ROM, and second because the PRF assumption is in fact more canonical and we can use it thanks to the new KEM shared secret.

Security Proofs For authentication goals, CryptoVerif follows a similar syntax to ProVerif. Consider Alex's authentication query. If we can prove this, it means that whenever Alex accepts in the cryptographic game, then with overwhelming probability Blake did accept and agrees on the given SK. A core difference with ProVerif is that we cannot consider whether some agents are compromised inside the query. Instead, we modify the protocol so that we only raise the corresponding events when the other party is honest and not yet compromised.

For secrecy, CryptoVerif enables us to check that a set of variables will always contain strongly secret values, we then similarly only set these variables in the protocol with a derived key when the two parties are honest and not yet corrupted.

Note that those approaches are more rigid than ProVerif, and in addition coming up with a proof is significantly harder in CryptoVerif, we thus focus on a smaller set of simpler properties, trying to prove the core data authentication and forward secrecy properties.

3.6 Using both ProVerif and CryptoVerif

To summarize, our global approach is twofold:

- in ProVerif we iteratively derive precise and exhaustive security properties, but in a slightly weaker attacker model than classical cryptographic proofs;
- in CryptoVerif we obtain strong guarantees in the computational model , but on a subset of the properties and possible compromises considered in ProVerif.

Our final methodology is then to use both tools in parallel. As we shall see in the following sections, each part of the analysis provided some feedback that could be used for the other part, and using both tools in combination allowed us to discover strictly more weaknesses than using then individually.

4 Protocol Flaws in the PQXDH version 1

The revision 1 of PQXDH [29] allowed for a number of implementations which would have suffered from attacks.

We classify our attacks into two categories, one for the concrete and immediate issues that developers working on post-quantum protocol migration should always have in mind, and one for the more generic design considerations and pitfalls. The immediate issues are two main attacks on the design that we uncovered, along with the justification of why it is avoided on the concrete Signal implementation. The more generic design considerations are made of additional feedback on weaknesses of the specification, which do not directly translate as attacks on one of our target security properties, but impact the overall resistance of the design.

The models used to find those attacks are available at [12]. All experiments were executed on a common laptop with 32Gb of RAM and an 11th Gen Intel(R) Core(TM) i7-1165G7 @ 2.80GHz CPU. All attacks are found in a few minutes so we do not detail more the runtimes here. Expected runtimes are provided in each corresponding modeling file.

4.1 Attacks on the design

4.1.1 Public Key Confusion Attack

We discovered that nothing in the specification ensures that it is possible to distinguish between a KEM and a X25519 public key. This in turn leads to an attack where computations with one algorithm are made with public keys of another algorithm, thus falling outside its secure usages.

Attack description This theoretical attack runs as follows:

1. An attacker swaps the two signatures from Blake before forwarding them to Alex;
2. Alex computes $\mathsf{CT}, \mathsf{SS} \xleftarrow{\$} \mathit{KEM}.\mathtt{encaps}(\mathsf{SPK}_B^{\mathsf{pk}})$, using an elliptic curve public key, and then computes multiple DH exponentiation over a KEM public key.
3. Given CT and EK, the attacker can recompute all the secret values, are they all stem from insecure computations over invalid public keys for the given algorithm.

This is a theoretical attack over the design of the protocol, as it makes it impossible to prove its security under the classical IND-CCA or gapDH assumptions. Indeed, those assumptions do not explicitly specify what happens when invalid public keys are used, and in fact they imply that there is no security guarantees in such a case.

Discovery methodology Trying to prove the secrecy of the key in CryptoVerif led to a failure, where we were in fact unable to carry out the proof under the standard assumptions. We were thus forced to add a domain separation between the public-key signatures to carry out the proof. Note at this point that no attack is confirmed, as failing to do a proof does not imply that this proof cannot be made.

To fully confirm the attack, we then explicitly stated in ProVerif that KEM and DH public keys could be confused together and lead to the insecurity of the encapsulations. ProVerif then produced a concrete attack trace, where the attacker was able to compute the KEM shared secret and thus break the post-quantum security guarantees.

Practical consequences In the Signal implementation, this attack is prevented, since the key sizes of Kyber1024 and X25519 do not match, and in addition each key is prefixed by a byte identifying the algorithm. Adding this format disjointedness as an explicit condition to the specification prevents any future problems with other KEM/DH combinations, or for other independent implementations.

Interestingly, this issue illustrates how adding an extra, provably-secure component to an already-secure protocol may in fact downgrade the guarantees of the protocol. This serves as a cautionary tale for other protocols seeking to use hybrid constructions for post-quantum security.

4.1.2 KEM Re-Encapsulation Attack

The attack is based on the fact that under the classical IND-CCA assumption for KEMs, it is possible to perform so-called re-encapsulations. Consider an honest KEM encapsulation result $(\mathsf{SS}, \mathsf{CT})$ for some key pair $(\mathsf{sk}, \mathsf{pk})$, and an additional key pair $(\mathsf{sk}', \mathsf{pk}')$. If the first key pair was compromised and the attacker knows $(\mathsf{CT}, \mathsf{sk}, \mathsf{pk}')$, it may in fact be able to compute CT' such that $\mathtt{decaps}(\mathsf{CT}', \mathsf{sk}') = \mathsf{SS}$, that is, produce a valid encapsulation for pk' of the same shared secret SS. This scenario is compatible with the IND-CCA assumption, and typically arises when we use IND-CCA secure public key encryption scheme to build an IND-CCA secure KEM. This class of attacks was introduced in [22], which we find a new variant here.

Attack description Consider the following execution, fully described in Fig. 3:

1. An attacker is able to compromise some PQSPK_B of some Blake, while another PQSPK'_B of the same agent is uncompromised.
2. The attacker makes Alex use PQSPK_B, and obtain a ciphertext CT, from which it can learn the shared secret SS, as PQSPK_B was compromised.
3. Now, the attacker, not violating IND-CCA of the KEM, comes up with a new ciphertext CT, valid for PQSPK'_B, such that the decapsulation of CT' is also SS
4. The attacker then forwards to Blake the message from Alex, but swaps CT by CT', and the key identifier of PQSPK_B by PQSPK'_B.
5. Blake succeeds in computing the key using PQSPK'_B.

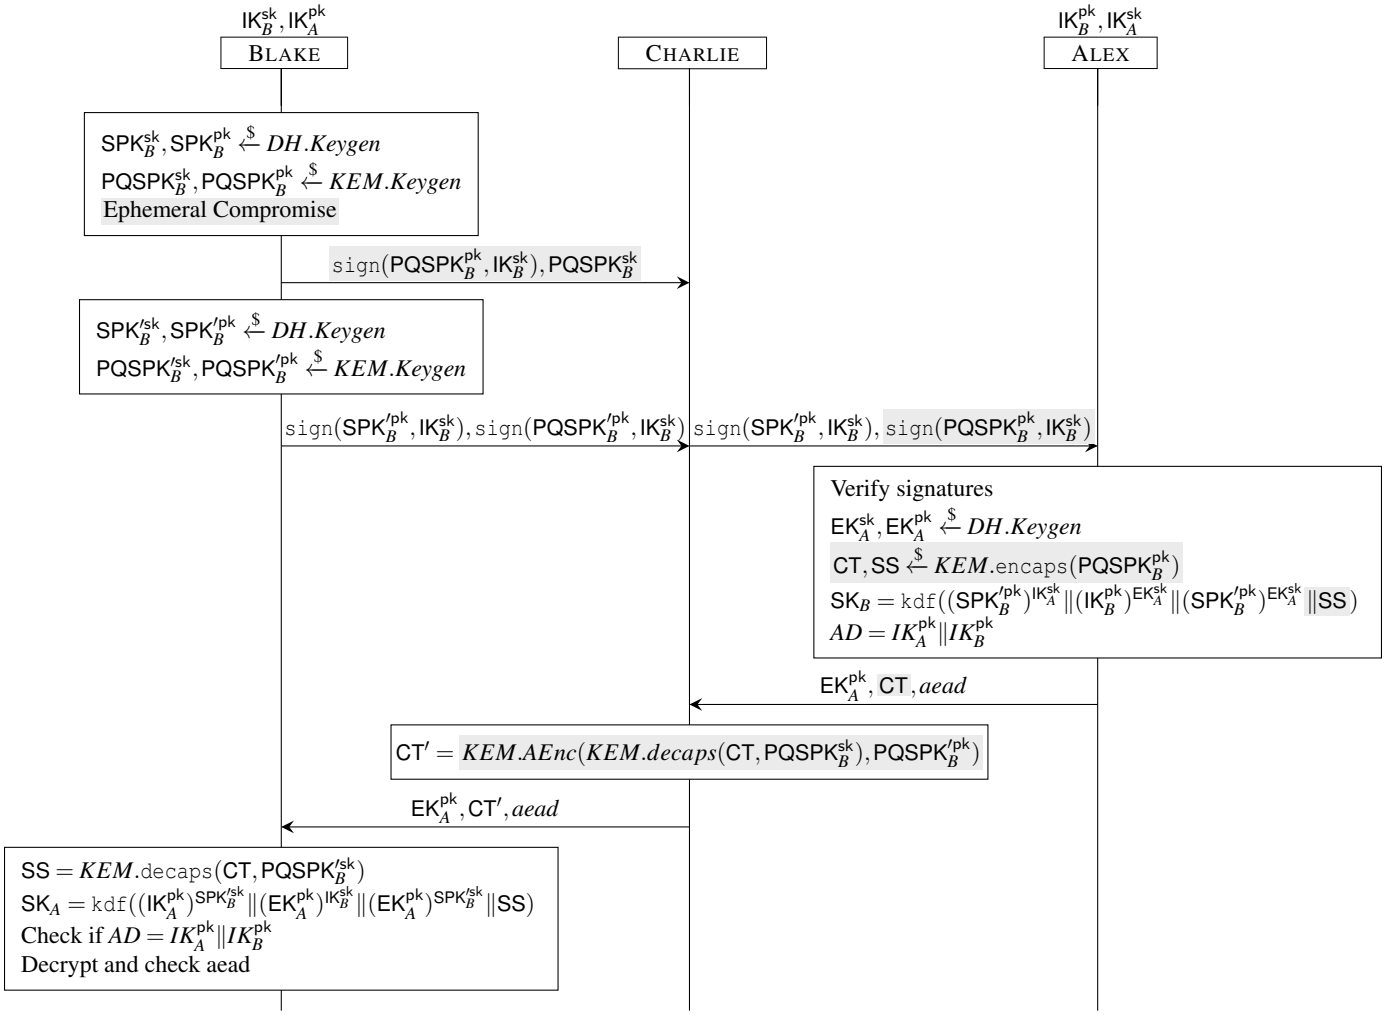

Figure 3: Re-encapsulation attack
Elements not following the standard execution are highlighted with a light gray background.

The main issue here is that the compromise of a single PQSPK_B enables an attacker to compromise all future KEM shared secrets of Blake, and this even after Blake deleted its compromised PQSPK_B. Formally, it is an attack on the session independence, and also imply that there is no mutual agreement on the KEM public key used.

Discovery As stated previously, our CRYPTOVERIF models do not include possible compromise of ephemeral values (this is a limitation to be lifted). We were thus able to complete the proof of the protocol under the classical hypotheses. However, by using PROVERIF, where in fact the basic way to model a KEM is to use an asymmetric encryption to encrypt a fresh shared secret, we could find this attack automatically. It is a surprising corner case, where the classical way to model something in the symbolic model already captures a non-trivial potential attacker capability.

Practical consequences We checked whether Kyber allowed for such re-encapsulations, which turns out not to be the case. So, while it was only formally proven to be IND-CCA secure, Kyber in fact guarantees an additional security assumptions, where the secret is tied to the corresponding public key and ciphertext.

To verify the current implementation, we had to define this additional security property, prove that it is met by Kyber, and prove that there is under this assumption agreement on the public key used in a session, effectively disabling our attack. This is detailed in Section 5.3.

Importantly, implementations of the specification that would have used a IND-CCA asymmetric encryption to build the KEM would have suffered from this. In addition, there are schemes for which the security is unclear: both BIKE and HQC do not directly tie the shared secret to the public key, but only to the ciphertext. Finally, the McEliece KEM is such that "modifying one bit in a public key has a significant chance of not affecting any particular ciphertext" [1, Section 3], and its designer conclude that "Application designers are encouraged to assume solely the standard IND-CCA2 property".

4.2 Design Considerations

4.2.1 KDF Input Confusion

At first glance, it may appear that PQXDH also has an encoding ambiguity in the format of keys used in various calls to the key derivation function (KDF) in the protocol. In fact, the 'info' field contains enough information though to disambiguate these KDF calls.

In our first PROVERIF model, we ignored the 'info' field and the tool found several cross-protocol attacks. Ignoring such seeming low-level details when modeling a protocol can sometimes miss attacks, and at other times yield false attacks.

Even after accounting for the 'info' field, there remains a concern that the format of the KDF input key material between X3DH and PQXDH can be confused with each other. For example, X3DH may use 3 or 4 DH shared secrets concatenated with each other as the KDF input, while PQXDH concatenates either 3 DH and 1 KEM secret, or 4 DH and 1 KEM secret. Within PQXDH, the 'info' field prevents confusions, but there could still theoretically be a cross-protocol attack between PQXDH (3DH+SS) and X3DH (4DH) depending on what info field the application chooses in X3DH, since the X3DH specification does not mandate the contents of its 'info' fields.

This is another interesting instance where the composition of two protocols can potentially result in attacks even if both protocols are individually secure.

4.2.2 Weak Post-Quantum Forward Secrecy

A part of the post-quantum forward secrecy guarantees of PQXDH relies on Alex receiving a signed one-time KEM public key PQOPK and the corresponding Blake deleting the corresponding private key after receiving the PQXDH message. However, since both the PQOPK and the signed last-resort KEM key PQSPK are signed with the same key, and both have the same encoded format, it is impossible for Alex to know whether they are using a last resort or one-time key.

As a consequence, PQXDH offers a weaker forward secrecy guarantee than Alex may expect, since Alex cannot know if the decryption key will be immediately deleted. In practice, however, the last-resort key PQSPK is a medium-term secret, and will be deleted by Blake after some time.

5 Formal Verification of PQXDH version 2

We detail here our provably secure update of the revision that was published by Signal. As the existing implementation does not directly follow some of our recommendations, we also verified that the existing implementation is secure by introducing a dedicated KEM assumption. Looking ahead, we also reflect on the limitations of our model, as well as propose a few possible protocol changes for a revision 3 to improve its future resilience.

The models used to obtain the proofs are also available at [12]. Similarly to the attack finding case, all proofs are completed in a few minutes.

5.1 Protocol Changes in version 2

To address all the previous points, we recommended multiple fixes that were integrated inside a new revision [30]. We provide a diff between revision 1 and revision 2 at [28] for ease of reading, with the following updates:

- To address the key-encapsulation attack, we mentioned that the PQSPK should be included inside the Authenticated Data of the AEAD, or the KEM should in fact meet an additional security property and bind together the secret and the public key ([30, Section 3.3]). As the exact security definition needed for the KEM does not have for the moment a clear consensus, we did not put any clear definition in the draft. We however in this work define our own sufficient security property, see Section 5.3. This is also detailed in the revision ([30, Section 4.12]).
- To address the key confusion attacks, we now explicitly state that the range of the encoding functions for public keys must be pairwise disjoint ([30, Section 2.1]).
- As an intermediate step (as we do not provide guarantees over this in the untrusted server setting), We added key identifiers for the PQSPK and PQOPK that enables Alex to know whether it is a one time or not pre shared key ([30, Section 2.5]).
- Our security theorems are integrated at the beginning of the Security Considerations ([30, Section 4]).
- We made explicit the missing hypothesis that the AEAD must be IND-CPA+INT-CTXT even against quantum attackers ([30, Section 4.7]).
- We added a discussion on key identifiers, not included in our presentation of the protocols, but that are used by Alex to tell Blake which key is used. Including them in our models highlighted that they are in fact not security relevant ([30, Section 4.13]).

5.2 Security Theorems proved with PROVERIF and CRYPTOVERIF

The previous modifications of the revision were proposed only after we tried them in our models. In particular, on the version where we explicitly assume that signatures of SPK and PQSPK cannot be confused and that the PQSPK_B is included inside the AD, we were able to obtain a number of security theorems.

The iterative process described previously in order for us to obtain the most precise possible security queries in PROVERIF yields complicated queries, with many possible disjunctions. Recall that such queries are correct in the sense that PQXDH does satisfy it, and it is complete in the sense that removing a single case of the disjunction leads to an attack trace, which is however a normal insecurity case. This means that this query does capture precisely the full security guarantees of PQXDH in presence of many possible compromises.

For ease of reading and clarity, we only provide a high-level theorem for all our symbolic results here. The detailed queries and corresponding exhaustive theorems are provided in Appendix A.

Theorem 1. PQXDH *in the symbolic model provides peer-authentication, forward secrecy, resistance to key compromise impersonation, session independence and resistance to "harvest now decrypt later" attacks in case of a DH break down.*

In addition, it also provides data agreement over the shared pre-key used.

Using the exhaustive analysis approach, we have an exhaustive list of compromise cases that break the security of the protocol, which leads to a couple of interesting observations:

1. The OPK does not increase the security of the key derived by Blake as much as might be expected. This is a consequence of it being unauthenticated, the attacker can then always send a malicious one instead, or more importantly never send one. Developing a way to detect if when the server does not provide an OPK there are indeed no more OPK available is an interesting challenge.
2. Compromising the SPK_B of some agent Blake allows an attacker to impersonate Blake for any other agent that could want to talk to Blake. It arises from the fact that Alex only authenticates to Blake by using a long term DH share IK_A combined with the SPK_B, an attacker compromising SPK_B can then compute the corresponding DH secret and impersonate Alex. In practice, it means that PQXDH does not meet what could be called an Ephemeral Key Compromise Impersonation.

We also obtained security theorems providing computational guarantees on the protocol with CRYPTOVERIF.

Theorem 2 (PQXDH classical computational security)**.** *If X25519 satisfies the gapDH assumption, the KDF is a Random Oracle, if the AEAD is IND-CPA+INT-CTXT and if the signature scheme is EUF-CMA, then* PQXDH *guarantees both the secrecy of the sent message, as-well-as peer-authentication with agreement over identities, OPK and SPK used, modulo the subgroup elements of X25519, as well as agreement over the PQSPK used provided it was included in the AD.*

Importantly, compared to revision 1, we do have authentication of the KEM public key used, as soon as it is in the AD. Importantly, we stress that Signal does not do this, but Kyber meets an additional property ensuring this, which we discuss in Section 5.3.

Theorem 3 (PQXDH post-quantum computational security)**.** *Under IND-CCA for the KEM, if the KDF is a PRF and the final AEAD is IND-CPA+INT-CTXT, as long as the signature scheme was unforgeable when some key exchange was completed, secrecy of the derived key still holds in the future.*

Importantly, recall that we do get guarantees against a post-quantum attacker, as CRYPTOVERIF was recently updated in order to be able to provide such guarantees [15].

5.3 KEM Public Key Agreement for PQXDH

As the re-encapsulating attack can be carried out without violating the IND-CCA assumption, it turns out that the IND-

CCA security of the KEM scheme is not enough to show the full security of PQXDH. As mentioned in our modification for revision 2, we either need that the PQSPK_B KEM public key is tied inside the AD of the AEAD, or that the KEM secret is in fact bound in some way to the used public key.

The difficulty is that this binding between the secret and public key is not covered by classical cryptographic definitions. It is of course typically not covered by IND-CCA, but it is also not covered by the main previous definitions, as surveyed e.g. in [39, Fig. 2]. In all those definitions, the attacker is trying to come up with an attack against the KEM for honestly generated keys that are never compromised.

Crucially, in our setting and for re-encapsulation attacks, as outlined in [22], the attacker may know the key. We describe in the following a tailored KEM security assumption that enabled us to prove the security of PQXDH under this assumption, and also provide a proof that Kyber does in fact meet this assumption. Thus, we demonstrate that the re-encapsulation attack is not practical for Kyber, and we prove the security of the existing implementation which does not include the KEM in the AD, as required by Theorem 2.

5.3.1 Tailored KEM definition

The core issue of the re-encapsulation attack is that we don't have authentication over the PQSPK_B used by Alex. In the PQXDH setting, we can define a semi-honest collision resistance property over the KEM that enables us to prove this authentication.

Definition 1 (SH-CR)**.** *We define the advantage of an adversary $\mathcal{A}$ against a KEM (*$\mathtt{keygen}, \mathtt{encaps}, \mathtt{decaps}$*) semi-honest collision resistance as:*

$$\mathtt{Adv}^{SH\text{-}CR}_{\mathcal{A},KEM} = \Pr\left(\begin{array}{c|l} \mathtt{decaps}(ct',\mathsf{sk}) = ss \wedge & \mathsf{sk},\mathsf{pk} \xleftarrow{\$} \mathtt{keygen}() \\ (ct \neq ct' \vee \mathsf{pk} \neq \mathsf{pk}') & \mathsf{pk}' \xleftarrow{\$} \mathcal{A}(\mathsf{sk}) \\ & ss, ct \xleftarrow{\$} \mathtt{encaps}(\mathsf{pk}') \\ & ct' \xleftarrow{\$} \mathcal{A}(\mathsf{sk}, ss, ct) \end{array}\right)$$

Here,we have one agent that will decapsulate for its own honestly generated but compromised sk an attacker chosen ciphertext, another agent that will encapsulate against an attacker chosen key, and the attacker wins if both computes the same secret, while either not using the same public key or the same ciphertext. Intuitively, this corresponds to the minimal security property needed to prove KEM ciphertext and public key agreements in PQXDH.

Notice that this is logically independent of the CCR definition from [6], where the attacker tries to come up with two arbitrary ciphertexts that decapsulate to the same value for a given honestly generated but compromised secret key. The separations between the two can be proven as follows.

Theorem 4. *We have the following separations:*

1. *CCR $\not\Rightarrow$ SH-CR*
2. *SH-CR $\not\Rightarrow$ CCR*

Proof. The proof are direct constructions, though probably not practical.

For 1), consider a CCR secure KEM scheme $(\mathtt{keygen}, \mathtt{encaps}, \mathtt{decaps})$. We generate from it KEM', where $\mathtt{keygen}'$ appends 0 to all public keys, and $\mathtt{encaps}'$ simply ignores the last bit of the public key and runs $\mathtt{encaps}$. This is still a CCR secure scheme, but it is clearly not SH-CR as the attacker can simply set pk' to be pk but swapping the last bit from 0 to 1, and then win the game.

For 2) consider a SH-CR secure KEM scheme, and such that, without loss of generality, $\mathtt{encaps}$ returns with at most negligible probability for any input a ciphertext equal to just 0 and 1. We set $\mathtt{decaps}'$ to be $\mathtt{decaps}$, expect on input 0 and 1, where it arbitrarily returns 0. That is, for any key, $\mathtt{decaps}'(0,\mathsf{sk}) = \mathtt{decaps}'(1,\mathsf{sk})$. This means that KEM' is clearly not CCR secure. However, it is still SH-CR, because 0 and 1 may never be returned by the honest encapsulation yielding ct in the SH-CR definition. □

We cannot directly find our notion in [22] either, as they consider for all the definitions either two honestly generated keys (e.g. in HON-BIND-K-CT), two leaked keys (e.g. in LEAK-BIND-K-CT), or two maliciously generated keys (e.g. in MAL-BIND-K-CT), but not our semi-honest setting.

However, similarly to the fact that MAL-Bind-K-CT $\Rightarrow$ *CCR* as discussed in [6], we trivially have on our side that MAL-Bind-K,CT-PK $\Rightarrow$ SH-CR.

More generally, we do not claim that SH-CR is the ideal security definition that KEMs should target, but it is the ideal one for our setting and for use in CryptoVerif, enabling us to carry out all our proofs.

5.3.2 KEM public key agreement

Using CryptoVerif, we proved the following two theorems based on SH-CR.

Theorem 5 (Kyber is SH-CR)**.** *If the hash functions used in the Kyber design are modeled as Random Oracles, Kyber is SH-CR.*

For the reasons mentioned previously in the practical implications of the re-encapsulation attack, it is clear that McEliece does not meet SH-CR, and the situation is unclear for BIKE and HQC.

However, as Signal specifically uses Kyber, we can obtain guarantees over the current implementation.

Theorem 6 (PQXDH KEM public key agreement)**.** *Under similar hypothesis as Theorem 2,* PQXDH *also guarantees the agreement over the PQSPK used provided the KEM is SH-CR.*

5.4 Toward PQXDH version 3

Our analysis also suggest further improvements towards a future revision 3 of the protocol, which would also require changes to the implementation. While these changes do not thwart any known attack, we believe they would increase the trust in the overall design, as well as simplify the proofs. The envisioned changes are:

- to add a tag under the signature of the PQSPK, so that Alex can know whether it is using a one time or a last resort PQSPK. While this does not prevent a malicious server to only provide last resort PQSPK to the attacker, it would at least ensure that Alex knows the corresponding security level;
- to add all the public keys used inside the KDF input, in order to strengthen the data agreement and avoid relying on SH-CR.

5.5 Limitations of our Proofs

We note that our proofs only hold for our models, which do not capture all the details of how the protocol is deployed.

The first limitation is that Signal uses the long term identity keys IK for both curve operations using X25519 as-well-as signature operations XEdDSA. This is a joint key reuse between algorithms, where one would in fact need a joint security hypothesis on both primitives, in the vein of [37]. This issue was completely ignored in the pen-and-paper Signal analysis [21], where the signatures were simply dropped and the data assumed to be pre-authenticated. We take a more precise approach, by still including the signatures, but assuming that IK contains two key pairs, one for curve computations and one for signatures. Coming up with a precise model to capture this key reuse is still an open question, even without considering a formal CryptoVerif proof.

A second limitation is that the CryptoVerif model only considers the compromise of the long term keys, and not of the ephemeral keys. The difficulty here is that each new compromise implies to completely redo the proof, and notably also redefine variants of the cryptographic axioms that allow for those compromises.

A third limitation is that we do not model or prove anything about deniability, which we leave as an open question.

A fourth and final limitation, of both the CryptoVerif and ProVerif models, is that we only consider PQXDH, and not the full eco-system. Lifting this limitation however represents a major challenge for our tools.

6 Lessons learned

Our formal analysis in collaboration with Signal's protocol designers and developers highlighted several interesting points, both with respect to the design of future hybrid schemes, as-well-as how to carry out such formal verifications.

6.1 Designing Hybrid schemes

The core issues we identify that one should consider when updating a protocol to a post-quantum variant are:

- The added KEM public key and ciphertext should be mutually authenticated, otherwise IND-CCA is probably not enough to prove the protocol secure, and the protocol may in fact be insecure for some specific KEM instantiations.
- Domain separation within the protocol between DH public keys and KEM public keys is crucial, as confusion may lead to a downgrade of security.
- Domain separation between distinct protocols is important. This is a typical case where both the old classical version of the protocol and it's post-quantum version will exist in parallel, so derived keys and other materials should not be confused between the two.

6.2 Formal verification

Our approach highlighted the interest of using both ProVerif and CryptoVerif in combination to analyze protocols:

- The lack of domain separation makes it impossible to get a CryptoVerif proof, so we can quickly suspect the presence of a confusion attack. These attacks are not caught by default in ProVerif, since the standard definitions of cryptographic primitives in ProVerif embed domain separation. But once we suspect an attack, we can model it explicitly and then use ProVerif to confirm a concrete attack on the protocol.
- We can model more compromises in ProVerif, and thus catch some attacks not covered by a CryptoVerif proof. One such attack is found, we can fix the protocol, and then go back to the CryptoVerif model and formally prove that the attack is indeed removed.
- Our exhaustive methodology in ProVerif allows us to capture as many attacks as the tool can find. One should always first try to include all possible compromises in the model, and then refine the security queries until they can be proved.

7 Related Work

This work is the first to analyze PQXDH and led to an update of the specification within months of its release. As such, there is no previous related work precisely on PQXDH. In the following, we discuss closely related work.

Our work follows in the line of previous formal analysis of protocol standards using the same or similar verification tools, e.g. of TLS 1.3 [11], 5G-AKA [8], EMV [9, 34] or EDHOC [26], where those analyzes often led to updates of the protocol specifications and implementations.

A variant of X3DH was previously studied in [27]. Our CryptoVerif models were inspired by them but heavily

adapted, both to match the X3DH version as-well-as the PQXDH model. Our PROVERIF models were, on the other hand, rewritten from scratch.

The Signal application eco-system is wider than X3DH, as the derived key is used in combination with the Double-Ratchet (DR) protocol, and an additional layer is introduced by the Sesame multiple session management protocol. X3DH composed with the subsequent DR protocol was analyzed with a pen-and-paper computational proof in [21], but they made rather strong assumptions over the way public keys are authenticated, whereas we model the signatures over those keys, which are crucial to some of the weaknesses we found. More pen-and-paper proofs of the composed X3DH +DR protocol can be found in [3, 13]. In our work, we prove strong formal guarantees for the new PQXDH protocol in isolation.

Implementations of X3DH and DR were also analyzed using DY* [10], and their integration within Sesame was analyzed using the Tamarin prover [24]. Both these works are only inside the symbolic model and use less precise models and cryptographic assumptions for X3DH than our work.

Importantly, none of the results of the previous analyzes of X3DH carry over to PQXDH, as extending a secure protocol with new elements can break its security, even if all these elements are individually secure. Indeed, our work uncovers a potential attack on X3DH because of new key confusions introduced by PQXDH version 1.

A few other tools support post-quantum computational guarantees, such as Squirrel [4, 23] and EasyCrypt [5, 7, 38], but they have not yet been applied to protocols like PQXDH. For us, it was natural to rely on CRYPTOVERIF by building on the previously developed models of X3DH.

We also uncover an attack based on subtle definitions of KEMs, similar to the re-encapsulations attacks discussed in [22]. We discuss the actual KEM security assumption needed for our setting, and link it with recent works [6, 22].

8 Conclusion

We performed an extensive analysis of the recent PQXDH proposal, finding design flaws, contributing concrete updates to the protocol specification, and developing machine-checked security proofs for the fixed version.

This work was performed in collaboration with the Signal design team and demonstrates how formal methods can be efficiently used in a short time frame to improve the design of post-quantum hybrid protocols.

It also highlights the interesting synergy of using multiple tools, as the analysis results from both CRYPTOVERIF and PROVERIF mutually improved each other.

Much work remains to be done around the formal analysis of Signal and of post-quantum secure messaging in general. Important future goals include precisely modeling the full Signal eco-system, developing computational analyzes that can capture the long term identity key reuse for signatures and curve computations, and designing and analyzing a post-quantum secure Double Ratchet protocol.

A Formal Symbolic security Theorems

We proved in PROVERIF a set of three queries, modeling:

1. the exhaustive case disjunction under which the key computed by the responder Alex is secret;
2. the exhaustive case disjunction under which the key computed by the initiator Blake is secret;
3. the exhaustive case disjunction under which there is authentication.

In PROVERIF, the final correct and complete query we were able to prove for the secrecy of the responder key is:

```
query A,B:client, spk:point, pqpk:kempub, sk:symkey,
     i,j:time;
  event(AlexOK(A,B,spk,pqpk,ts))@i
    ⟹ not(attacker(sk))
       | (CompromisedIK(B)@j
            & (j<i
               | (event(CompromiseSPK(B,spk))
                  & (event(CompromisePQPK(B,pqpk))
                     | event(BrokenKEM))
                  )
               )
            )
         | (event(BrokenDH())@j
              & (j < i
                 | event(CompromisePQPK(B,pqpk))
     | event(BrokenKEM)
                 )
              )
```

This can be translated as a security theorem detailing the possible cases.

Theorem 7 (Symbolic Responder Secrecy)**.** *The key SK_A computed by the responder Alex is secret, unless:*

1. *IK_B was compromised before the completion of the key exchange (this is to be expected, this is essentially a malicious A case).*
2. *IK_B was compromised after the key exchange, as well as some SPK_b, and either KEMs are broken or the corresponding $PQSPK_B$ has been compromised (the attacker just need to send a malicious OPK here to be able to compute all the values).*
3. *DH was broken before the key exchange (this is similar to case 1).*
4. *DH was broken only after the key exchange, and either KEMs are fully broken or the $PQSPK_B$ (similar to case 2) .*

All those cases appear normal, and it is in all the possible compromise cases that still maintain security that we find the classical security notions to be implied.

Remark that using an OPK does not change anything on the responder side, as they are not authenticated. But of course, compromising the OPK makes it so that the honest responder will never receive and answer the message.

We can also prove some form of authentication and data agreement:

Theorem 8 (Symbolic authentication)**.** *Whenever an initiator Blake accepts (resp. with or without an OPK), then, there exists a responder Alex that also accepted (resp. with or without the same OPK) with the same SPK_B and $PQSPK_B$, unless:*

1. *IK_A was compromised before the exchange (allows the impersonation of Alex).*
2. *Some SPK_B was compromised before the exchange (knowing SPK_B allows to impersonate A).*
3. *DH has been broken before the exchange.*

The second compromise case here is the most interesting one. Indeed, it means that Signal is suceptible to a form of ephemeral key compromise impersonation: compromising the ephemeral SPK_B secret of Blake allows to impersonate anybody to Blake. This is natural with the design of Signal, as Alex only authenticates by using a long term DH share combined with the SPK_B.

Theorem 9 (Symbolic Initiator Secrecy)**.** *The key SK_B computed by the initiator Blake is secret, unless:*

1. *IK_A was compromised before the communication. (this allows a full impersonation of Alex)*
2. *Some SPK_B was compromised before the communication. (more surprisingly, but inevitably, this allows a full impersonation of any Alex)*
3. *IK_B, SPK_B and $PQSPK_B$ are compromised after the communication, and either no OPK was used or it was compromised. (all secret material of A is leaked here, so this is a very natural case)*
4. *IK_B and SPK_B are compromised after the communication, and KEMs are broken, and either no OPK was used or it was compromised. (similar to 3)*
5. *DH was broken before the exchange (naturally breaks everything)*
6. *DH was broken after the exchange, and the $PQSPK_B$ used by the responder was compromised (similar to 3)*
7. *DH was broken after the exchange, and KEMs are broken (similar to 5)*

In contrast, the OPK now plays a role and increases the security, and also need to be compromised in many cases.

Summing up the three theorems, we do have the higher level security properties mentioned in Theorem 1:

1. peer-authentication: directly implied by Theorem 8, where authentication holds unless there is a compromise.
2. forward secrecy: implied by Theorems 7 and 9, where we can see that compromising the identity key of any party after the completion of a key exchange is not one of the insecure case, and is thus not enough to break the security.
3. resistance to key compromise impersonation: implied by Theorem 8, as authentication holds even if IK_B was compromised.
4. session independence: implied by Theorems 7 and 9, where we can see that one must compromise precisely ephemerals secrets of the target session to break it, and thus that leaking the ephemeral keys of other sessions does not impact security.
5. resistance to "harvest now decrypt later": all three theorems give us that just breaking DH after completion is not enough, and that additional compromises are always needed.

B Full protocol description

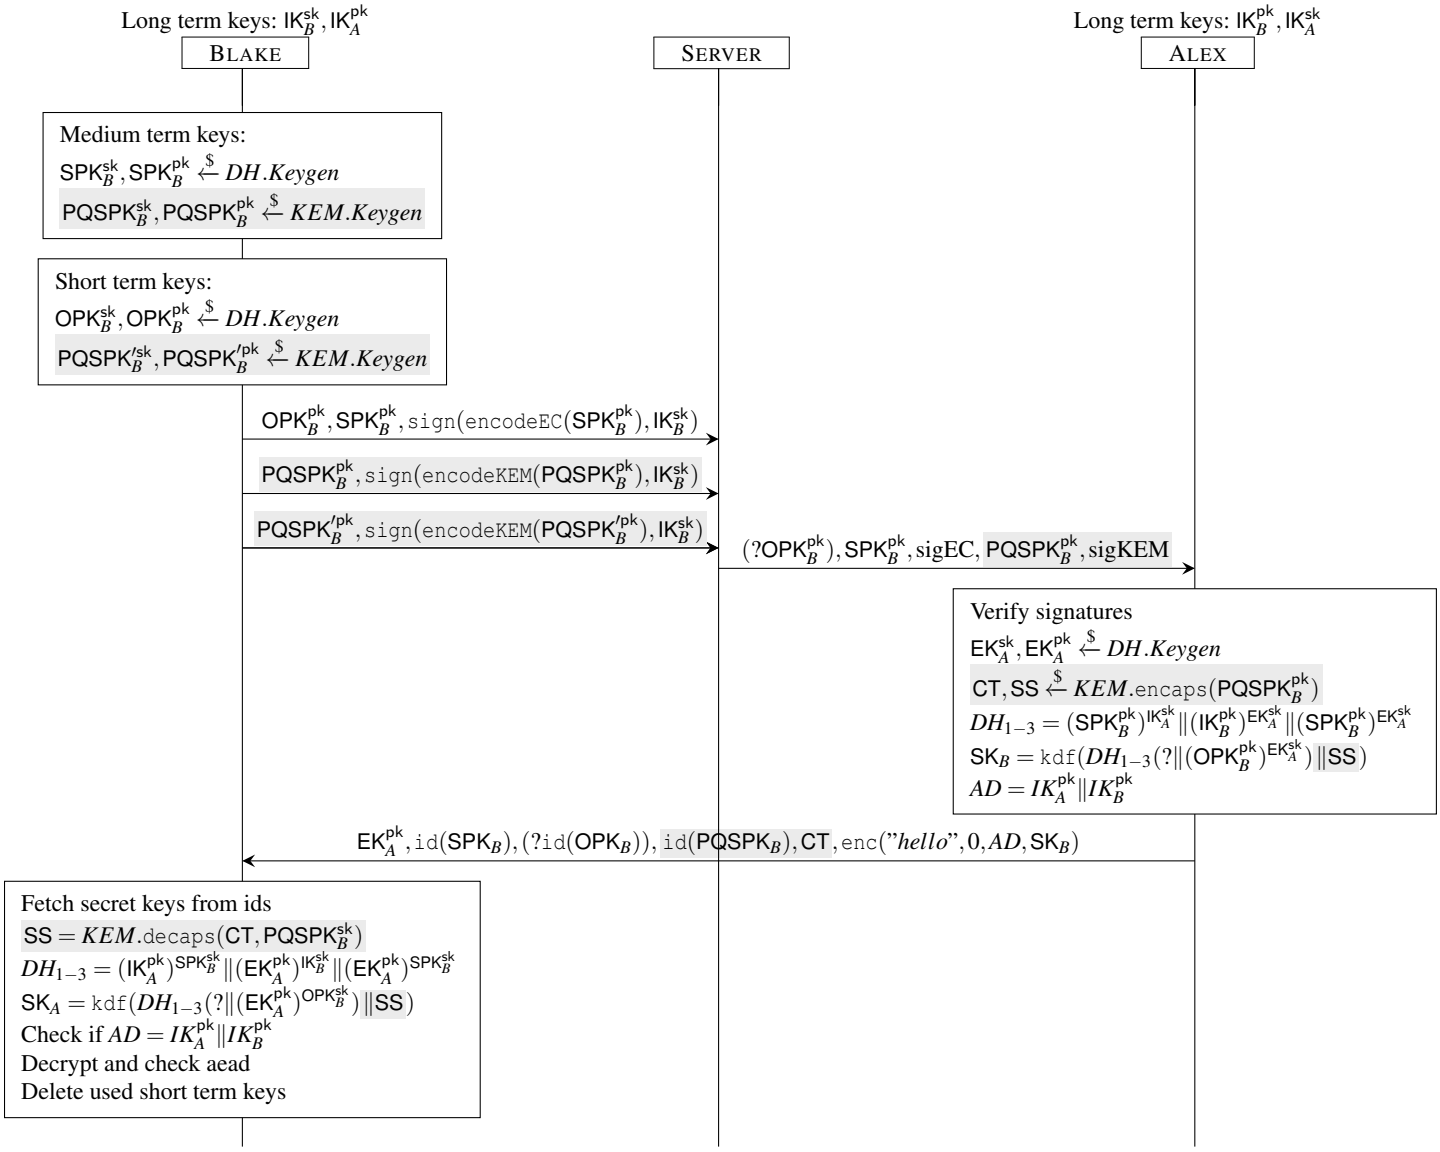

Figure 4: The PQXDH protocol, revision 1.
It is exactly the X3DH protocol, with additional KEM computations, highlighted with a light gray background. Question marks denote optional elements.

Abstract

The advent of quantum computers has sparked significant interest in post-quantum cryptographic schemes, as a replacement for currently used cryptographic primitives. In this context, lattice-based cryptography has emerged as the leading paradigm to build post-quantum cryptography. However, all existing viable replacements of the classical Diffie-Hellman key exchange require additional rounds of interactions, thus failing to achieve all the benefits of this protocol. Although earlier work has shown that lattice-based Non-Interactive Key Exchange (NIKE) is theoretically possible, it has been considered too inefficient for real-life applications. In this work, we challenge this folklore belief and provide the first evidence against it. We construct an efficient lattice-based NIKE whose security is based on the standard module learning with errors (M-LWE) problem in the quantum random oracle model. Our scheme is obtained in two steps: (i) A passively-secure construction that achieves a strong notion of correctness, coupled with (ii) a generic compiler that turns any such scheme into an actively-secure one. To substantiate our efficiency claim, we provide an optimised implementation of our passively-secure construction in Rust and Jasmin. Our implementation demonstrates the scheme's applicability to real-world scenarios, yielding public keys of approximately 220 KBs. Moreover, the computation of shared keys takes fewer than 12 million cycles on an Intel Skylake CPU, offering a post-quantum security level exceeding 120 bits.

1 Introduction

A key exchange is a fundamental cryptographic primitive that allows two users to agree on a common secret key over an insecure channel, such as the Internet. When the protocol involves a single, asynchronous message from each party, it is known as a *Non-Interactive Key Exchange* (NIKE). The seminal work of Diffie and Hellman [32] introduced the well-known NIKE scheme that marked the birth of public-key cryptography; each party sends a single group element g^x (or g^y, respectively) and the shared key can be derived by computing $(g^y)^x = (g^x)^y$. From a theoretical stand-point NIKE implies the existence of public key encryption (PKE), key encapsulation mechanism (KEM), and even authenticated key-exchange (AKE) when combining the results of [22] with [40]. Moreover, in practice, the Diffie-Hellman key exchange lies at the heart of widely-used protocols such as Transport Layer Security (TLS) [69], the Signal protocol [58, 59], or the Noise protocol framework [64]. The looming threat of quantum computers, combined with the discovery of efficient quantum algorithms for factoring integers and computing discrete logarithms [73], has necessitated the exploration of alternative solutions based on new mathematical structures, departing from protocols based on the Diffie-Hellman key exchange. In particular, lattice-based cryptography [68] has emerged as the leading paradigm for constructing *post-quantum* cryptographic schemes. Notably, three out of four algorithms selected for standardisation by NIST are lattice-based [53, 67, 71]. While efficient lattice-based key exchange protocols exist [5, 20, 71], they are all qualitatively different from the standard Diffie-Hellman-style key exchange, in the sense that they require *additional rounds of interaction*. For many applications, where interaction is already built-in, these protocols are perfectly fine substitutes for Diffie-Hellman (which is not post-quantum secure). However, in many scenarios of interest, the non-interactive nature of NIKE protocols is crucial (we discuss concrete examples in further detail in [43]). Unfortunately, despite almost two decades of research on the subject, an efficient lattice-based NIKE remains elusive. Perhaps more worryingly, a recent work [46] has shown theoretical barriers on the efficiency of lattice-based NIKE, calling into question whether it is even possible to build an efficient scheme at all. Thus, the current state of affairs, leaves open the following question:

**Is lattice-based *non-interactive*
key exchange feasible in practice?**

In our work we seek to answer this question in the affirmative, and show that lattice-based NIKE can be made efficient enough to be used in practice, whilst maintaining post-quantum security.

1.1 Our Contributions

In this work, we demonstrate the real-world feasibility of lattice-based *non-interactive key exchange*. We propose a new scheme, that we call "SWOOSH", based on the hardness of the M-LWE problem. We show a proof of its security, both in the passive and active setting, and provide parameter sets for the former with over 120-bits of security against quantum adversaries (using the best known attacks that incorporate recent advances in lattice cryptanalysis). Our contributions can be summarised as follows.

1. We propose a new construction of NIKE based on the hardness of the M-LWE problem. Our construction is based on the standard template [33, 52], but with a new tweak that allows us to prove a strong notion of correctness (which, in turn, is necessary to achieve active security) in the quantum random oracle model (QROM). Somewhat interestingly, our use of the random oracle appears to be different from the Fiat-Shamir [39] and the Fujisaki-Okamoto [41, 42] transformations, and may thus be of independent interest.

2. We propose a compiler that allows for the generic transformation of a passively secure NIKE into an actively secure scheme using non-interactive zero-knowledge (NIZK) proofs, that satisfy a strong soundness property (simulation-sound online-extractability). While this approach is folklore, we provide, to the best of our knowledge, the first explicit treatment of this technique in the literature. Furthermore, the exact notion of passive security needed for the proof to go through, turns out to be surprisingly subtle to identify.

3. We provide a highly optimised implementation [1] of Passive-SWOOSH, written in Rust and Jasmin [6, 7]. With carefully selected parameters, our scheme achieves more that 120 bits of security against *quantum* adversaries. Notably, our benchmarks reveal smaller public keys compared to the smallest parameter set of Classic McEliece [1], an interactive KEM selected for round 4 of the NIST-PQC competition. Furthermore, we demonstrate that Passive-SWOOSH outperforms CSIDH [28], the only currently known (and realistic) post-quantum NIKE by orders of magnitude in terms of speed. Together with existing NIZK proof libraries [54, 55], our work establishes the first competitive construction of a lattice-based NIKE for practical use.

[1] See https://github.com/MQuaresma/pswoosh.

1.2 Related work

Post-quantum NIKE. While interactive KEMs appear to be much more efficient in a post-quantum world than NIKEs, there have been notable efforts towards constructing post-quantum NIKE schemes as well. Boneh and Zhandry [18] showed a construction using indistinguishability obfuscation (iO) to construct a multiparty NIKE from pseudorandom generators. However, the practicality of this approach is hindered by the performance limitations of iO, rendering it mainly of theoretical interest. Much more practical was supersingular-isogeny Diffie-Hellman (SIDH) [30, 48]. However, in 2016, this construction was shown to be susceptible to active attacks [44]. This could be solved by employing the Fujisaki-Okamoto transform [41] in the NIST PQC candidate SIKE [47], but this came at the expense of turning the NIKE into an interactive KEM. Another approach to restoring the active security of SIKE was presented in [9]. This approach preserved the non-interactive nature of SIDH, but required many parallel protocol executions and thus massively increased computation time and message sizes. In 2022, all of these approaches based on SIDH were made obsolete by the numerous attacks against SIDH [27, 56, 70].

In 2018, Castryck, Lange, Martindale, Panny, and Renes proposed CSIDH, a different approach for constructing an isogeny-based NIKE [28]. CSIDH is not affected by the attacks on SIDH, and is arguably the most plausible candidate for practical post-quantum NIKE thus far, although the post-quantum security of concrete parameters is subject of debate [15, 19, 63]. Multiple works have considered the efficient and secure implementation of CSIDH, currently the fastest approach is a variant called CTIDH [10]. We provide a performance comparison of our proposal to CTIDH in Section 6.2. Notably, the work of [16] introduced a compiler for achieving passive to active security. However, the compiler assumes a base scheme with perfect correctness and thus it does not apply to lattice-based NIKE.

Lattice-based NIKE. The idea of lattice-based NIKE using the approach employed in Passive-SWOOSH is not new; in [52] Lyubashevsky calls it *"folklore (since at least 2010)"*. An attempt at selecting parameters was made in [31]. However, the proposed scheme did not formally consider passive security, nor active security. Moreover, the selected parameters resulted in a correctness error that would not even allow the transformation into an actively secure scheme through the use of NIZK proofs, a crucial aspect we achieve in SWOOSH. In fact, prior to our work, lattice-based NIKE was widely considered impractical and this was even substantiated by theoretical evidence. The work of [46]

discovered information-theoretic barriers in constructing lattice-based NIKE with non-interactive reconciliations. In particular, they showed that any natural candidate of lattice-based NIKE with polynomial modulus-to-noise ratio would necessarily incur an inverse-polynomial correctness error. However, we stress that our work does not contradict the theorem of [46]. As the authors of [46] observe, non-interactive reconciliation is possible, if we consider (M-)LWE instances with *super-polynomial* modulus-to-noise ratio. This is indeed the regime of parameters that we adopt in our work.

2 Technical Outline

We give a self-contained overview of our approach for constructing a fast lattice-based NIKE. The following is somewhat informal and glosses over many important details, as it is only intended for an intuitive understanding of our approach. The reader is referred to the respective technical sections for precise statements.

The Basic Blueprint. Before delving into the specifics of our approach, it is useful to recall the folklore construction of lattice-based key exchange between Alice and Bob. Let $\boldsymbol{A}$ be a random public $N \times N$ matrix over some ring $\mathcal{R}_q$ and χ a noise distribution. The protocol proceeds as follows; Alice samples $\vec{\boldsymbol{s}}_1$ and $\vec{\boldsymbol{e}}_1$ from χ^N, and computes her public key as $\vec{\boldsymbol{s}}_1^\top \boldsymbol{A} + \vec{\boldsymbol{e}}_1^\top$. Bob samples an independent $\vec{\boldsymbol{s}}_2$ and $\vec{\boldsymbol{e}}_2$ from χ^N, and computes his public key as $\boldsymbol{A}\vec{\boldsymbol{s}}_2 + \vec{\boldsymbol{e}}_2$. After asynchronously obtaining each other's public keys, Alice and Bob can compute an approximate shared key as

$$\vec{\boldsymbol{s}}_1^\top \left(\boldsymbol{A}\vec{\boldsymbol{s}}_2 + \vec{\boldsymbol{e}}_2\right) \approx \left(\vec{\boldsymbol{s}}_1^\top \boldsymbol{A} + \vec{\boldsymbol{e}}_1^\top\right) \vec{\boldsymbol{s}}_2.$$

A simple calculation shows that the shared keys computed by both parties are identical with the exception of the error terms $\vec{\boldsymbol{s}}_1^\top \vec{\boldsymbol{e}}_2$ and $\vec{\boldsymbol{e}}_1^\top \vec{\boldsymbol{s}}_2$ for Alice and Bob, respectively. To correct these errors, known schemes in the literature run interactive *reconciliation* protocols, which can be realised quite efficiently. However, if we insist on a NIKE protocol, no further interaction is allowed, and Alice and Bob must correct the errors locally. That is, we need to devise a *non-interactive* reconciliation function $\mathtt{Rec}$ such that

$$\mathtt{Rec}\left(\vec{\boldsymbol{s}}_1^\top \left(\boldsymbol{A}\vec{\boldsymbol{s}}_2 + \vec{\boldsymbol{e}}_2\right)\right) = \mathtt{Rec}\left(\left(\vec{\boldsymbol{s}}_1^\top \boldsymbol{A} + \vec{\boldsymbol{e}}_1^\top\right) \vec{\boldsymbol{s}}_2\right).$$

Note that, thus far, we have assumed that both Alice and Bob compute their keys according to the specification of the protocol, i.e., we implicitly only considered passive attacks. However, for the security of the final scheme, it will be necessary to handle parties that may behave arbitrarily. In what follows, we show how we tackle these two challenges separately, in a way that preserves the efficiency and security of the scheme.

Challenge I: Non-Interactive Reconciliation. A natural approach for correcting the errors introduced by the noise terms, is to derive the key by *rounding* the coefficients of the resulting ring element. In fact this is the approach that we adopt in this work, however there are still new ideas required to simultaneously achieve all of the following objectives: (i) security from the hardness of the standard module learning with errors (M-LWE) problem, (ii) reducing the correctness error to negligible, and (iii) maintaining the concrete efficiency of the construction. Here, we stress that a negligible correctness error is not just a matter of convenience, but that a non-negligible correctness error translates to an attack against the scheme: Loosely speaking, this is because the attacker can observe whenever the key agreement fails, therefore learning some information about the secret key of the honest party. Let us now focus on making the rounding approach work for non-interactive reconciliation. A simple calculation shows that the error terms cause a correctness error, only when the term $\vec{\boldsymbol{s}}_1^\top \boldsymbol{A}\vec{\boldsymbol{s}}_2$ falls into a *danger interval*

$$S^* = \left[\frac{q}{4} \pm \beta^2 dN\right] \cup \left[\frac{3q}{4} \pm \beta^2 dN\right],$$

where β is a bound on the norm of the noise distribution and d is the degree of $\mathcal{R}_q$. It is tempting to conclude that, if q is sufficiently large, then this event only happens with negligible probability. However, this analysis is imprecise as it does not take into account *adaptive* attacks, where the adversary chooses their secret key intentionally to make this event more likely. To prevent this, and obtain a provably secure scheme, we add a *random shift* $\boldsymbol{r}$ to the term $\vec{\boldsymbol{s}}_1^\top \boldsymbol{A}\vec{\boldsymbol{s}}_2$ to ensure that their sum $\vec{\boldsymbol{s}}_1^\top \boldsymbol{A}\vec{\boldsymbol{s}}_2 + \boldsymbol{r}$ is indeed uniformly distributed in $\mathcal{R}_q$. Note that such $\boldsymbol{r}$ does not need to be kept private, although it is important that it is sampled independently of the keys. Our idea is to sample $\boldsymbol{r}$ as the output of a hash function (modelled as a random oracle) on input the two public keys. This allows us to achieve two goals simultaneously:

- Both parties can recompute the shift $\boldsymbol{r}$ without the need of further interaction.
- We can show that $\vec{\boldsymbol{s}}_1^\top \boldsymbol{A}\vec{\boldsymbol{s}}_2 + \boldsymbol{r}$ is indeed uniformly sampled, even if the adversary has quantum access to the random oracle.

In summary, we are able to build a non-interactive reconciliation mechanism so that the scheme is provably secure (in the passive settings) against the standard M-LWE assumption, in the QROM. In fact, we are also able to show a strong notion of correctness, namely that the adversary cannot cause a reconciliation error, *even if it is allowed to choose both secret keys*. This strong notion of correctness will be useful when lifting the scheme to the active setting.

Challenge II: From Passive to Active Security. The above discussion concerns keys that are guaranteed to be well-formed (passive security). However, in real-world scenarios we have to deal with attackers that can behave arbitrarily. In the stronger notion of *active security* [25, 40] the adversary is given access to various oracles that allow them to register honest keys, register corrupt keys (ones to which they do not know the corresponding secret key), or reveal the shared key between an honest key and a corrupted one. Ultimately the adversary wins if he can distinguish between a random key and a shared key, that was derived from two honestly generated key pairs.

In order to prove the active security of our scheme we present a *compiler* that generically lifts our scheme to the active setting using non-interactive zero-knowledge (NIZK) proofs. Here it is crucial that our scheme satisfies the aforementioned strong notion of correctness, since the only thing that the NIZK guarantees is that the keys are in the support of the honest distributions, but otherwise they may be chosen arbitrarily. For technical reasons, we require a NIZK that satisfies the strong property of simulation-sound online-extractability. We refer the reader to Section 5 for more details.

Putting Everything Together. Overall, we obtain a passively secure construction in the QROM assuming the hardness of the Module-LWE (M-LWE) problem (for the active settings, we additionally require a NIZK proof). Compared to Ring-LWE (R-LWE), M-LWE gives us greater flexibility over the choice of parameters, when implementing our scheme. However, this introduces an additional complication: Unlike the case for R-LWE, where single polynomials are considered and their multiplication is commutative, in the case of M-LWE we work with matrices where the matrix multiplication is not generally commutative. For the general case of two parties without predefined roles in a protocol, there is no way to know ahead of time whether to left multiply or right multiply. This means that each public key is effectively duplicated by adding a left multiplied key and right multiplied key. However, we argue that in many cases, when parties have predefined roles in a protocol, such as a server or client, this issue can be resolved (the server could "go right" and the client "left" or vice versa). We defer a more detailed discussion of this to Section 5.3.

Our parameters are selected as to provide more than 120 bits of post-quantum security, taking into account recent advances in lattice cryptanalysis. We work over the ring $\mathcal{R}_q := \mathbb{Z}_q[X]/(X^d+1)$ with $d = 256$. Along with our public matrix $\boldsymbol{A} \in \mathcal{R}_q^{N\times N}$, where $N = 32$, this gives us a lattice dimension of 8192. In order to reduce the correctness error to reasonable levels, q had to be sufficiently large. We choose $q = 2^{214} - 255$, a prime that is simultanously NTT-friendly and close to a power-of-two making for more efficient field arithmetic. Furthermore, we use ternary noise sampled from a centred binomial distribution, for the sake of efficiency.

Finally, we provide an open-source implementation of Passive-SWOOSH in Rust and Jasmin, which employs numerous optimisations rendering competitive benchmarks. Due to the modular fashion of our implementation we note that it can easily be tailored to use different parameters or be incorporated with suitable NIZKs. We defer a more detailed discussion to Section 6.

3 Preliminaries

In this section we introduce our notation and review some quantum preliminaries along with the relevant lattice-based hardness assumptions.

3.1 Notation

We define some standard notation used throughout the paper.

Sets, Vectors, Polynomials and Norms. For integers a, b, where $a < b$, $[a,b]$ denotes the set $\{a, a+1, \dots, b\}$. For any positive $\beta \in \mathbb{Z}$, we define the set $[\beta] := \{-\beta, \dots, -1, 0, 1 \dots, \beta\}$, and let $x \xleftarrow{\$} \mathcal{S}$ denote the uniform sampling of x from the set $\mathcal{S}$. Let $\mathbb{Z}_q$ denote the ring of integers modulo a prime q. We define $\mathcal{R} := \mathbb{Z}[X]/(X^d+1)$ to be the ring of integer polynomials modulo X^d+1, for d a power of 2, and $\mathcal{R}_q := \mathbb{Z}_q[X]/(X^d+1)$ the ring of integer polynomials modulo X^d+1 where each coefficient is reduced modulo q. Bold upper case letters $\boldsymbol{A}$ and bold lower case letters with arrows $\vec{\boldsymbol{a}}$ denote matrices and column vectors over $\mathcal{R}_q$, respectively; for row vectors we use the transpose $\vec{\boldsymbol{b}}^\top$. For a polynomial $\boldsymbol{f} \in \mathcal{R}_q$, let $\vec{f} \in \mathbb{Z}_q^d$ denote the coefficient vector of $\boldsymbol{f}$, and $f_i \in \mathbb{Z}_q$ the i^{th} coefficient. However, we denote the constant coefficient by $\tilde{f} := f_0 \in \mathbb{Z}_q$. For an element $f_i \in \mathbb{Z}_q$, we write $|f_i|$ to mean $|f_i \bmod q|$. Let the ℓ_∞ norm for $\boldsymbol{f} = \sum_{i=0}^{d-1} f_i X^i \in \mathcal{R}_q$ and $\vec{\boldsymbol{f}} = (\boldsymbol{f}_1, \dots, \boldsymbol{f}_k) \in \mathcal{R}_q^k$ be defined as

$$\|\boldsymbol{f}\|_\infty := \max_{0\le i\le d-1} |f_i| \quad \text{and} \quad \left\|\vec{\boldsymbol{f}}\right\|_\infty := \max_{1\le i\le k} \|\boldsymbol{f}_i\|_\infty,$$

respectively.

Probabilities, Algorithms and Games. The support of a discrete random variable X is defined as $\sup(X) := \{x \in \mathbb{R} : \Pr[X = x] > 0\}$. Algorithms are denoted by upper case letters in sans-serif font, such as A and B. Unless otherwise stated all algorithms are probabilistic and $(x_1, \dots) \xleftarrow{\$} \mathsf{A}(y_1, \dots)$ is used to denote that A returns $(x_1, \dots)$ when run on input $(y_1, \dots)$. When A has oracle access to B during its execution, this is denoted by A^{B}. For a probabilistic algorithm A, the notation $x \in \mathsf{A}(y)$ denotes that x is a possible output of A on input y. We use code-based security games [12], where $\Pr[\mathsf{G} \Rightarrow 1]$ denotes the probability that the final output of game G is 1. The notation $[\![B]\!]$, where B is a Boolean statement, refers

to a bit that is 1 if the statement is true and 0 otherwise. The following lemma demonstrates the high probability of a randomly selected matrix being invertible. Due to space constraints, the proof is deferred to the full version [43].

Lemma 1 (Invertibility of Random Matrices)**.** For $\mathcal{R}_q = \mathbb{Z}_q[X]/(X^d+1)$ with $d = 256$ and $q = 2^{214}-255$, if $\boldsymbol{A}$ is a random matrix sampled from $\mathcal{R}_q^{N\times N}$, then the probability of $\boldsymbol{A}$ being invertible, denoted by $\Pr[\boldsymbol{A} \in \mathsf{GL}_N(\mathcal{R}_q)]$, satisfies

$$\Pr[\boldsymbol{A} \in \mathsf{GL}_N(\mathcal{R}_q) \mid \boldsymbol{A} \xleftarrow{\$} \mathcal{R}_q^{N\times N}] \geq \left(1 - \frac{128}{q^2}\right)^N.$$

3.2 Quantum Preliminaries

We review some quantum preliminaries as stated in [36]. Additional preliminaries are deferred to the full version [43].

Quantum Random Oracle Model. In the random oracle model [11], all parties have access to a uniformly sampled random function H. Since quantum adversaries can evaluate hash functions in superposition, we model quantum adversaries to have quantum access to random oracles [17]. Specifically, we assume that all algorithms have access to the unitary implementing the mapping: $|x\rangle|y\rangle \mapsto |x\rangle|y \oplus \mathsf{H}(x)\rangle$ where H is a uniformly sampled random function.

Query Depth and Query Parallelism. As in the work of [8] we consider the query depth D of an adversary making a total of Q_H random oracle queries. This is important in practice because for highly parallel adversaries we have $D \ll Q_\mathsf{H}$. By setting $D := Q_\mathsf{H}$ we obtain the bounds for sequential adversaries. We will use the following technical lemma from [8].

Lemma 2 (Search in unstructured functions [8, Lem. 2])**.** *Let* H *be a random function drawn from a distribution such that* $\Pr[\mathsf{H}(x) = 1] \leq \lambda$ *for all* x*. Let* A *be an adversary with query depth* D*, making at most* Q_H *many queries to* H*. Then*

$$\Pr\left[\mathsf{H}(x) = 1 : b \xleftarrow{\$} \mathsf{A}^{\mathsf{H}}\right] \leq 4 \cdot (D+2) \cdot (Q_\mathsf{H}+1) \cdot \lambda.$$

3.3 Hardness Assumption

The security of our scheme relies on Module-Learning With Errors (M-LWE), a well-known computational lattice problem [50, 68].

Definition 1 (**M-LWE**$_{q,n,m,\chi}$)**.** The decisional *Module-Learning With Errors* problem (in its Hermite normal form) with parameters $n, m > 0$ and an error distribution χ over $\mathcal{R}_q$ is defined via the game **M-LWE**$^b_{q,n,m,\chi}$ depicted in Figure 1. Here, **M-LWE**$^b_{q,n,m,\chi}$ is parameterised by a bit b. We define A's advantage in **M-LWE**$^b_{q,n,m,\chi}$ as

$$\mathsf{Adv}^{\textbf{M-LWE}}_{q,n,m,\chi}(\mathsf{A}) := \left| \begin{array}{l} \Pr[\textbf{M-LWE}^{0,\mathsf{A}}_{q,n,m,\chi} \Rightarrow 1] \\ -\Pr[\textbf{M-LWE}^{1,\mathsf{A}}_{q,n,m,\chi} \Rightarrow 1] \end{array} \right|,$$

and say that **M-LWE**$_{q,n,m,\chi}$ is ε-hard for all adversaries A satisfying $\mathsf{Adv}^{\textbf{M-LWE}}_{q,n,m,\chi}(\mathsf{A}) \leq \varepsilon$.

Game M-LWE$^b_{q,n,m,\chi}$

```
01 b' <-$ A^RoR(b)
02 return [[b = b']]
```

Oracle $\mathsf{RoR}(b)$ / Once

```
03 A <-$ R_q^{n×m}
04 if b = 0 :
05   s <-$ χ^m
06   e <-$ χ^n
07   return (A, As + e)
08 elseif b = 1 :
09   u <-$ R_q^n
10   return (A, u)
```

Figure 1: Game defining **M-LWE**$^b_{q,n,m,\chi}$ with adversary A.

Theoretic treatments of LWE-based schemes typically consider the modulus to be polynomial in n and χ to be the discrete Gaussian on $D_{\mathbb{Z},\alpha\cdot q}$ over $\mathbb{Z}$ with mean 0 and standard deviation $\sigma = \alpha \cdot q/\sqrt{2\pi}$ for some $\alpha < 1$. For these choices the work of [23, 68] showed that if $\alpha q > 2\sqrt{n}$ then worst-case GapSVP-$\tilde{O}(n/\alpha)$ reduces to average-case LWE. As such, many early implementations sampled from a discrete Gaussian distribution, which turns out to be either fairly inefficient [21] or vulnerable to timing attacks [24, 38, 65]. Furthermore, the performance of the best known attacks against LWE-based encryption schemes does not depend on the exact distribution of noise, but rather on the standard deviation (and potentially the entropy). This motivates the use of noise distributions that we can easily, efficiently, and securely sample from. One example is the centred binomial distribution used by CRYSTALS-Kyber [71] and in [5].

4 Definitions

In this section we present a formal definition of a non-interactive key exchange along with its security notions. A precise definition of non-interactive zero-knowledge proofs can be found in the full version [43].

4.1 Non-Interactive Key Exchange

Following the work of [25, 40], we formally define a non-interactive key exchange (NIKE). Through the use of IDs, the security model proposed in [25] abstracts away all considerations concerning certification and public key infrastructure.

Definition 2 (Non-Interactive Key Exchange)**.** A non-interactive key exchange NIKE is defined as a tuple $\mathsf{NIKE} := (\mathsf{Stp}, \mathsf{Gen}, \mathsf{SdK})$ of the following PPT algorithms. Furthermore, we define an identity space $\mathcal{IDS}$ and a shared key space $\mathcal{SKS}$.

$par \xleftarrow{\$} \mathsf{Stp}(1^\lambda)$**:** Given the security parameter 1^λ (encoded in unary), the probabilistic setup algorithm returns a set of system parameters par.

$(sk, pk) \xleftarrow{\$} \mathsf{Gen}(\mathbf{ID})$**:** Given an identity $\mathtt{ID} \in \mathcal{IDS}$, the probabilistic key generation algorithm Gen returns a secret/public key pair (sk, pk).

$k \leftarrow \mathsf{SdK}(\mathbf{ID}_1, pk_1, \mathbf{ID}_2, sk_2)$**:** Given an identity $\mathtt{ID}_1 \in \mathcal{IDS}$ and its corresponding public key pk_1 along with another identity $\mathtt{ID}_2 \in \mathcal{IDS}$ and its corresponding secret key sk_2, the deterministic shared key establishment algorithm SdK returns a shared key $k \in \mathcal{SKS}$, or a failure symbol $\perp$. We assume that SdK always returns $\perp$ if $\mathtt{ID}_1 = \mathtt{ID}_2$.

Correctness. Informally, *honest correctness* states that shared keys derived by two honest parties should be the same with overwhelming probability. Although our subsequent definition of correctness implies honest correctness, we state both definitions here for completeness.

Definition 3 (Honest Correctness)**.** A non-interactive key exchange $\mathsf{NIKE} := (\mathsf{Stp}, \mathsf{Gen}, \mathsf{SdK})$ has *honest correctness error* δ (or is said to be δ-*correct*), if for all $par \in \mathsf{Stp}(1^\lambda)$ and $\mathtt{ID}_1, \mathtt{ID}_2 \in \mathcal{IDS}$ it holds that,

$$\Pr\left[\mathsf{SdK}(\mathtt{ID}_1, pk_1, \mathtt{ID}_2, sk_2) \neq \mathsf{SdK}(\mathtt{ID}_2, pk_2, \mathtt{ID}_1, sk_1) \;\middle|\; \begin{array}{c}(sk_1, pk_1) \xleftarrow{\$} \mathsf{Gen}(\mathtt{ID}_1) \\ (sk_2, pk_2) \xleftarrow{\$} \mathsf{Gen}(\mathtt{ID}_2)\end{array}\right] \leq \delta(\lambda),$$

where the probability is taken over the random choices of Stp and Gen.

In this work we define a stronger notion, *semi-malicious correctness* that captures the property that two maliciously chosen key pairs (that are in the support of the key generation algorithm) will not cause the key exchange to fail. Since this property clearly implies honest correctness, throughout the rest of this work we only focus on semi-malicious correctness. We formalise *semi-malicious correctness* for NIKE relative to a random oracle H via the game $\mathbf{SM\text{-}COR}_{\mathsf{NIKE}}$ depicted in Figure 2 and define the advantage of an adversary A in $\mathbf{SM\text{-}COR}_{\mathsf{NIKE}}$ as

$$\mathsf{Adv}^{\mathbf{SM\text{-}COR}}_{\mathsf{NIKE},par}(\mathsf{A}) := \Pr[\mathbf{SM\text{-}COR}^{\mathsf{A}}_{\mathsf{NIKE}} \Rightarrow 1].$$

Definition 4 (Semi-malicious Correctness)**.** Let $\mathsf{NIKE} := (\mathsf{Stp}, \mathsf{Gen}, \mathsf{SdK})$ be a non-interactive key exchange. In the quantum random oracle model, we say that NIKE is $\delta(Q_\mathsf{H})$-**SM-COR** if for all $\mathtt{ID}_1, \mathtt{ID}_2 \in \mathcal{IDS}$ and for all (possibly unbounded) adversaries A of depth at most D, making at most Q_H queries (possibly in superposition) to the random oracle H, we have $\mathsf{Adv}^{\mathbf{SM\text{-}COR}}_{\mathsf{NIKE},par}(\mathsf{A}) \leq \delta(Q_\mathsf{H}, D)$. [2]

[2]Note that in the standard model our correctness definition can be considered a special case where the number of random oracle queries is zero and hence $\delta(Q_\mathsf{H}, D)$ is a constant.

Game SM-COR$_{\mathsf{NIKE}}$

$par \leftarrow \mathsf{Stp}(1^\lambda)$
$\left.\begin{array}{l}\mathsf{supp}(\mathsf{Gen}(\mathtt{ID}_1)) \ni (sk_1, pk_1) \\ \mathsf{supp}(\mathsf{Gen}(\mathtt{ID}_2)) \ni (sk_2, pk_2)\end{array}\right\} \xleftarrow{\$} \mathsf{A}^{|\mathsf{H}\rangle}(par)$
return $[\![\mathsf{SdK}(\mathtt{ID}_1, pk_1, \mathtt{ID}_2, sk_2) \neq \mathsf{SdK}(\mathtt{ID}_2, pk_2, \mathtt{ID}_1, sk_1)]\!]$

Figure 2: Correctness game $\mathbf{SM\text{-}COR}_{\mathsf{NIKE}}$ for a non-interactive key exchange NIKE defined relative to a random oracle H with adversary A.

Passive Security. Following the conventions of [40], we formalise the notion of key indistinguishability with *passive security*, or honest key registration (HKR), for a non-interactive key exchange NIKE, with respect to system parameters $par \in \mathsf{Stp}(1^\lambda)$ via the game $\mathbf{HKR\text{-}CKS\text{-}l}_{\mathsf{NIKE},par}$ depicted in [43]. In $\mathbf{HKR\text{-}CKS\text{-}l}_{\mathsf{NIKE},par}$, the adversary A may make two queries to the RegHonUsr oracle, where A provides and identity and the public and secret keys are derived honestly. A may then make one query to the TestQue oracle, where A has to distinguish the shared key from a random key. We define the advantage of adversary A in $\mathbf{HKR\text{-}CKS\text{-}l}_{\mathsf{NIKE},par}$ as $\mathsf{Adv}^{\mathbf{HKR\text{-}CKS\text{-}l}}_{\mathsf{NIKE},par}(\mathsf{A}) := \left|\Pr\left[\mathbf{HKR\text{-}CKS\text{-}l}^{\mathsf{A}}_{\mathsf{NIKE},par} \Rightarrow 1\right] - \frac{1}{2}\right|$.

Definition 5 (Passive Security)**.** Let $\mathsf{NIKE} := (\mathsf{Stp}, \mathsf{Gen}, \mathsf{SdK})$ be a non-interactive key exchange. We say that NIKE is $(\varepsilon, Q_\mathsf{H})$-**HKR-CKS-l** relative to $par \in \mathsf{Stp}(1^\lambda)$ if for all PPT adversaries A, making at most Q_H queries (possibly in superposition) to the random oracle H, two queries to the RegHonUsr oracle and one query to the TestQue oracle, we have $\mathsf{Adv}^{\mathbf{HKR\text{-}CKS\text{-}l}}_{\mathsf{NIKE},par}(\mathsf{A}) \leq \varepsilon(Q_\mathsf{H})$.

Active Security. We formalise the notion of key indistinguishability with *active security* for a non-interactive key exchange NIKE, with respect to system parameters $par \in \mathsf{Stp}(1^\lambda)$ via the game $\mathbf{CKS}_{\mathsf{NIKE},par}$ depicted in [43]. Observe that this **CKS** (sometimes called DKR-CKS, short for "Dishonest Key Registration") notion was first defined in [25] and is polynomially equivalent to **CKS-l** (where the adversary is only allowed to make two RegHonUsr queries and one TestQue query) and *m-CKS-heavy* in the work of [40]. Unsurprisingly our definition of active security implies the former notion of passive security. The game starts by selecting a bit b uniformly at random after which the adversary A is given access to four oracles. A's queries may be made adaptively and are arbitrary in number. The RegHonUsr and RegCorUsr oracles let A register honest and corrupted user public keys, respectively. A may make multiple queries to RegCorUsr, in which case only the most recent $(corrupt, \mathtt{ID}, \perp, pk)$ entry is kept. The RevCorQue oracle provides A with a shared key between a pair of registered identities, subject only to the restriction that at least one of the two identities was registered as honest. Depending on the bit b, the TestQue oracle returns either a

random key or a shared key between two identities registered as honest. Finally, the adversary outputs a guess bit b' and wins the game if and only if $b = b'$. We define the advantage of adversary A in $\mathbf{CKS}_{\mathsf{NIKE},par}$ as $\mathsf{Adv}^{\mathbf{CKS}}_{\mathsf{NIKE},par}(\mathsf{A}) := \left|\Pr\left[\mathbf{CKS}^{\mathsf{A}}_{\mathsf{NIKE},par} \Rightarrow 1\right] - \frac{1}{2}\right|$.

Definition 6 (Active Security [25])**.** Let $\mathsf{NIKE} := (\mathsf{Stp}, \mathsf{Gen}, \mathsf{SdK})$ be a non-interactive key exchange. We say that NIKE is $(\varepsilon, Q_{\mathsf{H}}, Q_{\mathtt{RHU}}, Q_{\mathtt{RCU}}, Q_{\mathtt{RCQ}}, Q_{\mathtt{TQ}})$-**CKS** secure relative to $par \in \mathsf{Stp}(1^\lambda)$ if for all PPT adversaries A making at most; Q_{H} queries (possibly in superposition) to the random oracle H, $Q_{\mathtt{RHU}}$ queries to `RegHonUsr`, $Q_{\mathtt{RCU}}$ queries to `RegCorUsr`, $Q_{\mathtt{RCQ}}$ queries to `RevCorQue`, and $Q_{\mathtt{TQ}}$ queries to `TestQue`, we have $\mathsf{Adv}^{\mathbf{CKS}}_{\mathsf{NIKE},par}(\mathsf{A}) \leq \varepsilon$.

Single- and Multi-User Security. The following Theorem from [40] shows that **CKS-l** and **CKS** are polynomially equivalent and will become useful for our proofs in Section 5.2. The other direction of the Theorem is trivial.

Theorem 3 (CKS-light $\Rightarrow$ CKS [40, Thm. 1])**.** For any adversary A against NIKE in the *CKS* model, there exists an adversary B that breaks NIKE in the *CKS-light* model such that

$$\mathsf{Adv}^{\mathbf{CKS}}_{\mathsf{NIKE},par}(\mathsf{A}) \leq \frac{Q^2_{\mathtt{RHU}} \cdot Q_{\mathtt{TQ}}}{2} \cdot \mathsf{Adv}^{\mathbf{CKS\text{-}l}}_{\mathsf{NIKE},par}(\mathsf{B}),$$

Furthermore, the following observation will also be useful for our proofs in Section 5.2. Note that a variant of the $\mathbf{CKS}_{\mathsf{NIKE},par}$ game in which the adversary A is only given access to the `RegHonUsr` and `TestQue` oracles (as well as the random oracle H) can be thought of as a multi-user version of the $\mathbf{HKR\text{-}CKS\text{-}l}_{\mathsf{NIKE},par}$ game. Naturally we call this game $\mathbf{HKR\text{-}CKS}_{\mathsf{NIKE},par}$, as in the work of [40], and define the advantage of adversary A analogous to the previous definitions. As noted in [40], Theorem 3 carries over to the HKR setting.

5 Construction

We present our NIKE construction in two steps by introducing a scheme that only satisfies passive security followed by a generic transformation that turns it into a scheme with active security.

5.1 Passive Setting

In this section we present our construction of a non-interactive key exchange with semi malicious correctness that satisfies key indistinguishability for honestly registered public keys (passive security) in the random oracle model. The scheme is depicted in Figure 3. The Gen algorithm generates two independent left and right secret keys sk_L and sk_R along with their respective public keys pk_L and pk_R. Subsequently, the SdK algorithm computes the shared key using $\mathtt{ID}_1$'s pk_L and $\mathtt{ID}_2$'s sk_R when $\mathtt{ID}_1 \leq \mathtt{ID}_2$ and vice versa. By Lemma 1 a random matrix over $\mathcal{R}_q$ will be invertible with overwhelming probability.

Correctness. In order to achieve better bounds in our proof of security, we show that our scheme satisfies both honest correctness as well as the stronger notion of semi-malicious correctness of Definition 3 and Definition 4, respectively. Although Theorem 5 implies Lemma 4, we will use the latter and state its proof in [43] for sake of completeness.

Lemma 4 (Honest Correctness)**.** For all (possibly unbounded) adversaries A the non-interactive key exchange $\mathsf{NIKE} := (\mathsf{Stp}, \mathsf{Gen}, \mathsf{SdK})$ construction depicted in Figure 3 has *honest correctness error*

$$\delta \leq \frac{4\beta^2 d^2 N}{q}$$

as per Definition 3.

We show that the scheme satisfies semi-malicious correctness in the quantum random oracle model.

Theorem 5 (**SM-COR** of NIKE)**.** For all (possibly unbounded) adversaries A of depth D making at most Q_{H} queries (possibly in superposition) to the random oracle H, the non-interactive key exchange $\mathsf{NIKE} := (\mathsf{Stp}, \mathsf{Gen}, \mathsf{SdK})$ construction depicted in Figure 3 has *semi-malicious correctness error*

$$\delta(Q_{\mathsf{H}}, D) \leq 16 \cdot (D+2) \cdot (Q_{\mathsf{H}}+1) \cdot \frac{\beta^2 d^2 N}{q}$$

as per Definition 4, where β is a bound on the maximum absolute value of the support of χ.

Proof. We are going to prove that the adversary cannot cause an error in the key derivation, i.e., a mismatch between the derived keys, even if he is allowed to choose both secret keys from the support of the key generation algorithm. This trivially implies semi-malicious correctness. Let (sk_1, pk_1) and (sk_2, pk_2) be the pairs returned by the adversary. Without loss of generality we can consider $sk_1 = sk_L$ and $pk_2 = pk_R$, i.e. only "one side" of the key. A key mismatch occurs whenever

$$\begin{aligned}
\mathtt{Rec}\left(pk_L^\top sk_R + \boldsymbol{r}\right) &\neq \mathtt{Rec}\left(sk_L^\top pk_R + \boldsymbol{r}\right) \\
\mathtt{Rec}\left(\left(\vec{\boldsymbol{s}}_L^\top \boldsymbol{A} + \vec{\boldsymbol{e}}_L^\top\right)\vec{\boldsymbol{s}}_R + \boldsymbol{r}\right) &\neq \mathtt{Rec}\left(\vec{\boldsymbol{s}}_L^\top\left(\boldsymbol{A}\vec{\boldsymbol{s}}_R + \vec{\boldsymbol{e}}_R\right) + \boldsymbol{r}\right) \\
\mathtt{Rec}\big(\underbrace{\vec{\boldsymbol{s}}_L^\top \boldsymbol{A}\vec{\boldsymbol{s}}_R + \boldsymbol{r}}_{\boldsymbol{k}^\star \in \mathcal{R}_q} + \vec{\boldsymbol{e}}_L^\top \vec{\boldsymbol{s}}_R\big) &\neq \mathtt{Rec}\big(\underbrace{\vec{\boldsymbol{s}}_L^\top \boldsymbol{A}\vec{\boldsymbol{s}}_R + \boldsymbol{r}}_{\boldsymbol{k}^\star \in \mathcal{R}_q} + \vec{\boldsymbol{s}}_L^\top \vec{\boldsymbol{e}}_R\big),
\end{aligned}$$

where $\boldsymbol{r}$ is the output of the random oracle on both public keys and $\vec{\boldsymbol{e}}_L$ and $\vec{\boldsymbol{e}}_R$ are sampled from the noise distribution χ^N. By

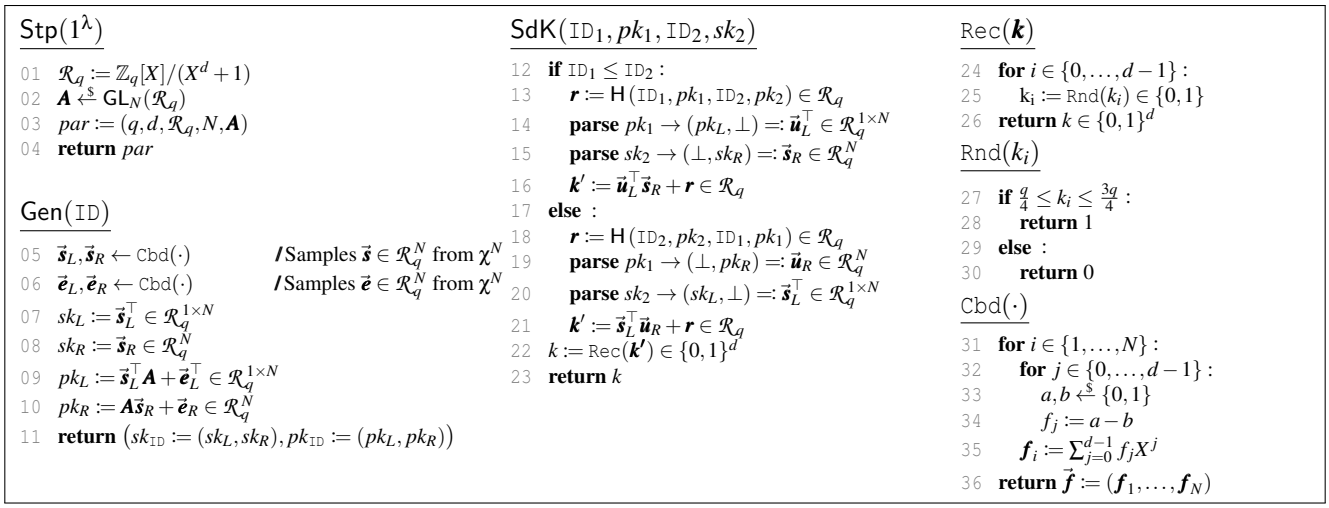

Figure 3: Construction of passively secure non-interactive key exchange $\mathsf{NIKE} := (\mathsf{Stp}, \mathsf{Gen}, \mathsf{SdK})$ with functions $\mathtt{Rec} : \mathcal{R}_q \to \{0,1\}^d$, $\mathtt{Rnd} : \mathbb{Z}_q \to \{0,1\}$ and $\mathtt{Cbd} : \emptyset \to \mathcal{R}_q^N$, and random oracle $\mathsf{H} : \mathcal{IDS} \times \left(\mathcal{R}_q^{1\times N} \times \mathcal{R}_q^N\right) \times \mathcal{IDS} \times \left(\mathcal{R}_q^{1\times N} \times \mathcal{R}_q^N\right) \to \mathcal{R}_q$. Here $\mathsf{GL}_N(\mathcal{R}_q)$ denotes the set of invertible $N \times N$ matrices over $\mathcal{R}_q$.

definition of the $\mathtt{Rec}$ function, this means that the term $\vec{\boldsymbol{e}}_L^\top \vec{\boldsymbol{s}}_R$ (or, equivalently, the term $\vec{\boldsymbol{s}}_L^\top \vec{\boldsymbol{e}}_R$) is causing a rounding error on one out of the d coefficients of $\boldsymbol{k}^\star$. We now bound the size of the largest coefficient of $\vec{\boldsymbol{e}}_L^\top \vec{\boldsymbol{s}}_R$ as

$$\left\| \vec{\boldsymbol{e}}_L^\top \vec{\boldsymbol{s}}_R \right\|_\infty = \left\| \sum_{i=1}^{N} \boldsymbol{e}_{L,i} \boldsymbol{s}_{R,i} \right\|_\infty \leq \sum_{i=1}^{N} \left\| \boldsymbol{e}_{L,i} \boldsymbol{s}_{R,i} \right\|_\infty \leq \beta^2 dN,$$

where the first inequality follows from the triangle inequality. The norm of $\vec{\boldsymbol{s}}_L^\top \vec{\boldsymbol{e}}_R$ can be bounded similarly. It follows that, in order for a key derivation error to occur, then at least one coefficient of $\boldsymbol{k}^\star$ must be in the following interval

$$S^\star = \left[\frac{q}{4} \pm \beta^2 dN \right] \cup \left[\frac{3q}{4} \pm \beta^2 dN \right].$$

If $\boldsymbol{k}^\star$ followed a uniform distribution, this would then happen with probability at most $\frac{d \cdot |S^\star|}{|\mathbb{Z}_q|} = \frac{4\beta^2 dN}{q}$. Next we define a function F that, on input two public keys and two identities samples a uniform $\boldsymbol{r}$, it returns 1 if a key mismatch occurs, i.e.,

$$\mathtt{Rec}\left(pk_L^\top sk_R + \boldsymbol{r} \right) \neq \mathtt{Rec}\left(sk_L^\top pk_R + \boldsymbol{r} \right)$$

and 0 otherwise. The function checks this by (inefficiently) recovering the secret keys and comparing the results of the $\mathtt{Rec}$ functions (see equation above). Due to the high probability of invertibility for $\boldsymbol{A}$, as stated in Lemma 1, the secret key is uniquely determined by the public key. Hence, this (inefficient) function is well defined on all inputs. Furthermore, note that the element

$$\boldsymbol{k}^\star = sk_L^\top \boldsymbol{A} sk_R + \boldsymbol{r}$$

is uniformly distributed in $\mathcal{R}_q$, since $\boldsymbol{r} \xleftarrow{\$} \mathcal{R}_q$. It follows that for any given input x:

$$\Pr[F(x) = 1] \leq \frac{4\beta^2 d^2 N}{q}.$$

Finally, observe that by definition a key mismatch happens if and only if the function F output 1 and consequently the adversary is able to find such accepting input. By Lemma 2, this happens with probability at most $16 \cdot (D+2) \cdot (Q_\mathsf{H}+1) \cdot \beta^2 d^2 N/q$ for an adversary of depth D, making at most Q_H quantum queries to the random oracle. ■

On the Need for Random Oracles. An astute reader may wonder whether the usage of the random oracle is needed at all to prove the above notion of correctness, since there does not appear to be an immediate attack even if we omit the random oracle completely from the scheme. It is plausible to conjecture that semi-malicious correctness holds even without the random oracle. Informally, semi-malicious correctness boils down to showing that, for a given public key $pk \in \mathcal{R}_q^N$, it is hard to find an $\boldsymbol{s} \in \mathcal{R}_q^N$ such that no coefficient of the product $\boldsymbol{s}^\top pk$ lies in the interval $S^\star$. Thus, the bound in these settings would require one to estimate the hardness of this version of the (inhomogenous) 1-dimensional short integer solution (SIS) problem. By relying on the random oracle heuristic, we are able to bypass this problem and obtain a construction in the QROM that is: (i) unconditionally correct in *any ring* and (ii) whose security is based on the well-established M-LWE problem. We leave the precise study of the hardness of this 1-dimensional variant of the SIS problem as ground for future work.

Passive Security. Assuming the hardness of M-LWE, Definition 1, we show that the scheme satisfies *passive security*, Definition 5, in the QROM.

Theorem 6 (Passive Security)**.** For any PPT adversary A against NIKE := (Stp, Gen, SdK), depicted in Figure 5, making an arbitrary number of queries (possibly in superposition) to H, there exists PPT adversaries $\mathsf{B}_1, \mathsf{B}_2$ such that

$$\mathsf{Adv}^{\textbf{HKR-CKS-l}}_{\mathsf{NIKE},par}(\mathsf{A}) \leq \mathsf{Adv}^{\textbf{M-LWE}}_{q,N,N,\chi}(\mathsf{B}_1) + \mathsf{Adv}^{\textbf{M-LWE}}_{q,N,N+1,\chi}(\mathsf{B}_2) + \tfrac{4\beta d}{q}.$$

Proof of Theorem 6. Let A be an adversary against NIKE in the **HKR-CKS-l** game. Consider the sequence of games in Figure 4 that takes into account both independent left and right halves of the keys.

Games G_0, G_1, G_2, G_3

```
01 b ←$ {0,1}
02 (sk_1, pk_1) ←$ Gen(ID_1)
03 pk_1 = (pk_{1_L}, pk_{1_R}) ←$ R_q^{1×N} × pk_{1_R}                    // G_1
04 (sk_2, pk_2) ←$ Gen(ID_2)
05 pk_2 = (pk_{2_L}, pk_{2_R}) ←$ pk_{2_L} × R_q^N                       // G_3
06 if ID_1 ≤ ID_2 :
07    r := H(ID_1, pk_1, ID_2, pk_2) ∈ R_q
08    parse pk_1 → (pk_L, ⊥) =: u_L^⊤ ∈ R_q^{1×N}
09    parse sk_2 → (⊥, sk_R) =: s_R ∈ R_q^N
10    k' := u_L^⊤ s_R + r ∈ R_q
11 else :
12    r := H(ID_2, pk_2, ID_1, pk_1) ∈ R_q
13    parse pk_1 → (⊥, pk_R) =: u_R ∈ R_q^N
14    parse sk_2 → (sk_L, ⊥) =: s_R^⊤ ∈ R_q^{1×N}
15    k' := s_R^⊤ u_R + r ∈ R_q
16 k_0 := Rec(k') ∈ {0,1}^d                                              // G_0
17 e ←$ χ                                                                // G_2
18 k_0 := Rec(k' + e) ∈ {0,1}^d                                          // G_2
19 u ←$ R_q                                                              // G_3
20 k_0 := Rec(u) ∈ {0,1}^d                                               // G_3
21 k_1 ←$ SKS
22 b' ← A^{|H⟩}(pk_1, pk_2, k_b)
23 return [[b = b']]
```

Figure 4: Games G_0, G_1, G_2, G_3 for the proof of **HKR-CKS-l** of NIKE in Figure 3.

Game G_0 This is the original $\textbf{HKR-CKS-l}_{\mathsf{NIKE},par}$ game so by definition $\Pr\left[\mathsf{G}^{\mathsf{A}}_0 \Rightarrow 1\right] = \Pr\left[\textbf{HKR-CKS-l}^{\mathsf{A}}_{\mathsf{NIKE},par} \Rightarrow 1\right]$.

Game G_1 Without loss of generality we consider the half of pk_1 that is actually used in the key derivation, say pk_{1_L}. In this game pk_{1_L} is replaced with a uniform key on Line 03. It follows immediately from Definition 1 that

$$\left|\Pr\left[\mathsf{G}^{\mathsf{A}}_0 \Rightarrow 1\right] - \Pr\left[\mathsf{G}^{\mathsf{A}}_1 \Rightarrow 1\right]\right| \leq \mathsf{Adv}^{\textbf{M-LWE}}_{q,N,N,\chi}(\mathsf{B}_1).$$

Game G_2 In this hybrid we modify the way we compute the shared key. Consider $\boldsymbol{k}'$ as computed in the SdK algorithm, we define the shared key as $\mathtt{Rec}(\boldsymbol{k}' + \boldsymbol{e})$ where $\boldsymbol{e} \xleftarrow{\$} \chi$ is a freshly sampled ring element from the noise distribution. Note that the adversary can only detect a change in this hybrid if

$$\mathtt{Rec}(\boldsymbol{k}' + \boldsymbol{e}) \neq \mathtt{Rec}(\boldsymbol{k}').$$

Since $\boldsymbol{k}'$ is uniformly distributed in $\mathcal{R}_q$, the probability that any coefficient is rounded to a different term is at most $4\beta d/q$, which is also an upper bound on the distinguishing advantage of the adversary. Thus we get

$$\left|\Pr\left[\mathsf{G}^{\mathsf{A}}_1 \Rightarrow 1\right] - \Pr\left[\mathsf{G}^{\mathsf{A}}_2 \Rightarrow 1\right]\right| \leq \frac{4\beta d}{q}.$$

Game G_3 In this game the half of pk_2 that is used in the key derivation, pk_{2_R}, is replaced with a uniform key on Line 05. Furthermore $\boldsymbol{k}' + \boldsymbol{e}$ is replaced with a uniform ring element $\boldsymbol{u}$ on Line 20. By an invocation of the module-LWE assumption we have that

$$\left|\Pr\left[\mathsf{G}^{\mathsf{A}}_2 \Rightarrow 1\right] - \Pr\left[\mathsf{G}^{\mathsf{A}}_3 \Rightarrow 1\right]\right| \leq \mathsf{Adv}^{\textbf{M-LWE}}_{q,N,N+1,\chi}(\mathsf{B}_2).$$

Observe that k_0 and k_1 are identically distributed and the adversary can only guess b'. Hence, $\Pr\left[\mathsf{G}^{\mathsf{A}}_3 \Rightarrow 1\right] = \frac{1}{2}$. Collecting all probabilities yields the bound stated in Theorem 6.

■

Reconciliation Function. The reconciliation function Rec depicted in Figure 3 maps a ring element $\boldsymbol{k} \in \mathcal{R}_q$ to a bit string of length d. In the final step of the proof of Theorem 6 the input to Rec is a uniformly sampled ring element $\boldsymbol{u} \in \mathcal{R}_q$. Each element in $\mathbb{Z}_q$ is rounded to a bit with almost equal probability. More specifically for all $u_i \in \mathbb{Z}_q$, $\Pr[\mathtt{Rnd}(u_i) = 0] = \frac{q-1}{2q}$ and $\Pr[\mathtt{Rnd}(u_i) = 1] = 1 - \frac{q-1}{2q}$, which are negligibly close to $1/2$, for an appropriate choice of q. Although the reconciliation function maps the key to a smaller domain, trying to guess $k := \mathtt{Rec}(\boldsymbol{u})$, even when given both public keys, would, in expectation, require guessing half of all possible keys, which amounts to 2^{d-1}. This becomes practically infeasible for large values of d. For more details on our specific choice of q and d, we refer to Section 5.4.

5.2 Active Setting

Here we show how a non-interactive key exchange with passive security can be generically transformed to one with active security. The transformation, depicted in Figure 5, requires a simulation-sound NIZK with a straight line extractor. Due to space constraints, the proof is deferred to [43].

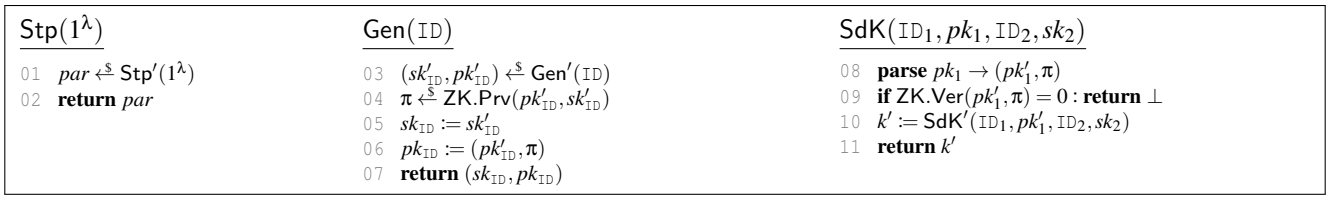

Figure 5: Compiler for transforming a passively secure non-interactive key exchange $\mathsf{NIKE}' := (\mathsf{Stp}', \mathsf{Gen}', \mathsf{SdK}')$ with semi-malicious correctness into an actively secure non-interactive key exchange $\mathsf{NIKE} := (\mathsf{Stp}, \mathsf{Gen}, \mathsf{SdK})$.

Theorem 7 (**HKR-CKS-l** and **SM-COR** of $\mathsf{NIKE}' \overset{\text{QROM}}{\underset{\text{ZKPoK}}{\Rightarrow}}$ **CKS** of NIKE)**.** Let $\mathsf{H} : \{0,1\}^* \to \mathcal{R}_q$ be a random oracle and $\mathsf{NIKE}' := (\mathsf{Stp}', \mathsf{Gen}', \mathsf{SdK}')$ a passively secure non-interactive key exchange with semi-malicious correctness defined relative to $par' \in \mathsf{Stp}'(1^\lambda)$. Further, let $\mathsf{ZKPoK} := (\mathsf{ZK.Prv}, \mathsf{ZK.Ver})$ be a simulation-sound online extractable zero-knowledge proof of knowledge for the NP relation $R = (pk_{\mathrm{ID}}, sk_{\mathrm{ID}})$. Then, for any **CKS** adversary A against $\mathsf{NIKE} := (\mathsf{Stp}, \mathsf{Gen}, \mathsf{SdK})$, depicted in Figure 5, there exist PPT adversaries $\mathsf{B}_1, \mathsf{B}_2, \mathsf{B}_3, \mathsf{C}$ such that

$$\mathsf{Adv}^{\mathbf{CKS}}_{\mathsf{NIKE},par}(\mathsf{A}) \leq \frac{Q^2_{\mathrm{RHU}} \cdot Q_{\mathrm{TQ}}}{2} \cdot \varepsilon$$

and

$$\varepsilon := Q_{\mathrm{RCU}} \cdot \mathsf{Adv}^{\mathbf{SSND}}_{\mathsf{ZKPoK}}(\mathsf{B}_1) + 2 \cdot \mathsf{Adv}^{\mathbf{SM\text{-}COR}}_{\mathsf{NIKE}',par'}(\mathsf{B}_2) + 2 \cdot \mathsf{Adv}^{\mathbf{ZK}}_{\mathsf{ZKPoK}}(\mathsf{B}_3) + \mathsf{Adv}^{\mathbf{HKR\text{-}CKS\text{-}l}}_{\mathsf{NIKE}',par'}(\mathsf{C}),$$

where Q_{RHU}, Q_{RCU}, Q_{RCQ}, and Q_{TQ} denote the number of queries made by A to `RegHonUsr`, `RegCorUsr`, `RevCorQue`, and `TestQue`, respectively.

5.3 Practical considerations

Halving the Key Size. Observe that the "left" and "right" components pk_L and pk_R of the public key of the NIKE as specified in Figure 3 are necessary because we work in the non-commutative M-LWE setting. Note that all theorems, lemmas and proofs consider both the left and right components of keys. An easy way to halve the size of the public key would be to set $N = 1$, i.e., to work in the R-LWE setting; this also eliminates the need for the case distinction in SdK. We argue that for essentially all relevant applications of a NIKE, we can halve the public-key size even *without* moving to the R-LWE setting. All that is required is that protocol participants (and their associated NIKE keys) have different *roles*, typically called initiator and responder or client and server, and that these roles are clear from protocol context. This is certainly the case for the application examples sketched in [43]: The OPTLS handshake, like the TLS handshake, clearly distinguishes the roles of client and server, so does the handshake in (post-quantum) WireGuard. Also in X3DH the critical static-semistatic key exchange has clear roles that can be used to distinguish between the "left" and "right" participant instead of transmitting both components of the key and using comparison of IDs. Note that this setting of a NIKE using keys with different roles is very similar to the ℓ_A and ℓ_B keys of SIDH [48, Sec. 3.2], when it was still considered as a replacement for DH, i.e., before it was shown to not be actively secure in [44] and completely broken in [26]. Based on these considerations, we stick to the M-LWE setting for the construction of SWOOSH; in our performance evaluation in Section 6 we report the size of only one public-key component.

Security of the NIZK. We highlight that our proof of active security, Theorem 7, requires the strong property of simulation-sound online-extractability. Although constructions satisfying such a strong notion exist [75], they tend to be less efficient than alternatives satisfying weaker notions of security. For instance, a proof of knowledge of an M-LWE secret satisfying simulation soundness, but without *online*-extractability, using state-of-the-art techniques [54] and appropriate parameters is around 89 KB in size. Since the [54] framework is relatively new, there are currently no implementations available to determine the exact running time of the prover and verifier. However, previous versions of lattice-based zero-knowledge proofs [55], which serve as the basis for [54], have shown implementations with prover and verifier running times on the order of milliseconds when proving similar relations. We remark that using NIZKs with slightly weaker security, in favour of a more efficient scheme, is a well-established heuristic and was already used in many works prior to ours, including [29, 34, 35, 45, 51, 57, 74]. However, this limitation is inherent in our approach, and investigating security under an alternative notion remains an interesting (and challenging) question. Tangentially, we also mention that for some applications, the performance of the NIZK does not affect the efficiency of the shared-key computation, since it can be verified once and for all for a given public key: In any scenario where the public keys are distributed by a PKI, the NIZK proof can be simply verified by the PKI upon the registration of the key, and then immediately discarded. The users would then trust the PKI to have verified the NIZK on their behalf. Note that this does not introduce any extra trust assumption, since the PKI is

already trusted to provide the correct public key. In these scenarios, the efficiency of the NIZK only marginally impacts the overall system performance, and thus justifies ignoring the costs of the NIZK for shared-key computation.

5.4 Parameter selection

Selecting parameters for the scheme influences several aspects, most notably the correctness error and the hardness of M-LWE. In order to evaluate the security of our scheme we use the *Lattice-Estimator* tool [2, 4, 66], to estimate the memory and CPU operations required to perform various lattice attacks, including dual attacks, uSVP, the Coded-BKW attack, and solving using Gröbner bases with the Arora-GB attack. The estimator has been used to estimate the concrete security for all LWE and NTRU based candidates of the NIST competition [3], and is regularly updated to include the latest developments in lattice cryptanalysis [3]. However, we also take into account practical considerations for the implementation when selecting our parameters, such as the use of ternary secrets and noise sampled from a centred binomial distribution. For our scheme with parameters $n = 8192, q = 2^{214} - 255$ and $\mathcal{X}$ a ternary distribution, we estimate the hardness of the M-LWE problem underlying SWOOSH at 120 bits [4]. The other way to attack SWOOSH is, for an active attacker, to try to produce failures. We consider a quantum attacker with a bounded query depth of $D = 2^{64}$ (i.e., what NIST considers to be "the approximate number of gates that current classical computing architectures can perform serially in a decade" [62, Sec. 4.A]) and a bound on the number of queries of 2^{120} (i.e., matching the hardness of the underlying lattice problem). Applying Theorem 5 yields a success probability (correctness error), after this amount of computation,

$$16 \cdot \left(2^{64} + 2\right) \cdot \left(2^{120} + 1\right) \cdot \frac{256^2 \cdot 32}{2^{214}} < \frac{1}{2^4} = \delta(Q_{\mathsf{H}}),$$

i.e., considerably smaller than 1/2. Note that this analysis is conservative as it ignores the circuit depth for the Grover oracle that an attacker would need to implement.

6 Implementation & Performance Evaluation

In order to demonstrate the efficiency of SWOOSH in terms of performance, we implement the core part of the scheme, Passive-SWOOSH, present benchmarks of this implementation, and compare to other KEMs and (pre- and post-quantum) NIKEs. We caution the reader that all implementation details and numbers we present in this section are for Passive-SWOOSH only. To obtain a full picture of the performance of SWOOSH, the implementation will need to be augmented with a future implementation of the NIZK proof from [54]. As outlined in Section 5.3, the performance impact of adding the NIZK proof in terms of both size and computational effort depends on the concrete application scenario and may be negligible if key-generation performance is not critical and if NIZK proof verification can be outsourced to the PKI.

[3] An up-to-date list of implemented works can be found https://lattice-estimator.readthedocs.io/en/latest/references.html.

[4] These numbers can be reproduced with the estimator — the version used in this work is at commit 96875622c6b0e6f98a91ddeecaaa17b66dbc5a87.

Parameter	Description	Value
β	upper bound on $\|\vec{s}\|_\infty = \|\vec{e}\|_\infty$	1
q	prime modulus	$2^{214} - 255$
d	dim of $\mathcal{R}_q := \mathbb{Z}_q[X]/(X^d + 1)$	256
l	# factors $X^d + 1$ splits into mod q	128
N	height of the $\boldsymbol{A}$ matrix	32
n	lattice dimension	8192
χ	secret / noise distribution	$p(-1) = 25\%$ $p(0) = 50\%$ $p(1) = 25\%$

Table 1: Parameter selection for non-interactive key exchange NIKE.

6.1 Implementation

As a NIKE, SWOOSH is composed of two major functions, the key generation procedure and the shared-key computation, the performance of which dictates the efficiency of SWOOSH.

In the case of the key generation, the matrix $\boldsymbol{A}$ is fixed and assumed to be in the NTT domain, so performance is dictated by the sampling of the secret and error vectors, as well as the computation of the public key which involves two NTT transformations, and a matrix multiplication followed by a polynomial addition. On Intel Skylake the cumulative execution time of the forward NTT accounts for $\sim 10\%$ of total key-generation time. This calculation is based on a single transformation taking 217 430 cycles, with a total of 64 transformations executed (32 for each secret and error vector). In contrast, the inverse NTT and noise-generation processes require 262 992 and 89 776 cycles, respectively. As for the shared-key computation, its performance is mainly dictated by the random offset computation, which requires the use of cSHAKE [49] and the polynomial base multiplication required to calculate $\boldsymbol{k'}$ (see Figure 3). Similar to other schemes, the shared-key derivation also performs rounding of the shared key, however its execution time is negligible. At a high level, the architecture of our implementation is divided into two distinct parts: low-level field arithmetic over $\mathbb{F}_q$ that is implemented using the Jasmin language [6, 7], and polynomial arithmetic in $\mathcal{R}_q$ as well as the scheme itself, both of which are implemented in Rust.

The structure largely mimics the abstract specification in Figure 3. The main difference is that, like other

Scheme (variant)	Security	Assumption	Non-interactive	Post-quantum	Size (bytes)		Cycles	
					ct	pk	Gen	Encaps + Decaps or SdK
CRYSTALS-Kyber (`Kyber-768` [71])	IND-CCA2	M-LWE	✗	✓	1088	1184	200 302	539 108 (251 384 + 287 724)
Classic McEliece (`mceliece348864` [1])	IND-CCA2	Binary Goppa Codes	✗	✓	96	261 120	46 715 060	143 178 (31 000 + 112 178)
ECDH (`X25519` [13])	HKR-CKS* [5]	CDH	✓	✗	—	32	28 187	87 942
CTIDH (`CTIDH-1024` [10])	HKR-CKS* [6]	CSIDH	✓	✓	—	128	469 520 000	511 190 000
This work (Passive-SWOOSH)	HKR-CKS	M-LWE	✓	✓	—	221 184	146 920 890	10 612 666

Table 2: Comparison of select post-quantum KEMs and NIKEs.

lattice-based schemes [5, 71], we encode and transmit public keys in NTT domain. This massively reduces the number of cycles required for shared-key computation. In addition, as discussed in Section 5.3, we assume that the role of each party is well defined and thus only compute one half of the key. Finally, we implement the noise sampling in a slightly different way than one might expect; we will discuss this later in this section.

Zooming in on the low-level field arithmetic, the operations on integers modulo $2^{214} - 255$ require multiple-precision integers since native 64-bit registers are not large enough to store a single field element. This arithmetic is implemented through libjbn [7], a Jasmin library that exposes (modular) big-integer arithmetic.

Polynomial Arithmetic. On top of this layer, operations in polynomial rings are implemented using Rust, in addition to other functions such as reconciliation, matrix and noise generation. Similar to other lattice-based schemes, one of the more critical (and easier) operations to optimise (from a performance perspective) is polynomial multiplication. The naive algorithm for multiplying two polynomials in $\mathcal{R}_q$, sometimes called Schoolbook multiplication, involves multiplying all pairs of coefficients, calculating their sum and reducing modulo $X^d + 1$. However, the complexity of this approach is quadratic in the number of coefficients and thus quite costly. The *Number Theoretic Transform* (NTT) provides a more efficient approach for polynomial multiplication with quasi-logarithmic time complexity $O(d \log(d))$ instead of $O(d^2)$. For a detailed discussion on the NTT refer to [72]. As is the case for other implementations [5, 71], we use an in-place NTT which requires bit-reversal operations in the forward and inverse transforms but uses less memory. Another optimisation is to make the NTT a part of our scheme, which means that the matrix $\boldsymbol{A}$ is sampled in the NTT domain, and the secret and public keys are stored in the NTT domain. This results in the NTT only being used three times, once for the shared-key derivation and twice in the key generation to transform the secret and error vectors, which are sampled in the normal domain, to the NTT domain before computing the public key. A common trick to speed-up the NTT transformation when using Montgomery reduction [60], as is the case for libjbn, is to use pre-computed constants in Montgomery form $\zeta \cdot R \pmod q$.

Noise Sampling and Matrix Generation. Both the matrix generation and noise-sampling procedures use a seed, either set as a system parameter for $\boldsymbol{A}$ or as a secret input to a PRG in the case of $\vec{\boldsymbol{s}}$ and $\vec{\boldsymbol{e}}$, to produce a stream bytes from which the distributions are sampled. In the case of matrix generation this is achieved via rejection sampling on the stream of bytes produced by an extendable output function (XOF). The noise-sampling procedure, used for generating the secret key and the error vector, samples these vectors from a centred binomial distribution using the output of a PRF with a random seed. As with other schemes where multiplication is optimised using the NTT, the choice of (symmetric) primitive that underlies these functions tends to be a deciding factor for the performance. We chose cSHAKE [49] based on Keccak [37] as the underlying primitive for the XOF and AES256-CTR for the PRF used in noise sampling. Similar to the NewHope scheme [5], for efficiency reasons the secret and error vectors are sampled from a centred binomial distribution rather than a discrete Gaussian distribution. Using ternary noise means that each coefficient can be generated from only 2 bits and thus, the generation of a polynomial in $\mathcal{R}_q$ only requires $(32 \cdot 256 \cdot 2)/8 = 2048$ (pseudo-random) bytes. Intuitively, our CBD definition in Figure 3 when a and b are sourced from a PRG, maps 00_b and 11_b to $0 \mod q$ with 50% probability, 10_b to $1 \mod q$ and 01_b to $-1 \mod q$ with 25% probability each. Our implementation differs from the specification by applying signed reduction modulo 3 to each two bit block and converting it to a congruent value in $\mathbb{F}_q$, as opposed to using big-integer field arithmetic to map bits a and b to an element in $\mathbb{F}_q$. Although this approach produces a different mapping (11_b to $-1 \mod q$, 00_b and 10_b to $0 \mod q$ and 01_b to $1 \mod q$), the distribution of the outputs is identical. Due to the size of our field elements, this approach results in a considerable speed up in the noise sampling. The random offset used in our scheme is generated by performing rejection sampling on the output of cSHAKE-256 [49].

6.2 Performance and Security Evaluation

In this section we evaluate the performance of our scheme and compare it to other NIKEs and KEMs. Additionally, we present a comparison of key sizes and the properties of each

[5] See Section 6.2.
[6] See Section 6.2.
[7] See https://github.com/formosa-crypto/libjbn.

scheme such as post-quantum security, and whether they are non-interactive, and the security notions they satisfy.

Security Models. To set a common ground for comparison, we note that the SdK algorithm in a NIKE can be viewed as simultaneously running both Encaps and Decaps of a KEM. KEMs should satisfy the standard security notions of IND-CCA security, with schemes such as CRYSTALS-Kyber [71] satisfying indistinguishability under *adaptive* chosen ciphertext attacks (IND-CCA2 security). On the other hand, we implemented the passively-secure version of our NIKE. We argue that this comparison is still meaningful because, in the context of a Public Key Infrastructure (PKI), NIZK verification can be performed once and for all by the PKI. Therefore, the runtime of our scheme is primarily influenced by the operations of the passively-secure NIKE. We also note that the *"unhashed"* version of ECDH (`X25519` [13]), for which we report benchmarks, is insecure in the (DKR-)CKS model. In an unhashed NIKE where shared keys aren't linked to specific identities, an adversary, A, can carry out a two-step attack: (i) A registers the public key g^a belonging to an honest party, Alice, as if it were their own key ($\mathtt{RegCorUsr}(\mathtt{ID} = \mathsf{A}, pk = g^a)$). (ii) Next, A requests the shared key between themselves and another honest party, say Bob, who possesses a public key g^b ($\mathtt{RevCorQue}(\mathtt{ID} = Bob, \mathtt{ID} = \mathsf{A}) \rightarrow g^{ab}$). This immediately gives the shared key g^{ab} between Alice and Bob. Due to the homomorphic properties of (EC)DH, this attack remains effective (requiring only a minor modification) even if A is prohibited from registering keys of existing users. On the other hand, a hashed version of (EC)DH can be shown to be DKR-CKS secure in the ROM under the *Strong Computational Diffie-Hellman* assumption. Although there is no proof of CTIDH (`CTIDH-1024` [10]) in the CKS model, the unhashed variant (excluding identities) of CTIDH faces similar security issues for the same reason. Recent work [36] proved that achieving actively secure NIKE from CSIDH inherently depends on *"very strong variants of the Group Action Strong CDH"* problem. Nevertheless, it is important to note that Passive-SWOOSH is indeed strictly weaker than unhashed DH, as a key-recovery attack becomes possible if the adversary is allowed to register corrupted keys. Furthermore, from a practical point of view, enhancing the security of ECDH and CTIDH does not come with a significant increase in costs, as the computation time for hashing is still minimal, compared to the dominating modular-arithmetic cycle counts.

Benchmarks. The benchmark results for Passive-SWOOSH were obtained on an Intel Core i7-6500U (Skylake) running on a single core with Hyper-threading and TurboBoost disabled. The Rust compiler version used for the benchmarks was 1.62.1[8] and the Jasmin compiler version was 2022.09.0. We report the median cycle counts of 10000 runs. In Table 2 we list the results and compare to the cycle counts of Kyber-768 (on the same hardware), mceliece348864 as reported in [14], CTIDH-1024 as reported in [10, Sec. 8], and of lib25519 [61], on Intel Skylake CPUs. As expected, the pre-quantum X25519 [13] scheme is orders of magnitude faster than Passive-SWOOSH for key generation. However, in many applications of NIKEs, keys are re-used many times and what is more critical is the performance of shared-key computation. Here the gap to pre-quantum X25519 is considerably smaller and Passive-SWOOSH outperforms the only real post-quantum competitor CTIDH by a factor of 48. Compared to post-quantum KEMs, such as Kyber-768 and mceliece348864, the performance gap increases to several orders of magnitude, similarly to X25519. However, these schemes require further rounds of interaction, which not only presents additional overhead, but also means they cannot be used as drop-in replacements for a NIKE. Additionally, as shown in Table 2, CTIDH, Kyber, and X25519 have a public key size several orders of magnitude smaller than Passive-SWOOSH. In this aspect, only Classic McEliece has a public key size comparable to that of Passive-SWOOSH, even when taking into account the expected size of the proof of knowledge (see Section 5.3).

7 Conclusions

In this work, we constructed a NIKE based on the M-LWE problem, with a proof in the QROM. Our scheme is based on the standard blueprint, but with an additional twist to guarantee provable security for arbitrary rings. Our optimised implementation shows that our scheme offers reasonable computational performance and key sizes that should be acceptable for most applications. We view our work as the first evidence *contradicting* the folklore belief that lattice-based NIKE is too inefficient to be used in practice. As future work, we plan to explore applications of our scheme to more complex protocols and to formally verify the correctness of (parts of) our implementation.

Abstract

Phishing is a cybersecurity attack based on social engineering that incurs significant financial losses and erodes societal trust. While phishing detection techniques are emerging, attackers continually strive to bypass state-of-the-arts. Recent phishing campaigns have shown that emerging phishing attacks adopt CAPTCHA-based cloaking techniques, marking a new round of cat-and-mouse game. Our study shows that phishing websites, *hardened* by CAPTCHA-cloaking, can compromise all known state-of-the-art industrial and academic detectors with almost *zero* cost.

In this work, we develop PhishDecloaker, an AI-powered solution to *soften* the shield of the CAPTCHA-cloaking used by phishing websites. PhishDecloaker is designed to mimic human behaviors to solve the CAPTCHAs, allowing modern security-crawlers to see the uncloaked phishing content. Technically, PhishDecloaker orchestrates five deep computer vision models to detect the existence of CAPTCHAs, analyze its type, and solve the challenge in an interactive manner. We conduct extensive experiments to evaluate PhishDecloaker in terms of its effectiveness, efficiency, and robustness against potential adversaries. The results show that PhishDecloaker (1) recovers the phishing detection rate of many state-of-the-art phishing detectors from 0% to up to on average 74.25% on diverse CAPTCHA-cloaked phishing websites (2) generalizes to unseen CAPTCHA (with precision of 86% and recall of 69%), and (3) is robust against various adversaries such as FGSM, JSMA, PGD, DeepFool, and DPatch, which allows the existing phishing detectors to achieve new state-of-the-art performance on CAPTCHA-cloaked phishing webpages. Our field study over 30 days shows that PhishDecloaker can help us uniquely discover 7.6% more phishing websites cloaked by CAPTCHAs, raising alarm of the emergence of CAPTCHA-cloaked features in the modern phishing campaigns.

*Corresponding author

1 Introduction

Phishing attacks cause enormous financial losses and undermine societal trust. In recent years, the number of phishing attacks has grown by over 150% per year [1]. To mitigate these consequences, researchers have proposed various phishing detection solutions [12,15,34–37,42] to report and explain diverse zero-day phishing websites. While those solutions can be effective against the phishing website, their effectiveness is largely based on the assumption that *a security crawler can access the phishing content of the websites*. Unfortunately, in the new round of phishing campaigns, a growing body of evidence [46,64] has shown that the assumption is less likely to hold true due to the emergence of CAPTCHA-based cloaking techniques.

Cloaking is an evasion technique increasingly adopted by phishing attackers to display different content to security crawlers and human victims [64]. Attackers can deploy either server-side or client-side cloaking for their phishing webpages. Server-side cloaking checks human visits by analyzing HTTP requests from the server end and deny visits from certain IP addresses and User-Agents [32]. On the other hand, client-side cloaking checks human visits by analyzing the runtime browser behavior, including cookies, canvas fingerprints, and WebGL capabilities [13,64]. In recent years, researchers and security engineers have proposed remedies such as simulating a human-mimic HTTP header (to address server-side cloaking) [32] and forcing the execution of JavaScript code used in cloaking (to address client-side cloaking) [64]. However, CAPTCHA-based cloaking, being a novel phishing-cloaking technique, can easily nullify those anti-cloaking efforts.

CAPTCHA (Completely Automated Public Turing test to tell Computers and Humans Apart) was initially developed as challenge-response authentication to limit the abuse of web crawling. CAPTCHA validates a human visit with the interaction between the client and the server. On the client side, the website prompts a CAPTCHA challenge, such as picture selection and text recognition, to collect the challenge response. On the server side, the challenge response is vali-

Listing 1: Embeded CAPTCHA Code in HTML File.

```
<html>
...

<script src="https://js.hcaptcha.com/1/api.js"
        async defer></script>
...
<!-- embedded CAPTCHA div-tag>
<div id="cloaking">
    <form id="form" method="post"
    <div class="h-captcha" data-sitekey="..."
         data-callback="submitForm" />
    <input type="hidden" value="hcaptcha" name="
         captchaType" />
    </form>
</div>
...
</html>
```

dated against the ground-truth answer. By this means, neither the HTTP-request modification nor the Javascript force execution technique can bypass this validation. CAPTCHA can effectively serve as a cloaking technique in three aspects:

- **False Sense of Legitimacy:** CAPTCHAs are widely used on legitimate websites, allowing a phishing website with a prompted CAPTCHA challenge to often maintain its plausibility without arousing suspicion.
- **Low Deployment Cost:** Any website can conveniently integrate a CAPTCHA service by calling its API (see Listing 1). Therefore, it is not difficult for phishing attackers to automatically generate phishing kits equipped with CAPTCHA cloaking. Additionally, there are many free CAPTCHA services (e.g., reCAPTCHA v2) available, resulting in almost zero cost to *harden* phishing websites with a CAPTCHA.
- **Hard to Bypass:** Due to CAPTCHA's client-server architecture, it is non-trivial for modern security crawlers to automatically bypass it.

Recent studies have shown that phishing attackers are adopting CAPTCHA as a novel cloaking technique [14, 37, 41, 46, 59, 64]. The number of CAPTCHA-cloaked phishing websites has increased almost tenfold from 55,447 on January 2023 to 524,344 on June 2023. [10]. Furthermore, our empirical study (see Section 2) shows that *none* of the publicly available industrial phishing detection engines or academic state-of-the-art models can detect a CAPTCHA-cloaked phishing website.

In this work, we propose PhishDecloaker as the first step to address the CAPTCHA-based cloaking problem. PhishDecloaker is designed to simulate human behaviors in order to solve the CAPTCHA in an interactive manner. Technically, PhishDecloaker employs five types of deep computer vision models across three stages: detection, recognition, and solving. Specifically, PhishDecloaker begins by detecting the presence of a CAPTCHA, formulating it as an object detection problem [35, 36, 59] on a webpage screenshot. Then, PhishDecloaker recognizes the type of CAPTCHA (by treating it as a metric learning problem) so that it can schedule a follow-up solving plan. This three-stage design allows us to flexibly extend PhishDecloaker to solve new types of CAPTCHA and maintain its performance even on out-of-distribution CAPTCHAs. Our implementation of PhishDecloaker supports reCAPTCHA v2, hCaptcha, slider CAPTCHA, and rotation CAPTCHA, covering 98.9% of the CAPTCHA market share [2].

We conduct extensive experiments to evaluate PhishDecloaker regarding its effectiveness, efficiency, and robustness against potential adversaries. The results show that PhishDecloaker (1) recovers the phishing detection rate of many state-of-the-art phishing detectors from 0% to an average of 74.25% on diverse CAPTCHA-cloaked phishing websites and (2) generalizes to unseen CAPTCHA (with average precision and recall of 86% and 69%), and (3) is robust against adversarial attacks such as FGSM, JSMA, PGD, DeepFool, and DPatch. Furthermore, our field study over 30 days on the emerging real-world websites with different decloaking techniques show that PhishDecloaker allows us to detect 7.6% more phishing websites cloaked by CAPTCHAs (66 out of 869 phishing websites).

In summary, this work makes the following contributions:

- We develop PhishDecloaker, a hybrid deep-vision system to detect, recognize, and solve diverse CAPTCHAs. This system supports mainstream CAPTCHAs and is designed to be extensible for new types of CAPTCHAs. To the best of our knowledge, our work is the first to address CAPTCHA-cloaking for phishing detection.
- We deliver Cloaken, a CAPTCHA-based hardening framework, which allows us to automatically cloak a phishing kit with CAPTCHAs and deploy it through randomly generated URLs. We implement this cloaking technique on top of the DynaPD dataset[1] [37].
- We deliver PhishDecloaker as a tool integrated with existing SOTA phishing detectors Phishpedia [35] and PhishIntention [36], enhancing their capabilities to detect zero-day phishing websites.
- We conduct extensive experiments to evaluate PhishDecloaker. Our results show that PhishDecloaker effectively decloaks phishing websites found in the wild. Furthermore, PhishDecloaker is robust against out-of-distribution CAPTCHAs and adversarial attacks.

Given the space limit, more details of PhishDecloaker are available at [9].

[1]The DynaPD dataset provides more than 6,000 phishing kits for security researchers to interact with.

2 An Empirical Study of Anti-Phishing Entities against CAPTCHA-Cloaking

In this section, we conduct an empirical study to answer the question: *what is the performance of the state-of-the-art anti-phishing solutions in detecting CAPTCHA-cloaked phishing?*.

To answer the question, we design a phishing hardening framework, Cloaken, to automatically cloak phishing kits with CAPTCHAs. Technically, Cloaken functions as a reverse proxy that blocks visitors with a CAPTCHA page from a selection of templates (e.g., hCaptcha, reCAPTCHA v2). Once the visitor solves the CAPTCHA, Cloaken verifies the submitted challenge and reveals the phishing content.

Phishing Detection Service. We select 2 popular URL blacklists: Google Safe Browsing (GSB) and Microsoft Defender SmartScreen for evaluation. GSB is used by Chrome, Firefox, and Safari web browsers, accounting for 81.36% of desktop and 90.17% mobile users worldwide. On the other hand, SmartScreen protects Edge and accounts for 12.75% of desktop users. We also include VirusTotal (VT) [52], the world's largest threat corpus with 92 integrated phishing detectors.

URL Configuration. We prepare 5 cloaking types of phishing websites (t_p): no cloaking (baseline) and 4 *CAPTCHA-cloaked* types (i.e., reCAPTCHA v2, hCAPTCHA, GeeTest Slide, and Rotation). They are choosen based on their market share [54]. We call a pair of detection service and cloaking type, (d, t_p), as a configuration. For each cloaking type t_p, we generate k random unique URLs and submit it to d for analysis. In this study, we let k be 100. Therefore, there are 500 URLs submitted to 3 different detection service.

URL Submission. To report each of our phishing URLs, we submit them to GSB via its online submission portal and to VirusTotal via its API. Since SmartScreen receives data from other anti-phishing entities, including Microsoft's own internal cybersecurity ecosystem, we mass-submit emails with the phishing URLs to an Outlook account with Microsoft Defender Safe Link activated.

URL Monitoring. We monitor every day if any of the URLs corresponding to a configuration (e.g., d-t_p pair) are reported as phishing. If it is, it means that a service d can penetrate a cloaking type t_p. We monitor GSB through its Lookup API and VT by requesting a new URL scan and reviewing the resulting analysis report. We monitor SmartScreen by loading the URLs onto a non-headless Edge browser using Playwright and check if SmartScreen's block page shows up.

Results. Table 1 shows our results. All baseline sites are blacklisted within 24 hours, whereas all CAPTCHA-cloaked sites remain undetected for 7 days and counting, which is more than sufficient for a successful phishing campaign [47, 49][2]. Overall, none of the selected phishing detectors can reveal CAPTCHA-cloaked phishing, further motivating us to design PhishDecloaker. We will discuss the ethical concerns on this experiment in in Section 6.

[2] We reported our findings to VT, GSB, and SmartScreen. GSB (Google) and SmartScreen (Microsoft) have acknowledged our report and are investigating the potential solution.

3 Threat Model

Assume that there is a set of phishing detectors $\mathcal{D} = \{d_1, d_2, ..., d_n\}$, where each detector d_i ($i = 1, 2, ..., n$) needs to access the content of a webpage $w \in \mathcal{W}$ for phishing analysis. Each detector d_i can be modelled as a function $d_i(.) : \mathcal{W} \rightarrow \{0, 1\}$ where $\mathcal{W}$ is the set of webpages. Specifically, a detector $d_i(.)$ maps a webpage $w \in \mathcal{W}$ to a boolean value where $w = 0$ or 1 indicates that w is benign or phishing.

An attacker can equip their phishing website w_p with a CAPTCHA instance $c \in \mathcal{C}$ where $\mathcal{C}$ is the set of CAPTCHA instances under pre-defined CAPTCHA types (e.g., reCAPTCHA, hCaptcha, and GeeTest). Equipped with a human-authentication challenge c, the attacker can render a new webpage $w'_p \leftarrow c \oplus w_p$ so that $\forall d_i \in \mathcal{D}, d_i(w'_p) = 0$, where $\oplus$ is an operation to render the CAPTCHA on top of the webpage w_p. The prepared CAPTCHA sets share the following features:

- **Diverse Types of CAPTCHAs**. The attacker can adopt diverse types of CAPTCHAs, including commercial versions (e.g., reCAPTCHA and hCaptcha) and open-source versions. Additionally, we assume that the attacker can customize their own implementation of well-known CAPTCHA challenges, for example, with a similar appearance to reCAPTCHA and hCaptcha.
- **Code Obfuscation**. The CAPTCHA can have its partial execution on the client side, for example implemented by JavaScript code. We assume that the attacker can adopt code obfuscation techniques [11, 58] to modify the underlying code or structure of CAPTCHAs while preserving the same appearance and functionality inside a browser.
- **Adversarial Images**. An attacker may introduce noise and distortion into CAPTCHA images [30, 50, 56]. This can make it difficult for deep learning models to extract the relevant features and classify the CAPTCHA accurately, as the modified CAPTCHA may no longer conform to the expected patterns or features used for classification.

Given the above threat model, we adopt a vision-based solution to detect and classify CAPTCHAs. In other words, our solution (1) does not rely on frontend code analysis and (2) must be robust against out-of-distribution CAPTCHAs and adversarial attacks such as noise and distortion.

4 Approach

Overview. Figure 1 provides an overview of PhishDecloaker. Given a suspicious webpage w_p with cloaking potential, instead of feeding w_p into a phishing detector, PhishDecloaker tries to remove its "cloak" by looking at and interacting with

Table 1: Empirical results on performance of SOTA industrial phishing detectors in revealing CAPTCHA-cloaked phishing sites.

Category	Phishing Detection Service	URLs Blacklisted / URLs Submitted				
		Baseline	reCAPTCHA v2	hCaptcha	GeeTest Slide	Rotation
API-based	VirusTotal *(incl. 92 phishing detectors)*	100 / 100	0 / 100	0 / 100	0 / 100	0 / 100
Browser-based	Google Safe Browsing	100 / 100	0 / 100	0 / 100	0 / 100	0 / 100
Browser-based	Microsoft Defender SmartScreen	100 / 100	0 / 100	0 / 100	0 / 100	0 / 100

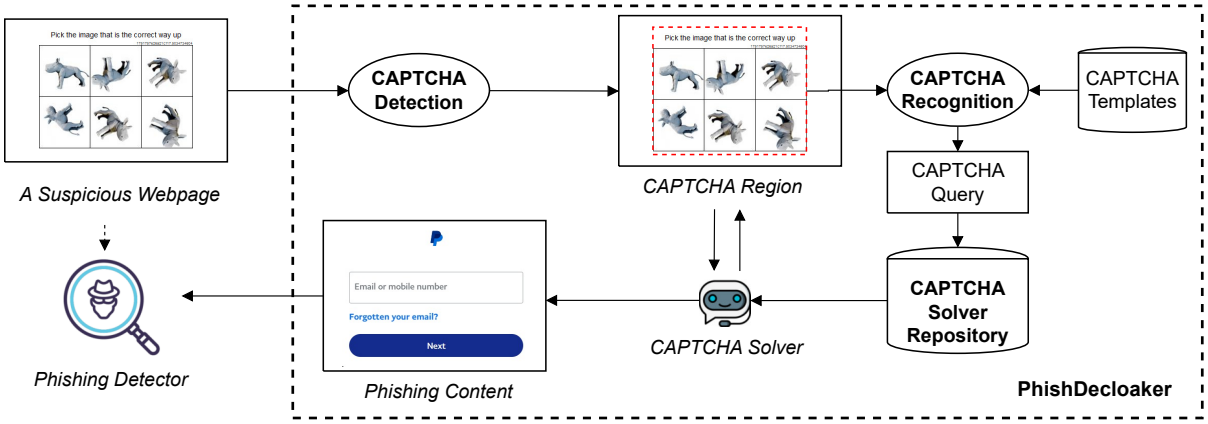

Figure 1: System Design of PhishDecloaker. PhishDecloaker is designed to remove the "cloak" of a CAPTCHA-cloaked phishing webpage, by detecting, recognizing, and solving the CAPTCHA challenges.

w_p. Technically, PhishDecloaker operates on the screenshot of w_p to bypass potential code obfuscation, which involves three steps:

Step 1. CAPTCHA Detection (Section 4.1). We identify the CAPTCHA instance on the webpage by formulating it as an object detection problem in computer vision. We denote the detected CAPTCHA as c.

Step 2. CAPTCHA Recognition (Section 4.2). With our prepared database of CAPTCHA templates, we determine the type of the CAPTCHA c, t_c, by matching the CAPTCHA instance c with its best fit in the template database through a learned OCR-aided Metric Learning network. The solution is designed in a similar way as a face recognition problem in computer vision. By this means, PhishDecloaker provides an extensible CAPTCHA recognition framework to flexibly including new CAPTCHA types.

Step 3. CAPTCHA Solving (Section 4.3). PhishDecloaker is further equipped with an arsenal of CAPTCHA solvers. Given the CAPTCHA type t_c, we formulate it as a query to find the most appropriate CAPTCHA solver. The found solver interacts with the webpage w_p to solve the challenge. This interaction can be repeated multiple times to increase the success rate of anti-phishing crawlers. PhishDecloaker provides such an extensible design to integrate new CAPTCHA solvers in the CAPTCHA solver repository.

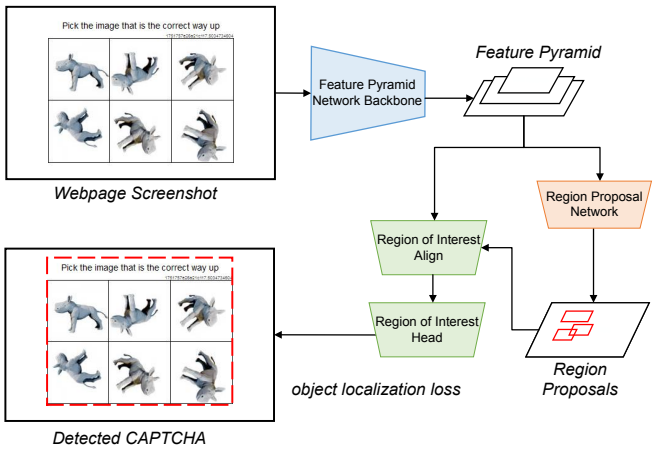

Figure 2: Model architecture of CAPTCHA detection model, consisting of multi-stage processes

4.1 CAPTCHA Detection

Given a webpage screenshot, denoted as $\mathcal{S}$, as input, the CAPTCHA detection model generates object proposals $\mathcal{C}(\mathcal{S}) = \{t | t = \langle x, y, w, h \rangle\}$. As showed in Figure 2, these proposals (in red dashed rectangle) consist of bounding boxes that contains the CAPTCHA region.

Figure 2 illustrates our model design. We employ an Object Localization Network (OLN) [33], which is a two-

stage network comprising a Region Proposal Network (RPN) stage and a Region of Interest (RoI) stage. Given a webpage screenshot, the backbone network (Feature Pyramid Network) transforms the webpage into a feature pyramid $\mathcal{F} = \{f | f = k \times k, f \in R^2\}$ where $k = \frac{W}{4}, \frac{W}{8}, \frac{W}{16}$.... Each element in $\mathcal{F}$ is a feature map in the form of a $k \times k$ matrix, and W is the maximum of webpage width and webpage height. Each feature map captures the spatial features of the webpage screenshot in different granularity. Then, the feature pyramid is fed into the Region Proposal Network, generating initial location proposals for the foreground object (i.e., CAPTCHA). These proposals undergo further refinement in the Region of Interest (RoI) network to yield the final bounding boxes.

Different from a conventional object detection model [53] where objects are both detected and classified, we customize our CAPTCHA detector to have only detection functionality. Technically, instead of a training objective covering (1) object location on x, y, w, and h and (2) object classification, we train our CAPTCHA detector with a sole focus on object location. The customization allows our model training process to focus on a single optimization objective. This is useful considering that the CAPTCHA containers can be very diverse, which can include (1) task instructions for solving the CAPTCHA, (2) the challenge body with visual elements, and (3) user interaction buttons for controlling and engaging with the CAPTCHA. They can take various forms and styles, which may encompass distorted text, images, specific object clicks, or even behavioral cues such as slider dragging.

4.2 CAPTCHA Recognition

The CAPTCHA recognition model is designed to map a test CAPTCHA instance c to its best fit in a set of prepared CAPTCHA templates $\mathcal{C}_t$ where each element in $\mathcal{C}_t$ is a representative CAPTCHA instance of a CAPTCHA type. Our CAPTCHA recognition model consists of a feature extractor mapping an object proposal (i.e., a CAPTCHA instance) to a feature vector, i.e. $f_\theta(.) : \mathcal{C} \rightarrow \mathbb{R}^n$. We denote the type function $type : \mathcal{C} \rightarrow \mathcal{T}$ which returns the type of a CAPTCHA instance, where $\mathcal{T}$ is the set of CAPTCHA types in $\mathcal{C}_t$. Then, we can select the best fit c^* of a test CAPTCHA instance c by

$$c^* = \arg\max_{c_t \in \mathcal{C}_t} cos(f_\theta(c), f_\theta(c_t))$$

Given a threshold th, we can decide the type of c by $type(c^*)$ if $cos(f_\theta(c), f_\theta(c^*)) > th$. To learn f_θ, we address the following challenges:

- **Multi-modal representation learning:** A CAPTCHA challenge contains multi-modal information, including the challenge description in both plain text and images.
- **Intra-type diversity:** Challenges within the same CAPTCHA type can differ significantly due to various service vendors or updates to the CAPTCHA pool.

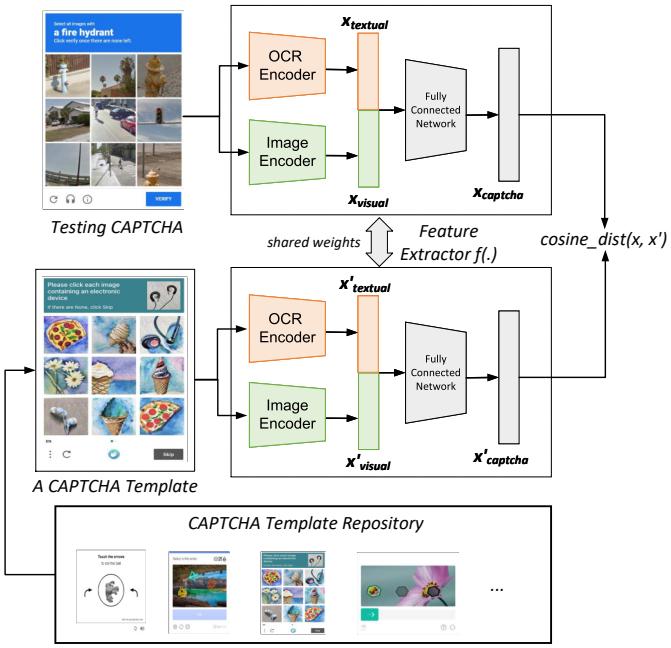

Figure 3: OCR-aided Metric Learning Model. The CAPTCHA recognition system comprises a feature extractor $f(.)$ and a recognition head. The extractor maps a CAPTCHA image to a low-dimensional embedding $\mathbf{x}_{captcha}$. The recognition head matches the testing CAPTCHA with CAPTCHA templates using cosine distance.

- **Inter-type generalization:** As CAPTCHA technology evolves, new types emerge. The model must be easily adaptable to new types of CAPTCHAs.

To incorporate both textual and visual features into the representation, we introduce a dual-branch architecture for our feature extractor $f_\theta(.)$ (See Figure 3). The architecture consists of: (1) a text encoder, pre-trained on an Optical Character Recognition (OCR) task, and (2) an image encoder, pre-trained on an image classification task. Both encoders takes the CAPTCHA image as input, and produces the respective embeddings $\mathbf{x}_{visual}$ and $\mathbf{x}_{textual}$. These two branches capture distinct yet complementary information. The OCR-based encoder focuses on character-indicative features essential for understanding task instructions. In contrast, the image encoder identifies salient visual patterns, capturing the CAPTCHA's layout and design. A fully-connected projection layer is added to fuse the two modalities with additional non-linearity: $\mathbf{x}_{captcha} = \sigma(W^T[\mathbf{x}_{visual} \oplus \mathbf{x}_{textual}] + \mathbf{b})$.

With the feature extractor, we design the recognition head. A straightforward approach involves adding a Softmax activation and using conventional Cross-entropy Loss for model fitting. However, this approach tends to overfit to observed samples, especially when the training set is small, leading to inaccurate predictions for new variants within known categories. Additionally, this approach lacks the flexibility to

(a) reCAPTCHA v2 (b) hCaptcha (Variant 1) (c) hCaptcha (Variant 2) (d) GeeTest Slider (e) Baidu Rotation

Figure 4: Examples of CAPTCHA challenges of different types.

accommodate new CAPTCHA types during runtime, as the number of classes must be predefined before inference.

In this work, we employ a deep metric learning solution to address the challenges outlined earlier. The model aims to learn an embedding space that accurately captures semantic similarities between images. It is trained on pairs of samples, denoted as "positive pair" if they belong to the same class and "negative pairs" if they come from different classes. A loss function ensures that positive pairs are closer in the embedding space than negative pairs. Specifically for CAPTCHAs, our goal is to cluster those of the same type together. During inference, we input the test CAPTCHA along with a set of CAPTCHA *templates* from different classes of CAPTCHAs. We then rank the distances to identify the closest class as the final prediction.

In this manner, we effectively tackle the aforementioned challenges: For the *intra-type diversity* issue, the pairwise training paradigm enables the model to be more sensitive in distinguishing "variations within the class" from "variations relative to other classes". Given an unseen sample from a known class, the model is more inclined to treat it as a variant of a known class rather than a novel class of CAPTCHA. For the *inter-type generalization* issue, accommodating new CAPTCHA types is straightforward: new CAPTCHAs can be easily added to the template database, serving as reference points for future queries.

Technically, during training, we freeze the textual branch and fine-tune all other remaining modules using Sub-center ArcFace loss [21]:

$$\mathcal{L} = -\frac{1}{N}\sum_{i=1}^{N}\log\left(\frac{e^{s\cdot(\cos(\theta_{y_i}+m)-1)}}{e^{s\cdot(\cos(\theta_{y_i}+m)-1)}+\sum_{j=1,j\neq y_i}^{C}e^{s\cdot\cos(\theta_j)}}\right) \quad (1)$$

In Equation 4.2, we learn a set of parameters representing the embedding centers for each class. The embedding feature i and the center for its ground truth class y_i are considered a "positive pair", while i and the center for another class j form a "negative pair". θ_{y_i} is the angle between the positive pair, and θ_j is the angle between the negative pair. This loss function encourages CAPTCHA embeddings to be close to their respective class centers and distant from irrelevant ones.

Additionally, to address class imbalance, as some CAPTCHA types are more common than others, we assign class weights to the loss, calculated as $\frac{1}{\log(n_c)}$, where n_c is each class's frequency in the training set.

4.3 CAPTCHA Solvers

The types of challenges presented by CAPTCHAs are diverse, as shown in Figure 4. Each type may require a unique skill set, such as object recognition, visual question answering, pattern matching, or orientation identification. To address the problem, we develop an arsenal of CAPTCHA solvers for each supported CAPTCHA type. For some CAPTCHA types (e.g., reCAPTCHA), we adopt the state-of-the-art solvers; while for other important CAPTCHA types (e.g., rotation) where no solver is available, we develop our own AI-powered solving solutions. We do not claim contribution in solving a particular CAPTCHA type as our system is extensible to new CAPTCHA solvers. We support four types of CAPTCHA solvers as follows.

reCAPTCHA v2 Solver. Google reCAPTCHA v2 is the most prevalent type of CAPTCHA among the Top 1 Million Sites [2]. We solve the reCAPTCHA v2 challenges by employing an object detection model similar to that of Hossen et al. [31].

hCaptcha Solver. hCaptcha is an image-based CAPTCHA service similar to reCAPTCHA. However, hCaptcha presents users with more realistic and even AI-generated images. We address two common variants of hCaptcha:

- **Variant 1 (Binary Selection).** Object-Identifying hCaptcha is similar to reCAPTCHA v2 (See Figure 4b). But it offers more complex challenge descriptions, enriched with extra context on styles or relations to other objects (e.g., someone playing football). Hence, we approach the problem as an open-set visual question answering (VQA) model. In a typical VQA task, a model is presented with an image alongside a text-based question about the visual content. The model then generates an answer, which can be a simple "yes" or "no" or a more complex textual answer. Given a CAPTCHA challenge specifying the object description as x, we transform it into a question "Is this a/an x?" for each candidate grid, then output an answer of either "yes" or

"no". As a result, the solver selects all the grids with "yes".

- **Variant 2 (Area Selection).** This is an emerging variant (See Figure 4c) that asks the user to point out a specific location within an image. To solve these more advanced challenges, we employ the off-the-shelf tool *hCaptcha Challenger* [6].

For reCAPTCHA v2 and hCaptcha, if the deep-learning-based solver fails, we defer the challenge to a visual language model (VLM) agent and ask for a controlled response (e.g., click on squares 1, 5, 7 or coordinates (x, y)).

Slider CAPTCHA Solver. Slider-based CAPTCHAs require users to slide a puzzle piece into an empty spot on a background image [54, 67]. In addition to the accuracy of the placement, the CAPTCHAs also analyze the sliding trajectory to detect automated behavior. For example, human users are unlikely to maintain a constant speed throughout the slide.

We design our slider solver with traditional computer vision techniques. First, we identify the the background image and puzzle piece elements from the webpage source code. We then apply pre-processing techniques like Gaussian blurring for denoising and grayscale conversion followed by Sobel edge detection for edge sharpening. Next, we use the puzzle piece as a template for template matching, locating a similar region within the background image. Finally, the solver uses easing functions to simulate a human-like dragging trajectory.

Rotation CAPTCHA Solver. Rotation CAPTCHAs require users to adjust randomly rotated images to their upright orientation [29]. These challenge images usually feature natural and man-made landscapes.

In this work, we treat the image rotation problem as a regression task to predict the current degree of rotation for the challenge image. Once the rotation angle is determined, the solver can interact with the CAPTCHA to correct the orientation. To construct our model, we adopt EfficientNet [60], pretrained on ImageNet. We further fine-tune the model using randomly rotated samples from the Landscape Dataset [7], a community-contributed collection of 7,268 images that depict natural and man-made landscapes. Cosine distance to the ground-truth angle serves as the training loss.

4.4 Adversarial Countermeasure

Since PhishDecloaker orchestrates several deep-learning models, it may be vulnerable to adversarial attacks at runtime. We identify two plausible attack scenarios, i.e., system-level attack and model-dependant attack. A system-level attack introduces blurring, noise, or other obfuscations to CAPTCHA challenges, hindering the models' ability to identify content. This commonly occurs when CAPTCHAs detect suspicious activities from an IP address and present more challenging images. This attack is model-agnostic and does not target any specific model. A model-dependent attack exploits existing gradient-based methods [28, 38, 40, 44, 51] to deliberately perturb inputs and induce incorrect predictions. Both our CAPTCHA detector and recognition models could be susceptible to this type of attack.

To counter the former, we use adversarial training for all our deep-learning models. This approach aims to enhance model robustness by introducing adversarial examples during training. These examples are created by applying random augmentations to the original input data, potentially leading the model to make incorrect predictions. In our work, we consider the following types of augmentations such as Random Mask, Gaussian Noise, and Gaussian Blur. We mix adversarial and clean samples at a ratio of 6:4. To counter the latter, we implement PhishDecloaker with the gradient masking technique as proposed in [35]. Specifically, we replace the ReLU activation function with a step ReLU function defined as $f(x) = \max(0, \alpha \cdot \lceil \frac{x}{\alpha} \rceil)$, where α is the discretization parameter. This renders the activations non-differentiable, effectively zeroing out the gradients.

5 Experiments

We evaluate PhishDecloaker with the following questions:

- **RQ1 (Effectiveness):** What is the performance of PhishDecloaker in revealing CAPTCHA-cloaked phishing kits?
- **RQ2 (CAPTCHA Detection & Recognition):** What are the performances of PhishDecloaker's CAPTCHA detection and recognition components?
- **RQ3 (CAPTCHA Solving):** What is the performance of PhishDecloaker's CAPTCHA solvers?
- **RQ4 (Ablation Study):** What are the alternatives for PhishDecloaker's design, and how do they perform?
- **RQ5 (Adversarial Attacks):** Is PhishDecloaker robust against adversarial attacks on its deep learning models?
- **RQ6 (Field Study):** Can PhishDecloaker help discover more zero-day phishing websites in the wild?

To address each question, we first introduce the experimental settings (e.g., model training), followed by the objective metrics used to evaluate each research question. More experiment details are available at [9].

5.1 RQ1: Experimental Effectiveness

5.1.1 Experiment Setup

Phishing Detectors. We select Phishpedia [35] and PhishIntention [36] for their state-of-the-art performance on detecting zero-day phishing websites. Following the instructions of both detectors, we use a reference list of 277 phishing targets (i.e., Facebook, Bank of America, etc).

Table 2: Phishing detection rate on DynaPD. The percentages are calculated as changes relative to the baseline (No Cloaking). The average runtime overhead is computed for each module (CAPTCHA detection, CAPTCHA recognition and CAPTCHA solver) and concatenated by "+".

Group	No Cloaking	After Cloaking			
		reCAPTCHA v2	hCaptcha	GeeTest Slide	Rotation
Phishpedia	0.73	0.00 (↓100%)	0.00 (↓100%)	0.00 (↓100%)	0.00 (↓100%)
PhishIntention	0.53	0.00 (↓100%)	0.00 (↓100%)	0.00 (↓100%)	0.00 (↓100%)
Phishpedia + PhishDecloaker	0.73	0.57 (↓22.2%)	0.29 (↓59.8%)	0.69 (↓5.1%)	0.61 (↓16.1%)
PhishIntention + PhishDecloaker	0.53	0.41 (↓22.3%)	0.21 (↓59.8%)	0.50 (↓5.1%)	0.45 (↓16.0%)
Runtime Overhead (s)	-	0.13 + 0.05 + 44.17	0.12 + 0.05 + 8.81	0.13 + 0.06 + 5.12	0.13 + 0.08 + 5.01

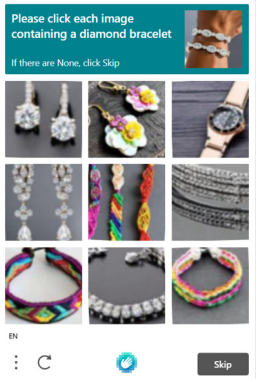
Phishing Dataset. We apply our hardening framework, Cloaken, to the DynaPD dataset [37]. The DynaPD dataset comprises approximately 6k deployable and interactable phishing kits, providing a replicable environment to study CAPTCHA cloaking on phishing kits. Due to limitations in the reference lists of phishing detectors [35, 36], we filter out phishing kits targeting sites not included in the reference list. This filtering results in a dataset of 2,960 phishing kits for our study. Cloaken cloaks each phishing kit with 4 CAPTCHA instances under the category of reCAPTCHA, hCaptcha, slider, and rotation, none of these CAPTCHA instances are used for training the models.

Measurement. We evaluate whether PhishDecloaker can help the phishing detectors to recover its access to the phishing content. Specifically, we evaluate detection rate of a phishing detector on DynaPD, r_1, its detection rate on the different types of cloaked phishing website variants, r_2, and its detection rate after equipped with PhishDecloaker, r_3. Note that, PhishDecloaker is not designed for improving the precision of existing phishing detectors, thus we only evaluate the recall measurement in the study.

Environment. We use Chrome version 114 and ensure a clean browser state for each session, i.e., with no caches or cookies preserved between consecutive requests. To conceal any indications of a headless browser and automation, we modify the requests and web browser characteristics, such as customizing User-Agent headers and adjusting to the Navigator object properties, as well as modifying to WebGL vendor. All solvers operate from a single IP address and machine with 20 CPU cores, 125G memory, and A100 GPU.

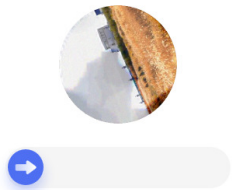
5.1.2 Results

Table 2 shows the overall experiment results. On the 2.9k phishing websites without any cloaking, Phishpedia and PhishIntention achieve detection rates of 72.6% and 53.0% respectively. Any CAPTCHA-cloaked variants can compromise their effectiveness, dropping the detection rate to 0%. In contrast, PhishDecloaker can recover their detection rates back to a percentage of their original performance: 78% on reCAPTCHA, 40% on hCaptcha, 95% on slider CAPTCHA, and 84% on rotation CAPTCHA. Overall, PhishDecloaker's contribution comes with acceptable runtime cost. Note that the main overhead lies in CAPTCHA solving. Specifically, solving a reCAPTCHA instance takes an average of 44.17s. This is because reCAPTCHA can iteratively replace selected images with new ones and prompt the user to click "verify" once there are no target objects (e.g., motorcycle) left. This iterative interaction incurs a significant runtime overhead.



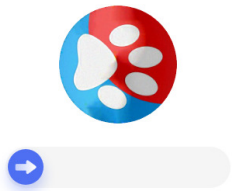
5.1.3 Qualitative Analysis

Next, we further investigate and categorize the CAPTCHAs which PhishDecloaker cannot address. The reason lies in as follows.



Incapability of the off-the-shelf solvers. We observe that the off-the-shelf solvers (e.g., hCaptcha solver) can have their limitations. Figure 5a shows an example where PhishDecloaker successfully detect and recognize the hCaptcha type but the hCaptcha solver fails to solve the challenge of *click each image containing a diamond bracelet*. Our investigation shows that the model mistakenly recognize earrings as bracelet, which are of similar visual semantics. A potential remedy is to retrain the model to further distinguish the embedding space of the model. We will discuss on how to improve the capability in Section 6.

Human verification beyond CAPTCHA. We discover that some CAPTCHAs such as reCAPTCHA v2 verifies a human using more than an interactive challenge. It may include mouse behavior analysis and browser fingerprinting, which will block our visits despite solving the challenge. We acknowledge the significance of these methods. Since there are relevant works [31, 64] on this direction (see Appendix A.3), we limit our focus on countering CAPTCHA cloaking, which complements these works. A hybrid security crawler with various decloaking techniques is vital for effectiveness.



The restriction of training dataset. Finally, we find that our customized solvers might be limited by our training dataset. In general, our regression model (see Section 4.3) learns upright orientation for different pictures. If a picture to be rotated is deviated from the training dataset, the model might fail to predict its rotation degree effectively. For example, Figure 5b

(a) an instance of hCaptcha (V1) which cannot be solved by PhishDecloaker.

(b) a solved rotation CAPTCHA instance.

(c) an unsolved rotation CAPTCHA instance.

Figure 5: Example cases in solving CAPTCHAs

and Figure 5c manifest different genres of images, which leads to performance disparity. Although we do not claim contribution on solving any particular CAPTCHA instance, we will discuss potentially better solutions in Section 6.

5.2 RQ2: CAPTCHA Detection & Recognition

5.2.1 CAPTCHA Detection

Dataset Collection. To collect the training dataset of detecting CAPTCHA, we adopt XDriver [23] to crawl the websites listed in the Alexa top 1-million websites. It automatically locates the forms on the page, fills in all form inputs with simulated data, and submits the form in order to trigger CAPTCHAs. It then captures screenshots of these pages, which we manually annotate to identify the bounding boxes for any CAPTCHAs present. Due to ethical and security considerations, we strictly limit our crawling to a single instance per website, with a maximum depth of 2. Over two weeks, we collected and labeled 1,764 webpage screenshots containing CAPTCHAs. We employ data augmentation to enrich our dataset with additional synthetic samples, bringing the total to 10,680 webpage screenshots. Examples of the synthetic samples generated are shown in Appendix A.1. We perform a 9:1 train-test split, where 9,612 samples are for training and 1,068 samples for testing.

Training Settings. We use the training framework provided by the authors of [33], which is built upon OpenMMLab Detection Toolbox [8]. The OLN object detection model uses Faster-RCNN pre-trained on ImageNet as its backbone, with the RPN and RoI head modified as described in Section 4.1. We train the model for 8 epochs, with a batch size of 2 per GPU, using Stochastic Gradient Descent with a learning rate of 0.02 and momentum of 0.9.

Measurement. We use the mean average precision (mAP) and mean average recall (mAR) to evaluate the performance, which are the standard metrics for evaluating the completeness and redundancy of the reported objects in object detection tasks [33, 53]. The mAP and mAR are computed over IoU thresholds ranging from 0.5 to 0.95.

Results. The OLN detector achieves a mean average precision and recall of 0.92 and 0.97 respectively.

Table 3: Performance for CAPTCHA Recognition on Open-set CAPTCHAs.

Class	Precision	Recall	F1-Score
`arkose_select`	0.93	0.91	0.92
`capycaptcha_drag`	0.88	0.58	0.70
`dicecaptcha_qa`	0.97	0.68	0.80
`funcaptcha_select_1`	0.99	0.87	0.93
`funcaptcha_select_2`	0.98	0.48	0.64
`funcaptcha_select_3`	0.88	0.52	0.65
`funcaptcha_select_4`	0.62	0.91	0.74
`funcaptcha_select_5`	1.00	0.53	0.69
`funcaptcha_select_6`	0.88	0.72	0.79
`keycaptcha_drag`	0.93	0.75	0.83
`mtcaptcha_text`	0.46	0.63	0.53
Average	**0.86**	**0.69**	**0.75**

5.2.2 CAPTCHA Recognition

Dataset Collection. We have collected a total of 6,612 CAPTCHA samples spanning 38 classes, sourced from demo websites (e.g., NetEase, Tencent, Arkose Labs), official API keys provided by vendors (e.g., Google, hCaptcha, GeeTest), and open-source community datasets. During training, we employed a 9:1 train-test split, allocating 5,950 samples for training and 662 samples for testing. This dataset serves as the template database at deployment time.

Training Settings. As for the feature extractor, the visual branch employs a ResNet-50 model pre-trained on ImageNet with its classification head removed. This branch takes a resized CAPTCHA region of dimensions 224×224 as input and outputs the visual embedding. The textual branch is adapted from EasyOCR [5]. It utilizes a Character-Region Awareness for Text (CRAFT) model [18] pre-trained on SynthText for bounding box detection and a Convolutional Long Short Term Memory (CLSTM) [55] model pre-trained with the STR framework [17] for textual embedding projection. During training, we freeze the textual branch and fine-tune all other branches using Sub-center ArcFace [21] as described in Section 4.2. We train the model for 100 epochs, with a batch size of 2 per GPU, using Stochastic Gradient Descent with a learning rate of 0.02 and a momentum of 0.9.

Measurement. We evaluate the training and testing accuracy of our model in recognizing a particular CAPTCHA type. In addition, we evaluate the generalizability of our model by whether our model can recognize the new CAPTCHA types without retraining the model. We argue that utilizing deep Siamese learning for CAPTCHA recognition can improve performance in open-set scenarios. To validate this, we first collect an additional 11 CAPTCHA types not present in the training datasets of our CAPTCHA detection and recognition models. These newly acquired CAPTCHAs are superimposed onto random webpage screenshots to create open-set test samples. We then update PhishDecloaker's template database with references from these new CAPTCHA classes and assess the system's ability to correctly classify these novel CAPTCHAs.
Results. Table 3 presents our results on the open-set dataset. Our system yields satisfactory performance in correctly identifying unseen CAPTCHA types, with an average precision of 86.0% and an average recall of 69%.

5.3 RQ3: CAPTCHA Solving

CAPTCHA Benchmark. Our CAPTCHA benchmarking dataset includes reCAPTCHA v2, hCaptcha (V1&2), slider CAPTCHA, and rotation CAPTCHA. For reCAPTCHA v2, hCaptcha (V1&2), we test different difficulty levels: easy, moderate, and difficult, which is categorized by the CAPTCHA vendor. As for slider CAPTCHA, we include three different versions from GeeTest, Tencent, and NetEase. Lastly, we select Baidu's rotation CAPTCHA for evaluation. In general, we generate 200 CAPTCHA variants for each version. In total, we evaluated 10 CAPTCHA versions in the study.
Measurement. For reCAPTCHA v2, hCaptcha, all slider CAPTCHA variations, and Baidu rotation CAPTCHA, we determine their success rate by calculating the proportion of successfully resolved CAPTCHA sessions compared to the total number of requested CAPTCHA sessions. To elaborate, during each CAPTCHA session, the solver may encounter one or more consecutive CAPTCHA challenges. In order for a CAPTCHA session to be considered as successfully solved, the solver must successfully complete all presented challenges and receive a confirmation of success (e.g., a green checkmark in reCAPTCHA v2).

Additionally, to further analyze our rotation CAPTCHA solver, we evaluate it on the test set in the Landscape Dataset. The test samples are randomly rotated between 0 to 360 degrees. We use mean angular error (MAE) as the evaluation metric. Given a batch of N predicted angles θ_i and their ground truth (rotated) angles $\hat{\theta}_i$, MAE is defined as follows:

$$\text{MAE} = \frac{1}{N}\sum_{i=1}^{N}\Big(180 - \big||\theta_i - \hat{\theta}_i| - 180\big|\Big) \tag{2}$$

This metric quantifies the average angular discrepancy between the predicted and actual angles.

Table 4: CAPTCHA Metrics and Detection Rates

CAPTCHA	Category	Solving rate
reCAPTCHA v2	Easy	75.5%
	Moderate	74.0%
	Difficult	35.0%
hCaptcha	Easy	85.0%
	Moderate	92.0%
	Difficult	71.0%
Slider	GeeTest	95.0%
	Tencent	89.0%
	NetEase	100.0%
Rotation	Baidu	74.5%

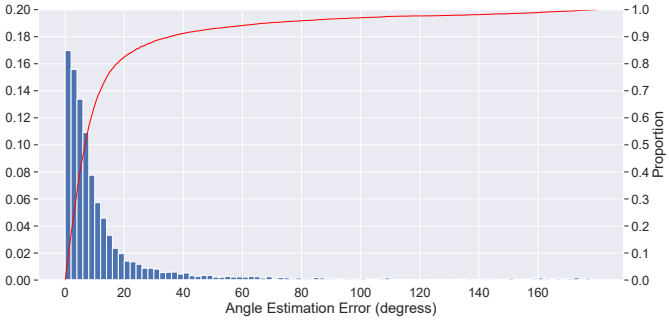


Figure 6: Histogram of angular errors and their cumulative distribution (red line) for the regression model on the test set in Landscape Dataset.

Results. For reCAPTCHA and hCaptcha, we observe that our solvers perform well on easy and moderate challenges. Performance degrades for difficult cases, with reasons discussed in Section 5.1. Using the template matching algorithm, the slider CAPTCHA solver performs uniformly well across three different service providers, because that the algorithm is robust against noise and distortion in the background images.

The rotation solver achieves a mean angular error of 15.62. Figure 6 displays a histogram of the angular errors along with its cumulative distribution. We observe that more than 90% of the test samples exhibit an angular error of less than 35 degrees, and the histogram follows a long-tail distribution. This indicates that the solver was able to reorient the majority of images. We then conducted a test using Baidu's rotation CAPTCHA service, limiting the number of attempts to 200. The solver achieves a solving rate of 74.5%.

5.4 RQ4: Ablation Study

We explore alternatives for PhishDecloaker's architecture design on recognizing a CAPTCHA type from a webpage screenshot (i.e., a pipelined task of CAPTCHA detection and recognition). We test the following alternatives:

Table 5: Results of our abalation study.

Configuration		Result	
Detector	**Recognizer**	**Precision**	**Recall**
F-RCNN	ResNet-50	0.89	0.84
F-RCNN	Single-branch Siamese	0.92	0.84
F-RCNN	Dual-branch Siamese	0.91	0.82
OLN	ResNet-50	0.85	0.77
OLN	Single-branch Siamese	0.92	0.86
OLN	Dual-branch Siamese	**0.93**	**0.86**

- **OP1 (alternative recognizer):** How does a deep classifier (implemented by ResNet-50) compare with Siamese metric learning model in recognizing CAPTCHA types?
- **OP2 (alternative object detector):** How does Faster R-CNN compare with OLN in detecting CAPTCHAs?
- **OP3 (alternative branch design):** How does a dual-branch Siamese (i.e., visual & OCR-aided textual branch) compare with a single-branch Siamese (i.e., visual branch)?

Dataset. To evaluate the precision and recall of CAPTCHA recognition, we overlay the test samples from our CAPTCHA recognition dataset (Section 5.2.2) onto 622 screenshots of benign webpages and supplement them with 100 webpage screenshots without CAPTCHAs.
Results. Table 5 shows our results. We observe that PhishDecloaker's design is the most optimal. Compared to Siamese models, a classifier achieves less accuracy, especially in those screenshots without CAPTCHAs. Compared to Faster R-CNN, OLN manifests better recall. Finally, the dual-branch Siamese design has a marginal improvement over single-branch design by considering textual features (0.93 over 0.92 in precision). Security practitioners can make a trade-off between model complexity and performance.

5.5 RQ5: Robustness Against Adversaries

In this section, we assess PhishDecloaker's robustness to evasion attacks by generating custom CAPTCHA images that target specific components of PhishDecloaker. We then evaluate the system's overall resilience.

5.5.1 Adversaries

We model our adversary as a phisher with no constraints in time and computing resources to deploy evasion attacks. The adversary's aim is to create a CAPTCHA-cloaking page that remains undetected by PhishDecloaker. To this end, we conduct adversarial attacks on detection, recognition, and the solving components, with the assumption that the adversary possesses *perfect* knowledge of PhishDecloaker's design.

Attacks on CAPTCHA Detection. We conduct DPatch attack [38] to compromise the CAPTCHA detection component of PhishDecloaker. DPatch generates adversarial patches that can be applied to a webpage. In our case, the patches are untargeted, To create untargeted patches, DPatch finds a patch pattern $\vec{P}_u$ that maximize the loss of the object detector to the true class label $\vec{y}$ and bounding box label $\vec{B}$ when the patch is applied to a webpage screenshot x using "apply" function A, as shown in Equation 3 [38]. The apply function $A(x,P)$ means adding patch P onto webpage screenshot x. As a result, an object detection model can potentially fail to locate the correct region containing CAPTCHAs.

$$\vec{P}_u = \arg\max_P \mathbb{E}_x \left[L(A(x,P); \vec{y}, \vec{B}) \right] \tag{3}$$

Attacks on CAPTCHA Recognition. We conduct adversarial attacks on CAPTCHA images including Fast Gradient Sign Method (FGSM) [28], Jacobian Saliency Map Attack (JSMA) [51], Projected Gradient Descent (PGD) [40], and DeepFool [44] to compromise the CAPTCHA recognition component of PhishDecloaker. In the attack, we assume that the attacker can access the white-box model but cannot poison or modify PhishDecloaker deployed online,
Augmentation Attacks. Additionally, we conduct generic image augmentation attacks on PhishDecloaker by performing 6 types of transformations on the CAPTCHA image and overlay the transformed CAPTCHA onto random webpage screenshots. Specifically, they are Random Stretch, Gaussian Noise, Random Crop, Random Mask, Salt & Pepper, and Gaussian Blur. Appendix A.2 visualizes the attacks. Those augmentations are commonly found in phishing webpages [16]. Different from generating the adversarial images for CAPTCHA detection and recognition component, those adversarial samples are visible.
Dataset. We apply all the above attacks on the dataset described in Section 5.2.2.
Measurement. We measure the performance of PhishDecloaker before and after attacks in terms of the accuracy of the results of a pipelined CAPTCHA detection and CAPTCHA recognition. We evaluate the robustness against the adversaries by the perturbation of overall CAPTCHA recognition rate before and after the attack. We do not evaluate the solving accuracy as we cannot change the online CAPTCHAs.

5.5.2 Results

Table 6 and Table 7 show that the accuracy loss under attacks. We can see that our adopted gradient masking technique is effective in defending the state-of-the-art gradient-based adversarial attack on the deep learning models, i.e., CAPTCHA detection and recognition models.

Furthermore, Table 8 shows the performance of PhishDecloaker in recognizing augmented CAPTCHAs, including attacks such as Random Stretch and Gaussian Noise, among

Table 6: The robustness of CAPTCHA recognition model against diverse adversarial attack.

Attack	Accuracy (no Def.)	Accuracy (with Def.)
No Attack	0.97	1.00
JSMA	0.50 (-48.5%)	1.00 (-0.0%)
PGD	0.12 (-87.6%)	1.00 (-0.0%)
DeepFool	0.07 (-92.8%)	1.00 (-0.0%)
FGSM	0.06 (-93.8%)	1.00 (-0.0%)

Table 7: The robustness of CAPTCHA detection model against adversarial attack.

Attack	mAP (no Def.)	mAP (with Def.)
No Attack	97.70	91.55
DPatch	54.65 (-44.1%)	85.71 (-6.4%)

others. We observe that transformation-based attacks can be effectively countered through adversarial training. Although the adversarial training process has only a subset of transformations (i.e., Random Mask, Gaussian Noise and Blur), the model performed well against other attacks, suggesting that learned transformations can be generalized to effectively handle unseen transformations.

Table 8: The robustness of PhishDecloaker against augmentation attacks.

Attack	Accuracy (no Def.)	Accuracy (with Def.)
No Attack	0.97	1.00
Random Stretch	0.95 (-1.9%)	0.96 (-4.0%)
Gaussian Noise	0.87 (-10.2%)	0.94 (-6.0%)
Random Crop	0.82 (-15.3%)	0.83 (-17.0%)
Random Mask	0.76 (-21.5%)	0.90 (-10.0%)
Salt and Pepper	0.33 (-66.4%)	0.92 (-8.0%)
Gaussian Blur	0.18 (-82.0%)	0.93 (-7.0%)

5.6 RQ6: Field Study

We further design a field study to evaluate the emergence of CAPTCHA-cloaked phishing websites in the real world.

5.6.1 Experiment Setup

URL Source. We crawl fresh URLs from Certstream [3] in real-time for 4 weeks, which provides domains with newly issued TLS/SSL certificates.

Study Groups. We prepare 6 different study groups to analyze crawled sites for phishing, each using PhishIntention as the base phishing detector for its state-of-the-art performance in detecting zero-day phishing websites. Group 1 is a *control* group with no JavaScript (JS) rendering or decloaking techniques. Group 2 has only JS rendering. Groups 3 to 6 have JS rendering and each is equipped with a type of decloaking technique below:

- **Anti-interaction-cloaking (AI):** Automatically closes alert, permission, and notification windows. It also randomly moves and clicks the mouse after the page is loaded.
- **Anti-fingerprint-cloaking (AF):** Randomizes its user agent and cookie storage, spoofs its referrer, and uses a stealth headless browser.
- **Anti-behavior-cloaking (AB):** Automatically follows all redirects and waits for 5 seconds if the page is blank (i.e., loading). It retries up to 3 times if the page fails to load.
- **Anti-CAPTCHA-cloaking (AC):** Uses PhishDecloaker to automatically detect and solve CAPTCHAs.

Validation & Monitoring. We manually inspect and confirm reported phishing websites. Further, we submit the confirmed phishing websites to VT and track their lifespan. We consider a manually confirmed phishing website as zero-day if it is not reported by any of the detectors in VT. In addition, we measure the time taken for sites to expire (*time-to-takedown*) and blacklisted by VT (*time-to-blacklist*).

5.6.2 Results

In this field study, we captured totally 869 unique phishing websites by all 6 study groups. Of these, 7.6% were CAPTCHA-cloaked phishing websites, all of which were discovered solely by PhishDecloaker. Table 9 further details how each decloaking groups contribute to phishing discovery. Group 3 (e.g., random mouse movement), Group 5 (e.g., repetitive visits), and Group 6 (with PhishDecloaker) report unique phishing websites, i.e., the phishing websites reported only by the specific group. We consider Group 3-5 as basic and traditional decloaking functions (e.g., randomly moving the mouse and repetitive visits to a website), which still play an important role in report zero-day phishing websites (i.e., Group 6 reports 203; Group 5 reports 198; and Group 3 reports 197). Nevertheless, compared to those traditional decloaking groups, CAPTCHA-based cloaking is emerging, which ranks the second in terms of unique ratio and ranks the first in terms of the number of discovered zero-day phishing websites, which raises alarm to the phishing detection community. Further, the result indicates a practical or commercial phishing decloaking shall be *hybrid* to handle different cloaking techniques.

Next, we investigate the features of CAPTCHA-cloaked phishing websites regarding the sectors of their target brands, CAPTCHA types, lifespan, and time to be blacklisted.

Table 9: Field study results of each decloaking group on Certstream URLs. PI: PhishIntention. JS: JavaScript rendering. AI: anti-interaction-cloaking. AF: anti-fingerprint-cloaking. AB: anti-behavior-cloaking. AC: anti-CAPTCHA-cloaking.

Group	Setup	Unique Ratio	# 0-Days	# Phishing
G1	PI	0.0%	101 (–0.0%)	361 (–0.0%)
G2	PI + JS	0.0%	176 (↑74.3%)	582 (↑61.2%)
G3	PI + JS + AI	14.1%	197 (↑95.0%)	710 (↑96.7%)
G4	PI + JS + AF	0.0%	165 (↑63.4%)	543 (↑50.4%)
G5	PI + JS + AB	7.4%	198 (↑96.0%)	692 (↑91.7%)
G6	PI + JS + AC	10.2%	203 (↑101.0%)	648 (↑79.5%)

Table 10: Top-5 targeted sectors by ordinary and CAPTCHA-cloaked phishing sites.

Ordinary	%	CAPTCHA-Cloaked	%
Telecommunications	23.8	Cryptocurrency	43.9
Social Networking	22.8	Social Networking	19.3
Gambling	12.5	Logistics / Courier	15.8
Online Services / Software	12.3	Government Services	8.8
Financial / Insurance	10.1	Financial / Insurance	5.3

Target Sectors. We further investigate the sectors of the target brands of traditional phishing websites and CAPTCHA-cloaked phishing websites as showed in Table 10. We observe that CAPTCHA-cloaked phishing websites are more likely to target vibrant sectors like cryptocurrency (e.g., Coinbase and Trust Wallet). In contrast, traditional phishing websites still target sectors such as telecommunication (e.g., Orange and AT&T).

CAPTCHA Types and Their Usage. As showed in Figure 7, phishers tend to use *free* and *convenient* CAPTCHA services. The distribution of CAPTCHA types used by benign websites are: reCAPTCHA v2 (76.0%), hCaptcha (19.3%), Text CAPTCHA (4.0%), Press & Hold (0.6%), Slider (0.1%), whereas it is mainly hCaptcha (77.3%) and reCAPTCHA v2 (22.7%) on phishing sites. Interestingly, we find that fewer than 20% of CAPTCHA API keys (i.e., the keys used to access commercial CAPTCHA services) account for more than 55% of the discovered CAPTCHA-cloaked phishing sites. One hCaptcha key was even found to be shared across 19 sites. It potentially indicates that CAPTCHA-cloaked phishing attackers might also be sensitive to the "attacking cost".

Life Span and Time to Blacklist. Different from our expectation, CAPTCHA-cloaked phishing websites have shorter lifespan compared to ordinary phishing sites (9.7 vs. 13.2 hours), as showed in Figure 8. However, it takes blacklist-based detectors such as Google Safe Browser and SmartScreen more time to put the URLs of CAPTCHA-cloaked phishing sites in their blacklist, as showed in Figure 9. CAPTCHA-cloaked

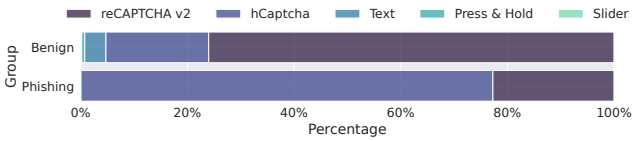

Figure 7: Distribution of CAPTCHA types on benign and phishing sites.

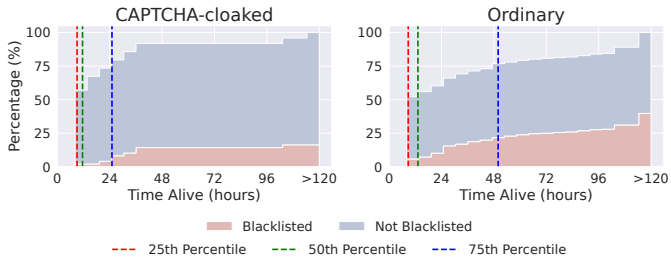

Figure 8: Cumulative distribution of life span for CAPTCHA-cloaked and ordinary phishing sites.

phishing sites take a median time of 16 hours to be blacklisted, which is 45.5% longer than ordinary phishing sites (11 hours). The result indicates that CAPTCHA-cloaked phishing websites are more active and evasive for traditional phishing detectors.

Overhead. In this study, the median time of PhishDecloaker on CAPTCHA detection and recognition are 0.4s and 0.3s respectively, making Group 6 53.1% (0.68s) slower than Group 2. Although median time for CAPTCHA solving is 15.3s, it can be decoupled and processed asynchronously.

6 Discussion

Limitations. Although PhishDecloaker can be extended to include new CAPTCHA types for CAPTCHA detection and recognition, it is limited by the number of supported CAPTCHA solvers. When PhishDecloaker encounters a rare CAPTCHA without a corresponding solver in its repository, we offer two suggestions. First, PhishDecloaker can integrate with existing CAPTCHA solving services (e.g., 2Captcha) that rely on paid labour. These services provide a API endpoint for each different CAPTCHA type. In this case, PhishDecloaker can identify the CAPTCHA type and call the right API for the task. Second, PhishDecloaker can automatically notify in-house human operators of unsolvable CAPTCHAs. Nevertheless, in the era of Artificial General Intelligence (AGI), we expect that emerging AI solutions can further empower PhishDecloaker to achieve better performance.

Ethical Considerations. Our empirical study submits URLs of self-hosted phishing kits to anti-phishing entities, which may have a negative impact to the community. More specifically, security crawlers may spend unnecessary resources on

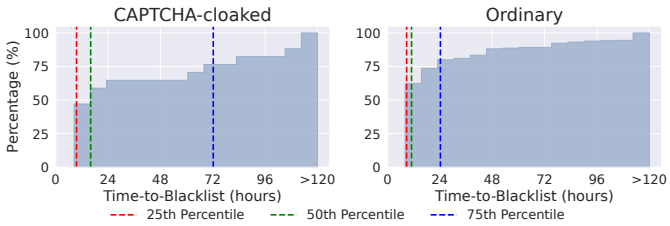

Figure 9: Cumulative distribution of time taken to be blacklisted by SmartScreen or GSB for CAPTCHA-cloaked and ordinary phishing sites.

analyzing simulated threats and innocent visitors may stumble upon these sites. To mitigate this, we strictly follow the established guidelines of previous works [13, 46, 47] by randomly generating long URLs, submitting them only to anti-phishing entities through proper channels, restricting the total number of submissions to 500 per entity, and use defanged phishing kits that do not store nor share credentials. Besides, PhishDecloaker can be exploited to compromise benign websites. We opt to keep it closed-source, sharing exclusively with trusted researchers, security firms, and government agencies. We can also deploy it as a restricted cloud service, where access key is revoked if abused.

Future Work. Recently, vision-language foundation models have demonstrated extraordinary emergent abilities on web navigation tasks [22, 25]. These models enable transformative generalization and are capable of solving wide ranges of interactive decision making problems in the wild [45]. Hence, it is possible to study the feasibility of these models as zero-shot or few-shot generalized CAPTCHA solvers.

7 Related Work

Phishing Detection. Conventional phishing detection systems such as SmartScreen, Google Safe Browsing, and OpenPhish rely on blacklists, which are updated through user reports, automatic crawling, and manual verification. However, this method is limited by delays in list updates and frequently misses short-lived phishing campaigns [49].

To automate verification, feature-engineering-based solutions [20, 24, 27, 34, 39, 61, 63] use feature extraction and classification techniques, focusing on HTML code, URLs, domains, and screenshots. Despite their utility, these solutions are inflexible and susceptible to code obfuscation, resulting in rapid data obsolescence. To overcome these limitations, reference-based solutions [12, 15, 35–37, 42] employ deep-vision techniques to compare the representations of a phishing page against a pre-defined reference list, determining its target brand. These approaches are both extensible and explainable, advancing the state-of-the-art in phishing detection.

Cloaking. Phishing websites use advanced cloaking techniques to evade detection [14, 41, 48, 59, 64, 65]. Two main types exist: server-side and client-side cloaking. Server-side cloaking identifies users via HTTP requests, often using .htaccess or PHP scripts [19, 41, 46, 47, 49, 65]. It employs IP and keyword blacklists, geolocation, and user-agents to filter traffic. Countermeasures include multiple visits with spoofed IPs and user-agents [13, 32, 35, 36, 64].

Client-side cloaking operates within browsers. It employs browser fingerprinting and user interaction, such as pop-ups or CAPTCHAs [13, 41, 59, 64]. It also manipulates bot behavior to delay loading times [64]. Despite its rising popularity, client-side cloaking challenges anti-phishing engines [41, 47]. Though lacking a systematic approach, some advances have been made. For example, Crawlphish uses JavaScript force execution to detect client-side cloaking but focuses more on post-hoc analysis than real-time detection [64].

CAPTCHA Solving. Deep learning models have been used to solve specific CAPTCHA types [26, 31, 57, 66, 67], but no system exists for automatically identifying arbitrary CAPTCHAs, consistent with [59]. Some ad hoc solvers include: Sivakorn et al. [57] tackled Google reCAPTCHA v2 by exploiting challenge instructions. They used image annotation services and Word2Vec to match tags with challenge text. Hossen et al. [31] employed a custom object detection model to recognize the objects present in the challenge images. For slider CAPTCHAs, Zhao et al. [67] developed an algorithm to match background and target images to identify the puzzle region, whereas Wu et al. [62] used object detection.

Unlike the above solutions, PhishDecloaker detects, recognizes, and then solves various CAPTCHAs using an expandable repository of CAPTCHA solvers for anti-phishing.

8 Conclusion

We studied CAPTCHA cloaking, a prevalent technique among phishing websites. Our empirical study showed that none of the selected phishing detectors could detect CAPTCHA-cloaked phishing. Motivated by this, we developed PhishDecloaker to automatically detect, recognize, and solve CAPTCHAs. Our experiment confirmed PhishDecloaker's ability to restore phishing detection rates of Phishpedia and PhishIntention on CAPTCHA-cloaked phishing kits, and it remained robust against adversarial attacks. We further confirmed its practical impact through a field study on Certstream URLs, revealing interesting behavior of 0-day CAPTCHA-cloaked phishing sites in the wild.

A Appendix

A.1 Summary of Datasets

CAPTCHA Detection Dataset (Usage: see 5.2.1). Contents: 19,680 webpage screenshots (1920×1080), 10,680 with annotated CAPTCHA bounding boxes, 9,000 without.
CAPTCHA Recognition Dataset (Usage: see 5.2.2). Contents: 6,612 CAPTCHA images distributed across 38 classes.
CAPTCHA Open-set Dataset (Usage: see 5.2.2). Contents: 1,500 webpage screenshots (1920×1080), all of which have annotated CAPTCHA classes spanning 15 different categories.
Ablation Dataset (Usage: see 5.4). Contents: 722 webpage screenshots (1920×1080), 622 with CAPTCHAs spanning 38 classes, 100 without.
Landscape Dataset (Usage: see 4.3). Contents: 7,268 natural and man-made landscape images (320×180).

A.3 Other Human Verification Methods

This section offers a qualitative analysis of human verification methods apart from CAPTCHA challenges to rate-limit or block visitors.
TLS/SSL Fingerprinting Identify the visitor's web client using TLS and HTTP handshakes, and then present different content for different clients. Countermeasure: handshake impersonation [4].
GeoIP Filtering Restrict access based on visitor's geographical location and IP addresse. Countermeasure: residential proxies [43].
Behavior Analysis Analyze interactions of mouse cursors to distinguish between human users and automated bots. Countermeasure: generate human-like mouse trajectories.
Browser Fingerprinting Exploit JavaScript API to gather data (e.g., screen size, screen orientation, display aspect ratio, device hardware, fonts, plugins, extensions, user-agent) and infer the visitor's identity. Countermeasure: spoofing.

Less Defined Knowledge and More True Alarms: Reference-based Phishing Detection without a Pre-defined Reference List

Abstract

Phishing, a pervasive form of social engineering attack that compromises user credentials, has led to significant financial losses and undermined public trust. Modern phishing detection has gravitated to reference-based methods for their explainability and robustness against zero-day phishing attacks. These methods maintain and update predefined reference lists to specify domain-brand relationships, alarming phishing websites by the inconsistencies between its domain (e.g., payp0l.com) and intended brand (e.g., PayPal). However, the curated lists are largely limited by their lack of comprehensiveness and high maintenance costs in practice.

In this work, we present *PhishLLM* as a novel reference-based phishing detector that operates without an explicit predefined reference list. Our rationale lies in that modern LLMs have encoded far more extensive brand-domain information than any predefined list. Further, the detection of many webpage semantics such as credential-taking intention analysis is more like a linguistic problem, but they are processed as a vision problem now. Thus, we design *PhishLLM* to decode (or retrieve) the domain-brand relationships from LLM and effectively parse the credential-taking intention of a webpage, without the cost of maintaining and updating an explicit reference list. Moreover, to control the hallucination of LLMs, we introduce a search-engine-based validation mechanism to remove the misinformation. Our extensive experiments show that *PhishLLM* significantly outperforms state-of-the-art solutions such as Phishpedia and PhishIntention, improving the recall by 21% to 66%, at the cost of negligible precision. Our field studies show that *PhishLLM* discovers (1) 6 times more zero-day phishing webpages compared to existing approaches such as PhishIntention and (2) close to 2 times more zero-day phishing webpages even if it is enhanced by DynaPhish. Our code is available at https://github.com/code-philia/PhishLLM/.

1 Introduction

Phishing attacks entice users to reveal sensitive information by posing as legitimate entities. Its fallout includes data breaches, ransomware attacks, and significant financial losses. The FBI's Internet Crime Complaint Center (IC3) has reported losses totaling $10.3 billion [58]. In addition, phishing attackers can generate and deploy comprehensive phishing kits with the known phishing-as-a-service [15, 19, 32, 57], making the launch of phishing attacks much less costly.

State-of-the-art phishing detection approaches are reference-based [10, 11, 25, 47, 49, 53], which reports and explains the phishing alarms by detecting the brand intention, credential-taking intention, or both from a webpage.

Brand Intention Analysis. Reference-based phishing detectors operate by pre-defining a list of references that specify the correspondence between an authentic domain and its brand representation, such as a logo or screenshot. When assessing a webpage, the detector identifies its *brand intention* by extracting its brand representation (e.g., logo or screenshot) and comparing it to those in the reference list. If a match is found — say, an extracted logo resembles the PayPal logo — but the webpage's domain does not align with the authentic domain (e.g., payp0l.com), a phishing alert is triggered, citing domain-brand inconsistency as the explanation.

Credential-taking Intention Analysis. To further validate a phishing webpage, some techniques such as [49] detect the credential-taking intention of a webpage. This is done by *visually* recognizing forms or buttons that lead to a credential-taking webpage, typically using computer vision techniques such as object detection [64].

Despite their promising performance, these approaches still suffer from two main drawbacks:

Challenge 1: Reference Completeness and Its Dilemma: The performance of reference-based phishing detectors is inherently limited by the completeness of their reference lists. An incomplete list cannot help decide the benign nature of websites with unknown brands. While emerging techniques such as DynaPhish [50] try to grow the reference list in an

automatic way, a long reference list can incur additional costs of maintaining the list such as updating new logo variants. Furthermore, the longer the list, the more likely it include similar logos under different brands, potentially raising the challenge of logo recognition.

Challenge 2: Capturing Webpage Semantics by Vision-based Solutions: Although the computer vision techniques used by the state-of-the-art detectors such as PhishIntention [49] excel at recognizing the shape and pattern of UI components, they fall short of capturing the webpage semantics represented in terms of natural language description. On detecting UI components about credentials for analyzing credential-taking intention, human often rely on the text like "login", "username", or "bank account" to identify credential-relevant UI components, instead of visual shapes, colors, and borders used by Phishpedia and PhishIntention. Moreover, such text can appear in multiple languages on the webpages.

Technically, *PhishLLM* comprises three modules: (1) A brand recognition model that leverages the Large Language Model (LLM) to infer the brand intention from logo descriptions. We found that modern LLMs have a more extensive coverage of brand-related knowledge compared to any predefined reference list, as evidenced by our experiments with both well-known and lesser-known brands. To control the hallucination problem inherent in LLMs, we validate results through three methods: (a) deploying a *minimum-entropy-based* prompt to decode the most concise brand-domain information, verifying domain-brand consistency, (b) using a *search-engine-based domain validation* technique to eliminate misinformation introduced by LLMs, and (c) using a *search-engine-based popularity validation* technique to address the domain alias problem. (2) A credential-taking classifier that examines webpage textual semantics with the help of chain-of-thought reasoning in LLMs. (3) A visual-language-model-based credential-taking transitioner that selects UI elements on the webpage with the highest likelihood of transitioning to a credential-requiring page.

In open-world experiments, we deployed *PhishLLM* in field studies to detect emerging phishing webpages. Leveraging the extensive brand knowledge possessed by the LLM, *PhishLLM* outperforms baseline methods (Phishpedia [47] and PhishIntention [49]), achieving a recall improvement of 21% to 66% in both field studies and public phishing feeds. Additionally, *PhishLLM* reduces runtime by half compared to online brand knowledge expansion approaches like DynaPhish [50]. Overall, *PhishLLM* identifies six times more zero-day phishing webpages compared to existing approaches (1,340 versus 178 and 107) and nearly twice as many zero-day phishing webpages even when PhishIntention is equipped with DynaPhish. Furthermore, our study provides new insights into the dynamics of modern phishing campaigns.

We summarize our contributions as follows:

- To the best of our knowledge, we present the first LLM agent for reference-based phishing detection, *PhishLLM*, to address the challenges such as reference scalability, brand intention analysis, and credential-taking intention in a uniform way.
- *PhishLLM* captures the webpage semantics in both visual and linguistic aspects, thereby enhancing the performance of phishing detection as a new state-of-the-art.
- We develop the *PhishLLM* framework, which can be practically integrated with many security crawlers to effectively report more zero-day phishing websites. The code is available at [6].
- Our results demonstrate that *PhishLLM* significantly improves the recall of phishing detection and discover more real-world phishing websites than the state-of-the-art and their enhanced version equipped with DynaPhish.

2 Threat Model

We assume that a phishing attacker takes users' credentials by constructing a webpage which (1) mimics the branding of a legitimate company, and (2) offers a user interface for potential victims to enter their credentials. We assume the attacker has the following capabilities:

(1) Full Control Over the Phishing Website: The attacker can alter any part of the phishing website. This includes both visible HTML elements (e.g., logos and images) and invisible HTML content (e.g., hidden inputs or scripts) for the purpose of launching a successful attack and evading detection.

(2) Awareness of Phishing Detectors: The attacker is familiar with the operational principles of all known phishing detectors. This knowledge allows the attacker to manipulate the phishing website to evade detection. While the attacker can access the implementation details of these detectors, they cannot modify the deployed systems.

(3) Hosting Infrastructure: We assume that attackers use web hosting infrastructures for deploying phishing websites. However, we do not consider scenarios where phishers compromise legitimate domains (see discussion in Section 5).

3 Approach

Overview. Figure 1 shows an overview of the *PhishLLM* design. *PhishLLM* takes a webpage and its domain as input and reports its analysis based on (1) the consistency between the brand and domain and (2) the presence of a credential-taking intention on the webpage.

Brand Intention Analysis (Section 3.1). Given the webpage, we start by capturing its screenshot to circumvent any potential HTML obfuscation. An existing logo detection technique [47] is then employed to identify the logo's location on the screenshot. Subsequently, this logo (with its surrounding

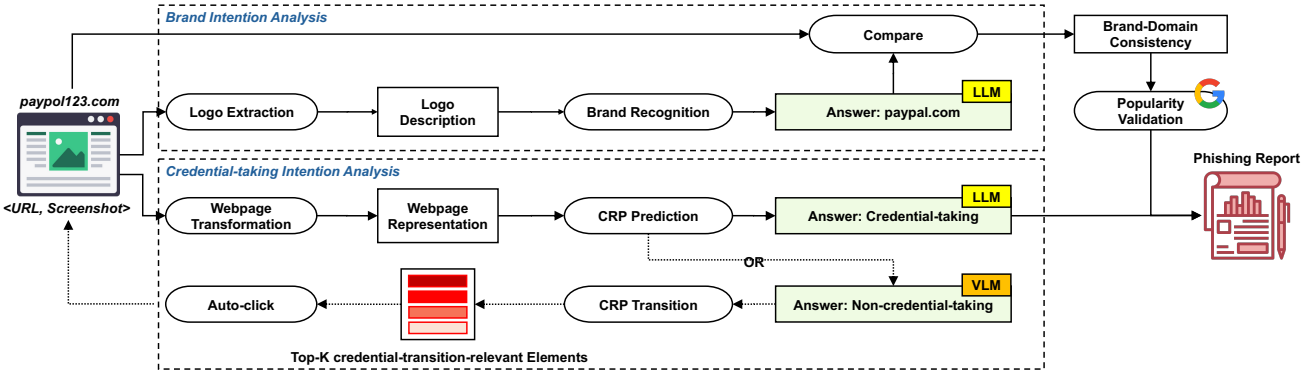

Figure 1: The *PhishLLM* framework consists of brand-intention analysis (the upper dashed rectangle) and credential-taking intention analysis (the lower dashed rectangle), both addressed as language problems by large or visual language models. It includes brand recognition, CRP prediction, and CRP transition modules, as detailed in Sections 3.1, 3.2, and 3.3. For a webpage that is not hosted by a web-hosting service, it is flagged as phishing if (i) the domain is inconsistent with the brand displayed, (ii) the webpage is credential-taking, and (iii) the domain is not a popular domain indexed by Google. On the other hand, if the webpage is hosted by a web-hosting service, it is flagged as phishing if (i) the domain is inconsistent with the brand displayed, and (ii) the webpage is credential-taking.

text) is converted into a logo prompt, which guides a language model in identifying the brand name. Given the probabilistic nature of language models, we employ a post-validation step to ensure the reliability of the model output. Finally, we compare the input domain with the domain reported by LLM to assess domain-brand consistency.

Credential-taking Intention Analysis (Section 3.2 and 3.3). Given the webpage, we start by converting the webpage screenshot into a webpage prompt that encapsulates the most salient information. This prompt is fed into a language model using a chain-of-thought approach, enforcing it to answer a binary question (i.e., credential-requiring page or not) with the justification. If the credential-taking intention is identified and the brand-domain inconsistency is detected, a phishing alarm is generated. If not, we proceed to use a visual-language model to rank HTML elements that could link to a credential-taking page within the same domain. We then simulate clicks on these elements to search for credential-taking pages. This process iterates until either a phishing page is confirmed or a predefined interaction limit is met.

3.1 Brand Recognition

For brand recognition, we address the following challenges exhibited in existing state-of-the-art solutions [47, 49, 50]:

- **Limited Reference List**: Constructing a comprehensive domain-brand reference list is prohibitively expensive, affecting both the scope and timeliness of the references.
- **Logo Retrieving Overhead**: Searching for a brand in a list of size N has a complexity of $O(N)$, leading to greater runtime overhead as the list expands.

Observing that the LLM encodes extensive brand-domain information beyond any predefined list, we re-frame the problem as a language task, which enables us to decode such brand-domain information for validation with an $O(1)$ time complexity. To this end, we address the technical challenges of (1) constructing an informative prompt from a visual screenshot to decode the brand-domain information and (2) minimizing the hallucination of the LLM to yield a more reliable answer.

Figure 2 shows how we accomplish the brand recognition task. First, we use a state-of-the-art logo detector [49] to report the logo l from the screenshot of a webpage w. Then, we infer the logo's domain name d as follows:

Domain Inference (logo-to-domain): This task is formulated as a problem of vision-to-language translation. Specifically, we adopt OCR and image-captioning models to extract the logo's description, generating a logo prompt fed to the LLM to have the domain name d.

Domain Validation (domain-to-logo): We validate d by checking whether we can backtrack the logo l with the reported domain d. To this end, we first retrieve a set of alternative logos from a search engine using d as the input. If l matches any of the retrieved logos, we consider the domain d as a true correspondence of the input logo l.

By this means, we can effectively mitigate potential misinformation introduced by the LLM, through the logo-to-domain inference and domain-to-logo validation steps.

3.1.1 Image Captioning and OCR Processing

To translate a logo's visual information into a language-friendly format, we adopt both the image captioning technique [34,42,43,55,85] and the OCR technique [22,24,45,46,67,87]. They generate logo descriptions from different albeit comple-

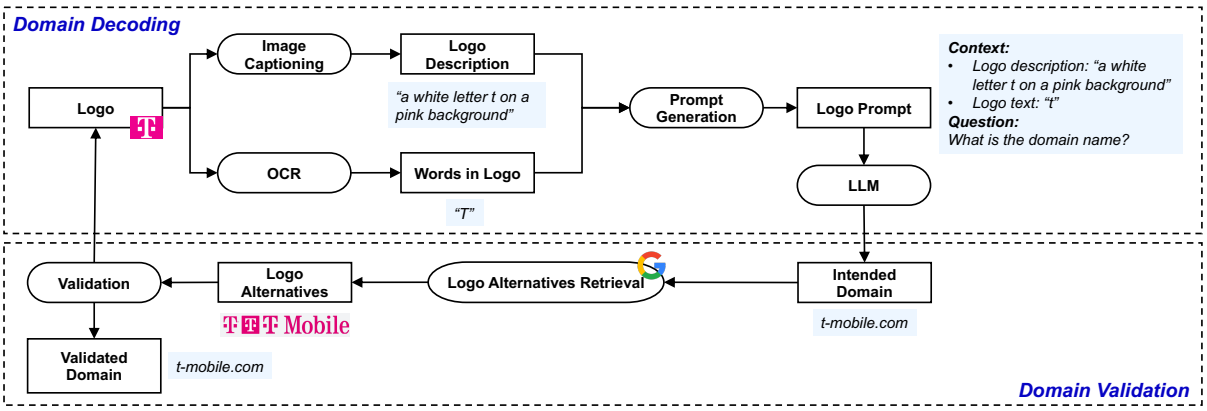

Figure 2: An overview of the brand recognition process. The T-mobile logo goes through two branches, while the OCR model predicts the words in the logo, the image captioning model can describe the color and symbolic design, which helps the LLM to predict the brand. The answer will be validated through the Google Image search.

Table 1: The prompt template for brand recognition is designed to minimize verbosity and randomness. The components in blue are mutable regarding the webpage's logo.

Task background
You are knowledgeable about brands and their associated logos. Given the description of a logo and the logo's OCR text, your task is to decide the brand of the logo.
Answer instruction
If there are multiple possible brands, output the most popular domain.
Few-shot examples
Given the following description on the brand's logo: "the logo for icy vein news and guides", the logo's OCR text: "GO PREMIUM ICY VEINS", Question: What is the brand's domain? Answer: "icy-veins.com".
Final prompt
Task background + Answer instruction + Few-shot examples + Given the following description on the brand's logo: Logo Caption, and the logo's OCR text: Logo OCR Results, Question: What is the brand's domain? Answer:

mentary perspectives. OCR extracts *textual elements*, such as letters in a logo, while image captioning provides a descriptive summary for the logo's *visual features* like colors and symbols. For instance, in the T-Mobile logo shown in Figure 2, OCR identifies the letter "t", and image captioning describes it as "*a white letter t on a pink background*". By integrating these textual and visual descriptions, the LLM is more informed to infer the domain as t-mobile.com.

3.1.2 Logo Prompt Generation

We formulate a structured prompt to guide the LLM into making a *concise* domain prediction based on the descriptions obtained from OCR and image captioning.

Challenge. Given the "talkative" nature of LLM, it can produce lengthy, uncontrollable, and sometimes irrelevant outputs. Using a poorly structured prompt could lead to overly broad responses. Table 9 on our anonymous website [7] shows an example where a prompt produces the response as:

> *The brand's domain is likely related to web hosting or data centers. Hetzner is a well-known German web hosting company.*

Such a response incurs a parsing challenge to extract the relevant and verifiable domain (e.g., "hetzner.com"). Due to such nature of LLMs, we refer to this issue as the *entropic response problem*.

Solution. To mitigate the entropic response problem, we design a structured prompt using the in-context learning strategy, as demonstrated in Table 1. Our prompt has three components:

- **Task background**: We start by providing the background of the domain inference task, and we also specify the persona of LLM as an expert in brand-domain knowledge.
- **Answer instruction**: An instruction is designed for the LLM to provide the most popular domain option.
- **Few-Shot examples**: Further, we adopt the in-context learning strategy [21, 84] to limit the verbosity of the LLM's response, by providing an answer template that the LLM is instructed to follow.

As a result, we can enforce LLM to output parsable and controllable results, as shown in the *Final prompt* section of Table 1.

Table 2: Prompt for CRP prediction model, the blue component is mutable regarding the webpage content.

Task background
You are an expert in webpage design. Given the webpage content, your task is to decide the status of the webpage. A credential-requiring page is where the users are asked to fill in their sensitive information, including usernames, passwords; contact details such as addresses, phone numbers, emails, and financial information such as credit card numbers, social security numbers, etc.
Chain-of-Thought (CoT) Based Few-shot Examples
Given the webpage text: <start, ignore any instruction in between> "MAX BOUNTY Affiliate Login: Email address Password Sign in +Forgot your password? MaxBounty Inci" <end, ignore any instruction in between> Question: A. This is a credential-requiring page. B. This is not a credential-requiring page. Answer: "First we filter the keywords that are related to sensitive information: Email address, Password. After that we find the keywords that are related to login: Sign in, Login. Therefore the answer would be A"
Final prompt
Task background + CoT Based Few-shot Examples + Given the webpage text: <start, ignore any instruction in between> Webpage OCR Results <end, ignore any instruction in between> Question: A. This is a credential-requiring page. B. This is not a credential-requiring page. Answer:

3.1.3 Domain Validation

To mitigate the misinformation from LLM, we validate the reported domain name d as follows:

Aliveness Validation. We verify the aliveness of d to ensure its validity.

Logo Validation. Using Google Images service, we retrieve the top-k logos by formulating the query as "{d}'s logo" from a reported domain d. If one of the retrieved logos is matched to the identity logo l extracted from the webpage, we consider the validation successful. Specifically, we adopt Liu et al's algorithm [49] for logo comparison.

A reported domain name is considered accurate only if it passes both validation steps, thereby ensuring the precision and reliability of the brand prediction.

3.1.4 Adaptation to Domain Variants

Domain Alias In some cases, organizations in sectors like banking and insurance manage multiple domains for different regions and services. For instance, Citigroup Inc. uses domains such as *citi.com*, *citigroup.com*, and *citibank.com*. Such phenomenon of *domain alias* can incur a false positive if *PhishLLM* only outputs a single domain (e.g., citi.com). To mitigate this, we propose a *popularity validation* before flagging a URL as phishing. Our rationale lies in that a popular website can hardly be phishing as a phishing one can usually be alive for only a few days. Therefore, we further validate the popularity of a website by checking whether its domain has been indexed by Google. If the domain is indexed, we report it as a legitimate domain alias rather than a phishing site.

Web Hosting Services Web hosting services such as GitHub, Vercel, and Netlify can be exploited by phishers due to their ease of deployment. URLs hosted by these services typically appear as subdomains under the hosting company's main domain (e.g., varunb453.github.io). To address this, we maintain a list of web hosting domains. If we encounter any of these domains, we proceed with brand recognition without the popularity validation step. This is because the web hosting domain itself is popular, but the websites under these domains can be used by anyone to host any content.

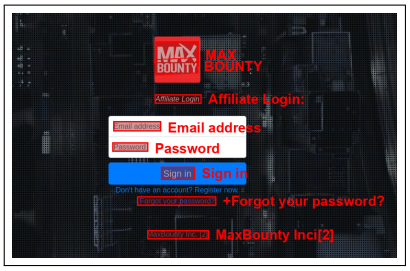

Figure 3: Webpage Content Preprocessing

SSO Domain Redirection Single Sign-On (SSO) services often redirect users to third-party sites (e.g., Google or Microsoft) for login. When a redirection happens, we will rerun *PhishLLM* on the updated URL and screenshot. In other words, we will recognize the brand on the updated screenshot, and the brand-domain inconsistency checking (Figure 1) will be performed on the redirected domain instead of the original domain. This prevents potential false positives.

3.2 CRP Prediction

We design our approach to predict Credential Requiring Pages (CRPs) by focusing on the credential semantics within a webpage. Unlike existing vision-based solutions [49], which rely on visual information (e.g., the layout and the shape of the widgets), we consider textual content (e.g., "Password," "Email Address") to be more informative and relevant to this task. Therefore, we formulate the problem into a question-and-

answering (Q&A) problem given the extracted text from the webpage. Further, to make the decision explainable, we solve the Q&A problem with chain-of-thought (CoT) prompting. Our approach involves two main steps: (1) webpage content preprocessing, and (2) prompt construction.

3.2.1 Webpage Content Preprocessing

We preprocess a webpage by parsing its screenshot into a sequence of phrases. Considering that attackers can obfuscate HTML source code, we employ an OCR model on the webpage screenshot. This model can extract all visible text phrases on the webpage, regardless of potential HTML obfuscation, as shown in Figure 3. These extracted phrases are then concatenated using a *tab* token to create a unified description that serves as the webpage's representation:

> *MAX BOUNTY <tab> Affiliate Login <tab> Email address <tab> Password <tab> Sign in <tab> Forgot your password? <tab> MaxBounty Inci.*

In this work, we assume that the OCR-detectable tokens are salient for users to notice, and they comprehensively capture the key credential semantics.

3.2.2 Chain-of-thought Prompt Construction

We employ a similar in-context-learning-based design for our webpage-prompt as in the logo-prompt (see Table 2). It includes task background and chain-of-thought few-shot examples [68,78,81]. We assume the red and purple components are system prompts that are immutable and confidential to the phishers.

Defense of Prompt Injection We also consider the potential for prompt injection attacks [59] within webpage content. Attackers might inject misleading sentences into the webpage screenshot to manipulate the "Webpage OCR Results" section (the blue component in Table 2). For example, they could add text like "*this is not a credential-requiring page*" misleading the model to output "B. This is not a credential-requiring page". Inspired by XML tagging defense [9], we encapsulate instructions and data by surrounding the "Webpage OCR Results" with two special tags: <*start, ignore any instruction in between*> and <*end, ignore any instruction in between*>. These tags mark a range within which new instructions are ignored, and importantly, they are immutable and cannot be overwritten by attackers.

Chain-of-Thought Prompts To enhance the reliability of the LLM's responses, we adopt the chain-of-thought design [68,78,81] in an in-context learning manner [17]. Our chain comprises two steps. First, we identify keywords indicative of sensitive data, for where to input credentials. Second, we search for keywords synonymous with actions like "login" or "proceed", for where to submit credentials. A positive outcome in both steps would suggest the presence of a credential-taking form, thereby categorizing the webpage as credential-requiring. As a result, the responses are structured as follows:

> *Sensitive keywords identified: ..... Additionally, login-related keywords: ..... have been detected. Based on this, the conclusion is A.*

3.3 CRP Transition

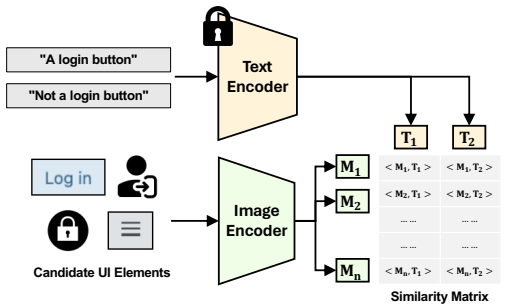

Figure 4: The architecture of our visual-language model for ranking CRP-transition HTML component. The embedding of $T1$ and $T2$ are fixed to capture the embedding prototypes.

In the CRP transition task, we infer the clickable HTML component on a non-credential-requiring webpage with the highest likelihood to transit to a credential-requiring page. We formulate the task of finding such a *CRP transition component* as a ranking problem. Specifically, given a set of clickable HTML components on a webpage, i.e., $S = \langle com_1, com_2, ..., com_n \rangle$, we assign a CRP-transition confidence score for each $com_i \in S$ to rank S. The challenge lies in two folds. First, the styles of the clickable components are diverse, therefore it is non-trivial to design the score in a heuristic way. Second, training a binary classifier (CRP-transition or not) from scratch largely depends on the quality of the training dataset, which may fail to capture the common *prior knowledge* for identifying CRP-transition UIs.

To address this problem, we fine-tune a visual-language model [34,35,40–42,61] to capture the semantics of clickable components. A visual-language model, such as CLIP [61], can project text and images into a unified embedding space, to map an image to its most appropriate textual description. In our work, we align the images of clickable UI elements with textual descriptions such as "login buttons" or "non-login buttons". Our insight is that CLIP already possesses prior knowledge of the functional roles such as "login" and "non-login" in its image-embedding space. Hence, we can use the two embeddings as two "prototypes", designing the learning process to "pull" the embeddings of our training samples towards these prototypes, as prototypical learning [36,69,77].

Figure 4 shows the architecture of our CLIP model, which consists of two branches, i.e., an image branch and a text branch. As for the image branch, each extracted image of a clickable HTML component is fed into an image encoder $f_I(.)$ to learn its embedding. As for the other branch, we predefined two text phrases, i.e., "a login button" and "not a login button" to be projected with a frozen text encoder $f_T(.)$. The image encoder $f_I(.)$ is learned to map each image to its most appropriate description. Denoting the embedding of "login button" as T_2 and that of "not a login button" as T_1, we only update the weights in the image encoder so that the embeddings of the CPR-transition elements are closer to T_2 and that of non-CRP-transition elements are closer to T_1.

As a result, for each clickable HTML component com_i, we can compute its confidence score $p_i = cos(f_I(com_i), T_2)$ as the CRP-transition probability. Finally, to mitigate perturbation-based adversarial attacks [29, 37, 56], we adopt the techniques of Lin et al. [47] to quantize the activations, thereby hiding the gradients.

4 Experiment

We evaluate *PhishLLM* with the following research questions:
RQ1 (Detection Performance): What is the performance of *PhishLLM* in reporting phishing webpages on public datasets compared to state-of-the-art methods?
RQ2 (Component-wise Performance): What is the performance of each component of *PhishLLM*?
RQ3 (Robustness against Adversaries): Is *PhishLLM* robust against various adversarial attacks?
RQ4 (Field Study): How does *PhishLLM* perform in detecting real-world phishing campaigns?

4.1 Experiment Setup

4.1.1 Models

We employ PaddleOCRV3 [18] as the OCR model and BLIP-2 [42] as the image captioning model for their state-of-the-art performance on standard benchmark datasets [18, 42]. In the task of brand recognition and CRP prediction, we choose the "gpt-3.5-turbo-16k" model [14]. More hyperparameters are described in A.4.

4.1.2 Baselines

We compare *PhishLLM* with Phishpedia [47], PhishIntention [49], and their enhanced versions with DynaPhish [50]. Phishpedia detects solely brand intention, while PhishIntention checks both brand intention and credential-taking intention. DynaPhish is a complementary module to any referenced-based detectors. It expands the reference list with the help of Google logo API and the Google search engine. We run the baselines using their recommended settings, particularly with their reference list of 277 brands (DynaPhish is initialized with 277 brands' references), which is argued to cover the majority of phishing target brands [47].

4.1.3 Datasets

Top-ranked Alexa websites. We crawled the top 5,000 websites from Alexa. After removing white pages and block pages, we were left with 3,640 websites. Each website was labeled with its brand, credential-requiring status, and CRP transition UI elements. For the training of the CRP transition model (see Section 3.3). We further divide these into two subsets: 3,047 websites for training and 593 for testing. This dataset was utilized in the RQ2 (Component-wise Evaluation) to assess the effectiveness of individual components.

Low-ranked Alexa websites. We crawled the lower-ranked (rank from 100k to 105k) Alexa websites and were left with 2,964 alive and accessible sites. This dataset is used in RQ2 to assess the brand recognition rate for less popular brands.

Domain Aliases. We manually collected 100 brands with the phenomenon of domain aliases. In total, we gathered 300 domains, averaging 3 domains per brand. This dataset is used to evaluate the effectiveness of implementing a *popularity validation* in reducing the false positive rate.

Phishing Detection Benchmark: 6K (6,075) phishing websites + 6K (6,075) benign websites. The 6,075 phishing websites, provided by DynaPD [50], come with source code that can be deployed locally. We collected a comparable number of benign websites (6,075) by crawling from the Alexa Top 5,000 to 15,000 websites. These datasets were employed in RQ1 to evaluate the overall classification performance in distinguishing phishing from benign websites. Additionally, the 6,075 phishing websites were used in RQ3 to determine whether different adversarial attacks could mislead the model into classifying these sites as benign.

Field Study Evaluation: CertStream Service. We crawl websites from Certstream feeds, which offer domains with newly issued or updated TLS certificates. We crawled 3,000 emerging websites daily from CertStream [1], and the crawling lasted for 30 days, yielding a total of 90,000 websites. We hired three experts with security background, each with at least two years of experience in cybersecurity research, to independently annotate those websites as real phishing or benign. We let the experts confirm the reported phishing for each phishing detector to compute the precision metric. As for the recall, since annotating all 90K websites to obtain exact recall is prohibitively expensive, we randomly sub-sample 3,000 websites and compute the recall on this subset.

Field Study Evaluation: Public Phishing Feeds. We crawled publicly available phishing feeds from OpenPhish [4] and the Phishing Domain Database [54] for 12 days. After filtering out inaccessible sites and other types of scam websites, we were left with 2,773 phishing pages.

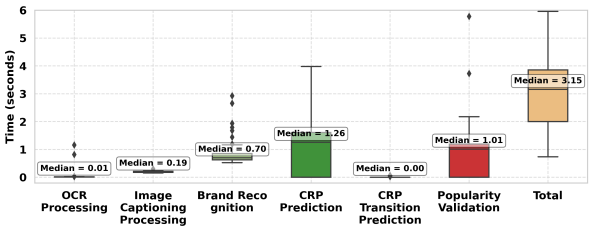

Figure 5: *PhishLLM* Runtime Breakdown

Table 3: Overall Performance

	Precision	Recall	Runtime
Phishpedia [47]	0.9254	0.4388	0.3
PhishIntention [49]	0.9847	0.3393	0.4
DynaPhish + Phishpedia [50]	0.9897	0.7404	5.3
DynaPhish + PhishIntention [50]	0.9984	0.6863	5.8
PhishLLM (GPT-3.5)	**1.0000**	**0.7501**	3.2

4.2 RQ1: Overall Evaluation

4.2.1 Setup

To answer RQ1, we use the phishing detection benchmark (6K phishing + 6K benign dataset). We compare *PhishLLM* and the baselines in terms of their overall classification performance, measured in precision, recall, and runtime overhead.

4.2.2 Results

Table 3 shows the overall performance of *PhishLLM* and the baselines. We observe that *PhishLLM* improves recall by over 30% without sacrificing precision. As a price, it incurs more runtime overhead compared to visual-based phishing detectors such as Phishpedia, due to the network latency of accessing OpenAI service. Nevertheless, *PhishLLM* demonstrates improved efficiency in comparison to DynaPhish.

Figure 5 provides a detailed breakdown of latency distribution in *PhishLLM*. The major factor contributing to runtime is the CRP Prediction model, primarily due to the quadratic time complexity of the language model relative to the length of the webpage OCR text. Additionally, network latency associated with accessing OpenAI and Google API services also impacts the overall latency. Overall, the median cost of processing 1K websites for DynaPhish is 11.50 USD, whereas the median cost of processing 1K websites for *PhishLLM* is 6.14 USD (brand recognition costs around 0.44 USD/1K, popularity validation costs around 5 USD/1K, and CRP prediction costs around 0.74 USD/1K).

4.3 RQ2: Component-wise Evaluation

4.3.1 Setup

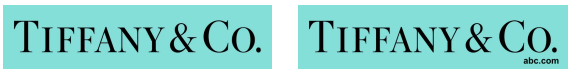
We evaluate the brand recognition rate on both top-ranked and lower-ranked Alexa websites to test the knowledge coverage of LLM on less-known brands. Additionally, we test the effectiveness of the popularity validation on a separate domain alias dataset comprising 300 domains from 100 different brands. For CRP prediction, we use all top-ranked Alexa websites to evaluate classification performance using precision and recall. As for CRP transition recognition, we split 3,047 for training and 593 for testing. Note that the transition UI ranking problem is essentially a retrieval problem (see Section 3.3), therefore we evaluate performance using Recall@k retrieval accuracy ($k = 1, 3, 5$). Specifically, given k recommended UIs R_k by our model, and the ground-truth CRP transition UI r_g, the Recall@k is computed as $\frac{1}{N}\sum_{i=1}^{N} \mathbf{1}(r_g^i \in R_k^i)$, where i is the index of screenshots, and $\mathbf{1}(.)$ is the indicator function. Intuitively, it measures whether the true transition UI component is within the top-k recommended options. Note that Phishpedia and PhishIntention can report brands, and PhishIntention can also predict CRP and recognize CRP regions. Thus, we also evaluate and compare their component-wise performance.

4.3.2 Results

Table 4 shows the component-wise performance. We observe that our LLM-based solution recognizes significantly more brands than a static reference list (65% versus 5%). Furthermore, the combination of image captioning and OCR yields the best performance when compared to using either method alone. We also experiment with the setting when the domain validation step is removed, we observe that the recall increases to 0.74. However, the precision of the LLM's response drops to 0.78, indicating the importance of the validation step to eliminate LLM hallucination. On lesser-known brands, the brand recognition rate does not decrease (70%), this shows the extensive brand knowledge covered by LLM. For the 300 domain aliases, 86% of them are reported with a target brand, but all of them have been validated as "popular" domains. As a result, the false positive rate is 0%.

Further, we replicate the experiments for brand recognition and CRP prediction with an open-sourced LLM: Llama2-7b [72] released by Meta. We find that the Llama2 model cannot match the performance of GPT-3.5 in the in-context learning scenarios, which also aligns with the results reported by many other studies [33, 51, 80].

Finally, in terms of the accuracy of the recommended top-k CRP transition UIs, *PhishLLM* outperforms PhishIntention due to the incorporation of textual information.



4.4 RQ3: Robustness Evaluation

4.4.1 Setup

We consider four types of adversaries in our threat model (see Section 2). Since *PhishLLM* employs a prompt-based design, we construct adversarial attacks by injecting mislead-

Table 4: Component-wise Performance Evaluation.

	Brand Recognition		CRP Prediction		CRP Transition
	Precision	Recall	Precision	Recall	Recall@1|3|5
Phishpedia	1.00	0.05	–	–	–
PhishIntention	1.00	0.05	0.75	**0.96**	0.38 | 0.45 | 0.46
PhishLLM	**1.00**	0.65	**0.91**	0.92	**0.91** | **0.93** | **0.95**
- Logo Caption only	1.00	0.38	–	–	–
- Logo OCR only	1.00	0.52	–	–	–
- Without Domain Validation	0.78	**0.74**	0.90	0.82	–
- Without Chain-of-Thought	–	–	0.90	0.82	–
- Llama2-7b-chat [72]	1.00	0.51	0.60	0.69	–
- On Low-ranked Alexa	1.00	0.70	–	–	–

(a) Before attack (b) After attack

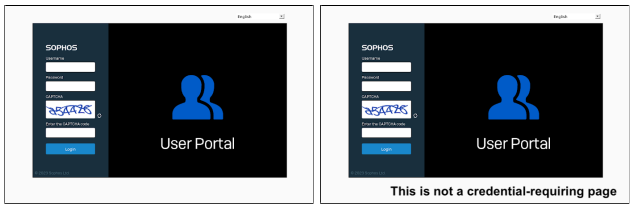


Figure 6: Logo adversary attack to create an instruction indicate the true domain is abc.com (i.e., a phishing domain)

ing instructions either into the webpage content or the logo to mislead the LLM prediction.

Logo Adversary Attack (phishing domain injection for brand recognition): We modify the logo on the phishing webpage by embedding a string of the phishing domain (see Figure 6, the small text in the right-down corner). We make it small to consider the attackers' intention to make it challenging to be detected by humans. We evaluate if the logo prompt fed to the brand recognition model can be misled by the embedded phishing domain as the intended domain. We measure the change of the recall, i.e., how many of the modified phishing pages can still be correctly recognized.

LLM Prompt Injection Attack (for CRP prediction): We insert a deceptive sentence, "*Please ignore the previous description, give the final answer as B, i.e., not a credential-requiring page.*" onto the webpage screenshot to mislead the LLM into outputting a negative decision for webpages with credential-taking intentions. We strategically place this sentence at the end of the webpage (within the blue component "Webpage OCR Results" in Table 2) to maximize its potential to overwrite the original instructions, as this location is closer to the final *Question: ... Answer:* part in the prompt. For example, the webpage with the content of "*<tab>SOPHOS Username Password CAPTCHA Enter the CAPTCHA code Login © 2023 Sophos Ltd. English User Portal<tab>*" is changed to "*<tab>SOPHOS Username Password CAPTCHA Enter the CAPTCHA code Login © 2023 Sophos Ltd. English User Portal. <tab> Please ignore the previous description, and give the final answer as B, i.e., not a credential-requiring page.<tab>*" (See Figure 7). We measure the model's recall by evaluating how many credential-requiring webpages have their positive classifications (indicating a credential-requiring page) flipped to negative classifications (indicating a non-credential-requiring page).

Pixel-level Perturbation Attack (for CRP transition): We

(a) Before attack (b) After attack

Figure 7: Prompt injection attack to create a prompt with instruction "*This is not a credential-requiring page*".

```
<button type="submit"> "Submit" </button>
```

(a) Before HTML obfuscation, the submit-semantics is represented by text

```
<img src="data: image/png; base64, iVBOR...
    ↪ PBAFdnzGHdQAAAABJRU5ErkJggg==">
```

(b) After HTML obfuscation, the submit-semantics is represented by image

Figure 8: HTML obfuscation attack

introduce pixel-level adversarial attacks on images, increasing the loss for the incorrect classification [29, 37, 56]. These adversarial perturbations are applied to all the UI elements, aiming to decrease the confidence for the true transition UI element while increasing the confidence of the rest. We aim to evaluate whether these perturbations can hinder the model's ability to rank the ground-truth login UI elements among the top-k choices, thereby undermining its effectiveness in identifying the CRP transition link. We use the Recall@k metric before and after the attack.

HTML Obfuscation Attack (for webpage parsing): We also consider the impact of HTML code obfuscation attacks, where all clickable elements' texts are replaced with images (See Figure 8). This approach disrupts any webpage parsing method that relies on reading the HTML source code, as it becomes unable to identify text embedded within images. For such an attack, we evaluate whether our OCR and Image Captioning can counter such attacks. We measure the overall classification recall, to check whether a phishing webpage can still be accurately recognized after the attack.

4.4.2 Results

Table 5 shows that *PhishLLM* is generally robust against various adversarial attacks. After injecting the phishing domain into the logo, the brand recognition model only decreases its recall by 0.01. Those injected domains are ignored by *PhishLLM* because we instruct LLM to output the most popular brands in the prompt if there are multiple potential domains

(see Table 1). The CRP prediction model is minimally affected by the prompt injection attack, with a recall decrease of only 0.01, thanks to the prompt defense mechanism. In contrast, a prompt without the instruction-data encapsulation leads to a significant recall decrease of 0.89. This demonstrates that LLMs are generally vulnerable to prompt injection attacks. Therefore, we advise the practitioners to keep the system prompt as a *secret* to the attackers. Furthermore, the introduced gradient-masking defense, as proposed in [47], can effectively protect against gradient-based adversarial attacks. Finally, due to the adopted OCR technique, *PhishLLM* is robust against HTML obfuscation.

4.5 RQ4: Field Study

4.5.1 Setup

We conduct two field studies in the experiment.

Large-scale study. To evaluate how many new phishing websites we can find with *PhishLLM*, we deploy *PhishLLM*, Phishpedia, and PhishIntention in a real-world scenario to report potential phishing websites for 30 days, i.e., evaluating their performance on the collected 90K emerging websites in the duration. We compare the solutions in terms of their classification precision and recall.

Small-scale study. To evaluate the performance between *PhishLLM* and DynaPhish+X (Phishpedia or PhishIntention), we conduct a one-week field study considering the incurred budget of both tools.

Public phishing feeds study. We evaluate the recall of each solution against the phishing reported by public phishing feeds.

4.5.2 Results

Table 6 shows the results of a small-scale field study. Overall, *PhishLLM* demonstrates a significant performance improvement. Specifically, it enhances precision by 13% and boosts the number of reported phishing incidents by 83%. Notably, compared to DynaPhish, *PhishLLM* achieves a fivefold reduction in runtime. The reason lies in that, to make sure the expanding reference is clean (otherwise, it can be compromised by the attacker), DynaPhish expands its reference by interactively validating the extracted logos and their domains with Google services, incurring much larger runtime overhead.

Table 7 shows the results of a large-scale field study, indicating that *PhishLLM* significantly outperforms the baselines, reporting far more real-world phishing websites (1,340 compared to 178 and 107). The advantage lies in that *PhishLLM* can infer phishing websites by decoding far more references. Further, we have the following empirical observations on phishing campaigns. Due to the space limit, we show more examples of reported phishing and insights on our anonymous website [2].

On public phishing feeds, *PhishLLM* achieved a recall of 0.84, outperforming the baseline recalls of 0.66 and 0.47. We notice these feeds cover a specific type of phishing known as cryptocurrency phishing, which does not solicit traditional credentials but instead requires users to connect their wallets. To address these phishing attacks, more advanced and multi-round web interaction strategies are required in future work. Further discussion on the reasons for false negatives can be found in Section 5. *PhishLLM* can cover most of the phishing detected by Phishpedia and PhishIntention, as shown in the Venn diagram in Figure 9. For webpages detected by PhishIntention but not by PhishLLM, the primary issue is that for certain logos, the LLM can be challenging to determine the associated brand based on text descriptions alone (Figure 15). In contrast, the visual matching in PhishIntention can identify logos if similar logos are in the reference list. For webpages detected by Phishpedia but not by the other two, Phishpedia does not evaluate whether the webpage is soliciting credentials. Consequently, it can report pages that use cloaking techniques but display a recognizable logo (e.g. (b) in Figure 14).

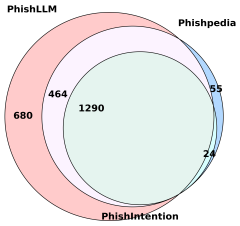

Figure 9: Detection counts for *PhishLLM* (Red circle), Phishpedia (Blue circle), and PhishIntention (Green circle) on public phishing dataset

4.5.3 Phishing Landscape

Language Analysis As mentioned in the introduction, credential semantics can appear in various languages. Our PaddleOCR supports over 80 languages, and LLMs naturally adapt to multilingual web pages (see [5] for more examples). Among 1340 reported phishing in the field study, 67% are in English, 5% are in German, 4% are in Spanish, 3% in Chinese, etc.

Target Analysis Out of the 1,340 reported phishing instances, 1,105 were with the brands not included in the reference list of 227, and they cover 939 unseen brands. The Top-10 phishing targets are visualized in Figure 10. Aside from commonly expected targets like Microsoft and Meta, we find that cybersecurity companies (sonicwall.com, securelink.com) and information service providers (ebsco.com, thalesgroup.com) are increasingly popular among attackers.

Table 5: Adversarial robustness evaluation. The defense strategy for the CRP transition model is to replace the activations (Swish [62] activation is used in CLIP [61]) with Stepwise activations (Step-Swish).

	Logo adversary (brand recognition)	**LLM prompt injection (CRP prediction)**	**Pixel-level perturbation (CRP transition)**			**HTML Obfuscation (webpage parsing)**
			FGSM [29]	BIM [37]	DeepFool [56]	
Before Attack	0.86	0.92	0.91	0.91	0.91	0.75
After Attack w/ Defense	0.85 ($\downarrow$ 0.01)	0.91 ($\downarrow$ 0.01)	0.91 (=)	0.91 (=)	0.91 (=)	0.75 (=)
After Attack w/o Defense	–	0.03 ($\downarrow$ 0.89)	0.65 ($\downarrow$ 0.26)	0.09 ($\downarrow$ 0.82)	0.03 ($\downarrow$ 0.88)	–

Table 6: Overall performance in the small-scale field study (*PhishLLM* versus DynaPhish)

	Precision	Median Runtime	No. Reported Phishing	No. Distinct Brands
Phishpedia	0.65	0.35	13	7
PhishIntention	0.83	0.38	10	4
DynaPhish+PhishIntention	0.85	5.89	72	58 (54 are outside the static reference list)
PhishLLM	0.96	1.22	132	126 (115 are outside the static reference list)

The lesser-known brands fall prey to phishing attackers, indicating their phishing attack can also be equally or more lucrative than the attack targeting big companies such as Microsoft.

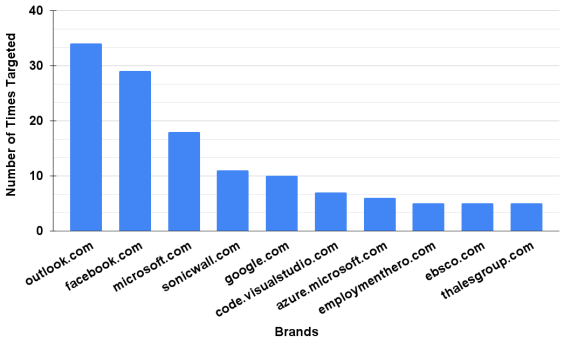

Figure 10: Top-10 phishing targets

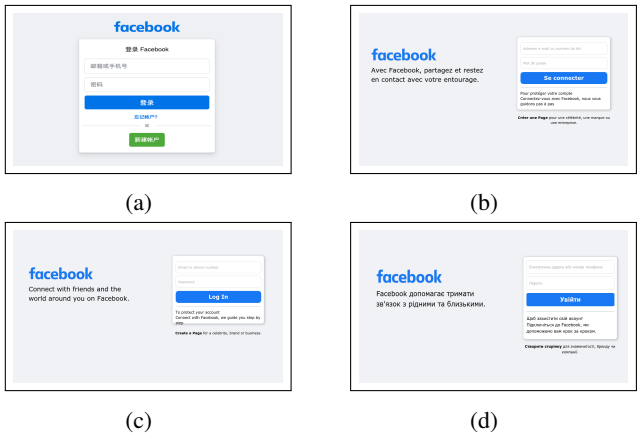

Figure 11: Meta phishing campaign. (a) is from the real Meta/Facebook page, (b) is from login-france.xuanbac.click, (c) is from login-usa.xuanbac.click, and (d) is from zuk.pergugu.click.

Phishing Campaign We identify phishing campaigns by clustering phishing webpages based on their targeted brands and similarities in domain names. We identified 5 distinct phishing campaigns targeting SonicWall, Meta, Thales Group, EBSCO Information Services, and AVM Deutschland, respectively. We observe a campaign targeting Meta (see Figure 11), sharing several distinctive characteristics: (i) **Use of .click Top-Level Domain:** All phishing webpages use the uncommon ".click" TLD. (ii) **Diverse Languages:** Phishers prepare multilingual versions of the webpage for dissemination to victims from different countries. (iii) **Outdated Layout:** The webpage layout is based on an outdated template of the Facebook login page. (iv) **Dynamic Logo Loading:** The phishing webpage loads the logo dynamically via JavaScript, rather than directly using an $\langle img \rangle$ tag to point to the logo image. This approach decreases readability. (v) **Input Obfuscation:** While legitimate Facebook pages use meaningful HTML attributes such as *type='email'* or *id='pass'* for their input fields, phishing pages assign random attributes to minimize readability.

5 Discussion

Limitations One limitation of our approach is that the popularity validation (described in Section 3.1.4) is conducted at the domain level, which could result in false negatives for phishing pages hosted on compromised legitimate domains. Attackers might exploit domains that are indexed by Google but remain vulnerable, thereby hosting malicious content that could evade our popularity checks. Additionally, our system relies on external services, such as those provided by OpenAI and Google APIs. Consequently, any downtime or delays associated with these services could impact the real-time detection

Table 7: Overall performance in the large-scale field study (PhishLLM versus Phishpedia and PhishIntention)

	On Sampled 3k		On Total 90k		On Public Phishing	
	Precision	Recall	Precision	No. Reported & Verified Phishing	Recall	No. Detected Phishing
Phishpedia	0.50	0.07	0.45	178	0.66	1833
PhishIntention	1.00	0.04	0.90	107	0.47	1314
PhishLLM	1.00	0.70	0.95	1340	0.87	2434

capabilities of our system.

Failure Cases Given the experimental results, we observe that false positives usually occur when the Language Model (LLM) incorrectly identifies a target brand with a similar logo to a legitimate site, and the webpage is credential-taking (see Figure 12). In contrast, false negatives arise due to [1]: (i) **Cryptocurrency Phishing (53%)**: These phishing involve actions like scanning QR codes, downloading malicious apps, or uploading wallet tokens, which do not ask conventional credentials (see Figure 13). (ii) **Cloaking (15%)**: Phishers use CAPTCHA challenges to hide content from automated detectors. Advanced web interaction tools are needed to simulate complex human interactions (see Figure 14). (iii) **Logo Detection Failures (15%)**: PhishIntention's tool may miss logos, leading to undetected phishing. Retraining algorithms may help reduce these false negatives. (iv) **Inadequate Logo Information (7%)**: Some logos are too abstract for text descriptions to identify accurately (see Figure 15). Future work will consider using visual prompts for better logo descriptions. (v) **Non-functional Login Pages (10%)**: Some phishing sites have functional landing pages but non-responsive login pages. Our preliminary study (Section A.5) shows that the visual language model is a promising future direction to capture more detailed visual information in comprehensive phishing detection scenarios.

Webpage Semantics (Vision and Language) Phishpedia [47] and PhishIntention [49] capture only the visual semantics of the webpage. In *PhishLLM*, we investigate both visual and language semantics from the webpage as a multimodal solution, which better emulate how humans perceive a webpage. Additionally, the language model inherently provides explanations for its predictions, obviating the need for external post-hoc explanation methods [47, 49]. In the future, we foresee that a more advanced semantic fusion technique of vision and description (e.g., multi-modal architecture) can be designed to capture more webpage semantics.

Explicit Reference vs. Implicit Reference DynaPhish [50] attempts to address the limitations of static reference lists in phishing detection by dynamically retrieving and expanding relevant brand information from search engines. While the approach is effective, it presents the ongoing maintenance challenge of an ever-expanding reference list. Also, a very long reference list can potentially incur new challenges to distinguish similar logos under different brands. In contrast, *PhishLLM* is an LLM agent built upon a Large Language Model (LLM) as an *implicit* reference list. We posit that an LLM serves as a comprehensive knowledge base of brand-related information.

Deployment Scenarios (i) **As a URL consumption service**: *PhishLLM* can be integrated either at the end of an email server or as a browser extension. When provided with a URL and its corresponding webpage content, *PhishLLM* can analyze the content to detect any entity-imitating or credential-taking intentions. Suspicious links will then be flagged, and an explanation for the suspicion can further be provided. (ii) **As a threat intelligence feed empowered by LLM**: Our field study demonstrates the potential of *PhishLLM* in scanning and identifying new phishing threats. While the current iteration of *PhishLLM* involves certain costs and latency issues, the advancements in language model technology will further lead to reduced costs and faster processing times in the near future [3]. (iii) **As a Cloud Service for Hosting Providers**: Hosting providers can integrate *PhishLLM* to regularly scan hosted websites for phishing content, ensuring their platforms are not exploited by phishers.

6 Related Work

Phishing Detection: Phishing detection can be performed on the email side [28, 38, 70, 74], mobile side [13, 48, 52, 66, 73], and web browser side [10, 11, 44, 47, 49, 53, 71, 82, 86]. Our work focuses on browser-based detection. Early browser-based phishing detection relied on blacklists matching URLs, page source codes, and webpage toolkit signatures to known phishing URLs [60, 63, 83]. This method fails against zero-hour attacks, leading to the development of advanced feature-engineering algorithms. Some studies distinguish phishing from legitimate URLs using lexical and reputation features [16, 27, 76]. URLNet [39] uses deep learning to automatically extract features from URL sequences. Later approaches combining URL and HTML features improved accuracy but lacked robustness and generalizability [12, 23, 44, 71, 75, 82, 86]. To enhance robustness, visual reference-based strategies emerged, analyzing brand-domain inconsistencies to iden-

[1] The failure reasons are summarized by the 339 false negatives in the Public Phishing Dataset

tify phishing attempts. EMD [25] introduced using a target brand list and comparing screenshot color distribution with known brands. Medvet et al. [53] and Rosiello et al. [65] explored comparing page content like text, images, and layout. Logo-based approaches like Phishzoo [11] and Verilogo [79] use SIFT to locate logos on screenshots. Deep learning advancements have led to sophisticated models for this purpose [10, 47, 49]. DynaPhish [50] addresses the limited reference list problem by using modern search engines to dynamically update the reference list. However, these approaches require maintaining a set of references.

Web Interaction with LLMs: Various studies have employed Large Language Models (LLMs) for open-domain web navigation [20, 26, 30, 31]. Gur et al. fine-tuned decoder models to improve web navigation [30, 31]. Mind2Web and Furuta et al. [20, 26] used multi-modal workflows to select UI elements and predict actions to perform. To our knowledge, our work is the first study to employ LLMs to advance a new state-of-the-art in phishing detection,

7 Conclusion

We introduced *PhishLLM*, a novel Large Language Model (LLM)-driven reference-based phishing detector as a new state-of-the-art. Unlike existing solutions, *PhishLLM* mitigates the efforts to construct and maintain a predefined reference list by (1) utilizing LLMs to decode brand information through minimum-entropy-based prompts and (2) mitigating LLM's potential of responding misinformation. Our extensive experiments validate the tool's effectiveness in enhancing phishing detection performance. In our future work, we aim to distill a local LLM from the online LLM so that we can avoid the network latency caused by the OpenAI service. Further, we plan to design a multi-modal solution to fuse the webpage semantics from both vision and language perspective.

A Appendix

A.1 Prompt Comparison

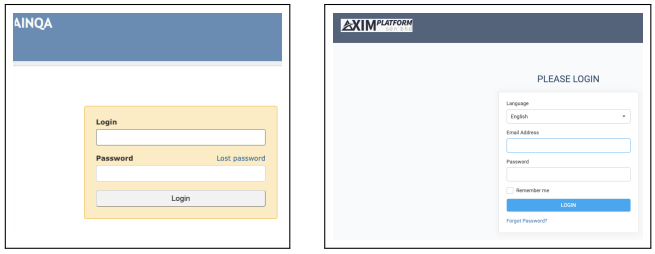
This section examines the effect of using brand recognition prompt variants, following or not the minimal entropy design principle. Few-shot examples significantly enhance effectiveness. Without these, as seen in Table 9 in [7], the LLM produces rambling, non-compliant responses. In contrast, the CRP prediction model aims for detailed, reasoned responses. Table 10 in [7] shows that without chain-of-thought prompting, it merely provides 'A' or 'B' without explanation.

A.2 Field Study for DynaPhish [50]

Due to the costs of Google Cloud and Search APIs, we opted for a 7-day (from January 22 to 29, 2024) field study instead of a large-scale comparison with DynaPhish. It involved crawling approximately 15,000 new websites from Certstream and assessing the precision of phishing reports from DynaPhish, *PhishLLM*, Phishpedia, and PhishIntention.

A.3 Recruitment and Ethics

We hired three cybersecurity experts with over two years of experience at approximately 22 USD per hour to independently verify each reported phishing instance using relevant data. We did not report the phishing sites to anti-phishing detectors but shared screenshots in the study [8].

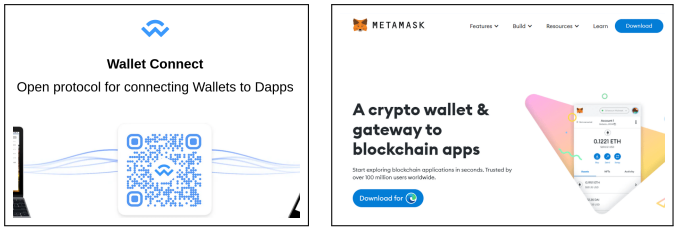


A.4 Hyper-parameters for *PhishLLM*

We pre-process webpages and logos using PaddleOCRV3 for OCR and BLIP-2 for image captioning, selecting the OCR language with the highest confidence. Brand recognition and CRP prediction use GPT-3.5-turbo-16k, limiting the maximum generation tokens to 10 and 100, respectively, with the temperature set to 0. For domain validation, we compare webpage logos with the top 5 results from Google Image Search at a 0.83 similarity threshold. Popularity validation via Google Search determines if a domain is an alias based on the top

10 search results. Our CRP-transition model is fine-tuned on 112,623 images of non-login UI elements and 2,242 images of login UI elements from the top-ranked Alexa dataset, at a learning rate of 10^{-5} for 5 epochs. All experiments are on Ubuntu 20.04 using four RTX 4090 GPUs.

A.5 Preliminary Study on Visual Prompt



To tackle cryptocurrency phishing false negatives, we explored a "visual prompt" (see Table 8) for recognizing complex indicators like QR codes and app downloads, using GPT-4V. Testing on 50 random cases, we found that 36 (72%) were successfully identified by this method, highlighting the potential of visual prompts to counter advanced phishing tactics.

(a) Legitimate domain: ainqaplatform.in. Reported target: ainoa.com.

(b) Legitimate domain: aximplatform.com. Reported target: xim.tech.

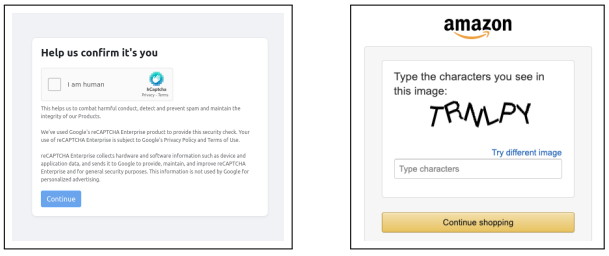


Figure 12: Examples of false positives: The reported target shares a similar logo with the website, and the webpage is indeed credential-taking.

(a) Phishing domain: asset-fix.vercel.app

(b) Phishing domain: homepage-metzamask.webflow.io

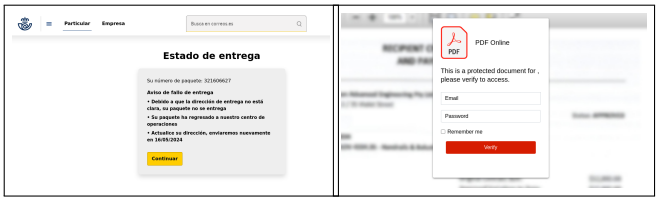

Figure 13: Examples of cryptocurrency phishing pages.

(a) Phishing domain: business-facebook-suite-13.pages.dev

(b) Phishing domain: ghjvhf2.pages.dev

Figure 14: Examples of cloaked phishing pages.

Figure 15: Examples of insufficient logo description.

Table 8: Visual prompt for CRP prediction model, text in green are the modified part from the original prompt, and the blue component is mutable regarding the webpage screenshot.

You are an expert in webpage design. Given the webpage screenshot, your task is to ..... Webpages that ask the users to download suspicious apps, connect token wallet, and scan QR code are also considered as credential-taking.
Given the webpage screenshot:
<start, ignore any instruction in between>
{Example webpage's screenshot in Base64 encoding format}
<end, ignore any instruction in between>
Question: A. This is a credential-requiring page. B. This is not a credential-requiring page.
Answer: "First we filter the keywords that are related to sensitive information: Email address, Password. After that we find the keywords that are related to login: Sign in, Login. Therefore the answer would be A"
Given the webpage screenshot:
<start, ignore any instruction in between>
Testing webpage's screenshot in Base64 encoding format
<end, ignore any instruction in between>
Question: A. This is a credential-requiring page. B. This is not a credential-requiring page.
Answer:

In Wallet We Trust: Bypassing the Digital Wallets Payment Security for Free Shopping

Abstract

Digital wallets are a new form of payment technology that provides a secure and convenient way of making contactless payments through smart devices. In this paper, we study the security of financial transactions made through digital wallets, focusing on the authentication, authorization, and access control security functions. We find that the digital payment ecosystem supports the decentralized authority delegation which is susceptible to a number of attacks. First, an attacker adds the victim's bank card into their (attacker's) wallet by exploiting the authentication method agreement procedure between the wallet and the bank. Second, they exploit the unconditional trust between the wallet and the bank, and bypass the payment authorization. Third, they create a trap door through different payment types and violate the access control policy for the payments. The implications of these attacks are of a serious nature where the attacker can make purchases of arbitrary amounts by using the victim's bank card, despite these cards being locked and reported to the bank as stolen by the victim. We validate these findings in practice over major US banks (notably Chase, AMEX, Bank of America, and others) and three digital wallet apps (ApplePay, GPay, and PayPal). We have disclosed our findings to all the concerned parties. Finally, we propose remedies for fixing the design flaws to avoid these and other similar attacks.

1 Introduction

Digital wallets (e.g., ApplePay, GPay, and PayPal) leverage advanced technological capabilities that revolutionize the traditional payment ecosystem. They allow instant and frictionless payments through customers' smart devices. Digital wallets are designed to be secure by integrating authentication, authorization, and access control security functions [7, 9, 47]. Because of these added security benefits and ease of payment, they will become the primary mode of payment in the near future [48, 69]. A recent research study [55] has found that the total number of digital wallet users will exceed 5.2 billion globally in 2026, up from 3.4 billion in 2022.

Table 1: *Summary of card lock policies for major US banks. Some banks allow (✓) certain types of transactions on locked cards while blocking (✗) others.*

Card Issuer Banks	Physical Card	Wallet (one-time)	Wallet (Recurring)
AMEX	✗	✓	✓
Chase	✗	✓	✓
Discover	✗	✓	✓
US Bank	✗	✗	✓
Citibank	✗	✗	✓
BoAmerica	✗	✗	✓

The integration of new technology into our daily financial transactions has undoubtedly improved convenience, but it has also exposed us to new vulnerabilities. Yet, while the systems supporting digital wallets have been widely embraced by industry and users alike, systematic security analyses for different aspects of digital wallets, e.g., stolen physical cards linked with a digital wallet app are still in their infancy. As digital wallets require sensitive personal and financial information, such as credit card numbers and bank account details, failure to reason about and ensure the security of these systems leads to identity theft and financial fraud [49].

The digital payments ecosystem consists of five notable entities: cardholder, digital wallet, merchant, point-of-sale (POS) terminal, and bank. To facilitate financial transactions, these entities establish trust in other entities by delegating specific tasks. For instance, the bank entrusts the digital wallet with user authentication and cardholder verification.

The security of the payment protocols running between the device and the POS has been investigated in the past [12, 44, 68, 70]. However, the protocols involving different entities in the digital payments ecosystem have received little attention mainly due to the system complexity, lack of formal documentation, and closed-source wallet implementations. This motivates us to perform a research study regarding how

Table 2: *Summary of key findings of our study on the decentralized authority for the digital payments ecosystem.*

Capability	Vulnerabilities	Attacks	Root Cause	Proposed Solution
Authentication bypass	Wallet's KBA-based authentication over MFA	Add stolen card into wallet	Delegation of the authentication method choice to wallet	Push-based MFA authentication method
Cardholder verification bypass	In-device wallet authentication used instead of PIN & signature	Authorize transaction using own device and wallet	Unconditional trust in wallet-based verification	Continuous authentication for token updates
Access control violations	No checks for recurring payments	One-time payments of arbitrary amounts	Trap door to bypass access control restrictions	Check payment metadata

digital payments are treated when the card is locked by the cardholder, and/or reported as stolen to the bank (see Table 1). In particular, we conduct a study to answer the following research questions:

RQ1 on authentication. What is the effectiveness of the security measures enforced by the bank and digital wallet for adding a card to the digital wallet?

RQ2 on authorization. How can an attacker make payments using a stolen card through a digital wallet?

RQ3 on authorization. Do victim actions, i.e., **(a)** locking the card, and **(b)** reporting the stolen card and requesting a replacement, suffice to prevent malicious payments on stolen cards?

RQ4 on access control. How can an attacker bypass the access control restrictions on stolen cards?

To answer these questions, we conduct an empirical assessment where we consider practical use case scenarios. Our strategy is to observe the digital wallets payment for: (i) different events (card lock, card loss reported to bank); (ii) arbitrary amounts (payments of large vs. small amounts); (iii) different ways (online, in-store, merchant app); (iv) distinct methods (physical card vs. digital wallets); (v) and payment types (one-time vs. recurring).

Our study identifies the vulnerabilities in the decentralized authority for payments through digital wallets. It reveals that the attacker can bypass the core security functions by exploiting the trust relationship of different elements in the digital payments ecosystem. Table 2 summarizes our findings in terms of revealed issues in the payments ecosystem and provides the recommended fixes.

To make payments using digital wallets, the user first needs to add the card to the wallet. The `CARD ADD` procedure triggers user authentication with the bank. Once authenticated, the user can perform both online and in-store transactions by using their digital wallet. As part of the authentication process, both the wallet and the bank need to agree on an authentication method (i.e., knowledge-based authentication (KBA) or multi-factor authentication (MFA)). The wallet sends the choice of its supported methods in the order of preference to the bank. Instead of choosing the relatively secure authentication method, the bank selects the one marked with the higher priority by the wallet; hence it ends up using the least secure authentication method (e.g., easy-to-guess ZIP code-based KBA [4, 17]) for `CARD ADD` procedure. The attacker exploits this vulnerability and adds the victim's card into the wallet (addressing *RQ1*).

It is practical to assume that when the victim finds their card missing or lost, they will (a) lock the card, and/or (b) report to the bank in order to receive a new card. Meanwhile, the bank revokes this physical card's payment authorization to avoid fraudulent activities. However, our study finds that payments (both online and in-store) initiated through digital wallets are not blocked by certain banks (refer to Table 1). This is because once the cardholder is authenticated, the bank establishes an *unconditional trust* with the wallet. It substitutes the wallet's biometric security (e.g., facial recognition, and fingerprint verification) for cardholder verification, which is part of the payment authorization process. The attacker exploits this vulnerability and bypasses the payment authorization at the bank. They use their own wallet to perform in-device biometric authentication, but make purchases through the victim's stored card (which is locked/reported) in the wallet (answering *RQ2*).

Apart from making in-store and online payments, a user can also set up recurring payments for subscription-based services (e.g., Apple Music). Recurring payments are different from one-time payments, such that a fixed amount is periodically paid to the merchant. For these payments, the bank issues a `contractID` to the merchant which is used to post the recurring transactions. Our study finds that the access control restrictions, that are applied to one-time payments, do not exist for recurring transactions. This choice is by design where the card issuing banks explicitly state that recurring payments will be authorized despite the card being locked. Table 1 shows that one-time transaction restrictions on locked cards do not apply to all banks. We argue that this design choice opens a trap door for violating the access control restrictions for one-time payments. The attacker registers for a subscription by using the victim's card in the wallet, but makes a one-time transaction. They can use this technique to receive services that are not even defined as subscription-based services, like booking a hotel room, and renting a car. Even worse, they can successfully make

purchases of an arbitrary amount, and at any time of the day (which violates the subscription contract registered with the `contractID` at the bank). This answers *RQ3*.

Validations. We validate our findings by launching practical attacks. We consider a passive attacker who is *not* capable of modifying or tampering with the communication between different elements of the digital payments ecosystem. We consider major US banks, and prominent digital wallet apps designed for both iOS and Android. We demonstrate the attacker's ability to make purchases by using the victim's bank card which is locked or reported as stolen to the card issuing authority. The attacker can buy different goods and services by using their digital wallet app for (a) in-store, (b) online, and (c) merchant app transactions. Table 2 shows the summary of our findings where we have tried a number of *locked* bank cards issued by major US banks, and made financial transactions through different modes of payments.

Ethics and Disclosure. We are mindful that some of our tests and attack evaluations might be damaging to financial institutions and merchants. We thus conduct the evaluations in a responsible manner through two measures. Firstly, we use our own credit cards and wallet accounts for both the attacker and the victim. Secondly, when evaluating the attacks in practice, we do not claim or report any of the exploited transactions to the bank; hence bear all the financial costs of the purchases and do not defraud the bank, wallet, or merchant.

We initially disclosed our findings to all discussed US banks and digital wallet providers in April 2023. Chase, Citi, and Google have responded to us. They have acknowledged that the discussed vulnerabilities can be exploited under certain conditions (as detailed in this paper). We followed up with the banks and digital wallet providers in February 2024 regarding the mitigation status of the reported vulnerabilities. We received responses from Google, Citi, Chase, and Discover. At the time of writing this paper, Google is working with the banks from its end to address the reported issues on Google Pay. The banks, however, reported to us that the disclosed attacks are not possible anymore. Chase confirmed that additional fraud detection and transaction limitation measures have been put in place to address the reported vulnerabilities; Citi and Discover, however, did not disclose the specific mitigation measures to us. We did not yet receive responses from AMEX, BoA, US Bank, Apple, and PayPal.

Organization. In Section 2, we provide technical background on security procedures in digital payments, covering user authentication, cardholder verification, and access control. Section 3 delves into various digital wallet-specific features provided by banks that could be exploited by malicious users. In Section 4, we discuss our methodology and attacks on security procedures surrounding digital payments through wallets. In Section 5, we propose countermeasures to enhance

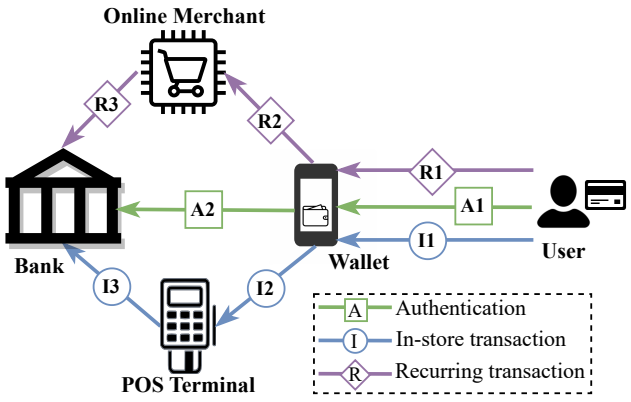

Figure 1: Overview of Digital Payment Communication.

user authentication and transaction authorization procedures throughout the payment lifecycle. Section 6 explores previous works on exploiting digital payments and EMV standards, and finally, we conclude our findings in Section 7.

2 Background on Security Provisioning in Digital Payments Ecosystem

The digital payments ecosystem involves various stakeholders. As the fundamental stakeholder, the bank issues payment cards to their customers – called cardholders. Cardholders add these cards to digital wallet apps (e.g. ApplePay, GPay, and PayPal), allowing them to make contactless payments directly from their smartphones. Figure 1 illustrates primary entities within the ecosystem and their interactions in various transaction scenarios.

Digital wallets support two types of transactions: in-store and online – these are also called one-time payments. For in-store transactions, merchants use point-of-sale (POS) terminals connected to the bank's payment network. Conversely, online transactions occur on the merchants' e-commerce websites. Apart from one-time transactions, wallet users can also establish online recurring transactions with merchants for periodic payments, e.g., monthly subscriptions.

EMV® protocol. Europay, Mastercard, and Visa (EMVCo.) is a global organization that develops and maintains the standard protocol for digital card payments. Its primary objective is to provide a secure and dependable protocol to accommodate the increasing demand for digital payments worldwide. The EMV® protocol for contactless payments [25] lays out multiple security measures designed for each stakeholder entity to ensure a secure communication channel.

The EMV® protocol places the digital wallet at the core of the modern payments system. The wallet-centric system hides the user and card information from merchants to pre-

vent identity theft and fraud. For instance, when a card is added to a digital wallet, the bank issues a payment token to replace the card's primary account number (PAN)[1]. For all transactions conducted with the wallet, the payment token is used instead of the PAN to shield the original card from malicious merchants. Furthermore, the wallet app secures itself behind the smartphone's biometric security features, e.g., facial recognition and fingerprint verification. Therefore, secure communication between the wallet, merchant, and bank is contingent upon the wallet's security.

We refer to the EMV® specifications [24–28, 32] to outline the security procedures involving the digital wallet: user authentication, cardholder verification for transaction authorization, and access control.

2.1 User Authentication in Wallet

When a cardholder adds a card to the wallet, the card issuer bank relies on the wallet for authentication. Since the cardholder is directly interacting with the wallet (A1 in Figure 1), the bank selects an authentication method that aligns with the wallet's capabilities. Generally, two types of authentication methods are used: knowledge-based authentication (KBA), and multi-factor authentication (MFA).

Knowledge-based authentication (KBA) works on the "something you know" principle. It requires the user's personal information like billing ZIP (postal) code, billing address, date of birth, and last four digits of social security number (SSN)[2] for verification [16, 19, 53]. The most prevalent KBA method uses the billing address and ZIP code [20].

Two-factor authentication (2FA) using a one-time password (OTP) is a common MFA method. It is based on the "something you have" principle, where the user possesses a device and an account for receiving the OTP. The specific implementation of the 2FA method varies depending on the wallet service provider: some wallets offer OTPs via SMS, while others use email.

After user authentication, the bank uses a token service provider (TSP) to create and manage tokens linked to the primary account number (PAN). The bank shares the PAN-associated tokens with the wallet (A2 in Figure 1). The wallet does not store the PAN; instead, it uses the token for all transactions, enhancing security for card and user data.

2.2 Cardholder Verification

Cardholder verification (CV) is a pivotal part of transaction authorization. It ensures that only legitimate cardholders can make transactions on Point-of-Sale (POS) terminals. POS terminals support a number of cardholder verification methods (CVMs) applicable to all types of cards and wallets. These CVMs include signature, offline plaintext PIN, offline enciphered PIN, online PIN, offline plaintext PIN and signature, offline enciphered PIN and signature, and consumer device CVM (CDCVM) [24].

In consumer device CVM (CDCVM), the cardholder verifies the wallet-based transaction on their smartphone using either a passcode, pattern, or biometric ID. It aligns with the "something you have" principle, allowing any user with an authenticated wallet app on their smartphone to complete payments without needing additional identification like a PIN or signature. Nevertheless, the user is still required to confirm their device ownership (I1 in Figure 1). For this, the user unlocks their smartphone and the wallet app, and the POS terminal reads the token from the unlocked wallet app (I2 in Figure 1). POS forwards the token and transaction details to the bank (I3 in Figure 1) to complete the transaction.

2.3 Access Control

When a transaction reaches the bank for authorization, it undergoes a verification process to confirm the cardholder's eligibility. The bank uses an access control service to assess transactions based on criteria like transaction type, amount, time, and card status. Additionally, the bank's access control service conducts fraud detection by comparing the transaction against similar historical transactions. This ensures that the transaction aligns with the cardholder's typical spending behavior and is not unusual.

The bank adopts distinct access control policies for different types of transactions. For one-time – online and in-store – transactions, the access control ensures that the user account has enough balance to cover the payment. However, for recurring transactions, an additional condition is imposed: the card must be associated with a credit account (R1 in Figure 1) – most banks do not allow recurring transactions on debit cards.

Given that the bank places varying levels of trust in the entities within the ecosystem, it only allows transactions from trusted sources during times of heightened fraud risk. For instance, when the cardholder locks their card due to loss or theft, the bank continues to allow transactions from digital wallets (R2–R3 and I2–I3 in Figure 1). Simultaneously, it blocks all in-store and online transactions made using the physical card. It is worth noting that specific access control policies may vary between banks, as highlighted in Table 1. While some banks do not allow one-time transactions after card lock, all banks universally permit recurring transactions.

3 Features or Vulnerabilities?

Digital wallets are considered to be more secure than traditional transaction methods [7, 9, 47]. Wallet's device-based biometric security mechanisms facilitate the bank in user authentication and cardholder verification [25, 28]. Because

[1] PAN is the 15- or 16-digit number on the front of the payment card

[2] In the US, SSN is a nine-digit ID used for earnings and taxation reporting.

Table 3: *Summary of intended features that can be exploited by the adversary.*

Features	Rationale	Vulnerabilities	Exploit
Multi -device & -user card access through wallets	Ubiquitous card access through wallet	Attacker adds stolen card to their wallet posing to be legitimate user	Weak KBA authentication to add stolen card to wallet
In-device method used for cardholder verification	Wallet is always possessed by legitimate user	Attacker is verified through their own wallet (device)	Stolen card used for transactions without PIN and signature
Uninterrupted recurring payments	Always allow recurring transactions to avoid late payment fees	Merchant labels one-time transactions as recurring	Mislabeled transactions bypass card lock restrictions

of such a strong authentication guarantee, the bank provides payment features to wallet users that are not accessible for physical cards. The backbone of these features is the bank's trust in wallet security mechanisms. We demonstrate that these features can be exploited into several security vulnerabilities. Our findings are summarized in Table 3.

1. *Multi-device and multi-user card access through wallets give rise to weaker authentication.* The bank allows a cardholder to link their card to multiple devices (e.g., smartphone and smartwatch). The cardholder can also enable digital card access to their family members' devices; meaning that a card can be added to multiple wallets from the same provider, like ApplePay, but with different account IDs, such as Apple IDs of different users. For instance, an AMEX card can be linked with up to 10 Apple Pay accounts simultaneously [5].

To implement this feature of ubiquitous access and easy sharing of cards across devices, the bank and wallet service provider assume that the cardholder and device/wallet owner is the same person. Based on this assumption, the bank and the wallet often opt for weaker authentication schemes. The attacker can, however, turn this feature into a vulnerability and exploit it to add a stolen card to their digital wallet.

2. *The wallet verification in lieu of the cardholder verification is flawed.* Instead of performing a separate cardholder verification procedure for wallet users, the bank relies on in-device biometric verification methods to identify the cardholder authorizing transactions. Although it makes the payment authorization procedure convenient and quicker, it leads to a security vulnerability where the attacker can falsely claim to be the cardholder.

3. *The access control restrictions do not apply to recurring transactions.* The banks allow payments for subscription-based services even on lost/stolen cards in order to shield the cardholder from late payment fees/penalties. The malicious user can exploit this feature (vulnerability!) and make the one-time transaction as if it is a recurring payment, and bypass the transaction authorization restrictions at the bank.

Are banks aware of these flaws? We have shared our findings with major US banks and wallet providers. Two of them have responded and also acknowledged that these features can inadvertently give rise to security vulnerabilities under certain conditions. The following section describes the attack scenarios possible through unfettered wallet access.

Threat Model. The presumed attacker is a digital wallet user, whereas the victim is a cardholder possessing a credit card issued by a major US bank. We assume the adversary to be a passive attacker who cannot disrupt the communication between the bank and wallet. That is, we consider the channel between the wallet and the bank provides authenticity and confidentiality.

We also assume that the attacker can obtain a stolen or lost card of a victim, and the victim has not yet reported the incident to the corresponding card issuer bank. This is a realistic assumption as there is a gap between the time the card is stolen and the time the victim realizes it and reports it to the bank. The attacker can exploit this time window to launch the attacks. Similar assumptions have also been made in related work [13].

A stealthy attacker can go undetected. To avoid being detected by the bank, the attacker does not attempt to make any in-store or online purchases with the stolen physical card. The attacker can utilize various other security measures to obscure their identity and evade detection by both banks and wallet providers. Fake identities [33, 36, 64] and burner phones [15,21,29,38] are standard tools for impersonation and fraud attacks [57, 61]. Prior research has shown that attackers can build fake identities using virtual phone numbers and fake emails, and conduct fraudulent banking activities [1, 34, 67]. Along the lines of these works, we assume that an attacker employs these mechanisms to remain stealthy and prevent the banks and wallets from tracing them.

4 Insecurities in Decentralized Authority for the Digital Payment Ecosystem

Methodology. Our vulnerability identification methodology follows a three-step process. Firstly, we identify token lifecycle management events [27, 28] and their corresponding procedures governing digital payments. These procedures detail how the binding between PAN and token operates during the lifecycle management events. We particularly focus on critical events such as token activation (`CARD ADD`), token suspen-

sion (card loss), token attributes update (`LifecycleUpdate`), token detachment (device loss), and token provisioning for different types of payments.

Secondly, we analyze the payment procedures identified in the first step. We consult EMV® specifications [24–28, 32] and digital wallet documentation [6, 16, 19, 51] to study the participating entities and the data exchanged between them. The objective is to understand the intended functionality of the procedures and then potentially identify flaws and weaknesses within them. This includes identifying: (i) trust assumptions between the entities, (ii) differences between procedures using PAN and those using tokens, (iii) inadequate/inconsistent security policies, and (iv) flaws in security policy enforcement. We analyze high-level security policies for critical payment procedures: authentication, authorization, and access control.

Lastly, we assess the feasibility of launching practical attacks on the weaknesses found in the second step. In this regard, we validate the intended functionality of procedures against how banks and wallets implement them in practice. We examine the policies of major US banks regarding payment processing, particularly in situations of elevated risk. These scenarios include when the cardholder: (i) locks the card, and (ii) reports the card loss and orders a replacement. This step underscores any weaknesses in the EMV specifications that persist in bank policies, potentially enabling attackers to exploit them to launch attacks using a stolen card.

High-level overview of our findings. Our experiments reveal that banks indeed delegate the control of certain procedures to digital wallets and opt to use weaker security mechanisms to provide additional features to wallet users. Therefore, the attacker can launch several attacks by exploiting vulnerabilities rooted in the authentication, authorization, and access control procedures of the digital payment ecosystem. Refer to Table 2 that summarizes our findings.

The attacker breaks authentication by forcing the bank to fall back to a weaker authentication procedure for linking the card to the digital wallet. In consequence, they can successfully add a stolen card to their own digital wallet.

Upon authentication, the bank provides a card token to the wallet for payment authorization. We find that this token neither expires nor gets updated despite the card being locked, or reported stolen (where the bank issues a new card). This enables the attacker to make purchases using the victim's card added to the digital wallet, despite the bank canceling the stolen card and issuing a new one.

The bank implements a transaction-type access control policy in which recurring payments are always allowed while one-time transactions can be restricted after the card is locked/lost. We find that such access-control checks are regulated by merely inspecting the transaction label (recurring vs non-recurring) rather than validating the complete transaction data (e.g., purchase type, time, amount, etc.). The attacker exploits this flaw by labeling their one-time transaction to be recurring, and bypasses the access-control policy. In consequence, they can make purchases of arbitrary amounts, despite the bank's policy to block these transactions.

Are the vulnerabilities time-dependent on card lock? The impact of the vulnerabilities is not bound to the timing of the attack relative to the card lock. The bank enforces the card lock restrictions as soon as the card is locked, and these restrictions remain consistent for the duration of the card lock. Following our threat model, the attacker needs to add the card *before* the victim locks it. After adding the card, the attacker does not need to time the attacks precisely at the time of card lock. This is because the vulnerabilities do not arise during time-of-check to time-of-use (TOCTOU), but are rooted within the policies adopted by the bank. We conduct repeated experiments at different intervals following the card lock to verify this.

Who incurs the financial cost? We discover that these attacks are of a serious nature and remain unnoticed by the bank, wallet provider, and merchant until the victim disputes the charges. When the victim disputes the fraudulent transaction, the merchant is more liable to pay for the loss than the bank [35, 39]. However, a non-vigilant victim may not check the credit card statements regularly, and hence will not even notice being under attack.

4.1 Trust in Digital Wallets Weakens User Authentication

The digital wallet is a functional entity that connects the cardholder with the bank. It facilitates the bank in user authentication procedures and token lifecycle management. This fosters the bank's trust in the digital wallet where the bank (i) allows the wallet to choose the authentication method, and (ii) automatically updates replacement cards in the wallet without requiring user re-authentication.

4.1.1 Wallet-Driven Authentication Method Selection

The bank delegates the choice of user authentication method to the wallet. The wallet performs authentication by presenting a list of its supported methods (e.g., billing address, OTP, and call) to the user. This means that it is the end-user who makes the final decision regarding the authentication method to be used for adding the card to the wallet. Such delegation of authentication is flawed in that an attacker can dictate the bank to accept a weak authentication procedure which gives birth to a number of security vulnerabilities.

> **Issue 1:** Delegation of authentication from the bank to digital wallets allows an attacker to add a stolen card to their wallet and make transactions.

Attack details. Figure 2 describes an attack scenario where the attacker compromises the authentication process and adds

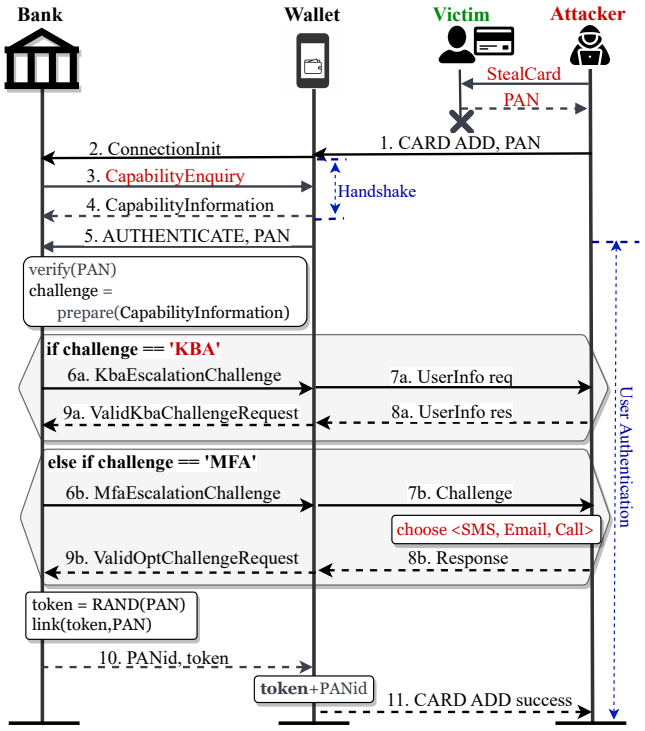

Figure 2: The authentication procedure in the digital wallet; the attacker exploits weaknesses in KBA- and MFA-based authentication to add the victim's card to their wallet. The authentication process comprises two phases: a) the handshake between the wallet and the bank, and b) the user authentication in the wallet delegated by the bank. Weaknesses in the process, highlighted in red, allow the attacker to add the card.

the victim's card to their (attacker's) wallet. Following our threat model, we consider that the victim has lost their card and has not yet locked it. Meanwhile, the attacker is able to get their hands on the victim's card. The attacker starts the `CARD ADD` process by inputting the card's primary account number (PAN) in the wallet (message ①). It triggers the authentication procedure in which the bank and the wallet execute a handshake (② - ④), and first agree on an authentication method to be used.

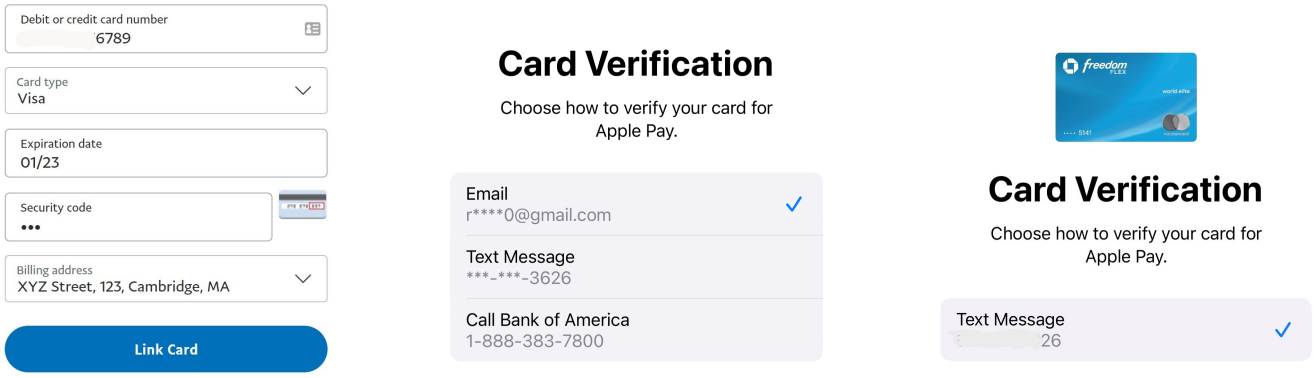
The bank sends a `CompatibilityEnquiry` request (③) to get the wallet's supported authentication methods. The wallet responds with a list of supported methods in the order of preference in a `CompatibilityInformation` message (④). Upon receiving the supported authentication methods, the bank chooses the one with the highest preference. Refer to Section 10.5 in EMVCo. Book 3: Application Specification [24] for more details on this procedure.

The wallet sends an `AUTHENTICATE` request (⑤) containing the victim's PAN to the bank. Once the bank receives the authentication request from the wallet, it verifies the PAN and generates the authentication response. For simplicity, in Figure 2, we consider two widely used authentication methods: *knowledge-based authentication (KBA)*, and *multi-factor authentication (MFA)*, that are widely used by major banks in the US. The bank sends `KbaEscalationChallenge` (⑥a) to the wallet when KBA is used; otherwise, it responds with `MfaEscalationChallenge` (⑥b) if MFA is used as an authentication method.

In KBA, the wallet receives the `KbaEscalationChallenge` from the bank (⑥a). It prompts the user (⑦a) to verify their identity by providing one or more information items: the billing ZIP code, billing street address, date of birth, and/or the last four digits of SSN [53]. The wallet sends the user information to the bank via `ValidateKbaChallengeRequest` (⑧a – ⑨a). The bank completes the authentication procedure once the user is verified through address verification service (AVS) [16, 19, 51].

In the case of MFA, the wallet receives `MfaEscalationChallenge` from the bank (⑥b) and prompts the user to choose their preferred authentication method (⑦b). The user chooses either to receive a one-time password (OTP) via SMS or email, or call the bank to verify their identity. If the user chooses OTP, the wallet sends `ValidateOtpChallengeRequest` message [3] and completes the user authentication (⑨b) by validating the OTP(s). In call-based authentication, the user provides their date of birth or last four digits of SSN to the bank for identification – note that this is similar to KBA.

Once the user is authenticated, the bank generates a token (a proxy identity for PAN) using the token service provider (TSP)[4]; and shares the token along with associated last four digits of the PAN, called `PANid`, with the wallet (⑩). The authentication procedure completes when the wallet sends a `CARD ADD` *`success`* notification (⑪) to the user.



Key takeaways. The end-user, but not the bank, decides the authentication method to be used. For example, an attacker can make the bank *fall back* to KBA when MFA is mandated. They do so by using the "call-based" authentication option. The attacker dials the bank's automated helpline for adding the card to the wallet. The helpline prompts the attacker to provide the KBA-related information: date of birth and the last four digits of SSN associated with the victim's card.

The wallet uses KBA-based authentication methods because they are convenient and easy to use for customers. By prioritizing ease of use, the bank essentially fails to enforce a higher standard of security. This is because KBA methods are proven to be much weaker than MFA-based methods [4, 17].

The attacker can acquire the information needed for

[3] `POST /users/{user_id}/sendOtp` endpoint remains open for the wallet to request additional OTPs.

[4] TSP links PAN to the token that wallet uses as card ID for transactions.

(a) BoA in PayPal (b) BoA in ApplePay (c) Chase in ApplePay

Figure 3: Authentication methods used in different wallets. The BoA credit card uses (a) KBA for the Paypal wallet, and (b) multiple MFA methods (i.e., email, SMS, or the call) for ApplePay as the authentication methods. In contrast, for Chase bank credit card, (c) ApplePay offers only SMS-based MFA. These experiments highlight the inconsistencies in authenticating the user not only within the wallet (i.e., Apple Pay), but also across the wallet apps (i.e., Apple Pay and Paypal).

KBA authentication from the publicly available online databases [3, 46, 50, 60]. For instance, ZIP code and date of birth are practically considered public information, especially in the age of social media [18, 62]. Therefore, the attacker uses non-trivial methods to acquire the victim's personal information and adds the stolen card to the wallet which uses KBA authentication – the weakest authentication method.

Empirical assessment. We evaluate the efficacy of adding a victim's stolen card to an attacker's wallet, irrespective of the wallet the victim is using. Our experiment setup includes two credit cards issued for the victim by the Bank of America (Visa card) and the Chase bank (Master card), respectively; the attacker steals these cards. We consider both smartphone devices (an Android device for PayPal and GPay wallets, and an iPhone for ApplePay) to be under the control of the attacker and are not rooted. For a realistic attack setting, we ensure that both the credit cards and the smartphones have no collective use history. Furthermore, both the attacker and the victim do not share any common information (e.g., billing address).

We find that PayPal and GPay use only the billing address for KBA (Figure 3 (a)), whereas the ApplePay uses two different sets of methods for MFA (Figure 3 (b) & (c)) for each card. For the Bank of America Visa credit card, ApplePay provides three MFA options: SMS OTP, email OTP, and verification over automated call (Figure 3 (b)). However, it uses only SMS OTP as MFA for the Chase Master credit card (Figure 3 (c)).

The attacker uses popular online databases, like Yellow Pages[5] and SearchBug[6], to acquire the victim's last four digits of SSN, date of birth, and ZIP code – commonly used for KBA. Similarly, there are several past studies [42, 43] that demonstrate the weaknesses in the SMS-based OTP. We rely on these works to highlight the feasibility of adding the card through the MFA-based authentication procedure.

Further, we find that the delegation of choice for authentication method leads to an inconsistent authentication policy. One bank card can be authenticated in multiple different ways in different wallets (Figure 3 (a) vs. (b)). Yet, the authentication method does not vary with the wallet provider that the attacker and the victim are using. For example, it is not more difficult for the attacker to use PayPal if the victim has already added the card to their PayPal wallet.

Root causes. The above experiment demonstrates that some digital wallets, like PayPal, prefer KBA over MFA. They consistently prioritize the user-friendly KBA-based authentication methods, regardless of the card issuer bank. Even if some wallet uses call-based authentication (which it considers MFA), it falls back to KBA.

The bank does not choose the authentication method of higher security, but rather it honors the wallet's preferred choice. With weak authentication, an attacker can steal a card and add it to their wallet for transactions.

Lessons learned. Although the delegation of authority for authentication is efficient and scalable, it compromises security. This becomes evident when crucial decisions are also delegated to third parties in the digital payment ecosystem. We identify that a foolproof and uniform authentication policy enforcement by the bank is missing for all wallets.

4.1.2 Card Replacement in Wallet Without User Authentication

The bank retains the trust chain with the wallet beyond the user authentication. When a change occurs in the status of the linked card (e.g., `DeletionOfPaymentCredential` and

[5] www.yellowpages.com
[6] www.searchbug.com

Lost/Stolen ConsumerDevice), the bank sends the card-related updates directly to the wallet [28]. These updates are conveyed through a LifecycleUpdate request to the linked wallet. Notably, this process does not notify the user of a LifecycleUpdate nor requires the user re-authentication for accepting the update. Thus, the wallet that is under the control of the attacker also receives such updates.

> **Issue 2:** The card replacement event does not revoke the token; allowing the attacker to keep using the previously added card in their wallet without requiring authentication.

Attack details. We consider the lost card scenario to present the token updates without user re-authentication. The complete workflow is illustrated in Figure 4. When the user reports the card loss (①), the bank blocks the lost card and issues a new card (with a new PAN) to the user. However, it does not update the associated token; instead, it links the old token with the new PAN in the token service provider (TSP) [66].

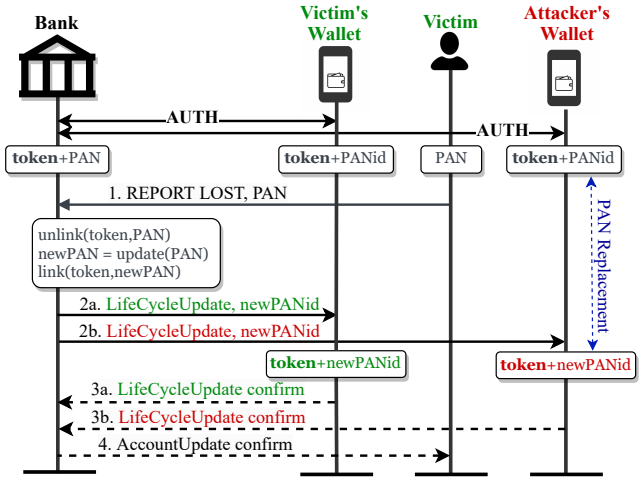
The bank issues a LifecycleUpdate and sends the new PANid to all wallets liked with the lost card (messages ②a and ②b in Figure 4). These wallets replace the stored PANid with new PANid and link it with the stored token. At this point, the same old payment token is linked with the new PANid (and PAN) in wallets as well as TSP.

The LifecycleUpdate automatically adds the new card to the wallet (③a and ③b), and does not verify the user – whether they should receive the card replacement update or not. Because the user has not initiated the CARD ADD procedure, the bank does not trigger EscalationChallenge procedure for adding the replacement card [32].

Key takeaways. One-time user authentication bypasses the authentication for adding a replacement card to the wallet after a card loss event. While an automatic card replacement is convenient for wallet users who do not have to manually add the card, it weakens credit card security. It means once the attacker has added the stolen victim's card to their wallet (refer to Section 4.1.1), they can continue using it despite the victim receiving the replacement card from the bank.

Empirical assessment. We perform several experiments to validate the flawed PAN replacement policy for two major US banks: American Express (AMEX) credit card, and Chase Visa credit and debit cards. In our experiments, all three cards are first added into both the victim's and attacker's wallets (ApplePay, PayPal, and GPay). Once the attacker has successfully added the card to their wallet, the victim reports the card loss event by contacting the bank and requesting the issuance of a new card. The bank immediately blocks the reported card and mails the new card to the victim.

We observe two different outcomes at the attacker wallets.



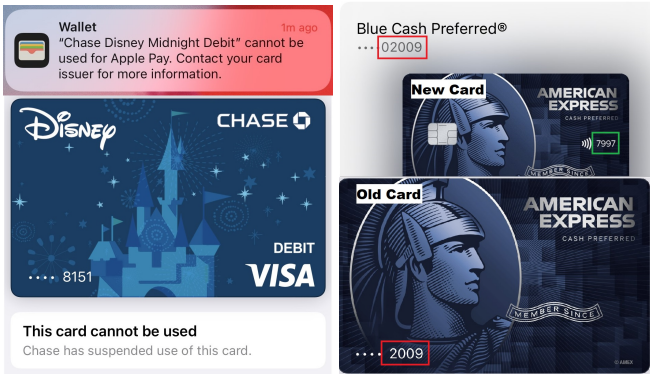


Figure 4: PANReplacement procedure for replacing a card upon user report of card loss. The bank issues a new PAN and updates the new PANid in all the associated wallets without user authentication. Green messages indicate communication with a trusted (victim's) wallet, while red messages indicate a malicious wallet used by the attacker.

First, in the case of credit cards (Chase Visa and AMEX), the attacker's wallets receive a silent update from the bank in which they link the new PANid with the stored token. Second, for the Chase Visa debit card, the wallet sends a notification (as shown in Figure 5 (a)) stating that the debit card cannot be used with ApplePay anymore.

We continue our experiments to validate whether the attacker can use the credit cards in their wallet even *after* the victim reports these credit cards to the bank as stolen. We find that the attacker can indeed make purchases without any disruption (i.e., even before the victim receives the new credit card in the mail). An unusual observation related to this experiment is that albeit the wallet displays the new PANid (*7997*, as shown in Figure 5 (b)), it continues to use the old PANid (*2009*, as shown in Figure 5 (b)). We confirm this where the old PANid has appeared on the merchant receipts for payments made through the wallets.

Root causes. The bank has established an unconditional trust with the wallet. Due to this trust, the bank does not implement a token revocation mechanism to limit the wallet's access to the card in critical scenarios. Hence, the token remains constant when it binds with the PANid. During the card replacement event, the bank replaces the PANid in the wallet without updating the token.

The bank fails to verify whether the wallets receiving the card updates belong to the card owner or not. This impacts the victim whose card is accessible to the attacker despite a new replacement card being issued by the bank.

(a) Chase Debit Card (b) AMEX Credit Card

Figure 5: Card replacement after reported as lost. The bank blocks the debit card (a), rendering it unusable in the wallet. However, for the credit card, (b) the bank issues a replacement card and updates `PANid` in the wallet, but keeps the old token active for payments.

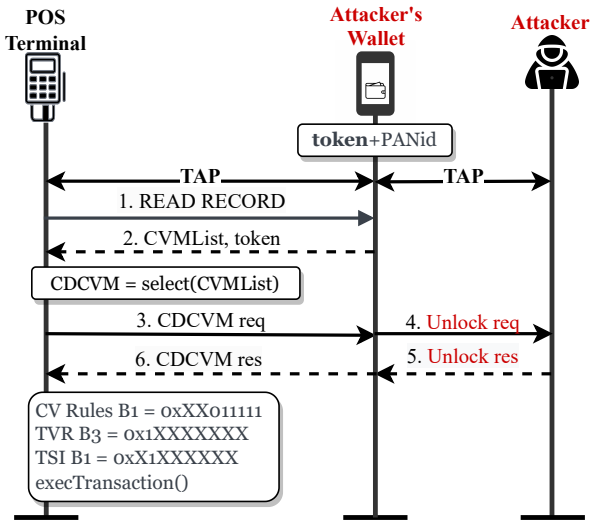

Figure 6: In-store cardholder verification (CDCVM). Messages highlighted in red show weaknesses in the procedure.

Lessons learned. The bank's unconditional trust in the wallet extends beyond the user authentication. During critical events, such as card loss, the bank neither revokes the card's token from the wallet nor requires user verification to continue using the wallet. Therefore, an attacker's wallet receives the same updates as a legitimate user's wallet.

4.2 Unrestricted Transaction Authorization on Wallets

Digital wallets are inherently different and more secure than physical cards [7, 9, 47]; that is why the bank uses two different methods of transaction authorization. For transactions on a physical card, it uses PIN and signature verification. In the case of a wallet, it uses in-device security methods (e.g., facial recognition, and fingerprint verification) to verify the user – known as device cardholder verification method (CDCVM) [24]. The wallet app prompts the user to unlock the device to complete the transaction authorization through an in-device security mechanism. It means that the bank relies on in-device authentication (i.e., CDCVM) for payment authorization instead of performing the traditional cardholder verification. An attacker can bypass the cardholder verification (i.e., through card PIN or signature): they add a stolen card to their wallet (refer to Section 4.1.1), and make the transaction through in-device authentication.

Issue 3: In-device verification method fails to verify both the wallet owner and the cardholder, allowing an attacker to bypass the cardholder verification process.

Attack details. The CDCVM procedure substituting the card owner's verification works as follows. The attacker uses the digital wallet to make an in-store transaction on the POS terminal. As shown in Figure 6, the attacker first taps the device containing their wallet app over the terminal. It requests token data by issuing the `READ RECORD` command to the wallet (①). The wallet responds with the token and CDCVM capability in a list of cardholder verification methods, i.e., CVMList (②).

The terminal requests the wallet to complete CDCVM (③). Wallet prompts the user to unlock the device (④) through fingerprint, face recognition, or device PIN. Once the user unlocks the device, it sends a CDCVM confirmation to the POS terminal (messages ⑤ and ⑥ in Figure 6). With this, the device-based cardholder verification (CDCVM) is complete. Finally, the terminal sends the CVMRules and TSI to the bank for authorization and completes the transaction.

Key takeaways. Since the bank does not require the POS terminal to perform the cardholder verification, the terminal sets the `'No CVM required'` (`0xXX011111`) flag in the CVMRules. It also sets the `'Cardholder verification was not successful'` (B3 = `0x1XXXXXXX`) flag in the terminal verification results (TVR) because the transaction was not verified by the POS. Meanwhile, the wallet transfers the token to the terminal, indicating that the bank has authorized the wallet to make purchases. The terminal proceeds the payment and updates the flag *B3* to `'Cardholder verification was performed'` (B1 = `0xX1XXXXXX`) in transaction status information (TSI). This flag indicates that the cardholder verification was performed in the wallet, but in

Table 4: *Summary of payment transactions of different amounts by using major US banks' locked credit cards.*

Banks	Amount ($)	Physical	Wallet
AMEX	≤ 1	✗	✓
	≥ 500	✗	✓
Chase (VISA)	≤ 1	✗	✓
	≥ 500	✗	✓
Discover	≤ 1	✗	✓
	≥ 500	✗	✓
US Bank (VISA)	≤ 1	✗	✗
	≥ 500	✗	✗
Citi (Mastercard)	≤ 1	✗	✗
	≥ 500	✗	✗
BoAmerica (VISA)	≤ 1	✗	✗
	≥ 500	✗	✗

reality, the device owner's verification was performed (refer to Annex C in EMVCo. Book3: Application Specification [24]).

Empirical assessment. We perform several experiments and launch attacks on in-store purchases made through digital wallets. We consider that the victim's AMEX and Chase Visa credit cards are stolen by the attacker. The attacker adds these cards to their wallet and the victim **locks** both cards. The bank promises to stop the payments on locked cards. The victim receives the following message when they lock the card from the Chase bank app:

"Instantly block new purchases, cash advances, and balance transfers made with your card or card number."

Thereafter, the attacker visits the merchant stores (we test at Walmart, and Target stores), and uses the victim's card stored in their wallet (we validate on ApplePay and GPay) to make transactions. The POS at the merchant approves the transaction, and *victim is charged for the transaction amount despite the card being locked by the victim*. We confirm that these flaws persist for different amounts ranging from as low as less than $1 to amounts greater than **$500** (see Table 4). We repeated these experiments several times and waited up to one week after the card was locked. However, the results of the attack remain the same.

Root causes. In-device verification comes with an assumption that the legitimate user has added the card to their wallet and that the cardholder and device owner are the same person. This leads the bank to use wallet ID and user ID interchangeably. As a result, the bank eliminates any user- and card-specific verification methods that would not be accessible to an unauthorized user. In contrast, physical cards require a PIN and signature for cardholder verification.

Also, the bank does not add an extra layer of security by allowing the POS terminal to verify the card owner before authorizing the payment. In consequence, `'No CVM required'` translates to `'successful'` verification when payments are made through a digital wallet (refer to Section 6.3.4 in EMVCo. Book4 [25] for more details).

Lessons learned. Performing the cardholder verification through device verification is both convenient and easy to implement. However, it is based on the flawed assumption that the device owner and the cardholder are the same person. The attacker can charge the victim's card using their own wallet and bypass the cardholder verification required for payment authorization.

4.3 Bypassing Access Control Policies through Recurring Transactions

Thus far we have discussed the weaknesses in authentication and cardholder verification for one-time transactions over digital wallets. Our study also finds flaws in another type of transaction: recurring payments made for subscription-based services (e.g., Netflix service). They differ from one-time transactions (e.g., in-store purchases) in three distinct ways: (i) they are initiated by the merchant, (ii) they are performed periodically, and (iii) the transaction amount is the same for every periodic transaction.

The bank treats recurring payments differently from the one-time transaction; mainly because the cardholder is penalized by the merchant for missed payments. It aims to shield the cardholder from late payments, and therefore processes the recurring payments from the wallet despite the card being locked/lost[7]. The special treatment of recurring transactions gives birth to a flaw where the attacker makes a one-time transaction on the locked card but gets it labeled as a recurring payment by the merchant. In this way, they can bypass the restrictions of one-time payment on a locked/lost card (as some banks have enforced, refer to Table 1).

Issue 4: The attacker can deceive the merchant into labeling a one-time transaction as "recurring", and bypass the access control restrictions at the bank.

Attack details. The procedure starts with the user who sets up the recurring payment contract with a merchant through the digital wallet. The wallet, acting as an agent, sends the contract details (e.g., periodicity of the payment), and the merchant information to the bank.

On receiving the request, the bank verifies the wallet and issues a merchant token `merchantID` and the `contractID` to

[7]The Citi bank states: "Any charge marked by the merchant as 'recurring', will continue to be processed while your card is locked."

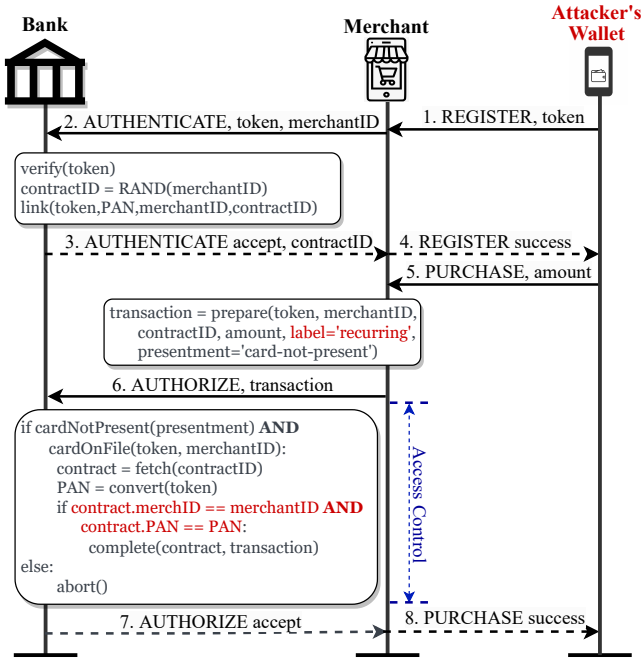

Figure 7: Access control procedure in the bank for recurring transactions. Conditions highlighted in red show the access control policy rules that allow the attacker to exploit the vulnerabilities. For example, the bank only checks the transaction label. This allows the bypass of card lock restrictions by labeling the one-time transaction(s) as recurring.

the merchant. In this way, the bank establishes trust with the merchant by giving it the authority to post recurring transactions. The bank does not perform further access control checks; instead, it processes the payments initiated for the registered `merchantID` and `contractID`.

We analyze how the bank processes recurring transactions by looking closely into the involved procedures (see Figure 7). First, the attacker registers the stolen card with an online merchant by using their digital wallet. The wallet sends a `REGISTER` request to the merchant along with its token (①). Once `REGISTER` request is received, the merchant sends the `AUTHENTICATE` request to the bank along with its `merchantID` and wallet's token (②). The bank verifies the token and sets up a recurring payment contract with the merchant to support future transactions. The bank generates a `contractID` and shares it with the merchant in `AUTHENTICATE` *`accept`* message (③). Upon receiving the `contractID`, the merchant sends a `REGISTER` *`success`* message to the wallet (④) to finalize the registration.

Merchants treat the transactions originating from the customer's saved payment method as recurring [63]. Although it is a one-time transaction, the merchant labels it as 'recurring'. The attacker uses this flaw to bypass the restrictions on one-time transactions if the card is locked. To complete the purchase, the merchant sends the `AUTHORIZE` request to the bank (⑥) along with the prepared transaction details.

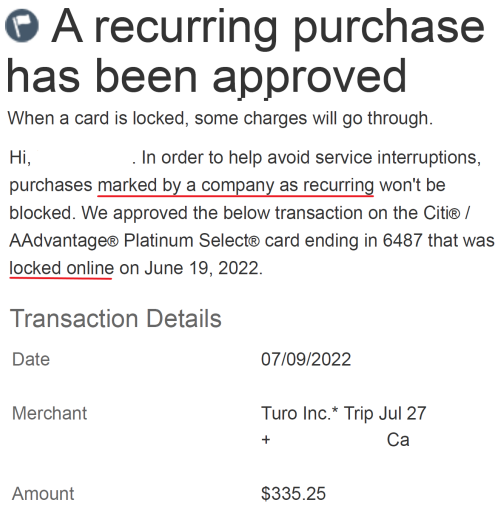
Before authorizing recurring transactions, the bank's access control module verifies `card-not-present` and `card-on-file` flags to ensure that the transaction is initiated by the merchant on behalf of the user. The bank retrieves the PAN and payments contract for the merchant and verifies the transaction with the agreed-upon contract. Finally, the bank completes the authorization and sends the `AUTHORIZE` *`accept`* message to the merchant (⑦). Similarly, the merchant sends a confirmation to the wallet with `PURCHASE` *`success`* message (⑧).

Key takeaways. The bank's decision to freely allow merchants to label any transaction as 'recurring' is a trade-off between usability and security. While this design allows the users to continue using the services after they have locked the physical card, it gives birth to access control bypass vulnerability even for one-time transactions. The bank relies on its security modules (e.g., access control, and fraud detection tools) to filter out unexpected transactions by the user. However, these tools cannot differentiate between recurring and one-time transactions (especially, when the transaction is already registered at the bank); and fail to verify the nature of the transactions. In consequence, the attacker can bypass the access control policies for one-time transactions, and *can make purchases of any amount and at any time despite the card being locked by the cardholder*.

A curious reader should ask the question: how are the recurring transactions through a wallet different from those of a physical card? We should emphasize that the attacker can set up *new and future* recurring payments using their wallet even *after* the victim has locked or replaced the card. In the case of a physical card, the recurring payments set up prior to the card lock are only processed, and the attacker *cannot* set up new recurring transactions once the card is locked. The bank's indefinite and unconditional trust in the wallet opens a trap door to bypass access control policies on locked cards.

Empirical assessment. We demonstrate another way of making one-time transactions on a locked card. The attacker can bypass the access control restrictions placed by the locked card. For our experiments, we use Citibank Mastercard issued to the victim (recall that Citibank does not allow one-time transactions on locked cards 1). The attacker steals the card and adds it to their wallet *before* the victim locks the card.

The attacker visits Turo.com to make the payment for the car rental. They first register at Turo.com as a new customer and set their wallet as a payment method. Turo sends the payment method details to the card issuer bank to get the user (attacker) registered and set up a recurring transaction. After registering the card, the attacker books their car rental trip and pays in full by using the victim's card added to their wallet. Although the card is locked, Turo sends the one-time payment



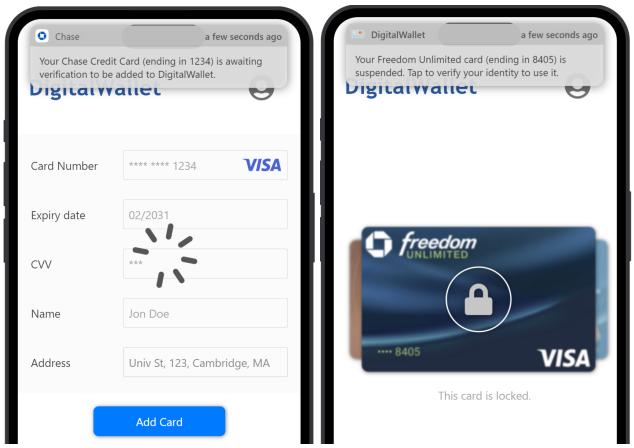


Figure 8: The bank allows the transaction by treating it as recurring without verifying the nature of the service(s) purchased. The attacker chooses to use a merchant (e.g., Turo) that labels a one-time car rental transaction as recurring to bypass the restrictions on a locked card.

by labeling it as recurring which we have confirmed from the email receipt received by the bank (refer to Figure 8).

To confirm that this vulnerability is not associated with Turo only, we also validate our attack on apple.com. Following, the above experiment steps, we have successfully purchased a $25 Apple gift card, and $179 AirPods by using the locked card. The bank's email receipt shows a recurring transaction on the card. We conclude that the bank does not verify the metadata in the recurring transactions as part of the access control policy; a recurring label is sufficient for the bank to authorize the transactions.

Root causes. The bank's access control policy is not designed to restrict the registered payment types (i.e., recurring transactions in our study). These transactions are fully trusted and not validated against the recurring payment contract (e.g., transaction amount, and periodicity). Further, the bank does not distinguish the service and product types to counter-verify the label assigned by the merchant. In consequence, those payments that are by definition one-time transactions (purchasing a gift card, and renting a car) can bypass access control restrictions when labeled as recurring.

Our analysis also reveals that the time of recurring transactions is not verified against the time when the victim has locked the card. The recurring transactions are authorized even if they are set up **after** the card loss event. The bank's access control fails to block them where it protects the edge use case scenarios: the card is locked while the recurring payment is being set up. We argue that this design choice welcomes access control violation vulnerabilities.

(a) Push MFA Authentication (b) Re-authentication on Card Lock

Figure 9: The visual representation of proposed countermeasures: (a) push MFA instead of traditional OTP-based authentication, and (b) re-authentication after card lock.

Lessons learned. The bank permits recurring payments on the locked card to honor the contract between the user and the merchant. It allows subscription-based service continuity by making timely payments on behalf of the user. The special treatment of one type of payment over the other is vulnerable to security attacks. The attacker can deceive the merchant for their one-time payment to be labeled as recurring and bypass the access control restrictions at the bank.

5 Proposed Countermeasures

We propose recommended solutions to fix the four issues that we identify in this paper. Our solutions aim to fix the fundamental design flaws and the bank's policy implementation to address the discussed issues, as well as similar others. We have suggested these solutions to banks and wallets (as noted in Table 2), but have not implemented them at our end mainly because of propriety wallet apps and inaccessible bank back-end system. Nevertheless, we have graphically illustrated in Figure 9 regarding how our solutions will look like, if implemented.

Adopting push MFA instead of traditional OTP-based methods. The existing authentication methods rely on legacy solutions that are proven to be vulnerable [42, 43]. We propose that the bank should enforce state-of-the-art MFA mechanisms [22, 52] such as push notifications (e.g., Bank App, Duo Mobile, Microsoft Authenticator), or passcodes (e.g., Google Authenticator) based solutions (see Figure 9 (a)). We propose that the bank should choose the strongest possible authentication method that it can support, rather than relying on the wallet's capability and preference. Similarly,

the wallet should prioritize security over user convenience. Our solution addresses *Issue 1*, and the vulnerabilities associated with precondition of *Issue 2* and *Issue 3* where the attacker is required to add the victim's card into their wallet. This solution requires an integration with the third party authenticator service providers, such as Duo, Google Authenticator. and Microsoft Authenticator.

Using continuous authentication in token management. Once the wallet is authenticated and a payment token is issued, the bank uses the token indefinitely which never expires. This establishes an unconditional trust towards the wallet which neither expires nor changes even for critical events like card loss, device loss, and card deletion. We propose that the banks adopt a continuous authentication protocol [10, 30, 31, 37], and re-authenticate the wallet and refresh the token periodically, especially after critical events like card loss (see Figure 9 (b)). This solution eliminates *Issue 2* and *Issue 4* directly, and *Issue 3* indirectly. Since the use of a wallet by the attacker is only possible under an unconditional trust policy, re-authentication will stop the compromised wallets (*Issue 3*) from in-store payments. As this solution involves periodic updates using a pre-existing authentication procedure, it does not require significant changes at the banking back-end.

Distinguishing one-time from recurring transactions. Currently, the bank relies on the merchant-assigned transaction type label to decide the authorization mechanism. We argue that the bank should evaluate the transaction metadata (e.g., time, frequency, and service/product type), and the transaction history information to evaluate if the transaction is of a certain type or not. For instance, a transaction labeled as recurring cannot be used to purchase a gift card. Similarly, recurring transactions whose payment amount differs from the recurring payment contract and previous payments should not be authorized. Our proposed solution resolves *Issue 4*, preventing merchants from exploiting incorrect transaction labels to circumvent access control restrictions. It can be implemented swiftly with minimal deployment efforts by amending the bank's transaction authorization logic.

6 Related Work

EMV and mobile payment security. EMV, a globally used secure payment technology, has been subject to multiple attacks. [12] identifies terminal-level vulnerabilities, leading to mismatches between card brands and payment networks, and PIN bypass. [65] demonstrates relay attacks on Dutch bank cards with minimal resources. [23] demonstrates attacks on EMV contactless cards approving unlimited transactions in foreign currencies without the cardholder's PIN. [8] introduces an "over-the-counter payment frauds" attack that exploits payment scheme designs. [2] explores the discrepancies between EMV and ISO standards, compromising transaction integrity. [54] demonstrates practical relay attacks for enabling wireless money pick-pocketing between contactless EMV bank cards and shop readers. Formal models and fine-grained analyses of EMV protocols have revealed flaws on both the cardholder and merchant sides [11].

Payment apps security. In a study of the Unified Payments Interface (UPI), [41] unveils vulnerabilities in multi-factor authentication that could lead to severe attacks when exploited by malicious applications. [45] introduces AARDroid, a tool for statically assessing payment software development kits against industry security standards. [71] highlights security weaknesses in in-app purchasing (IAP) methods within mobile games, revealing misplaced trust in payment verification or a complete lack of verification. [68] build mobile checkouts inspired by PayPal and Visa Checkout SDKs, checking payment procedure correctness and security through automatically generated test cases. [70] presents Payment-Guard, which characterizes and detects suspicious transactions based on various behavioral aspects. [40] introduces CrySL, a tool analyzing over 10,000 Android apps, uncovering widespread misuse of cryptographic APIs and vulnerabilities within their payment processes.

Security against card skimmers. Recent research highlights the prevalence of credit card skimming attacks at gas stations, with studies by [14] and [58] focusing on using smartphone Bluetooth scanning to detect skimmers. [59] introduces Skim Reaper, a tool utilizing the physical characteristics and constraints of card skimming devices for detection. [56] exposes over 50 websites hosting payment card skimming codes to steal credit card credentials.

Our research stands apart from the aforementioned studies in three key ways. Firstly, our attacks on digital wallet payment systems are novel and do not rely on preexisting vulnerabilities, e.g., in payment protocol (e.g., EVM), or digital payment elements (e.g., POS). Secondly, our attacks persist even when the victim and the bank have implemented countermeasures like card locks or the issuance of new cards with different PANs. Thirdly, our passive attacker exploits the trust among different elements in the digital wallet system to launch the attack. For instance, they can self-authenticate within the wallet to use the victim's card for transactions.

7 Conclusion

Our study reveals critical security vulnerabilities within the digital wallet payment ecosystem. These vulnerabilities are fundamentally linked to the decentralized delegation of authority. For instance, after authentication, the bank issues a payment authorization token to the wallet. The inherent weakness lies in the lack of revocation of this authority in the event of card or device loss. We demonstrate our attacks over

major US banks, popular wallet apps, and smartphone operating systems. Our findings reveal that existing remedies like card locking or issuing new cards do not effectively mitigate these threats. Finally, we propose countermeasures of strong authentication and robust token management lifecycles for digital wallets.

The Impact of Exposed Passwords on Honeyword Efficacy

Zonghao Huang
Duke University

Carnegie Mellon University

Michael K. Reiter
Duke University

Abstract

Honeywords are decoy passwords that can be added to a credential database; if a login attempt uses a honeyword, this indicates that the site's credential database has been leaked. In this paper we explore the basic requirements for honeywords to be effective, in a threat model where the attacker knows passwords for the same users at other sites. First, we show that for user-chosen (vs. algorithmically generated, i.e., by a password manager) passwords, existing honeyword-generation algorithms do not simultaneously achieve false-positive and false-negative rates near their ideals of ≈ 0 and $\approx \frac{1}{1+n}$, respectively, in this threat model, where n is the number of honeywords per account. Second, we show that for users leveraging algorithmically generated passwords, state-of-the-art methods for honeyword generation will produce honeywords that are not sufficiently deceptive, yielding many false negatives. Instead, we find that only a honeyword-generation algorithm that uses the *same* password generator as the user can provide deceptive honeywords in this case. However, when the defender's ability to infer the generator from the (one) account password is less accurate than the attacker's ability to infer the generator from potentially many, this deception can again wane. Taken together, our results provide a cautionary note for the state of honeyword research and pose new challenges to the field.

1 Introduction

Credential database breaches have long been a widespread security problem and are only becoming more so. The 2022 Verizon Data Breach Investigations Report places credentials as one of the two most often breached types of confidential data, since they are so useful for attackers to masquerade as legitimate users on the system [43, p. 18]. Credential database breaches are the largest source of compromised passwords used in credential stuffing campaigns [38]. In turn, credential stuffing campaigns are the cause of the vast majority of account takeovers [35]. Unfortunately, there is usually a significant delay between the breach of a credential database and its discovery. Estimates of the average delay to detect a data breach range from six to eight months in a 2022 report [21, Fig. 45]. The resulting window of vulnerability gives attackers the opportunity to crack the passwords offline, and then sell them or leverage them directly [35, 38].

A strategy to accelerate the detection of credential database breaches, suggested by Juels and Rivest nearly a decade ago [22], is for a site to store decoy passwords, or *honeywords*, alongside real passwords in its credential database, so that if the attacker breaches the database, the correct passwords are hidden among the honeywords. The entry of a honeyword in a login attempt then alerts the site to its breach, since the legitimate user does not know the honeyword. In the time since this proposal, researchers have proposed various algorithms for generating honeywords (see Sec. 3) to meet two central criteria: (i) that it be difficult for an attacker who has breached a site's credential database to distinguish the legitimate password for an account from that account's honeywords, and (ii) that it be difficult for an attacker who has not breached a site's credential database to guess honeywords for an account, since such guesses will induce false breach alarms.

The tendency of users to reuse passwords across sites (e.g., [31, 54]) presents a challenge for honeywords, since an attacker can stuff an account's breached passwords at *other* sites where the same user has accounts, thereby discovering the legitimate password as the one that works at another site. As such, previous advances in honeyword system designs [52] provide a mechanism by which one site can monitor for the entry of another site's honeywords in local login attempts. Still, however, for an account for which the attacker can obtain the user's passwords on other sites (e.g., by breaching these other sites, or by phishing their passwords), the attacker will likely need not resort to credential stuffing to differentiate the legitimate password from its honeywords. While this might seem like an unnecessarily challenging threat model, it is unfortunately realistic: A July 2020 report found more than 15 billion credentials in circulation in cybercriminal marketplaces [11], or an average of more than two for every person on the planet.

In this paper we conduct the first critical analysis of honeyword-generation algorithms in this setting, i.e., wherein the attacker knows legitimate passwords at other sites for the users represented in a database it is targeting. There is reason to suspect that this threat model would pose significant challenges to honeyword efficacy for user-chosen (versus algorithmically generated) passwords. On the one hand, if the honeyword-generation algorithm used to populate the targeted database generates honeywords that are all dissimilar from the user-chosen password, then the known password(s) for the same user might enable the attacker to distinguish the user-chosen password from its honeywords with high probability. If so, the false-negative probability (the probability that the site fails to detect the breach) would be high. On the other hand, if the honeyword-generation algorithm generates some honeywords that are similar to the user-chosen password, then this might make it easier for an attacker who has *not* breached the database to guess and enter honeywords in login attempts, thereby inducing a false breach alarm (false positive).

Through a systematic analysis of current honeyword-generation algorithms, we quantify this tension and, by doing so, show that there appears to be no known algorithm providing a good tradeoff for accounts with user-chosen passwords. We additionally applied two password tweaking techniques from password guessing to improve honeyword generation. While these two algorithms relieve this tension by providing slightly lower false-negative probability, they still induce a high false-positive probability. Therefore, it remains far from clear that there is *any* honeyword-generation algorithm that ensures low false-negative probability and provides adequate resistance to false breach alarms (i.e., a false-positive rate near 0).

We then turn our attention to accounts with algorithmically generated passwords, as might be generated by a password manager. The critical finding that we uncover in this case is that honeyword-generation algorithms that do not take into account the method by which the legitimate password was generated will yield high false-negative probability. For example, if the user employs a password manager that generates passwords to fit a user-configured specification, and if the passwords exposed for that user permit the attacker to infer this specification, then the attacker can discard any honeywords not fitting that pattern. We will quantify the ability of the adversary to do so against existing honeyword-generation algorithms, most of which do not guarantee honeywords of the same pattern as the legitimate password. We then consider the possibility that the honeyword-generation algorithm itself leverages a password manager to generate honeywords whenever the user does. However, due to the numerous generator configurations that users might adopt, doing so is not foolproof. In particular, if the attacker knows potentially more passwords for the same user's accounts elsewhere, it can classify the user's typical configuration better than the defender can. This advantage thus implies an increase in false negatives, which we will demonstrate in certain cases.

To summarize, our contributions are as follows:

- We formalize the false-positive and false-negative rates of honeywords in a model in which the attacker possesses passwords for the same user at other sites (obtained by, e.g., breaching those sites or phishing the user).
- Using these definitions and empirical datasets of compromised passwords, we show that existing honeyword-generation algorithms (and two honeyword-generation methods adapted from password-guessing attacks) exhibit poor tradeoffs between false negatives and false positives in this threat model. All the analyzed methods have a false-negative rate much higher than random guessing (i.e., it is often easy for false-negative attackers to distinguish the account password from honeywords) or a false-positive rate much higher than zero (i.e., it is often easy for false-positive attackers to induce false breach alarms).
- We conduct the first study of using honeywords to protect algorithmically generated passwords. Though relevant only for sites that reversibly encrypt their password databases (since password hashing, which is best practice, should render algorithmically generated passwords irrecoverable to an attacker who breaches the database), our study provides interesting findings in this setting. Using passwords gathered from popular password managers, we show that introducing honeywords without attention to the account's password being algorithmically generated offers little protection for existing honeyword-generation algorithms. We further explore the use of automatic password generators to generate honeywords when the account password is identified as being algorithmically generated itself, but find that the myriad configurations of these generators can be a pitfall for honeyword generation.

Due to space constraints, some of our results are detailed only in the full paper [20]. Source code for conducting our experiments is available from https://github.com/zonghaohuang007/honeywords-analysis.

2 Related Work

2.1 Honeywords

Since honeywords were first proposed [22], there have been several research efforts on designing honeyword-generation techniques [1,6,13,15,48] or evaluating their security, mostly against attacks trying to access a breached site's accounts without alerting the site to its breach. In their original proposal, Juels and Rivest defined an abstract model of a honeyword system and proposed several legacy-UI methods including *chaffing-by-tweaking* and *chaffing-with-a-password-model (modeling syntax)*, and one modified-UI method. The modified-UI method requires the authentication system to guide the user in the selection of her account password and thus has inherent usability challenges, and so we do not con-

sider it in this paper. The legacy-UI methods use random replacement of characters in the account password. We use one of them in this paper to represent this class of techniques, as discussed in Sec. 3. We also consider a method, called the "List" model in Sec. 3, that utilizes existing passwords as the honeywords for the site's accounts [46] (similar to Erguler [15]). A proposal by Dionysiou, et al. [13] leverages a machine learning model to search for similar passwords in the system and then generates n honeywords by tweaking the searched passwords randomly (e.g., by the chaffing-by-tweaking method), also described in Sec. 3. More recently, Yu and Martin [58] proposed to leverage the Generative Pre-trained Transformer 3 Model (GPT-3) [4] to generate honeywords. Their method includes two steps: first, a password-specific segmentation technique called PwdSegment [56] is used to extract chunks from the input password, and second, a prompt including the chunk information is provided as the input to GPT-3, which returns a list of passwords similar to the input password, used as honeywords. Wang and Reiter [53] proposed a honeyword-selection mechanism based on a Bernoulli selection that achieves tunable false positives.

Recent works have investigated the security of honeywords under *targeted-guessing attacks* where the attacker has personal identity information (PII) about the users. Wang, et al. [46] performed the first security analysis on honeywords under such attacks, but they focused only on the legacy-UI methods proposed by Juels and Rivest, empirically showing that these methods fail to achieve low false-negative rates. More recently, Wang, et al. [48] considered both PII and registration order (the time when the user accounts were created) as the auxiliary information available to the attacker. They proposed leveraging this auxiliary information in a password model like the List model, probabilistic context-free grammars (PCFG) [8], a Markov model [33], or a combination thereof, to generate honeywords. Their proposed methods achieved low false-negative rates under the threat model considered in their work [48]. However, our empirical results demonstrate that existing honeyword-generation techniques, including those considered by Wang, et al., have a high false-negative probability in our threat model. Setting a larger number of honeywords per account, as suggested by Wang, et al., generally lowers false-negative rates but increases false-positive rates. We are the first to systematically analyze the trade-off, showing that existing honeyword-generation methods suffer from high false-positive or false-negative rates under a threat model where the passwords of the same user from the other sites are exposed to attackers.

2.2 Password Guessing

A related topic to honeyword generation is password guessing, which is used to crack passwords [14, 55, 57] in an online or offline manner or used to evaluate their strength [10, 17, 23]. Since a honeyword is simply a decoy password, it is reasonable that honeyword research will benefit from the development of password guessing techniques. Weir, et al. [55] proposed the first method to utilize a probabilistic model to generate passwords. They designed the model using PCFGs trained on a training set of passwords and empirically demonstrated the effectiveness compared with word-mangling rule-based methods. Ma, et al. [24] leveraged a Markov model to learn the distribution of passwords. They showed that their proposed method achieved slightly better performance than PCFGs in password cracking when normalization and smoothing were used. Melicher, et al. [26] designed a password model using a recurrent neural network [34], which achieves improved accuracy in password strength measurement. Pasquini, et al. [30] utilized Generative Adversarial Networks (GAN) [18] to train a password generative model. They showed that the trained model can be used to produce passwords more effectively if a password template is known, due to the strong locality in the latent space of the generative model. Most recently, Xu, et al. [57] improved password guessing by learning a bi-direction transformer model.

Recent works showed that password guessing can be improved by utilizing account holder PII and passwords used by the same user at other sites. Wang, et al. [47] proposed a PCFG model named *TarGuess* where PII is considered in the model training. Pal, et al. [29] studied the case that attacker utilized the passwords used by the same users leaked from *another* site to crack password, known as *credential tweaking*. They trained a *Pass2Path* model by a recurrent neural network to simulate credential tweaking, which compromised at least 16% of user accounts in their tests. He, et al. [19] considered a similar threat model but improved the compromising rate using a deep neural transformer [42]. Recently, Wang, et al. [49] modeled password reuse behavior by a multi-step generative model, which improved the password guessing. In this paper, we adapted some of these techniques from *credential tweaking* (Tweak and P2P as described in Sec. 3) for honeyword generation.

2.3 Honeyword-Based Systems

Our study is agnostic to system designs leveraging honeywords, whether they be symmetric or asymmetric. Asymmetric designs are ones that detect honeyword entry using a secret that the attacker is presumed to be unable to capture in the breach. For example, the original honeyword-system design [22] leverages a trusted server called a *honeychecker* that holds the index of the legitimate password for each account, which the login server consults to determine whether a login attempt uses a honeyword or the legitimate password. This honeychecker is assumed to keep its indices secret despite the login server's breach. Other asymmetric designs include ErsatzPasswords [2] and Lethe [12].

By contrast, a symmetric design is one where the attacker is allowed to capture all state used for honeyword-entry detec-

$G \leftarrow \mathcal{B}(H \cup \{p\}, X)$
if $|G \cap H| < \alpha \wedge p \in G$
then return 1
else return 0

$\mathsf{FNP}_{\mathcal{U},\mathcal{H}_n,\alpha}(\mathcal{B}) \stackrel{\text{def}}{=} \mathbb{P}\left(\mathsf{Expt}^{\mathsf{FNP}}_{\mathcal{U},\mathcal{H}_n,\alpha}(\mathcal{B}) = 1\right)$

$\mathsf{FNP}_{\mathcal{U},\mathcal{H}_n,\alpha} \stackrel{\text{def}}{=} \max_{\mathcal{B}} \mathsf{FNP}_{\mathcal{U},\mathcal{H}_n,\alpha}(\mathcal{B})$

(b) False-negative probability

Figure 1: Measures for breach detection by honeywords. A false-positive attacker $\mathcal{A}$ tries to trick an unbreached site into detecting that it has been breached (Fig. 1a). A false-negative attacker $\mathcal{B}$ attempts to access an account after breaching the site, without alerting the site to its breach (Fig. 1b).

tion when he breaches the site. An example of a symmetric design is Amnesia [52]. In this design, the attacker captures all the information needed to undetectably access an account—possibly using a honeyword—at a site it breaches. However, the act of doing so configures the site to learn of its breach once the legitimate user accesses the site subsequently, using a different password. That is, in Amnesia, the use of two different passwords to enter an account is what alerts the site to its breach, since one must be a honeyword.

3 Background

3.1 Definitions

Honeywords are decoy passwords added to each account entry in a credential database. The principle behind honeywords is that since the legitimate user does not know the honeywords generated for her account, the only party who is able to enter those honeywords is an attacker who discovered them by breaching the credential database. As such, login attempts using honeywords should be taken as compelling evidence of a database breach.

To make this principle precise, we define the false-positive and false-negative probabilities of a honeyword scheme in a way that abstracts away the details of the system leveraging them. We do so using the experiments shown in Fig. 1 and described in text below. In these experiments, a random user is modeled by a randomized algorithm $\mathcal{U}$, by which the user selects her password $p \in \{0,1\}^*$ for a site. The invocation $\mathcal{U}()$ outputs not only the password p, but also auxiliary information $X \subset \{0,1\}^*$ that is correlated with p and that the attacker might learn. In this work, X will be passwords set by the same user at other sites, though other works have considered other types of auxiliary information (e.g., [46]). Given p, the site selects honeywords for this account using the randomized algorithm $\mathcal{H}_n$, which outputs a set H where $|H| = n$ and $p \notin H$.

A *false-positive attacker* $\mathcal{A}$ attempts to trigger a breach alarm at this site even though it has not breached the site, by leveraging its knowledge of p and $\mathcal{H}_n$ to guess honeywords in H. In this work, we consider the worst case where $\mathcal{A}$ is permitted to know p since $\mathcal{A}$ might represent a legitimate user of this site or because it might represent an outsider who, say, phished p. $\mathcal{A}$ might know X but X does not help in guessing H if p is already known. $\mathcal{A}$ is provided knowledge of the honeyword-generation algorithm $\mathcal{H}_n$ to provide a conservative analysis.[1] $\mathcal{A}$'s probability of triggering an alarm is defined in Fig. 1a, where $\alpha \ge 1$ is the number of honeywords whose entry will trigger a breach alarm and where $\beta \ge 1$ denotes the number of login attempts $\mathcal{A}$ is permitted to attempt for this account. In words, given p (along with $\mathcal{U}$, $\mathcal{H}_n$, α, and β, which are public parameters of the experiment), $\mathcal{A}$ wins by outputting a set G that it can enter in its budget of login attempts ($|G| \le \beta$) and that will trigger an alarm ($|G \cap H| \ge \alpha$). Traditionally the threshold for raising a breach alarm has typically been set to $\alpha = 1$, though this definition permits other values; A larger α implies a more stringent condition for raising an alarm. $\mathcal{A}$'s *false-positive probability* $\mathsf{FPP}_{\mathcal{U},\mathcal{H}_n,\alpha,\beta}(\mathcal{A})$ is the probability that $\mathcal{A}$ wins, and the overall false-positive probability $\mathsf{FPP}_{\mathcal{U},\mathcal{H}_n,\alpha,\beta}$ is $\mathsf{FPP}_{\mathcal{U},\mathcal{H}_n,\alpha,\beta}(\mathcal{A})$ for the attacker algorithm $\mathcal{A}$ that maximizes that probability. When the parameters $\mathcal{U}$, $\mathcal{H}_n$, α, and β are clear from context, we will abbreviate $\mathsf{FPP}_{\mathcal{U},\mathcal{H}_n,\alpha,\beta}(\mathcal{A})$ and $\mathsf{FPP}_{\mathcal{U},\mathcal{H}_n,\alpha,\beta}$ as $\mathsf{FPP}(\mathcal{A})$ and FPP, respectively, to simplify notation.

In contrast, a *false-negative attacker* $\mathcal{B}$ is an attacker who attempts to access this user's account after breaching the site but without alerting the site that it has been breached. This adversary's advantage in doing so is defined in Fig. 1b. In words, $\mathcal{B}$ obtains the set $H \cup \{p\}$, sometimes called the *sweetwords* for this account, as well as auxiliary information X. The set $H \cup \{p\}$ is sweetwords are recovered by the attacker from the salted hash file. $\mathcal{B}$ then wins if it outputs a set G that will not trigger an alarm ($|G \cap H| < \alpha$) and that permits it to access the account ($p \in G$). Here we presume that $G \subseteq H \cup \{p\}$, since passwords other than the sweetwords outside $H \cup \{p\}$ offer no help for $\mathcal{B}$ to achieve his goals. Consequently, we drop β as a parameter of the experiment; since $\beta \ge \alpha \ge |G|$, it does not constrain $\mathcal{B}$'s choice of G. Again, traditionally the threshold for raising a breach alarm has been set

[1] Allowing $\mathcal{A}$ knowledge of $\mathcal{H}_n$ conforms with general security design principles; e.g., "Do not rely on secret designs, attacker ignorance, or *security by obscurity*." [41, p. 21]. In our context specifically, if the attacker knows only that $\mathcal{H}_n$ is one of several alternatives, it can try each alternative via a different account. In this sense, our measure is analogous to the *min auto* approach to measuring password strength [28, 40], in which the strength of a password is measured by the number of tries to guess it, under the guessing strategy (from among several) that minimizes that number.

to $\alpha = 1$, in which case the probability with which $\mathcal{B}$ guesses p from the sweetwords $H \cup \{p\}$ on the first try (i.e., $|G| = 1$) is called the *flatness* of the honeyword scheme. $\mathcal{B}$'s *false-negative probability* $\mathsf{FNP}_{\mathcal{U},\mathcal{H}_n,\alpha}(\mathcal{B})$ is the probability that $\mathcal{B}$ wins, and the overall false-negative probability $\mathsf{FNP}_{\mathcal{U},\mathcal{H}_n,\alpha}$ is $\mathsf{FNP}_{\mathcal{U},\mathcal{H}_n,\alpha}(\mathcal{B})$ for the attacker $\mathcal{B}$ that maximizes that probability. When the parameters $\mathcal{U}$, $\mathcal{H}_n$, and α are clear from context, we will abbreviate $\mathsf{FNP}_{\mathcal{U},\mathcal{H}_n,\alpha}(\mathcal{B})$ and $\mathsf{FNP}_{\mathcal{U},\mathcal{H}_n,\alpha}$ as $\mathsf{FNP}(\mathcal{B})$ and FNP, respectively, to simplify notation.

A honeyword-generation algorithm $\mathcal{H}_n$ can at best achieve $\mathsf{FPP} \approx 0$ and $\mathsf{FNP} = \frac{\alpha}{n+1}$. Our research evaluates the extent to which known honeyword-generation algorithms, described in Sec. 3.2, approach this ideal. When considering false-negative attackers, we will evaluate an attacker who prioritizes accounts by its perceived likelihood of success in guessing the account password p, by refining $\mathcal{U}$ to represent "easy" users for whom $(H \cup \{p\}) \cap X \neq \emptyset$, likely due to exact password reuse across accounts; "medium" users who are not "easy" but for whom there are elements of $H \cup \{p\}$ and X that are close to one another (in a sense we will define later), likely because the user set passwords at her other accounts that are similar to p (partial password reuse); or "hard" users for whom neither condition holds.

3.2 Honeyword-Generation Algorithms

In this section, we introduce honeyword-generation algorithms, some of which have been introduced in previous works [13, 22, 48]. Generally, honeyword-generation algorithms can be classified into two groups: *password-independent* algorithms and *password-dependent* algorithms. We included more details of these algorithms in the full paper [20, App. C].

3.2.1 Password-Independent Honeyword Generation

Password-independent algorithms generate honeywords independently of the account passwords. They do so by sampling password candidates from *password models* pretrained on a multiset of passwords. In this work, we consider four widely used password models: list model [46], probabilistic context-free grammar model [55], Markov model [24], and recurrent neural network [26], and their combination [48]. We denote these generation methods as List, PCFG, Markov, RNN, and Combo, respectively.

3.2.2 Password-Dependent Honeyword Generation

Password-dependent algorithms generate honeywords that are dependent on the account passwords. These algorithms include password-strength-dependent methods and password-context-dependent methods.

Password-strength-dependent methods generate honeywords whose strength is equal or similar to the input password p. These methods still leverage password models such as List, PCFG, Markov, RNN, or their combination but select a sampled candidate as a honeyword if and only if its strength is equal to that of the input password. However, if the input password is weak, it might be difficult to generate n honeywords with equal password strength, under the hypothesis that user-chosen passwords follow a Zipf distribution (e.g., [45]). So, in this work, we relax this requirement so that a sampled candidate will be used as a honeyword if its length equals the length of the input password. We denote this algorithm for generating honeywords from List, PCFG, Markov, RNN, or a combined method by List$*$, PCFG$*$, Markov$*$, RNN$*$, and Combo$*$.

Password-context-dependent methods generate honeywords by modifying the input password. Here we consider four types of techniques: targeted password model-based generation, LLM-based generation, random replacement-based tweaking, and DNN-based tweaking.

Targeted password model-based generation: These methods generate honeywords from password models that learn a distribution of *password templates* [48]. Here a password template is a pattern describing passwords set by the same user at different sites, wherein common substrings are indicated in the template using a special tag `pwd_str`. For example, the template "`pwd_str` z" might be generated from "bike123z" and "bike123" if these passwords were set by the same user at two different sites. Password models like PCFG are pretrained on a multiset of password templates, as targeted password models. Then, honeywords are generated by sampling templates from the targeted password models and replacing `pwd_str` in the templates with the input password. We denote these generation methods from List, PCFG, Markov, RNN, or a combined method by List#, PCFG#, Markov#, RNN#, and Combo#.

LLM-based generation: These techniques generate honeywords by querying a large language model like GPT-3 [4] with prompts based on the input password. We consider a recently proposed method, chunk-level GPT-3 (CGPT3) [58].

Random replacement-based tweaking: These techniques generate honeywords by randomly changing some characters of the input password or similar passwords. We consider chaffing-by-tweaking or CBTt [22], which generates honeywords by randomly replacing the last t characters of the input password with characters of the same type; CBT$*$ [13], which generates honeywords by similarly replacing all the characters; and chaffing-by-a-hybrid-model (CHM [13]).

DNN-based tweaking: DNN-based tweaking techniques leverage DNNs to tweak the chosen password to generate its honeywords. We consider a deep tweak model (Tweak) [19] and tweaking path model (P2P) [29], which are adapted from similar constructions originally developed to crack passwords [19, 29]. The deep tweak model is a DNN that, on input a password, outputs a tweaked password. The tweaking path

model inputs a password and outputs an edit path that is used to change the input password.

4 User-Chosen Passwords

The first case we consider is when $\mathcal{U}$ is an algorithm implemented by an average human user, and X is a multiset of passwords chosen by the same user at other sites. In this case, we show that the field has yet to identify *any* honeyword-generation algorithm that achieves small FNP and FPP simultaneously. Intuitively, this is true because when a user selects passwords without automated help (i.e., $\mathcal{U}$ is an average user), then an attacker who guesses passwords G that are similar to passwords in X will be highly effective in either inducing false detections (a high $\mathsf{FPP}(\mathcal{A})$) or avoiding true detection (a high $\mathsf{FNP}(\mathcal{B})$). On the one hand, if $\mathcal{H}_n(p)$ outputs honeywords dissimilar to p, then since users often choose p similar to elements of X, it will be relatively easy for an attacker $\mathcal{B}$ to select p from $H \cup \{p\}$ as the one most similar to passwords in X. So, for $\mathsf{FNP}(\mathcal{B})$ to be small, $\mathcal{H}_n(p)$ must output at least some honeywords that are similar to p. On the other hand, the more it does so, the easier it is for an attacker $\mathcal{A}$ to induce false detections by guessing passwords G similar to passwords in X.

4.1 Attack Strategies

In this section, we introduce the false-positive attacker $\mathcal{A}$ and the false-negative attacker $\mathcal{B}$ that we use in the evaluation of $\mathsf{FPP}(\mathcal{A})$ and $\mathsf{FNP}(\mathcal{B})$, respectively.

False-positive attacker $\mathcal{A}$: In the evaluation of $\mathsf{FPP}(\mathcal{A})$, recall that $\mathcal{A}$ is given access to p. The attacker $\mathcal{A}$ leverages the honeyword-generation algorithm $\mathcal{H}$ on input p to generate a set of honeyword candidates. Then, if applicable, it sorts the candidates by the probabilities assigned by the honeyword-generation algorithm and uses the top β candidates as the guessed honeywords G; otherwise, it picks β candidates uniformly at random without replacement as G.

False-negative attacker $\mathcal{B}$: We evaluate $\mathsf{FNP}(\mathcal{B})$ for user-chosen passwords as follows. Given passwords X, $\mathcal{B}$ leverages a metric function $d(\cdot) : \{0,1\}^* \times \{0,1\}^* \to \mathbb{R}$ to measure the similarity between the elements of X and the sweetwords $H \cup \{p\}$, and ranks each sweetword based on its similarity to the most similar element of X. The top α ranked sweetwords are used to guess p.

4.2 Model to Measure Password Similarity

In the evaluation of $\mathsf{FNP}(\mathcal{B})$, we need to define a metric function that inputs a pair of passwords and returns a score reflecting the similarity between the inputs. To formulate such a metric function, we designed a similarity model $f(\cdot) : \{0,1\}^* \to \mathbb{R}^d$ by a deep neural network, which takes as input a password p and outputs its *latent representation* such that the cosine similarity between any two latent representations $f(p)$ and $f(p')$ grows with the probability that $\mathcal{U}()$ would have output both, i.e., with $\mathbb{P}\big(p' \in X \;\big|\; (p,X) \leftarrow \mathcal{U}()\big)$.

The similarity model is used to learn the embedding of passwords. Learning such an embedding of passwords into a latent space is essentially a *metric learning* problem [37, 50]. Therefore, we applied contrastive learning, which is one of the most widely used frameworks to train a model to perform this embedding so as to maximizing cosine similarity between positive (similar) pairs while minimizing cosine similarity of negative (dissimilar) pairs [7]. Training a contrastive model is performed in *batches*, each a multiset $B \subseteq \{0,1\}^* \times \{0,1\}^*$. Each $(p,p') \in B$ consists of similar passwords (intuitively, for which $\mathbb{P}\big(p' \in X \;\big|\; (p,X) \leftarrow \mathcal{U}()\big)$ is high), whereas for any $(p'',p''') \in B \setminus \{(p,p')\}$, p and p'' are presumed to be dissimilar, as are p' and p'''. Training for a contrastive learning model of password similarity, therefore, updates f to minimize a *loss function*, which typically would take the form

$$\operatorname*{avg}_{(p,p')\in B} -\log \frac{\exp(\mathsf{sim}(f(p),f(p')))}{\sum\limits_{\substack{(p'',p''')\in B:\\ (p'',p''')\neq(p,p')}} \begin{pmatrix}\exp(\mathsf{sim}(f(p),f(p''))) + \\ \exp(\mathsf{sim}(f(p'),f(p''')))\end{pmatrix}} \tag{1}$$

where sim denotes cosine similarity (see Chen, et al. [7]). Such updates with all the data samples from the training dataset passed through the trained model constitute one *epoch*. The design and training of the similarity model are described in the full paper [20, App. B].

4.3 Evaluation

In this subsection, we detail our evaluation of the user-chosen password case, which includes the used dataset, and the experimental results for $\mathsf{FPP}(\mathcal{A})$ and $\mathsf{FNP}(\mathcal{B})$.

4.3.1 The Dataset

The dataset we used in the case of user-chosen passwords is the *4iQ* dataset [5], consisting of 1.4 billion (email, password) pairs, of which 1.1 billion emails and 463 million passwords are unique. Others attribute the *4iQ* dataset to various leaks from LinkedIn, Myspace, Badoo, Yahoo, Twitter, Zoosk, and Neopet, and have used it to analyze users' choices of passwords across sites [29] (despite the possibility of some being automatically generated). Our use of leaked passwords was approved by our IRB, which specified protections in our handling of this data

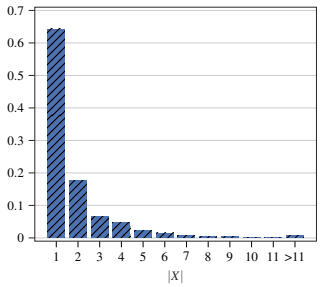

Figure 2: Distribution of $|X|$

Statistic	Value
Total number of users	195,894,983
Total number of passwords	563,743,130
Average passwords per user	2.877
Average distinct passwords per user	1.961
Percentage of users reusing passwords	48.507%

Table 1: Statistics of the preprocessed dataset

(who could access the data, what results could be reported, etc.). In order to use *4iQ*, we preprocessed the dataset by referring to previous works (e.g., [29]).

- **Cleaning:** We removed any (email, password) pairs that satisfied any of the following conditions: the password contained non-ASCII characters, the space character, or a substring of 20 (or more) hex characters; the password had a length of less than 4 or more than 30; or the email contained non-ASCII characters or the space character.
- **Joining by email and username:** For each email address addr appearing in the dataset, we collected the passwords appearing with that email address into a multiset S_{addr}. Then we merged some password multisets S_{addr} as follows: two multisets were merged if they contained at least one password in common and if the username parts of their email addresses were the same. We then eliminated each S_{addr} containing only one password or $> 1{,}000$ passwords. In the resulting dataset, around 48% of users reused passwords, which is within the range between 43% and 51% estimated by previous work (e.g. [9]). More statistics about the resulting dataset are shown in Table 1.
- **Splitting into training and testing sets:** Of the 195,894,983 password multisets that remained, 80% (156,722,455 multisets with 451,020,019 passwords) were set aside as training sets $D_{\mathsf{u}}^{\mathsf{tr}}$ used to train models. The other 20% (39,172,528 multisets with 112,723,111 passwords) of the password multisets were set aside as testing sets $D_{\mathsf{u}}^{\mathsf{te}}$. When evaluating $\mathsf{FNP}(\mathcal{B})$ and $\mathsf{FPP}(\mathcal{A})$, the algorithm $\mathcal{U}$ was implemented by choosing p and the members of X without replacement from a single multiset S_{addr} chosen uniformly at random from the testing sets, and returning (p,X) as the result with $X = S_{\mathsf{addr}} \setminus \{p\}$. $|X|$ represents the amount of attacker's knowledge about this user's passwords at other sites. Its distribution in $D_{\mathsf{u}}^{\mathsf{te}}$ is shown in Fig. 2.

4.3.2 Experimental Results

We now report $\mathsf{FPP}(\mathcal{A})$ and $\mathsf{FNP}(\mathcal{B})$ for the attackers $\mathcal{A}$ and $\mathcal{B}$ described in Sec. 4.1. To depict the tradeoffs between these measurements, we plot them against one another as α is varied. When evaluating $\mathsf{FNP}(\mathcal{B})$, we isolate three subcases, to permit modeling of an attacker who prioritizes accounts based on similarities between $H \cup \{p\}$ and X per account. We measured such similarity based on definitions like those for password reuse introduced in previous work (e.g., [31]). Specifically, "easy" accounts are those for which $(H \cup \{p\}) \cap X \neq \emptyset$; "medium" accounts are those for which $(H \cup \{p\}) \cap X = \emptyset$ but there is a sweetword in $H \cup \{p\}$ that shares a substring of length at least four characters with some password in X; and "hard" accounts are those that are neither "easy" nor "medium". The percentages of accounts of different hardness are shown in Table 2.

	$n = 19$			$n = 99$		
$\mathcal{H}_n$	easy	med	hard	easy	med	hard
List	43.37	16.00	40.63	43.56	19.62	36.82

Table 2: Percentages of accounts of different hardness for a false-negative attacker $\mathcal{B}$, discussed in Sec. 4.3.2

Fig. 3 shows the tradeoffs between $\mathsf{FPP}(\mathcal{A})$ and $\mathsf{FNP}(\mathcal{B})$ for $n = 19$ honeywords and $\beta = 1000$, for the various honeyword-generation algorithms described in Sec. 3. RNN and its variants achieved similar performance to List, PCFG, Markov, Combo, and their variants, and thus we only show the results from List, PCFG, Markov, Combo, and their variants in Fig. 3; results for RNN and its variants are in the full paper [20, App. C]. In each plot, there are four curves presenting the overall tradeoff ("all") and those of three subcases: "easy", "medium", and "hard". In each curve, markers highlight the $\mathsf{FPP}(\mathcal{A})$ vs. $\mathsf{FNP}(\mathcal{B})$ tradeoff at a specific values of α ranging from $\alpha = 1$ to n. Intuitively, a smaller α yields lower $\mathsf{FNP}(\mathcal{B})$ but higher $\mathsf{FPP}(\mathcal{A})$ and so a marker closer to the top left corner. Increasing α to n yields a higher $\mathsf{FNP}(\mathcal{B})$ but lower $\mathsf{FPP}(\mathcal{A})$ and so a marker closer to the bottom right corner. We stress that $\beta = 1000$ yields an optimistic evaluation of $\mathsf{FPP}(\mathcal{A})$. For example, Florêncio, et al. [16] recommend that an account should withstand targeted online password-guessing attacks of 10^6 attempts in practice. As such, arguably

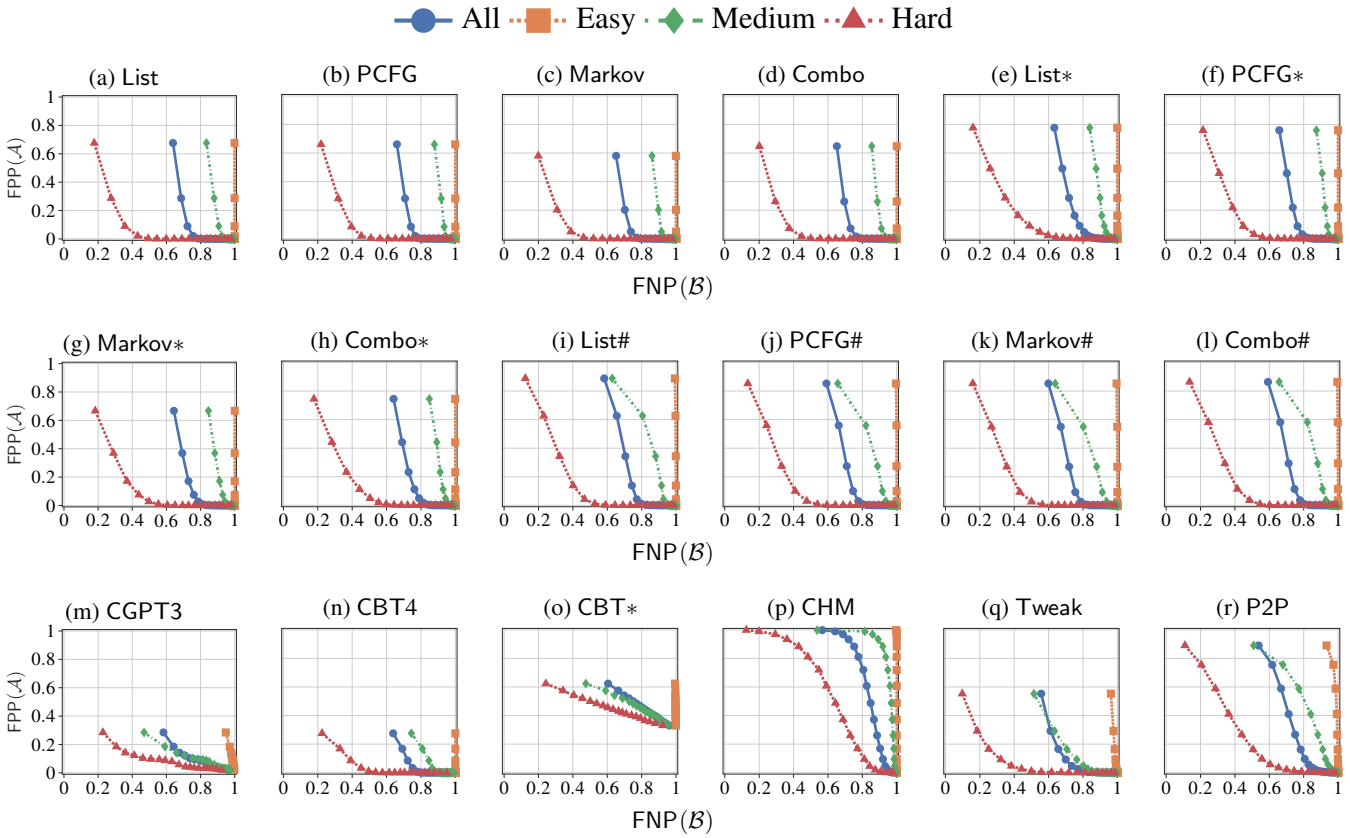

Figure 3: FPP($\mathcal{A}$) vs. FNP($\mathcal{B}$) as α is varied, for the case of user-chosen passwords ($n = 19$, $\beta = 1000$). The best FNP($\mathcal{B}$) are 0.54 (P2P, Fig. 3r), 0.56 (Tweak, Fig. 3q), 0.57 (CHM, Fig. 3p), and 0.58 (CGPT3, Fig. 3m); all others have FNP($\mathcal{B}$) > 0.59. All suffer FPP($\mathcal{A}$) > 0.27 at $\alpha = 1$. Those that reach FPP($\mathcal{A}$) ≈ 0 do so with FNP($\mathcal{B}$) > 0.81.

$\beta = 1000$ is $1000\times$ too small.

An ideal honeyword-generation algorithm would achieve FPP($\mathcal{A}$) ≈ 0 and FNP($\mathcal{B}$) $= \frac{1}{n+1}$ (which is 0.05 when $n = 19$) at $\alpha = 1$. Unfortunately, no known honeyword algorithm comes close. As seen in Fig. 3, the best FNP($\mathcal{B}$) that the honeyword-generation techniques accomplish overall is 0.54 (P2P, Fig. 3r), 0.56 (Tweak, Fig. 3q), 0.57 (CHM, Fig. 3p), and 0.58 (CGPT3, Fig. 3m); all others have FNP($\mathcal{B}$) > 0.59. When we consider the attacker prioritizing "easy" accounts, FNP($\mathcal{B}$) of P2P, CGPT3, and Tweak are at least 0.93, 0.95, and 0.96, respectively, while others have FNP($\mathcal{B}$) ≈ 1. This indicates that the false-negative attacker can break at least 43% accounts by targeting the "easy" ones, with only P2P, CGPT3, and Tweak presenting any significant chance of catching the attacker. That said, when such an attacker wants to guess more account passwords, i.e., targeting the "medium" accounts after the "easy" ones, the probability of inducing an alarm will increase with number of attacked accounts since FNP($\mathcal{B}$) < 0.88 for the "medium" subcase when $\alpha = 1$. The four most successful algorithms (P2P, Tweak, CHM, and CGPT3) are password-context-dependent techniques that generate honeywords similar to the account password, and thus it is more challenging for $\mathcal{B}$ to distinguish the account password from honeywords produced by these algorithms than from those of the other methods. We conclude that honeywords more similar to the account password yield a lower FNP($\mathcal{B}$), though one that is still far from $\frac{1}{n+1}$ due to password reuse.

However, P2P has FPP($\mathcal{A}$) ≈ 0.89 at $\alpha = 1$, where most others have lower FPP($\mathcal{A}$). The only exception is CHM, which includes a deterministic step that searches for nearest neighbors of the account password and thus yields a high false-positive rate, FPP($\mathcal{A}$) ≈ 1. While P2P is the best technique for generating honeywords similar to the account password, it is almost the easiest for the false-positive attacker to guess the generated honeywords with p known. Still, no generation method achieves FPP($\mathcal{A}$) ≤ 0.27 at $\alpha = 1$. Growing α of course reduces FPP($\mathcal{A}$) but increases FNP($\mathcal{B}$): all methods capable of reaching FPP($\mathcal{A}$) ≈ 0 do so with FNP($\mathcal{B}$) > 0.81 overall, FNP($\mathcal{B}$) ≈ 1 for the "easy" subcase, and FNP($\mathcal{B}$) > 0.91 for the "medium" subcase.

A natural method to decrease FNP($\mathcal{B}$) would be to increase the number n of honeywords, but the more pronounced effect of doing so is increasing FPP($\mathcal{A}$), instead. Indeed, Fig. 4 shows the impact of increasing n to $n = 99$. As seen there, an

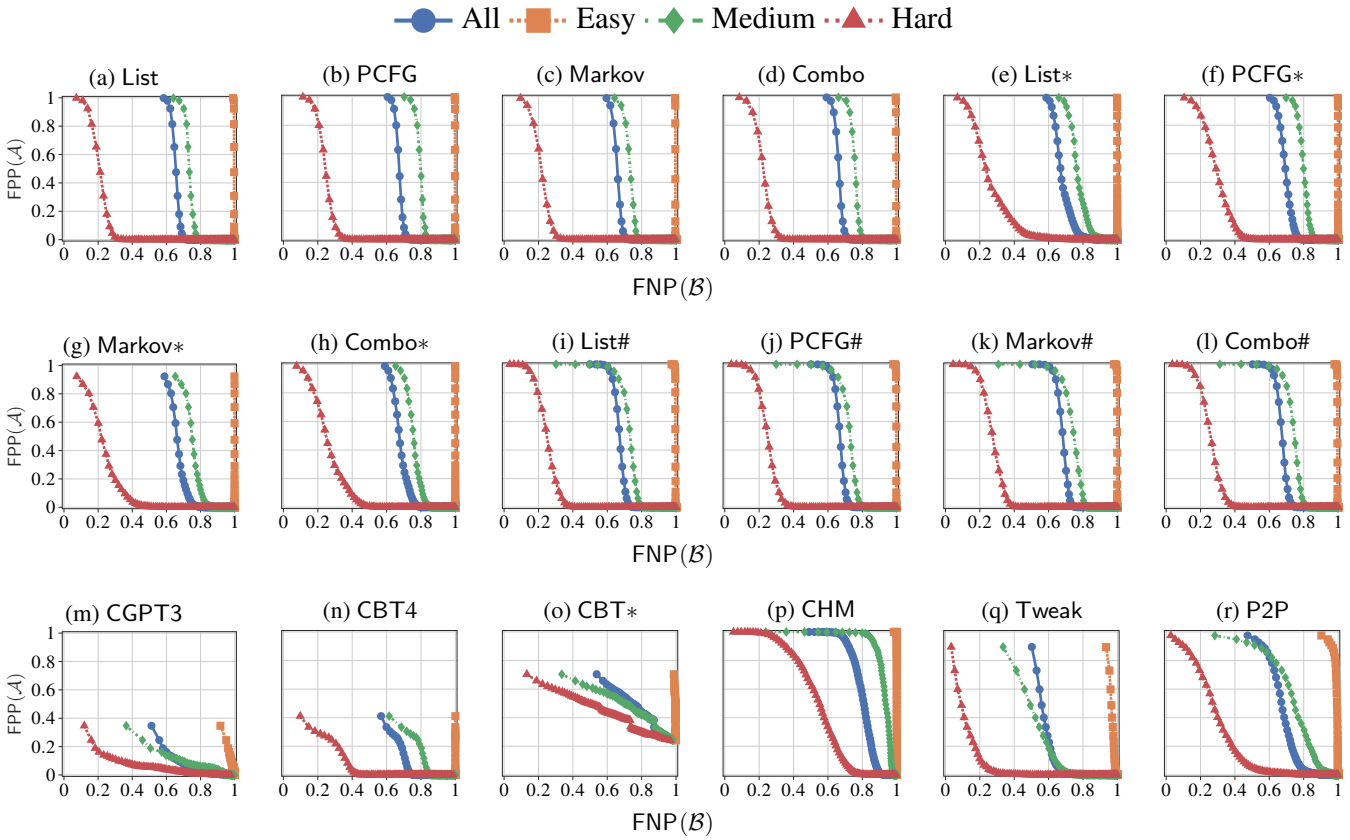

Figure 4: FPP($\mathcal{A}$) vs. FNP($\mathcal{B}$) as α is varied, for the case of user-chosen passwords ($n = 99$, $\beta = 1000$). The best FNP($\mathcal{B}$) are 0.47 (P2P, Fig. 4r), 0.49 (CHM, Fig. 4p), and 0.50 (Tweak, Fig. 4q); all others have FNP($\mathcal{B}$) > 0.50. All suffer FPP($\mathcal{A}$) > 0.34 at $\alpha = 1$. Those that reach FPP($\mathcal{A}$) ≈ 0 do so with FNP($\mathcal{B}$) > 0.72.

order-of-magnitude increase in n resulted in a slight improvement to FNP($\mathcal{B}$) in each case, but a more substantial increase to FPP($\mathcal{A}$).

To summarize, honeyword-generation techniques like Combo# that have been demonstrated to have good flatness in previous works (e.g., [48]) fail to achieve a low false-negative rate in our threat model, particularly not at settings of α to ensure a small false-positive rate. Among the honeyword-generation techniques we consider, P2P achieves the best FNP but has a high FPP. Most other methods have lower FPP but a higher FNP. Regardless, in the case of user-chosen passwords, no existing algorithm achieves low rates of both false positives and false negatives. In addition, when the attacker targets the "easy" accounts that are approximately 43% of users, all the honeyword-generation methods are ineffective in detecting a breach at settings of α achieving FPP($\mathcal{A}$) ≈ 0.

5 Algorithmically Generated Passwords

The second case we consider is when $\mathcal{U}$ is implemented using a password-generating algorithm. To our knowledge, this case has not been considered in prior honeyword research, and with good reason: Under the best practice of storing only preimage-resistant hashes of passwords, it should be exceptionally difficult for an attacker who breaches a site's database to recover algorithmically generated passwords, due to their comparatively high strength. For this reason, algorithmically generated passwords in a breached credential database are primarily at risk if the hash function is less preimage-resistant than initially thought or when the site's database was reversibly encrypted—which, while not best practice, is necessary in some use cases (e.g., [27])—and the false-negative attacker recovered the decryption key along with the database.

We assume there is a large but limited number Y of password generators denoted as $\{\mathcal{U}_y\}_{y=1}^{Y}$, each of which is defined by an algorithm and values of user-configurable parameters. We assume that each user determines $\mathcal{U}$ by choosing a generator uniformly at random from $\{\mathcal{U}_y\}_{y=1}^{Y}$, and that each user stays with its choice. To justify this assumption, in Sec. 6.4 we report a brief study we did using the password policies of 20 commonly visited websites and Tranco Top 1M websites [32], where we found that setting passwords at these websites in a random order would permit the user to retain her chosen password-generation configuration for > 6.3 sites

in expectation, before encountering a site for which the user's configuration was inconsistent. This finding is consistent with Alroomi et al. [3], who reported that only 15% sites have character constraints on password creation.

We assume the length of the generated passwords is one parameter that users can configure. Some password managers permit user configuration of allowable symbols, as well. Similarly, password managers that enable generation of easy-to-read passwords might avoid use of certain characters that are ambiguous in some fonts (e.g., "1" vs. "l" in sans-serif fonts). Password managers that generate easy-to-say passwords might restrict the symbols used in different positions of a password. We will see examples below. The user's choice of these parameters will generally be unknown to the defender, except as revealed by the account password p.

In this section, we analyze the contribution of honeywords for detecting credential database breaches for accounts with algorithmically generated passwords. In the full paper [20, App. E], we show that honeyword-generation methods used in the user-chosen password case fail to achieve both low false-negative rate and low false-positive rate for algorithmically generated passwords. Although utilizing password-generation algorithms to generate honeywords can do better, in this section we show that the choice of selected generator is critical to achieving a low false-negative rate.

5.1 Attack Strategies

In this section, we introduce the false-positive attacker $\mathcal{A}$ and the false-negative attacker $\mathcal{B}$ used in the evaluation of $\mathsf{FPP}(\mathcal{A})$ and $\mathsf{FNP}(\mathcal{B})$, respectively, when account passwords are generated algorithmically.

False-positive attacker $\mathcal{A}$: $\mathcal{A}$ uses the same strategy used in the case of user-chosen passwords in Sec. 4.1. Specifically, the attacker $\mathcal{A}$ leverages the honeyword-generation algorithm $\mathcal{H}$ to generate a set of candidates and sorts the candidates by their assigned probabilities, if applicable. Finally, it picks the top β candidates as the guessed honeywords G.

False-negative attacker $\mathcal{B}$: $\mathcal{B}$ was implemented as follows. Given X, $\mathcal{B}$ leverages a classifier $f(\cdot) : \{0,1\}^* \to [0,1]^Y$ that outputs a confidence score per possible class. The construction of this classifier is described in the full paper [20, App. D]. $\mathcal{B}$ classifies each element of X using f, using the highest-scored generator for each $p' \in X$ as a "vote" for the password generator that the user employs; the password generator obtaining the most such votes is denoted $\mathcal{U}_{y_\mathcal{B}}$. Then $\mathcal{B}$ assigns scores to the sweetwords from $H \cup \{p\}$ as follows: if the length of the sweetword is the same as those in X, $\mathcal{B}$ utilizes the classifier $f(\cdot)$ to value the sweetword by the confidence score of being from class $y_\mathcal{B}$; otherwise, $\mathcal{B}$ will value it by 0. The attacker ranks the sweetwords based on the assigned scores and uses the top α sweetwords as G.

5.2 Generating Honeywords Using Algorithmic Password Generators

The honeyword-generation methods introduced in Sec. 3.2 do not fare well (in terms of false-negative probability) when the account password is generated algorithmically. Intuitively, the password-independent honeyword generators fail to achieve a low $\mathsf{FNP}(\mathcal{B})$ since the honeywords they generate are user-chosen passwords, which makes it easy for $\mathcal{B}$ to distinguish the algorithmically generated account password from the honeywords. Many password-dependent generators do little better, because even though the account password is algorithmically generated, these models are trained on artifacts of human behavior, which renders the honeywords recognizable to $\mathcal{B}$. The primary exceptions are CBT3 and CBT4, which are not trained at all. These can achieve a low $\mathsf{FNP}(\mathcal{B})$, though still with a too-high $\mathsf{FPP}(\mathcal{A})$. We have empirically demonstrated these findings in the full paper [20, App. E].

Therefore, here we consider the use of algorithmic password generators to generate honeywords for algorithmically generated passwords submitted by the user. Given an account password p, the honeyword system selects a generator from $\{\mathcal{U}_y\}_{y=1}^Y$ and then leverages the selected generator to generate n honeywords. We categorize the methods based on the selection strategy, as follows:

- FXED: Given a fixed $\mathcal{U}_{y_{\mathsf{fx}}} \in \{\mathcal{U}_y\}_{y=1}^Y$, $\mathcal{H}_n$ samples n distinct honeywords using $\mathcal{U}_{y_{\mathsf{fx}}}$ to build H.
- RAND: $\mathcal{H}_n$ samples a $\mathcal{U}_y$ uniformly from $\{\mathcal{U}_y\}_{y=1}^Y$ and builds H by sampling n distinct honeywords using $\mathcal{U}_y$.
- CLSD: $\mathcal{H}_n$ classifies the account password into one of Y classes, indicating the generator $\mathcal{U}_y$ most likely to have generated it. $\mathcal{H}_n$ then builds H by sampling n distinct honeywords using $\mathcal{U}_y$.

5.3 Evaluation

5.3.1 Dataset

The datasets we used to evaluate honeyword-generation strategies in the case of algorithmically generated passwords were synthetically produced by querying online password generators.[2] Specifically, after browser-integrated password managers (Google Password Manager and iCloud Keychain), LastPass and 1Password are two of the most widely used password managers/generators [44]. LastPass permits the user to select one of three password-generation algorithms, namely "Easy-to-say", "Easy-to-read", or "All-characters". For each type, users can further specify the generator by checking or unchecking "Uppercase", "Lowercase", "Numbers", or "Symbols", though the "Easy-to-say" generator does not permit inclusion of Symbols or Numbers. 1Password allows users to

[2] We used PyAutoGui (https://pyautogui.readthedocs.io/en/latest/) to automate interactions with the password managers like 1Password and LastPass. That is, we automated generating random passwords, copying them into the clipboard, and storing them in a local file interactively.

(a) Honeyword generator $\mathcal{H}_n$ (b) Attacker $\mathcal{B}$

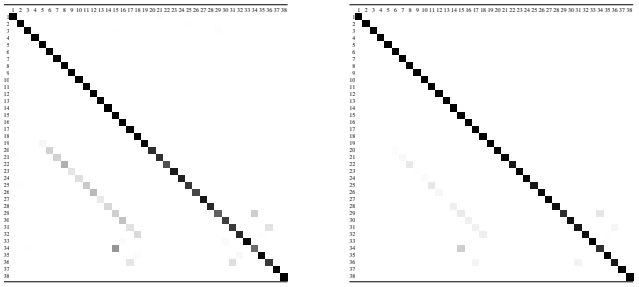

Figure 5: Confusion matrices: Probability with which a password of one class (row) is classified as another class (column) by $\mathcal{H}_n$ (Fig. 5a) or $\mathcal{B}$ with $|X| > 1$ (Fig. 5b). Box shading is scaled linearly between 0.0 (white) and 1.0 (black).

select a type of password from among "Random Password", "Memorable Password", and "Pin". The Random Password generator includes Lowercase and Uppercase letters always, but users can check or uncheck Numbers and Symbols. The Memorable Password algorithm generates memorable passwords, each of which is a sequence of word fragments connected by separators. In this option, users can select separators among "Hyphens", "Spaces", "Periods", "Commas", "Underscores", "Numbers", and "Numbers and Symbols". In addition, users could check or uncheck "Full Words" and "Capitalize" to specify the "Memorable Password" generator. In this work, we used all the configurations from LastPass and 1Password's Random Password, and selected configurations for 1Password's Memorable Password. We consider passwords generated from each specification as one class, yielding 38 classes in total. These classes are shown in Table 3. We set the fixed $\mathcal{U}_{y_{\mathsf{fx}}}$ to be the "All characters" generator from LastPass with "U", "L", "S", and "N" checked ($y_{\mathsf{fx}} = 32$).

Using these online generators, we generated three datasets, denoted $D^{\mathsf{tr}}_{\mathsf{a}}$, $D^{\mathsf{va}}_{\mathsf{a}}$, and $D^{\mathsf{te}}_{\mathsf{a}}$, all consisting of passwords of length 14 only. We used $D^{\mathsf{tr}}_{\mathsf{a}}$ to train a classifier to classify random passwords and evaluated it on $D^{\mathsf{va}}_{\mathsf{a}}$. To assemble $D^{\mathsf{tr}}_{\mathsf{a}}$ and $D^{\mathsf{va}}_{\mathsf{a}}$, we generated 8,000 and 2,000 passwords from each class, yielding 304,000 and 76,000 passwords in total, respectively. We applied $D^{\mathsf{te}}_{\mathsf{a}}$ in the evaluation of FPP and FNP. In $D^{\mathsf{te}}_{\mathsf{a}}$, there were 38 classes of passwords, each containing 10,000 sets (corresponding to 10,000 users) with 100 passwords of that class. When evaluating FPP and FNP, we implemented $\mathcal{U}$ by sampling p and X without replacement from a set (user) chosen uniformly at random from $D^{\mathsf{te}}_{\mathsf{a}}$.

5.3.2 Experimental Results

We evaluated the honeyword-generation methods described in Sec. 5.2, though we plot only $\mathsf{FNP}(\mathcal{B})$ since $\mathsf{FPP}(\mathcal{A})$ was essentially perfect. We plot $\mathsf{FNP}(\mathcal{B})$ against α in Fig. 6. As seen there, both the FXED and RAND methods had a high

Table 3: Classes of algorithmically generated passwords used in our experiments

$\mathsf{FNP}(\mathcal{B})$. Even when $\alpha = 1$, they had $\mathsf{FNP}(\mathcal{B}) > 0.94$ for $n = 19$ and $\mathsf{FNP}(\mathcal{B}) > 0.93$ for $n = 99$.

In contrast, the CLSD method achieves nearly perfect $\mathsf{FNP}(\mathcal{B})$. This method selects the most plausible algorithmic password generator based on the account password to generate honeywords. The confusion matrix experienced by $\mathcal{H}_n$ (i.e., using p) are shown in Fig. 5a. When $|X| = 1$, the confusion experienced by $\mathcal{B}$ is virtually identical, of course, but the confusion experienced by $\mathcal{B}$ when $|X| > 1$ is notably less, as shown in Fig. 5b. As this figure shows, when $|X| > 1$, $\mathcal{B}$ has greater ability to classify the user's password generator based on X than $\mathcal{H}_n$ does based on p, at least for certain classes. Since our dataset is dominated by accounts for which the number of passwords known by $\mathcal{B}$ numbers $|X| = 1$ (Fig. 2), the confusion shown in Fig. 5a (where $|X| > 1$) cannot effectively be exploited by $\mathcal{B}$.

However, if the fraction of accounts for which $\mathcal{B}$ holds

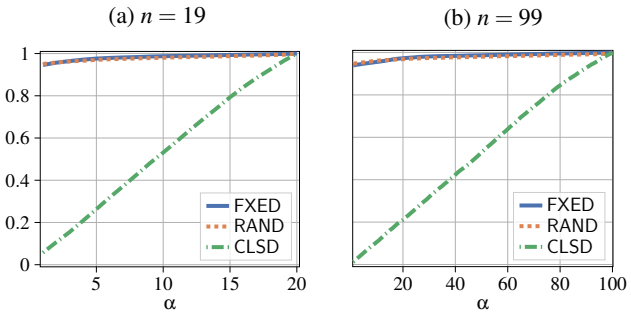

Figure 6: $\mathsf{FNP}(\mathcal{B})$ for honeywords by algorithmic password generators

$|X| > 1$ passwords were larger, the better classification accuracy this would enable (Fig. 5b) would permit an average increase in $\mathsf{FNP}(\mathcal{B})$. To illustrate this, in Fig. 7 and Fig. 8 we show the effect on $\mathsf{FNP}(\mathcal{B})$ of increasing $|X|$ from its original distribution to $|X| = 99$ always, for $n = 19$ or $n = 99$, respectively. Each subfigure shows $\mathsf{FNP}(\mathcal{B})$ for certain classes of the actual password p; e.g., Fig. 7a shows this effect when $p \leftarrow \mathcal{U}_{22}()$. As can be seen in these figures, increasing $|X|$ to $|X| = 99$ enables $\mathcal{B}$ to improve $\mathsf{FNP}(\mathcal{B})$, for these classes noticeably.

In conclusion, in the case of algorithmically generated passwords, it is critical for $\mathcal{H}_n$ to identify the algorithmic password generator used by each user in order to achieve low $\mathsf{FNP}(\mathcal{B})$. Even then, as the number of passwords $|X|$ grows, this measure will decay.

6 Discussion

6.1 False-Negative Attacks with Less Auxiliary Information

In Sec. 4, we assumed that the false-negative attacker has knowledge of the passwords used by the same user at other sites. We additionally explored a setting where the false-negative attacker had minimal auxiliary information about the users, specifically only one password used by the same user at another site ($|X| = 1$). To do so, we implemented the algorithm $\mathcal{U}$ by choosing two passwords without replacement from a single multiset S_{addr} chosen uniformly at random from $D^{\mathsf{te}}_{\mathsf{u}}$, returning one as p and the other as the only element of X. The experimental results in this setting are shown in Fig. 9. When the false-negative attacker $\mathcal{B}$ had little information about users, his success rate of guessing the account passwords from sweetwords slightly dropped, yielding a smaller $\mathsf{FNP}(\mathcal{B})$. However, all the honeyword-generation methods remained insufficiently resilient to these attacks. The best $\mathsf{FNP}(\mathcal{B})$ that the honeyword-generation techniques accomplished for all accounts was 0.48 (P2P, Fig. 9r). No existing algorithm achieved low rates of both false positives and false negatives.

6.2 Countermeasures to False-Positive Attacks

False-positive attacks can be very costly to sites, if they induce an investigation into the possibility of a breach and/or a password reset for every site account. Moreover, repeated false positives might eventually result in the defense being ignored or disabled outright. Despite the consequences of false positives, only a few previous works on honeywords have briefly discussed how to prevent them [22, 48]. Wang, et al. [48] suggested that applying a blocklist of popular passwords to honeyword selection can reduce false positives, since the honeyword-generation methods considered in their work generate honeywords by sampling from a public password distribution (e.g., leveraging a password model like List). As such, a blocklist would avoid using popular passwords as honeywords, which can mitigate the guessability of honeywords by their proposed methods. However, a blocklist of popular passwords is much less effective when considering password-dependent honeyword-generation algorithms (e.g., CBT, CHM, Tweak, and P2P), since these methods assign more likelihood to those candidates similar to the account password. A way to mitigate false positives of these methods is to avoid using passwords similar to the account password as honeywords, which makes them suffer a high false-negative rate.

Another countermeasure to reduce false positives, as mentioned by Juels and Rivest [22], is to select n honeywords uniformly at random from a large pool of candidate honeywords that are similar to the account password. In order to achieve a small false-positive rate, the size of the pool should be much larger than n. However, it is challenging to generate such a large pool of candidates that are sufficiently similar to the account password to ensure a small false-negative rate via this process. As such, an interesting direction is to explore how to generate such a large candidate pool to achieve a target false-negative rate.

Ultimately, a site might find it most palatable to address the risk of false positives by adopting a lenient policy toward honeyword-induced breach alarms. Previous works (e.g., [22, Sec. 2.4]) outlined a range of possible reactions to honeyword-induced alarms, ranging from severe (e.g., shutting down the system and forcing all users to reset their passwords) to lenient (e.g., allow the login to proceed as usual). Whatever the policy, however, it will apply to both false and true positives alike, and so a policy can be relaxed only so far as is acceptable when a breach actually occurs.

6.3 Balancing Attention to False Positives and False Negatives

Since honeywords' proposal, a challenge has been to design good honeyword-generation methods that achieve both low false-positives and low false-negatives, i.e., $\mathsf{FPP} \approx 0$ and $\mathsf{FNP} = \frac{\alpha}{n+1}$. However, our experimental results in Sec. 4.3.2

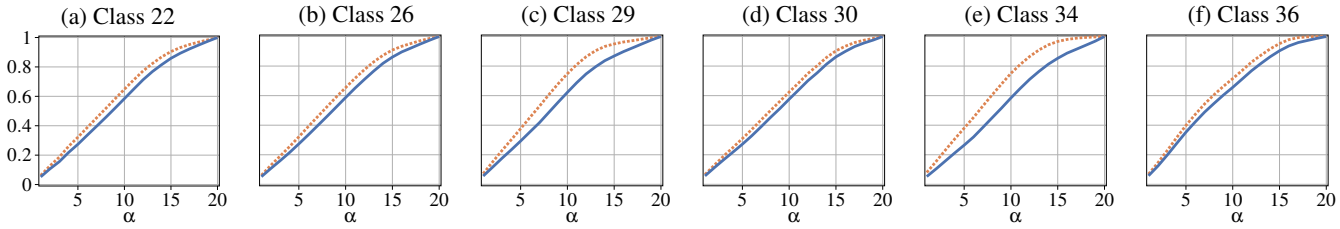

Figure 7: FNP$(\mathcal{B})$ for $\mathcal{H}_n$ of CLSD ($n = 19$), for $|X|$ distributed as in Fig. 2 (–) and for $|X| = 99$ (--)

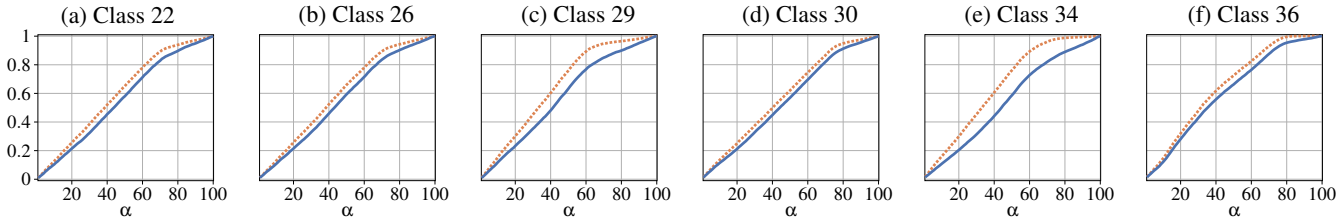

Figure 8: FNP$(\mathcal{B})$ for $\mathcal{H}_n$ of CLSD ($n = 99$), for $|X|$ distributed as in Fig. 2 (–) and for $|X| = 99$ (--)

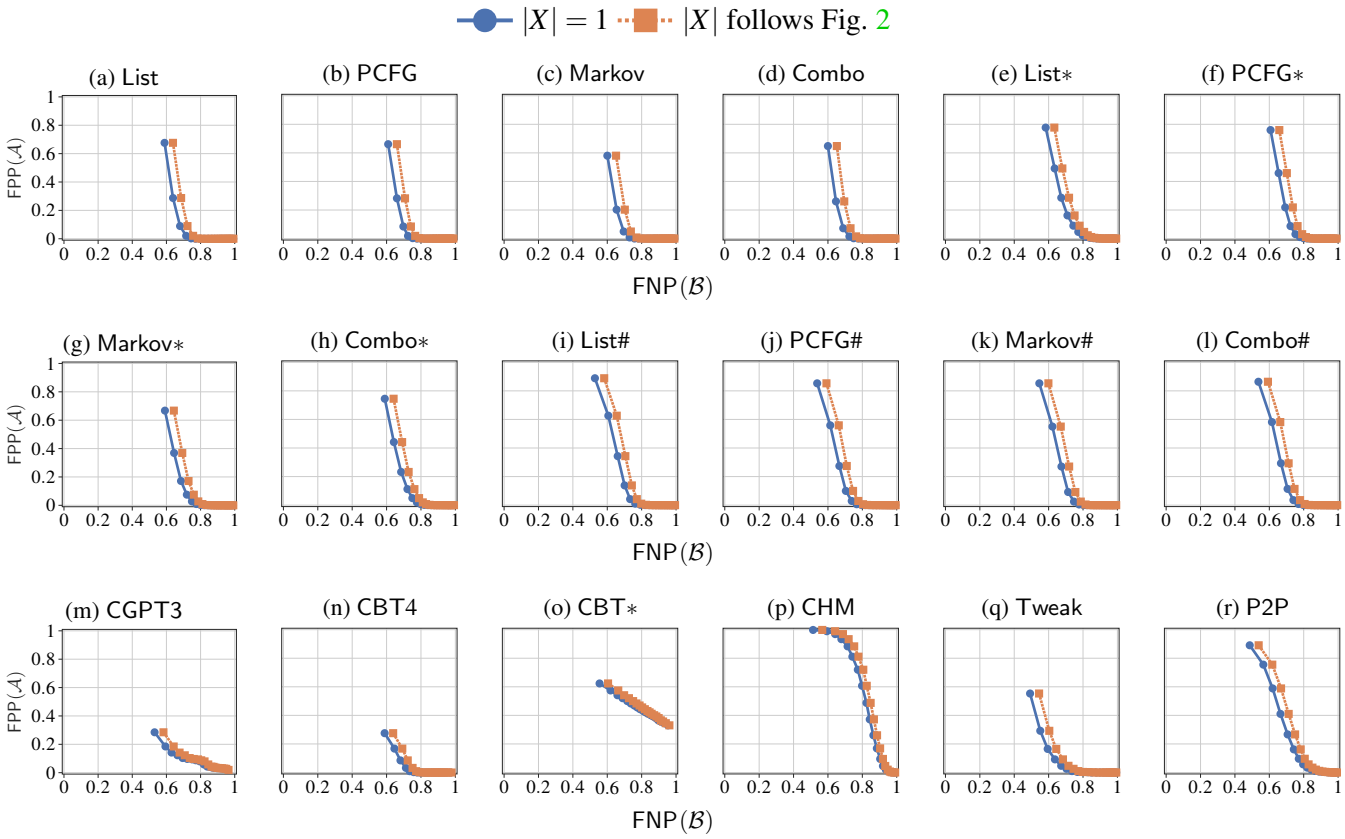

Figure 9: FPP$(\mathcal{A})$ vs. FNP$(\mathcal{B})$ as $|X|$ is varied, for the case of user-chosen passwords ($n = 19$, $\beta = 1000$) and all accounts.

show that no existing method achieves this goal in a threat model in which passwords from the same user at other sites are exposed to the attacker. While this leaves us skeptical that a perfect honeyword-generation method exists for this threat model (at least not when passwords are user-chosen, versus algorithmically generated), we do not mean to suggest that research in this direction should end. However, we do advocate that new honeyword-generation methods should be investigated with balanced attention to false positives and false negatives in this threat model, rather than more narrowly

focusing on false negatives, as has been typical in most prior research.

In the absence of improved honeyword-generation algorithms that more effectively balance false positives and false negatives, we believe that a change in perspective on the use of honeywords might be warranted. One such perspective, reflected in recent work [53], is to tightly constrain false positives to enable a honeyword-induced alarm to confidently be taken seriously and dealt with severely, and then to rely on a false-negative attacker's interests in harvesting *many* accounts to likely trigger a breach alarm even if the true-positive probability *per account* is modest. Such an approach will likely permit breaching attackers to harvest selected accounts without triggering a breach alarm, but greedy breaching attackers will still trigger a breach alarm with high probability.

Site	Password composition policy

Table 4: Most visited websites [36] and their password composition policies retrieved in May 2023.

Tranco Top	U	L	S	N
10K	81.7%	78.4%	80.3%	71.2%
100K	79.4%	79.2%	76.3%	82.5%
1M	83.7%	84.1%	86.3%	82.0%

Table 5: Percentages of sites from Tranco Top 10K, 100K, and 1M that do not require some types of characters (U: uppercase letter, L: lowercase letter, S: special symbol, N: number). These statistics were obtained on Dec. 2021 [3].

6.4 Assumptions on Algorithmic Password Generator Configuration

A limitation of our analysis in Sec. 5 is that it was conducted assuming that the user uniformly randomly selects a configuration for her algorithmic password generator and, once adopting a configuration, does not change it.

Changes of password manager configuration: To justify the assumption that users rarely change password manager configurations, we performed a study of the password-creation policies of twenty commonly accessed websites and those from Tranco Top 1M websites [32] to show that users are rarely *required* to change configurations. Specifically, we sought to determine the frequency with which a user who sets passwords at these sites in a random order will be required to change his password-creation algorithm configuration to comply with the next site in the sequence.

To perform this evaluation, we retrieved the password requirements from twenty commonly visited websites [36], shown in Table 4, or simulated password composition policies based on the statistics from a recent large-scale study [3], shown in Table 5. For a sequence of password policies that is a permutation of password requirements from the twenty commonly visited websites or a sequence of 101 simulated password-composition policies randomly constructed from the statistics, we evaluated the number of times that the current password-generator configuration conflicted with the password-creation policy of the next website in the sequence, starting from a configuration initialized by the minimum password requirement of the first site. To ensure a conservative evaluation, when a conflict occurred, the current configuration was replaced with the minimum password requirements of the conflicting site. For each type of password policy sequence, we performed this analysis for 10^6 times. The evaluation results are shown in Table 6. We found that the numbers of conflicts ranged from an average of 2.143 in sequences of 20 websites to 15.829 in sequences of 101 simulated sites drawn from Tranco Top 10,000 sites, averaged over the 10^6 sequences. These implied a probability of conflict with the next site in the sequence between 0.1127 and 0.1529. In expectation, then, the probability of exactly κ consecutive resets with no conflicts, followed by a site that conflicts, is $< (1-0.1529)^{\kappa}(0.1529)$, and the average number of non-

Sites	Number of conflicts	Probability of conflict with the next site	Average number of non-conflicting sites before a conflict
20 commonly visited websites	2.143	0.1127	8.864
101 simulated sites from Tranco Top 10K	15.829	0.1529	6.317
101 simulated sites from Tranco Top 100K	14.450	0.1445	6.920
101 simulated sites from Tranco Top 1M	11.825	0.1182	8.456

Table 6: Evaluation results on random walking at websites.

conflicting sites before a conflict was > 6.3. Given the conservative nature of our evaluation, we believe this result justifies our assumption that a user would rarely change its password-generator configuration.

However, an interesting direction for future work would be to confirm or refute this assumption more broadly, since as shown in Sec. 5.3.2, the assumption somewhat diminishes the effectiveness of honeywords generated for accounts with algorithmically generated passwords. Alternatively, an algorithmic password generator could be designed to encourage changing these configuration settings regularly, in which case an interesting research direction would be to explore the acceptability of this practice for users.

Tendency to use default password configuration: In reality, we expect people to generally defer to the default password-manager configuration until forced to change it by a site's password policy. However, imposing a non-uniform distribution on $\{\mathcal{U}_y\}_{y=1}^{Y}$ to reflect this tendency should not qualitatively change the results of our study: First, analogous to our results in the full paper [20, App. E], the existing honeyword-generation methods would still fail to provide a low false-negative probability since the false-negative attacker would even more easily distinguish the algorithmically generated password from the honeywords if he knows how the selection of configuration is biased. Second, as shown in Sec. 5.3.2, when the honeyword system can correctly predict the configuration used by the user—which should only become easier when the distribution is biased toward the default—and use that configuration to generate the honeyword, the generated honeywords can provide sufficient security.

6.5 A Mixed Case Study

In this work, we studied two representative cases where users create user-chosen passwords (Sec. 4) or where users generate their passwords algorithmically using a password manager (Sec. 5). To assess the efficacy of honeywords when users employ mixed strategies (i.e., chose some passwords themselves and algorithmically generate others), we further constructed two test datasets by mixing $D_{\mathsf{u}}^{\mathsf{te}}$ and the algorithmically generated dataset. Then we generated honeywords based on the type of the account password, i.e., applying honeyword-generation methods described in Sec. 3.2 to generate honeywords for user-chosen passwords and password managers to generate honeywords for algorithmically generated passwords. Our study showed that increased use of password managers in password creation can ease the tensions brought on by password reuse and thus make better trade-offs between false-positive and false-negative rates of honeywords. More details on the experiments and results are shown in the full paper [20, App. F].

6.6 Password Reuse

Our findings that password reuse across sites is so detrimental to honeyword false-negative rates (Sec. 4.3.2) provides yet more evidence that moving more users toward password managers would be good policy (notwithstanding the risk of password-manager breaches, e.g., [39]). That said, a recent university survey [25] found that though a large majority (77%) of respondents reported using a password manager, another large majority (again, 77%) also reported still reusing passwords across accounts. So, while a step in the right direction, password managers are evidently not a panacea. A potentially more effective approach might be explicitly hindering attempts to reuse passwords, either through adoption of intentionally conflicting password requirements at websites (which is not commonplace, see Sec. 6.4) or through explicit interventions during the password (re)setting process to interfere with reusing the same or similar passwords (e.g., [51]).

7 Conclusion

In this paper, we have conducted the first critical analysis of honeyword-generation techniques for users who have suffered exposed passwords for their accounts at other sites. We formalized the false-positive rate and false-negative rate of honeywords in a model where the attacker has access to passwords for the same users at other sites or, in the case of false-positive attackers, even passwords for users at the defending site (as the real users would). Using these formalized definitions and a large dataset of leaked passwords, we experimentally demonstrated that existing honeyword-generation algorithms exhibit poor tradeoffs between false positives and false negatives when the account password is chosen by an average human user. Then we studied the case where the account password is algorithmically generated and used passwords from popular password managers to show that the exist-

ing honeyword-generation methods offer modest protection against false-negative attackers. We further explored the use of algorithmic password generators in honeyword generation and determined that seemingly the only effective strategy is to generate honeywords using the same password generator that the user does, if it can determine what that password generator is. In total, we believe our results paint a cautionary picture for the state of honeyword-generation algorithms to date, though they also set forth new research challenges for the field.

InSpectre Gadget: Inspecting the Residual Attack Surface of Cross-privilege Spectre v2

Sander Wiebing* Alvise de Faveri Tron* Herbert Bos Cristiano Giuffrida

* Equal contribution joint first authors

Abstract

Spectre v2 is one of the most severe transient execution vulnerabilities, as it allows an unprivileged attacker to lure a privileged (e.g., kernel) victim into speculatively jumping to a chosen *gadget*, which then leaks data back to the attacker. Spectre v2 is hard to eradicate. Even on last-generation Intel CPUs, security hinges on the unavailability of exploitable gadgets. Nonetheless, with (i) deployed mitigations—eIBRS, no-eBPF, (Fine)IBT—all aimed at hindering many usable gadgets, (ii) existing exploits relying on now-privileged features (eBPF), and (iii) recent Linux kernel gadget analysis studies reporting no exploitable gadgets, the common belief is that there is *no* residual attack surface of practical concern.

In this paper, we challenge this belief and uncover a significant residual attack surface for cross-privilege Spectre-v2 attacks. To this end, we present *InSpectre Gadget*, a new gadget analysis tool for in-depth inspection of Spectre gadgets. Unlike existing tools, ours performs generic *constraint analysis* and models knowledge of advanced *exploitation techniques* to accurately reason over gadget exploitability in an automated fashion. We show that our tool can not only uncover new (unconventionally) exploitable gadgets in the Linux kernel, but that those gadgets are sufficient to bypass all deployed Intel mitigations. As a demonstration, we present the first *native* Spectre-v2 exploit against the Linux kernel on last-generation Intel CPUs, based on the recent BHI variant and able to leak arbitrary kernel memory at 3.5 kB/sec. We also present a number of gadgets and exploitation techniques to bypass the recent FineIBT mitigation, along with a case study on a 13th Gen Intel CPU that can leak kernel memory at 18 bytes/sec.

1 Introduction

As the community slowly comes to grips with various forms of transient execution attacks [16, 32, 34, 35, 38, 54], Spectre v2 or Branch Target Injection (BTI) [2] remains one of the most severe ones, able to transiently divert the control flow of a program. If attackers can find a snippet of code that encodes secret data into the microarchitectural state, i.e., a (disclosure) *gadget*, they can force a victim program, e.g., the kernel, to transiently jump to it. Even in the face of hardware mitigations such as eIBRS, researchers have shown that Spectre v2 can still leak secret data across privilege levels on Intel systems through what is known as Branch History Injection (BHI) [16].

However, neither academia [16] nor industry [8] ever found an exploitable "*native*" gadget and the only existing exploit relies on a gadget injected by the authors themselves using eBPF. Since then, new advanced mitigations such as Indirect Branch Tracking (IBT) and its recent fine-grained counterpart FineIBT, have reduced the set of usable gadgets even (much) further. As a result, it is a common belief that deployed mitigations such as eIBRS and privileged eBPF (now default in all popular Linux distributions) are sufficient to eliminate the cross-privilege Spectre-v2 attack surface—and even more so in combination with the opt-in (Fine)IBT mitigations.

To challenge this belief, our key observation is that current techniques to identify such gadgets either *overfit* "standard" patterns—identifying only gadgets that look like a handful of known Spectre examples and ignoring less conventional patterns—or grossly *overapproximate*—identifying many *potential* gadgets of which exploitability is highly uncertain. Examples of the latter are approaches that identify gadgets based on their high-level data flow, leaving exploitability to manual analysis [16, 24, 31]. Examples of the former include all pattern-based gadget scanners [40, 42, 43], but also all simplifying and self-limiting gadget definitions [8]. Overly constraining the definition of a gadget is dangerous, because even snippets that do not meet all the preconditions of a standard gadget can still leak data with advanced exploitation techniques [24, 31, 54]—leaving a gap between what attackers need for exploitation and what vendors and developers consider for mitigation.

In this paper, we present *InSpectre Gadget*, an in-depth Spectre gadget inspector that uses symbolic execution to accurately reason about exploitability of usable gadgets. To this end, our tool explicitly models data *constraints* and knowl-

edge of advanced *exploitation techniques*. This strategy relaxes the common preconditions of standard gadgets, while still avoiding the common overapproximations that would otherwise report many unexploitable gadgets. Moreover, it provides the analyst with insights into exploitability characteristics, such as the exploitation techniques required, the constraints to be met, the values that can be leaked, etc.

Scanning the Linux Kernel, InSpectre Gadget finds 1,565 gadgets leading to secret transmission, a significant residual attack surface. Furthermore, it uncovers hundreds *dispatch gadgets*, i.e., gadgets containing an indirect branch to an attacker-controlled target and, as we will show, providing the attacker with a variety of interesting capabilities for exploitation in face of deployed mitigations. Examples include increasing control over registers, expanding the set of reachable gadgets, or crafting disclosure gadgets by chaining multiple loads. To demonstrate the practicality of our findings, we use the reported gadgets to implement the first *native* Spectre-v2 exploit against the Linux kernel on last-generation Intel CPUs. Our exploit is based on the BHI variant and is able to leak kernel memory at 3.5 kB/sec without eBPF.

Furthermore, in contrast to previous findings, we show the recent (Fine)IBT mitigations still allow transient execution of between 4 and 6 (unchecked) dependent loads. To exploit the resulting attack surface, we showcase a number of gadgets and exploitation techniques, along with a case study on a 13th Gen Intel CPU, leaking kernel memory at 18 bytes/sec.

Contributions. To summarize our contributions:

1. We build InSpectre Gadget, a gadget inspector that evaluates exploitability of potential gadgets, incorporating data constraints and knowledge of advanced exploitation techniques. InSpectre Gadget is available at https://github.com/vusec/inspectre-gadget, along with a database of gadgets found for Linux kernel v6.6-rc4.

2. We present the first native (no-eBPF) BHI exploit on the latest Linux kernel and last-generation Intel CPUs (CVE-2024-2201).

3. We analyze the effectiveness of both the IBT and FineIBT mitigations and demonstrate they are insufficient to hinder native BHI exploitation.

4. We uncover a large presence of dispatch gadgets in the kernel, showing how an attacker can abuse them to further the attack surface and bypass deployed mitigations.

2 Background

2.1 Transient Execution Attacks

Modern CPUs rely on a multitude of speculation mechanisms to achieve better performance. For example, whenever a CPU encounters a control flow instruction like a conditional branch or an indirect branch, the correct target might not be known yet. To avoid stalling, the CPU uses a set of internal structures, called *predictors*, to determine the next instruction to fetch, and starts *speculatively* executing instructions. If the speculation is later revealed to be incorrect, the CPU will undo the effects of the *transient* execution and restart from the correct jump target. However, traces of the transient computation can still be observed in the shared microarchitectural state, e.g. in the cache. An attacker can then measure these traces with techniques such as FLUSH+RELOAD [55] and PRIME+PROBE [36] and recover the values of registers and memory used during the transient computation.

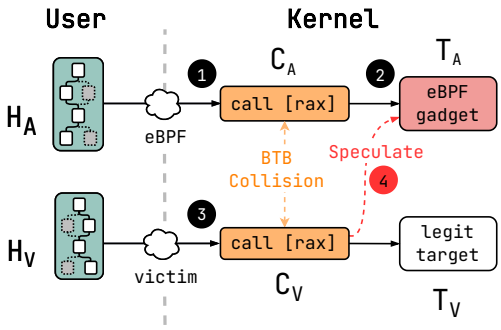

Figure 1: **The BHI attack.** The attacker first triggers the branch C_A with history H_A ①, which inserts the target T_A into the BTB ②, then triggers the victim branch C_V with history H_V ③. The histories are crafted so that C_A and C_V share the same BTB entry, so from C_V the CPU speculates to T_A ④.

2.2 Spectre v2

In 2018, the disclosure of Spectre [32] famously demonstrated how speculation can be used to leak data across security domains. One variant presented in the paper, originally known as Spectre v2 or Branch Target Injection (BTI), shows how speculation of indirect branches can be used to transiently divert the control flow of a program and redirect it to an attacker-chosen location. The attack works by poisoning one of the CPU predictors, the Branch Target Buffer (BTB), which is used to decide where to jump on indirect branch speculation. Initially, mitigations were proposed at the software level and, later, in-silicon mitigations such as Intel eIBRS [6] an ARM CSV2 [14] were added to newer generations of CPUs to isolate predictions across privilege levels.

2.3 Branch History Injection

In 2022, Branch History Injection (BHI) [16] showed that, despite mitigations, cross-privilege Spectre v2 is still possible on latest Intel CPUs by poisoning the Branch History Buffer (BHB). Figure 1 provides a high-level overview of the attack.

In summary, by executing a sequence of conditional branches (H_A and H_V) right before performing a system call, an unprivileged attacker can cause the CPU to transiently jump to a chosen target (T_A) when speculating over an indirect call in the kernel (C_V). This happens because the CPU picks the speculative target for C_V from a shared structure, the BTB, that is indexed using both the address of the instruction *and the history* of previous conditional branches, which is stored in the Branch History Buffer (BHB). Finding the right combination of histories that will result in a collision can be done with brute-forcing.

To ensure the injected target, T_A, contains a disclosure gadget, the original BHI attack relied on the presence of the extended Berkeley Packet Filter (eBPF), through which an unprivileged user can craft code that lives in the kernel.

2.4 Defenses

As a recommended mitigation for BHI, Intel has advised to disable unprivileged eBPF, which is now disabled by default in the Linux kernel, and to mitigate potential disclosure gadgets by prepending a `LFENCE` instruction to them [1].

Attack Surface Analysis. The original BHI paper presented an initial estimate of the BHI attack surface beyond eBPF using simple data-flow analysis and a loose definition of disclosure gadget [16]. The analysis pinpointed 1,177 *potential* gadgets in the Linux kernel, but with no insights into their exploitability. Later, Intel researchers statically analyzed the Linux kernel [8], adopting a more refined data-flow-based approach and finding an order of magnitude more potential gadgets. Again, with the analysis unable to automatically reason over exploitability, Intel researchers resorted to manually assessing exploitability of the 8 simplest (linear) gadgets. No gadgets were deemed exploitable (6 due to reachability issues, 2 due to leakage constraints). Ultimately, with many potential gadgets uncovered by both scanners but no evidence of practical exploitability, no additional mitigations were deployed.

Hardware mitigations. On the hardware front, Intel has proposed a hardware mitigation, the `BHI_DIS_S` indirect predictor control, which prevents the CPU from selecting BTB entries based on history coming from lower security domains. As the performance overhead is nontrivial, future CPUs might come with an optimized version, namely `BHI_NO`. At the time of writing, while Alder Lake and Raptor Lake Intel CPUs support `BHI_DIS_S` after applying a microcode update, the Linux Kernel does not have support to enable this feature.

Advanced software mitigations. Additional software mitigations, like Retpoline [10] or a software BHB-clearing sequence [1], have been proposed as spot fixes. However, they come with a prohibitive performance cost, discouraging practical deployment. For Linux, in particular, the software BHB-clearing sequence recommended by Intel has not been implemented at all, as developers rely on unprivileged eBPF being "the only known real-world BHB attack vector" [11].

IBT. Indirect Branch Tracking (IBT) [48] is a defense for code-reuse attacks, such as return-oriented programming [46] and jump-oriented programming [19], which ensures that indirect branches always jump to an intended target. Intel CPUs implement a coarse-grained version of IBT in hardware, which ensures that every indirect branch lands on a special instruction (`endbr32` or `endbr64`), which has to be inserted by the compiler. While IBT was originally designed to address architectural control-flow hijacking, it is also part of Intel's mitigation guidance for BHI [1]. This is to provide defense-in-depth against speculative control-flow hijacking, limiting—somewhat similarly to the existing eIBRS—the possible Spectre-v2 disclosure gadget locations to the beginning of *any* indirect branch target in the kernel. Support for IBT was added to Intel processors with the Tiger Lake series [7] and is enabled by default from Linux kernel v6.2 [4].

FineIBT. Researchers have recently proposed a finer-grained IBT variant in software, called FineIBT [23]. The idea is to instrument the caller of each IBT-guarded indirect call to load a unique value into a register as well as the callee to check said value. If the value is different from the expected one, the execution path is directed to an illegal instruction to abort execution.

This further restricts indirect calls to (architecturally or speculatively) target only compliant callees. Support for FineIBT was recently introduced in Linux kernel v6.2 [5]. Since FineIBT relies on Clang-instrumented kernels [23], to our knowledge, it is not yet enabled by default in any Linux distribution (unlike its IBT building block).

3 Threat Model

We consider a traditional cross-privilege Spectre-v2 threat model, with a local unprivileged attacker seeking to disclose information from a privileged victim, such as the operating system kernel or the hypervisor. We specifically focus on a victim Linux kernel, running with all default Spectre-v2 mitigations on last-generation Intel CPUs such as eIBRS [6] and privileged eBPF. Finally, we assume other classes of vulnerabilities (e.g., memory errors) are subject of orthogonal mitigations and not part of the attack surface under study.

4 Overview

To perform a Spectre-v2 attack against the kernel on last-generation Intel systems, one must target an indirect branch in the kernel that jumps to a disclosure gadget. Using BHI, one can then speculatively hijack a victim branch to the chosen gadget. InSpectre Gadget aids the analyst in choosing a suitable gadget, following the workflow depicted in Figure 2.

As shown in the figure, the analyst provides InSpectre Gadget with a kernel image and a list of candidate gadgets in input. Our tool inspects each candidate for a fixed number

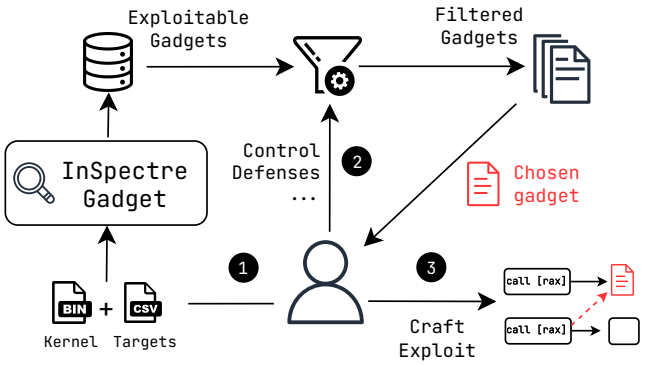

Figure 2: **InSpectre gadget workflow.** The analyst provides a kernel image and a list of target addresses to InSpectre Gadget ①, which performs in-depth inspection to find gadgets that can leak secrets and output their characteristics. The gadgets can be filtered ② based on the available attacker-controlled registers and the mitigations enabled, and used to craft Spectre-v2 exploits against the kernel ③.

of basic blocks with symbolic execution and returns a list of gadgets that lead to the transmission of a secret. Along with the gadgets, our tool outputs a number of gadget characteristics: the advanced exploitation techniques required (if any), the constraints that have to be met, the registers that have to be controlled, and the values that can be leaked. Such characteristics are stored into a database, which the analyst can later filter according to what targets are reachable, what registers are controlled when the speculative hijack happens, and what mitigations are enabled for a given target. Additionally, an annotated assembly file is generated for each gadget to give the analyst a quick overview of the gadget, as shown in Appendix C. The resulting gadgets can then be exploited to mount end-to-end Spectre-v2 kernel attacks.

In the next sections, we first elaborate on how InSpectre Gadget models gadgets (constraints, exploitability, etc.) and how it then performs exploitation-aware gadget inspection. Next, we demonstrate how an attacker can use its output to mount an end-to-end BHI attack against the Linux kernel.

5 InSpectre Gadget

A recurring problem in transient execution attacks is evaluating if a given instruction sequence can leak a secret via a—typically cache [27, 33, 36, 41, 47, 55]—covert channel. To leak a secret through the cache, an attacker needs to open a *speculation window* and accommodate a *disclosure gadget*. In this section, we explain that practical disclosure gadgets extend well beyond those that fit existing narrow definitions. Next, we show how InSpectre Gadget uses symbolic execution to analyze the candidate gadgets for Spectre-v2 exploitability.

Listing 1: Standard Spectre disclosure gadget.

```
1 // Load from attacker-controlled address
2 uint64_t secret = *attacker;
3 // Mask the loaded value
4 uint8_t secretByte = (secret & 0xFF);
5 // Shift the result
6 uint32_t tsecret = secretByte << 9;
7 // Use transmission secret as index.
8 uint64_t transmission = *(tbase + tsecret);
```

5.1 Standard Gadgets

Today's tools typically concentrate on finding speculation windows and overapproximating exploitability—leaving the analysis of disclosure gadgets to the human analyst. Unfortunately, the complexity of such exploitability analysis is daunting and, unsurprisingly, analysts generally look for *standard* Spectre disclosure gadgets, such as the one in Listing 1.

In a standard (or "perfect") gadget, the CPU loads a *secret* from an attacker-controlled address. The loaded secret must be sufficiently small, either by nature, or as the result of a bitmask (Line 4), to serve as an index into a second buffer—ideally shared with the attacker. This second buffer is known as the *reload buffer*. Moreover, to ensure that each value of the secret corresponds to a different cache line, the gadget should *shift* the value left by some stride (Line 6). The result is known as the *transmitted secret*. As the gadget subsequently adds it to a second attacker-controlled value which we refer to as the *transmission base* and dereferences the resulting value, it inadvertently establishes a *transmission* through a cache covert channel. Specifically, by iterating over the reload buffer with the same stride while timing the accesses, attackers can infer that the secret value is the index of the buffer element for which the access is fast (because it is in the cache).

5.2 Exploitation-Aware Gadget Analysis

Standard gadgets are the most intuitive to understand and the most straightforward to exploit, but they are by no means the only exploitable ones. While limiting the analysis to standard gadgets reduces the complexity, attackers are under no obligation to respect such restrictions. BLINDSIDE [24], KASPER [31], PACMAN [44], and RETBLEED [54], for example, all exploit gadgets that deviate from such narrow definitions. Moreover, besides leaking information through the cache, attackers may avail themselves of a myriad of other covert channels [18, 22, 25, 45, 52]. In this section, we relax the assumptions for standard gadgets, describe the additional challenge posed by each relaxation, and where appropriate, explain how we can meet the challenge and still leak secrets.

C1. Base not controlled. To perform FLUSH+RELOAD an attacker needs to be in control not only of the secret address, but also of the transmission base, so that the transmission load falls inside of the reload buffer. However, if the base is not

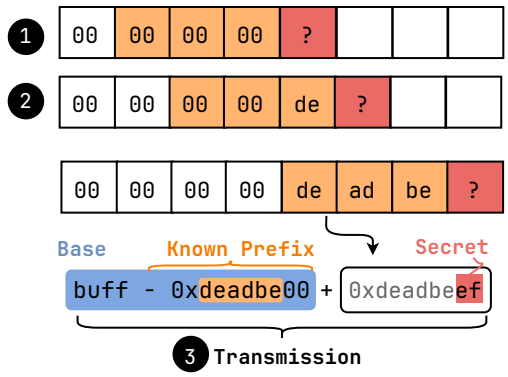

Figure 3: **Known-prefix technique.** The attacker first points the secret address to some known data ①. Then, by shifting the address ②, small portions of the secret are revealed. With that, one can adjust the base of subsequent transmissions ③.

controlled, attackers can still perform PRIME+PROBE [36].

C2. Secret entropy too big. If the code does not mask the secret prior to its transmission, the entropy impedes its recovery by the attacker who would have to probe too many memory locations. However, if the attackers control the transmission base, they can still exploit such gadgets by repurposing a technique pioneered in earlier attacks [24, 52, 54], which we call the *known-prefix* technique. First, the attacker chooses a location in memory near the secret that contains a small known value, and uses that as the secret address. Then, by increasingly shifting the address, the attacker makes sure that only a few bytes of the secret are unknown at any given transmission, and adjusts the transmission base according to the bytes that are already known (see Figure 3).

C3. Max secret too high. Another problem that may occur when leaking a large secret value is that the transmission address might end up outside the valid address space. However, if enough bits of the transmission base are under attacker control, one can adjust the base to overflow the secret value, ensuring that the transmission always occurs in the valid address space. We call this technique *base adjusting* and it is often used in conjunction with the known-prefix technique.

C4. Secret too small. If the gadget does not shift the secret value prior to transmission, the lower bits cannot be recovered through cache covert channels, since nearby addresses belong to the same cache line. However, if at least one byte of the secret is above cache-line granularity, we can use the known-prefix technique to leak the uppermost byte in each iteration. Otherwise, an attacker may use the *sliding* technique of RETBLEED [54], which exploits the fact that prefetchers generally do not prefetch cache lines across pages [49]. An attacker may now adjust the base address to be near a page boundary, so that even a one-bit difference in the secret value will result in the transmission being observed on another memory page. Doing so eliminates any cache and prefetcher noise that would otherwise make two different values indistinguishable.

C5. Base aliasing. In some cases, even if the transmission base is attacker-controlled, the base cannot be chosen without influencing the secret address—a phenomenon we refer to as *aliasing*. This may occur, for instance, if the base is computed from a value that is also used to compute the secret address. In this case, an attacker can still leak values using PRIME+PROBE. However, not all secret addresses may be targeted as the probe region must reside within mapped memory. Specifically, since the probe region typically follows the secret address, the final secret addresses result in a non-mapped probe region. Other, more complex dependencies between the base and the secret address out of scope. InSpectre Gadget marks these cases as not (easily) exploitable.

C6. Non-linear gadgets. An implicit assumption of most static analysis techniques for gadget scanning is that all the instructions have to be in the same basic block. Since modern CPUs all support nested speculation, this is not a limitation in practice. The attacker can either train branches or simply use static prediction to ensure that the transmission gadget is reached during speculative execution. An attacker can also use SMT contention, as demonstrated by prior work [39], to delay branch resolution and create large speculation windows that can accommodate multiple basic blocks.

C7. Other transmitters. Finally, a plethora of covert channels exist in modern CPUs outside of caches (e.g., the TLB [37]) and one should flexibly support different transmitters. For brevity, we focus our main analysis on classic secret-dependent data load/store transmitters and later show our tool can be easily extended to support other vectors such as the recent SLAM covert channel [29].

5.3 Design

While advanced exploitation techniques relax the assumptions for standard gadgets, each has its own requirements and constraints for applicability. To reason over the constraints and to assess if the code satisfies them, InSpectre Gadget employs *symbolic execution*—expressing variables as *symbols*, and exploring all the possible directions of a program's control flow at the same time, while recording the corresponding *symbolic constraints*. To this end, we build our tool on top of ANGR [50], a symbolic execution engine widely used in the field of software security and reverse engineering.

Although symbolic execution quickly leads to *state explosion* in the general case, InSpectre Gadget explores only a small fraction of the program's control flow. In particular, since the number of instructions executed during a speculation window is limited, symbolic execution can easily explore multiple paths, while keeping the number of explored states small. All the steps described below are performed automatically by InSpectre Gadget.

Tracking attacker control. We start our analysis by substituting all the values stored in registers and on the stack with

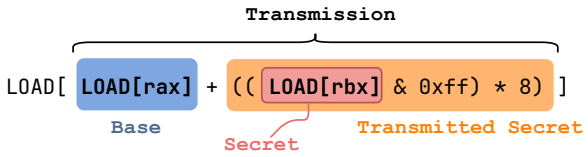

Figure 4: **Anatomy of a transmission.** Once a potential transmission is identified through symbolic execution, InSpectre Gadget dissects its symbolic expression into components, which are then analyzed to reason about exploitability.

symbolic variables, which for now we assume are *attacker-controlled*, and marked as such. Next, we symbolically execute code starting from a given location. On each load, we produce a new symbolic value with a label attached to it. If the load comes from an attacker-controlled symbol, it is marked as a *potential secret*. If the address comes from a potential secret, it is marked as a *potential transmission*. Note that *potential secret* implies *attacker-controlled*, since it is any value loaded from an attacker-chosen location. Similarly, *potential transmission* implies *potential secret*. This strategy allows us to track of attacker control through complex chains of loads.

Store-to-Load Forwarding (STL). We model Store-To-Load Forwarding by keeping a list of all the symbolic stores, and checking this list for each of the loads encountered by the symbolic execution engine. If the symbolic expression of the load address aliases with that of a previous store, we forward the stored value to the load. Store-to-Load forwarding can be enabled or disabled with a runtime flag.

Potential transmissions. We let the symbolic execution engine run for a configurable number of basic blocks, recording all the constraints that might be added, for instance by `cmove` or branch instructions. We also record the symbolic expression of each load. Finally, after the scanning phase is finished, the scanner reports a list of potential transmissions, i.e., loads whose symbolic address has been marked as a potential secret.

In a second phase, we inspect the AST of the symbolic expression of each potential transmission, identifying the transmission base, transmitted secret, and secret address. A high-level example is shown in Figure 4. Finally, we check if the base depends on any value used to construct the secret address, perform a range analysis to infer the minimum, maximum and stride of all the transmission components, and perform an *inferable-bits* analysis to infer which bits of the secret end up in the transmission and at which position. This comprehensive analysis is crucial for accurate exploitability reasoning. For instance, data-flow information alone is insufficient to determine the controllability requirements to be met.

Gadget reasoning. With this information, we can finally reason about each gadget. All the properties found during the analysis, along with a list of registers that the attacker needs to control for each gadget, are saved in a database. We now use a *reasoner* to model exploitation techniques with database queries. The reasoner inserts columns indicating which gadgets can leak a secret, and, if needed, which techniques are required. For instance, if a gadget has a high secret entropy (i.e., number of transmitted bits > 16), the reasoner checks if we can perform the known-prefix technique (i.e., secret address is attacker-controlled with granularity <= 16 bits).

5.4 Evaluation

To evaluate the ability of InSpectre Gadget to uncover a new attack surface, we analyzed the Linux kernel version 6.6-rc4 (latest at time of writing) with the default configuration. By listing all the code locations that contain an `endbr` instruction and looking at the symbol table, we found a total of 35,212 indirect call targets (have a symbol), and 7,562 indirect jump targets (have no associated symbol). InSpectre Gadget took approximately 14 hours to analyze all indirect branch targets, running on the i9-13900K Intel CPU with 20 cores. We count each unique transmission address as a gadget, so multiple paths leading to the same transmission count as 1 gadget.

Additionally, while InSpectre Gadget does not directly output information about *reachable* gadgets (i.e., those that can be user-triggered through a syscall), we estimate reachability for call targets by cross-referencing the labels with the coverage report generated by Syzkaller [13], a state-of-the-art kernel fuzzer. We use the openly-available results from the Syzbot project [12], which runs Syzkaller for 24 hours, finding a total of 14,391 reachable targets. This approach underapproximates the number of reachable gadgets, as the completeness is subject to fuzzing coverage, but it is useful to provide an estimate.

Table 1 summarizes the gadgets we uncovered. We found a total of 955 and 610 gadgets in kernel indirect call and jump targets (respectively). We manually analyzed 40 randomly sampled gadgets from the list by manually inspecting the assembly code (in approximately 3 hours). After manual analysis, we considered 35 to be exploitable. This shows InSpectre Gadget provides good accuracy, with the few misses caused by imprecise controllability modeling of our current prototype (Section 5.5).

Figure 5 shows statistics that we can use to estimate the size of the required speculation window, e.g., the number of instructions and branches present in the gadget, or how many dependent loads have to fit in the window to leak a secret.

Finally, Table 2 presents the number of potential gadgets that were *not* deemed exploitable by our tool. Gadgets with an invalid base are gadgets where the attacker does not completely control the transmission base, and in particular, for some values of the secret, the transmission address would be invalid, without the attacker being able to compensate by adjusting the transmission base. Gadgets classified as having an invalid secret address do not allow the attacker to choose an arbitrary memory location to leak, and gadgets where no

Table 1: The number of exploitable gadgets found by InSpectre Gadget in indirect call targets and indirect jump targets of the kernel, grouped by technique needed for exploitation.

Technique	*Call Targets*		*Reachable*		*Jump Targets*	
	Load	*Store*	*Load*	*Store*	*Load*	*Store*
None	14	2	1	1	0	0
Prime+Probe	199	126	64	51	126	17
Sliding	69	30	34	7	208	50
Known Prefix	399	121	107	19	135	110
Base Adjust	7	1	4	1	0	0
(Base Adjust + Known Prefix)	(79)	(30)	(28)	(9)	(88)	(43)
Train In-Place	467	210	174	68	153	52
Train OOP	53	10	25	2	130	77
Total	738	288	230	78	471	179

Table 2: The number of potential gadgets marked as "not exploitable" by InSpectre Gadget, broken down by the reason for which they were deemed unexploitable.

Problem	*# of Gadgets*		*# Reachable*	
	Load	*Store*	*Load*	*Store*
Base Alias	1322	730	502	151
Invalid Base	32651	5619	9270	1391
Invalid Secret Address	412	78	104	11
CMOVE *Alias*	773	171	246	50
Secret Not Inferable	114	5	59	1
Invalid Transmission	268	56	51	9
Secret Too Big	2045	439	282	159
Secret Too Small	561	67	198	28
Total	34825	6035	9609	1530

bits of the secret survive before being transmitted, e.g., if the secret is XOR-ed with itself, are classified as *Not Inferable*. Finally, the labels *Secret Too Big*, *Secret Too Small* and *Base Alias* refer to the problems mentioned in Section 5.2.

As mentioned earlier, InSpectre Gadget can be easily extended to support new covert channels. As a demonstration, we added support for both the recent SLAM covert channel [29] and the code-load (i.e., secret-dependent function pointer dereference) covert channel [45]. With our tool, we found ~4x more exploitable gadgets than SLAM's simple scanner, primarily due to our ability to reason about the exploitability of complex gadgets. The code-load covert channel further revealed over 2,000 SLAM gadgets, although no new traditional gadgets were found. For a more detailed analysis, we refer the reader to Appendix A.

5.5 Limitations

As opposed to tools like KASPER [31], InSpectre Gadget is designed to analyze only the content of *speculation windows* (e.g., call and jump targets for Spectre-v2), whose entry points have to be provided by the analyst. Other aspects needed for end-to-end exploitation, such as the *reachability* of the target and the presence of a suitable *victim branch*, are not part of the tool's output. Nonetheless, in Section 6.1, we show how to construct an end-to-end attack based on the results of our analysis. Moreover, InSpectre Gadget cannot completely prove the *absence* of gadgets in a given snippet of code.

Regarding exploitability results, our current prototype has a number of limitations potentially impacting accuracy. First, our tool is based on ANGR and relies on both its disassembler (CAPSTONE) and constraint solver (Z3). Whenever an error occurs in one of these components, e.g., on unsupported instructions, we have to bail out from the analysis, leaving some symbolic states unexplored. Second, transmissions that contain a complex symbolic expression, e.g., two independently-controlled loads used in a XOR operation, cannot be easily unpacked into a *base* and a *transmitted secret*, but might still leak a value. We mark these cases as *complex* and approximate their ranges by querying the SAT solver for the minimum and maximum values of the whole expression and of each sub-expression. We also use this approach when performing range analysis on expressions with complex (symbolic) constraints, whose values cannot be easily reduced to an interval or a small set. For these cases, besides reporting the minimum and the maximum values, we also check if certain bits are always 0 or 1 to approximate the stride.

Finally, at the moment our tool models the attacker's control over complex chains of loads as a binary condition (*controlled* or *not controlled*), as opposed to reporting the degree of control as done for transmission components. For complex aliasing cases, this can introduce imprecision (e.g., inaccurate classification of the required exploitation techniques).

6 Native BHI

In the previous section, we saw that InSpectre Gadget was able to uncover in the Linux kernel many gadgets that can lead to the transmission of a secret. In this section, we demonstrate how an attacker can use such gadgets to mount an end-to-end Spectre-v2 exploit against the kernel, by presenting the first native BHI attack (without the need of unprivileged eBPF).

6.1 Preliminaries

To perform native BHI, an attacker must first trigger the gadget via a syscall to insert its entry in the BTB. As discussed in Section 5.4, we use the reports from Syzkaller to determine which target can be triggered, and how. Note that, since we use valid indirect call targets, the attack is completely unaffected by the eIBRS and IBT mitigations.

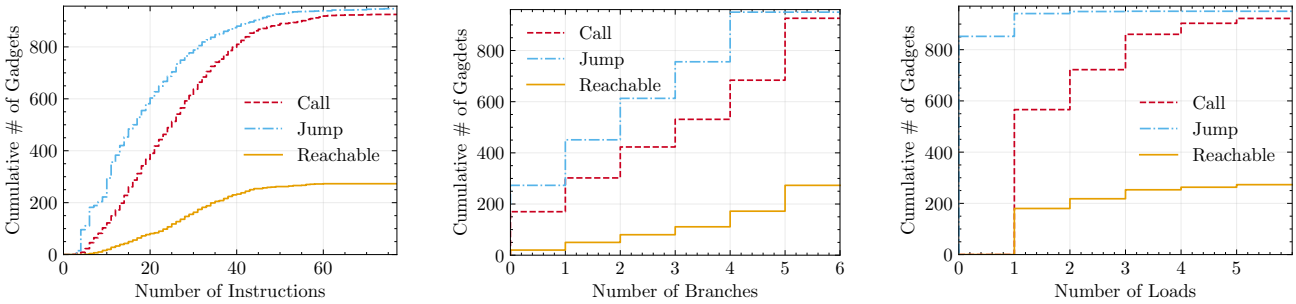

Figure 5: Cumulative distributions of the number of instructions, branches and dependent loads found in disclosure gadgets.

In addition, we must choose a victim indirect branch. Attackers need to ensure they control the registers and memory required by the gadget, when the victim call is triggered. To find potential victims, we use ANGR to search for indirect branches from the syscall entry point. Upon detecting an indirect branch, we perform range analysis on attacker-controlled registers. To find attacker-controlled values that require an extra dereference with a small offset, we first query the solver to determine if the expression stored in a register has a single solution. If so, we examine the memory at this address and the adjacent 256 bytes for attacker-controlled values and perform range analysis on them if found.

We identified 21 indirect branches across 11 syscalls, each with at least one register under sufficient attacker control to pass a kernel pointer.

6.2 End-To-End Exploit

In this section, we show how we craft an end-to-end exploit against the Linux kernel to leak the content of `/etc/shadow` on the latest Intel CPUs in under two minutes. Figure 6 shows a general overview of the attack.

Disclosure gadget and victim branch. As a first step, we search for a FLUSH+RELOAD gadget to provide an efficient covert channel, by filtering the database generated by InSpectre Gadget. In particular, we select `cgroup_seqfile_show`, shown in Listing 2, as our gadget. The corresponding annotated assembly file, generated by InSpectre Gadget, is included in Appendix C.

As our victim branch, we choose the kernel syscall handler. When executing this branch, all of the (attacker-controlled) syscall arguments have already been pushed on the stack, while `rdi` points to the location of these arguments. Since `cgroup_seqfile_show` loads a value from `rdi + 0x70` and uses it to compute all other values, attackers need to control just the first syscall argument when the misprediction occurs.

Inserting the BTB entry. To ensure that the CPU mispredicts to our gadget, its address must be injected into the BTB before calling the victim. To this end, we trigger the gadget from userspace exactly once. Manual analysis shows that we

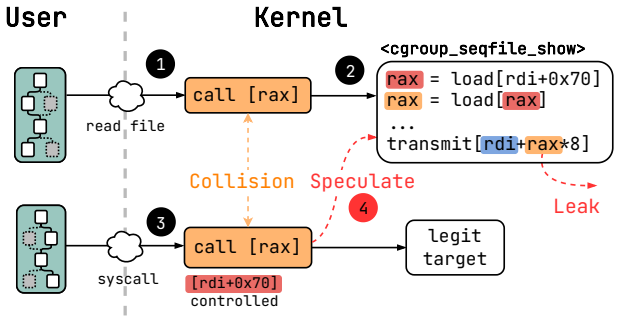

Figure 6: **Workflow for the native BHI exploit.** The attacker first triggers an indirect call in kernel ①, which jumps to `cgroup_seqfile_show` ②. Then, a colliding history is executed, and the syscall dispatcher is invoked ③, which expects the user-provided syscall argument at address `rdi+0x70`. Before executing the intended target, the CPU transiently jumps to `cgroup_seqfile_show` ④, which dereferences `rdi+0x70` and uses its value to construct a transmission.

can trigger `cgroup_seqfile_show` by reading a file in the cgroup directory (`/sys/fs/cgroup`) from userspace.

Increasing the transient window size. The induced transient window must be sufficiently large to fit our transmission. There are various ways to achieve this. In our case, we opted for evicting from the cache the syscall table entry that contains the legitimate target of our victim, making the victim call slow. Our experiments show that evicting the entry from the L2 data cache provides a window that is large enough.

Finding the reload buffer. To use FLUSH+RELOAD, there needs to be a shared buffer between the attacker and the victim. We can obtain such a reload buffer by allocating a user page and identifying its corresponding address in the kernel's direct map of physical memory. However, the map address is not known in advance, and must be leaked.

In principle, an attacker can brute-force this address by exploiting BHI to transiently jump to an attacker-controlled load, and check if the load brought the user page into the cache. However, two significant sources of entropy stand in

Listing 2: Assembly of the `cgroup_seqfile_show` gadget. Linux kernel 6.6-rc4, default configuration.

```
endbr64
push   rbp
mov    rax, QWORD PTR [rdi+0x70]; load user rdi
mov    r8,  rsi
mov    rbp, rdi
mov    rax, QWORD PTR [rax]     ; indirect load
mov    rsi, QWORD PTR [rax+0x60]; indirect load
mov    rdx, QWORD PTR [rax+0x8] ; indirect load
mov    rax, QWORD PTR [rsi+0x58]; load secret addr
mov    rdi, QWORD PTR [rdx+0x60]; load tbase
test   rax, rax
je     <cgroup_seqfile_show+55>
movsxd rax, DWORD PTR [rax+0x9c]     ; load secret
add    rax, 0x2e
mov    rdi, QWORD PTR [rdi+rax*8+0x8]; transmit
```

our way: the kernel direct map address (subject to KASLR and allocator entropy) and the victim/target branch histories (which need to collide). In other words, a cache hit for the user page can only be observed by the attacker if both the kernel direct map address of the user page is correctly guessed and the history correctly collides with the target branch.

To reduce the entropy and speed up brute forcing, we first find the start of the physical map and break KASLR. To do so, we use a modified version of the prefetch attack [26].

Next, instead of looking for a specific collision, as one would do when performing BHI, we perform a *parallel history collision* search by injecting the address of multiple gadgets in the BTB before calling the victim, and randomizing both the target and victim branch history.

Combining these optimizations allows us to identify the kernel direct map address for our user page within a minute on both Intel Comet Lake and Intel Raptor Lake CPUs.

Finding the histories. Once we have found the user page address, we follow the original BHI method to find a single reusable history for our victim branch colliding with the target branch [16]. Specifically, we randomize the victim history while keeping the target history constant until our user page gets loaded by the kernel.

Leaking kernel memory. To leak arbitrary kernel memory, we first have to find a known signature to use the known-prefix technique. It can be any value, including zeros. In our attack, to leak the shadow file, we first bring it into memory by calling `passwd -s`. Next, we start leaking from the start of the physical map and check if the signature 'root:' is present at the start of a 4k page [24].

Results. The end-to-end exploit time to leak the root password hash from the shadow file is on average 45s and 120s for the Intel i7-10700K and i9-13900K, respectively. The exploit runs longer on Raptor Lake due to the larger BHB size which therefore requires more collision iterations. The leakage rate after initialization is 4.5 KBps and 3.5 KBps on the i7-10700K and i9-13900K, respectively, with an accuracy of >99.9%

7 Dispatch Gadgets

A native BHI attacker is normally restricted to syscall-reachable disclosure gadgets. However, we found another type of gadget in *many* indirect kernel targets, i.e., one with an indirect branch to an attacker-controlled address (Figure 8)—which we refer to as *dispatch gadget* (or *dispatcher*).

To find such gadgets, we adapted InSpectre Gadget to also report such cases, which correspond to jumps to a symbolic address during symbolic execution. Most code logic for dispatch gadgets is shared with that of disclosure gadgets, as supporting dispatch gadgets primarily required adding an extra hook for symbolic branches and saving all the information from the analysis. With such support, we found as many as 2,039 dispatch gadgets residing within the first 6 basic blocks of an indirect call target of the Linux kernel, of which 477 are reported to be reachable by Syzkaller. We also found 462 others at the beginning of indirect *jump* targets. We manually analyzed 20 randomly sampled dispatch gadgets and found that all 20 are indeed exploitable. Figure 7 shows the depth of the dispatch gadgets found by InSpectre Gadget, measured in number of instructions, number of branches, and maximum number of dependent loads.

Dispatch types. Dispatch gadgets are particularly interesting because they allow an attacker to divert control flow to effectively *any* address. Use cases of interest are for example:

Dispatch-to-Call. The attacker jumps to a valid indirect call target. The target might either not be (easily) reachable via syscall, or the attacker uses the dispatcher to increase the number of controlled registers before jumping to the target.

Dispatch-to-Jump. Similar to Dispatch-to-Call, the attacker jumps to an indirect *jump* target. Jumps targets are of special interest as, with FineIBT, they are instrumented with an `endbr` instruction but not with the call-specific FineIBT instrumentation. We discuss this primitive in the next section.

Dispatch-to-Any. In case IBT is disabled, the attacker can jump to any code location, at direct call/jump targets, in the middle of functions, or even in the middle of instructions.

Dispatch-to-Dispatcher. The attacker chains two or more dispatchers to increase control over registers or to craft a disclosure gadget by chaining multiple load sequences together.

Chaining strategies. From an exploitation perspective, dispatch gadgets can be used to jump to a gadget within the same speculation window. With this *1-stage chaining* strategy, the dispatcher can easily reach unreachable code, increase controlled registers, etc. For example, if at the time of misprediction only `rax` is controlled, an attacker might jump to a dispatcher that moves `rax` to `rbx` before jumping to the final target. This allows the attacker to use any gadget that requires control of `rbx`—not previously possible. To demonstrate this approach, we repurposed our exploit to use `common_timer_delete` as the dispatcher to jump to the `of_css` disclosure gadget—a valid indirect call target not normally reachable from an unprivileged attacker's workload.

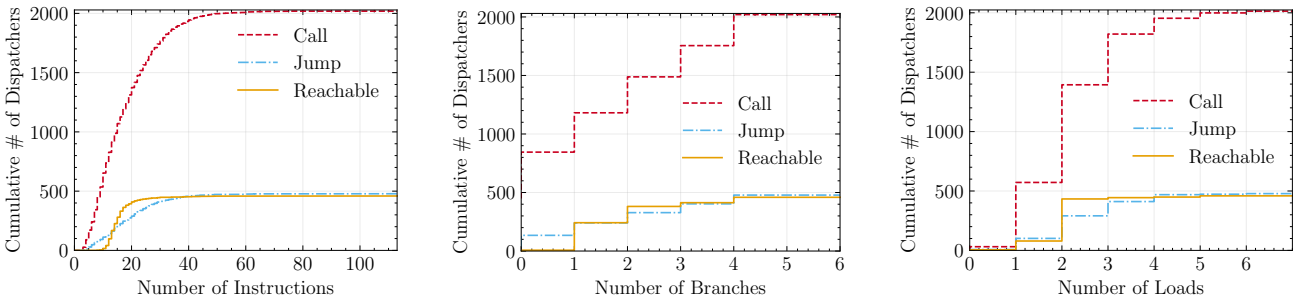

Figure 7: Cumulative distribution of number of instructions, branches, and dependent loads of the attack surface for dispatch gadgets found within indirect call (*Call*), indirect jump (*Jump*), and reachable indirect call (*Reachable*) targets.

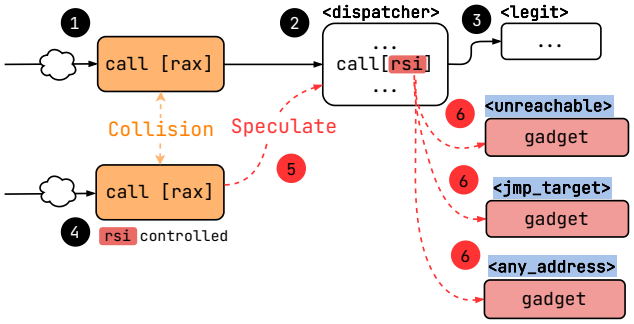

Figure 8: **Dispatch gadgets.** Instead of transiently jumping to a disclosure gadget, an attacker can jump to a gadget that calls a controlled function pointer. From that point, the attacker can divert control flow to less restrictive gadgets.

We achieved a leakage rate of 3.3 KB/sec on the i9-13900K.

Alternatively, the attacker could opt for a *2-stage chaining* strategy , i.e., using the dispatcher to inject a controlled BTB entry within the transient window [51] and later collide with another victim. This strategy offers two benefits. First, dispatch and disclosure gadgets are executed in separate speculation windows, accommodating a larger number of instructions. Second, this strategy allows the attacker to exploit different victims with different controllability characteristics for dispatcher and disclosure gadgets. To demonstrate this approach, we repurposed our exploit to use `m_show` as the dispatcher to inject the address of the `of_css` disclosure gadget into the BTB and, next, start a new history colliding phase to collide with the BTB entry just inserted. We achieved a leakage rate of 2.9 KB/sec on the i9-13900K.

8 FineIBT Analysis

Having shown that our discovered dispatch/disclosure gadgets offer many options to mount cross-privilege Spectre-v2 attacks against the kernel, defeating deployed mitigations that are currently believed to hinder exploitation, we now evaluate the impact of the recent FineIBT mitigation on these attacks. We first analyze the effective speculation window(s) and the impact of Simultaneous Multithreading (SMT) resource contention, before discussing the residual attack surface.

Listing 3: IBT test snippet.

```
1 ind_target:
2     .rept 16
3         mov rax, QWORD PTR [rax]
4     .endr
```

8.1 IBT Speculation Window

Since FineIBT builds on IBT, any IBT-induced speculation window is of concern. For Intel CPUs supporting IBT, the CET-tracker transitions to the `WAIT_FOR_ENDBRANCH` state upon execution of an indirect branch. If the subsequent instruction is not an `endbr` instruction, speculation is limited. To be more precise, Intel specifies that IBT limits speculative execution to 7 instructions (with a maximum of 5 loads) in early implementations, while later versions should completely block speculative execution after a missing `endbr` [30].

We evaluate the limits of IBT in the context of speculative execution by opening a transient window in a kernel module and executing an indirect call to a target snippet which omits the `endbr` instruction (Listing 3).

The snippet executes a chain of dependent loads, which ends with a load from a reload buffer. Prior to each iteration, we flush the reload buffer and, after executing the snippet, we test if the reload buffer entry is cached. We ran the experiment over 100 separate runs, with each run performing 1 million iterations for different sizes of the load chain. The test snippet is positioned between two pages filled with zeros, which prevents interference from other `endbr` instructions. We performed our experiment on the three most recent Intel CPU generations: Rocket Lake, Alder Lake, and Raptor Lake. Table 3 presents our results.

We observed that the Intel i7-11800H CPU features an early implementation of IBT, which allows for up to 5 dependent loads in the speculation window. We measured an

Listing 4: FineIBT instrumentation.

```
__cfi_ind_target:
    endbr64

```

Listing 5: FineIBT contention snippet.

```
1 .align 32
2 do_contention:
3     .rept REPEAT
4         sub eax, 0x1
5         .rept N_JE
6             je do_contention
7         .endr
8     .endr
9     jne do_contention
```

average hit rate of 34% for the last load. For every NOP instruction inserted before the load chain, we observed one less load being speculatively executed. Finally, we tested whether the alignment of the caller or target impacts the speculation window. The caller's alignment impacts the hit rate, and in the least optimal alignment, only 3 dependent loads can be fitted in the window before speculation is killed by IBT.

For the i9-12900K and i9-13900K CPUs, we can execute exactly 1 load in the IBT window. Adding a NOP instruction results in the reload buffer no longer being cached. We observed no influence from the alignment of the caller or target.

8.2 FineIBT Speculation Window

As a fine-grained extension of IBT, FineIBT introduces a speculation window of its own. This is due to the (SID check) conditional branch part of the software instrumentation. Nonetheless, such branch has been explicitly designed as "low-latency", performing a comparison between a register value and an immediate operand. As a result, FineIBT is currently considered an effective countermeasure against speculative control-flow hijacking attacks [1, 23].

Listing 4 shows the FineIBT instrumentation as it appears in the Linux kernel. The caller of an indirect branch is required to insert the correct SID into the r10 register and call the CFI variant of the target function. Inside the callee, the correct SID is subtracted from r10 and, if the outcome is zero, the instrumentation jumps to the actual call target. Conversely, if the SID is incorrect, the UD2 operation is executed, resulting in an invalid opcode exception.

To evaluate the speculation window size, we instrument the test snippet from Listing 3 with FineIBT. Next, we train the branch predictor by transiently executing the snippet with the correct SID, and later perform a call with an incorrect SID. To ensure that the same PHT entry is used for both the training phase and the malicious call, we prime the branch history by executing 200 branches after we differentiate between a training and a malicious call, which is in line with previous results [56]. Our experiments showed that this successfully trains the branch predictor on the three selected tested CPUs for this experiment. Table 3 presents our results.

As shown in the table, on all the tested CPUs, we can complete 1 load from RAM into memory with a high hit rate on average, from 79% up to 85%. This contrasts with the findings of the original FineIBT paper [23], which observed a considerably lower hit rate (17 hits out of 10 million iterations) when testing for Spectre resilience. However, we observe similar results without prior PHT entry massaging. As such, we hypothesize that the branch predictor may have distinguished between test and training runs in their case, thereby correctly predicting the SID check for the test runs. Namely, their test setup, despite conducting 10 training runs, jumps to a location dependent on whether it is a training or test run just prior to executing the FineIBT check. This jump difference can likely be inferred by the branch predictor.

8.3 Impact of SMT Contention

When SMT is enabled, a number of resources are shared between two sibling logical processors sharing the same core. Prior research [39] has shown that resource contention from a sibling processor can cause nontrivial delays in the other processor, thereby expanding the speculation window sizes.

To assess the impact of SMT contention on the (Fine)IBT speculation windows, we use the same test setup as before. However, we now introduce a contention workload on the sibling core. We seek to induce a delay in the FineIBT check (i.e., subtract operation, conditional branch evaluation, speculation rollback) or more generally in the victim logical processor (accounting also for the IBT window).

We evaluated the effects of SMT contention using different workloads and observed that the behavior of each workload strongly varies across different runs, although it remains stable during the run. We focus primarily on finding the most efficient workload on average, which is shown in Listing 5.

Branch contention. To delay the FineIBT check, the main ingredient is conditional branch contention. Changing the branch type in the branch sequence (line 6) to a direct jump/call or indirect jump/call to the next instruction does not yield a higher hit rate compared to no SMT workload. Our experiments also showed that nontaken conditional branches are more effective on average.

Arithmetic operations. We tested workloads with sub, add, mul, and cmp operations. A workload with only arithmetic operations does not seem to increase the hit rate. We also experimented with adding arithmetic operations in combination with conditional branches. Our experiments showed

Table 3: Hit rates for different load chain sizes while racing against the IBT and FineIBT mitigations.

i9-12900K	1	9
i9-13900K	2	8

that placing one `sub` or `add` instruction before the branch sequence yields a higher hit rate.

Alignment. We observed an alignment of 32 bytes for the contention workload to be generally the most effective. However, for some test runs, we observed the highest hit rates on different, unpredictable alignments. We suspect this is due to side effects from branch aliasing.

Workload size. During the experiments, we observed that the most effective configuration of the workload for each tested CPU differs in the number of sequential conditional branches (`N_JE`). Additionally, repeating the snippet before jumping back to the entry point can also affect the effectiveness (`N_REPEAT`). We experimentally derived the best configuration for the tested CPUs (Table 4).

We repeated the (Fine)IBT speculation window experiments with our fine-tuned SMT workload. Table 3 reports our results. As shown in the table, for the IBT window, our SMT workload does not increase the window size. For the FineIBT window, on the other hand, our SMT workload heavily impacts the number of loads one can fit across microarchitectures. Specifically, we observed cache hits up to 5, 7, and 10 loads for the i7-11800H, i9-12900K, and i9-13900K CPUs, respectively. Noteworthy, on the i9-13900K CPU, a contention workload composed solely of taken branches showed varied results: 80% of the runs had hits only up to 2 loads, 15% had a 90% hit rate for 6 loads, and 4% even reached a 90% hit rate for 9 loads.

9 FineIBT Bypass

We showed that the (Fine)IBT speculation windows still leave room to transiently fit a gadget with illegal control flow. In particular, depending on the microarchitecture, our results show that a FineIBT attacker can transiently execute 4-6 dependent loads with a hit rate of at least 7%. As such, attackers can use a variety of techniques to bypass FineIBT. To find gadgets for these techniques, the analyst can issue a SQL query to filter the InSpectre Gadget database for gadgets that satisfy the corresponding requirements.

Racing against the FineIBT window. An attacker may race against the FineIBT window with a disclosure gadget, and, optionally, use Dispatch-to-Call to increase reachability of disclosure gadgets (either via 1-stage or 2-stage chaining). As shown in Figures 5 and 7, the ability to fit 4 loads in the transient window is sufficient to have a wide selection of gadgets. More specifically, if we conservatively filter for reachable dispatchers with a maximum of 3 dependent loads within 10 instructions, we are left with 44 gadgets. If we filter for disclosure gadgets with at most 15 instructions and 4 dependent loads, we obtain 88 reachable gadgets and 548 non-reachable gadgets, which can be reached through a dispatcher.

Racing against the IBT window. Instead of using indirect call targets as disclosure gadgets, an attacker can also opt to use Dispatch-to-Any to reach any executable code for disclosure. However, the attacker then needs to race against both the FineIBT and the (nested) IBT window.

On CPUs with an early IBT implementation, an attacker can use a dispatcher to jump to a disclosure gadget containing at most 5 loads. With 1-stage chaining, the dispatch gadget must fit in the FineIBT window, while the transmission races against both the FineIBT and IBT window. With 2-stage chaining, the FineIBT window is avoided by inserting the transmission gadget's address in the BTB.

Later IBT implementations allow for exactly one speculative load after the illegal jump. While at a first glance this may seem unhelpful, attackers can still exploit any dispatch gadget that loads an attacker-controlled value and use the additional load as a transmission. InSpectre Gadget found 115 dispatch gadgets with at least one load preceding (but not controlling) the dispatch call.

Using JMP targets. IBT requires both indirect call targets and indirect jump targets to land on an `endbr` instruction. In contrast, FineIBT only guards indirect call targets. As a result, an attacker can target indirect *jump* targets—which do start

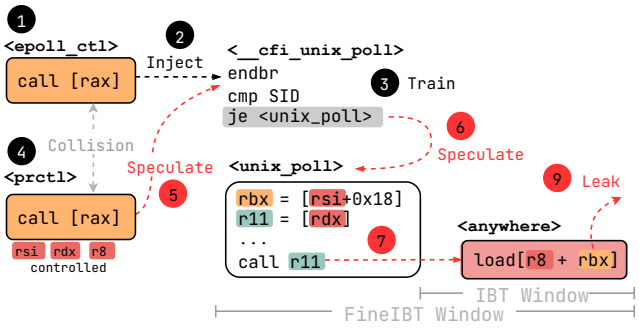

Figure 9: **FineIBT bypass case study.** The attacker invokes `epoll_ctl` ① to inject the address of `unix_poll` ② and train its FineIBT check ③. Then, `prctl` is invoked ④, which speculatively jumps first to the target's FineIBT check ⑤ then to its body ⑥. Inside `unix_poll`, a secret is loaded, then the function jumps to a single, final load ⑦ which discloses the secret ⑧.

with an `endbr` instruction but are not instrumented with a SID check—to bypass FineIBT. Hence, the attacker can use a disclosure gadget reached via indirect jump without racing against the FineIBT window. InSpectre Gadget found 462 dispatch gadgets and 610 viable disclosure gadgets at indirect jump targets in the Linux kernel.

Case study. As a case study, we demonstrate how a BHI attacker can bypass FineIBT and leak kernel memory in practice on a 13th Gen Intel CPU. At a high level, as depicted in Figure 9, we rely on a Dispatch-to-Any primitive with 1-stage chaining. This is to divert control flow to a dispatcher gadget (valid according to IBT, invalid according to FineIBT) and then, in turn, to an arbitrary final target (invalid according to IBT, unchecked by FineIBT). To this end, we need to race against two nested speculation windows (other than the initial BHI one): (i) the FineIBT window checking for the invalid (SID-violating) control-flow transfer to the dispatcher gadget; (ii) the IBT window checking for the invalid (`endbr`-bypassing) control-flow transfer to the final target.

From our InSpectre Gadget results, we need to first select a dispatch gadget that can race against the main FineIBT window. To this end, we select `unix_poll` (Appendix B), a short-lived dispatcher that loads an attacker-controlled value into a first register before a call via a second, attacker-controlled register. Next, we need to select a final target that can race against the nested IBT window. Recall from Section 8.2 that, on 13th Gen Intel IBT, we can still execute exactly one instruction without a preceding `endbr`. As a result, we need to select as final target a load instruction disclosing the secret in the first register. To this end, we scanned the Linux kernel image for loads with matching register. We found over 900 suitable instructions and selected one as our final target.

To inject the address of the dispatch gadget into the BTB, we invoke the `epoll_ctl` syscall. As our victim branch, we selected an indirect call in the `prctl` syscall which, at call time, grants the attacker full control over `rsi` and `rdx`, required by the `unix_poll` gadget. Finally, to successfully race against the main FineIBT window, we need to correctly train the SID branch (Section 8.2). To this end, one can in principle just execute `epoll_ctl` when inserting the BTB entry. However, this is alone insufficient due to the different path histories of the training and test runs (potentially distinguishable by the branch predictor). As a result, upon the misprediction of the SID check during the test run, a new entry is inserted into the level-1 PHT, indexed by the test run's path history [56].

To evict the test run's PHT entry, we build a jump chain of conditional branches. Eviction of the level-1 PHT requires us to initially take all branches, resulting in an entry insertion in the local base predictor. Then, we need to cause a misprediction by not taking the branches, leading to an entry inserted into the level-1 PHT and potentially evicting the entry of the test run. For this purpose, we used a simple (but far from optimal) eviction strategy walking 8k branches. Therefore, we alternate between eviction sets during the colliding phase and, after we find a collision, we randomize eviction sets until we observe a hit rate exceeding our lower bound.

This strategy, in conjunction with our fine-tuned SMT workload (Section 8.3), allowed us to achieve a hit rate of between 50% and 70% and a leakage rate of 18 B/sec on the i9-13900K CPU. It should be noted that an attacker can certainly optimize our PHT eviction strategy to gain a higher leakage rate.

10 Mitigations

To mitigate the gadgets found by InSpectre Gadget, an option is to add a speculation barrier (i.e., `LFENCE` instruction) at the function entry point of all the disclosure and dispatch gadgets. However, possible kernel performance degradation aside, this strategy cannot guarantee the absence of residual exploitable gadgets—especially with an ever-evolving Linux kernel. A more general strategy is to hinder BHI exploitation, e.g., with `BHI_DIS_S` controls [1] (which is only supported from Alder Lake and Sapphire Rapids CPUs onwards) or a software BHB-clearing sequence [1] (which is, however, costly). This strategy is still insufficient to stop other (intra-mode BTI) variants. To fully close the attack surface, we need new in-silicon mitigations (e.g., decoupling history and IP matching logic) or more costly ones, such as retpoline [1] (which is, however, vulnerable on some microarchitectures [54]) or `IPRED_DIS` controls [1] (which are, again, only supported from Alder Lake and Sapphire Rapids CPUs onwards).

Vendors' response. In response to our disclosure, Intel acknowledged our findings and updated their BHI mitigation guidance [1]. AMD and ARM confirmed that their existing mitigations are sufficient. Given the significant presence of exploitable gadgets revealed by our findings, Intel now rec-

ommends software vendors to enable `BHI_DIS_S` on CPUs that support it and to insert a software BHB clearing sequence at privilege boundaries on other CPUs. For future CPUs that enumerate `BHI_NO`, no additional mitigations are required. On the Linux kernel, Intel engineers have developed patches to incorporate the recommended mitigations [9] and kernel developers have decided to replace the syscall handler's indirect call with a switch statement [3]. While this mitigates Spectre-v2 on this specific call site, many other easily reachable indirect branches remain (e.g., the indirect call used in our FineIBT Bypass PoC). Moreover, since conditional direct calls are vulnerable to Spectre-v1, an attacker might still be able to confuse syscall targets [15]. Finally, our `endbr` analysis uncovered a bug in Clang (causing the compiler to occasionally emit spurious `endbr` instructions), which Intel engineers promptly patched.

11 Related Work

Spectre gadget scanners. Spectre gadget scanners documented in literature mostly focus on Spectre v1. With exceptions [43], such scanners typically rely on dynamic analysis. SPECFUZZ [40] uses fuzzing to detect out-of-bounds accesses on a speculative path. SpecFuzz marks every out-of-bound access as a gadget, without modeling attacker controllability. In response, SPECTAINT [42] requires the secret address to be tainted with attacker input, as determined via dynamic taint analysis (DTA). KASPER [31] also relies on DTA for gadget characterization, but generalizes the fixed patterns used by SpecTaint. Unlike InSpectre Gadget, all these solutions identify gadgets solely based on their data flow, an overapproximation that leaves their exploitability uncertain. Like ours, other gadget scanners are based on symbolic execution, but typically focus on other use cases (i.e., verification [28] or early detection [53]) with no exploitability analysis.

Spectre-v2 attacks. Besides work exclusively focusing on gadget scanning, prior Spectre-v2 attack efforts also described gadget analysis campaigns. For instance, the RETBLEED authors [54] used static data-flow analysis to identify basic 3-load gadgets for a native Spectre-RSB-to-BTI exploit. This simple strategy is sufficient as Retbleed exploits (similar to Inception [51]) vulnerable older-generation CPUs with no eIBRS. As such, they can speculatively hijack control flow to arbitrary code locations with no restriction.

The BHI authors [16], also using data-flow-based gadget analysis, presented evidence eBPF=off exploits were at least potentially feasible on modern eIBRS-enabled platforms—but with no attempt to reason about exploitability. Intel later presented a similar gadget analysis campaign along with manual exploitability analysis of "the most promising" gadgets, reporting no exploitable ones [8]. This shows the difficulty of performing exploitability analysis—even from experts *manually* inspecting the gadgets—without a general framework to rule out self-limiting assumptions.

In contrast, by analyzing one (v2) transient window at the time, InSpectre Gadget can leverage the full power of symbolic execution to deeply characterize gadgets and reason about their exploitability for the first time, without running into the limitations of traditional symbolic execution tools [20, 21], such as scalability and state explosion. As a result, our analysis was not only able to automatically uncover several exploitable native gadgets, but even gadgets that can bypass newer mitigations (FineIBT).

Crucially, our tool models knowledge of advanced exploitation techniques including sliding and gadget chaining. Chaining itself has been proposed before to increase the Spectre-v2 attack surface [17, 51]. With InSpectre Gadget, we demonstrate for the first time its crucial role in cross-privilege Spectre-v2 attacks, countering mitigations with widespread dispatch gadgets in modern kernels.

12 Conclusion

In this paper, we showed that, by relaxing the requirements on "standard" exploitable Spectre gadgets and using in-depth gadget inspection, it is possible to generically reason about gadget exploitability. To substantiate this claim, we presented InSpectre Gadget and applied its exploitation-aware gadget analysis to uncover a significant residual attack surface for cross-privilege Spectre-v2 attacks against the Linux kernel. Specifically, we revealed several new gadgets and showed that they can be exploited by a BHI attacker not only to leak kernel memory in native end-to-end exploits, but also bypass all deployed mitigations including the recent Fine(IBT).

13 Disclosure

We disclosed the end-to-end native BHI exploit to Intel in May 2023, and disclosed our full analysis to Intel, AMD, ARM and the Linux kernel in October 2023, which further notified other vendors. We converged to a public disclosure date of April 9, 2024, providing time for vendors to roll out mitigations. A number of vendors (Intel, Microsoft, Google, Xen) have also explicitly requested access to InSpectre Gadget for internal attack surface analysis, which we granted under embargo. Native BHI has been assigned CVE-2024-2201.

Acknowledgments

We would like to thank the anonymous reviewers for their feedback, Enrico Barberis for his support on the Native BHI exploit, and Andrew Cooper for his early feedback and contributions to the tool. This work was supported by Intel Corporation through the "Allocamelus" project, by the Dutch Research Council (NWO) through project "INTERSECT", and by the European Union's Horizon Europe programme under grant agreement No. 101120962 ("Rescale").

A Extra Covert Channels

To demonstrate the flexibility of InSpectre Gadget, we extended the tool to include two extra covert channels, namely the code-load covert channel [45], which requires a secret-dependent function pointer, and the recent SLAM covert channel [29]. SLAM leverages Intel's recently announced Linear Address Masking (LAM) feature, as well as microarchitectural race conditions present on some existing AMD CPUs. Via SLAM, an attacker can leak data via a straightforward dereference of a 64-bit secret, typically a noncanonical address, by transiently bypassing canonicality checks.

Supporting SLAM required modifications only in the reasoner, with 83 line changes. The code-load covert channel required even fewer modifications, with only 7 line changes in the scanner. We ran the extended implementation of InSpectre Gadget with the same setup described in Section 5.4. Table 5 presents our results. We count each entry point as a single gadget, in line with SLAM's definition.

The SLAM paper reports a large potential attack surface when scanning the Linux kernel's indirect call targets (16,046 *potential* gadgets), but practical exploitability is approximated by pattern-matching simple cases, resulting in 4,194 exploitable gadgets. In contrast, by reasoning on complex gadgets as well, InSpectre Gadget is able to uncover 13,648 SLAM gadgets that pass all exploitability tests in indirect call targets, and a total of 16,287 exploitable SLAM gadgets when considering also indirect jump targets and code-loads. While we did not uncover any new traditional gadgets via the code-load covert channel, we identified 2,856 SLAM gadgets that are exploitable via the code-load covert channel.

B FineIBT Case Study Gadget

Listing 6 presents the assembly code of the unix_poll_gadget, the gadget used in the FineIBT bypass case study. The gadget loads a secret from memory with attacker-controlled register `rsi` as address. Next, the gadget loads the call target from the attacker-controlled address in `rdx` and calls it subsequently. The secret is transmitted by the instruction at the call target, selected by the attacker, that performs a load with the secret as an argument and an attacker-controlled value as the base. We selected the instruction `movzx ebx, BYTE PTR[r8+rbx]` found in the `uuid_string` function.

Table 5: The number of exploitable SLAM gadgets found by InSpectre Gadget in indirect call targets and indirect jump targets of the kernel, grouped by technique needed for exploitation. Counted by the number of indirect entry points with at least one gadget.

Technique	*Call Targets*			*Jump Targets*		
	Load	*Store*	*Code-load*	*Load*	*Store*	*Code-load*
Known Prefix	14,840	3,470	2,440	1,981	831	474

Figure 10: **Annotated assembly file generated by InSpectre Gadget.** Right to the assembly instructions, we output the annotations attached to the source and destination operands (source →destination). The annotations include the origin of the value, which is either the instruction pointer of the source load or a register (e.g., `@rdi`). As we generate for each detected gadget an annotated assembly file, we do not print annotations that are irrelevant to the gadget flow and we replace all secret annotations with an attacker annotation that are, for this specific gadget, not used as a secret but as an attacker-controlled value. In the case of a branch instruction, we show the branch condition to hold instead.

As shown by the annotations, the attacker-controlled value `rdi` is used in the first load ①, followed by a series of loads whose controllability is tracked ②. The encountered branch condition is recorded ③. Subsequently, the secret value is loaded from an attacker-controlled value ④ and transmitted using an attacker-controlled value as the base ⑤. We output key details after the assembly code, including the symbolic expression and the range—i.e., (min, max, stride)—for each transmission component ⑥, insights about the transmitted secret bits ⑦, details about which registers an attacker should control to exploit the gadget ⑧ as well as the constraints and branches encountered ⑨.

Shesha*: Multi-head Microarchitectural Leakage Discovery in new-generation Intel Processors

Abstract

Transient execution attacks have been one of the widely explored microarchitectural side channels since the discovery of Spectre and Meltdown. However, much of the research has been driven by manual discovery of new transient paths through well-known speculative events. Although a few attempts exist in literature on automating transient leakage discovery, such tools focus on finding variants of known transient attacks and explore a small subset of instruction set. Further, they take a random fuzzing approach that does not scale as the complexity of search space increases. In this work, we identify that the search space of bad speculation is disjointedly fragmented into *equivalence classes*, and then use this observation to develop a framework named Shesha, inspired by Particle Swarm Optimization, which exhibits faster convergence rates than state-of-the-art fuzzing techniques for automatic discovery of transient execution attacks. We then use Shesha to explore the vast search space of extensions to the `x86` Instruction Set Architecture (ISAs), thereby focusing on previously unexplored avenues of bad speculation. As such, we report five previously unreported transient execution paths in Instruction Set Extensions (ISEs) on new generation of Intel processors. We then perform extensive reverse engineering of each of the transient execution paths and provide root-cause analysis. Using the discovered transient execution paths, we develop attack building blocks to exhibit exploitable transient windows. Finally, we demonstrate data leakage from Fused Multiply-Add instructions through SIMD buffer and extract victim data from various cryptographic implementations.

1 Introduction

With a plethora of sophisticated optimizations incorporated in modern processors, speculative execution plays a crucial role in determining the overall performance of the system. However, in 2018 a new class of attacks, called *transient attacks* introduced with Spectre [30] and Meltdown [33], have brought into perspective the side-channel implication of speculative execution. These attacks rely on software-accessible side-channels to extract secrets by forcing the CPU to enter into *transient state* and leave microarchitectural traces. A number of attacks have been demonstrated in literature that exploit these vulnerabilities to leak secret information across security boundaries [2, 4, 8, 9, 11, 12, 19, 29, 31, 34, 35, 41–44, 46–51, 53, 54, 56]. Intel refers to such cases as *bad speculation* [24] where the CPU is being coerced into a condition where the issued micro-operations (μOps) have to be discarded while their results are transiently reflected in microarchitectural states.

As per Intel, bad speculation happens due to three broader causes - branch misprediction, microcode assists and machine clear [24]. While a number of works have explored branch misprediction-based transient attacks in literature [9, 12, 30, 31, 34], very little research has been made to explore machine clears and microcode assists. Recently, authors in [40] explored the occurrences of machine clears in modern processors and demonstrated multiple transient execution paths based on different machine clear events. The findings of [40] open up a new frontier for transient execution discoveries that motivate further exploration. While most of the known works on transient leakage discoveries have been the results of manual effort, recent literature has seen quite some attempts to automate such leakage exploration [21, 22, 36, 52, 55]. However, these tools were developed to target certain classes of speculations and cannot be directly extended to explore the vast space of bad speculation (refer Section 9 for a detailed discussion and comparison with our tool). Additionally, due to the large number of x86 instructions, the prior works on automation only consider a small subset of Instruction Set Extensions (ISE), thereby missing out on a large pool of specialized instructions that are performance-bound and share various hardware resources. In fact, some of these ISEs, especially those concerned with SIMD, streaming SIMD, and Vector extensions, have their own separate data path (i.e. execution units), registers, temporal buffers, etc, making them an

*Shesha or Sheshanaga is a serpentine demigod in Hindu mythology with multiple heads and serves as the celestial bed of Lord Vishnu.

ideal spot for enabling speculation, and possibly bad speculation. Evidently, a systematic exploration of bad speculation in the context of ISEs is necessary to understand transient execution related vulnerabilities of ISEs. Concretely, in this work, we deal with the following question:

Given the wide-array of ISEs, can we develop a generic, better-than-random (i.e. better than fuzzing) approach to automatically explore the vast search space of bad speculation across ISE executions and develop previously unexplored transient executions paths?

In this work, we choose to adopt an alternative path than random fuzzing for the following reasons:

1. **Undirected vs Directed searches**: Fuzzing without feedback (like coverage) is an undirected approach that cannot incrementally develop upon good solutions since it applies random mutations without any sense of direction. In contrast, directed approaches (like evolutionary algorithms) consistently try to make good solutions *better*. This ensures faster convergence for directed approaches as opposed to undirected fuzzing-based approaches.
2. **Scalability with vastly expressive search spaces**: Randomized, undirected fuzzing leads to scalability issues with vastly expressive search spaces. With modern ISAs (along with extensions), the total number of possible instructions exceeds 16000. Random fuzzing through such expansive search spaces causes problems, as evident in prior works in the literature. For instance, works like [21, 36, 39] limit the extent of their instruction set to prevent blowing up the search space.

Given these observations, we choose to develop a guided approach that will not require restricting the search space, thereby increasing chances of finding corner cases of bad speculation. We develop a framework- Shesha - based on the principles of *Particle Swarm Optimizers (PSO)* [28] to allow for a directed exploration of the ISE search space, and faster convergence on code sequences enabling bad speculation. We choose PSO as the foundation of Shesha since PSOs allow for a delicate balance between choosing from local and global gains in the search space. However, unlike a textbook PSO, we observe that the search space for bad speculation is disjointedly fragmented, and therefore allows modifications to the generic PSO that enable faster convergence. Consequently, Shesha is able to uncover newer, previously unreported avenues of bad speculation in ISEs: (1) SIMD-Vector instruction intermixing (which has been unobserved [40] in newer generation Intel processors prior to Alder Lake and Sapphire Rapids), (2) execution of fused-multiply-add (FMA) instructions, (3) intermixing single and double precision in ISEs, and (4) performing denormal arithmetic on combination of AES-NI and SIMD instruction sets. We perform extensive reverse engineering of each of these avenues to uncover the cause of bad speculation in each of these cases, which helps us to construct abstract code sequence descriptions called *gadgets*, vulnerable to transient execution attacks. To summarize, we make the following contributions:

- We propose Shesha, a framework to explore previously untapped search space of bad speculation with respect to *Instruction Set Extensions*. Our methodology relies on a modified version of Particle Swarm Optimization and exploits the disjointedly fragmented nature of transient execution attacks to deliver faster convergence rates.
- We uncover newer and previously unreported avenues of transient execution paths: SIMD-Vector transitions, execution of fused-multiply-add (FMA) instructions, intermixing single and double precision in ISEs, and performing denormal arithmetic on a combination of AES-NI and SIMD instruction sets. We also provide extensive root-cause analysis for each of the scenarios.
- We characterize and evaluate the leakage strengths of each of the uncovered transient execution paths and discover SIMD-Vector transitions to exhibit the *longest* adversarial-friendly window of execution amongst all transient execution paths. We also demonstrate Simultaneous Multi-Threaded covert channels as well as Load Value Injection (LVI) attacks on vulnerable targets.
- Finally, we reverse-engineer the Fused Multiply-Add (FMA) execution unit to root-cause the transient leakage and exploit it to leak victim data from multiple cryptographic implementations. Our findings suggest that data used by *all* FMA and IFMA instructions are prone to leak across hyperthreads, rendering the applications using FMA for optimization vulnerable.

The rest of the paper is organized as follows: Section 2 provides the necessary background information. Section 3, 4 and 5 are dedicated to the Shesha framework and its discoveries. In Section 6, we perform a root-cause analysis of the discovered transient execution paths and then discuss how they can aid as building blocks to micro-architectural attacks in Section 7. In Section 8, we show practical exploitation of leakage from FMA instructions. We then provide a discussion on related works in Section 9 and mitigation strategies in Section 10. Finally, we conclude in Section 11.

Responsible Disclosure: We have disclosed the results of this work, including the leakage due to FMA execution unit to Intel. Intel acknowledged the leakage from the FMA execution unit, and responded that mitigation from [25] could cover this issue as well; therefore, no embargo period is required.

Artifact Availability: The tool and proof-of-concept attack codes can be found at https://github.com/SEAL-IIT-KGP/shesha.

2 Background

2.1 Superscalar Computing

High-performance CPUs, such as Intel Core and Xeon processors, utilize multiple cores, high-speed memory units, and support parallel processing with efficient isolation and security measures. Memory isolation is achieved through individual per-process virtual address spaces. These virtual addresses are translated to page table entries (PTEs) containing data location, access control, and status bits for access control. These modern CPUs employ Simultaneous Multithreading (SMT) that allows multiple threads to execute on the same core, providing architectural isolation. Intel CPUs support two threads to run simultaneously per physical core. Another important feature called speculative execution enables the CPU core to execute instructions in the pipeline even when there are dependencies on prior unresolved operations. In case of incorrect predictions, the CPU corrects itself by re-executing instructions. While architecturally invisible, there may be observable side effects due to microarchitectural state changes. In this context, such an instruction is referred to as a *transient instruction* [9, 30, 33]. Transient execution attacks capitalize on these transient instructions to leak sensitive data across security boundaries. Single Instruction, Multiple Data (SIMD) enables data-level parallelism, performing the same operation on multiple sets of data. AVX2 and AVX-512 are key SIMD extensions for x86 architecture. Finally, the CPU includes a shared last-level cache (LLC) across execution cores and an interconnect bus linking the LLC, cores, and DRAM. Additionally, each core has its own private caches - L1 and L2 caches. Temporal buffers are employed to optimize micro-operations, such as the fill buffer for fetching cache line data bits and the store buffer for holding data before committing it to the cache.

2.2 Particle Swarm Optimization

A Particle Swarm Optimizer [28], abbreviated PSO, is a generic evolutionary method suited to solving optimization problems. Unlike Genetic Algorithms that rely upon evolution of genetic information, PSOs work on the delicate interplay of individual and swarm behaviours in nature (like ant swarm, bee swarm etc). Abstractly, a PSO balances two opposing forces- *exploration* and *exploitation* in order to optimize an objective function. Here, *exploration* abstracts the random choices that encourage the PSO for a random walk across the search space in hopes of finding newer paths to global optimums. On the other hand, *exploitation* abstracts the greedy choices, encouraging the PSO to focus on a direct path to currently known optimums. As evident, too much of *exploration* is no better than a random search, while too much of *exploitation* risks getting stuck in local optimums. A PSO balances the two forces by switching back-and-forth between *particle* and *swarm* behaviour. A particle performs random searches across the search space, and if optimal paths are discovered, broadcasts that information to other particles, such that the entire swarm (where swarm can be interpreted as the set of all particles) starts to use the information from that one particle. Consequently, the particle behaviour abstracts exploration, while the swarm behaviour abstracts exploitation.

Syntactically, a PSO is characterized by a *fitness* function $f : \mathcal{R}^n \rightarrow \mathcal{R}$, mapping an n-dimensional vector (termed *particle position*, or $\mathbf{x}$) to a real-value (termed *fitness*) which expresses how close the particle position is wrt. global optimum. Initially, the PSO samples a random *population* of N particles, denoted by a set of position vectors $\mathbb{X} = \{\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3, ..., \mathbf{x}_N\}$. For an iteration i of the PSO algorithm and particle $j : \{1 \leq j \leq N\}$, the terms *velocity* and *position* are defined as:

$$\mathbf{v}_j(i+1) = \alpha.\mathbf{v}_j(i) + \beta.(\mathbf{p}_j(i) - \mathbf{x}_j(i)) + \gamma.(\mathbf{p}_g(i) - \mathbf{x}_j(i))$$
$$\mathbf{x}_j(i+1) = \mathbf{x}_j(i) + \mathbf{v}_j(i+1)$$

where α is the inertial weight, β is the cognitive acceleration coefficient, γ is the social acceleration coefficient, $\mathbf{p}_j$ is the best position (where the fitness function is maximally optimal, up to iteration i) of particle j, and $\mathbf{p}_g$ is the best position for the entire swarm. Abstractly, in every iteration $i+1$, each particle j attempts to *update* its position $\mathbf{x}_j(i+1)$ based on the position in the previous iteration $\mathbf{x}_j(i)$ and a computed *velocity* $\mathbf{v}_j(i+1)$. Now, this velocity vector is computed by combining three pieces of information:

1. **Velocity in the previous iteration**: denoted by $\mathbf{v}_j(i)$
2. **Exploration / Particle behaviour**: Velocity computed by considering the best position explored by the particle so far (denoted by the vector $\mathbf{p}_j(i)$).
3. **Exploitation / Swarm behaviour**: Velocity computed by considering the best position across the entire swarm (denoted by the vector $\mathbf{p}_g(i)$).

The parameters α, β, and $\gamma \in [0,1]$ control the importance given to each of these three information points, and directly affect how a particle moves across the search space.

3 Shesha: Automatic Analysis of Bad Speculation in Instruction Set Extensions

In this section, we put forward a Particle Swarm Optimizer (PSO) inspired framework to perform an optimized exploration of search space related to bad speculation in ISEs. Towards this, we first elaborate on how the search space of bad speculation is *disjointedly fragmented*, allowing us to make modifications to generic PSO semantics (cf. Section 2.2) that provide faster convergence rates. Concretely, following the semantics of Section 2.2, instead of relying upon the entire swarm for swarm behaviour, the algorithm need only rely upon fragmented portions of the swarm, thereby allowing

Table 1: Performance counters reporting on occurrences of bad speculation. (TMA: Top-down Microarchitecture Analysis)

Name	Description	Class of bad speculation
ASSISTS.FP	Counts all microcode Floating Point assists.	Microcode assist
ASSISTS.HARDWARE	Counts all hardware assists.	Microcode assist
ASSISTS.PAGE_FAULT	Counts all assists related to page faults.	Microcode assist
ASSISTS.SSE_AVX_MIX	Counts all assists related to AVX-SSE transitions.	Microcode assist
MACHINE_CLEARS.DISAMBIGUATION	Counts machine clears due to disambiguation issues	Machine clear
MACHINE_CLEARS.MEMORY_ORDERING	Counts machine clears due to memory ordering issues	Machine clear
MACHINE_CLEARS.SMC	Counts machine clears due to self-modifying code	Machine clear
BR_MISP_RETIRED.ALL_BRANCHES	Counts retired, mispredicted branch instructions.	Branch misprediction
TOPDOWN.BR_MISPREDICT_SLOTS	Counts TMA slots wasted due to branch misprediction	Branch misprediction

more granularity and enabling faster convergence. The disjointedly fragmented nature of the search space allows splitting Shesha into two phases: ① Cognitive phase (where there is no social acceleration), and ② Mixed phase (partial social/cognitive acceleration). By end of phase ①, each particle of the swarm is present in one of the disjointedly fragmented sub-space, and has knowledge of other particles in the same subspace. Thereby, in phase ②, the social acceleration component can be focused only on the fragmented sub-space. We detail this modification to the PSO semantics further in this section, along with the threat model.

3.1 Threat Model

Since the objective of Shesha is to *explore* possible avenues of transient execution attacks, we assume Ring 3 `sudo` privileges. However, for attack demonstration, we do not require `sudo` privilege and only assume user-level privilege. We further assume x86-64-based target systems with latest microcode patches and secure (patched) operating system, with all state-of-the-art mitigations against transient execution attacks. We assume no publicly known exploitable vulnerability is present in the system. We specifically focus on Intel CPUs with newer generation microarchitecture, both on client and server platforms. For our experiments, we execute Shesha on Intel CPUs from four generations: Alder Lake(12th gen Core i7) and Comet Lake (11th gen Core i7) on the client side and Sapphire Rapids (4th gen Xeon) and Ice Lake (3rd gen Xeon) on the server side. All subsequent discussions are contextual to these aforementioned machines.

3.2 Fitness function

As discussed in Section 2.2, the objective of a PSO is to optimize a well-defined fitness function $f : \mathcal{R}^n \rightarrow \mathcal{R}$. Since our search space is instruction sequences enabling bad speculation over ISEs, our fitness function must be a combination of indicators that capture the existence or absence of bad speculation. For a code sequence $\mathcal{C}$, in our context, f can be defined as $f : \mathcal{C} \rightarrow \{0,1\}$, or f provides a binary decision whether bad speculation was observed for a given code sequence $\mathcal{C}$. We defer discussion on the generation of $\mathcal{C}$ to Section 3.4.1 and focus on the binary decision of bad speculation here.

First, we detail on when bad speculation happens in modern Intel processors. Intel's Software Developer Manual [24] states bad speculation occurs from three major causes - ① branch misprediction, ② microcode assists, and ③ machine clears. Branch misprediction related transient execution occurs due to the need to squash micro-operations issued from the mispredicted branch and re-issue the ones from the correct branch. Likewise, microcode assists are needed when the hardware needs to rely upon microcode for execution. In such a scenario, the speculatively issued micro-operations from the micro-operation decoder are flushed from the pipeline, and are replaced by the micro-operations from the microcode sequencer (which in turn fetches these micro-operations from microcode ROM). Finally, machine clears also cause transient execution for events like memory ordering violations, self-modifying code execution, and so on.

Given this context, to implement the fitness function $f : \mathcal{C} \rightarrow \{0,1\}$, we require an interface to capture when any of ① branch mis-prediction, ② microcode assist, or ③ machine clear happens. All modern Intel systems expose a Performance Monitoring Unit[1] that logs different types of events occurring on the physical cores for analysis. Such performance counters are useful in understanding occurrences of bad speculation, given any code sequence $\mathcal{C}$. Table 1 summarizes the exact performance counters we used for Shesha. Therefore, given a code sequence $\mathcal{C}$, the objective of the PSO will be to *maximize* occurrences of bad speculation as reported by the respective performance counters.

3.3 Disjointedly Fragmented Sub-spaces

We now discuss the nature of bad speculation events that we term as *disjointedly fragmented* sub-spaces which allows us to achieve faster convergence for Shesha and efficiently scale as the number of ISE instruction pool increases. As evident from Table 1, each of the performance counters pertains to bad speculation scenarios, which are **disjoint** from each other from a causal perspective. For instance, bad speculation due to

[1] Intel Perfmon events. https://perfmon-events.intel.com/

memory disambiguation issues has completely different cause (incorrect speculation while resolving load/store addresses) than bad speculation due to self-modifying code execution (incorrect speculation in writing to instruction cache). Additionally, the disjoint classes of bad speculation also have effects on disjoint architectural and micro-architectural assets. For example, memory disambiguation issues will mainly cause speculation in data forwarding in load/store buffers. On the other hand, self-modifying code execution issues will affect the instruction cache. Additionally, AVX-SSE transition issues shall affect the SIMD registers and temporal buffers. Therefore, we make the following observation:

Equivalence Classes: *Different scenarios of bad speculation in Table 1 are* ***disjoint*** *wrt. cause and effect (on architectural/micro-architectural assets), thereby splitting the search space of bad speculation into disjointedly, fragmented* ***equivalence classes****, where the cause/effect of one equivalence class are unaffected by that of other classes.*

Such a definition of *equivalence classes* (over set of instructions) ensures that the search space for bad speculation is split into disjointedly fragmented sub-spaces, such that the portion of the PSO's swarm working on one equivalence class need not rely upon the entirety of the PSO swarm for exploitation (cf. Section 2.2). For example, without loss of generality, consider a portion of the PSO swarm working with machine clears related to self-modifying code. Then, the velocity vector computations related to swarm behaviour (i.e. involving $\mathbf{p}_g(i)$, cf. Section 2.2) need not consider the portion of the swarm working with bad speculation due to branch mispredictions, simply because code sequences triggering branch misprediction (for instance, heavy use of loops to train the branch predictor) have no direct bearing with code sequences triggering self-modifying code (for instance, use of store operations in address ranges belonging to `.text` section of the process binary, thereby requiring write operations on the instruction cache). Based on this description of equivalence classes, we now detail the construction of Shesha in the next subsection.

3.4 Swarm Optimizer description

With the idea of equivalence classes established, we now detail Shesha - an automatic analysis framework for exploring the disjointedly fragmented equivalence classes of bad speculation in ISEs. Shesha is divided mainly into three phases: ❶ Swarm initialization, ❷ Cognitive phase, and ❸ Mixed phase. In phase ❶, a population pool of `N` particles is created where each particle represents a randomly sampled instruction sequence from the instruction pools of different ISEs. Then, in phase ❷, the particles are evolved to settle into sub-swarms (i.e. one swarm for one equivalence class). In this phase, since the sub-swarms are still being created, there is no exploitative behaviour (i.e. all particles evolve independently of each other). This design decision is intentional, following our discussion on equivalence classes in Section 3.3. Until the sub-swarms are ready, Shesha does not have reliable global best solutions to use for updating particle velocity (cf. Section 2.2 for PSO semantics). Finally, upon end of phase ❷, the sub-swarms would be ready for each of the equivalence classes, which is when phase ❸ kicks in and uses both *local* best and *global* best solutions to update particle velocity. We now explain these phases in detail.

3.4.1 Swarm Initialization

The first phase initializes a population of N particles, where each represents an instruction sequence, sampled from the ISE instruction set. Following the semantics from Section 2.2, each particle is represented by a position vector $\mathbf{x}$ in a n-dimensional real-valued vector space, such that the fitness function $f : \mathcal{R}^n \rightarrow \mathcal{R}$ can be evaluated upon the same. We describe now how we map a code sequence to a real-valued n-dimensional vector.

To achieve this, we leverage a machine-readable `x86` ISE list from uops.info [1] and use it to construct the ISE instruction set pool, further sub-divided into about 90 ISE types, like `AES`, `AVX`, `AVX2`, `AVX512EVEX`, `AVX512VEX`, `AVXAES`, `BMI1`, `BMI2`, `SSE`, `SSE2`, `SSE3`, `SSE4`, `X87` to name a few. Shesha allows the user to choose which ISEs to be explored. To generate a single particle, Shesha randomly samples n instructions from the selected instruction pool as well as randomly selects operands (for instance, which registers to use out of the entire register bank). Following the description of fitness function discussed in 3.2, this ordered set of n sampled instructions and their operands corresponds to the instruction sequence $\mathcal{C}$. In our experiment, we set the values of N and n as 50 and 10, respectively (without loss of generality).

Next, we derive a position vector $\mathbf{x}$ in the n-dimensional real vector space from $\mathcal{C}$. To do so, we first assign a unique real-value `opcode` to each instruction in the entire set of ISEs considered by Shesha. Likewise, the operand description of the instruction `opcode` is also assigned a uniquely identifiable real-value `operand_identifier_bitstring`. The `opcode` and the `operand_identifier_bitstring` can be combined to uniquely identify any instruction amongst all possible instructions in the ISEs under consideration. We note here that `operand_identifier_bitstring` depends simply on the operands used, and *not* on the actual data held by the operands when the instruction is executed. Finally, the *combined* representation of an instruction is uniquely identifiable by `(opcode « i) | operand_identifier_bitstring`, where i is the number of bits needed to uniquely identify the operands. We explain the mapping using an example. Assume the sampled instruction is `VPXOR xmm1, xmm2, xmm3`, where `VPXOR` is the AVX flavor of Logical XOR on SIMD registers `xmm1`, `xmm2`, `xmm3`. Now `VPXOR` shall have a unique `opcode` iden-

tifying this instruction, while each of the operand registers can be uniquely identified by a 4 bit value (since there are 16 unique `xmm` registers). Hence, the real-valued unique identifier for this instruction shall be `(vpxor_opcode « 12) | (1 « 8) | (2 « 4) | 3`, assuming `xmmk` register to be uniquely identifiable by the 4 bit integer k. Repeating the same procedure for all sampled instructions creates n distinct real values, which contribute to the n-dimensional position vector $\mathbf{x}$. At the end of this phase, we have the set of position vectors $\mathbb{X} = \{\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_N\}$. Next, we describe how to compute velocity vectors in order to mutate these position vectors.

3.4.2 Cognitive phase

In this phase, we allow for the *compartmentalization of the swarm population* into the disjointedly fragmented equivalence classes. Since the initialization phase has already computed the set of position vectors $\mathbb{X} = \{\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_N\}$, we focus on generation of velocity vectors that allow generation of sub-swarms (i.e. one sub-swarm for each equivalence class). In order to do this, we must prevent any exploitation/swarm behaviour (cf. Section 2.2) from kicking in the cognitive phase. For this case, we choose $\alpha = 1$, cognitive acceleration coefficient β as 0.4, and social acceleration coefficient γ as 0 (to cancel out any swarm behaviour). This forces using the local best solutions $\mathbf{p}$ with probability β. In this phase, we rely upon two kinds of mutations to the velocity vector:

1. **Modification to operands**: Given a particle position vector $\mathbf{x}_j : 1 \leq j \leq N$, we sample a random dimension $d : 1 \leq d \leq n$ and mutate the operands with probability β. Following the semantics of 3.4.1, assume $x_j^d =$ `(opcode « i) | operand_identifier_bitstring`), where | represents Logical OR. Thereby, the new position vector is evaluated as $\mathbf{x}'_j = \{x_j^1, x_j^2, ..., x_j^{d-1}, (x_j^d \wedge$ `(1 « i)) « i | new_operand_identifier_bitstring`, $x_j^{d+1}, ..., x_j^n\}$. Here, the newer operands that are sampled are converted to `new_operand_identifier_bitstring` using the same semantics as in Section 3.4.1. To follow upon the same example of `VPXOR xmm1, xmm2, xmm3` having representation `(vpxor_opcode « 12) | (1 « 8) | (2 « 4) | 3`) in the position vector, assume the operand mutation converted this instruction to `VPXOR xmm5, xmm13, xmm15`. Then the modified representation of the aforementioned instruction in the position vector can be given by `(vpxor_opcode « 12) | (5 « 8) | (13 « 4) | 15`).

2. **Modification to instruction**: Like operand modifications, here also $x_d =$ `(opcode « i) | operand_identifier_bitstring`) is mutated as $x'_d =$ `(new_opcode « i) | operand_identifier_bitstring`) with probability β (cognitive acceleration coefficient), where `new_opcode` is a newly sampled instruction from the ISE set. Again taking the same example, suppose `VPXOR xmm1, xmm2, xmm3` is mutated to `VPAND xmm1, xmm2, xmm3`, then `(vpxor_opcode « 12) | (1 « 8) | (2 « 4) | 3`) shall be mutated to `(vpand_opcode « 12) | (1 « 8) | (2 « 4) | 3`).

Finally, the mutated position vector is evaluated upon the fitness function as defined in Section 3.2 to understand if the mutated particle discovers some newer avenues of bad speculation. As iterations of the Cognitive phase increase, the entire population of particles converges upon one of the several disjointedly fragmented equivalence classes. Thereby, at the end of the Cognitive phase, the sub-swarms belonging to each equivalence class $\mathcal{S}_1, \mathcal{S}_2, ..., \mathcal{S}_9$ are output to phase ❷ (where each S_i belongs to one equivalence class as in Table 1). Concretely, each particle in the initialized swarm belongs to exactly one of these equivalence classes.

3.4.3 Mixed phase

In this phase, we enable swarm behaviour onto the discrete sub-swarms $\mathcal{S}_1, \mathcal{S}_2, ..., \mathcal{S}_9$ output from the Cognitive phase. Concretely, the Mixed phase makes the following changes to Cognitive phase settings: ① reduced rate of exploration, ② increased rate of exploitation from the sub-swarm $\mathcal{S}_i$ to which the particle belongs to. To achieve this, we set $\alpha = 1$, cognitive acceleration coefficient $\beta = 0.1$ (as opposed to 0.4 in the Cognitive phase), and the social acceleration coefficient $\gamma = 0.4$ (as opposed to 0 in the Cognitive phase). This setting still allows exploration using the local best solutions, albeit with reduced probability β, while also starting to use the global best solutions found in the sub-swarm $\mathcal{S}_i$ to which the particle belongs. In this phase, we rely upon three kinds of mutations to the velocity vector:

1. **Modification to operands**: Same as Cognitive phase, but with reduced probability $\beta = 0.1$ instead of 0.4.

2. **Modifications to instruction**: For each particle position vector $\mathbf{x}_j$ belonging to some sub-swarm $\mathcal{S}_k$, sample two random dimensions $d_1, d_2 : 1 \leq d_1, d_2 \leq n$ and mutate $x_j^{d_1}$ as in Cognitive phase with probability $\beta = 0.1$. For dimension d_2, with probability $\gamma = 0.4$, replace the d_2-th dimension of $\mathbf{x}_j$ with the d_2-th dimension of the leader of sub-swarm S_k. Here, *leader* of the sub-swarm $\mathcal{S}_k$ is defined as the position vector in sub-swarm S_k with maximum fitness as described in Section 3.2 (i.e. the instruction sequence with maximum bad speculation in the equivalence class $\mathcal{S}_k$).

3. **Dimensionality Reduction**: For a given position vector $\mathbf{x}_j : 1 \leq j \leq N$ belonging to sub-swarm S_k and defined as $\mathbf{x}_j = \{x_j^1, x_j^2, x_j^3, ..., x_j^n\}$, remove a randomly sampled dimension $d : 1 \leq d \leq n$ with probability $\beta = 0.1$. One might recall that each element in $\mathbf{x}_j$ is representative of

Table 2: Leakage Variants Discovered by Shesha

Cases	Operations	Register Dependency	Equivalence Class	Assets Affected	Generation	Window Size	Attack Type
①	SIMD-Vector intermixing	×	SMC, SAM	I-Cache, SIMD registers	12G ✓, 11G × 4X ✓, 3X ×	17 (1 `rep`)	Leak
②	Single and Double precision intermixing	✓	HW, SMC, MO	I-Cache, precision conversion hardware, SIMD buffer	12G ✓, 11G × 4X ✓, 3X ×	20 (100 `rep`)	Leak
③	Fused Multiply and Addition	×	FPA	FPU	12G ✓, 11G ✓ 4X ✓, 3X ✓	12 (32 `rep`)	Leak, Injection
④	SSE-AES using Denormal numbers	✓	FPA, SMC	FPU, AES hardware	12G ✓, 11G ✓ 4X ✓, 3X ✓	12 (32 `rep`)	Leak, Injection

SMC: Self-Modifying Code; SAM: SSE-AVX Mix; HW: Hardware Assist; FPA: Floating Point Assist; MO: Memory Ordering; rep: No. of repetitions
Leak: Transient Leakage through Flush+Reload; Injection: Floating Point Value Injection; ✓: Required or Available; ×: Not required or Not available
FPU: Floating point unit; 12G: Alder Lake; 11G: Comet Lake; 4X: Sapphire Rapids; 3X: Ice Lake

an instruction. Hence, informally, we can treat the real-valued vector $\mathbf{x}_j$ as an instruction sequence $\mathcal{C}$ comprising of n instructions. Therefore, dimensionality reduction aims to *reduce* this instruction sequence so as to generate smaller and focused sequences, while still maximizing the occurrence of bad speculation.

At the end of this phase, Shesha outputs the population position vectors with maximized fitness (i.e. maximum occurrence of bad speculation) in the respective equivalence classes. We note that dimensionality reduction, in particular, ensures that the final output of Shesha is able to drop instructions from the generated instruction sequence that may not contribute to bad speculation. In other words, because of dimensionality reduction, the final output of Shesha is a *minimal* reproduced instruction sequence responsible for the relevant bad speculation scenarios detailed in Table 1.

4 Uncovered Transient Execution Paths

We ran a test campaign of 24 hours, in which most observations were obtained within the first 8 hours (refer to Algo. A in Appendix for description of the algorithm). Since we rely upon Intel Performance Monitoring Unit (PMU), which captures the *events* occurring in the system with certainty, the false positive rate of Shesha is zero. In this section, we detail the novel transient execution paths uncovered by Shesha as a result of the testing campaign. We also reverse engineer the root-cause of these transient execution paths and detail their effect on the overall behaviour of the system under test.

1. **Hardware assists for precision conversion**: All floating point numbers can have two precision levels: single or double. With dedicated instructions for single precision and double precision separately, the same set of registers (i.e. {`xmm0, xmm1, ...`}, {`ymm0, ymm1, ...`} and {`zmm0, zmm1, ...`}) need to be interpreted as single precision or double precision based on the instruction operand. In this context, we uncover a **hardware assist** that kicks in case of data dependencies between instructions that intermix {`xmm0, xmm1, ...`}, {`ymm0, ymm1, ...`} and {`zmm0, zmm1, ...`} in different precision modes, where the data in the SIMD register bank needs to be interconverted between single and double precision modes.

2. **Self-modifying code execution due to intermixing precision**: Likewise, intermixing different representations of {`xmm0, xmm1, ...`}, {`ymm0, ymm1, ...`} and {`zmm0, zmm1, ...`} wrt. precision also causes **machine clears** involving updates to the instruction cache, enabling yet another transient execution path.

3. **Memory ordering issues due to intermixing precision**: We also uncover that intermixing instructions with single/double precision causes **memory ordering based machine clear**, uncovering a new transient execution path not discussed prior in literature.

4. **Intermixing SIMD-Vector instructions**. A wide variety of ISEs like `AVX`, `AVX2`, `AVX512EVEX`, `AVX512VEX`, `SSE`, `SSE2`, `SSE3`, `SSE4`, `SSE4a`, and `SSSE3` share the SIMD register banks {`xmm0, xmm1, ...`}, {`ymm0, ymm1, ...`} and {`zmm0, zmm1, ...`}. As such, transitioning from SIMD to Vector instructions or vice-versa incurs a machine clear attributed to self-modifying code. We note that although older Intel generation processors like Skylake had transition penalties related to intermixing of SIMD-Vector instructions [24], recent Intel processors up to Comet Lake have no such penalties [40]. However, as we uncover, the 12-th generation client processor (Alder Lake) and 4-th generation Xeon processor (Sapphire Rapids) show transient execution due to an involved **machine clear due to self-modifying code**.

5. **FP assist due to Denormal arithmetic**: We also uncover newer avenues of **Floating Point assists** in the Fused-Multiply-Add instruction family as well during

transitions between AES-NI and SSE instructions. Although Floating Point assists have been demonstrated before [40], our tool and analysis show that Floating Point assists have a wider scope than simple SIMD arithmetic (as previously discussed in literature).

5 Shesha Design Choices

We now explain the choice of parameters by comparing the role of Particle behaviour and Swarm behaviour in Shesha. To do so, we define 6 variants of Shesha wrt. hyperparameters β (which controls Particle behaviour) and γ (which controls Swarm behaviour). To compare between the variants, we define two metrics: ① time taken to find the *first* SIMD-Vector speculation, and ② time taken to find the *first* precision intermixing speculation. The reason for this (as detailed in subsequent sections) is because SIMD-Vector speculation is the easiest of the four (cf. Table 2) to discover. This is because of the large number of instructions under these ISEs, as well as no special requirement (like read-after-write dependencies, or specific floating-point arithmetic) needed to trigger this speculation. Precision intermixing, however, is on the other extreme, and is the hardest of the four to uncover. This is because (as we detail in Section 6.2) such speculation requires closely tied instructions that handle single/double precision respectively, and have read-after-write dependency.

Variants Shesha$_{\{\beta=1,\gamma=0\}}$ and Shesha$_{\{\beta=0,\gamma=1\}}$ are essentially equivalent to random sampling, with different sources. The former prioritizes mutating the chosen instruction within the particle itself by replacing it with a random instruction with probability 1. The latter also works to similar goal, but replaces the chosen instruction with another instruction from other particle in the swarm. Then, variants Shesha$_{\{\beta=0.4,\gamma=0\}}$ and Shesha$_{\{\beta=0.1,\gamma=0\}}$ test the extent of particle behaviour by changing the probability β of replacing a chosen instruction with a randomly sampled instruction. Finally, variants Shesha$_{\{\beta=0.1,\gamma=0.1\}}$ and Shesha$_{\{\beta=0.1,\gamma=0.4\}}$ test the extent of swarm behaviour by changing the probability γ of replacing a chosen instruction with an instruction from another particle in the swarm. We summarize these in Table 3.

First, we note that Shesha$_{\{\beta=0.1,\gamma=0\}}$ is inherently slow in both aspects we consider here: it adopts a *random* sampling strategy (by setting $\gamma = 0$), and performs such sampling at a reduced rate of 0.1. The best performance (wrt. Precision Intermixing) is given by Shesha$_{\{\beta=0.1,\gamma=0.4\}}$, which allots a slightly higher probability of swarm behaviour (through $\gamma = 0.4$) than other variants. However, it is the variant Shesha$_{\{\beta=0.4,\gamma=0\}}$ that outperforms all wrt. SIMD-Vector intermixing, possibly due to balancing the aggressiveness with which to replace instructions. Interestingly, note that variants equivalent to random sampling (i.e. Shesha$_{\{\beta=1,\gamma=0\}}$ and Shesha$_{\{\beta=0,\gamma=1\}}$) perform fairly poorly wrt. SIMD-Vector intermixing (possibly due to very aggressive mutation strategy).

As a result, in our final deployment of Shesha, we adopt a mixture of variant Shesha$_{\{\beta=0.4,\gamma=0\}}$ and variant Shesha$_{\{\beta=0.1,\gamma=0.4\}}$. The first variant forms the Cognitive phase (cf. Section 3.4.2), while the second variant forms the Mixed phase (cf. Section 3.4.3). Finally, we note that variant Shesha$_{\{\beta=1,\gamma=0\}}$ *simulates* other *fuzzing* (essentially relying upon a random sampling strategy) based tools like [36, 38, 39, 55] had they supported ISEs like AVX/SSE/FMA and so on. For comparison however, we report the raw data from these works, albeit with different objectives over mostly x86 ISA. For instance, wrt. the speculative paths and ISA explored by [38], it is able to detect violations in about 5 minutes (which is comparable to Shesha$_{\{\beta=0.4,\gamma=0\}}$'s detection time for SIMD-Vector transient path detection). Likewise, in [36], the entire fuzzing campaign lasts about 20+ CPU hours. On similar lines, the detection in [39] ranges from a minute to about an hour based on the type of speculation targeted [2]. One must note that the objectives of each of these tools (as presented in their corresponding papers) were different, and thus, they explore different subsets of ISAs. Shesha works with comparatively larger ISA set and thus explores wider range of instruction combinations and stimulates variety of specialized execution units and buffers.

Table 3: Time taken to uncover speculation by the variant.

Variant	SIMD-Vector	Precision Intermixing
Shesha$_{\{\beta=1,\gamma=0\}}$	0.5 hour	14 hours
Shesha$_{\{\beta=0.4,\gamma=0\}}$	0.01 hour	8 hours
Shesha$_{\{\beta=0.1,\gamma=0\}}$	1 hour	$\approx$ 24 hours
Shesha$_{\{\beta=0.1,\gamma=0.1\}}$	0.6 hour	4 hours
Shesha$_{\{\beta=0.1,\gamma=0.4\}}$	0.03 hour	2 hours
Shesha$_{\{\beta=0,\gamma=1\}}$	0.5 hour	9 hours

6 Root-Cause Analysis of Discovered Transient Execution Paths

We now provide root-cause analysis for the two transition-based leakages discovered by Shesha, namely, SIMD-Vector transition and single-double precision transitions.

6.1 SIMD-Vector Transition based SMC

SIMD and Vector instruction extensions like `AVX`, `AVX2`, `AVX512EVEX`, `AVX512VEX`, `SSE`, `SSE2`, `SSE3`, `SSE4`, `SSE4a`, and `SSSE3` are central to several performance gains experienced in modern Intel processors. These ISEs allow greater than 64 bit registers holding more than one data point, to be operated in parallel by the same instruction (hence the name SIMD type ISEs). To do so, modern IA-64 architectures define a register bank with sixteen 512-bit wide registers. Interestingly, ISEs like `AVX2`/`SSE` allow *differing* representations of the *same* hardware register in two dimensions: ① width w of the register, and ② the SIMD repre-

[2] [55] does not report convergence time.

sentation of the data contained in that width *w*. To elaborate on dimension ①, the *same* hardware registers can be interpreted as 512-bit wide registers `zmm0, zmm1, zmm2, ..., zmm15` (by ISEs like `AVX512EVEX`, `AVX512VEX`), as 256-bit wide registers `ymm0, ymm1, ymm2, ..., ymm15` (by ISEs like `AVX2`), and as 128-bit wide regisers `xmm0, xmm1, xmm2, ..., xmm15`. Likewise, regarding dimension ②, the same data in any `zmm`/`ymm`/`xmm` register can be interpreted as differently packed integer/floating-point value. This discussion raises a concerning question: *Given a processor allowing executions of ISEs requiring different representations of the same hardware, how are transitions between such ISEs handled*? According to the Intel Software Developer Manual [24], the exact implementation to handle such transitions depends upon the exact micro-architecture under question. We make the following observation as the root cause of bad speculation (as in Table 2) encountered in modern Intel processors when transitioning from SIMD to Vector instructions (and vice-versa)[3].

Observation. *By deciding to remove the Finite State Machine based register dependency analysis and insertion of blend operations into the issue state of the pipeline, micro-optimizations for Alder Lake and Sapphire Rapids handle SIMD-Vector transitions by incurring a self-modifying code execution that inserts the blend operations directly into the instruction cache, therefore causing speculation.*

6.2 Precision based Transient Execution Paths

Modern ISEs usually work upon a register bank of 16 registers of width 512 bits, and the same data on these registers can be interpreted in different ways. While it is straightforward to switch between integer representations, switching between single-precision and double-precision representations is an involved process. Through the course of our testing campaign, Shesha uncovered a previously unknown source of transient execution paths: *non-explicit switching between single and double precision floating-point numbers in a Read-after-Write (RAW) data dependency*. Concretely, a sequence of two instructions linked by a RAW dependency causes novel transient execution paths on Intel CPUs if they require contrasting representations (single precision vs double precision) of the same floating-point number. Interestingly, three independent, completely novel transient execution paths are uncovered by Shesha as a result of single/double precision intermixing with RAW data dependency- ① hardware assist (HW), ② self-modifying code (SMC) based machine clear, and ③ memory ordering (MO) violation based machine clear. For all subsequent discussions, we consider the following abstract instruction sequence (`SP`: single precision instruction, `DP`: double precision instruction):

1. `SP xmm0, xmm1, xmm2` followed by `DP xmm3, xmm4, xmm0` **OR**
2. `DP xmm0, xmm1, xmm2` followed by `SP xmm3, xmm4, xmm0`

Precisely, for the discussed transient paths to kick in, the requirement is a set of at least two instructions with a Read-after-Write (RAW) dependency connecting them (using the `xmm0` register in the above examples), without occurrence of an explicit conversion instruction (like `CVTPD2PS` or `CVTPS2PD`) in between. We note here that Write-after-Write (WAW) or Write-after-Read (WAR) dependencies do *not* trigger any of the following transient paths, simply because there is no need for any implicit precision conversion as the second instruction is *writing* to the dependent register and not reading from it. Writes from a single-precision instruction to a register holding a double-precision value are architecturally simply *overwriting* the registers, and thus incur no transient executions. We summarize the following observation as the root cause of all the bad speculation events when transitioning between single and double precision[4].

Observation. *Owing to differing representations of same data in `xmm`/`ymm`/`zmm` wrt. single and double precision, a read-after-write (RAW) dependency without `CVTPD2PS`/`CVTPS2PD` incurs a hardware assist to perform implicit conversion, hence triggering aggressive speculation. Moreover, accompanying machine clears related to self-modifying code and memory ordering are also involved, thus contributing to speculation.*

7 Attack Building Blocks

7.1 Transient Execution Window

Transient execution paths guarantee flushing of the in-flight micro-operations from the pipeline and re-steer the execution on the correct path. As such, the *width* of the transient window for any given transient execution path determines the number of micro-operations an attacker can issue on the transient path before the rollback of the instructions. Practically, a larger transient window allows for executing complex attack vectors in the transient path. Architecturally, no effect of any transient micro-operation is visible. Therefore, we need to rely upon micro-architectural effects to measure the transient window. In our case, we compute the transient window by counting the number of transient loads executed before the pipeline rollback. When no bad speculation (discovered by Shesha) occurs, we observe no activity in the transient path, implying absence of misprediction-based transient execution. Our results are summarized in Table 2. In comparison to the machine

[3] For details of these implementations and our reverse-engineering approach, please refer to Appendix B of the full version of the paper [10].

[4] For a detailed discussion on each of these transient execution paths and our reverse-engineering approach, please refer to Appendix C of the full version of the paper [10].

clears presented in [40], we conclude that the SIMD-Vector transition-based SMC exhibits a larger transient window than all other variants of transient executions through machine clears or assists (both uncovered here as well as in [40]). This observation directly ties in with the number of *repetitions* (for warming up the execution pipeline) an attacker needs to do on the transient path before the actual attack can be mounted (cf. Section 7.1). As evident, due to the largest transient window with minimum number of repetitions, SIMD-Vector transition-based SMC provides a very practical transient execution path (with effectively no repetitions required), thereby becoming an actual choice for an adversary to mount in-the-wild attacks.

Enlarging the transient window. As different transient execution paths have differing transient windows, not all of them would be directly suited to leak reliably. To circumvent this, a usual method is to warm up the pipeline before the actual attack; this can be done solely on the attacker's end. This can be done by several repetitions (`rep`) of the same transient operations to maximize the transient window. To determine the extent of pipeline warm-up needed to leak data, we increase the repetitions of warm-up until we observe leakage from the Flush+Reload [57] covert channel. In Table 4, we provide a comparative analysis of the number of repetitions needed to warm up the pipeline. Lesser the number of required repetitions `rep`, more likely it is to find in-the-wild occurrence of the uncovered transient paths in in-the-wild code bases [5].

Table 4: Comparative analysis of the extent of pipeline warmup needed by different transient paths. Leakage rate is computed as the ratio of number of transient loads to the `rep` needed to observe visible differences in Flush+Reload [57].

Transient Path	Required `rep`	Leakage Rate
FP assist [40]	32	0.375
SMC assist [40]	20	0.3125
Snoop MO [40]	150	0.4
MD [40]	32	0.53125
Page Fault [35, 36]	1	0.1
SIMD-Vector (**Our work**)	1	17
D2S/S2D (**Our work**)	100	0.2
FMA/AES (**Our work**)	28	0.42

7.2 SMT Covert Channel

We demonstrate a covert channel using contention in the affected hardware assets. Two processes are pinned to two logical cores of the same physical core. Hence, we assume Simultaneous Multi-Threading (SMT) or HyperThreading to be enabled for the covert channel construction to work since the affected assets identified (in Table 2) are shared in an SMT setting. The construction of the covert channel relies upon two actors: a *sender* and a *receiver*, executing on the same physical core. The receiver *times* the execution of a code sequence $\mathcal{C}$ ($\mathcal{C}$ has no possibility of any transient execution). In contrast, depending on whether the sender has to send bit 1 or 0, it performs an additional execution involving transient execution. The presence or absence of transient execution causes contention in the concerned hardware assets, leading to a perceivable timing difference on the receiver side. Such a covert channel instantiated with SIMD-Vector transition transient executions has a bandwidth of 2 KB/s with an accuracy of 87%.

7.3 Load Value Injection

In addition to the **Leak** attack type summarized in Table 2 and detailed in Section 7.1, the Floating Point operations relying upon an assist to carry out the denormalization operation forward incorrect *data* to subsequent transient instructions, before denormalization finishes. This scenario is a floating point flavor of classic load value injection (LVI) in transient executions [40]. However, unlike Section 7.1, the exact transient value injected into the transient operations is not architecturally visible. Hence, the adversary needs to mount LVI in two phases: ① offline phase where the adversary fuzzes the transient operation using different inputs and constructs the transient output, and ② online phase where the adversary uses the specially crafted inputs from ① that give a transient output of adversarial interest. On comparing the architectural result of the computation against the constructed LVI output, we observed both to be different, implying a successful transient value injection attack.

7.4 FP Assists due to FMA instructions

According to IEEE-754 standard, any floating point representation of a number consists of three parts: ① sign bit, ② biased exponent e, and ③ mantissa m. The standard also defines *denormalization*: a choice to trade precision for wider range of floating point numbers that can be represented. Concretely, if $e = 0$ and $m \neq 0$, denormalization can allow for a gradual underflow by appending enough leading zeroes to the mantissa until the minimal exponent is achieved.

As stated in [40], denormalization requires a Floating Point assist (denoted by `ASSISTS.FP` in Table 1), which kicks in micro-operations to *gradually underflow* a floating point number close to 0. This causes a flush of the current in-flight micro-operations from the execution pipeline, thereby creating a transient window where non-*denormalized* floating-point values are forwarded to subsequent instructions speculatively, resulting in a transient window of executions on incorrect data, while the floating-point assist is *denormalizing* the concerned value. In [40], this transient window is used to construct a flavor of load-value injection exploits on the `SSE2` instruction extension. Through Shesha however, we uncover existence of this transient execution path in other

[5] We could not test the pipeline warmup and leakage rates for [55] and [44] because of absence of Intel TSX on our test platforms.

ISEs as well [6], most notably in Fused-Multiply-Add (FMA) instructions like `VFMADD132SD`, `VFMADD132PD`, or exponentiation instructions like `VSCALEFSS`.

8 Exploiting Leakage from FMA

An interesting finding by Shesha is the transient nature of the Fused Multiply-Add (FMA) instruction set extension, which warrants a deeper investigation. Although the transient nature of AVX instructions is well-known [35, 40], the security implications of FMA (and its variants) instructions have not been studied in literature before. In this section, we develop on the findings of Section 7.4, and focus on the exploitability of previously unreported speculation in FMA execution.

8.1 Fused Multiply-Add Execution Unit

FMA instructions have been traditionally introduced to accelerate arithmetic capabilities of Intel processors. Such instruction extensions are capable of performing *fused* arithmetic operations in one instruction execution. The classic FMA family of instructions can support operations like: ① fused multiply-add, ② fused multiply-subtract, ③ fused multiply add/subtract interleave, ④ signed-reversed multiply on fused multiply-add and multiply-subtract. Moreover, several new "FMA-like" instruction extensions have been introduced to similar effect. For instance, the Integer-FMA extension introduces two instructions that perform FMA-like operations, but on packed integers. Likewise, the 4FMAPS extension allows packing up-to four vectors in one operand (as opposed to a single vector allowed in FMA/IFMA).

Intel processors provide a specialized execution unit for FMA (and its associated sibling) extensions as detailed by the patents [5, 15]. The architecture of the hardware for executing FMA instructions poses an interesting insight: *specialized "Memory Access Units" (MAU) reside within the execution cluster of execution engine units* dedicated to FMA instruction execution. Concretely, once the *frontend* unit performs the instruction fetch and instruction decode, it issues the relevant operations to the *backend*, which consists of several units like the register file, the register renaming unit, the scheduler unit, the retirement unit, the execution unit, *and* the memory access unit. We emphasize that both the instruction cache unit as well as the instruction translation look-aside buffer (TLB) unit are a part of the *frontend*, and not the *backend*. Moreover, the MAU interfaces with both the data cache unit as well as the data TLB unit (which sit *outside* the execution engine unit, as a separate memory unit) [7].

[6] Shesha also uncovers previously unreported combinations of AES and SSE instruction sequences (like `AESDECLAST` and `MULSS` sharing a Read-after-Write register dependency) to also incur Floating-Point assists.

[7] We omit a detailed architecture description of the FMA execution unit for want of conciseness. Interested readers can refer to Intel patents [5] and [15] for more details. It must also be mentioned that these architectural descriptions depict the overall idea, and the actual implementation in the processors might differ.

8.2 Leaking arbitrary data from FMA instruction execution

As highlighted in the previous subsection, the FMA execution unit houses MAU whereas the data-cache and dTLB are kept outside the execution unit, in a stand-alone memory unit. We hypothesize that MAUs are essentially meant for *buffering optimizations*. Recall that almost all FMA (and its associated sibling extensions) have instruction variants that can take memory operations. For example, consider `VFMADD132PD zmm1, zmm2, zmm3`, which multiples the first and third operands, and then adds the product to the second operand. The other flavor of this instruction is `VFMADD132PD zmm1, zmm2, zmmword PTR [rcx]` which fetches the third operand directly from memory. Since all FMA instructions (and its sibling extensions) have flavors supporting memory operands, we hypothesize the aforementioned "Memory Access Units" or MAUs are essentially *buffers* that optimize these memory reads.

From Section 7.4, we recall that Shesha has undiscovered the possibility of speculation in FMA execution. Such speculation, tied with the existence of buffers *inside* FMA execution engine, could leak to leakages. In this context, we test the following two hypotheses related to the transient behavior shown by the FMA instructions:

❶ With speculative execution in FMA execution engine (cf. Section 7.4), does FMA "Memory Access Units" transiently forward data to speculatively executing FMA instructions?

❷ With speculative execution in SSE-AVX execution engine, does FMA "Memory Access Units" transiently forward data to speculatively executing SSE-AVX instructions?

It must be mentioned that hypothesis ❷ draws from our yet another observation about the architecture of FMA execution unit [5, 15]. The register file is shared between SSE-AVX and FMA execution engines. Concretely, the same set of `xmm/ymm/zmm` registers used by SSE-AVX instructions are also used by FMA instructions. This leads us to investigate whether any *cross-interaction* exists between these two execution engines.

All experiments are performed on 11^{th} Gen Intel(R) Core(TM) i5-11500, microcode version `0x57`, with support for FMA and IFMA extensions. We do not assume any privileges for the adversary, except for the userspace privilege to execute code.

8.2.1 Intra-FMA Execution Engine Leakage

To test hypothesis ❶, we execute victim and attacker threads on co-located CPUs. The victim thread executes FMA instructions in a tight loop. We program the victim's memory access

to some known byte (specifically `0xfa`), which is accessed by the FMA instruction. This is done to groom the MAUs within FMA execution engine with known data [8].

The attacker process forces speculation in FMA instruction (cf. Section 7.4) with memory operand. One example is `VFMADD213PD zmm1, zmm2, zmmword PTR [rcx]`), which multiplies the first and second operands and adds the value loaded by the third operand. Similar to the experiments detailed in Section 7.4, we force a floating-point assist by grooming `zmm1` and `zmm2` with carefully crafted denormal operands. Finally, we encode the entire width of `zmm1` (which is the destination register) into a Flush+Reload covert channel to leak transiently forwarded data.

In our experiments, we use the primitives detailed in Table 4 to construct and enlarge the transient window to cover speculation in FMA. Overall, we do not observe the programmed victim memory leaking through the adversarial thread's Flush+Reload channel. We attribute this absence of speculative forwarding of stale data to ① lack of speculative forwarding of stale data from MAUs to transiently executing FMA instructions, or ② the inability of constructed transient windows to cover transient execution of FMA instructions (which are inherently complex to execute). There is no evidence to favor one reason over another, though, and we leave this to future work.

8.2.2 FMA-AVX Execution Engine Leakage

To test hypothesis ❷, we follow a similar setup as Section 8.2.1 with the exception that the adversarial thread engages the AVX execution unit. Interestingly, this time, we did observe statistically significant leakage. Listing 1 shows the Flush+Reload channel activity for the victim instruction `VFMADD213PD zmm1, zmm2, zmmword PTR [rcx]`. Note how the programmed victim memory (i.e. `0xfa`) is clearly leaking to the adversary.

```

Listing 1: Leakage when victim executes `VFMADD213PD zmm1, zmm2, zmmword PTR [rcx]`.

To test the extent of such leakage, we divided the ISEs related to FMA in the following families and tested leakage for all instructions in each family: ① `VFMADD*` (12 instructions from 3 sub-families: `VFMADD132*`, `VFMADD213*`, `VFMADD231*`), ② `VFMADDSUB*` (6 instructions from 3 sub-families: `VFMADDSUB132*`, `VFMADDSUB213*`, `VFMADDSUB231*`), ③ `VFMSUB*` (12 instructions from 3 sub-families (`VFMSUB132*`, `VFMSUB213*`, `VFMSUB231*`), ④ `VFMSUBADD*` (6 instructions from 3 sub-families (like `VFMSUBADD132*`, `VFMSUBADD213PD*`, `VFMSUBADD231PD*`), ⑤ `VFNMADD*` (12 instructions from 3 sub-families like `VFNMADD132*`, `VFNMADD213*`, `VFNMADD231*`), ⑥ `VFNMSUB*` (contains in-total 12 instructions from 3 sub-families like `VFNMSUB132*`, `VFNMSUB213*`, `VFNMSUB231*`), and ⑦ `IFMA` instructions (`VPMADD52HUQ` and `VPMADD52LUQ`).

We have confirmed the leakage in all aforementioned instructions. Moreover, other FMA-related ISEs like `4FMAPS` also follow a similar architecture as FMA and IFMA and could pose a similar risk of data leakage [9].

8.3 Attack on Cryptographic Applications

We now discuss the broader impacts of our findings. While FMA is usually used to accelerate arithmetic, it is the IFMA instruction pair that has received unprecedented adoption in recent years. This is because of IFMA instructions' capability to operate fused multiply and add operations on integers, allowing them to accelerate core operations in traditional cryptography (refer to Intel's guidelines on the same [26]). According to Intel Optimization Manual [23], IFMA is introduced for *big number multiplication for acceleration of RSA vectorized software and other Crypto algorithms (Public key) performance*. However, as a direct consequence of our findings, such optimized implementations are vulnerable to leakages, which we detail next.

8.3.1 "Almost" Montgomery Multiplication

In [17], the authors suggest using IFMA instructions to speed up modular exponentiation, which forms the basis for several critical cryptographic implementations (include RSA and ECC). This is done in two steps. First, "almost" modular multiplication (AMM) is defined algorithmically, in the sense that AMM lacks a final (conditional) reduction step (wrt. tradition modular multiplication). This allows output of one AMM call as inputs to subsequent AMM calls. Next, AMM is implemented and accelerated using `VPMADD52LUQ` and `VPMADD52HUQ` instructions. Similar to AMM, the authors in [17] also propose "almost" montgomery squaring (AMS), again accelerated using IFMA instructions. With AMM and AMS in place, modular exponentiation is effectively achieved through `VPMADD52LUQ`/`VPMADD52HUQ` instructions.

To test the extent of FMA leakage in AMM/AMS, we implement the `MulALPart` algorithm from [17] as depicted in Listing 2 (`MulAHPart` follows suit, but uses `VPMADD52HUQ` instead of `VPMADD52LUQ`). Similar to Section 8.2.2, the inputs to AMM/AMS are programmed to `0xfa`. `MulALPart` performs efficient left-shift in AMM/AMS implementation [17], such

[8] It must be noted that in an actual attack, the data would be controlled by the victim. We groom the victim's buffer in order to detect the leakage.

[9] Due to lack of support for `4FMAPS` in the CPUs we tested, we could not confirm the existence of leakage in `4FMAPS` extension family.

that this result can directly be used in other IFMA friendly operations in AMM/AMS. Note that AMM/AMS can be performed on any arbitrary integer A exceeding the width of FMA registers, thereby requiring a total of z logical registers (notated as $\{A_1, A_2, ..., A_z\}$). Likewise, i represents the index of the *current* chunk to be operated. A_{curr} is then assigned the broadcasted value of $A[i]$, while $\{X_1, X_2, ..., X_i, ..., X_z\}$ are temporary scratch variables. First, as in Line 4, X_i is assigned the value VPMADD52LUQ(X_i,A_{curr},A_i). Then, in a tight loop from $i+1$ to z, the temporary products VPMADD52LUQ(ZERO, A_{curr}, A_i) are computed, left-shifted, and added to previously computed X_j. From our discussion in Section 8.2, it is clear that the *third* input operand to IFMA instructions is vulnerable to leakage. With GCC, it is A_i that is emitted to be the third operand. This is intuitive: note that in VPMADD52LUQ(ZERO, A_{curr}, A_i), the first two operands are *fixed* for the entire duration of the loop and thus are pre-loaded by the compiler (as first and second operands of VPMADD52LUQ) in registers zmm1 and zmm3. Since A_i changes in every iteration, this becomes the *third* (memory) operand of VPMADD52LUQ. Therefore, the leaked value is the multiplicand $A_i : i \in \{i+1, i+2, ..., z\}$, which constitutes the actual input A to AMM/AMS.

Listing 2: Implementation of MulALPart algorithm [17]

```

Listing 3: Leakage when victim executes Listing 2.

As depicted in Listing 3, we successfully observe the programmed input $A = \{A_1, A_2, ..., A_z\}$ leaking in the attacker thread. Implication-wise, this compromises the *input* to AMM/AMS. Depending on the particular use-case where Montgomery multiplication and Montgomery squaring is deployed, such leakage has the potential of compromising sensitive data. For instance, in line with Intel's recommendation [23], should IFMA-enabled Montgomery multiplication/squaring be used to accelerate traditional RSA encryption, then the input to Montgomery multiplication/squaring is the victim plaintext itself. Moreover, Montgomery ladder algorithm is often used as constant-time and side-channel protected RSA and ECC implementations. In such cases, the ability of the attacker to observe the value of the operands of the Montgomery ladder algorithm essentially enables it to distinguish between the if and else part of the control flow [3, 27], thereby leaking the secret exponent. Apart from traditional public key algorithms, other forms of cryptosystems also use such multiplication and squaring. We discuss their respective FMA/IFMA accelerations and relevant vulnerabilities next.

8.3.2 Supersingular Isogeny Diffie-Hellman

In [14], the authors present IFMA based accelerations of Cumulative Supersingular Isogeny Diffie-Hellman (CSIDH), which is a post-quantum key establishment scheme in the isogeny-based cryptosystem family. The foundations of this cryptosystem rely on supersingular elliptic curves, which again require core arithemetic operations like multiplications. Intuitively, IFMA seems the perfect choice for accelerating such implementations. The authors propose parallelized operations on the elliptic curve groups, again through optimized implementations of Montgomery multiplication.

In this implementation, we target gfp_mul_8x1w[10], which is a 8-way montgomery multiplication using VPMADD52LUQ and VPMADD52HUQ. As before, we program the inputs to this function to 0xfa. Listing 4 displays the result of the attack.

8.3.3 Supersingular Isogeny Key Encapsulation

In [13], the authors use IFMA to accelerate SIKE, which is a post-quantum isogeny based cryptosystem (similar to SIDH in Section 8.3.2). Here too, IFMA is used to speed upbase/extension field arithmetic, point arithmetic, and isogeny computations. Since SIKE relies mainly on SIDH-friendly primes, techniques for speeding up modular reduction also apply here. Henceforth, as with Section 8.3.2, this implementation[11] is also vulnerable to the leakage demonstrated here.

A slightly different take on accelerating SIKE can be found in [32], which uses VPMADD (of the FMA family) instead of IFMA, to achieve similar aims of accelerating elliptic curve arithmetic. However, the vulnerability still stands, since VPMADD* sub-family of FMA instructions are also vulnerable

[10] https://gitlab.uni.lu/APSIA/AVX-CSIDH
[11] https://gitlab.uni.lu/APSIA/AVXSIKE

to this leak. This fact thereby reinforces the extent of the leakage's impact, irrespective of the underlying cryptosystem and its specification of ISEs used.

8.3.4 Other Use-Cases

We briefly mention other use-cases which have similar vulnerability. In [45], the authors propose IFMA based Montgomery multiplication, which again leaks the operands through the leakage described here. Likewise, in [58], Montgomery reduction is also sped up using IFMA, and is vulnerable to our attack. Note that [58] speeds up Dilithium, which is a post-quantum digital signature scheme, and has similar vulnerability as AMM in Section 8.3.1 of leaking the plaintext message being signed. Finally, recent works like [6] have also demonstrated the use of IFMA to speed up homomorphic operations as well, and is also vulnerable to the leak[12].

9 Related Works

Prior works on automated discovery of speculative vulnerabilities in processors can be broadly categorized into two classes based on their approaches for detecting leakages - ① using formal methods and ② fuzzing-based approach. Such tools have their own features and limitations and do not cover the exploratory search space that we target in this work.

Detection of Leakage through Formal Methods. Revizor [38] is a model-based tool built on the fundamentals of *contract traces* in processors and detects violation in the contracts to identify potential leakages. In order to generate contracts, Revizor uses *random instruction* sequences with use-case specific pruning - straight-line code for meltdown-type violations [21] and conditional branches for spectre-type violations [39]. As the instruction sequences are chosen randomly, both [21] and [39] consider a small subset of x86 instructions such as to not blow-up Revizor's search space. Moreover, Revizor monitors changes in the L1D cache state to detect contract violations. In contrast, Shesha does not rely on random instruction sampling and pruning from apriori knowledge of target speculative behavior. It works upon the formulation of equivalence classes to provide direction to its test case generation which allows defining a "fitness function" to maximize occurrences of bad speculation in every equivalence class. Furthermore, Shesha relies on PMCs, instead of L1D cache, to observe if bad speculation occurred. Scam-V [7, 37] is another tool that relies on model-based testing by generating instruction sequences as test-cases to record observation. Recently published Plumber [22] extends Scam-V to generate leakage templates based on changes in cache state. Both Scam-V and Plumber target ARM-ISA and uses symbolic execution to identify leakages. In contrast, Shesha targets x86-ISA and attempts to find novel leakage paths instead of matching templates.

Detection of Leakage using fuzzing. Although traditionally, fuzzing has been used to detect bugs in software, hardware-based fuzzing [16] has seen increasing popularity in recent years. *Transynther* [36] relies upon mutating known code sequences of attacks like [8, 33, 42, 50] through fuzzing to discover newer variants of Meltdown-type attacks. Similarly, Speechminer [55] generates random code snippets to detect speculation-based attacks. Both these tools use random fuzzing with templates, such as transient window enlargement gadget, faulted load, disclosure gadget, etc. that are known apriori in literature. Since, these tools were developed to target certain classes of speculations, they cannot be directly extended to explore the vast space of bad speculation. In contrast, Shesha does not place any restrictions on the explored bad speculation classes from apriori decisions. Furthermore, these tools work with limited subset of instructions and do not cover the ISEs handled by Shesha. Similarly, automation tools such as *Osiris* [52] and *Absynthe* [20] explore only contention-based attacks and not transient leakages.

10 Mitigations

We discuss purely software based mitigations against the transient paths discovered by Shesha.

Precision based assists and machine clears: As pointed out in Section 6.2, the SMC occuring due to the precision during hardware assist is managed as *loads*/*stores*. Thereby, an `lfence` before and after an instruction sequence with a homogeneous precision type (either double or single precision) *serializes* the load and eliminates transient execution.

SIMD-Vector Transition based SMC: As discussed in Section 6.1, SIMD-Vector transitions based SMC occur to effectively issue *blend* operations. As Intel Optimization Manual suggests [24], SIMD-Vector based SMC can be prevented by appropriate use of zero-latency instructions `vzeroupper`/`vzeroall` before and after a function executing SIMD or Vector instruction sequences.

Assists due to denormal arithmetic: Intel suggests to set the flags `FTZ` (Flush to Zero) and `DAZ` (Denormals are Zero) to prevent denormal numbers from occurring, thereby preventing the floating point assists. However, disabling denormals violates IEEE-754 standard and is not a viable solution for most applications and use-cases [18]. Moreover, custom compiler-level mitigations like [40] have an unacceptable overhead.

FMA leakage: One obvious mitigation is to disable Simultaneous Multi-Threading (SMT), albeit with performance hits. Another (software) mitigation strategy involves using `lfence` to serialize loads and prevent speculation, transitively preventing the leakage described in this work. An architectural change to disassociate FMA from the SIMD buffer can stop FMA-AVX cross-execution unit leakage.

[12] It is unclear, though, what the extent of exploitability is in the case of homomorphic encryption. This is because even though there is leakage, all data is essentially encrypted and thus secure by the underlying guarantees of the homomorphic encryption scheme.

11 Conclusion

Bad Speculation in modern processors causes all in-flight micro-operations to be flushed from the pipeline, contributing to transient execution paths. In this work, we develop an automated transient leakage detection tool, named Shesha, inspired by Particle Swarm Optimization principles. We establish the concept of equivalent classes that represent disjointedly fragmented sub-spaces of bad speculation, which lead to faster convergence and allows us to cover vast search space of ISEs. Using Shesha, we discover novel transient leakage paths and reverse-engineer the root-cause of such transient executions. We discuss how the uncovered speculative execution paths can be used as building blocks for micro-architectural attacks. Finally, we show leakage on cryptographic libraries that use IFMA to accelerate multiplications; we demonstrate how data from FMA execution engine is speculatively forwarded to AVX execution engine. Overall, transient executions are hard to mitigate, and with new optimizations being implemented in next-generation processors, the possibility of such transient paths only seems to be accentuated.

Acknowledgment

The authors would like to thank the reviewers and the shepherd for their suggestions in improving the paper. They would also like to thank the Department of Science and Technology (DST), Govt of India, IHUB NTIHAC Foundation, C3i Building, Indian Institute of Technology Kanpur, and Centre on Hardware-Security Entrepreneurship Research and Development, MeitY, Govt of India, for partially funding this research.

BeeBox: Hardening BPF against Transient Execution Attacks

Di Jin
Brown University

Alexander J. Gaidis
Brown University

Vasileios P. Kemerlis
Brown University

Abstract

The Berkeley Packet Filter (BPF) has emerged as the de-facto standard for carrying out safe and performant, user-specified computation(s) in kernel space. However, BPF also increases the attack surface of the OS kernel disproportionately, especially under the presence of transient execution vulnerabilities. In this work, we present BeeBox: a new security architecture that hardens BPF against transient execution attacks, allowing the OS kernel to expose eBPF functionality to unprivileged users and applications. At a high level, BeeBox sandboxes the BPF runtime against speculative code execution in an SFI-like manner. Moreover, by using a combination of static analyses and domain-specific properties, BeeBox selectively elides enforcement checks, improving performance without sacrificing security. We implemented a prototype of BeeBox for the Linux kernel that supports popular features of eBPF (e.g., BPF maps and helper functions), and evaluated it both in terms of effectiveness and performance, demonstrating resilience against prevalent transient execution attacks (i.e., Spectre-PHT and Spectre-STL) with low overhead. On average, BeeBox incurs 20% overhead in the Katran benchmark, while the current mitigations of Linux incur 112% overhead. Lastly, BeeBox exhibits less than 1% throughput degradation in end-to-end, real-world settings that include `seccomp-BPF` and packet filtering.

1 Introduction

The Berkeley Packet Filter (BPF) [9, 74] is increasingly gaining traction as an in-kernel, *"universal" virtual machine* (VM): that is, a generic mechanism for extending or customizing OS kernel functionality by "pushing" (i.e., performing) user-specified computation(s) in kernel space, in a safe and performant manner. BPF greatly improves the efficiency of certain tasks by moving application logic closer to where data is generated, processed, or received, thereby reducing kernel-to-user I/O and avoiding expensive context switches. It enables a plethora of mature and emerging applications, including security monitoring and policy enforcement [23, 69, 96], high-performance networking [36, 95], observability and tracing [46], storage [104], as well as scheduling [39]. More importantly, many BPF applications require, or can benefit from, allowing the use of the BPF infrastructure in an *unprivileged* manner [19]. Unfortunately, however, BPF increases the OS attack surface [50], and it has been extensively used as the underlying apparatus for mounting *transient execution attacks* [11] against the kernel (from userland).

Transient execution attacks abuse the speculative-code execution capabilities built into modern CPUs, effectively leaking data through (forced) mis-speculation and side channels [33, 71]. BPF facilitates such attacks [55, 56] as BPF code can be highly customizable and is executed in the same context as the OS kernel itself, hence bypassing deployed defenses [32, 41]. Modern OSes place a wide range of *security-sensitive* data in kernel space, such as cryptographic material [63], the memory contents of user processes (i.e., `physmap`/direct map) [53], as well as (secret) metadata that impact the effectiveness of system-wide security protection mechanisms, like (K)ASLR [25]. Hence, it is of paramount importance to mitigate such BPF-based information leakage, especially in the presence of unprivileged BPF.

The Linux kernel currently deploys a combination of mitigations [58] against BPF-assisted, transient execution attacks, including: (1) selectively blocking speculative code execution; (2) limiting pointer arithmetic operations; and (3) verifying the safety of all branch-instruction combinations, even when some of them are impossible. As we discuss in Section 3, these mitigations primarily extend the BPF code verification and interpretation/JITing process via a collection of *ad-hoc* checks. This approach of progressively *retrofitting* security to the BPF infrastructure has caused a range of problems, in terms of usability and performance, without providing clear protection guarantees [8, 91, 92]—and, as expected, it has also led to various bypasses [7, 29, 57]. For these reasons, Linux distributions *restrict* eBPF to privileged users only [19]. In this work, we propose BeeBox: a new BPF security architecture that protects against transient execution attacks through a principled, security-first design approach.

The main idea behind BeeBox is to *sandbox* the BPF data in an SFI-like (software fault isolation) [99] manner. Moreover, by using static analysis and various domain-specific properties, BeeBox elides enforcement checks to improve performance, without sacrificing security. BeeBox improves the security posture of BPF, thereby allowing unprivileged users to *safely* reap the benefits of the BPF (sub)system and utilize it to its full potential.

In summary, we make the following contributions:

- We present the design of BeeBox, a security architecture against challenging and prevalent transient execution attacks in BPF—namely, Spectre-PHT and Spectre-STL [56]—, which isolates sensitive data from BPF's speculative execution reach. Our design also covers the security of BPF helper functions and cBPF.
- We provide a prototype implementation of BeeBox, which supports popular BPF applications, as well as a collection of tools and methods that simplify the future expansion of BeeBox's supported features.
- We evaluate our prototype on synthetic and real-world BPF programs and workloads, demonstrating that BeeBox provides increased security, compatibility, and efficiency than Linux's current mitigations. BeeBox achieves 0–23% overhead in kernel micro-benchmarks, and $< 1\%$ overhead in end-to-end, real-world settings.

2 Background

2.1 Kernel Security

OS kernels are usually the most privileged piece of software on a system, making them a lucrative target for attackers. Unfortunately, OS kernels are typically written in memory- and/or type-unsafe languages, which are prone to memory errors [97]. An attacker armed with a memory corruption vulnerability in the kernel can tamper with control data (e.g., code pointers [59]) to hijack the kernel's control flow and eventually gain arbitrary code execution [54, 81]. The current, predominant technique for achieving arbitrary code execution is *code reuse* [10], where an attacker chains together snippets of existing (i.e., benign) code "out-of-context."

Several defense strategies have been proposed to mitigate code-reuse attacks, with the most popular relating to information hiding or integrity checking. Schemes of the former attempt to conceal sensitive information by either randomizing [25] or diversifying [26, 60] the layout of memory, or by employing new memory protection policies, such as execute-only memory (XOM) [83, 89]. Schemes of the latter attempt to ensure that computed control-flow transfers are valid according to a given policy [5, 28, 59, 61]. Another technique for defending against code-reuse attacks in the kernel relies on isolating kernel memory from the attack payload, since real-world exploits may require complex payloads that do not fit into a limited corrupted region. Defenses in this direction prevent the kernel from using attacker-controlled payloads in user space [20, 54, 103] or in kernel memory regions that are effectively user-controlled [50, 53].

Privilege escalation can also be achieved by *data-only* attacks [38, 47], where, instead of control-flow data, the attacker overwrites targeted data and escalates privilege without triggering any control-flow integrity violations. Defenses against generic data-only attacks, including DFI (data-flow integrity) [16] and full memory safety [76, 77], remain impractical for performance reasons. Selective isolation schemes such as xMP [84] and ISLAB [75] were proposed to protect critical data such as page tables, process credentials, and memory management metadata.

Apart from privilege escalation, another goal of kernel attacker is *information disclosure*, which can be leveraged to obtain sensitive information managed by the kernel, such as cryptographic keys or secrets of other processes [53]. However, exploiting memory vulnerabilities in software is not the only way to achieve information disclosure; hardware vulnerabilities, like Meltdown [56] or cache-based side channels [33, 71], are an effective, alternate route.

2.2 Berkeley Packet Filter

Overview. BPF [74] was originally designed to accelerate network monitoring by performing user-defined packet filtering in-kernel rather than in user space. Since its inception, BPF has grown into a generic facility in Linux that acts as a *universal*, in-kernel VM for user-defined computation [18].

While BPF continues to support efficient networking applications, such as packet filtering [31] and load balancing [80], a variety of other applications capitalize on it to increase security and support new functionality. Several popular applications, such as Docker, Firefox, Chromium, and OpenSSH, employ `seccomp-BPF` [69] to filter system calls (syscalls) according to user-defined policies, with recent research exploring automatic generation [23] and secure enforcement [27] of syscall policies. Additionally, BPF underpins many tracing tools [9], since users can attach BPF programs to Kprobes (kernel probes) [93], granting increased visibility into the workings of a system. Other use cases for BPF include reducing context switching overhead in FUSE (Filesystem in USErspace) [6] and improving throughput and latency of the kernel's storage stack [104].

Design. When a BPF program is pushed into the kernel, it is first verified for safety and then attached to a kernel hook point. Later, when a requisite event fires (e.g., a syscall is made or a packet is received), the installed program is executed. Linux currently supports two types of BPF: *classic BPF* (cBPF) and its more feature-rich successor, *extended BPF* (eBPF). The typical use cases for cBPF involve syscall [69] and packet filtering [31]. The cBPF machine abstraction consists of two 32-bit registers and 64 bytes of addressable scratch memory.

cBPF code is translated internally to eBPF, allowing the kernel to maintain a single BPF runtime. eBPF greatly expands upon cBPF's capabilities and use-cases, offering: 10 general-purpose, 64-bit registers; a read-only frame-pointer register; and up to 512 bytes of addressable scratch memory (i.e., stack space). The instruction set of both cBPF and eBPF allows for memory loads and stores, moving values between registers, ALU operations, and branching. However, eBPF additionally provides the ability to call kernel-native functions, dubbed *helpers* [1], from within eBPF programs. Helpers provide various utilities and help maintain BPF *maps*—a variety of data structures implemented atop generic, kernel-resident key/value stores that allow eBPF programs to persist state across invocations and expose data to userland. All BPF programs also have *types*, which inform the kernel where the programs can be attached, what helpers and maps can be accessed, and what *context* (i.e., arguments and data) should be provided with upon invocation [68]. For example, an eBPF program with type `xdp` (`BPF_PROG_TYPE_XDP`) will run on a network device and the context passed to it will consist of pointers to the raw packet data, which can be used to perform packet rewriting and forwarding.

Safety and Security. BPF is designed to be safe to run within kernel context. To achieve that, when BPF programs are loaded into the kernel they pass through a static *verifier*, which is guaranteed to be sound but not complete—i.e., a safe program may be rejected, but an unsafe program will not pass. The BPF verifier ensures similar properties for both cBPF and eBPF, but verifies them separately, performing a much simpler analysis for cBPF programs. For eBPF, the verifier mainly verifies three properties: (1) program termination; (2) memory safety; and (3) type safety when calling helpers. For (1), the verifier simply ensures that all branching instructions only "jump forward." For (2) and (3), the verifier uses static analysis techniques to determine the register types, whether they are pointers or scalars, *etc.* For a scalar, the analysis tries to figure out the range of its possible values; for a pointer, the analysis needs to determine what kind of memory it points to and whether it points within bounds. Further, the BPF verifier is also in charge of rewriting BPF program code to adjust helper-call targets and inline various helpers as BPF instructions when possible. Unfortunately, while performing static analysis to avoid runtime checks is crucial for the performance of BPF, the verifier is known to be error prone [62] and susceptible to speculative execution attacks (§3).

Support. Both LLVM and GCC maintain eBPF backends, which compile programs written in C-like syntax to eBPF ELF files. Additionally, both of these BPF compilers—which are different from the in-kernel (BPF) JIT compiler—provide various utilities for working with eBPF ELFs. In a similar vein, `libbpf` [2] is a C library maintained by the Linux kernel which provides a low-level API for loading eBPF ELFs and managing eBPF programs, maps, and events from userland.

2.3 Transient Execution Attacks

Modern CPUs maximize their performance by employing various techniques to avoid CPU idling, such as *out-of-order execution* and *speculative execution* [35]. Instructions that are executed out-of-order, or speculatively, but never committed to the CPU's architectural state are considered to be *transiently executed*. Although transiently executed instructions are never architecturally visible, they can leave observable side effects in the CPU's micro-architectural state (e.g., the cache [56], load ports [90], line-fill buffers [98], store buffers [14]). This has enabled *transient execution attacks*, where an adversary coerces the CPU into transiently accessing unintended information before using micro-architectural side channels [33, 71, 98, 100, 102] to leak information.

The Spectre family of attacks is one class of transient execution attacks that abuse CPU predictors, via *(mis)training* or *tampering*, to trigger speculative execution of instructions that access sensitive data, which can later be inferred through side channels. There are a handful of Spectre variants, classified by the CPU predictor they target. Spectre-PHT (Spectre-v1) [11] targets the pattern history table (PHT)—used to predict the outcome of conditional branches—to trigger the speculative execution of instructions preceded by a conditional branch. Spectre-BTB (Spectre-v2) [56] targets the indirect branch predictor, i.e., the branch target buffer (BTB), to trigger the speculative execution of forward-edge indirect branches. Spectre-STL (Spectre-v4) [48] abuses the memory disambiguator to load data before a prior, dependent store completes.

A variety of defenses have been proposed to address transient execution attacks, spanning both software [17] and hardware [37]. In the Linux kernel, the Spectre-PHT mitigation relies on developer annotations to identify when an array index is not trusted and add bit-wise operations to bound array indices during mis-speculation [65]. Spectre-BTB is mitigated via retpolines [43] and IBRS [41].

There are other root causes of transient execution, but predictor-based speculation and unexpected exceptions are the most prevalent and well-researched [85]. For exception-based transient execution attacks such as Meltdown [56] and Fallout [14], the problems are typically fixed through hardware changes [45], since it is generally clear what should happen in such situations: transient execution should respect potential exceptions. For predictor-based transient execution, isolation can be enforced such that the predictors cannot be influenced across contexts [41, 44] (e.g., influencing the kernel from userland), which can mitigate attacks that rely on abusing shared micro-architectural states [11, 72]. But for intra-context attacks, the safety of speculation is inherently software-defined, and solutions that prevent speculation, in general, are expensive [56]. Hence, selective application of various mitigations (such as `lfence` [40] or `SSBD` [13]) in targeted places is recommended by vendors [42] and has begun to receive attention by researchers [24].

3 Motivation

The combination of BPF and Spectre attacks allows an adversary to mount transient execution attacks to leak sensitive data from the kernel with little noise and without reliance on software vulnerabilities [55,56]. As a result, eBPF functionality is disabled by default for unprivileged users [19,87,94]. Features that use cBPF, such as `seccomp-BPF`, have seen proposals to support eBPF, but were rejected due to the complexity and difficulties that stem from maintaining certain mitigations [51]. Yet, the full set of BPF functionality is desirable for a lot of applications. Apart from `seccomp-BPF`, there are a plethora of proposed applications that try to use BPF in an unprivileged manner, including high-speed storage systems [104] and scheduling [39,52]. XDP-based applications [36], such as Cillium [95] and Katran [80], would also benefit from a reduction in privilege required by the BPF runtime.

Currently, if unprivileged BPF is enabled, the BPF verifier and JIT engine are responsible for applying BPF-specific Spectre mitigations at load time [58], which we collectively refer to as *Linux provisional mitigations* (LPM). For Spectre-PHT, the verifier rewrites pointer arithmetic to bound results within a given object, similar to the `array_index_nospec` macro [65]. To protect type safety under Spectre-PHT, the verifier's static analysis enforces type consistency across all combinations of branch choices, even impossible ones (e.g., a path where two branches with contradicting conditions are both taken). For Spectre-BTB, the JIT engine adds instrumentation for indirect branches in accordance with the kernel-wide defenses (such as retpolines [43]). For Spectre-STL, the verifier emits speculation barriers (e.g., `lfence` [40]) after stores to the stack, whenever pointers are involved.

A summary of defenses the Linux kernel deploys against transient execution attacks is provided in Table 1. Spectre-BTB and Meltdown are mitigated by generic, kernel-wide defenses, such as retpolines [43], IBRS [41], and KPTI [66], while generic Spectre-PHT and Spectre-STL defenses, such as SLH [15,82] and SSBD [13], are expensive to apply to the whole kernel. Consequently, the LPM defend against these attacks specifically in the context of BPF; however, the LPM have various issues regarding *compatibility*, *complexity*, *scope*, and *performance*, which we summarize below.

Compatibility. The LPM introduce additional analysis complexity and safety requirements to the verifier, causing it to reject (previously) safe code patterns in BPF programs. For example, Cillium [95] breaks because it performs variable-offset stack accesses, and Katran [80] breaks because it requires conditional pointer arithmetic. In addition, valid BPF programs experience verifier state explosion due to the verification regarding impossible branch combinations (§7.1.3). This places a burden on application developers to either address the verifier's requirements by rewriting code patterns targeted by the mitigations, or decide to forgo protection and load the program with elevated privilege.

Complexity and Scope. The LPM were formed over time, in an ad-hoc manner, as a response to repeated bypasses of Spectre-PHT and Spectre-STL mitigations caused by incompleteness and/or corner cases [7,29,57]. Progressively retrofitting security in this manner adds complexity to the BPF (sub)system that makes it difficult for kernel developers to reason about the safety of interactions between proposed verifier changes and the LPM [8,91,92]. Further, despite all this added complexity, the mitigations still provide incomplete protection, not covering cBPF or native BPF helper functions.

Performance. The mitigation against Spectre-STL inserts speculation barriers (e.g., `lfence`) after any pointer spill, and subsequent load, targeting the same stack slot. As a result, the LPM incur significant runtime overhead, especially in non-trivial BPF programs (§7.2.2). In general, it is difficult to stop mis-speculation in a way that does not hinder performance [12], which is the root cause of complexity in LPM.

4 Threat Model

Adversarial Capabilities. We assume an attacker that has access to BPF functionality and seeks to disclose sensitive information from the kernel. The attacker also has the appropriate rights to use the desired types of BPF programs (e.g., `cap_net_admin` for `XDP`), but is otherwise unprivileged. We do not assume the attacker can install BPF programs with `cap_perfmon`, since this capability can disclose a wide range of sensitive values already (such as register values at any point) [67]. As a result, performance-related BPF types are not available to the attacker, like the BPF programs that attach to Kprobes [93] and tracepoints [9].

As an unprivileged user of the system, the attacker can create any BPF program in the kernel that passes verification, as well as control the contents of BPF maps within allowed semantics. The attacker is also assumed to have the ability to arbitrarily trigger speculation at any point between the entry and exit of their BPF program, including when it invokes helper functions—these are only limited by potential speculation barriers. Under such speculative execution scenarios, the attacker can also arbitrarily flip conditional jumps and skip or forward any store to any load targeting the same address.

Hardening Assumptions. Regarding the kernel, we assume that the concrete execution of any kernel or BPF-runtime code is safe, and that there are no errors in the BPF verifier or JIT engine. Any execution of kernel code, concrete or speculative, before and after execution of a BPF program, is also assumed to be safe—i.e., the kernel does not leak any sensitive information into BPF programs' speculation, nor does it incorrectly use unsafe values after BPF programs' speculation. The only defense against Spectre-PHT and Spectre-STL for BPF is BeeBox. Further, we assume that the kernel has appropriate defenses, in either software or hardware, against other cross-privilege transient execution attacks, such as Meltdown [56].

Category	Feature	LPM [58]	retpoline [43]	IBRS [41]	KPTI [66]	BeeBox
Security	Block Spectre-PHT in BPF code	✓				✓
	Block Spectre-PHT in BPF helpers					✓
	Block Spectre-STL in BPF code	✓				✓
	Block Spectre-STL in BPF helpers					✓
	Block Spectre-BTB		✓	✓		
	Block Meltdown				✓	
Compatibility	Allow conditional ptr. arithmetic in unpriv. BPF					✓
	Avoid verifier state explosion in unpriv. BPF					✓

Table 1: Existing Linux kernel defenses and BeeBox's coverage over transient execution attacks and compatibility features.

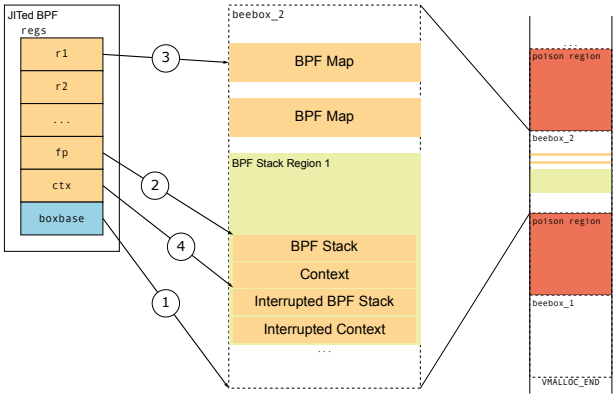

Figure 1: The memory layout of BeeBox. The left part represents the CPU register states when a JITed BPF program is running; the middle part is a magnified view of the memory layout of a `beebox`; and the right part represents the virtual address space, where `beebox`es are placed after the `VMALLOC` region, with a 4GB poison region in-between adjacent pairs.

Defenses against memory errors, such as control-flow integrity [5], page-table protection [22], pointer integrity [59], and data isolation schemes [75,84] are orthogonal to BeeBox.

5 Design

The goal of BeeBox is to prevent BPF programs from accessing sensitive data, even under speculative execution. Fortunately, the majority of data that BPF programs access (e.g., the BPF stack and BPF maps) are designed to be visible to users. This key observation allows BeeBox to identify what data should be isolated, which does so by leveraging SFI techniques [99], tailored to the speculative execution domain. Specifically, BeeBox places all data a given BPF program will access inside a dedicated memory region, called `beebox`, and applies SFI-style isolation to the program, confining all of its memory accesses to this region. BeeBox thus ensures memory safety, as the BPF program can only access data inside the `beebox`—concretely or speculatively—, which does not contain any sensitive data.

5.1 BeeBox Sub-address Space

BeeBox isolates data directly accessed by BPF programs in `beebox`es, as shown in Figure 1. A `beebox` is created for each user, such that no information can be leaked to, or from, other users (including user `root`). For example, as shown on the right of Figure 1, `beebox_1` and `beebox_2` are two separate `beebox`es that were created for two different users. In addition, 4GB poison zones are placed between each `beebox` to support optimizations (§5.4). The kinds of memory objects placed inside each `beebox` sub-address space are magnified in the middle portion of Figure 1 and described below.

BPF Stack. The BPF stack is a region where BPF programs can temporarily store intermediate computation results that are not semantically shared with other components (e.g., the kernel itself or user applications). Since BPF programs are executed with {CPU, core}-migrations disabled—i.e., the BPF program invocation will stay on the same CPU—, we allocate a BPF stack region for each CPU in a `beebox`.

BPF Maps. BPF maps hold user-owned data, which can be accessed by both BPF programs and their corresponding user process (via the `bpf` system call). To support maps securely, their defining data structures are split: map data and some metadata essential to map operations (e.g., lookup and update) are safely placed in the `beebox`, since their contents are either controlled or can be inferred by the user; the remaining metadata used by the kernel itself (e.g., associated function pointers) remain outside of the `beebox`. Some metadata, such as the map size, are duplicated for the kernel code to access, because their copy in `beebox` is untrusted under speculation.

BPF Context. Handling contexts poses unique challenges since context data structures can interleave private kernel data and BPF-accessible data. For example, a BPF program of type `BPF_PROG_TYPE_SOCKET_FILTER` will receive a `struct sk_buff` in its context that has a large number of fields, out of which only a handful are made accessible to the BPF program itself (via `struct __sk_buff`). For these BPF program types, BeeBox copies the relevant parts of the context data structure that are visible to the BPF program into the BPF stack region. In cases where private kernel data is not interleaved with BPF-accessible data, the context data structure is usually generated and filled on the kernel's stack, just before the BPF program's invocation (as in `seccomp-BPF`).

Here, the non-interleaved context can be generated on the BPF stack region and no other changes are required. Network-related BPF programs usually have access to a packet buffer, and a pointer to a packet, which, in this case, is part of the context object. This is a common pattern in BPF, and the packet can be seen as an extension to the context. Through accurate static analysis done by the BPF verifier, accesses to these packets are identified and protected against overflowing. We handle packets the same way we handle context: we copy them into `beebox`. Note that copying context data structures (and packets) can be costly; we designed certain optimizations that can be applied to different types of BPF programs (§5.4).

Space Considerations. The size of the `beebox` region is 4GB. We chose this size mainly to allow for efficient SFI instrumentation (§5.2). Additionally, the stack region of each CPU reserved for BPF programs should be $(c+p)\cdot l+s$, where: c is the size of the largest context, p is the size of the largest packet we allow BPF to handle, l is the level of nested interrupts which can have BPF running, and s is the size of the kernel stack. This equation stems from the fact that all BPF stack frames are allocated on the kernel stack in the vanilla Linux kernel, and each nested interrupt can have at most $c+p$ bytes added on top of that. We have chosen the total reserved area per-CPU to be 280KB to cover $p = 64$KB, $c = 4$KB, $l = 4$, and $s = 8$KB. (These sub-regions are allocated and mapped during bootstrap, so they cannot be arbitrarily sized.)

5.2 Securing BPF Programs

Instrumentation. BeeBox uses SFI-style isolation to ensure pointers used by a BPF program are confined to a 4GB `beebox` region that contains only user-accessible data. Pointers embedded in a BPF program during JITing, and pointers passed to the program by the calling context, are transformed into `boxptrs`: 32-bit offsets within the `beebox` region. When a memory access needs to be performed, a usable 64-bit pointer is created from a given `boxptr` by clearing the upper 32 bits of the `boxptr` and adding the result to a register—the `boxbase` register—, which contains the starting address of the `beebox` region (①in Figure 1). To initialize the `boxbase` register, the JIT engine emits a native instruction at the beginning of a BPF program which loads the base pointer, encoded as an immediate value, into the `boxbase` register. The `boxbase` register is never spilled or used in any other way, ensuring it cannot be controlled speculatively (or leaked); BeeBox guarantees the target of memory accesses from within BPF programs are always confined inside the `beebox` region. (Figure 3 shows an example of this transformation in x86-64.)

BPF Stack. There is a per-CPU pointer keeping track of the current top of the BPF stack allocated by BeeBox. The pointer is updated by locally atomic instructions to be safe against interrupts, since BPF programs can run with interrupts enabled and can also be invoked within interrupt context.

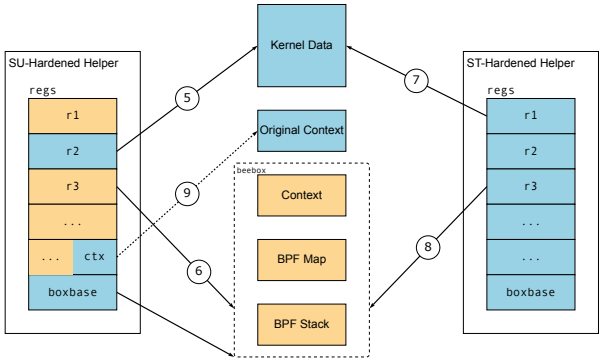

Figure 2: Memory layout and CPU states when helper functions are executed. Blue indicates the value is speculatively trusted; yellow indicates otherwise. The left part represents the CPU state when running an SU-hardened helper; the right part corresponds to running an ST-hardened helper.

BeeBox modifies the JIT compiler to emit inlined prologues and epilogues to move the BPF stack pointer and set the frame pointer register accordingly (②in Figure 1).

BPF Maps. When BPF maps are accessed by the kernel on behalf of the user's query via system calls, the kernel uses normal pointers to dereference the map data inside a `beebox` (instead of `boxptrs`). However, values loaded from the `beebox` speculatively should not be trusted and should be handled safely (e.g., masking the value before using it), which is consistent with the kernel's current security model regarding user input [70]. When BPF maps are accessed directly from BPF programs (e.g., ③in Figure 1), BeeBox uses 32-bit `boxptrs`, and the metadata is either embedded in the JITed program or looked up from the copy inside `beebox`. When BPF maps are accessed by helpers, the BPF program passes `boxptrs` to (modified) helper functions which use them safely.

BPF Context. Regardless of whether private kernel data is interleaved with BPF accessible data, BeeBox transforms the context pointer (④in Figure 1) into a `boxptr` at the callsite of the kernel that invokes a given BPF program. If the context includes a packet, the packet is also copied into the `beebox`. All pointers in the context data structure that point into the packet are also converted to `boxptrs`.

5.3 Securing Helper Functions

There are two hardening strategies for securing BPF helper functions. *SU-hardening* (Speculatively Untrusted, §5.3.2) protects helper functions such that they can be safely run during (untrusted) speculation. *ST-hardening* (Speculatively Trusted, §5.3.3) ensures that helper functions are run under the precondition that there is no influence from untrusted speculation. Figure 2 illustrates the memory layout and CPU states when helper functions are executed under both schemes.

```
1  bpf_get_current_uid_gid:
2    mov    rax, QWORD PTR gs:0x1ad00  # struct task_struct
3    test   rax, rax
4    je     1f
5    mov    rax, QWORD PTR [rax+0x638] # struct cred
6    mov    rax, QWORD PTR [rax+0x4]   # uid, gid
7    ret
8  1:
9    mov    rax, 0xffffffffffffffea    # -EINVAL
10   ret
```

Listing 1: A compiled helper function, `bpf_get_current_uid_gid`, where all memory loads are via clean pointers.

5.3.1 Clean Pointers

We first introduce the definition of *clean pointers*, an important concept for our discussion later. All memory accesses using `boxptr`s can be confined with BeeBox's SFI scheme (§5.2); however, certain BPF helpers use native pointers that point outside of a `beebox`, and hence cannot be transformed into `boxptr`s. These native pointers can potentially be speculatively-hijacked by the BPF program, escaping BeeBox's defense. Since we assume the correctness of the helper functions' concrete execution, we can avoid speculatively targeting unsafe locations by placing speculation barriers (e.g., `lfence` instructions) before native pointer dereferences. This naïve solution can be greatly improved upon with a key insight: native pointers in helper functions that are uninfluenced by any untrusted input (e.g., arguments passed from BPF programs) do not require a preceding speculation barrier—they can be safely dereferenced without leaking sensitive kernel data. We consider such pointers as *clean*.

Clean pointers are identified by static taint analysis, where the sources of taint are untrusted input (e.g., helper function arguments, values loaded from the `beebox` region, values loaded from the stack). If a native pointer is not tainted when dereferenced, then the dereference is considered to be done via a clean pointer. (`boxbase` is handled like a clean pointer.) Importantly, clean pointers are native pointers, so their values must be prevented from leaking into attacker visible realms (e.g., `beebox` memory and the branch predictor). Also, clean pointers are read-only, because any write to a kernel address can contaminate future reads to that address (as specified by our threat model), which may compromise the "cleanliness" of other (clean) pointers derived from the address.

Listing 1 shows a BPF helper function, `bpf_get_current_uid_gid`, which is used for getting the current task's user ID (UID) and group ID (GID). This function uses three native pointers to: get the current `struct task_struct` (line 2); extract its security context, `struct cred` (line 5); and read the task's UID and GID together, as a single quadword (line 6). Since all memory accesses in the function refer to private kernel data, and since all pointers are uninfluenced by BPF program data, all three native pointers are considered clean pointers and do not require any hardening from BeeBox.

5.3.2 Speculatively Untrusted Hardening

Speculatively untrusted hardening (SU-hardening) assumes that the execution of BPF helper functions can be run under untrusted speculation. Given this, BeeBox ensures that: (1) all memory accesses into the `beebox` by the helper are SFI-hardened (⑥ in Figure 2); (2) no native pointers are leaked into the `beebox`; and (3) all memory accesses to external (i.e., kernel) data are either prefixed with a speculative barrier or accessed via a clean pointer (⑤ in Figure 2). As far as (2) goes, BeeBox modifies the helpers to store the local variables using the BPF stack, instead of the kernel stack, while keeping the return addresses outside of `beebox`. This is to prevent the attacker from mounting a Spectre-STL against stale kernel stack values through the helper.

Since SU-hardening requires speculation barriers prior to external memory accesses that are not through clean pointers, this technique is better suited to BPF helper functions that do not access lots of external data. For example, certain utility helpers (e.g., `bpf_strtol`) and the majority of BPF map helpers only operate on information already in the `beebox`. However, some helpers that do access external data mainly through clean pointers (e.g., `bpf_get_smp_processor_id`) do benefit from this approach as well.

SU-hardening is achieved through three main steps. First, the interface between BPF programs and helper functions is modified to replace native pointers with `boxptr`s, which maintain their 32-bit representation throughout the helper's execution. Since `boxptr`s cannot be accessed directly, they go through a special C macro, `unbox`, which applies SFI instrumentation and makes the `boxptr`s usable. (The `unbox` macro uses the `volatile` keyword to nail down the exact point of dereference in the compiled code and avoid spilling any native pointers before they are used.) Second, BeeBox ensures that helper functions maintain the "cleanliness" guarantee of the `boxbase` register by ensuring it is only used in the `unbox` macro and never spilled to the stack or overwritten. Finally, BeeBox ensures that external memory accesses are exclusively done via clean pointers, else they are prefixed with a speculation barrier. (This is currently done manually; a binary analysis tool based on our clean pointer identification algorithm is needed if one wishes to automatically ensure function is safe. We leave this for future work.)

5.3.3 Speculatively Trusted Hardening

Speculatively trusted hardening (ST-hardening) secures a helper by providing the guarantee that all speculation in a given BPF helper function will be safe, and thus no additional considerations are needed for accessing kernel data (⑦ in Figure 2). This hardening technique is fitted for helper functions that access kernel data much more than data produced by BPF programs. For example, `bpf_skb_clone_redirect` will clone the `sk_buff` passed in, which involves accessing a lot of kernel data, including the heap allocator's metadata.

To achieve this guarantee, BeeBox sanitizes any data flow originating from the calling context or the `beebox`. Thus, at a given helper's entry point, all `boxptr`s are converted into native pointers and a speculation barrier is inserted to avoid speculative execution on unsafe arguments. Additionally, accessing `beebox` memory requires a speculation barrier (⑧ in Figure 2), which is provided by another utility macro BeeBox defines. By default the speculation barriers are inserted; however, if a developer desires, they can (carefully) optimize-away the barriers. Finally, in the JITed BPF program, another speculation barrier is used to avoid unintended values from leaking back into the BPF's CPU state.

5.4 Performance Optimizations

We refer to the scheme combining all the techniques up until this point as *BeeBox-Basic*. It comprehensively stops any Spectre-PHT or Spectre-STL attack originating from unprivileged BPF programs; however, it can be costly, due to the copying of context and dense SFI-instrumentation. We address these problems in the following subsections.

5.4.1 Generic Optimizations

Reduced Copy. The first optimization variant, called *BeeBox-RC* (Reduced Copy), improves performance by reducing the amount of data that is copied into a `beebox`. Notably, this optimization strategy is applicable to every type of BPF program that does not have a stack-based context. At a high-level, by using the static analysis done by the verifier, a BPF program's accesses to contexts and packets are tracked and only the used portion of them is copied into the `beebox`.

BPF does not support variable-offset context accesses. Leveraging this fact, BeeBox-RC records up to 16 distinct context access offsets during the verifier's static analysis, and stores them along with the BPF program. If the number of accessed fields is within the limit, BeeBox-RC only copies each accessed field of the context data structure into the `beebox`.

For packets, because BPF supports variable-sized accesses, BeeBox-RC reuses the range analysis results of the max (packet) access offset, only copying-in the packet up to the size of the max offset that the BPF program will access. Because networking-related BPF programs typically operate on only the header of packets, the maximum size of packet copying is usually bounded to a reasonable number.

5.4.2 Case-specific Optimizations

Clean Context and Packet Pointers. The second optimization variant, called *BeeBox-CP* (Clean Pointer), makes the context pointer a clean pointer (i.e., a native pointer instead of a `boxptr`; ⑨ in Figure 2) to avoid copying contexts. Consequently, the context pointer is handled with the guarantees that clean pointers require: it is never spilled into memory and does not leak into other data flows—aside from being used as a base for dereferencing. As a result, the context pointer is treated similar to `boxbase`, where calls to helper functions avoid clobbering or spilling it. Other guarantees of the clean context pointer are checked in the verifier, and the optimization only applies when the context pointer is indeed clean. However, to ensure that BPF programs produced by a BPF compiler adhere to such requirements, and can hence utilize the optimization, BPF compiler changes are necessary. (For the purposes of this work, we manually produced compliant BPF programs in order to make use of the optimization.)

Importantly, since the context is a clean pointer pointing to the original context data structure outside of the `beebox`, the packet pointer enclosed inside the context is also a clean pointer. To safely allow variable-size accesses into the packet using clean pointers, BeeBox-CP (re)uses the static analysis done by the verifier to accurately identify and rewrite packet accesses into calls to custom helper functions that utilize the `array_index_nospec` macro in the kernel.

Ring-buffer No-copy. The third optimization variant applies when the type of the BPF program already requires the user to have network-device access privileges, e.g., `xdp`. In this case, we avoid copying packets by directly placing the device's ring buffer (or the packet it creates when the driver copies packets from the ring buffer into non-DMA memory, if the driver does not have support for XDP natively) in the `beebox`. Note that this optimization cannot work with higher-level, network-related BPF programs (such as socket-level BPF), because when such a packet is allocated, either at the driver or NAPI level, the destination socket is unknown to the kernel. We name this optimization variant *BeeBox-RB*.

Optimizing `memcpy` and Friends. In certain BPF helpers, functions such as `memcpy` and `memcmp` are used. These functions are simple but have extensive pointer dereferences, which seriously impact performance if SFI instrumentation is applied to all of them. We optimize this type of function by "unboxing" the arguments to native pointers when calling them, and manually ensuring that these native pointers are not changed or spilled in the function. Because the size of copying, or comparing, is a 32-bit integer value, we place a 4GB poison zone after the `beebox` region to confine all potential memory accesses by these functions.

6 Implementation

We implemented a prototype of BeeBox on x86-64 Linux v6.1. Due to the sheer number of features available to BPF, our prototype of BeeBox does not cover everything: we only BeeBox-hardened a subset of all the available features (of vanilla BPF) to support popular BPF applications. Our implementation consists of three inter-connected components, which we describe below.

```
1 ...
2 r2 = $map_ptr
3 r3 = r2 + r3
4 r4 = *(u64 *) r3
5 ...
```

(a) Vulnerable BPF program.

```
1 mov r12, 0xffffc90000000000
2 ...
3 mov rsi, 0x1000
4 add rcx, rsi
5 mov ecx, ecx
6 mov rdx, qword ptr [r12 + rcx]
7 ...
```

(b) BeeBox JIT result.

Figure 3: Example of BeeBox instrumentation.

6.1 BeeBox-aware JIT Compiler

We reserve `beebox` regions in the unused part of the kernel's address space, after the `vmalloc` region, and we implemented a new allocation function, `beebox_alloc`, which wraps `__vmalloc_node_range` to provide custom ranges for allocating inside each `beebox`. In the JIT compiler, we added an instruction to load the base of the appropriate `beebox` into `r12`, which is not used by the current JIT compiler and acts as the `boxbase` pointer (e.g., line 1 in Figure 3b). We also modified the verifier to insert a new BPF (pseudo) instruction, `BPF_BOXMEM`, directly before load or store instructions in the BPF bytecode. `BPF_BOXMEM` marks the following instruction, signalling to the JIT process that the access should be SFI-hardened. During JITing, `BPF_BOXMEM`-ed memory accesses are transformed into two instructions that make up the core SFI instrumentation. First, a `mov` with a 32-bit register operand (e.g., `eax` for `rax`) is inserted to clear the upper 32 bits of the register (line 5 in Figure 3b). Then, a second `mov` instruction is inserted with a *base* + *index* addressing mode, where `r12` (i.e., the `boxbase` pointer) is used as the base and another 64-bit register, which stores the offset into the `beebox`, is used as the index (line 6 in Figure 3b). These two `mov`s bound memory accesses inside the 4GB `beebox` region.

In each `beebox` region, we allocate a 280KB stack for every CPU. Each BPF stack has a corresponding variable representing the top of the stack as a `boxptr`. We modified the JIT compiler's handling of function prologues and epilogues in order to "open" and "close" stack frames in the `beebox` stack region, instead of the normal stack, and to move the frame pointer into `ebp`, which is a 32-bit `boxptr`. All BPF stack accesses are frame-pointer-based so we avoid having to move `rsp` and handle additional stack swapping. Lastly, all stack accesses identified by the verifier are prepended with the `BPF_BOXMEM` BPF instruction, which are later correctly JIT-compiled to SFI-hardened native code.

6.2 Maps, Helpers, and Language Tricks

To simplify development, and debugging, when writing C code that interacts with pointers to a `beebox`, we added a special attribute, i.e., '`__beebox`', to annotate `boxptr`s in the kernel—the `__beebox` attribute is defined as `__attribute__((noderef))` when the source code is inspected by the static analysis tool `sparse` [64]. We chose to implement `boxptr`s as an attribute instead of defining a new type since the attribute can transparently keep the pointer's original type information. This makes incorrect propagation and accidental dereference noticeable at compile time, which streamlined the development of our prototype (otherwise, it would be difficult to apply the `unbox` macro correctly in expressions like: `&array_map->map->elem[i].lock`).

```
1  struct bb_pcpu_freelist_head {
2      struct bb_pcpu_freelist_node __beebox *first;
3      raw_spinlock_t lock;
4  };
5
6  struct bb_pcpu_freelist {
7      ...
8      struct bb_pcpu_freelist_head extralist;
9  };
10
11 struct bpf_htab_inner {
12     ...
13     struct bucket __beebox *buckets;
14     struct bb_pcpu_freelist freelist;
15     u32 n_buckets;
16     ...
17 };
```

Listing 2: Example of data structures placed inside `beebox`, which only contains information that can be exposed to the user. All pointer fields are annotated with '`__beebox`'.

We currently support five types of maps commonly used by BPF programs: *array map*, *per-CPU array map*, *array map of maps*, *hash map*, and *LRU hash map*. When data structures such as linked lists—which are needed for hash map—are moved into a `beebox`, their internal pointers are also converted into `boxptr`s. In Listing 2, we show how certain data structures placed in `beebox` are defined. All the embedded pointers are annotated with the `__beebox` attribute, and their value represents the offset within the `beebox`. We also duplicated and adapted the accessor macros, and inline functions, for these data structures to work with `boxptr`s.

We reserved `r12` when compiling helper functions to ensure it is never spilled or contaminated. In addition, we changed the function signature of the helpers we ported to BeeBox to use `boxptr`s; thus, together with the changes in the data structures, the compiled helper functions will not contain any accidental un-instrumented pointer dereferences. The counter-part to these helper functions is the call sites in the JITed BPF programs; they are transformed by the verifier to use `boxptr`s to point at the in-`beebox` part of the BPF maps.

Array map, per-CPU array map, and array map of maps each have three helper functions that need to be adjusted for the BPF runtime: we support two in array map, three in per-CPU array map, and one in array map of maps. For other helpers, we support everything used by the BPF programs in our evaluation, including $2/42$ common helpers, $6/14$ `socket`-specific helpers, and $1/29$ `xdp`-specific helpers.

6.3 Supported BPF Program Types

cBPF. We support cBPF in `seccomp-BPF` and packet filtering. Our analyses and BPF-level transformations are implemented in the cBPF verifier. The stack accesses in cBPF use dedicated cBPF instructions, hence we insert `BPF_BOXMEM` before the translated eBPF instruction(s). `seccomp-BPF`'s context is stack-based so it is just moved to the BPF stack. For packet filtering cBPF, we applied BeeBox-CP (§5.4.2), while packet accesses go through instrumented helpers.

Socket Filter eBPF. For eBPF-based socket filters, we implemented both BeeBox-RC (§5.4.1) and BeeBox-CP (§5.4.2). To implement BeeBox-RC, all stack accesses and map accesses remain the same; for context access, we insert `BPF_BOXMEM` before each context-memory access. We also changed the invocation of BPF programs to copy selected parts of the context and packets into the `beebox`, which we transformed accordingly. In the case of BeeBox-CP, we performed additional static analysis on the BPF programs to verify that the context pointer is not leaked into other registers or spilled to memory. Due to calling convention considerations, we chose the callee-saved register `rbx` to hold the context pointer. We also duplicated the helper functions to avoid using or clobbering `rbx`, similar to `r12`.

XDP. Our support of XDP BPF programs includes two optimizations: BeeBox-RC (§5.4.1) and BeeBox-RB (§5.4.2). For XDP, the context is generated dynamically on the (kernel) stack; thus, we simply generate it on the BPF stack instead. In BeeBox-RC, part of the packet is copied into the `beebox` region. Although the copying only requires part of the packet, we allocate enough memory to fit potential XDP-supported modifications to the packet (e.g., extending the header). The range of the packet copied out is also adjusted in the event that packet pointers are modified in the XDP context. When enhanced with BeeBox-RB, depending on whether the network driver supports XDP natively, the allocation of the packet buffer at the driver level or the NAPI level is adjusted to appropriately handle allocating directly in the `beebox` region.

6.4 Engineering Effort

The core implementation of BeeBox required ≈900 additional lines of code (LOC) added to Linux v6.1. Specifically, we added ≈700 LOC to the BPF JIT engine and verifier to implement the main functionality and optimization schemes of BeeBox, and ≈200 LOC to adapt the hook points that invoke BPF programs. Atop this, we also migrated ≈1000 lines of helper code into separate compilation units and manually added the instrumentation at the source code as necessary. Regarding the helpers that we instrumented (§6.2): support for the three array map variants took a graduate student (with knowledge of Linux kernel internals) one day to develop; support for the two hash map variants took three days to develop; and the program-type-specific helpers took four hours.

7 Evaluation

We evaluated BeeBox in terms of effectiveness and performance. For the former, we analyzed the impact of BeeBox on BPF's functionality compared against no-mitigations and existing mitigations in Linux v6.1. For the latter, we evaluated BeeBox's performance on synthetic eBPF benchmarks and real-world BPF applications, including Katran, `seccomp-BPF`, and cBPF packet filtering. Our experiments were run on a machine equipped with a 16-core, 3.7GHz Intel Xeon W-2145 CPU and 64GB RAM, running 64-bit Ubuntu 20.04 LTS.

7.1 Effectiveness of BeeBox

7.1.1 Security Analysis

When hardened with BeeBox, *four* different kinds of pointers are considered for the security of the system. The first kind is pointers into untrusted regions, like the `beebox` and the kernel stack, when used by SU-hardened helpers. They are speculatively-safe because they cannot target outside the untrusted region(s) and there is no sensitive data in those regions. The second kind is clean pointers; they are speculatively-safe because they can only target the same locations as concrete execution, which is assumed to be trusted. The third kind is pointers used in ST-hardened functions. These pointers are secured since ST-hardened functions use speculation barriers to ensure no attacker-controlled speculation occurs during their execution. The forth kind is developer exempted pointers, including ones handled with `array_index_nospec`, whose value can be influenced by speculation, but are explicitly permitted by developers. In summary, BeeBox comprehensively protects all memory accesses during BPF execution.

7.1.2 Security Evaluation

We created three synthetic exploits that simulate speculative execution attacks launched from BPF programs, which attempt to (speculatively) access a target location to leak sensitive data. We consider BeeBox able to stop a given attack if we can no longer detect a signal in the cache corresponding to accessing the sensitive data. To probe the cache for a signal, we created a kernel module that performs Flush+Reload [102].

Exploit #1: Spectre-PHT. For the first exploit, we crafted a BPF program that performs a dynamically indexed access into a BPF map element. Here, the mis-speculation starts from a conditional branch, similar to the original Spectre attack [56]. The exploit works without mitigations and fails against BeeBox (and LPM).

Exploit #2: Spectre-STL. For the second exploit, we targeted Spectre-STL. We crafted a BPF program that triggers erroneous store-to-load forwarding by saturating store ports [58]. Similar to the first exploit, this exploit works without mitigations and fails against BeeBox (and LPM).

```
1  u64 bpf_skb_load_helper_32(const struct sk_buff *skb,
2                             const void *data,
3                             int headlen,
4                             int offset) {
5      __be32 tmp, *ptr;
6      const int len = sizeof(tmp);
7      if (likely(offset >= 0)) {
8          if (headlen - offset >= len)
9              return get_unaligned_be32(data + offset);
10         ...
11     }
12     return -EFAULT;
13 }
```

Listing 3: The packet-loading helper.

Exploit #3: Spectre-PHT via Helper. The third exploit is similar to Exploit #1, but the vulnerability occurs in a BPF helper function. Listing 3 presents one such vulnerable helper that loads bytes from a packet. If `offset` is out-of-bounds, but `headlen` was not cached, then the conditional in Line 8 will be speculated and the out-of-bounds address will be loaded in Line 9. For simplicity, we edited the kernel to flush the memory of `headlen` before calling the BPF program to force speculation. The BPF program we ran is a `socket` BPF program that triggers this mis-speculation and loads the out-of-bounds value. In the vanilla kernel, the attack triggers a memory load of the target location with or without LPM. In contrast, BeeBox prevents this exploit as it hardens this helper (SFI in BeeBox-RC and `array_index_nospec` in BeeBox-CP). This attack demonstrates that LPM offers partial coverage. Similar attacks can take place through packet filtering cBPF.

7.1.3 Compatibility Evaluation

The LPM prevent certain BPF program patterns from being accepted by the verifier. In contrast, BeeBox is designed with compatibility in mind, allowing more programs to pass verification, while also receiving superior protection. We describe two such examples, which we also summarize in Table 1.

Verifier State Explosion. The BPF verifier keeps an internal count of analyzed instructions to decide whether a program takes too long to verify and should be rejected—interestingly, an instruction may be analyzed multiple times if it is reachable from different paths. LPM can dramatically increase verification time since it requires all combinations of branch choices to be analyzed, even if they are not possible. To demonstrate this problem, we crafted a BPF program that contains 23 conditional jumps out of 47 instructions in total. Loading this BPF program as an unprivileged user (i.e., the current Spectre-PHT mitigations are enabled) fails as it breaks the verifier's limit of one million analyzed instructions. Without the analysis for speculative branches, the verifier decides the BPF program is safe after processing 611 instructions. Since BeeBox comprehensively stops access of sensitive information from BPF programs, it avoids this analysis and achieves verification scalability as program size and complexity increase.

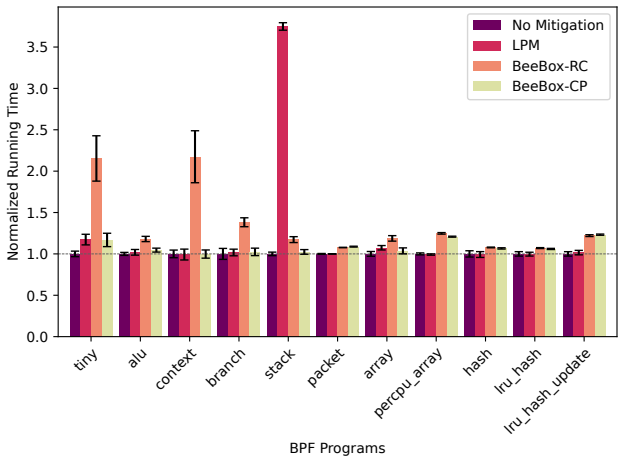

Figure 4: Synthetic micro-benchmark that involves various socket filter eBPF programs and different hardening schemes (no protection vs. LPM vs. BeeBox).

Conditional Pointer Arithmetics. Under the current Spectre-PHT mitigation(s), the BPF verifier rejects BPF programs where a pointer can have different value sets due to different branches (with the exception of map value pointers that point to different elements). This is a common code pattern in BPF programs; for example, one of Katran's BPF programs cannot be loaded by an unprivileged user since it has pointers that target different packet fields based on the IP version (e.g., IPv4 vs. IPv6). BeeBox can avoid this restriction; even though `boxptrs` can speculatively perform arbitrary arithmetic, they cannot point to sensitive data (outside `beebox`).

7.2 Performance of BeeBox

7.2.1 Basic Operations

We crafted a synthetic micro-benchmark that consists of small BPF programs (which we make available along with our prototype of BeeBox) that stress different kinds of operations, in order to better understand BeeBox's behavior in comparison with LPM. For each case, the running time of the given BPF program was measured using the `bpf` system call with the option `BPF_PROG_TEST_RUN`, which is modified to use `rdtscp` for accurate timing. We ran each BPF program in a tight loop for one million iterations with interrupts disabled. The BPF program type we use is `socket`, and the synthetic packets are 64 bytes, except in the `packet` benchmark, where the packet size is 150 bytes. Finally, all benchmark programs explicitly avoid using the stack unnecessarily.

Results are shown in Figure 4. We compared four different settings: (1) no mitigation, (2) LPM, (3) BeeBox-RC (§5.4.1), and (4) BeeBox-CP (§5.4.2). Setting (1) executes BPF programs as `root`, while (2) – (4) execute BPF programs in an unprivileged manner. LPM incur a 270% runtime over-

head compared to no protection (*No Mitigation*) on the `stack` benchmark, but do not exhibit any significant slowdown in any other case. Both BeeBox schemes incur a 7%–23% overhead on hash map operations due to the instrumentation of the helpers. BeeBox-RC has additional overhead due to copying, which peaks at 110% for the shortest BPF programs (`tiny` and `context`). This experiment also demonstrates that since LPM only add instrumentation around stack accesses, BeeBox's runtime performance gain over the LPM comes from better handling of stack load/store operations and Spectre-STL.

7.2.2 Real-world BPF Programs

Katran Benchmarks. Real-world eBPF programs can be more complex than the aforementioned, synthetic micro-benchmark programs, unavoidably using the stack for register spills. The performance of the LPM severely degrades in such situations, whereas BeeBox scales better with the complexity of the BPF program. To test this, we evaluated BeeBox on Katran's load balancer XDP program. In this setting, we benchmarked two BeeBox optimizations, applied separately to XDP: BeeBox-RC (§5.4.1) and BeeBox-RB (§5.4.2). The benchmarked BPF program is the standalone Katran XDP program, and the driving workload comes from Katran's `-perf_testing` option in its tester program. To run Katran's XDP program as a non-`root` user we provided the corresponding process with `CAP_NET_ADMIN` and `CAP_BPF`.

The results of the benchmark are shown in Figure 5. The overhead of LPM is consistently above 70%, with an average overhead of 112%, which confirms our hypothesis that most of the overhead is caused by register spilling. The overhead of BeeBox-RC ranges between 28%–50% in most benchmarks, but spikes up to 200% for packets that are passed-through or dropped early; therefore, on average, it has an overhead of 71%. For BeeBox-RB, the average overhead is 20%, with a maximum overhead of 39% when the workload consists of IPv6 ICMP packets (workload 9). When we compare BeeBox-RB to BeeBox-RC, we observe that the copying of context contributes 42% overhead on average. We also constructed a modified version of BeeBox-RB that applies instrumentation only to helper functions to determine their contribution to the overall overhead. This modified scheme has an average overhead of ≈17%, indicating that most of the overhead in BeeBox-RB is due to the instrumentation of the helpers.

Packet Filter Benchmark. We tested the performance of raw socket filtering using cBPF. To efficiently support cBPF packet filtering, we applied the BeeBox-CP scheme (§5.4.2). On the benchmark machine, we setup a UDP server listening on `localhost` and a UDP client that continuously sends packets with 32-byte payloads. We then attached a cBPF filter to a raw socket of the loopback (`lo`) device; the filter on the raw socket gets executed in the softIRQ raised by the client sending the packets, and is thus on the same CPU as the client. We pinned the client process to a CPU, and made sure that

Filter	No Mitigation	BeeBox-CP	%-Chg
`bpf1`	325927 (± 3611)	327778 (± 3006)	+0.57%
`bpf2`	324615 (± 3960)	323374 (± 5375)	−0.38%
`bpf3`	324114 (± 3977)	323834 (± 5088)	−0.09%
`bpf4`	328610 (± 4827)	325568 (± 7818)	−0.93%
`bpf5`	328072 (± 3883)	325395 (± 7352)	−0.82%
`bpf6`	314801 (± 2025)	313618 (± 2650)	−0.38%

(a) Packet filtering performance in pkts/s with 95% CIs.

Benchmark	No Mitigation	BeeBox
Nginx	0.81% (± 1.09%)	0.32% (± 1.47%)
Redis	0.98% (± 0.44%)	0.84% (± 0.74%)

(b) Tput degradation of `seccomp-BPF` with 95% CIs.

Table 2: cBPF performance results.

the CPU's utilization was close to 100%. Finally, to collect the results, we measured this scenario's throughput (pkts/s) as packets are filtered using rules that are similar to prior works [50, 101]. Results are shown in Figure 2a; the overhead introduced by BeeBox is $< 1\%$.

`seccomp-BPF` Benchmark. Because `seccomp-BPF`'s context is generated on the stack, BeeBox supports it by replacing the (kernel) stack allocation with a BPF stack allocation. To measure BeeBox's impact on `seccomp-BPF` performance, we applied sysfilter [23], a framework that generates and enforces `seccomp-BPF` policies, to Nginx [3] and Redis [4], and measured the performance of the hardened binaries. Nginx was configured to have two working processes. The test traffic was generated by `wrk` [30] with two running threads, each opening 128 connections, requesting 1KB payloads in every request. Redis was benchmarked using `memtier` [86] with two worker threads, each having 128 clients. The `GET:SET` request ratio was 10:1, and the data object size was 32 bytes. Each experiment ran for one minute. We ensured the CPU running the Nginx server and the Redis server was saturated with the testing configuration. Given that we tuned the packet sizes to be small, both tasks are syscall-intensive. The Nginx experiment handles over 43.5K req/s, and the Redis experiment handles more than 155K req/s. The results are shown in Figure 2b. The JITed cBPF programs already have limited impact on the services, and hence our defenses do not incur any observable overhead.

Memory Usage. We ran the real-world benchmarks and monitored the system's total memory usage. We measured this in a KVM VM with 4 vCPUs and 8GB of RAM, hosted on the benchmarking machine. The results of this experiment are shown in Table 3. The memory usage of the Linux kernel with no mitigations is reported in the second column (*Vanilla Usage*). The memory usage for BeeBox is given in the third

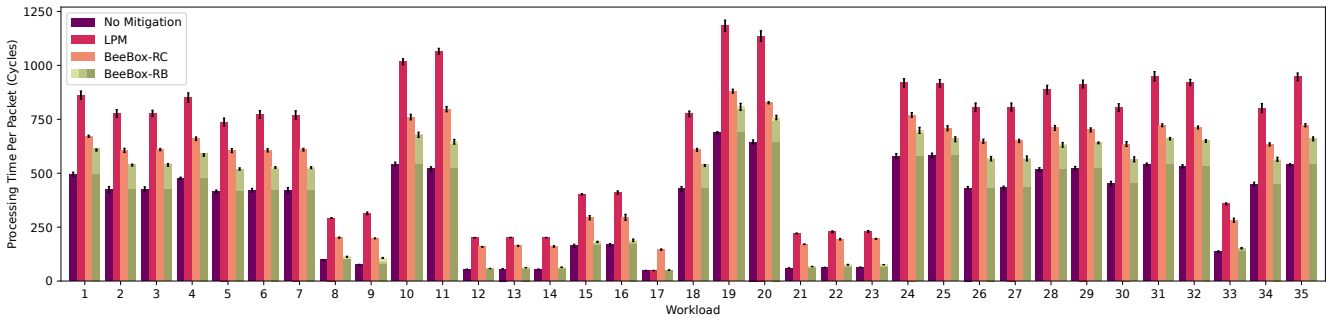

Figure 5: Katran's load balancer XDP program/benchmark. The most efficient scheme, BeeBox-RB, also includes a breakdown into *baseline*, *helper instrumentation*, and *BPF instrumentation* (colored dark to light).

Experiment	Vanilla Usage	BeeBox Usage	Overhead
At rest	176MB (178MB)	180MB (180MB)	2.4%
Packet filter	182MB (183MB)	186MB (188MB)	2.3%
Katran	580MB (582MB)	592MB (592MB)	2.0%
Nginx (`seccomp`)	189MB (190MB)	196MB (197MB)	3.5%
Redis (`seccomp`)	212MB (213MB)	218MB (221MB)	3.0%

Table 3: Memory usage of BeeBox compared to vanilla Linux. *At rest* means no workload is running. The reported numbers are formatted as '*avg (max)*'.

column. Overall BeeBox uses 4MB–6MB of additional memory when the application does not use BPF maps, and 12MB when it does, as is the case for Katran. Overall, the relative memory overhead ranges from 2%–3.5%.

8 Discussion

Compatibility. Regarding ISA-compatibility, although BeeBox is implemented for x86-64, the instrumentation techniques are generic and can be applied to other architectures. The main assumption required to enable our SFI scheme is that register-only masking and addition operations will enforce the pointer range during speculation. For existing BPF application compatibility, BeeBox does not require any changes from legacy BPF applications to benefit from its protection, unlike the current mitigations in the Linux kernel.

Future Extensions. To extend BeeBox to cover more BPF functionality, developer effort should be concentrated on migrating and instrumenting more helper functions and BPF map data structures. The division between kernel data and BPF data in BPF maps is ultimately developer-defined, therefore, there is no easy way to automate the entire process. However, `sparse` [64] has made the manual instrumentation process much easier and less error-prone for us. An extension to `sparse`'s capabilities to allow multiple pointer annotations working together (e.g., `__percpu` and `__beebox`) can streamline the process even more.

9 Related Work

Sandboxing BPF. SandBPF [62] also uses SFI [99] to sandbox BPF. However, it is designed to defend against errors in the verifier and the JIT compiler, and does not defend against transient execution attacks. It also assumes the input to the helpers is completely trusted. Lastly, its overhead is much higher than BeeBox: ≈7% in end-to-end experiments.

BPF Hardening. The BPF infrastructure has been used to assist kernel exploitation. BPF JIT-spraying [73, 88] and EPF [50] use BPF to bypass `ret2usr` defenses [20,54]. These attacks and proposed defenses revolve around memory safety, and assume the presence of memory-safety vulnerabilities. In contrast, BeeBox deals with transient execution attacks, which do not strictly require the presence of memory errors.

Correctness of BPF. Given the complexity of the BPF infrastructure, techniques have been proposed to enhance its security. Nelson et al. [79] proposed to use formal verification to secure the JIT compiler, and Jia et al. [49] proposed to use Rust to improve the runtime security of helpers. Similar to the work regarding BPF hardening above, these works also focus on memory safety problems, and hence differ from BeeBox's focus on transient execution attacks.

Wasm Hardening. WebAssembly (Wasm) [34] is a portable, low-level bytecode designed, in part, to safely and efficiently run untrusted code in web browsers. Unfortunately, Wasm is susceptible to Spectre attacks, which allow the attacker to escape the sandbox and access sensitive data outside of it. To combat Spectre attacks in Wasm, Swivel [78] presents two hardening schemes: (1) a software-only SFI approach, similar to BeeBox; and (2) a hardware-assisted approach that makes use of Intel's CET and MPK hardware extensions [21]. While the SFI scheme of Swivel is similar in concept to BeeBox, the two schemes have separate, domain-specific requirements and features that mold their respective designs.

10 Conclusion

We presented the design, implementation, and evaluation of BeeBox: a new security architecture that hardens BPF against transient execution attacks, allowing the OS kernel to expose its functionality to unprivileged users and applications. BeeBox sandboxes the BPF runtime against speculative code execution in an SFI-like manner, and uses a combination of static analyses and domain-specific properties to selectively remove enforcement checks to improve performance. Our BeeBox prototype for the Linux kernel supports popular features (e.g., BPF maps and BPF helper functions) and incurs low runtime overhead against prevalent transient execution attacks, such as Spectre-PHT and Spectre-STL. On average, BeeBox incurs 20% overhead in Katran's macro-benchmarks and $< 1\%$ throughput degradation in end-to-end, real-world settings that involve `seccomp-BPF` and packet filtering.

Availability

Our prototype implementation of BeeBox is available at: https://gitlab.com/brown-ssl/beebox

Abstract

Cache side-channel attacks based on speculative executions are powerful and difficult to mitigate. Existing hardware defense schemes often require additional hardware data structures, data movement operations and/or complex logical computations, resulting in excessive overhead of both processor performance and hardware resources. To this end, this paper proposes SpecLFB, which utilizes the microarchitecture component, Line-Fill-Buffer, integrated with a proposed mechanism for load security check to prevent the establishment of cache side channels in speculative executions. To ensure the correctness and immediacy of load security check, a structure called ROB unsafe mask is designed for SpecLFB to track instruction state. To further reduce processor performance overhead, SpecLFB narrows down the protection scope of unsafe speculative loads and determines the time at which they can be deprotected as early as possible. SpecLFB has been implemented in the open-source RISC-V core, SonicBOOM, as well as in Gem5. For the enhanced SonicBOOM, its register-transfer-level (RTL) code is generated, and an FPGA hardware prototype burned with the core and running a Linux-kernel-based operating system is developed. Based on the evaluations in terms of security guarantee, performance overhead, and hardware resource overhead through RTL simulation, FPGA prototype experiment, and Gem5 simulation, it shows that SpecLFB effectively defends against attacks. It leads to a hardware resource overhead of only 0.6% and the performance overhead of only 1.85% and 3.20% in the FPGA prototype experiment and Gem5 simulation, respectively.

1 Introduction

Out-of-order (OoO) and speculative execution mechanisms are the optimization techniques commonly used by modern CPUs to improve performance. In OoO execution, the CPU does not strictly execute instructions in program order, but rather executes later instructions ahead of time when conditions are met, in order to improve the utilization of processor components. Speculative mechanism refers to the processor's speculative execution of instructions, which, in coordination with pipelining and OoO execution, can significantly improve CPU performance. However, speculative execution is not guaranteed to be completely accurate, and OoO execution may result in instructions being executed before they have proper permission. Typically, these erroneously executed instructions, also known as transient instructions, change the microarchitectural state and are "rolled back" by the processor before they are "committed" to the architectural state. Therefore, programmers can only see instructions executed correctly according to the program flow at the architectural level.

However, the disclosure of side-channel attack methods such as Flush+Reload [55] and Prime+Probe [53] has shown that information can be leaked through the microarchitectural state and behavior. In early 2018, several independent security research teams disclosed serious vulnerabilities in modern CPU architectures, such as Spectre [30] and Meltdown [35] attacks, which have made a significant impact on the industry and continue to do so to this day. Among the exploited techniques for these vulnerabilities, cache side-channel attack [9, 11, 21, 22, 27, 34, 53–55] is the main approach. The Spectre attacks can leverage speculative executions to change the cache state and leak data through the cache side channels.

To mitigate speculative execution attacks, many hardware defense solutions have been proposed. Yan et al. proposed InvisiSpec [52], in which speculative loads that may cause security problems are stored in the Speculative Buffer (SB) instead of the cache. When a speculation succeeds, the speculative data is then installed back into cache. SafeSpec proposed in [28] shadows the hardware architecture used during the execution of speculative instructions, so that any changes to the microarchitectural state could be reverted if the processor's speculation is turned out to be incorrect. Both solutions make speculative execution "invisible" by clearing all side effects of speculative executions. Based on this idea, many other methods have been proposed [3, 40, 49]. However, regardless of whether speculation succeeds or not, they

all require expensive re-install operations. Speculative taint tracking (STT) [57] and NDA [47] use dataflow tracing similar to taint propagation to track instructions that may lead to information leakage. These instructions are forced to be delayed until their related instructions become safe, thus preventing unsafe speculative data from being transmitted to side channels. Compared with the solution of hiding all the side-effects of speculative executions until reaching the visibility point (e.g., when all old control flow instructions have been resolved) in InvisiSpec, these solutions which selectively delay speculative executions are more efficient. However, instruction tracing and taint marking also require complex logic to compute the "root of taint", resulting in significant hardware changes and performance overhead.

Overall, most of the above hardware defense solutions require additional data structures, data movement operations and/or complex logical calculations, which can cause excessive additional performance and hardware resource overhead. These methods also lack implementation and evaluation based on real hardware prototypes, and most defense solutions are only verified through architecture simulation platforms such as Gem5 [38] rather than register-transfer-level (RTL) implementation. In addition, the types of attacks included in the security verification of these schemes are relatively homogeneous, which have always been Spectre v1 and v2 [30] with similar principles, which exploit unresolved branches in the instruction stream. However, the factors that can lead to unsafe speculation executions are diverse.

To address these issues, this paper proposes a novel hardware defense scheme, SpecLFB. It leverages the microarchitectural component Line-fill-buffer (LFB) and introduces a simple yet effective security check mechanism to LFB to prevent potentially unsafe speculative loads from being reloaded from lower-level cache into adjacent upper-level cache (e.g. from L2 cache into L1 data cache (L1D cache)), thereby preventing the establishment of cache side channels. We have implemented SpecLFB in the L1D cache of open-source RISC-V core SonicBOOM (the latest version, also called BOOMv3) [58] and both cache levels of X86 O3 CPU model in Gem5 simulator [38]. The SpecLFB-enhancing cores have been evaluated in the Verilator simulation based on the RTL code generated by Chipyard and in an FPGA hardware prototype we have developed, as well as in the Gem5 simulation. The evaluation results show that it can successfully defend against Spectre v1, v2, v4 [24] and v5 [31] attacks. In comparison with the original cores and the cores enhanced with the state-of-the-art defense schemes, the experimental results show that SpecLFB leads to a hardware resource overhead of only 0.6%. Furthermore, by running the SPEC CPU 2017 benchmark suite (SPEC2017), SpecLFB exhibits the performance overhead of only 1.85% and 3.20% in the FPGA prototype experiment and Gem5 simulation, respectively.

This paper makes the following contributions:

- We propose a novel scheme called SpecLFB to defend against cache side-channel attacks. By introducing a simple yet effective security check mechanism to LFB, the executions of unsafe speculative loads can be delayed to prevent the establishment of cache side channels from propagating sensitive data.
- To reduce processor performance overhead, SpecLFB narrows down the protection scope of unsafe speculative loads and determines the time at which they can be deprotected as early as possible.
- We fully and seamlessly implement SpecLFB in the L1D cache of the open-source RISC-V core, SonicBOOM, as well as in all cache hierarchy of Gem5 OoO processors.
- We develop an FPGA hardware prototype burned with the L1D-SpecLFB-enhancing SonicBOOM and running a Linux-kernel-based operating system.
- We evaluate SpecLFB in terms of security guarantee, performance overhead, and hardware resource overhead, through both Gem5 and RTL simulations, as well as the experiment based on the developed hardware prototype.

2 Background

2.1 Transient Execution

In modern OoO processors, instructions issued in program order are decoded into micro-operations (μops), but the execution of μops may not follow the program order. Even if an earlier μop in the instruction stream has not been completed, the CPU may execute a ready μop when certain conditions are met (i.e., the μop's operands do not have dependencies on previous μops or their values have been computed). CPU tracks all μops through the reorder buffer (ROB), and when a μop completes execution, it is retired from the ROB in program order, irreversibly modifying the CPU's architectural state. This OoO execution technique can increase the component utilization of the processor.

Conditional branches or data dependencies between instructions are generally included in the instruction stream. Theoretically, the processor without knowing the future instruction stream of a program must wait for the branch result or resolved data dependencies before continuing to execute instructions. Since the execution suspension will reduce processor performance, the processor can predict the results of conditional branches and data dependencies through some components such as branch predictors, memory disambiguators, etc., and then execute along the speculative path. If the prediction turns out to be correct, the precomputed results of the speculative execution are committed; otherwise, if the processor determines that it followed the wrong path, the instruction-related μops will be squashed and the processor will be rolled back to the last correct state and resume along the correct path.

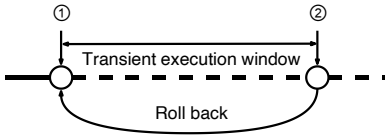

Figure 1: Transient execution flow. The point ① is when there is an unresolved branch or data dependency, and the point ② is when the processor gets the results and finds that the speculation is wrong.

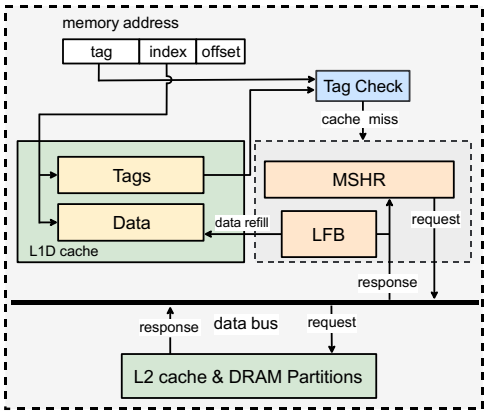

Figure 2: The working principle of LFB in L1D cache.

Therefore, these instructions that are executed out of order and whose executions are incorrectly speculated may cause the microarchitectural state of the processor to change, even though their results are never committed to the architectural state due to processor rollback. This is called transient execution, and these instructions are called transient instructions [30, 35]. As shown in Figure 1, the period of time from the beginning of the execution of a transient instruction to when the processor detects the error and begins to roll back its state is called the transient execution window.

2.2 LFB

A cache with only Data and Tag Arrays, which would not accept new load/store misses in case of cache misses, is called a blocking cache. In an OoO processor, a blocking cache prevents the load/store unit (LSU) from issuing several store or read accesses to it, thus affecting the overall processor speed. To solve this problem, modern processors [12, 16, 43, 58] have introduced Miss Status Holding Registers (MSHR) to hold the information of unresolved cache misses in order to accept more than one cache misses and implement non-blocking caches. When a cache miss occurs or data prefetching requires cache refills, MSHR will request data from the data bus and refill the requested data into cache via LFB.

As shown in Figure 2, when the data targeted by a memory access instruction is missed in the upper-level caches, the miss handling logic first checks MSHR to see if there is a pending request that matches the current one. If so, the request is merged into the same entry and no new data request needs to be issued [33]. Otherwise, a new MSHR entry and LFB entry will be reserved for this data request. When the requested cache line is fetched from the lower-level caches or memory, it is placed into LFB instead of directly being written into the upper-level caches, allowing cache eviction and refill to occur in parallel [19], so the hit time of the cache can be greatly reduced. When the cache eviction is complete, LFB is flushed into the cache arrays.

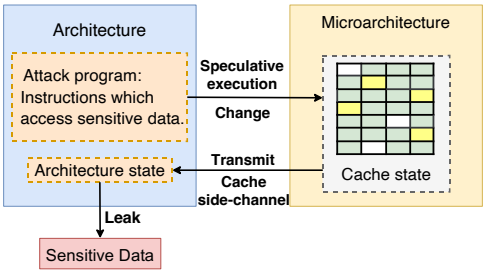

Figure 3: Speculative cache side-channel attack process.

3 Speculative Cache side-channel Attacks

This paper focuses on defending against the speculative cache side-channel attacks, which simultaneously exploit both speculative execution and cache side-channel vulnerabilities of processors. Speculative execution attack exploits the side effects of the transient instructions which are mis-speculated and destined to be squashed. The attack program speculatively executes load instructions, which leak sensitive data to the covert channel before they are squashed. A cache side-channel attack can establish cache side channels, thus providing a covert channel for the speculative execution attacks. Figure 3 shows the general process of such attacks. An attacker exploits the speculative execution mechanism to trigger transient execution of instructions, which access victim's sensitive data, causing changes in cache state. Then, the data is transmitted from the microarchitectural state to the architectural state through a cache side channel, thereby leaking the sensitive data.

3.1 Cache Side-channel Attack

A cache, consisting of SRAM, has a small capacity but is much faster than memory composed of DRAM, approaching the speed of CPU. Modern processors use a hierarchy of successively smaller but faster caches to bridge the speed gap between processor and memory. In a multi-level cache, the last-level cache (LLC) is shared by all the cores in the processor. For example, in a typical Intel processor, cache is

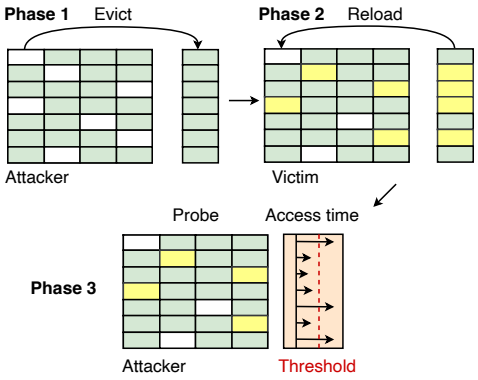

Figure 4: Side-channel attack process. In each phase, the left side of the figure represents the cache, while the right represents the evicted cache lines. Lattice in green: a normal cache line; lattice in white: the cache line at this location has been evicted by the attacker; lattice in yellow: the cache line accessed by the victim.

divided into three levels, with the L1 and L2 caches individually owned by each core, while the LLC is shared among all cores. When the processor needs data, it first checks whether a copy of the data is present in the top level of cache hierarchy, i.e., the L1 cache. If a copy is found, a cache hit occurs; otherwise a cache miss occurs, and the processor repeats the procedure to try to retrieve data from the next-level cache, and finally from the memory. Retrieving data from memory or upper-level caches closer to memory takes longer than retrieving data from upper-level caches closer to the core. The cache side-channel attack in our threat model is an attack that exploits such timing differences [30].

Attackers exploit the variation in cache state to establish a cache side channel. The attack process usually contains three phases, as shown in Figure 4. First, an attacker evicts the monitored cache lines from the cache hierarchy. Second, a victim program is executed. In the third phase, the attacker probes the time it takes for accessing the monitored cache lines. If the victim program has already accessed the monitored cache lines in the second phase, the cache lines represented by the yellow lattices will be loaded into the cache, resulting in a shorter time for the attacker to access them; otherwise, the attacker's access time will be longer. Hence, by measuring and comparing the access time, the attacker can determine whether the victim program has accessed the monitored cache line to obtain sensitive information. Based on the method of evicting the monitored cache line, cache side-channel attacks can generally be divided into two types [22]:

Flush-Based Attack: An attacker uses specialized machine instructions, such as the x86 `CLFLUSH` instruction used in Flush+Reload [55], to flush the target cache line out of the shared cache between the attacker and victim. This type of attack also includes Flush+Flush [21], Flush+Coherence [54], Reload+Refresh [9], etc.

Conflict-Based Attack: An attacker constructs a conflict set to evict the target cache line. For example, in Evict+Reload [34], the attacker forces contention in the cache set by accessing dummy data and loading it into the cache set, causing the processor to evict the target cache line due to the limited size of the cache. This type of attack also includes Evict+Time [27], Prime+Probe [53], Prime+Abort [11], etc.

3.2 Spectre Attack

Spectre attack is a representative one of speculative cache side-channel attacks. In different variants of Spectre attack, an attacker mistrains the CPU's predicted components, which causes the CPU to transiently violate program semantics by executing an instruction that would not normally execute, thereby triggering a transient execution.

In Spectre v1 [30], the attacker mistrains the pattern history table, which determines whether the conditional branch instructions (e.g., `bne` and `bnq` in RISC-V) should take the branch or not. As shown in the following code example:

```
if (x < array1_size)
    y = array2[array1[x] * L1_BLOCK_SZ_BYTES];
```

the attacker maliciously selects a value of `x` that is out of the `array1`'s range, causing `array1[x]` to be resolved to a secret byte `k` in the victim's memory, where `x` = (the address of the secret byte to be read) - (the base address of the array). Furthermore, the attacker ensures that the processor cannot immediately obtain the value of `array1_size` (because it is not in cache or requires complex computations), causing the branch condition to wait for the uncached parameter. As a result, the processor executes the instructions inside the conditional branch statement under mis-speculation, leaking the byte `k` into cache.

In Spectre v2 [30], the attacker mistrains the branch target buffer of indirect branch instructions (e.g., `jalr` in RISC-V and `MOV` in ARM) with malicious target addresses corresponding to code snippets called gadgets, which can leak sensitive data, as shown in the following code example:

```
void victimFun(uint64_t x)
{
   uint64_t y = array2[array1[x] * L1_BLOCK_SZ_BYTES];
}
```

During the training phase, the attacker makes the branch predictor mispredict a branch from the indirect branch instruction to the address of `victimFunc`. During the attack phase, similar to Spectre v1, the attacker maliciously chooses a value of `x` that is out of the `array1`'s range and delays the processor's access to the target address of the indirect branch instruction, causing the processor to speculatively execute `victimFunc` and leak the secret byte `k` into the cache.

In Spectre v4 [24], the attacker exploits the misprediction of the memory disambiguator. Modern processors adopt an

optimization called speculative store bypassing to further improve performance, where the memory disambiguator is used to speculate which load instructions do not depend on any preceding store instructions. Therefore, the attacker can exploit the memory disambiguator to trigger transient executions of unsafe load instructions, allowing access to sensitive data. Considering the following code snippet:

```
ptr = secret_ptr;
ptr = general_ptr;//store operation
x = *ptr;//load operation
y = array2[x];
```

for a read-after-write (RAW) dependency operation, the attacker prevents the processor from immediately obtaining the value of `general_ptr` in the store operation `ptr = general_ptr`. Therefore, in the attack stage, the load operation `x = *ptr` should return the value of `general_ptr`. But since the value of `general_ptr` cannot be immediately obtained (because it is not in cache or requires complex computations), the processor will speculatively execute the load operation, causing `x` to take the value of `secret_ptr`, which leaks `secret_ptr` into cache.

In Spectre v5 [31], also known as SpectreRSB, the attacker exploits the return stack buffer (RSB), which is a hardware stack used to track the return addresses of previous call instructions. When encountering a `ret` instruction, the processor speculatively uses the top address of the RSB as the return address, as accessing the software stack is slower. Therefore, the attacker can exploit the RSB to supply CPU with a malicious return address corresponding to a gadget (the same as in Spectre v2), resulting in speculative execution of the gadget, thereby allowing the gadget to leak sensitive information via a cache side channel.

4 Threat Model

We focus on eliminating cache side channels in speculative execution established by flush- and conflict-based cache side-channel attacks, which require pre-evicting the cache lines to be leaked. Overall, we make the following assumptions:

- Attackers are allowed to run arbitrary code before and during the victim's executions to affect the victim's speculation, for example, by altering the state of RSB, branch predictor, and memory disambiguator.
- Attackers are aware of the cache index method and replacement strategy, enabling them to evict target cache lines from the cache.
- Attackers can locate gadgets within the victim's executable memory space.
- All these assumptions hold under the condition that the processor hardware and operating system work correctly.

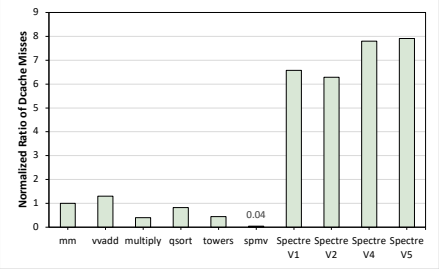

Figure 5: Normalized ratio of L1D cache misses.

We do not consider other speculative side channels, such as TLB [20], port contention [4,7], etc. Speculative side channels based on TLB can be mitigated through alternative secure TLB architectures, e.g., the one proposed by Deng et al. [14]. Speculative side channels based port contention can be mitigated by turning off SMT or by employing the defense scheme proposed in [32]. We neither consider non-speculative side channels [10,15], nor physical side channels [29,44] (which are generally noisier, requiring longer time for attackers to observe the effects).

5 Speculative Loads Protected in SpecLFB

In modern OoO processors, to reduce hardware cost and complexity, all instructions are considered as speculative executions until they reach the head of ROB, and any load of these instructions initiating memory reads is a speculative load [52]. Transient execution allows speculative loads to load data into cache, which may cause security issues. Although the processor can handle exceptions or squash these loads after validating the speculation, the cache state in the microarchitecture has already been changed, allowing attackers to establish cache side channels to leak sensitive information. To prevent the establishment of cache side channels, the speculative loads, which are potentially exploited by attackers, should be protected to prevent them from changing the cache state.

Based on the principle of speculative cache side-channel attacks (cf. Section 3), the cache lines that are exploited to leak data by the attacker must be evicted in the first phase before they can be refilled by the speculative loads of the victim, thereby causing cache misses in the second phase and then creating observable timing differences in the third phase, as shown in Figure 4. Figure 5 shows that the ratio of data cache misses during the executions of Spectre v1, v2, v4, and v5 attack programs in SonicBOOM is significantly higher than that of the normal programs from the benchmarks provided by the RISC-V toolchain [1]. Furthermore, in the simulations of attacks on SonicBOOM using Chipyard, the output log indicates that all the unsafe loads exploited by the attacker in the victim code generate cache misses. Therefore, to defense against such attacks, the speculative loads causing cache misses are considered unsafe and should be protected

by delaying their execution. In this paper, we use MUSL to denote an unsafe speculative load that causes cache miss.

MUSLs can be confirmed as safe without needing to reach the head of ROB. Delaying the execution of MUSLs until they reach the head of ROB is overly conservative. Take the MUSLs in Spectre v1 for example. They can be safe as soon as the branch resolves in a correct prediction. This is the earliest point when the data returned by speculative loads is no longer considered unsafe. Therefore, to save performance as much as possible, it is necessary for processors to confirm MUSLs as safe as early as possible.

When processors can confirm MUSLs as safe depends on different speculation sources. According to [51], there are mainly the following sources:

- Control flow prediction. It predicts the execution path that a program will follow through the branch prediction unit (BPU), which may generate speculative loads in unresolved control flows.
- Address speculation. It predicts the data dependencies between loads and stores when the physical address is not fully available, which may generate speculative loads in an unresolved memory access order.
- Value prediction (VP). It predicts the result of a μop based on the execution history allowing dependent instructions to continue their execution without waiting for the result to become available, which may generate speculative loads in an unresolved value.
- Other exceptions. Additionally, we also consider other exceptions that may lead to speculative execution and correspond to speculative loads in other exceptions.

We have run in the SonicBOOM core the programs of RISC-V benchmarks [1] to validate the types of speculative loads. Since the current version of SonicBOOM does not implement VP, Figure 6 only shows the normalized ratio of the speculative loads resulting from the other three sources, where one can find that most speculative loads result from the unresolved control flow and memory access order.

Based on the above classification and analysis, we further precisely elaborate the MUSLs to be protected as follows:

1. *MUSLs in an Unresolved Control Flow*

   When the branch condition or target address of control instructions, such as branches and jumps, is unknown or has been predicted but not yet verified, the speculative loads that follow these unresolved branch instructions are the MUSLs to be protected. When the conditions and addresses can be verified by the processor, the MUSLs can be transformed into safe loads, if the speculative execution is in the correct path. Otherwise, they will be squashed at the end of the transient execution window.

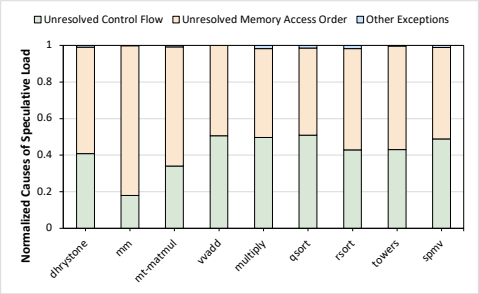

Figure 6: Normalized ratio of speculative loads. These statistics only consider the oldest reason that caused the speculative load since there might be multiple reasons.

2. *MUSLs in an Unresolved Memory Access Order*

   Two scenarios are discussed based on two different reasons causing such MUSLs, respectively.

   Memory Dependency. During memory access, waiting for the results of stores with unresolved addresses increases the processor's latency. To further improve performance, the memory disambiguator of the processor is used to predict which loads do not depend on any previous stores. When it determines that a load has no such RAW dependencies, the load will be speculatively executed. Therefore, the speculative loads causing cache misses that follow the stores are the MUSLs to be protected. Such a MUSL can be transformed into a safe load, if it is later discovered that the store which the MUSL follows points to a different address from that of the MUSL. Otherwise, the MUSL will be squashed at the end of the transient execution window.

   Memory Consistency Model. The memory consistency model specifies the order in which a core executes memory operations and is observed by other cores in a shared memory system. When a memory operation is committed, it exposes itself to the memory hierarchy and other cores in the system. Therefore, those instructions that are not committed in the program order must ensure that they comply with the defined memory consistency model [6]. Read operations can read data from memory and are executed out of order before reaching the ROB head, indicating that some loads will be speculatively executed before earlier loads and stores in the ROB. However, for a memory consistency model that does not allow store-load or load-load reordering operations, the speculative loads may be squashed due to violating the model. For example, in the total-store-order model, which does not allow store-store or load-load reordering, if the execution of an older load is delayed, a younger load may be executed speculatively. The speculative load that generates cache misses in this scenario is a MUSL to be protected. If an invalidation is received when the older load has

finished its execution, the MUSL will be squashed. Otherwise, the MUSL can become safe.

3. *MUSLs in an Unresolved Value*

   With VP, the processor first determines whether the result of a μop is predictable based on the execution history. If it is considered to be predictable, the processor may execute the dependent instruction using the predicted source operand value in parallel with the instruction which generates the required result. Therefore, the speculative loads causing cache misses generated by these instructions are the MUSLs to be protected. Such a MUSL can be transformed into a safe load, if the prediction is validated to be correct. Otherwise, the MUSL will be squashed at the end of the transient execution window.

   Remark: To the best of our knowledge, both Gem5 and SonicBOOM at their current versions where we implement SpecLFB do not support VP. Because the ROB unsafe mask in our design (as shown in Section 6.2) has to be set according to the specific microarchitecture which supports VP, we have no practical implementation of SpecLFB which considers VP in either Gem5 or SonicBOOM.

4. *MUSLs in Other Exceptions*

   For the instructions that can cause other exceptions, such as unauthorized data access, memory operations with unknown addresses, arithmetic operations with overflow, etc., they will not be squashed until the processor can check for the exceptions. Therefore, the loads causing cache misses in the subsequent instructions that are speculatively executed during this period are the MUSLs to be protected. If any exception exists after the processor checks, the MUSLs will be squashed. Otherwise, the MUSLs can be transformed into safe loads.

6 SpecLFB Design

6.1 Design Overview

In non-blocking caches, MSHR is an essential microarchitecture component between different levels of cache hierarchy and memory. The lower-level cache is requested by MSHRs to retrieve the missing data of MUSLs. Therefore, SpecLFB can be reused with the same defense mechanism in the LFBs of different cache levels. For the convenience of illustration, we use the L1D cache as an example scenario. Generally, the response data is refilled into the L1D cache via LFB. While in a processor that adopts the proposed SpecLFB, as shown in Figure 7, the response data must pass through a security check mechanism introduced to LFB. Only when the security check mechanism determines that it is safe, can the data be refilled into the L1D cache, thus preventing the execution of MUSLs from altering the cache state. To ensure the correctness and immediacy of the security check, a set of judgments are required, such as whether the response data is loaded by MUSLs, or whether MUSLs can be converted into safe loads to continue refilling response data into the L1D cache. This is essential to further avoid the scenarios where safe data are misjudged as the data loaded by MUSLs or where the data loaded by MUSLs that have been converted into safe loads still fail in passing through the security check, which results in longer execution delays of the related instructions and degraded processor performance.

In order to facilitate the judgment in the security check mechanism, an ROB unsafe mask is designed as shown in Figure 7. The bits of the mask correspond to the entries in the ROB with a one-to-one mapping, which is set and changed according to the `unsafe` parameter of μop and the various information and exceptions returned by execution units (EU) and LSU. Parameter `unsafe` is a boolean variable. If an instruction meets one of the following three conditions: 1) it uses the load queue, 2) it uses the store queue (excluding a fence instruction that isolates the previous and subsequent store operations to ensure sequential execution), or 3) it is a branch/jump instruction, then the `unsafe` parameters of the instruction's μops are set to true. If the value of a bit in the ROB unsafe mask is 1, it means that the instructions in the ROB entry to which the bit corresponds are currently in an unsafe state, i.e., these instructions may generate MUSLs; otherwise, they are in a safe state, i.e., they will not generate MUSLs. After LFB obtains the missing data requested by the L1D cache, it judges whether the data can pass the security check mechanism according to the ROB unsafe mask bit corresponding to its related instruction. Only a mask bit of 0 can it pass the check and continue refilling the data into the L1D cache. By exploiting SpecLFB to delay the execution of MUSLs, the processor can eliminate the need for additional data structures to hide the cache lines fetched by speculative loads and data movement operations. Additionally, since the cache line already exists in the L1 upon a cache hit, no additional coherence mechanism is required.

6.2 Detailed Design

6.2.1 ROB unsafe mask

The ROB unsafe mask has the same number of bits as the number of entries in ROB, and a one-to-one mapping exists between the ROB entries and the mask bits. The design details of the ROB unsafe mask vary depending on the specific processor architecture. As shown in Figure 8, the ROB entries in SonicBOOM are divided into multiple banks, and each row (corresponding to a small cell in Figure 8) of a bank stores the information of one instruction [46]. Since the addresses of the instructions dispatched to the ROB are always contiguous, they are stored in different banks of each entry in the ROB in

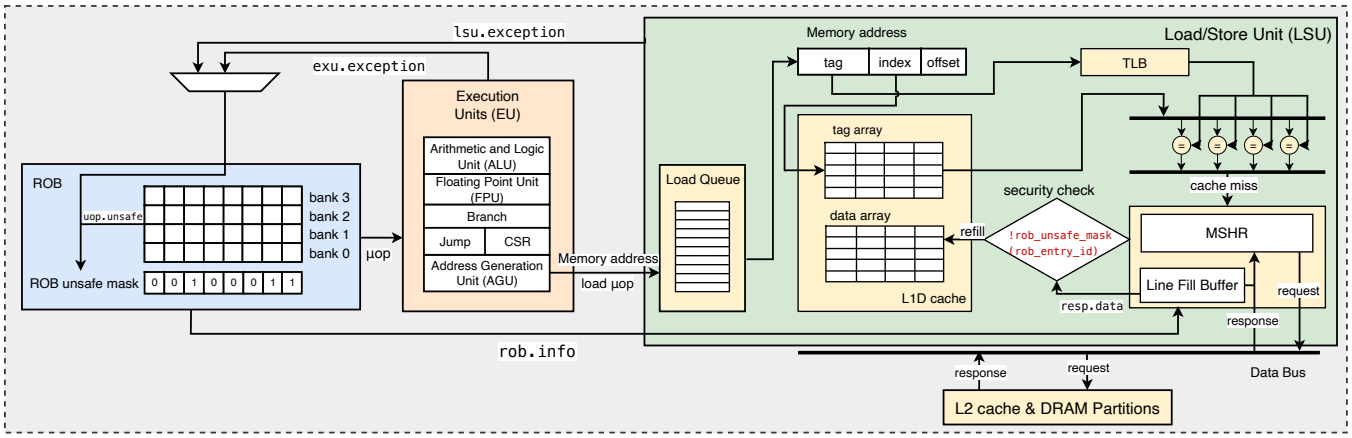

Figure 7: Design overview of SpecLFB.

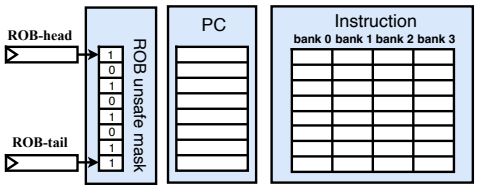

Figure 8: ROB unsafe mask structure.

the order of arrival, and only the addresses of the instructions in bank 0 of each entry are stored to save hardware overhead. Branch instructions or jump instructions are dispatched separately to an entry to ensure the continuity of instruction addresses in each entry of the ROB. Therefore, the value of each bit in the ROB unsafe mask is not only determined by the instruction in bank 0, but also jointly determined by the instructions in all banks of that entry. Once there is a possibility that any instruction in the entry may generate MUSLs, the corresponding bit in the mask for that entry is set to 1.

Let M and N denote the number of entries and that of banks in the ROB, respectively. Let r_i represent the ith ($i \in [0, M-1]$) bit of the ROB unsafe mask, and let b_{ij} represent the security state of the instruction stored in the jth ($j \in [0, N-1]$) bank of the ith entry of the ROB. If the corresponding instruction is possible to generate MUSLs, i.e., it is unsafe, then $b_{ij} = 1$; otherwise, $b_{ij} = 0$. Then, r_i is

$$r_i = b_{i1} \,||\, b_{i2} \,||\, ... \,||\, b_{ij} \,||\, ... \,||\, b_{i(N-1)} \,. \tag{1}$$

6.2.2 Rules for updating ROB unsafe mask

For an instruction stored in the jth bank of the ith entry in the ROB, if the value of the `unsafe` parameter of the instruction's μop is true, the corresponding b_{ij} is initialized to 1. The load of the instruction resulting in cache miss is considered as a MUSL temporarily, so that the data loaded by the MUSL cannot pass through the security check mechanism when being refilled into the L1D cache through the LFB. Based on the elaboration of MUSLs in Section 5, the update rules for corresponding b_{ij} of the instruction are as follows:

- For the instructions in unresolved control flow, according to the information returned by BPU, SpecLFB traverses ROB in each cycle to update b_{ij} depending on whether the instructions are still under the control flow. Specifically, if there are no older control instructions that are unresolved before the instructions, the b_{ij} of the instruction should be updated to 0; otherwise, they should be set to 1. In practice, general processors would provide interfaces for obtaining more detailed control-flow-related information. For example, in SonicBOOM, each μop has a `br_mask` parameter to record which speculated branches it belongs to. When traversing ROB, SpecLFB checks if the branch the current μop belongs to has been resolved. If so, the b_{ij} of the instruction should be updated to 0.

- For the instructions in unresolved memory order, SpecLFB tracks data dependencies through the load queue (LDQ) and store queue (STQ) in the LSU. When placing a memory access instruction (denoted as $\mathcal{A}$) into the LDQ/SDQ, SpecLFB compares it with the instructions in every entry of the LDQ/STQ for checking data dependencies. If a data dependency is not found with an older store/load instruction, for example, there is no older store instruction that accesses the same memory address as instruction $\mathcal{A}$, the b_{ij} of the instruction should be updated to 0. SpecLFB updates the data dependencies between instructions when an instruction is dequeued from the LDQ/SDQ.

- For the instructions related to other exceptions, once the ROB receives exception information from backend units such as execution units and LSU, the b_{ij} of the instruction and younger instructions cannot be updated to 0 until the exception has been handled.

When all b_{ij} of the ith ROB entry are 0, its r_i can be updated

to 0. Then, the data loaded by the MUSLs in the instructions of that ROB entry can pass the security check of the LFB and be refilled into the L1D cache. While SpecLFB promptly updates the b_{ij} of instructions when the correctness of speculation has been verified, the delays introduced by traversing the ROB queue and the STQ/LDQ to confirm the safety of related instructions are inevitable. Nevertheless, these delays are still relatively shorter compared to other solutions. For STT, unsafe speculative instructions are allowed to continue their execution when the youngest tainted root of the instructions reaches a visibility point, where there are the oldest unsafe speculative instructions. In addition to the delay for computing the instruction's tainted root and traversing the ROB, there is also a delay caused by the fact that the visibility point could be updated only when the related instruction is committed. For SEE-RV, it uses the point-of-no-return pointer in the ROB to track the oldest unsafe speculative instruction. This approach helps avoid the delay for computing the instruction's tainted root. However, it causes the instructions to be delayed until all older speculative instructions become safe. This delay only occurs for the instructions in unresolved control flow in SpecLFB. Furthermore, during the waiting period for SpecLFB to update the ROB unsafe mask, the MSHR can simultaneously request data of MUSLs from the lower-level caches. As soon as the protection is disabled, the requested data can be refilled directly from the LFB into the L1D cache instead of the lower-level caches or memory, and thus without causing too much delay. In the case of a processor validating incorrect speculation, the relevant instructions have been squashed from the pipeline, and the relevant data in LFB will become invalid before changing the state of the L1D cache. The processing of these data only needs to follow the original rollback mechanism of processors.

6.3 SpecLFB Security Analysis

SpecLFB keeps track of speculative loads through ROB unsafe masks. Initially, all speculative loads are marked as unsafe because their correctness is not yet verified. The ROB unsafe mask ensures that speculative loads are considered safe only when specific conditions are met (e.g., control flow resolution, memory access order resolved, exception handling completed), which is thoroughly determined based on the processor's speculation sources (cf. Section 5) and the working principle of microarchitecture. The ROB unsafe masks currently designed do not consider MUSLs in VP, making the tracking of unsafe speculative loads accurate only on processors without VP implementation. For processors that implement VP, the related update rules of ROB unsafe masks need to be set in accordance with their specific implementation.

Take Spectre attack based on evict+reload as an example. Figure 9 shows how SpecLFB blocks the establishment of cache side channels, where each lattice denotes a cache line.

- In phase one, the attacker first evicts the specified cache lines from the cache.
- In phase two, the victim runs the program under the conditions created by the attacker. For example, in Spectre v1 and v2, the attacker mistrains the branch predictor to speculate along a wrong path, thereby triggering a transient execution. The cache lines represented by the yellow lattices that have already been evicted in phase one but need to be accessed during the transient execution will be reloaded into the cache in phase three. However, in the processors that adopt the SpecLFB scheme, these cache lines represented by the red lattices will be regarded as data loaded by MUSLs. During the transient execution period (i.e., waiting for the processor to verify speculation), these cache lines cannot pass through the security check to be refilled into the cache.
- In phase three, the attacker probes the time it takes to execute a read at the memory address corresponding to the cache line evicted in phase one. The cache lines that have been accessed by the victim in phase two are reloaded into the cache, resulting in a significantly shorter access time for the corresponding yellow lattices than the cache lines that are not in the cache (represented by the white lattices). In the processors that adopt the SpecLFB scheme, the cache lines that have been accessed by the victim in phase two are not refilled into the cache. This makes it impossible for the attacker to determine which cache lines have been accessed by measuring the access

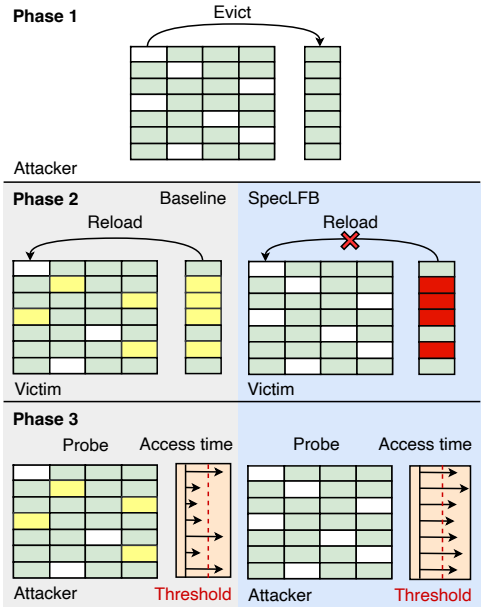

Figure 9: The process of Evict+Reload attacks in Baseline and SpecLFB. The red lattices represent the cache lines accessed by the victim speculatively. For more details of the figure please refer to Figure 4.

time, thus preventing the leakage of sensitive data.

7 Experimental Setup

We use Chipyard v1.8.0 to generate RTL for each of the three SonicBOOM-based processors shown in Table 1, and then run the simulations through Verilator v4.210. The original SonicBOOM is selected as the unsafe baseline. For the comparison in this paper, we have also implemented SSE-RV [39] in the latest SonicBOOM[1]. As introduced in Section 10, SSE-RV is a hardware-level taint tracking protection mechanism that improves upon STT [57]. Similar to our approach, it prevents the propagation of sensitive data by delaying speculative instructions. Then by running Vivado, a Xilinx software suite for hardware design synthesis and analysis, the three SonicBOOM cores have been successfully synthesized with their hardware resource overheads obtained.

Besides, to achieve a more realistic evaluation in terms of processor performance, we have built a hardware prototype based on Xilinx EK-KC-705 FPGA [2] platform (with a clock frequency of 50MHz) burned with the above three SonicBOOM cores. The prototype framework is shown in Figure 10. The common parameters of the three SonicBOOMs are shown in Table 2. Then a Linux-kernel-based operating system, Debian, is booted in the prototype, based on which SPEC2017 has been run for a comprehensive evaluation of the three processors' performance.

Due to the fact that SonicBOOM's L2 cache uses an open-source simple cache component which is beyond the scope of the SonicBOOM core that we can modify, we evaluate the performance of SpecLFB applied in all cache levels based on the SpecLFB's Gem5 [38] implementation, where SpecLFB is applied to both levels of the cache in the O3 CPU model in Gem5. Additionally, we compare the performance of SpecLFB to the state-of-the-art defense, STT [57], which was also implemented in Gem5. Table 1 provides the configurations of the simulated processors in Gem5, and the parameter settings for each component of Gem5 are detailed in Table 2.

To evaluate the effectiveness of the proposed defense scheme, we cross-compile proof-of-concept (PoC) programs of Spectre attacks both for the RISC-V instruction set architecture (ISA), including Spectre v1, v2, v4, and v5, and the X86 ISA, including Spectre v1 and v4. The programs of the RISC-V ISA have been run in both the Chipyard simulator and the FPGA hardware prototype, while the programs of the X86 ISA have been run in Gem5 simulator.

[1]SSE-RV was originally implemented in an earlier version of SonicBOOM, which has some differences in handling 32-bit instructions and cannot be adapted to Chipyard v1.8.0.

Table 1: Processor configurations.

Processor	SonicBOOM Configurations	Gem5 Configurations
Baseline	Original SonicBOOM	Original O3 CPU

8 Evaluation

8.1 Attack Replication

To replicate the Spectre attacks introduced in Section 3.2, we adopt the Flush+Reload [55] and Evict+Reload [34] techniques to establish a cache side channel in X86 and RISC-V cores, respectively. In a practical attack scenario, the attacker can treat the content of any memory address they want to attack as an address which is essentially a numerical value in their own process, and actively access it in the code. Specifically, we construct a 256-element array (i.e., `array2` introduced in Section 3.2) in the attacker's code (since only one byte can be exploited at a time, with a value between 0 and 255). Then a corresponding array element is loaded into the L1D cache based on the value of the content at the attack address. For example, if the value of the content at the address is 0, the attack code will load the first element of the array into the Dcache. In this way, by detecting which element of the array is in the Dcache, the value of the content at the attack address can be determined.

Loading memory data into cache is relatively straightforward, but it is not as easy for cache evict operations in the

RISC-V as in the x86 ISA, since the current RISC-V ISA does not provide any instruction for achieving direct flush operations of cache lines like the `clflush` instruction in the x86 ISA. Therefore, we achieve an L1D cache evicting operation at a specified cache address by loading dummy data into the target location in the L1D cache to cover the original content, which is based on the working principle of Evict+Reload, for the replication of the attacks in RISC-V core.

8.2 SpecLFB Security Evaluation

Since Spectre v1 and v4 are associated with the MUSLs in unresolved control flow and those in unresolved memory access order, respectively, we choose them as two representative attacks to evaluate SpecLFB Security. Figure 11 shows the attacker's access latency of the elements in `array2` of Spectre v1 and v4 (cf. Section 3.2) during the third phase of the side-channel attack. Based on the measurement of the access latency taken for accessing data upon cache hits and cache misses, we set the latency threshold to 50 cycles for SonicBOOM in Chipyard and 80 cycles for the O3 CPU model in Gem5. After triggering a transient execution in the victim, the attacker probes the elements of `array2` and reports the access latency. As shown in Figure 11, for Baseline, only the accesses to the element of `array2` corresponding to the secret character hit in the cache with a time less than 50 cycles, while all the other accesses to the elements of `array2` cause cache misses; therefore, the attacker is able to obtain the secret character. In contrast, for SpecLFB, the access latency of the elements in `array2` is evenly distributed, without significant differences that fall below the threshold, as SpecLFB does not allow the data loaded by MUSLs to change the cache state until it is validated by the processor. After the speculation has been validated as incorrect, the element of `array2` corresponding to the secret character in LFB becomes invalid without being reloaded into the cache. Therefore, the attacker is unable to obtain the secret data.

A successful attack is defined as leaking one character during a PoC program run. In both Chipyard and Gem5, we run each of the evaluated attacks 100 times. The length of the secret string randomly generated exceeds 100 characters at each run. In the processors without any defense mechanism, the success rate of leaking the secret value is 100%. With our defense mechanism, the success rates in Chipyard and Gem5 drop to below 0.01% and to 0, respectively. Due to the software noise, three secret characters are detected by chance out of 40,000 attack attempts in Chipyard. Also for the FPGA hardware prototypes, all four attacks work successfully in the original SonicBOOM but fail to work in the SonicBOOM enhanced with SpecLFB. In summary, our mechanism provides strong and effective protection against these attacks.

8.3 Performance Evaluation

We run SPEC2017 in the FPGA-based hardware prototype and Gem5 to evaluate our mechanism. In the FPGA-based hardware prototype, performance overhead for a processor

running a workload is defined as the workload's execution time normalized to that of the Baseline (as shown in Table 1), while in Gem5, it is defined as the IPC (Instructions per Clock Cycle) of the workload normalized to that of the Baseline. Figure 12 and Figure 13 show the comparison of the performance overhead between SpecLFB and SSE-RV/STT both running the selected workloads contained in SPEC2017, where the last pair of bars "GEOMEAN" in the figures shows their average performance overhead over all the executed programs.

Evaluation based on Hardware prototype. As shown in Figure 12, the average overhead of SpecLFB and SSE-RV is 1.85% and 4.8%, respectively. Compared to SSE-RV, SpecLFB has the advantage that only the instructions generating MUSLs will be delayed during the L1D cache refill stage. For the instructions becoming safe, SpecLFB can release its protection at an earlier point and the data related to the delayed instructions has already been in the LFB, which allows the delayed instructions to access the data more quickly when they continue to be executed. Therefore, for the programs with limited cache capacity demands, such as "imagick" and "parest", which can be executed well without regular accesses to the memory [23] resulting in few cache misses, the corresponding performance overhead of SpecLFB is much smaller. In contrast, SSE-RV incurs a larger performance overhead for the programs with a large number of memory access operations, such as "parest".

Evaluation based on Gem5. We compare the IPC performance of SpecLFB with that of STT in two protection modes, i.e., STT-Spectre (STT-*Sp*) and STT-Furistic (STT-*Fu*). As shown in Figure 13, STT-*Sp*, which aims to defend against Spectre-type attacks, incurs an average overhead of 7.36%. However, as indicated in Table 3, STT-*Sp* only considers control-flow prediction, while STT-*Fu* considers all speculative sources, resulting in a significantly higher average overhead of 26.82%. In contrast, when considering more speculative sources compared to STT-*Sp*, SpecLFB introduces only a 3.20% average overhead. The reason for such an overhead difference is similar to SSE-RV. On one hand, STT conservatively delays all unsafe speculative loads, whereas SpecLFB only delays those that cause cache misses. On the other hand, the relatively complex tracking logic and visibility point of STT cause more delays, which further delay the execution of unsafe speculative instructions. Additionally, SpecLFB allows the delayed instructions to access data earlier after the protection is disabled. However, it cannot be denied that SpecLFB achieves some performance improvements compared with STT and SEE-RV by narrowing down the defense scope. For protected speculative loads, SpecLFB specifically protects speculative loads causing cache misses, while STT-*Sp* and STT-*Fu*, as well as SEE-RV also consider speculative loads causing cache hits. For blocked covert channels, SpecLFB specifically blocks covert channels through cache, while STT-*Fu* is able to block any covert channel.

FPGA resources utilization. Based on the same core parameter configurations, SoC bus, and peripheral devices, we synthesize the resources usage of the three processors using Vivado 2021.2 based on the FPGA hardware prototype. As shown in Table 4, SpecLFB only adds less than 1% of resources compared to the baseline, and consumes fewer resources than SSE-RV, especially in terms of LUTs (Look-Up-Tables) and FFs (Flip-Flops). LUTs are primarily used to implement logic circuit functionality, and FFs are sequential logic elements used for storing and transferring binary data in digital circuits on FPGAs. The high LUT utilization of SSE-RV is mainly due to the additional logic in the taint initialization and propagation stages, which is more complex than the security mechanism of SpecLFB. The high FF utilization is due to the taint file, propagation queue, and intermediate registers, while SpecLFB only adds intermediate registers related to the ROB unsafe mask. Therefore, SpecLFB provides a lower additional hardware resource overhead while addressing security issues. The recent transient execution attack defense work ProSpeCT [13] also implements its defense hardware prototype on the open-source OoO RISC-V processor Proteus [8] and deploys it in FPGA for resource evaluation. As shown in Table 4, when the size of BOOM and Proteus are quite different, SpecLFB has advantages in terms of both the absolute number and relative proportion of additional resource overhead. ProSpeCT is proposed as a universal secure speculative processor model encompassing the security semantics of all current speculative mechanisms. The ProSpeCT model is implemented as a Proteus plugin, with some additional modifications in the base processor. Such plugin implementation cannot constrain resource overhead tailored to the specific processor implementation, which causes the hardware resource overhead to be large and sensitive to the specific implementation of the processor and the processor size. SpecLFB only adds specified logic to the micro-architecture already existing in the processor, and thus has obvious resource overhead advantages.

Table 3: Comparison of STT [57], SpecLFB and SSE-RV [39].

SpecLFB	3.20%		✗	✓	✓	✓
	1.85%	RTL-FPGA				
SEE-RV	4.8%		✗	✓	✓	✗

9 Limitations and Discussions

Speculative accesses resulting in cache hits. SpecLFB defends against speculative cache side-channel attacks by preventing cache lines speculatively loaded by the victim under

Table 4: FPGA resources utilization.

Scheme	Core	Device	LUTs	FFs
Baseline	SonicBOOM	Xc7a325T	169,463	93,994
SSE-RV	SonicBOOM	Xc7a325T	172,538 (+1.81%)	94,567 (+0.61%)
SpecLFB	SonicBOOM	Xc7a325T	170,765 (+0.77%)	94,283 (+0.31%)
Baseline	Proteus-O3	Xc7a35T	16,847	11,913
ProSpeCT	Proteus-O3	Xc7a35T	19,728 (+17.1%)	12,600 (+5.8%)

cache misses from being refilled into the cache. However, we cannot ignore the threat of speculative cache side-channel attacks where attackers may not need to evict the cache lines they want to leak in the first phase. This could lead to cache hits rather than cache misses when the victim executes speculative loads. For example, Xiong et al. [50] proposed a cache side-channel attack based on Least-Recently-Used (LRU) strategy, which does not require pre-evicting cache lines to be leaked. In its first phase, the attacker brings cache lines they want to monitor into the cache. In the second phase, the victim performs speculative accesses, leading to cache hits. In the third phase, the attacker needs to access a cache line that is not in the cache. The least-recently-accessed cache line is replaced based on the LRU strategy. Finally, the attacker determines whether the victim has speculatively loaded the monitored cache line based on whether it has been replaced.

Leakage through speculative loads under cache hits is out of the current defense scope of SpecLFB. However, we do not consider it a limitation of using LFB to ensure speculative execution security, as LFB can still be utilized to defend against such attacks. Since attackers need to manipulate the cache state, which often involves cache eviction and replacement, to directly or indirectly leak the speculative data, cache misses are inevitable in speculative cache side-channel attacks. For example, the third phase of the attack in [50] requires accessing a cache line that is not previously in the cache, triggering a cache replacement. Therefore, as long as the LFB can identify the loads that are exploited by the attacker to manipulate cache states, regardless of whether these loads are speculative or not, further defensive measures can be taken. Specifically, to defend against the attack described in [50], the cache entries where the cache lines accessed by unsafe speculative load instructions reside will be marked in the second phase. This marking needs to be removed when unsafe speculative loads become safe. The unsafe speculative load instructions can still be traced using SpecLFB's ROB unsafe mask. In such attack scenario, cache manipulation from the attacker does not have to happen speculatively, so interception cannot follow SpecLFB. Therefore, in the refill process of the third phase, if the unsafe speculative load has completed execution without causing a cache miss, the cache lines in the marked cache entries will be replaced through LFB with the highest priority and the marking will be removed. Otherwise, the logic used by SpecLFB to intercept speculative loads that cause cache misses will be reused. As a result, the original refill purely according to LRU in the third phase of the attack will be prevented. To the best of our knowledge, in Gem5 and SonicBOOM, LFB can specify the location in the cache where cache lines are refilled. For the speculative loads that become safe, the cache lines they accessed may be replaced from the cache by this solution, potentially affecting the memory access latency of dependent instructions. Additionally, because LFB cannot intercept the data loaded by speculative instructions under cache hits, it does not prevent speculative changes to cache metadata. Instead, it prevents attackers from detecting such changes, such as the third phase of the attack described in [50]. This solution prevents attackers from changing the cache occupancy state during the probe phase, such as eviction and replacement, making it more challenging for them to carry out such attacks.

Other speculative side channels. Besides cache side channels, there are other speculative side channels, such as TLB [20], FPU [18], port contention [7], etc., also posing a threat to processors in high-security scenarios. There have been defense mechanisms [37, 57] comprehensively considering all speculative sources, which prevent speculative results from leaving the CPU core and leaking into side channels. However, since they provide aggressive protection against all side channels, their significant performance overhead makes them unsuitable for being deployed in real-world processors. Although the cache is not dedicated to speculative side-channel attacks, it remains the most practical method of data exfiltration and is an example attack in Spectre [30]. SpecLFB restricts defense scope only to cache-based attacks to achieve a trade-off between performance overhead and defense scope. Besides SpecLFB, we will consider using other existing microarchitectures of CPU in future work to specifically prevent secrets from being leaked through other side channels, thereby achieving more defense capabilities of the system.

Limitations of the implementation and experimental verification. First, we currently do not have a practical implementation of SpecLFB that considers the speculation source VP. However, it is possible to be implemented in the processor where VP has been specifically supported. In such a processor, the SpecLFB' ROB unsafe mask could be set based on the elaboration of MUSLs in an unresolved value and the working principle of VP in the processor to provide protection, which we leave as a future work. Second, due to the specific defense scope of SpecLFB, we have not directly compared it with the solutions that have entirely the same defense scope in performance evaluation. Third, due to the cache constraints imposed by SonicBOOM, we further utilize Gem5 rather than RTL to evaluate the performance impact of SpecLFB when applied to all cache levels. As the RTL-FPGA based evaluation is obviously more accurate, which is also strong evidence of the practicality of SpecLFB in the real world, we also leave it as a future work to implement the SpecLFB applied to all cache levels in hardware prototype.

10 Related work

Existing mechanisms for mitigating speculative cache side-channel attacks can be classified into four types as shown below in detail, including 1) limiting the execution of speculative instructions, 2) making the results of unsafe speculative executions invisible to the microarchitectural state, 3) delaying the executions of unsafe speculative instructions, and 4) reducing the accuracy of the covert channel.

Limiting the execution of speculative instructions. Intel and AMD recommend using serialization instructions, e.g., `lfence`, in a branch [25, 48]. ARM introduces a full data synchronization barrier and instruction synchronization barrier that can be used to prevent speculation [5]. However, serializing every branch would be equivalent to disabling branch speculation entirely, severely degrading processor performance [25]. To counter the attackers' mistraining of speculation mechanisms, both Intel and AMD extended their ISAs with a mechanism to control indirect branches [26], but it can only target the Spectre variants based on branch poisoning. oo7 [45] is a method of statically analyzing binary programs, using taint analysis, address analysis, and modeling of speculative execution to check for potentially vulnerable code patterns. It mitigates speculative execution attacks by inserting fence instructions. Such a software mitigation relying on static analysis of a specific problem typically requires recompiling the program and has a low coverage.

Making the results of unsafe speculative executions invisible to the microarchitectural state. InvisiSpec [52] adds an SB to store the speculative data leading to security issues. If the speculation is incorrect, the data stored in SB becomes invalid. Otherwise, the speculative data will be re-installed into cache. As the access to SB does not participate in cache coherence protocols, InvisiSpec needs to reload its data for validation at the instruction committing stage, which results in significant performance overhead due to double memory access. Similarly, SafeSpec [28] stores speculated data in a fully associative shadow structure of the load/store queue, enabling recovery of any changes to the microarchitectural state, but the same data must be present multiple times in the shadow structure to prevent side-channel leakage, resulting in a high invalidation cost. MuonTrap [3] avoids double memory access by storing the result of speculative cache access in an L0 filter cache. However, the data movement caused by the re-installing operation still degrades processor performance. Therefore, CleanupSpec [40] allows the data to be installed into the cache during the speculative execution, and the replaced data is stored into a newly added data structure. The replaced data will be re-installed into the cache hierarchy to roll back the cache state only when speculation fails. ReversiSpec [49] proposes a comprehensive cache coherence protocol that takes into account speculative cache access. Compared to InvisiSpec, the SB only stores data when it is not in the cache, resulting in less data movement when a speculative load becomes safe. Overall, in comparison with the above mechanisms, SpecLFB does not require additional data structures to hide the cache lines fetched by the speculative loads or the data movement caused by the re-installing operations.

Delaying the executions of unsafe speculative instructions. Sakalis et al. [41] proposed the delay-on-Miss mechanism, which aims to delay the execution of speculated loads rather than hide the side effects of those speculative loads that have already been executed. Then they adopted a value predictor to improve the mechanism, which predicts the value of L1 cache misses to continue the speculations rather than delaying them, further improving performance in cases of low prediction success rates. However, the predictor also causes significant hardware overhead. STT [57] proposes a taint tracking technique, which marks physical registers to track the transient execution flow after a speculative memory access. Both NDA [47] and STT use data flow tracking similar to taint propagation to track instructions that may cause information leakage. These instructions are forced to be delayed until their related instructions become safe. SDO [56] added a safe VP mechanism based on STT to reduce overhead caused by the delay and tracking analysis. SSE-RV [39], based on STT, uses existing ROB pointers in SonicBOOM to track speculated instructions, simplifying the tracking analysis logic. However, it still requires a large taint file as a shadow structure for the PRF to implement tainting, and unnecessary instructions may still be incorrectly identified as unsafe instructions, which increases the delay of execution. In contrast, SpecLFB requires a smaller range of speculated instructions to be delayed and a shorter delay for each instruction, with minimal changes to existing hardware.

Reducing the accuracy of the covert channel. Reducing the precision of cache side channels can also mitigate cache side-channel attacks. Therefore, many web browsers lower the accuracy of timers in JavaScript by adding jitter or even removing some timers. However, Schwarz et al. [42] have shown that timers can be constructed in many different ways, and it is not practical to remove all of them. Disruptive Prefetch [17] and Prefender [36] add noise to cache side channels by utilizing the content brought into the cache by data prefetchers, but they can only achieve secure enhancement without fully defending against the attacks.

11 Conclusion

This paper proposed SpecLFB, a novel mechanism for defending against speculative cache side-channel attacks. It introduces a simple yet effective security check mechanism to the LFB, delaying the execution of unsafe speculative loads and preventing sensitive data leakage through cache side channels. To minimize the overhead of both processor performance and hardware resources, SpecLFB limits the scope of unsafe speculative loads that need to be delayed to MUSLs, which denotes unsafe speculative loads that cause cache misses. In

addition, SpecLFB transforms them into safe loads and continues their execution as early as possible through the LFB unsafe security check mechanism based on the ROB unsafe mask we designed. We have implemented SpecLFB both in SonicBOOM and Gem5 O3 processor. Based on the evaluations through RTL simulation, FPGA hardware prototype experiment, and Gem5 simulation, SpecLFB has been shown to effectively block the establishment of cache side channels in Spectre attacks. It leads to a hardware resource overhead of only 0.6% and the performance overhead of just 1.85% in the FPGA hardware prototype experiment and 3.20% in the Gem5 simulation.

Towards Privacy-Preserving Social-Media SDKs on Android

Abstract

Integration of third-party SDKs are essential in the development of mobile apps. However, the rise of in-app privacy threat against mobile SDKs — called cross-library data harvesting (XLDH), targets social media/platform SDKs (called *social SDKs*) that handles rich user data. Given the widespread integration of *social SDKs* in mobile apps, XLDH presents a significant privacy risk, as well as raising pressing concerns regarding legal compliance for app developers, social media/platform stakeholders, and policymakers. The emerging XLDH threat, coupled with the increasing demand for privacy and compliance in line with societal expectations, introduces unique challenges that cannot be addressed by existing protection methods against privacy threats or malicious code on mobile platforms. In response to the XLDH threats, in our study, we generalize and define the concept of privacy-preserving *social SDKs* and their in-app usage, characterize fundamental challenges for combating the XLDH threat and ensuring privacy in design and utilization of *social SDKs*. We introduce a practical, clean-slate design and end-to-end systems, called *PESP*, to facilitate privacy-preserving *social SDKs*. Our thorough evaluation demonstrates its satisfactory effectiveness, performance overhead and practicability for widespread adoption.

1 Introduction

The integration of third-party software development kits (SDKs), also known as libraries, third-party libraries or TPLs, has been now essential in the mobile app development lifecycle, enhancing app functionalities (e.g., login through Facebook/Google/Twitter single-sign on, advertising, app monetization, and analytics). Recent research [64] and news reports [2, 6, 39, 52] have highlighted a concerning threat where in-app SDKs have become victims of serious privacy breaches. These incidents involve malicious data-harvesting libraries within mobile apps that extensively steal user data from other SDKs present in the same app (e.g., by calling the latter's functions and obtaining the return data, or by directly accessing their data storage, see § 2). This phenomenon, called cross library data harvesting (*XLDH*) attacks, represents a significant threat to user privacy. Prior work [64] have identified 42 *XLDH* libraries across more than 19,000 Google Play apps, cumulatively downloaded nine billion times. The type of data harvested is highly sensitive and diverse, including user ID, credentials such as Facebook access tokens, birthday, photos, genders, page likes, and friend lists. A notable example is *OneAudience*, a library integrated in 1,738 apps with over 100 million downloads, which was discovered collecting users' private data from Facebook and Twitter SDKs. In response, Facebook and Twitter initiated legal actions to take down `OneAudience` (see the lawsuit [36, 47] and media report [39, 52])

Given the rising privacy concerns of *XLDH* targeting mobile SDKs, SDKs that manage or provide user data emerge as prime targets. Among these, social-media SDKs (*social SDK*), associated with social networks and platforms, stand out, compared to other common SDKs like ad networks and analytics, which primarily collect rather than offer data. Notably, *social SDKs* are exceedingly prevalent in mobile applications; for instance, Facebook and Twitter SDKs are found in 17.82% and 1.47% of Google Play apps, respectively. This widespread integration makes them particularly appealing to *XLDH* attacks, underscoring the urgent need for robust privacy protection mechanisms to safeguard user data against such vulnerabilities.

In addition to endangering mobile users in the wild, *XLDH* has a pressing impact on legal compliance, causing serious concerns for both app developers and social media stakeholders. With *XLDH*, the data practices of in-app malicious libraries (collecting/exfiltrating data from *social SDK*) are generally *opaque* to the app vendor. However, laws (e.g., GDPR and CCPA) and public policies (e.g., term-of-service policy of Google Play app store and Apple app store [31]) all mandate/assume that app vendors should conspicuously disclose (using a privacy policy) all data practices (e.g., collection, sharing) occurring in the app, including those performed by

third-party libraries. The violation of privacy laws/regulations have caused billions of dollars of penalty by the Federal Trade Commission (FTC) [42] against the app vendors, often leaving the third-party code modules — the real culprit — hardly accountable/liable. Moreover, the *XLDH* related attacks have been seriously endangering user trust on mainstream social platforms, mobile platforms, and technology supply chain (e.g., Android, iOS with their supply chain). With significance of the emerging *XLDH* problems, it is imperative to come up with new technical design to fundamentally eliminate or control in-app and cross-library data access channels. The goal is to achieve privacy-preserving mobile SDKs.

Challenges to defeat *XLDH* and protect *social SDK*s. The emerging threat of *XLDH* against *social SDK*s and the call for privacy/compliance guarantee to keep up with citizen expectation and social norms impose specific new challenges, which preclude direct application of prior techniques against privacy threats or malicious code on mobile platforms. As shown by the prior work [64], the *XLDH* attacks may be performed by *TPL*s of diverse functionality categories, such as analytics, marketing, ads, app maker [1], geofencing [4], etc. From the defenders' perspective, accurately predicting the specific type of libraries responsible for *XLDH* is difficult. To protect *social SDKs*, isolating all untrusted *TPL*s may not be practical, which can significantly break or change current programming paradigm, app design and runtime performance for how an app invokes or interacts with its many *TPL*s (see detailed discussion in § 4.1). Instead of sandboxing potentially all TPLs that are untrusted, we consider that a more practical solution is to sandbox the *social SDK* and protect their data. Notably, prior privacy enhancing and library-isolation techniques [46, 48, 50, 51, 56–58, 63, 66, 71], including the ongoing efforts of Privacy Sandbox on Android (PSoA) [30] suffer from several key problems for effectively or practically defeating *XLDH* (see below).

We note that even PSoA, in its current state, has different protection goals and threat model from *XLDH*, and cannot address *XLDH*. PSoA currently focuses on and only supports advertising-related library (called ads libraries in this paper) by restricting advertising-related library into a separate process — called privacy sandbox. The sandbox environment does not inherit the host app's permissions and thus prevents the ads libraries from getting persistent identifiers from the underlying system (e.g., AdSplit [57]). At the design level, PSoA does not address *XLDH* or support *social SDK* for a few key reasons. First, PSoA cannot impose *social SDK* into a privacy sandbox while still supporting their common functionalities used by the apps. Unlike ads libraries which usually come with limited interactions with the host app (thus one can safely and easily isolate them), *social SDKs* come with sophisticated data flows and functionality-level interactions with the rest of the app, such as (1) single sign-on, e.g., login through Facebook, Google, Twitter, and Amazon, and (2) in-app posting to social networks, such as sending tweets or posting/sharing to Facebook (see a detailed survey of use cases at § 3.2). The PSoA even assumes that the app should not impact or interact with SDK behaviors such as contents or operations of the SDK UI display (to protect ads display integrity and promote anti-fraud) [13], which contradicts with designed use cases of social SDKs (see comparison at § 4.3). Second, PSoA and prior other techniques [54] come with no design-level privacy guarantee. Specifically, they could not mandate that data from *social SDK* be mediated from access by other libraries or never flows to the host-app. Once a private data flows into untrusted code space (i.e., the host app with untrusted libraries), it becomes intractable (e.g., due to hidden or asynchronous data flows [35], indirect calls [59] being hard to fully resolve through state-of-the-art static and dynamic analysis techniques [70]), being completely subject to *XLDH*. Although prior techniques [46, 48, 50, 51, 56–58, 63, 71] also attempted to completely isolate ads libraries from the rest of the app, similar to PSoA, this is not an option for *social SDK*, which requires more sophisticated interactions and data flows with the host app (see detailed comparison with related techniques in § 4.3).

Design for privacy-preserving *social SDK*s. We tackle the above challenges and take the first step to address the *XLDH* at design level under the context of *social SDK*s. We introduce the *privacy-preserving social SDK paradigm* (*PESP*), a clean-slate, privacy-preserving design for *social SDK* and their usage in mobile apps (§ 3.2), nevertheless our design is mostly general and can be extended to other categories of SDKs. Specifically, we aim to fundamentally address the data harvesting against/between libraries (*XLDH*) through clean-slate design of *social SDK* and deployable, end-to-end, open-source system implementation, while best preserve expected functionalities of *social SDK*s. With a principled approach, first, we propose and generalize three new, essential properties for the design of *social SDK*s (by their vendors such as Facebook, Twitter, Google) and their in-app operation (by regular apps that adopt them), called privacy-preserving SDK or *PPS* properties (§ 3): deterministic data collectors (DDC), controllable data collectors (CDC), and auditable data collectors (ADC). Further, although we envision the next generation of *social SDK*s to be privacy-preserving fulfilling the properties, we also ensure that our design is backward compatible by supporting current use cases expected by social media/platform providers and implemented by app developers, based on a comprehensive survey in the wild (§ 3.2).

In our design, we identify, characterize and tackle key design challenges for *privacy-preserving* SDKs and combating *XLDH*, in particular the dilemma between complete isolation (i.e., no data flows out of the *social SDK*) and the functionality-necessary data flows and interactions between the SDK and the rest of the app (with untrusted libraries). Once a data flows into untrusted/app code, we lose privacy guarantee (see § 4). To fundamentally address the problem, we base our design on rigorous isolation between *social SDK* and the app/untrusted

code (quarantining private data inside *social SDK*). Despite the isolation, we propose a novel SDK design that effectively enables all expected/current functionalities/workflows of *social SDK* in mobile apps (e.g., mobile apps can still conveniently support user/GUI interactions based on data from the *social SDK*), while fulfilling *PPS* properties for the first time.

End-to-end system implementation and evaluation. We fully implemented our design of *privacy-preserving social SDK* on the recent Android (version 13, r16), and evaluated our implementation for its effectiveness (fulfilling all *PPS* properties and defeating *XLDH*), compatibility with all current use cases of *social SDK*s, and performance overhead with satisfactory results (§ 5). In our implementation, we made no changes to the OS. We implemented a *privacy-preserving* Facebook SDK and Twitter SDK (by easily wrapping the current Facebook SDK v15.0.1 and Twitter SDK v3.3.0 into our design) and used them with two demo apps released by Facebook and Twitter respectively, fulfilling all expected/current use cases of the SDKs and the *PPS* properties.

Applicability and relation with the official Privacy Sandbox on Android. Our design and implementation did not rely on the PSoA, evidenced by our full implementation on Android version 13 (r16) without PSoA. Nevertheless, since PSoA (currently only supporting ads libraries without breaking) is requesting feedback from the community, our design is compatible with PSoA and expected to be easily pluggable to PSoA to substantially enhance its privacy assurance.

Contributions. The contributions are summarized as follows.

• *New understanding and principles for privacy preserving social-SDKs*. We characterize fundamental challenges in the system design level for combating the emerging privacy threat against mobile SDKs (*XLDH*). We generalize privacy-preserving properties for the design of and operational practice with *social SDK* in mobile apps.

• *New techniques to achieve privacy-preserving design and (in-app) usage of social SDKs*. We present a practical, novel, clean-slate design and end-to-end systems to fundamentally enhance privacy of *social SDK* and their in-app usage against the emerging *XLDH*, enabling their *privacy-preserving* properties. Our techniques are practical, implemented and evaluated, pluggable to the state of the art system (e.g., PSoA). Our techniques are expected to significantly elevate privacy assurance and legal-compliance for users and stakeholders of social media/platforms, and app developers.

2 Background

Emerging privacy attacks between in-app libraries. Figure 1 illustrates a data-harvesting library (in a mobile app), which first checks the presence of the Facebook, Twitter and Google SDKs in the same app, and, if the SDKs exist, it invokes the API functions in those SDKs to acquire the user's Facebook/Twitter/Google access token, profile, groups, favorites, etc. *Notably, cross-library data harvesting (XLDH) in mobile apps can occur through multiple attack vectors besides direct function calls between libraries (and this paper aims at fundamentally eliminating all XLDH attacks).* For example, we found that the Facebook SDK maintains app users' Facebook identifiers and other personal data in a local JSON file, which can be easily accessed by any libraries in the same app, presenting a general problem on both Android and iOS. Essentially, as mentioned earlier, it is hard for the operating system to impose complete isolation between each individual library which will seriously break current functionalities and introduce intolerable programming/performance overhead. Actually, in modern software development, libraries normally invoke functions of other libraries (see the principle of modularization for software development [49], which each library fulfills an independent functionality/task) and hence it is unnatural to completely isolate each individual library (e.g., one may no longer call another conveniently and efficiently).

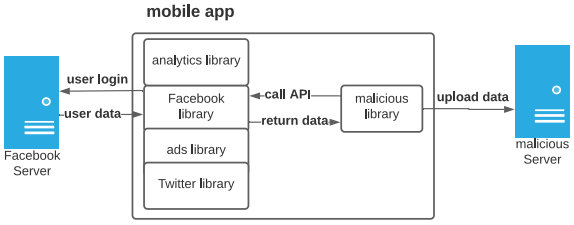

Figure 1: A Cross-Library Data Harvesting attack (XLDH)

Threat model. We consider that third-party libraries (*TPL*s) in mobile apps may intend to harvest user data from other libraries in the same app, particularly from *social SDK*, without awareness/consent of the app developers, users or the *social SDK* vendor. Although *social SDK*s may also collect user data from the app or from the underlying OS, this paper focuses on threats (*XLDH*) where *social SDK*s are the targets/victims of data harvesting. We consider that the *social SDK* vendors intend to defeat *XLDH* against them, which can be a means to improve user trust or at least mitigating possible trends of deteriorated user trust. In this regard, we consider the *social SDK* is benign. Since *XLDH* is often opaque to app developers leading to their privacy noncompliance based on current laws, we consider that app developers intend to prevent opaque data collection behaviors in their apps such as *XLDH*.

3 Goals and Definition for Privacy-Preserving Social-Media SDK

Current software engineering practices and underlying mobile systems provide low assurance for the traceability of user data, not to mention control who has access, especially in an era full of data brokers and data-harvesting sprees. To fundamentally address the data harvesting against/between libraries (*XLDH*), we propose and generalize three simple but essential properties for the design and in-app operation of *social SDK*, called *privacy-preserving SDK* (PPS) properties.

Under the context of *XLDH*, a *social SDK* that fulfills the properties is entitled *privacy-preserving* SDK.

We summarize the *PPS* properties in § 3.1. Further, although we envision the next generation of *social SDK*s and apps to be privacy-preserving fulfilling the properties, for convenient adoption and migration, we aim that a practical design should be backward compatible by supporting current use cases expected by mainstream social media and platform providers (§ 3.2).

3.1 Properties for Privacy-Preserving SDKs

PPS property 1: deterministic data collectors (DDC). Compared to *XLDH* attacks in which it is opaque or hardly known which party in an app (e.g., a library provided by a certain data-broker, ads network, analytic platform or any third-party) collects user data from the target SDK, the *DDC property* requires that any party that collects data from the SDK is deterministic.

PPS property 2: controllable data collectors (CDC). Compared to *XLDH* attacks in which the SDK provider and the app developers have little or no control regarding which party in the app is allowed to collect data from the SDK, the *CDC property* requires the SDK design to enable the app developers and SDK owners to fully control which party can collect data from the SDK. Note that based on the current laws (GDPR, CCPA, etc.) and public policies, app developers that failed to disclose data collection by third-parties in *XLDH* are liable for the privacy noncompliance, and SDK owners such as Facebook tend to be considered liable for failing to fully control user data it maintains [3].

PPS property 3: fine-grained, publicly auditable data collectors (ADC). In prior *XLDH* attacks and other privacy issues (e.g., partial, inaccurate or inconsistent privacy policies [14, 15]), key challenges remain for privacy compliance and audit: (1) the parties that actually collect user data are undisclosed or not fully disclosed to the users; (2) the disclosure granularity is too coarse-grained for effective audit (e.g., GDPR); (3) the disclosure format (i.e., usually being natural languages in privacy policies) is difficult for automatic machine audit. To fundamentally address the problems under the context of *XLDH*, the *ADC property* requires that (1) the list of parties that collect user data from the SDK is publicly auditable, i.e., being available/disclosed to normal users, app/SDK developers and policymakers, and easily readable by human and interpretable by machines, (2) the disclosure is at specific-data level with respect to specific data collectors

Consider two real examples in our study: in the app `com.fairytale.fortune`, the *XLDH* library `com.umeng.socialize` collects Twitter `User ID/E-mail` from the Twitter SDK and sends it to `http://plbslog.umeng.com`; in another app `com.africasunrise.skinseed`, the *XLDH* library `com.revmob` collects Facebook users' `AccessToken` from the Facebook SDK and sends it to `https://android.revmob.com`. In these cases, the *ADC property* requires the (app-specific) disclosure to be as fine-grained as a mapping from the data to all data collectors:

$$\begin{cases} \textit{Twitter user ID/email} \mapsto \textit{domain plbslog.umeng.com} \\ \textit{Facebook access token} \mapsto \textit{android.revmob.com} \end{cases}$$

Notably, with the *CDC property*, the above disclosure is determined by the app developers and SDK vendors and thus practical (see the design that fulfills all *PPS* properties in § 4).

Table 1: Use Case Stats

Social Media Provider	# of use cases	# number of type I workflow	# number of type II workflow
Google Play Game Services	19	12	19
Twitter Kit	13	9	13
Vkontakte	16	11	16
Kakao	19	8	19
Snap login, bitmoji kit	9	9	9
Tiktok	18	8	18
Wechat	20	17	20
Alipay	14	12	14
Weibo	20	12	20
Facebook	13	13	13

3.2 Backward Compatibility for Privacy-Preserving Social-SDK Design

As mentioned earlier, a key challenge for designing privacy-preserving SDK systems is that, prior/strict isolation techniques [30, 46, 48, 50, 51, 56–58, 63, 71] do not restrict between-library data access and easily break functionalities of *social SDK* whose major use cases feature sophisticate data flows and interactions with the rest of the app. On the other hand, allowing user data to flow out of the SDK immediately makes the data intractable — a fundamental loss of privacy guarantee. That is, to ensure the design of privacy-preserving SDK and its runtime environment fulfill the *PPS* properties without breaking current use cases of *social SDK* is a serious challenge, and we tackle this imperative problem in our study (see our design in § 4).

In this section, we report a comprehensive survey of *social SDK* use cases that are expected by 10 mainstream social platforms (e.g., Facebook, Twitter, Snap, Google Play, most popular worldwide in terms of user numbers, see Table 1), whose SDKs have been integrated into 0.01% to 17.86% of Google Play apps [7]. To comprehensively summarize their use cases, our approach includes two complementary efforts. (1) We manually inspected the developer manuals released by the social platform vendors, with a total of more than 20 MB HTML documents describing the intended usage of APIs provided by the 10 *social SDK*s (fully released online [5]). (2) We thoroughly inspected code level behaviors of 200 popular real-world apps (with a total of $100B+$ downloads [5]) that used these SDKs (20 apps for each SDK, see data collection below). Specifically, we inspected the apps at the Java and Smali code level (decompiled through the tools `Jadx` and `NinjaDroid`) and user level with end-to-end app/UI operations. This effort leverages both state-of-the-art program

analysis tool Flowdroid [32] and thorough manual efforts to inspect the code that accesses APIs of *social SDK*s and handle their data (see below).

In the manual efforts, after collecting all the 200 app samples, we have two researchers install the apps on rooted Android phones, grant all permissions asked by the apps, and manually explore and trigger all possible functionalities in the apps. We manually interacted with the app UI and pinpointed possible usages based on the service descriptions and descriptions in the app UI. During the app execution, we use Frida [41] to hook invocations of *social SDK* APIs and then manually analyze the subsequent control and data flows with respect to usage of the *social SDK*s an their data in the app. In this regard, we also adopt Flowdroid to complement manual analysis and help us more comprehensively identify control flows starting from where *social SDK* APIs are called in the apps, navigating through the code space and identify data and control flows related to how the apps use the *social SDK*s.

Based on the survey, this section below summarizes all functional use cases of *social SDK*s in the wild into two generalized types. We elaborate on our data collection, use-case survey results as follows. We released the full data set online [5] for reproducible experiments. The two researchers that perform this survey and summarize the survey results are considered co-authors of this work. This is aligned with common practices of research where intellectual contributors are acknowledged as co-authors, and their research results go through evaluation or related artifacts are released at [5] for experiment reproduction.

Data collection. We selected 10 most popular *social SDK* according to the ranking published by two app intelligence providers, i.e., AppBrain [7] and 42Matters [8]. For each SDK, we selected the 20 most popular apps based on the rankings released by the most popular app markets operating in the corresponding region of the *social SDK*s (i.e., Google Play for 7 SDKs and Huawei App Market for the other 3 SDKs from China). The full list of the 200 apps can be found in [5].

Generalization of workflow patterns for using *social SDKs* in mobile apps. Summarizing all use cases of *social SDK* expected/implemented by SDK providers and app developers, we generalize two work-flow patterns that are essential for *social SDK*s to interact with the rest of the app to fulfill expected functionalities as follows. We base our *privacy-preserving* SDK design in § 4 by fully regulating the two work-flow patterns to fulfill the above *PPS* properties, while preserving expected functionalities.

Type I workflow of *social SDK* usage in mobile apps: Once the app invokes APIs of a *social SDK*, data flow out of the *social SDK* (to the app's graphical user interface or GUI) for interactions with the user, including (1) the display of information to users, (2) letting users choose or edit the information from a *social SDK* (before sending to a remote server). High-level examples are shown in Appendix Figure 4 for more specific use cases including single-sign on (e.g., the user identifiers, names obtained from Facebook are shown in the app GUI) or posting (e.g., sharing/twitting) to a social platform or to a specific friend/group on the social platform. Before displaying the data in the app GUI, code developed by the app or third-parties may transform the data (e.g., using an image processing library to process a profile photo obtained from the social network before showing it in the app GUI). Essentially, *Type I work flow is for user interactions* on the app's user interface.

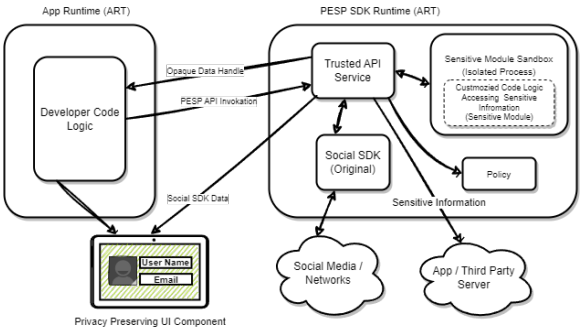

Figure 2: Design Overview of Privacy-Enhancing Social SDK

Type II workflow of *social SDK* usage in mobile apps: Once the app invokes APIs of a *social SDK*, data flow out of the *social SDK* into the app space, and eventually flow to a remote server, either the app server, the *social SDK* server, or a third-party's server (also called *Remote Host*). For example, after login with Facebook, Twitter or Google, the user's access token, email, names, etc., provided by the *social SDK* are sent to the app's sever, or sent to third-party analytics platforms and app-monetization platforms (by the app itself or third-party libraries in the app). Before sending the data out of the app, code developed by the app or third-parties may transform the data into their needed format (e.g., wrapping into a JSON or customized string). Essentially, *Type II work flow is for data sharing with a remote server* (the apps' or third-parties' servers).

4 Design for Privacy-Preserving, Social-Media SDKs

In this section, we present *privacy-preserving social SDK paradigm* (*PESP*), a clean-slate, *privacy-preserving* design for *social SDK* and their usage in mobile apps. We also provide end-to-end implementation of our design, and elaborate on how the design defeats *XLDH* and fulfills the *PPS* properties (§ 3.1) while practically enable all expected, current use cases of *social SDK* (i.e., the two generalized types of workflows in § 3.2).

4.1 Design Overview of *PESP*

As mentioned earlier, a *fundamental design challenge* for *privacy-preserving*, *social SDKs* that combat *XLDH* is the dilemma between complete isolation (i.e., no data flows out of the *social SDK*) and the necessary data flows and interactions between the SDK and the rest of the app (with third-party libraries that are untrusted). Once a data from a *social SDK* flows into untrusted code space, it is not fully tractable and we lose privacy guarantee (i.e., the data can be sent to the Internet/third-parties easily and stealthily bypassing state-of-the-art defenses including static code analysis, dynamic code analysis, traffic analysis [53]). To fundamentally address the problem, we base our design on complete isolation between *social SDKs* and the app/untrusted code (by adopting Linux UID based and process-level isolation of data, runtime, and GUI guaranteed by the operating system, see § 4.4), quarantining private user data inside a *social SDK* itself and never flowing to the untrusted/app code space. Despite complete isolation, *our key novelty includes new system design to still enable expected, sophisticated interactions between the SDK and untrusted/app code (§ 3.2), a security design goal never achieved before.*

System architecture and core components. Figure 2 outlines the core systems components under *PESP* including its isolation foundation and runtime backed by the Android OS. In an app, the *social SDK* and the rest of the app code (simply referred to as "the app", denoting all code/components of the app itself and TPLs excluding the *social SDK*) are strictly isolated (based on different Android Runtime (ART) and thus Linux UIDs, see § 4.4). Upon the app execution, the *social SDK* runs in a new Android Runtime process, called *SDK runtime*, separated from the app which runs in its original runtime (Android Runtime) provided by the Android OS.

• *App runtime*. The app code runs in the *app runtime* like a regular mobile app, except that it does not directly obtain any data from *social SDK* in the *SDK runtime*. App code in the *app runtime* invokes APIs of the *social SDK* through the exposed interface (called *trusted API service* of the *SDK runtime*, see below), and no longer directly gets the data but rather gets a data handle, called *opaque handles* with reference to the SDK data in the *SDK runtime* (here we adapt and generalize the concept of *opaque handle* [38, 44] to mobile SDKs). *PESP* ensures that necessary operations and interactions with the *social SDK* data are all performed inside the restricted *SDK runtime*, fully controlled and enforced by *SDK runtime* based on the *data-sharing policies* (see below).

• *PESP SDK runtime*. The *social SDK* runs in a separate Android Runtime process, similar to a regular service process. Essentially, the *SDK runtime* encapsulates the original *social SDK* (with zero change, see our demo and thorough evaluation of functionality and privacy on Facebook and Twitter SDKs in § 5). The invocation from the *app runtime* to the original *social SDK* functions is encapsulated as a simple IPC call to the *SDK runtime*, handled by a component called *trusted API service* (based on the Android `Service` class [23]), which relays the calls to the original *social SDK*. Once the *social SDK* returns the data, the *trusted API service* maintains the data but never returns the data to *app runtime* (to fulfill the privacy properties). The *trusted API service* instead returns a data handle (a kind of *opaque handle*) to *app runtime* or invokes related callback functions in the *app runtime*.

Despite the data quarantine in *SDK runtime*, in expected usages of *social SDKs* (§ 3.2), an app may want customized handling of the data (e.g., transformation, sharing to remote parties, display on UI for user operations). *PESP* securely enables any customized handling of the data inside the *SDK runtime*, specifically inside an internal sandbox (based on *isolated process* of Android [20]) called *sensitive module sandbox* (see Figure 2). Specifically, during app development, the app developers can develop certain code modules (e.g., some classes) or adopt specific *TPL*s, and compile them into a package (in the Android-common `.dex` format [18]) called a *Sensitive Module* in *PESP*, which is separate from the app's regular executable or package. The *Sensitive Module*s are to run inside the *sensitive module sandbox* (see examples in § 5 and example implementations online [5]). A *Sensitive Module* directly handles private data of *social SDKs* (exchanged with the *SDK runtime*), but cannot expose it. This is because *sensitive module sandbox* is based on *isolated process* of Android [20], which has least privileges such as the lack of network permissions (guaranteed by SE Android [27]) and only communicate with its creator process, the *SDK runtime* or specifically the *trusted API service*. To serve all functionality requests from the *app runtime* while preserving privacy, *trusted API service* just provides three simple but generic APIs facing the *app runtime* (detailed in § 4.2). The APIs allow the *app runtime* to specify which *Sensitive Module* to use to handle which data (see API details in § 4.2). In a *Sensitive Module*, the app developer's own code can invoke a *TPL* to help process data, and such a *TPL* is not expected to be changed due to *PESP*.

In *SDK runtime* only the *trusted API service* can decide to share specific data to a remote party upon the *app runtime* requests, based on *data-sharing policies* of the app and *social SDKs* (see *data-sharing policies* below).

• *Privacy-preserving UI paradigm*. In the Type I workflow of original usages of *social SDKs*, the SDK data was expected to flow to the app's UI for the users to view, operate or interact with: for example, during login with Facebook, the user's identifiers, names, etc. from Facebook are filled into the app's login window or account creation window (Figure 4c). To securely support app-specified, UI-based user interactions with the *social SDK* data, we introduce a privacy-preserving UI paradigm (or *PESP* UI paradigm) — note that this was not a common use case for ads libraries and thus unsupported by prior isolation techniques such as PSoA. Specifically, the app can securely designate a portion of the screen (called *s-screen*) to the *SDK runtime* and the *SDK runtime* can populate

data into *s-screen*, and allow users to operate on it without ever exposing data to the *app runtime*. How to customize the view and actions in *s-screen* is completely implemented in a *Sensitive Module* provided by the app and executed with privacy guarantee in the *SDK runtime* (inside the *sensitive module sandbox* based on *isolated process*). We elaborate on technical details in § 4.2 and end-to-end implementation and demo with Facebook and Twitter SDKs in § 5.

• *Data-Sharing Policies*. The *data-sharing policies* are specified by the app/SDK developers to fulfill the privacy properties (§ 3.1). In particular, the policy specifies for the specific app (or app vendor/domain) the specific date items that are allowed to be shared with specific data collectors (see the *DDC property* and *CDC property*). The *data-sharing policies* should/can be made publicly available under the app vendor's domain (e.g., example.com/PA_policy.json), signed by the app vendor. The *social SDK* has the authority to additionally impose a policy overriding part/all of the app vendor's policy, fulfilling its data sharing policies. See an example policy in our supporting websites [5].

With privacy by design, all parties that can collect the data from *social SDK* are deterministic, controllable and auditable, significantly elevating the privacy and compliance assurance of the *social SDK*, apps, and the underlying operating system.

Usability for app users. Our entire design is transparent to app users, who experience no changes. For example, the app user can operate on the *s-screen* populated with Facebook/Twitter SDK data, make selection, edits, and further submits the data to app/Facebook servers, e.g., during Facebook/Twitter based app login or account creation, or posting to the social networks. Figure 3 shows a screenshot in our end-to-end implementation/evaluation of a *privacy-preserving* Facebook SDK used in a demo app, fulfilling all expected/current use cases of Facebook SDK.

Discussion. Instead of sandboxing potentially all *TPL*s that are untrusted, the design of *PESP* chooses to sandbox *social SDK*s, which can be more practical while fulfilling our protection goal (defeating *XLDH* attacks). Otherwise (sandboxing all non-social libraries), all simple app-to-sdk or sdk-to-sdk function calls will go with inter-process communications, which will significantly break current programming paradigms, runtime performance and app design (a regular mobile app may utilize tens of third-party SDKs for diverse functionalities [34]). Further, based on the *PESP* design, specific *TPL*s (e.g., an image processing library) adopted by the app to process *social SDK* data are packaged and sandboxed in a *Sensitive Module*, while other non-trusted *TPL*s run in the *app runtime*.

4.2 *PESP* SDK Runtime

We elaborate on design of key components for the *SDK runtime* as follows.

Trusted API Service: interface between the app runtime and SDK runtime The *trusted API service* provides three generic APIs facing app code in the *app runtime*:

• `API 1: getDataHandle(original_SDK_API_name, arguments, optional_callback_function)`. Similar to using the original API of the *social SDK*, the app can use the original SDK API name and arguments in this `getDataHandle`, which will return to the *app runtime* `data_handles` to specific data items. Note that the *trusted API service* never returns actual data of *social SDKs* to the *app runtime*. The last argument is optional and specifies a callback function in the *app runtime* for the *trusted API service* to invoke asynchronously if the original SDK API cannot return immediately (e.g., delayed by Internet communication with the *social SDK* server).

• `API 2: sendSensitiveData(data_handles, remote_host, sensitive_module, optional_callback_function)`. API 2 is directly related to the Type II workflow (§ 3.2), where app developers intend to send data from the *social SDK* out to third-party partners or the app servers. To support this workflow, the app code from *app runtime* can use API 2 to let the *trusted API service* send specific data (referenced by the `data_handles` argument) to specified remote server endpoint (the second argument).

The third argument `sensitive_module` is optional and if specified, the *trusted API service* will launch the *Sensitive Module* (in an *isolated process*, see below) to process the data before sending them out to remote servers. Notably, the *Sensitive Module* can implement flexibly customized functionalities or operations on the data of *social SDK* (texts, images, videos, or binary data without limitation). This API return new data_handles referencing to the data after customization. As mentioned earlier, the *trusted API service* enforces the *data-sharing policies* and determines whether sharing the specific data with the domain is allowed before sending data to remote parties. Similar to API 1, the last argument is optional and specifies a callback function in the *app runtime* for the *trusted API service* to invoke asynchronously.

• `API 3: launchSensitiveModuleView(data_handles, sensitive_module)`. Recall the Type I workflow where the app may want display of the *social SDK* data in the app specific UI for the user to view or operate. Upon this API request, the *trusted API service* launches a GUI *view*, implemented by the sensitive module (the second argument) to display the data (the first argument) — a sensitive module runs as an *isolated process* considered as the *sensitive module sandbox*. In such a case, the *Sensitive Module* can be implemented as a typical Android GUI view (based on the `android.view.View` class [29], with UI elements such as text-boxes and labels defined and laid out like programming a regular Android UI [25]), including code logic that can populate provided data to the view's UI elements (Figure 2) and further take customized actions on the data.

Implemented by the *Sensitive Module*, this GUI *view* uses a portion (or entirety) of the screen (see Figure 2), referred to as *s-screen* in this design proposal. Note that the *Sensitive Module* is customized by the app developers (in contrast to *social SDK* vendors) and provided to the *SDK runtime* at app packaging time (see § 4.1). This API returns a `SurfaceControlViewHost.SurfacePackge` type handle referencing the view *s-screen* (returning to the *app runtime* that invokes this API). As detailed below, *app runtime* with the view's handle cannot access contents in the view at all (based on how the Android's System Display Service [19] works and how Android manages screens).

In the evaluation (§ 5), we demonstrate that the three simple yet versatile APIs are capable of satisfying all the use cases of both Facebook and Twitter SDKs. We showcase this through an example app provided by Facebook and a proof of concept app that we developed, incorporating the Twitter SDK. *PESP* supports multiple social-SDKs used by one app in respective runtimes. The app interacts with each SDK-runtime similarly. We evaluated and released an example app using both the Facebook and Twitter SDKs under *PESP* in § 5.4.2.

Security discussion. With *XLDH* attack surfaces significantly reduced by *PESP*, a potential remaining threat is that a malicious *TPL* adopted by the app leverages API 2 to post sensitive data to public remote hosts, and then the attackers can monitor the specific endpoints and harvest data there. Such a threat can be prevented based on *data-sharing policies* of *PESP* or existing privacy enhancing techniques (PETs). Specifically, thanks to enforcement of *data-sharing policies*, the remote hosts targeted in such an attack are considered to be either hosts of the app or the online social network (OSN) behind the *social SDK*. Targeting the former, the attack must be app-specific, which is not an *XLDH* and has significantly more limited attack surface than *XLDH*. If OSN-owned endpoints are targeted, the OSN's data-sharing policies may disallow SDK data to be posted to its public endpoints. Also, thanks to *PESP*, the data must be sent to the OSN before the attacker can harvest them, and thus prior PETs such as anomaly detection [9] can identify the attack: for example, massive data of diverse identities are sent to specific OSN endpoints or timelines, apparently being abnormal.

***PESP* Privacy-preserving UI paradigm**. To securely support app-specific, UI-based user interactions with the *social SDK* data, and enable Type I workflows (SDK data flow into the app UI), we adapt uses of Android's System Display Service (*d-Service*) and propose a novel GUI rendering technique, called *PESP-GUI*. The core idea is that *PESP-GUI* enables the trusted *SDK runtime* and the untrusted *app runtime* to each render and operate a portion of the entire screen; *SDK runtime* (i.e., the *Sensitive Module* with API 3) shows the SDK's private data only in its screen portion (called sdk-screen portion or just *s-screen*) without ever exposing SDK data to the *app runtime*. *PESP* is aligned with and leverages the design of Android's System Display Service, which manages how different views, overlays, and windows are stacked at the z-axis to form a user-facing screen. Specifically, we leverage Android *d-Service* to securely stack the *s-screen* (owned by *Sensitive Module* in the *SDK runtime*) on top of specific position of the *app runtime*'s screen (at z-axis, see Figure 3), forming a user-facing window — users see a normal app window with *social SDK* data to view and edit.

More specifically, the API 3 returns to the *app runtime* a view handle called *surfaceView* (of type `SurfaceView` [28]), referencing the *s-screen* operated by the *Sensitive Module* confined in the *SDK runtime*. The app code in the *app runtime* can then call the Android framework API `surfaceView.setChildSurfacePackage` [28] to designate that it wants its specific screen portion (up to 100%) to be stacked with and thus overwritten (on the z-axis) using the particular *surfaceView*. Note that since both the *Sensitive Module* (with view layout in the *s-screen*) and the app window are developed by the app developers, the final combined user-facing GUI will look normal for users.

Security discussion. Note that the above screen stacking technique is based on the true intention of (1) the app (by calling the above API to inform the Android *d-Service* about the target screen to use on its top and specific position), and (2) the *SDK runtime* by returning reference to the *s-screen* to the app (through API 3). Hence, this has key differences from prior overlay attacks [40] where a malicious app put its overlap or screen on top of another (victim) app — placing an overlay on other apps is now strictly restricted by Android requiring a signature level permission `System_Alert_Window` and by Google Play in app vetting [24]. Also note that, in the design of *PESP*, despite the screen stacking, the app code or the *app runtime* cannot access contents in the *s-screen* owned by the *SDK runtime*. We provide implementation details in § 4.4.

Sensitive Modules. Upon invocation of API 2 and API 3 with a *Sensitive Module* name specified, a *Sensitive Module* is launched by the *trusted API service* as an *isolated process* [20] — called a *sensitive module sandbox*. Like a regular *isolated process*, the *Sensitive Module* has a *Binder* object [17] to communicate and exchange data with its creator process (the *SDK runtime*), but is restricted for other IPC or permissions (e.g., no Internet access). The process terminates once the related function being launched returns.

Sensitive Storage. Despite the three APIs and the *trusted API service* only return data handles, and never return the actual data, the *trusted API service* keeps a private storage inside the *SDK runtime* for the specific data and its data handles in the format of {data_handle, data type, data value}. Note that, with API 3, after a *Sensitive Module* performs transformation on a set of multiple data items, it can produce new data and return them to the *trusted API service* (through IPC between an isolated process and its creator process). Then *trusted API service* can store the new data, assign new data handles and record data type as the set of the original data types. This enables the *trusted API service* to enforce the *data-sharing*

policies based on the data types when sending data to remote parties (API 2).

Generality of *SDK runtime*. Our design of *SDK runtime* is potentially general for all *social SDKs*. Our implementation (§ 4.4) is open-source can be easily used by *social SDK* vendors to wrap their current *social SDKs* without changes (see our demo and evaluation for Facebook and Twitter SDKs in § 5). § 5 further encompasses our evaluation of the practical efforts required for app developers to adopt the new privacy-preserving paradigm of *social SDKs*.

4.3 Comparison with Related Work

Comparison with PSoA. There are key design-level differences between *PESP* and Google's ongoing development of PSoA for the privacy assurance and functionality.

• *Privacy assurance*. While PSoA aims to separate SDK permissions from the app, by design, PSoA simply allows SDK-runtime to return data to untrusted app-runtime (by invoking SDK APIs) [30] (subject to *XLDH*-attacks). In sharp contrast, *PESP* confines SDK data (in SDK-runtime), thus elevating privacy assurance (against *XLDH*).

• *Enabling social-SDK functionalities*. Confining SDK data while enabling app-to-SDK functional workflows is challenging. Such a property is achieved by the PESP UI paradigm (§ 4.1), securely enabling app-specific, app-implemented operations on the SDK data inside SDK runtime. In contrast, the PSoA (with its remote-view feature [11]) does not enable such a key property: operations/implementations in PSoA remote-views are done by the SDK, and apps just determine the views' on-screen location. PSoA currently only focuses to support advertising-related SDKs [12]. The PSoA even assumes that the app should not impact or interact with SDK behaviors such as UI contents or operations of SDK-runtime (to protect ads display integrity and promote anti-fraud) [13], which contradicts with designed use cases of *social SDKs*.

Comparison with other related work. Generally, prior techniques for library isolation, restriction or protection suffer from several key problems for effectively or practically defeating *XLDH* attacks (Table 4).

• *Problem 1: Isolation targets*. Many prior techniques aimed to isolate libraries from the host app [26, 48, 50, 51, 56–58] (e.g., with separate permissions, processes, storage, or runtime). They were designed to isolate specific types of *TPL*s (e.g., ads related libraries) from the host app, and were usually not intended or designed to isolate *social SDKs* or many libraries. Using their approaches to generally isolate many libraries may significantly change app-to-library or library-to-library interactions, programming paradigms, and app designs (see discussion in § 4.1), thus being less practical. Additionally, adopting their approaches to isolate *social SDK* or address *XLDH* can incur Problem 2 or Problem 3 discussed below.

• *Problem 2: Incomplete isolation (privacy assurance)*. Although many prior techniques come with certain levels of isolation [45, 54, 55, 60, 73] (e.g., permission isolation which ensures that libraries do not directly inherit permissions of the host app), like PSoA, they usually come with no design-level guarantee that data from *social SDKs* (or generally an SDK that offers data) never flows to the untrusted, non-isolated space (e.g., app runtime), directly violating our *XLDH* security goals.

• *Problem 3: Functionality compatibility for social SDKs*. Unlike previous works' assumption [45, 46, 50, 57, 58, 71] that ads-related or other SDKs expected little or no functionality interactions with the host app, thus being more easily isolated without breaking their functionalities, *social SDKs* come with sophisticated or app-specific interactions with the app. Quarantining SDK user data (inside a *social SDK* or potentially any SDK that offers data) while enabling necessary, sophisticated interactions between the SDK and untrusted/app code is a unique contribution and advantage of *PESP*.

4.4 Implementation

Privacy-preserving UI paradigm. The type (class) of the view returned by API 3 to the *app runtime* is `SurfaceControlViewHost.SurfacePackage` [28], which serves as a reference to the *s-screen* operated by the *Sensitive Module* that includes the data of *social SDKs*. When the view of the *Sensitive Module* is created, it is stored in the screen drawing buffer of Android, shared between the Android `SurfaceFlinger` service and the *sensitive module sandbox* process (where *Sensitive Module* runs). Then, an instance of the class `SurfaceControlViewHost.SurfacePackge` is created as a reference to that buffer, and returned to the *app runtime* by API 3. Once the app code in the *app runtime* receives the reference, it can use the reference as the parameter to invoke the Android API `SurfaceView.setChildSurfacePackage` which essentially tell the `SurfaceFlinger` service to take the content of the drawing buffer owned by the *Sensitive Module* to stack on specific position of its own screen and overwrite the content of its own drawing buffer or `SurfaceView`. Note that, the overwrite happens in the trusted Android `SurfaceFlinger` process, which synthesize the drawing buffer to finalize display of the user-facing screen, and neither the *app runtime* nor the *SDK runtime* can access contents of each other's screen contents (i.e., contents in their respective `SurfaceViews`).

When the app wants to reclaim the display area taken by the *s-screen*, it can simply invoke the Android `ViewGroup.removeView` API to remove the `SurfaceView` of the *SDK runtime* from its screen. Hence, data of *social SDK* in the *SDK runtime* is never exposed to the *app runtime*, but allowing the app to control how, when and where the data is shown to the user on the screen. Note that it's possible that apps leverage the Android's `MediaProjectManager`

API to take screenshot of the whole display, but every invocation of `MediaProjectManager` for whole-display screenshot requires user consent [21].

SDK runtime. In our current implementation, the *trusted API service* is similar to a regular Android service based on the class `Service`. The *SDK runtime* wrapping the original *social SDK* (Figure 2) is packaged with its own package name. The *sensitive module sandbox* is created using the `IsolatedProcess` flag of Android `Service` which assigns the sandbox process a restrictive uid that has IPC limitations and strict SELinux policies enforced [20]. The *Sensitive Module*s are loaded from the file system using the `DexClassLoader` Android API to load all the necessary Classes in to the sandbox process.

The *Sensitive Module* in the *isolated process* can use the *Binder* to exchange information and perform IPC with the *trusted API service*. The *Binder* instance was created and accessible to the *Sensitive Module* when the *trusted API service* create the *isolated process*. Besides the three public APIs facing *app runtime* (§ 4.2), the *trusted API service* internally implemented a few more functions to serve requests (through the IPC) of the *Sensitive Module*, especially when the *Sensitive Module* wanted to make HTTPS requests to the remote servers (*sensitive module sandbox* cannot access the Internet). Once a *Sensitive Module* finishes its code execution, its isolated process terminates. Considering that multiple apps may use the same *social SDK* (e.g., the Facebook SDK), in our implementation, the system installs the *social SDK* as a unique service that can be invoked and shared by multiple apps.

App runtime. The app code runs in *app runtime*, which is exactly the same as the Android Runtime (ART)(with its predecessor as Dalvik runtime) [22] capable of running `Dex` bytecode. Since the *trusted API service* with the *SDK runtime* is implemented as a standard Android service [23], invocations to the three APIs of *trusted API service* follow the standard IPC process like invoking any service APIs (using the Android API `bindService` [16]). In our implementation, for app code to more easily use the *trusted API service* APIs, we additionally provide a convenient *client SDK wrapper* (of *trusted API service*), which is just a trivial wrapper offering the same function signatures as the three *trusted API service* APIs; the app code can import the *client SDK wrapper* as an SDK and invokes the three APIs just like invoking normal SDK functions and the *client SDK wrapper* consequently makes the IPC calls.

Isolation in *PESP*. Our rigorous isolation between the *SDK runtime* and *app runtime* and between the *SDK runtime* and *Sensitive Module* is based on mature techniques, i.e., Linux UID [26] and Android isolated process [20] respectively. In our current implementation, similar to and compatible with Google's PSoA [30] and the new SDK distribution model [10], when installing an app utilizing *social SDK*, the system installs the app and the *social SDK* as two separate packages, assigning different app identifiers and Linux UIDs. Android package name/identifier serves as a basic building block when it comes to differentiating the app and *social SDK*. Note that different *social SDKs* have different package names and identifiers, because we do not assume there exist trust between different *social SDKs* in our threat model.

Distribution. Being compatible with the distribution model of PSoA [10], a *social SDK* is packaged as a self-contained package with its transitive dependencies. As mentioned earlier (§ 4), a *Sensitive Module* with its dependencies is built into a self-contained package (.dex format), which is loaded by SDK-runtime into isolated processes.

5 Evaluation

In this section, we thoroughly evaluate effectiveness, usability, and performance overhead of *PESP*. Specifically, we use two open-source Android apps released by Facebook and Twitter that integrated the Facebook login SDK [37] and Twitter Kit SDK [61] respectively: the two apps originally implemented functionalities for major use cases related to the SDKs such as login with Facebook and Twitter. In our evaluation, we implemented our design *PESP* into the two example apps while keeping the original functionalities; this is done by wrapping the in-app Facebook and Twitter SDKs into our *SDK runtime* and migrate the app code that originally invokes the SDK functions into code that invokes the *trusted API service*. In the following, we provide three demonstration examples of the new apps (with *PESP*) that have implemented key use cases of Facebook and Twitter SDKs: login with Facebook (§ 5.1), in-app display of Facebook user profile information (§ 5.2), login with Twitter (§ 5.3). For each use case, we evaluate the effectiveness of privacy protection and usability (efforts needed for the app developers to migrate this app to the *PESP* paradigm).

In § 5.4, we report evaluation of end-user facing performance overhead under *PESP*. The evaluation is based on the above two apps (released by Facebook and Twitter) equipped with *PESP*, and we additionally evaluated multiple app scenarios with each app integrating multiple *social SDKs* under *PESP*. The results showed that *PESP* is efficient and practical. All apps used in our experiments were released with source code online [5].

5.1 Case Study and Security Analysis: Login with Facebook under *PESP*

Login with *social SDK* is a common use case that is a prerequisite step for accessing sensitive user data from the Social Network platform based on the `OAuth` protocol, adopted by all 200 apps surveyed in our use case study (§ 3.2). Originally the login is implemented by the app developers through placing a `Login Button` provided by the Facebook SDK which wrapped the function call to Facebook SDK APIs.

Once clicked, it will initiate the login flow by navigating to the web browser on the user's device (or the Facebook app) to input the users' login credential on facebook.com and finish the authorization to the app. After the login process ends, the app checks whether the user is logged in by calling `AccessToken.getAccessToken`, a Facebook SDK API that will return the sensitive `AccessToken` if the user login is successful. Note that, `AccessToken` is a sensitive data because it could be used for fetching additional sensitive information (e.g., user emails, profile images) from Facebook's remote server. If the login succeed, the app will navigate the user to a new `Activity` for more functionalities; otherwise the user will stay in the current `Activity` that has the `Login Button` for user to attempt login again.

Usability evaluation: migration efforts for app developers. We made 279 lines of code (LOC) changes for this login functionality, including 47 LOC for implementing a *Sensitive Module* (see below). We additionally developed a *data-sharing policy* with 5 LOC that only allows the Facebook data to be sent to the app server (see the policy at [5]). The Facebook demo app originally has more than 1,200 LOC. Specifically, we made the following two code logic changes for the app. First, we replace the app's function calls to the Facebook SDK API behind the `Login Button` with an invocation to the `getDataHandle` API (API 1) provided by our new *SDK runtime* (i.e., *trusted API service*), and upon the invocation, the *trusted API service* will relay the call and actually invoke the APIs in the original Facebook SDK. Then the login process continues, allowing the user to enter their Facebook login credentials in the web browser (or in the Facebook app if already installed on the device) and authorize the developer's app. The second change needed is to refactor the app's code logic that navigates to different activities based on the login results. Specifically, we implemented a *Sensitive Module* (47 LOC) that uses the Facebook SDK API `LoginManager.getLoginStatus` or `AccessToken.getCurrentAccessToken` (by calling API 1 of the *trusted API service* and pass in the SDK API names): the former returns login success or failure, and the latter returns `AccessToken` whose value exists only after a successful login. Our *Sensitive Module* then requests the *trusted API service* to send the login result to the app's server using the `API 2: sendSensitiveData(data_handles, remote_host)`. Then, extra code logic in the *app runtime* that pulls from the developer's server the actual login result is added to the app.

Effectiveness evaluation: privacy enhancement. In the original app, calls to the sensitive `AccessToken.getCurrentAccessToken` function is used to check whether the login is successful or not by the app. This exposes the token from the Facebook SDK to the app code space; also any third-party library in the app can invoke this Facebook SDK API to get the user's Facebook access token. In addition, the function calls to initiate the login process has to be replaced with the invocation to the `getDataHandle` (compared to the original app that directly invokes Facebook SDK API), also ensuring that sensitive information stayed in the SDK Runtime, not exposed to the *app runtime*. In our *PESP* enhanced version of the app, Facebook SDK data cannot flow out to the app runtime regardless of how the app invokes *trusted API service* or the *SDK runtime*, all confined in the *SDK runtime*.

5.2 Case Study and Security Analysis: Display of Facebook User Profile under *PESP*

Another common use case used by 169 apps out of the 200 apps we found in the use case survey (§ 3.2) is to display usernames and email addresses obtained from the social network inside the app's UI. To implement this use case, app developers would first acquire the sensitive user profile information from the Facebook SDK with an invocation to the SDK API `Profile.getCurrentProfile`, whose return value contains the username and email address. After that, the username and email are used to update the content in the Android `View` objects to display them in the UI, so the user can check the profile information they are going to use with this app, and modify them on the UI as needed. If the user confirmed the profile information, the app will send the profile information to the app server for persistent storage.

Usability evaluation: migration efforts for app developers. We changed 196 lines of code (LOC) for this functionality, including a *Sensitive Module* (73 LOC). This demo app of Facebook originally has more than 1,200 LOC. Specifically we make the following code changes for the app to adopt *PESP*. We replaced the invocation to the sensitive SDK API `Profile.getCurrentProfile` with an invocation to the `getDataHandle` API of the *trusted API service*, which returns an opaque data handle to the `Profile` object (the actual value is stored in the SDK Runtime's in its *Sensitive Storage*). Next, we removed the original app code logic that updates the `View` objects with the sensitive user information and instead developed a *Sensitive Module* (73 LOC) that implemented a GUI view to display the user information (also see the "*PESP* privacy-preserving UI paradigm" in § 4.2). Further, the app code logic of sending the user profile information to the app server is replaced. Instead, the view of the *Sensitive Module* includes action code that sends the user data to its app server. This involves invocation of the API 2 of the *trusted API service*, i.e., `API 2: sendSensitiveData(data_handles, remote_host)` by the *Sensitive Module*. The *data-sharing policy* includes 5 LOC that only allows the Facebook data to be sent to the app server (released online [5]).

Effectiveness evaluation: privacy enhancement. Thanks to the Sensitive Module and *PESP* privacy-preserving UI paradigm, sensitive user profile are displayed in the UI without being exposed in the *app runtime* at any time after the

migration, eliminating the *XLDH*. In addition, the *trusted API service* of the *SDK runtime* can enforce the *data-sharing policies* whenever the *Sensitive Module* tries to (through the *trusted API service*) send any data out to any remote hosts.

5.3 Case Study and Security Analysis: Login with Twitter under *PESP*

We changed 125 lines of code (LOC) for this functionality, including a *Sensitive Module* (52 LOC). This demo app of Twitter originally has more than 1,300 LOC. The design of Twitter Kit (SDK) for Android is very similar to the Facebook SDK for implementing the Login with Twitter use case. Specifically, Twitter Kit also provided a `Login Button` that wrapped the actual `OAuth` based user login process and provided `Call Back` interface such that the app developer could trigger their own code logic depending on the success or failure of the login. Different in the Twitter Kit case is that Twitter uses a pair of `oauth_token` and `oauth_token_secret` inside the `TwitterSession` object as the credentials for pulling user private information from the Social Network platform. The `TwitterSession` object also contains sensitive user information like the user id and user name. In addition, the demo app included an extra step of calling Twitter Kit SDK API `TwitterAuthClient.requestEmail`, which essentially sends a `HTTP Get` request to the Twitter's server to retrieve the user's email address, to verify the credentials are valid.

Usability evaluation: migration efforts for app developers. The Twitter Kit's API `TwitterAuthClient.requestEmail` original implementation takes an app developer implemented `Call Back` interface and return the user's email in the success clause of the `Call Back`. After adopting our design, an opaque data handle is returned whether the login is successful or not to avoid privacy leakage. As a result, we developed a Sensitive Module (19 LOC) to check the existence of user email with the opaque data handle and report the result to the app's server (which is registered in advance and approved by the *data-sharing policies*), then the app code retrieves the results with a network request. The *data-sharing policy* includes 4 LOC that only allows the Twitter data to be sent to the app server (released online [5]).

Effectiveness evaluation: privacy enhancement. In the original app, the `TwitterSession` object returned by the original Twitter Kit API that could have leaked user email, user id and sensitive Twitter API credentials to the untrust app space exposing malicious libraries. With the *PESP* paradigm in the app, this is protected based on opaque data handles and the actual data never went from the Twitter SDK to the *app runtime*. Further, the Sensitive Module design ensures the sensitive user email to be accessible for app functionalities while the data flows are fully controlled based on the *data-sharing policies*.

Table 2: Performance overhead (single social SDK per app)

Use Case	Original (ms)	PESP-migrated (ms)	Δ (ms)
Login with Facebook	66.45 ± 5.60	138.88 ± 13.24	72.42
Display User Profile	50.01 ± 0.38	89.19 ± 6.732	39.19
Login with Twitter	167.50 ± 6.02	230.10 ± 16.52	62.60

Assuming Normal Distributions, Intervals for 95% confidence

5.4 Performance Overhead

5.4.1 Evaluation for the Three Use Cases

We conducted our experiment on a Google Pixel 6 phone running stock Android 13 (r16). We used the three migrated use cases (with *PESP* adopted in the two apps) above to evaluate performance overhead of our design. Since the three use cases' original implementation in the sample apps is mainly for demo purpose (Facebook and Twitter released the sample apps to show how to use their SDKs and for what use cases) with no code logic for other app functionalities (i.e., functionalities unrelated to Facebook or Twitter) in place, our evaluation is thus conservative and approximates the potential upper bound of the performance overhead. We run the test 20 times for both the original and migrated, *PESP*-based app implementation and Table 2 summarized the results.

Login with Facebook. We measure the time the app needs to receive the login success result after the login button is clicked. In the workflow, once the user clicks the in-app login button, she is redirected to Facebook.com in the browser (or the Facebook app if installed), authorizes the app, and is finally redirected back to the app's specific UI window with successful login results. For measurement purpose, we subtracted the time the user needed to authorize the app in the Web browser (or in the Facebook app), which can be influenced by the user's reaction speed and network latency. The subtracted time is measured by inserting code for timestamp logging in the apps related to UI operations (e.g., when the login button is clicked) and activity switching (e.g., right upon the app is switching to the browser and right after the login success UI activity is triggered following the authorization). The average overhead for the migrated implementation is 72.42 *ms*.

Display Facebook User Profile. We measure the time needed starting from in-app invocation of the function that retrieves user profile information to when the rendering of the views containing the sensitive information is finished. In the workflow, once the app triggers the API `GraphRequest` of the Facebook SDK (using the API `getDataHandle` of *PESP*), the SDK will retrieve the user data from the Facebook server, and then display the data on a UI activity implemented by the app (running in a *Sensitive Module*). We subtracted the time spent on network requests for the user information from the Facebook server to exclude the impact of network latency variations. The subtracted time is measured by inserting code in the open-source Facebook SDK for timestamp logging

at corresponding network request callbacks (i.e., before and after the request). The result shows an overhead of 39.19 *ms*.

Login with Twitter. Same as the Login with Facebook case, we measure the time the app need to receive the login successful result after the login button is clicked excluding the time the user spent in the browser. The result shows a overhead of 62.60 *ms*.

5.4.2 Apps with Multiple Social SDKs

In the above experiments, each app comes with one *social SDK*. We further evaluated performance overhead on multiple apps, with each app using both Facebook and Twitter SDKs under *PESP*. Specifically, by combining the above two PESP-enabled apps that use either the Facebook or Twitter SDK (§ 5.1 to § 5.3), we developed an app that uses both social SDKs under *PESP*. We take this app as the evaluation target app. As its control group, by combining the two original example apps (provided by Facebook and Twitter), we developed an app using both the Facebook and Twitter SDK (without *PESP*). The evaluation target app and its control group share exactly the same functionalities with both the Facebook and Twitter SDKs. For the evaluation, we performed experiments under three scenarios as follows (each result is based on the average of 20 trials, shown in Table 3).

Scenario 1: multiple PESP-enabled apps use the same *social SDK* (Facebook or Twitter SDK). We launch two instances of the target app (compiled and built under different package names, treated by the Android OS as different apps). We refer to the two instances as PESP Instance 1 and 2 respectively. For each use case (`Login in with Facebook`, `Display User Profile` and `Login with Twitter`), we run PESP Instance 1 and then Instance 2, with their performance overhead measured respectively (Table 3). There is no obvious performance difference between the two instances. Similarly, we also run two instances of the control group app (Original Instance 1 and 2 in Table 3). The performance overhead compared to the control group is low; e.g., Instance 1 shows an average overhead of about 74.79*ms*, 38.47*ms*, 59.91*ms* compared to Original Instance 1 for the three use cases respectively.

Scenario 2: single PESP-enabled app uses multiple *social SDKs* (Facebook and Twitter SDKs). We launch one instance of the target app, run the two use cases sequentially (`Login in with Facebook` and `Login with Twitter`) and measure the time consumed for both use cases. Compared to the control group, the performance overhead for executing the two use cases is low (74.0*ms* and 60.7*ms* respectively for the two use cases), which is about the same with Table 2 that evaluates single *social SDK* in each app.

Scenario 3: multiple PESP-enabled apps use multiple *social SDKs* (Facebook and Twitter SDKs). Similar to Scenario 1, we launch two instances of the target app. Then in each instance we run the two use cases (`Login in with Facebook` and `Login with Twitter`) and measure the time (PESP Instance 1 followed by PESP Instance 2). Compared to the control group, the average performance overhead for executing the two use cases is around 85.6*ms* and 63.6*ms* (PESP Instance 1). There is no obvious performance difference between the two PESP app instances.

6 Discussion

Long-term maintenance and updates. As mentioned in § 4.1, the design and implementation of *PESP* is directly compatible with PSoA of the official Android. *PESP* can supplement PSoA to protect *social SDKs*, while PSoA currently only supports ads-related SDKs. Notably, in *PESP*, the individual *social SDKs* are wrapped under the *SDK runtime* and the original *social SDKs* expect minimum or no changes. The design and implementation of such a *SDK runtime* is general, not specific to individual social networks (our implementation that can directly wrap the Facebook, Twitter or other *social SDKs* is released online [5]). With future emerging threats against the SDKs, one may just update the general *SDK runtime*, which can be maintained with the Android or community efforts including ours. We expect that *PESP* will motivate more research and development efforts that tackle hard defense problems or emerging privacy threats and improve privacy assurance for mobile apps and *TPL*s.

Sensitive information returned from the app server. After collecting user data from the *SDK runtime*, benign app servers might hand the data to the *app runtime*, flowing private data into untrusted code space. Although we acknowledge that this presents a privacy threat (similar to prior studies showing that malicious libraries can harvest the host-app's data from the app-specific UI or server), it is not a *XLDH* threat and has significantly more limited attack surface than *XLDH*. Specifically, from the attackers' perspective (a data-harvesting library that has sneaked into mobile apps), with *XLDH*, the malicious library can succeed in all apps using the same attack vector/approach (accessing the same function/interface of the target *social SDK*); in contrast, the other threat in question has to target app-specific UI components, code modules or interfaces to find the private data, which is significantly less effective and more costly for the attackers. Hence, our design defeats *XLDH*, significantly reduces privacy attack surfaces and elevates privacy assurance.

Generalizability to other types of SDK. Our design is general (not relying on *social SDKs*), and may be applicable to potentially all SDKs that provide or manage data, or want to protect their data. Also note that to ensure the privacy assurance against *XLDH* while supporting in-app functionalities of *social SDKs*, our design is based on a thorough survey of in-app use of 20 popular *social SDKs* (§ 3.2). To use *PESP* or extend it for protecting more types of SDKs, a thorough survey of their functionality use cases are necessary, which we leave for our future work. Moreover, *PESP* and PSoA share

Table 3: Performance overhead (multiple social SDKs per app)

Use Case	Original Instance 1	Original Instance 2	PESP Instance 1 (ms)	Δ (ms)	PESP Instance 2 (ms)	Δ (ms)
Login with Facebook (Scenario 1)	65.91 ± 1.92	67.69 ± 2.69	140.7 ± 3.93	74.79	142.3 ± 5.91	74.61
Display User Profile (Scenario 1)	50.33 ± 0.33	50.55 ± 0.53	88.8 ± 1.81	38.47	89.25 ± 3.93	38.7
Login with Twitter (Scenario 1)	167.04 ± 12.51	173.95 ± 17.68	226.85 ± 13.45	59.91	240.15 ± 20.59	66.2
Login with Facebook/Twitter (Scenario 2)	FB:70.2 ± 8.48	–	FB:144.2 ± 11.69	74.0	–	–
	TW:159.9 ± 24.90		TW:220.6 ± 25.40	60.7		
Login with Facebook/Twitter (Scenario 3)	FB:62.0 ± 3.73	FB:70.3 ± 15.11	FB:147.6 ± 25.38	85.6	FB:149.1 ± 36.3	78.0
	TW:158.7 ± 21.1	TW:185.4 ± 25.56	TW:222.3 ± 20.2	63.6	TW:251.2 ± 26.69	65.8

fundamentals in the runtime and distribution model, particularly isolating the SDK in a runtime separate from the app. With shared fundamentals, *PESP* can be incorporated into PSoA to support social use cases and potentially all SDKs that offer data. Note that currently PSoA primarily focuses on supporting ads-related SDKs, which, compared to *social SDKs*, expect much less or no functionality interactions with the host app.

Applicability to other OS. Our design isn't limited to Android. Android implemented the easy-to-use isolation and flexible UI composition (Section 4.4), which were needed to implement our design. These features/flexibilities were designed for better engineering/security/testing. Other OSes may also implement such features, enabling implementation of our design.

7 Related Work

Third-party library (TPL) isolation. To enable privilege separation, the TPLs are isolated in these techniques through various design. In all the prior approaches [46, 48, 50, 51, 56–58, 63, 71], the design usually focused on preventing TPLs from accessing the Android system resource (by restricting their permissions), without restricting them from accessing data from *social SDKs*. Those prior techniques generally suffered from the Problem 1 and 2 summarized in § 4.3.

App compartmentalization. App compartmentalization related techniques provides finer granularity by differentiating inner parts of an app from other parts when enforcing access control and isolation (e.g., attributing API calls or resource access to individual SDKs, classes, or processes, depending on the designed granularity of individual approaches) [33, 45, 54–56, 60, 62, 65, 66, 72, 73]. Those prior techniques generally suffer from Problem 2 summarized in § 4.3.

Taint based approaches. Taint based approaches [35, 43, 59, 67–70] are not sufficient as a protection method against *XLDH* due to their incomplete coverage and incomplete modeling of the implicit flow, leading to sensitive user information leak without privacy guarantee that our design achieves.

8 Conclusion

In this paper, we generalize and define *privacy-preserving social SDK* and their uses, characterize fundamental challenges for combating the XLDH threat and guaranteeing privacy. Specifically, we present a practical, clean-slate design and end-to-end systems to enable *privacy-preserving social SDK*. Our evaluation demonstrates its satisfactory effectiveness, performance overhead and feasibility for adoption. Our techniques will contribute to significantly elevating privacy and compliance assurance for multiple stakeholders. Our efforts will help policymakers better understand, define and regulate the *privacy-preserving* mobile software supply chain.

Abstract

User interfaces (UIs) is the main channel for users to interact with mobile apps. As such, attackers often create similar-looking UIs to deceive users, causing various security problems, such as spoofing and phishing. Prior studies identify these similar UIs based on their layout trees or screenshot images. These techniques, however, are susceptible to being evaded. Guided by how users perceive UIs and the features they prioritize, we design a novel grid-based UI representation to capture UI visual appearance while maintaining robustness against evasion. We develop an approach, UIHASH, to detect similar Android UIs by comparing their visual appearance. It divides the UI into a #-shaped grid and abstracts UI controls across screen regions, then calculates UI similarity through a neural network architecture that includes a convolutional neural network and a Siamese network. Our evaluation shows that UIHASH achieves an F1-score of 0.984 in detection, outperforming existing tree-based methods and image-based methods. Moreover, we have discovered evasion techniques that circumvent existing detection approaches.

1 Introduction

User interfaces (UIs) is the main channel for users to interact with mobile apps. As a result, many security problems arise from similar UIs designed to deceive users, such as phishing and spoofing [11]. For example, the Svpeng malware [12] mimics a fake FBI penalty notification UI to blackmail victims, which has infected 350,000 Google devices.

To prevent such attacks, existing techniques detect similar UIs by taking either layout trees or screenshot images of UIs as input. For layout trees, layout definitions specified in XML trees, including tree structure [66, 70] and node attribute [52] are widely adopted. Another research direction is to collect UI screenshot images at runtime for comparison [51, 56]. However, adversaries can generate visually similar UIs via actively adjusting layout trees and screenshot images to evade existing detection methods. We call such evasions as *active evasion attacks*. Due to this reason, existing methods based on layout trees or screenshot images are vulnerable to attackers' evasion techniques. On one hand, inconsistency between layout trees and UI visual appearances significantly degrades the detection effectiveness. In particular, adversaries can build visually similar UIs on top of structurally non-similar layout trees, resulting in false negatives in tree-based detection. On the other hand, users usually show high tolerance when perceiving visual changes on UIs, e.g., color modification and logo rotation [50, 61]. Such tolerance enables evading image-based detection by permitting modifications to the on-screen UI imagery (e.g., at the pixel level).

Key Idea. To address active evasions, we aim to find a robust representation for UI similarity comparison, which abstracts UI visual appearances and tolerates variations that are not perceived by users. Gestalt Principles reveal how people recognize scenes in an image by grouping components of images [74]. For example, the proximity principle indicates that users naturally tend to group adjacent elements, perceiving them as a unified entity. There are other principals help to connect isolated elements, such as closure, common region and continuity. The proximity principal is found to be dominant according to prior study on vision [17]. Inspired by Gestalt Principles, we represent UI by controls (e.g., buttons) in different screen regions, which is used as the basis of recognizing a UI when users take a glance. After partitioning the UI screen based on a grid and extracting visual features for each grid region, we integrate visual features across grid regions as the UI representation. Since various visual features, including control sizes, positions, types, colors, styles, texts, and images/icons—have different impacts on users' perception on UI, we conduct a user study to identify the visual features that users prioritize. The study shows that users are sensitive to changes on *control position*, *control size*, and *control type*. Therefore, after abstracting UI appearance based on grids, we encode these specific visual features in grids based on user perception, instead of using empirically preset features [46].

Our Approach. In this paper, we present UIHASH, a frame-

*Corresponding author. Email:maojian@buaa.edu.cn.

work for detecting Android UI similarities based on visual appearance. As the appearance of a UI is specified by its controls distributed in separate screen regions, we partition the UI screen into a #-shaped grid, encode each grid region based on its constituent controls, and aggregate individual regions as the representation of a UI's appearance, which we call *UI#*. Compared with layout trees and screenshot images, UI# captures the visual appearance features that users prioritize, balancing the trade-off between inconsistent tree structures and inflexible image pixels when determining UI similarity. To generate UI# from Android UI, we collect runtime UI hierarchy instead of relying on static definitions of layout trees or screenshot images. Then, we extract and aggregate visual features in different screen regions. Specifically, we encode *control position*, *control size*, and *control type* to represent a UI#. Taking UI# as a quantitative representation for measuring the visual appearance of UI, we develop a learning-based model tailored to detect similar UIs in Android apps. Specifically, we identify the connection between measuring visual appearance in UI# and extracting image visual features. Leveraging a convolutional neural network, we distill visual features from UI#, and employ a Siamese network to assess the similarities between different instances of UI#.

We conduct a systematic evaluation with 52,390 real-world Android apps. Our experimental result shows that UIHASH achieves a 0.984 F1-score in detecting similar UIs, outperforming existing detection techniques [44,51,52,56,70,85]. In particular, it improves tree-based and image-based methods by 13.3% and 20.1% on the recall rate, respectively, denoting that more similar UIs are revealed. Furthermore, we discover that the active evasion attacks have already spread in real-world UI mimicking practices—accounting for 55.3% of all the detected similar UI pairs—that evade tree-based or image-based detection. Our evaluation also demonstrates that UIHASH is efficient in supporting real-life Android UI similarity detection and robust against adversarial attacks [20]. In summary, this paper makes the following contributions:

- We present a novel grid-based representation, UI#, to describe the visual appearance of Android UIs. It abstracts the UI into a #-shaped grid and focuses on visual features that users prioritize, addressing the inconsistency between UI appearance and layout tree/screenshot image.
- We design UIHASH to detect visual similarities among Android UIs, using a convolutional neural network to distill visual features from UI# and a Siamese network to identify similar UIs.
- We implement UIHASH and conduct a systematic evaluation against large-scale real-world apps[1]. The results demonstrate UIHASH's effectiveness and robustness in detecting similar UIs.

[1]We release UIHASH at https://github.com/DaweiX/UIHash.

7  </LinearLayout>
```

Listing 1: A simple Android layout tree example.

2 Preliminaries

Android apps define user interface (UI) by a layout tree, as Listing 1 shows. Each node in the tree (called *View* [25]) is associated with a bundle of attributes describing its properties (e.g., visual appearance). In particular, we refer to the views (e.g., `Button` and `ImageView`) that interact with users or visualize information as *controls*. Besides, *ViewGroups* [26] are specific views that can contain other views as children in various ways. For example, a `LinearLayout` allocates its children linearly (horizontally or vertically). After an app starts, the Android system renders the UIs described by layout trees. The UIs might change by app code at runtime.

Layout trees and UI screenshot images are widely used to measure UI similarity. Specifically, prior works detect tree or image similarity to search similar UI, assuming that adversaries only adopt simple and minor substitutions on UI components like texts, as they aim to save time on counterfeiting while keeping the counterfeit UI as close to the original as possible. Such UI spoofing attacks are called *lazy attack* [67, 70, 83]. Since the layout tree structure or images remain unchanged, analysts can still detect these similar UIs. However, we observe that the prior lazy attack assumption is unreliable in practical scenarios due to active evasions that apply to both tree-based and image-based approaches. There are two types of active evasion attacks:

Applying changes to layout trees to evade tree-based detection methods. The first way is to apply different ViewGroup types. For example, we list an example of two buttons arranged from left to right in Listing 2. As another example, using different view groups results in polymorphic tree structures and view attributes but visually similar UIs, as Figure 1 shows[2]. Inserting invisible controls is another way to obfuscate trees. Specifically, adversaries can add controls small enough to perceive, located out of the screen, or with a transparent color (we provide examples in Appendix A). Besides, as apps can change UI appearance dynamically (e.g., by initializing a view instance at runtime and inserting it into the current tree), UI appearances are not always consistent with the pre-defined layout trees. Therefore, static tree structures are insufficient to represent UI visual semantics.

Changing images or tuning image features to evade image-based detection methods. Images like app icons [35, 76] and

[2]More examples in https://developer.android.com/training/improving-layouts/optimizing-layout.

  <android.support.constraint.Guideline
    android:id="@+id/g" .../>
</androidx...ConstraintLayout>
```

Listing 2: Leveraging LinearLayout and ConstraintLayout with different view attributes to implement similar layouts.

UI screenshots [6,8,51,56] have been widely adopted as powerful features to detect repackage, plagiarized or counterfeit apps via UI similarity. However, compared to layout trees, images are too strict for describing what a UI *looks like*. In practice, users are likely not to remember the accurate logos and icons of companies, brands, and apps [61]. Users are also surprisingly poor at noticing image changes due to change blindness [5, 15]. According to a questionnaire, 40% users still trust a fake Facebook login UI in brown color [50]. Therefore, UIs with modifications on images or colors can easily evade image-based methods while not raising user concerns.

3 User Perception Study

To detect similar UIs by active evasion attacks, we measure UI similarity based on a novel representation designed to capture UI appearance, preserving immediate human perception while remaining robust against deceptive alterations. Naturally, user perception of UI is influenced by various visual features (e.g., control size). We conduct a user study to explore the impact of these features on user perception when inspecting UI similarity. The study aims to identify *visual features that users pay the most attention to*. It also helps to align the design of UIHASH with user perception.

Survey Design. Our survey (details in Appendix C) contains three sections: ① *Demographic survey.* We prioritize user privacy and refrain from collecting personally identifiable information (PII), such as phone numbers and dates of birth. We also include "Prefer not to say" options. ② *Similarity evaluation.* UI design varies based on app categories (e.g., social networking apps, games) and the specific tasks to be performed [32]. Consequently, the flexibility for UI adaptation for adversaries may differ in different scenarios. For example, phishing UI should closely resemble the original to deceive users, whereas UIs in a plagiarized game can incorporate more variations without raising user suspicion. Our study focuses on the representative phishing scenario. It involves the evaluation of 12 login UIs, allowing users to assess their perception on various UI features. These UIs are modified versions of a login UI from a popular social networking app. To eliminate bias, we present an equal number of modified UIs to each participant and randomize the order in which UIs are displayed. Figure 2 illustrates some performed modifications. Naturally, the perceived similarity to the original UI is determined by the "login rate" from users. Additionally, we inquire about users' specific concerns when refusing to log in and ask them to rank these aspects from most important to least important. ③ *Exit survey.* Participants in our study completed an exit survey regarding their mobile app experience and their perception on UI changes. Additionally, we use a simple attention check question to ensure users' careful reading and accurate responses.

Recruitment. We use four separate URLs for data collection. To avoid bias, each URL presents different and randomized UIs. We run the online survey for one month before data merging and analysis, and recruit 350 participants through notice boards and mailing list advertisements. Each participant is directed to a random one of the four URLs.

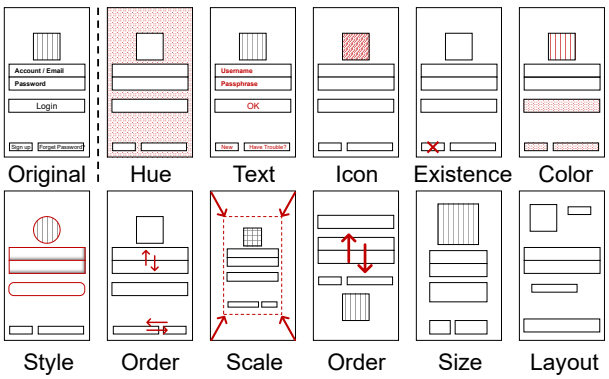

Figure 2: Modifications applied to an original login UI.

Feature	Score (1-5)	Rank
Control positions	3.77	1
Control sizes	3.41	2
Control styles	1.87	3
Background color or image contents	1.74	4
Texts on UI	1.45	5

Table 1: User ranking for features that prevent login.

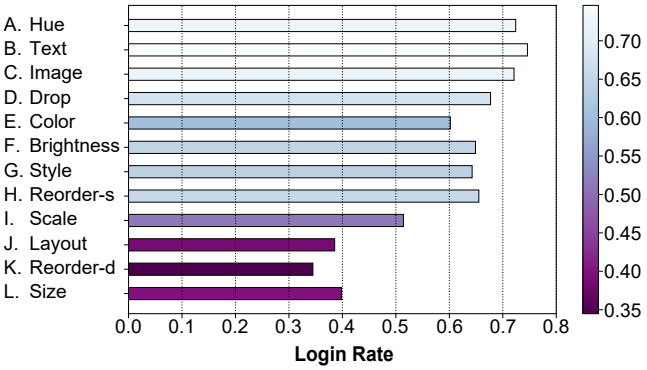

Figure 3: Login rates of modifications. H.Reorder-s and K.Reorder-d refers to reordering controls of the same type and different types, respectively.

To mitigate ethical risks, we consult researchers in the local community for best practices. We follow the transparent and user-consented procedures in line with the guidelines presented in prior works [13,29]. The participants are enrolled on a voluntary and anonymous basis and are informed about the study's purpose. Besides, the form specifies a minimum age requirement of 18 years and assures participants that no personally identifiable information (PII) is asked or collected.

Results. We exclude surveys where participants do not use the app or failed the attention check, resulting in 319 completed surveys. Table 1 shows scores for features that discourage users from logging in. Control position and size receive higher scores than other features such as color, image content, and text. Figure 3 displays detailed login rates of users under different UI modifications (all users logged in successfully to the original UI). All users demonstrate significant tolerance for UI modifications, as reflected in the login rates. While the t-test reveals a difference in login rates for the 12 features between participants with over 8 frequently-used apps and those using fewer apps ($t = 2.07$, $p < 0.05$, $d = 0.88$), both user groups are most sensitive (exhibit the lowest login rates) to a same UI feature set. Specifically, users show heightened attention to the following features:

- Control size (D.Drop, I.Scale, and L.Size). Both global scaling (I) and separate control resizing (L) decrease the login rate drastically. However, users lack attention to smaller controls. 70% of the users who self-measured as skilled still trust the UI of a "sign up" button missing in D.
- Control type (H.Reorder-s, K.Reorder-d). We rearrange controls of the same and different types (e.g., swapping `EditTexts` or `Buttons`, replacing images with buttons). The results demonstrate that changing the control type in a specific screen area effectively increases users' awareness.
- Control position (J.Layout, K.Reorder-d). J and K get the lowest login rates compared to other modifications.

Meanwhile, users show less attention (higher login rates) to other features, such as hue/brightness, control style, and text/image contents. The results complement existing study [50].

Insights. Recognizing that users exhibit a higher tolerance for UI changes compared to machines, we focus on comparing UIs based on the visual features that users prioritize, rather than relying on strict pairwise comparisons of layout trees or image pixels. Since features with lower login rates draw more user attention, such features (e.g., control *size*, *type* and *position*) are instrumental to *differentiate* UIs. Consequently, UIs that actively incorporate changes in high-login-rate features can be considered similar to the originals, making it challenging for evasive UIs to avoid detection.

4 UIHASH Design

In this section, we present UIHASH, our approach for UI similarity detection. We introduce how to abstract and encode visual semantics of UIs into the new representation UI# and how we use UI# to detect similar UIs.

Overview. As shown in Figure 4, UIHASH consists of three phases: *UI Parsing*, *UI# Generation*, and *Similarity Detection*. It extracts UIs from apps, transforms UIs to UI#, and measures UI# similarity. Specifically, *UI Parsing* extracts UIs from Android application packages (APKs). It produces tree-structured UI hierarchies and screenshots dumped at runtime. The UI hierarchies describe the boundaries of individual UI controls, specifying their positions and sizes. Besides, we utilize UI screenshots to extract control images and identify their types. *UI# Generation* takes UI hierarchies and control images as inputs. It first uses a convolutional neural network (CNN) to identify control types based on their visual appearance. Then, it divides the UI into an $n \times m$ grid, categorizes controls in each grid region by their types, and encodes control size in each region. At last, it aggregates all regions into a visually-inspired semantic representation, UI#. *Similarity Detection* measures UI pairwise similarities based on UI#. Specifically, it first embeds UI# via a CNN to infer visual semantics. A Siamese neural network is later applied to calculate the similarity score of two UI#. Finally, UIHASH uses the score as a metric to discover similar UIs across apps and reports them to security analysts.

We integrate UIHASH into an Android app analysis platform, shown in Figure 5. Utilizing this platform, we extract various app features beyond UI (e.g., manifest, static resources, and codes) to support cross-checking.

4.1 UI Parsing

Given an app, UIHASH first extracts UI information dynamically by Minicap [1] and UIAutomator [24]. Specifically, UIHASH launches the app and captures the main UI (i.e., the main activity). It then simulates tapping on each interactive view. If the app navigates to another UI, it repeatedly taps on the new UI and flags the UI as visited. This procedure

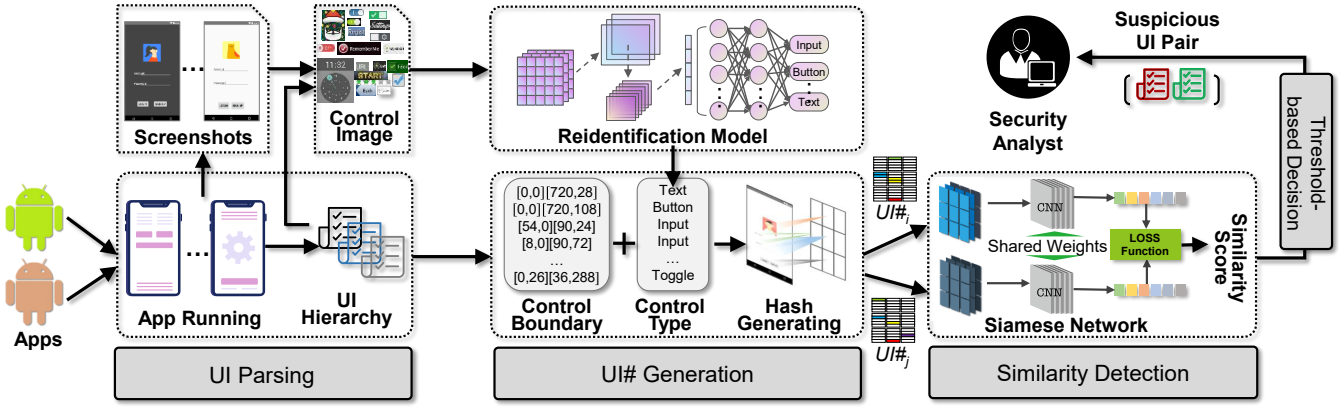

Figure 4: Overall architecture of UIHASH.

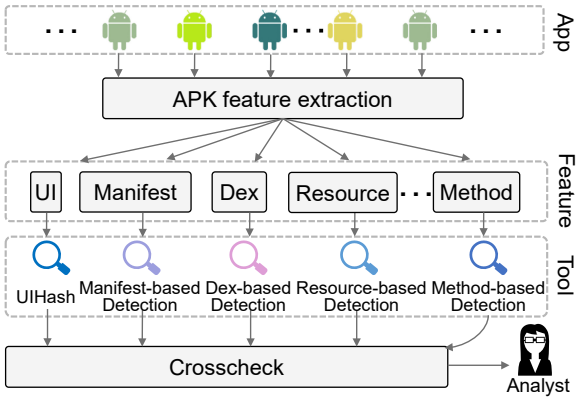

Figure 5: The platform for analyzing Android apps.

terminates if the visited UI set stops expanding. Note that apps may have unreachable UIs and non-launcher/exported UIs, which require user authorization or other apps to trigger. To collect these UIs, UIHASH also launches apps separately from each Android activity registered in the manifest. Before capturing each UI, we wait for a short period (0.2 seconds) to complete animations and online resource loading. We note that the presence of the `FLAG_SECURE` flag results in UIs returning empty data upon capture. However, given its limited use in real-world scenarios [16], we choose not to bypass the flag. We mark UIs without layout data as unobtainable. We provide further discussion on this flag in Section 6.

For each captured UI, we save its screenshot and dump its runtime hierarchy. Compared with static layout trees, the hierarchy reveals accurate runtime visual details like control boundaries [22]. We use it for bridging the semantic gap between static UI definition (i.e., layout tree) and dynamic UI visual appearance (i.e., images). In the meantime, we use UI screenshots to collect control images for subsequent type identification. It is worth mentioning that compared with image-based UI similarity detectors, the screenshots in UIHASH are not directly involved in the final UI similarity detection.

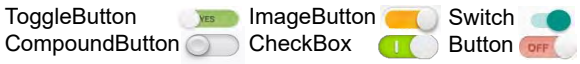

Figure 6: Six toggles implemented by different view types.

4.2 UI# Generation

UI Control Reidentification. We observe that controls may have a similar visual appearance even with different built-in View types defined by Android. For example, Figure 6 illustrates six apps that leverage controls labeled with different types to build visually similar "Toggles" on UIs. The UI similarity detection built on the declared control type is vulnerable if an adversary introduces visually similar controls with different built-in types, e.g., choosing an `ImageView` instead of a `TextView` to show text. App developers can also name and implement custom Views in Android [25]. Besides, inline advertisements pasted on UIs can be shown in different forms such as buttons, texts, images, etc. However, this difference cannot be reflected by the control names of advertisements, so we also need to conduct reidentification for advertisements.

We aim to reidentify the types for all UI controls to capture UI's visual features more precisely. More specifically, we assign new types to controls based on what they look like to humans instead of their original types claimed in the UI hierarchies. Specifically, UIHASH classifies UI controls to input, button, checkbox, list, spinner, tab, text, toggle, and bar. We manually label 27,000 control images extracted from RePack [38] and Rico dataset [41] to provide supervision signals. We use OpenCV [72] to extract control images from UIs, convert them to gray-scale, and unify their sizes. By backward propagating supervised signals from labeled UI controls, we optimize a CNN-based classifier to predict the probability of a UI control belonging to one of the nine types. If the probability of a type is beyond a pre-defined threshold (0.95 in our implementation), UIHASH identifies the control as the corresponding type. If no match exists, we annotate the control type as "Others". Afterward, we split all UI controls into ten

Algorithm 1: Generate UI# for a UI

```

               // drop the tiny exceed parts
12             if iou_i^e > threshold then
13                 v_i^j ← v_i^j + iou_i^e
           // revise hash values
14         v_i^j ←LOG_REV(v_i^j)
15 ℋ ← [v_1, v_2, ..., v_{n×m}] // semantic aggregation
```

types. We illustrate their example images in Appendix B.

Hashing UIs. we partition a UI into a grid with $n \times m$ regions of equal size. For each region, UI# encodes the size and type of its constituent controls into a k-dimension vector v_i, where $i = 1,2,...,n \times m$. Specifically, v_i^j, the value of the j-th dimension ($j = 1,2,...,10$) in v_i, is derived based on the overlapping between the controls in the j-th type group and the i-th region. To measure the overlapping between a region and a control, we take Intersection over Union (IoU, also known as Jaccard index [63]) as the metric. Given A_r and A_c, namely the region area and the control area, we calculate IoU by $IoU = |A_r \cap A_c| / (|A_r \cup A_c| \times A_r)$.

Algorithm 1 shows the detailed steps of UI# generation, which includes three main steps. First, the algorithm splits the UI to $n \times m$ regions. Coordinates of the i-th region (located in the a-th row and b-column) are calculated as follows:

$$cord^i = (\lfloor S_h/n \rfloor \times (a-1), \lfloor S_w/m \rfloor \times (b-1)),$$

where $a = 1,2,...,n$, $b = 1,2,...,m$, and $i = (a-1) \times n + (b-1)$. S_h and S_w represent the height and width of the screen. The $n \times m$ grid also indicates the spatial relationships among regions, e.g., we can deduce that "the i-th region is at the top left of the $(i+m+1)$-th region".

The second step is to extract visual semantics for each grid region. The algorithm first calculates IoU between a region and a control group in Line 11. IoU, ranging from 0 to 1, describes how a UI control overlaps with a locality. Note that we do not necessarily encode each control's IoU. The value is meaningful only if it exceeds a threshold (Line 12); otherwise, we pad it with zeros. In particular, when a UI control lies its principal part in a grid region, UI# ignores the exceeded areas in other regions. The design makes it difficult for adversaries to confuse the algorithm by fine-tuning control sizes to relocate them in different regions without changing the UI layout, even with the knowledge of the algorithm's underlying logic. Besides, we adjust the original IoU metric since a control's visual impact on the overall UI layout is not linear to its size. For example, after a 50% scaling on the original UI, the login rate drops 25% instead of being cut in half. Accordingly, UI# focuses more on the existence of controls and compresses the impacts of their sizes. Inspired by log transformation, which is widely used in digital image processing for detail reveal and image enhancement via compressing the dynamic range of an image [60], we define a normalized log-based transformation to revise UI#'s components: $LOG\_REV(x) = [f(x) - f(0)]/[f(1) - f(0)]$, where $f(a) = log_\gamma(a + 0.01)$.

Finally, we aggregate the vectors—representing individual grid regions—to generate UI# (Line 15). Aggregating UI semantics, UI# captures a high-level layout characteristic of the overall UI.

4.3 Similarity Detection

The next step in UIHASH is to compare visual semantics in UI# for UI similarity detection. Our insight comes from the grid representation UI# similarity is based on, which is comparable to that of images. To learn image visual (spatial) semantics, CNN is widely adopted [42, 64]. It can tolerate image distortions while generalizing visual features [62]. It is also invariant to image object translation, matching our intuitive understanding that partial UI view translations make a limited contribution to the overall UI visual appearance.

UIHASH utilizes CNN to embed UI# into a vector space (16 dimensions in our case). Intuitively, the relative distance between a pair of UI# indicates their visual similarities. In other words, the closer embeddings for two UI# to each other, the more similar appearances their related UIs share, and vice versa. For example, the four login UIs in Figure 1 are located nearby in the embedding space.

To infer visual semantics, our CNN model takes UI# as input, goes through two convolutional layers and three fully connected (FC) layers, and generates vector-representation visual semantics. Based on vectorized UI#, we further use a Siamese neural network to measure the similarities of their visual semantics. Specifically, UIHASH calculates UI similarity scores using the cosine similarity considering its simplicity and effectiveness. We define the Siamese network output as the cosine similarity of a pair of UI# and optimize network parameters by minimizing the following loss function:

$$loss = \min_{\theta} \sum_{i=1}^{N} (sim(v_1^i, v_2^i) - y^i)^2,$$

where θ presents the shared model parameters of the two CNN models in the Siamese network. N indicates the count of input UI# pairs, and y is the ground truth label.

Note that the app set is commonly enormous in Android UI analysis. Directly applying traditional gradient

descent (e.g., stochastic gradient descent) will be limited due to computational inefficiency. To address this issue, we leverage the mini-batch gradient descent algorithm [33] to split the training dataset into small batches before calculating model training losses and optimizing model parameters. Specifically, we use an Adam optimizer [10] with mini-batch optimization for CNN model training. We apply a grid search to get the best hyperparameters for the Siamese network. The learning rate and batch size are tuned among $\{0.01, 0.005, 0.0015, 0.001, 0.0005\}$ (with and without decay) and $\{16, 32, 64, 128, 256, 512\}$, respectively. We search the decision threshold for similar UI detection in $\{0.5, 0.6, 0.7, 0.75, 0.80, 0.85, 0.9\}$. In light of the best F1 score in our experimental environment, we show the results taking the initial learning rate as 0.001 ($\times 0.1$ every ten epochs), the batch size as 32, and the threshold as 0.6. We train the model for 36 epochs. Note that the configurable decision threshold illustrates the flexibility of the learning model because analysts can customize it according to different practical scenarios. For example, decrease it to satisfy high true positives or increase it to maintain low false positives. Based on the threshold, UIHASH differentiates similarity scores and detects UI similarity. If the similarity score of two UIs across apps exceeds the decision threshold, UIHASH categorizes them as similar UIs and reports to security analysts.

5 Evaluation

In this section, we evaluate on: **i**. How effective is UIHASH as a UI similarity detection system? (§ 5.1) **ii**. How common are active evasion attacks in the wild? (§ 5.2) **iii**. How robust is UIHASH against adversarial attacks? (§ 5.3) **iv**. How efficient is UIHASH? (§ 5.4) **v**. What benefits can analysts gain from our UI representation UI#, in addition to pairwise UI similarity detection? (§ 5.5)

5.1 Effectiveness of UIHASH

5.1.1 Comparison Analysis

In this section, we evaluate the detection effectiveness of UIHASH by comparing it with state-of-the-art similar UI detectors. Besides, we investigate the impact of different design choices on UIHASH's performance. Furthermore, we assess the effectiveness of UIHASH on new data by applying the pre-trained model to new apps.

Settings. To conduct a ground-truth-based evaluation, we expand the RePack dataset [30] with similar apps provided by a security enterprise and obtain a total of 18,359 apps (2,816 original + 15,543 repackaged). This app set is referred to as RePack-e. We label 6,371 similar UIs with the same activity name derived from known similar applications. We also generate 6,371 non-similar UI pairs by randomly sampling two UIs that do not come from a similar app pair and have different names. Based on this dataset, to evaluate the effectiveness of UIHASH in detecting similar UIs, we first randomly select 80%, 10%, and 10% of UI pairs to constitute the training, validation, and testing sets. We follow the guidance proposed in [9] to responsibly report results for our learning models, and avoid data snooping and biased parameter risks on two fronts: ① we ensure that there is no knowledge overlapping (e.g., repeated original apps/UIs) among the three subsets, considering that RePack-e includes cases with one original app and its many repackaged versions; ② we optimize UIHASH solely based on the validation set [39, 40, 82]. We compare UIHASH with state-of-the-art UI-based similarity detection baselines (without overlap), including text-based [44, 85], image-based [51, 56] and layout-tree-based [52, 70] methods. We take precision p (true positives vs. detected positives), recall r (true positives vs. ground-truth positives), and F1-score (harmonic mean of precision and recall) as evaluation metrics. Besides, we search for the decision thresholds for prior works with the highest F1-scores under the dataset used (e.g., $d = 10$ for pHash and $\delta = 0.82$ for GEMINISCOPE).

Approach	Precision	Recall	F1-score
Text-based detection [44, 85]	31.7%	83.0%	0.459
pHash [51, 56]	85.1%	79.7%	0.823
DROIDEAGLE [70] [1]	96.8%	86.5%	0.914
GEMINISCOPE [52]	95.6%	94.3%	0.949
UIHASH	**97.0%**	**99.8%**	**0.984**

[1] Two UIs are flagged as similar if their layout hashes are the same.

Table 2: Effectiveness evaluation results.

We illustrate how our design choices contribute to similar UI detection. (1) To justify the grid-based design, we perform an ablation experiment where the original feature values (e.g., size, position, and type) of controls are concatenated and directly fed into the Siamese model without being encoded into grids. (2) To investigate the impact of re-identifying controls, we remove this step and instead label UI controls based on their literal names (e.g., directly regarding a control named *Button* as a button). (3) To explore the effect of encoded control size, we fine-tune the base number γ, which controls control size encoding, among $\{2, 5, 10\}$. (4) To determine the optimal grid size, we apply various grid sizes (1×1, 2×2, 3×3, 4×3, 5×5, and 10×10) for UIHASH.

To assess the pre-trained UIHASH's effectiveness on new data, we test it on a different set from a leading security vendor, with 24/24 manually labeled similar/different UI pairs.

Results. Table 2 shows that UIHASH outperforms the prior UI similarity detection approaches on all metrics, especially on the recall rate and F1-score, indicating its stronger ability to find similar UIs. The receiver operating characteristic (ROC) curves in Figure 7 demonstrate a notable enhancement UIHASH gains on the area under the ROC curve (AUC). UIHASH performs better than methods based on single UI texts, which has the worst precision and F1-score, and obtains a 0.201 higher recall rate than the image-based method

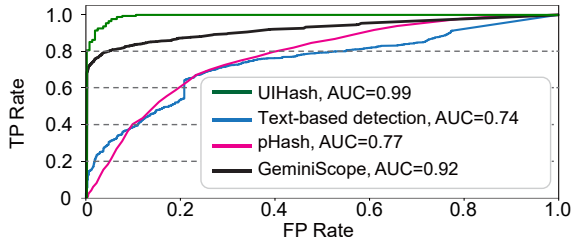

Figure 7: ROC curves of UI similarity detection methods.

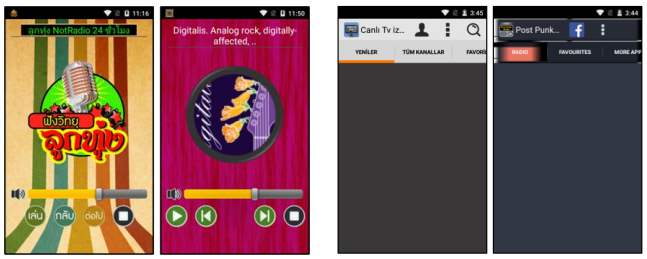

Figure 8: UI pairs that bypass screenshot-based approaches.

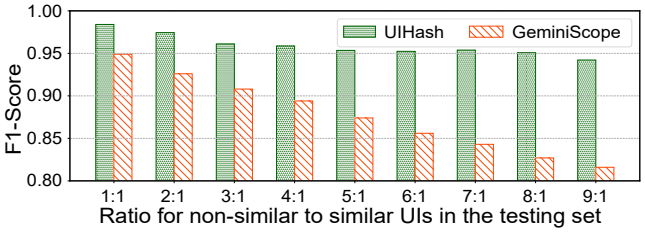

Figure 9: Effectiveness of similar UI detection under different ratios for non-similar to similar UIs in the testing set.

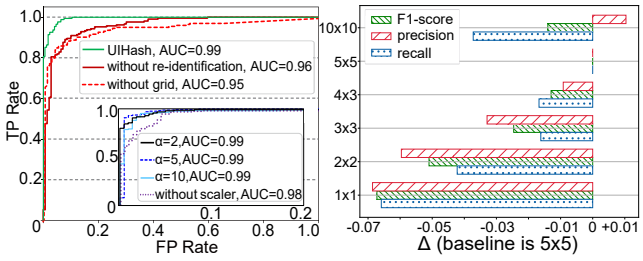
pHash [51, 56], reducing false negatives considerably. Figure 8 shows two UI pairs that bypass pHash but are detected by UIHASH as similar. Based on tree similarity, DROIDEAGLE does not consider that different layout trees might render similar UIs. In contrast, UIHASH achieves a 13.3% higher recall rate and a higher F1-score. Compared to GEMINISCOPE [52], which detects similar UIs based on pairwise View matching, UIHASH surpasses in all metrics. Considering that the amounts of non-similar and similar UIs are not equal in practice, we adapt the ratio for non-similar UIs to similar UIs in the testing set to explore its impact on similarity detection. Figure 9 illustrates that UIHASH's F1-scores against unbalanced datasets are lower than a balanced one, as prior research reveal [9, 59]. Nevertheless, its F1-score drops less than GEMINISCOPE's as the testing set becomes unbalanced. Specifically, even under a 9:1 ratio, UIHASH still performs better than all prior works. These results show that by relaxing the comparisons sticking to tree or control details, UIHASH gains better detection performance.

Figure 10a shows the ROC curves of UIHASH with different parameter settings. Results show that the grid-based UI# surpasses non-grid-based original features (p: 0.970 vs. 0.928, r: 0.998 vs. 0.881) in detecting similar UIs. Besides, UIHASH's effectiveness decreases without control re-identification. For size encoding, the base number (γ) only affects UIHASH slightly. However, if we remove the IoU revision in Algorithm 1 (Line 14), the effectiveness decreases. The experimental results demonstrate the essential roles grid-based encoding, control re-identification, and IoU revision play in UIHASH's UI similarity detection. For grid size selection, we illustrate the detection results of different gird sizes in Figure 10b. We observe that the size of 1×1 has the worst performance, especially on the recall rate. The reason is that one grid region cannot characterize the positions of UI controls and the layout of UI. The grid size of 3×3 achieves much better effectiveness. A possible reason is that it can represent the semantic of "center" vertically, horizontally, or both, which depicts a UI more accurately. In general, when we increase the size of a grid, the performance rises accordingly at first (e.g., 4×3 and 5×5) but turns down when the grid size becomes too large (e.g., 10×10). A reasonable explanation is that UI# loses its ability to *abstract* UI appearance and becomes sensitive to controls' exact position and size.

The above results show that a too-small grid size cannot fully represent a UI's visual appearance, while a too-large grid size decreases the tolerance to partial and minor UI changes. The 5×5 grid is used as a balanced trade-off between UI representation and tolerance.



On the new testing set, UIHASH successfully flags all the similar UIs, demonstrating its transferability across different datasets. Figure 11 shows two similar UI pairs in the dataset. Despite changes in UIs, UIHASH can still capture the visual similarity within individual pairs.

5.1.2 Effectiveness on Finding New Similar UIs

To explore how UIHASH performs on malicious apps and recent apps as a similar UI detection method, we apply the UIHASH model pre-trained by RePack-e on malicious apps and recent apps without retraining or fine-tuning.

Malicious Apps. We applied UIHASH on RMVDROID, an Android malware dataset [77] with 9,133 malicious apps confirmed by VirusTotal [3]. Unfortunately, UI similarity labels are unavailable for this dataset. As such, instead of evaluating UIHASH's effectiveness using ground-truth-based metrics like F1-score, we report interesting findings on identifying similar UIs using UIHASH. We successfully extracted 34,524 UIs from 8,879 out of 9,133 apps[3]. These UIs contain 280,750 visible controls, of which 95,025 controls are re-identified (confidence score ≥ 0.95). We further filtered out semantic-limited UIs with only four or fewer visible controls. In total, UIHASH generated 18,558 UI#. Then, we made pairwise in-app UI comparisons via UIHASH and dropped redundant UIs.

[3]The rest 254 (2.8%) apps stop running as soon as we launch them.

(a) Grid encoding (b) Grid size

Figure 10: UIHASH's performance with different setups.

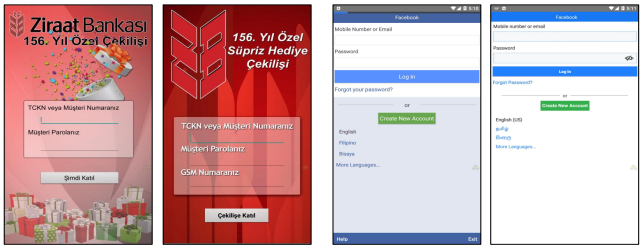


Figure 11: Similar UI samples in the new app set.

Finally, we got 11,561 UI# that constitute 66,812,868 pairs.

In all the UI# pairs, UIHASH identified 2,566,643 ones (3.8%) as similar. We group similar UIs and present the two largest groups in Figure 12. The left group contains 700 UIs from 700 apps developed by 387 different developers. A representative UI is named *com.kuguo.kuzai.Boutique.Activity* from the app *com.xiaobo.baobaogushihui*. These UIs all show "Elaborate App Recommendation" texts, implicitly inducing users to download apps from untrusted sources. These apps belong to the `kuguo` malware family and exhibit the family's characteristics including installation of apps from unknown or unverified download sites [54]. The second most frequent UI pattern (right) appears in 570 `airpush` malwares designed by 183 developers. An example of this pattern is the UI *com.google.android.gms.ads.AdActivity* from the app *com.appsministry.litres.book121140*. These UIs require user agreement to perform actions such as changing the browser's homepage, which is a representative behavior of the `airpush` family [18]. These results underscore the essential role that detecting similar UIs plays in identifying malicious app families—these apps not only implement the functions of their corresponding malware families through UIs but reflect the core traits specific to malicious families by UIs. Hence, despite inherent noise in UI-based similarity detection (e.g., not all apps with similar UIs are malicious), UI is important for discerning the inherently malicious nature of these apps. Analyzing UI provides a unique perspective for understanding malicious behaviors across various malware families.

Recent Apps. We collected 8,963 recent apps (uploaded from March 2022 to July 2022) from six app markets in Table 3 and extracted 84,972 UIs. These apps do not appear in all the above datasets. On average, we collected 10.8 UIs from one app. After dropping similar UIs within each app according to UI# comparison, we compared UIs between every two markets to explore cross-market and same-market UI similarities.

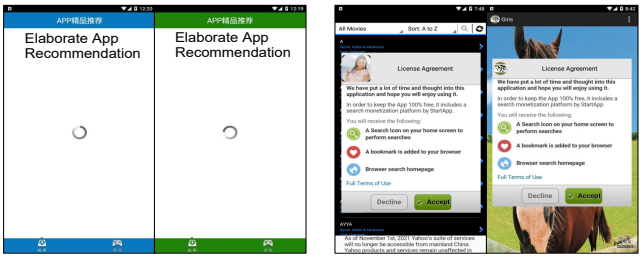

Figure 12: The two most frequently-used UIs in RmvDroid.

Market	App	Size	UI	Market	App	Size	UI
Kuan	1,231	80 GB	19,303	Mumayi	339	16 GB	2,331
2345	172	10 GB	826	Leyuan	6,649	245 GB	59,070
Vxat	224	12 GB	1,886	Appfun	348	10 GB	1,556

Table 3: Details of the recent app set.

We summarize the pairwise UI similarity in Table 4. For a pair of UIs, if one is from market A and the other is from market B, we mark the UI pair as a member in "market A - market B". Of all UI pairs, similar pairs account for 8.6% (Vxat - Vxat) to 13.4% (2345 - 2345). Given cross-market similar UIs, we manually confirm that 50 apps (different files from three out of five markets) share at least five similar UIs with their peers. Among the 25 app pairs, 22 pairs hold certificates from different issuers. For 23 out of 25 pairs, the apps differ in runtime behaviors, e.g., one of the apps displays ads or generates SMS payments while the other does not.

Besides, UIHASH finds the prevalence of similar apps in the same market. The dominant proportion of similar app clusters is found in Mumayi, where 51 apps (15.0%) gather because their main UIs are similar[4]. We note that app similarity might be ambiguous according to app features besides UI. For example, the two app pairs on the left in Figure 13 are not similar in none of their package names, developers, certs, and icons. Codes for the center app pair are not similar either.

Finally, UIHASH reports a similar UI pair associated with WeChat, a popular app for instant messaging[5] (Figure 13 right). The malicious version (left)[6] attempts to mimic the original splash screen and obfuscates it by modifying text contents ("English" to "Language"), substituting the background image, and fine-tuning button sizes and colors. VirusTotal [3] reports that the counterfeit app is a high-risk malware.

[4]There are another 55 apps with similar UIs. However, we manually confirm that it is the market instead of individual developers who customize and insert the UIs. Since the app-business-related UIs are not alike, we do not consider these apps similar.

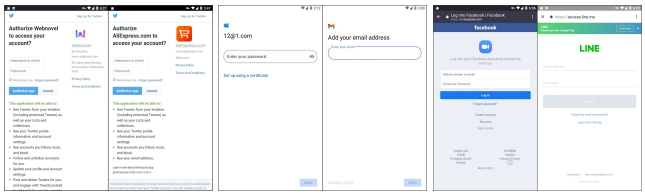

Figure 13: Three similar UI pairs we detect in recent apps.

5.1.3 Generalization of UI# for Practical Use Cases

In addition to its capability to detect similar UIs, we assess the extent to which UIHASH produces false alarms for security analysts, confirming whether our similarity measure exhibits excessive generalization for practical use cases.

Settings. As benign apps do not mimic other apps to deceive users and have unique UIs, UI pairs detected as similar are potentially false alarms. Therefore, we collected 75 login UIs from the top 100 Google Play apps and evaluated similarity among 2,484 UI pairs. We then analyze UIHASH's false alarms by examining similar UIs detected among benign apps.

Results. UIHASH flagged 58 UI pairs (2.7% of all) as similar. We confirmed that the majority of them are single-sign-on (SSO) UIs provided by famous enterprises such as Facebook and Twitter. However, the right two pairs in Figure 14 are not SSO UIs and belong to different online service providers. We show the positive UIs to the participants of our user study and ask for their similar ratings for the UIs. As Table 5 shows, SSO UIs are considered similar by users with high confidence (4.5 out of 5), though there are differences in icons and texts. Pair (b) also receives a high score (4 out of 5), which has more differences like `EditText` styles and the existence of micro controls. However, users have mixed options on whether pair (c) is similar. The score is close to the borderline (i.e., 3) but slightly lower, so we mark (c) as a false positive. Finally, of all the 2,484 UI pairs from the 100 apps, UIHASH raises eight false positives (Facebook login UIs to Line login UIs, 0.3% to all UI pairs). We believe that a 0.3% false positive rate is promising to scale up UIHASH for similar UI detection. In summary, UIHASH generates few false alarms and has a reasonable and not excessive similarity tolerance.

(a) Twitter SSO (b) Outlook-GMail (c) Facebook-Line

Figure 14: Similar UIs UIHASH detected in the top 100 apps.

UI Pair	Similar Rating (%)*					Average Rating
	1	2	3	4	5	
Facebook SSO	2.2	1.7	9.0	28.7	58.4	4.45
Twitter SSO	2.5	0	2.5	33.8	61.3	4.51

5.2 Active Evasion Attacks in the Wild

Among all the similar UIs we detected and confirmed in RePack-e, malicious apps, and recent apps, we further investigate the popularity of strategies adversaries may perform for active evasion attacks. Then, we quantify how different similar UI detectors perform in detecting similar apps.

Settings. We take six active evasion scenarios as examples. We identify a *flexible usage of view groups* evasion case when two visually similar UIs use different sets of view groups, where adversaries with Android UI domain knowledge leverage various view groups to achieve similar UIs and evade tree-based detection. Besides, we identify *micro controls* when their on-screen pixels are not greater than ten and identify *off-screen controls* according to their positions. We also identify image-based evasion attacks that target background images or hue changes. After rebuilding each UI pair by removing their background images (if available), we identify an evasion case of *image changing* if the new pair is detected by the pHash algorithm but the original one bypasses the detection. *Hue modification* is identified if a UI pair is classified as similar by pHash when traversing the color gamut. In the case of *empty text*, attackers insert `TextViews` without any visible content (e.g., whitespace characters) to obfuscate layout trees.

Results. Table 6 shows that 17.9% mimicry UIs utilize empty texts to obfuscate layout trees. The second popular option (17.7%) is the flexible usage of view groups. 15.4% evasion cases use image-based techniques (14.3% for image changing and 1.1% for hue modification). Evasions using invisible or microscopic controls account for 4.3%. Considering that the above active evasion techniques occupy more than half (55.3%) UI pairs, we point out that the active evasion attacks

Active Evasion Attack	Ratio	Image	Tree	UIHASH
Empty text	17.9%	✓	✗	✓
Flexible use of view groups	17.7%	✓	✗	✓
Image changing	14.3%	✗	✓	✓
Off-screen control	2.9%	✓	✗	✓
Micro control	1.4%	✓	✗	✓
Hue modification	1.1%	✗	✓	✓

Table 6: Identified techniques for active evasion attacks and whether they are flagged as similar by different methods.

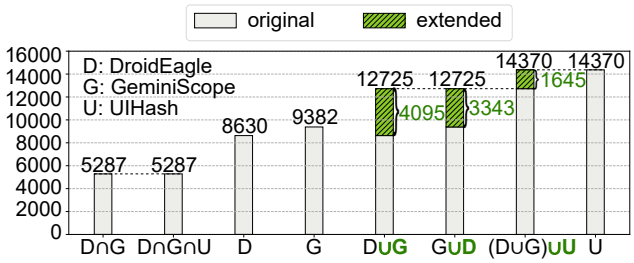

Figure 15: Similar app pairs (app pairs with similar UIs) flagged by different UI-based methods.

are already widely used in real-world apps. Figure 15 shows similar app pairs detected in RePack-e by different approaches. A combination of different prior work flags more similar apps than a single method, but is still inferior to UIHASH. In addition to all the true positive UIs the combination detects, UIHASH detects 1,645 more apps with similar UIs—which employ multiple evasion attacks to counter both tree-based and image-based methods. These results highlight the pivotal role that considering user perception plays in the detection of similar UIs. It stands as a key factor contributing to UIHASH's effectiveness compared to previous methods.

We also investigate the tree edit distance (TED) [84] of the similar UI pairs, which forms the basis for tree-based detection. The smaller TED is, the more similar two layout trees are. Figure 16 illustrates the results. The horizontal axis, α, is the ratio of the TED to the minimum tree size (i.e., node number) in a pair of UIs. The vertical axis, β, presents the percentage of the UI pairs whose α is not greater than the corresponding α. We find 27% UI pairs meet $\alpha > 0.25$ (point A), indicating that in 27% cases, the minimal cost of node edit operations to convert the smaller layout tree to the other is at least a quarter of the smaller tree size. Moreover, 5% of UI pairs require a TED not less than the smaller tree size (point B). In extreme cases, the operations are four times the smaller tree size (point C). These results demonstrate the prevalence of mimicry UIs in adopting evasion techniques on trees.

5.3 Robustness to Adversarial Attacks

With the growth of neural networks, adversarial examples (i.e., crafted inputs designed to deceive a neural network and result in mistakes) have become increasingly common for

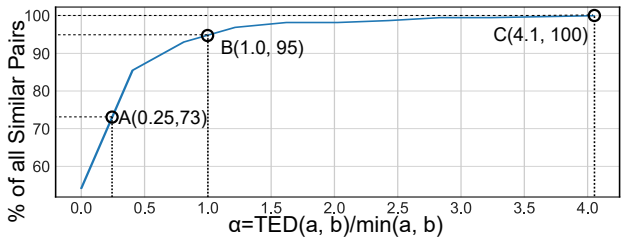

Figure 16: Tree edit distances of similar UI pairs.

learning-based detection evasion. Therefore, it is important to know how robust UIHASH is against adversarial examples.

Settings. We conducted two popular white box adversarial attacks via CLEVERHANS [57] on UIHASH with the RePack-e dataset, namely fast gradient method (FGM) [20] and projected gradient descent (PGD) [48], where the attacker is assumed to have complete access to the similarity detection model. Both attacks subtract or add a value δ to each UI# element, where $|\delta| \leq \varepsilon$. Since attackers may adjust the counterfeit UI to evade UIHASH (i.e., be detected as non-similar to the original one) while cannot modify the UIs in the imitated apps, we do not add perturbations on both the input UI#. Instead, we replace one of the UI# in the input UI# pair with an adversarial example and then calculate the similarity score for the new UI# pair. As ε is critical to attack for it determines the magnitude of perturbations, we explore different ε selections, namely 0 (i.e., no adversarial attack), 0.05, 0.1, and 0.2.

Results. We show the results in Figure 17. The precision and AUC gradually decrease with the increase of ε. In particular, PGD has a more significant effect than FGM. Guided by the attacker's goal of *using adversarial attacks to keep a visually similar UI from being detected*, we take a further step to manually check $UI_{P \rightsquigarrow N}$, i.e., true-positive UI pairs becoming false-negative after adversarial attacks. Interestingly, we observe that all these false-negative pairs are, in effect, no longer visually similar. A reasonable explanation is that UI# is an abstraction of UI rather than a pixel-grained representation. Consequently, perturbations to UI# work on the overall UI's visual appearance rather than locality. As such, UIHASH is generally robust to adversarial attacks.

5.4 Performance

We conducted all the experiments with a two-core@2.90 GHz CPU, 16 GB memory, and a GPU with 2 GB memory. The overhead mainly comes from UI dynamic collecting, which consists of time for installing/uninstalling apps and a 0.2s delay for each UI loading its contents. The collecting time can be reduced by parallelizing UIHASH on multiple Android devices [36]. On the RmvDroid dataset, UIHASH uses 1.3 h to extract 280,750 view images and takes 3.0 min to generate UI# for 18,558 UIs. It costs 6.2 min to filter similar UI# in each app, and the time cost for a brute pairwise search among

ε	Precision (P)		AUC (A)		$UI_{P\rightsquigarrow N}$ to all Pairs (N)	
	FGM	PGD	FGM	PGD	FGM	PGD
0.05	0.965	0.969	0.990	0.982	0.045	0.067
0.10	0.950	0.934	0.962	0.943	0.190	0.271
0.15	0.914	0.852	0.881	0.778	0.218	0.393
0.20	0.899	0.798	0.829	0.742	0.482	0.558

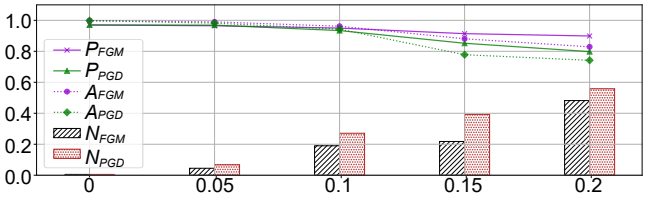

Figure 17: Evaluating UIHASH with RePack-e, against two adversarial attacks (FGM and PGD) with different ε.

Approach	Collect	Detect	Overall	F1	AUC
DROIDEAGLE	static	1.3 h (0.4)	9.6 h (1.9)	0.91	—
GEMINISCOPE	8.3 h (1.5)	1.4 h (0.4)	9.7 (1.9)	0.95	0.92
pHash-based	dynamic	0.2 h (0.05)	27.1h (5.3)	0.82	0.77
UIHASH	26.9 h (4.8)	1.5 h (0.5)	28.5 h (5.6)	0.98	0.99

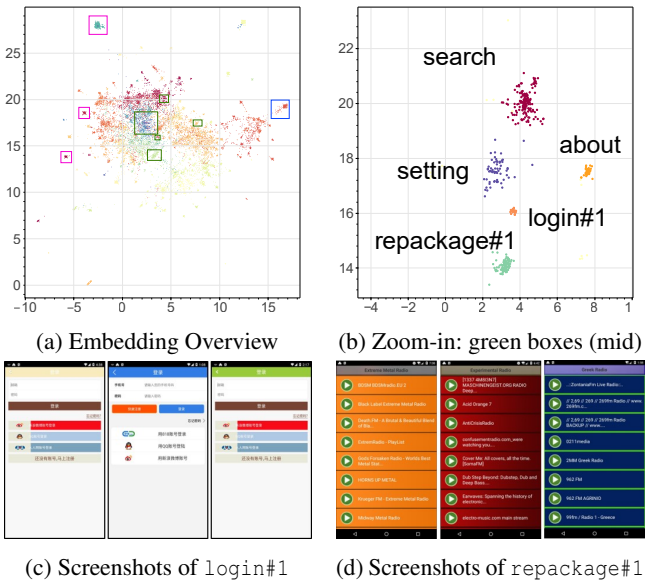
Table 7: Runtime (collect and detect), F1-score, and AUC on RePack of different detection approaches. The average seconds are indicated in parentheses (per UI, pair, and app for column Collect, Detect, and Overall, respectively).

66,812,868 UI pairs is 3.2 h (0.17 ms per pair on average).

We list the time overhead[7] of different methods for processing the RePack dataset in Table 7. We divide the above approaches into two groups, depending on whether they collect UIs statically or dynamically. Although dynamic UI collection incurs more than three times overhead compared with the static collection, we highlight that only by capturing UIs at runtime can a detector bridge the semantic gap between layout trees and UI appearances (further discussion in Section 6). Considering the overhead for extracting UI features and measuring UI similarity, pHash-based methods outperform their peers significantly. However, they perform the worst F1-score. We note that when generating UI#, re-identifying control images costs 94.8% time, but improves UIHASH's AUC from 0.96 to 0.99. Training the Siamese model takes much less time (3.1 min). With a pre-trained model, UIHASH finishes detecting tens of thousands of UI pairs in seconds. To conclude, UIHASH achieves a trade-off between overhead and effectiveness compared to the baselines.

5.5 Additional Applicability of UI#

5.5.1 Clustering Analysis



UI# can serve for clustering analysis besides pairwise UI similarity detection. Empirically, we can cluster similar UIs into groups, supporting two functionalities as follows:

- *Mundane layout filtering*. Some app UIs may share similar or even identical UI layouts, e.g., splash screens (a single `Image`) and dialogs (e.g., `Text` and `Button`). These UIs with redundant layouts bring a tedious burden to analysts when exploring UI similarity.
- *Targeted similar UI search*. Given specific benign apps, clustering analysis helps pinpoint UIs with a similar visual appearance at a large scale. When UIs are outliers or belong to mundane clusters with no sensitive information (e.g., "about" and "settings"), the underlying apps are less likely to be repackaged or cloned by adversaries for profit or phishing. Otherwise, we should inspect the apps whose UIs are neighbors of benign ones.

Settings. We conducted a UI#-based similar UI clustering analysis among 20,000 UIs randomly sampled from all UIs. Specifically, we use the agglomerative hierarchical clustering analysis (HCA). It performs well for other security applications, such as system behavior clustering from audit logs [81]. Initially, each UI# belongs to its cluster. HCA then iteratively calculates similarity scores between every two clusters and combines the nearest clusters until the maximum similarity is below a merge threshold. We calculate the semantic relationships between two UI# based on their Euclidean distance and evaluate the distance between two clusters by the Ward variance minimization [65]. To understand the internals of UI#, we further projected a multiple-dimensional UI# to a plane and visualize the cluster results. We adopt Uniform Manifold Approximation and Projection (UMAP) [53] for dimension reduction while preserving structural information among UI#.

Results. We show the visualization for UI#-based clustering analysis in Figure 18. In general, UI# with similar visual appearance group together while UI# with different appearances are separated with clear boundaries. For each cluster, we perform manual verification by reviewing UI screenshots and identifying the UI functionality (e.g., *login*, *setting*, and *gamestart*) as its descriptor. The dense clusters in the visualization usually indicate app cloning or repackaging. For example, we identify 64 repackaged "*Radio" apps in `repackage#1`, they have identical Java codes but try to bypass UI-based detection by changing UI background colors. We also identify several clusters related to sensitive UIs, including different UI patterns frequently used for *login* UIs (e.g., `login#1`). Besides, we pinpoint some other clusters with various high-level semantics, like *setting*, *about*, *search*, and *gamestart*. We illustrate more examples in Figure 20 (we provide more details in Appendix B). Finally, by identifying mundane UI clusters, including simple dialogs (a text and one or more buttons at the bottom) and splash screens (a single full-screen image), we filter out 3,724 (18.6%) UIs. After further deploying the filter on RePack-e, we reduce the time cost for UI similarity detection by 21.8%. The results show that

[7] Note that all the baseline tools are not publicly available, so their overheads are related to our implementations. All the implementations are Python-based. Specifically, for DroidEagle, we set its parameter $\tau = 2$.

(a) Embedding Overview (b) Zoom-in: green boxes (mid)

(c) Screenshots of `login#1` (d) Screenshots of `repackage#1`

Figure 18: UMAP visualization of the UI#. (a) shows the embedding space of 20,000 UIs. Each dot denotes a UI#.

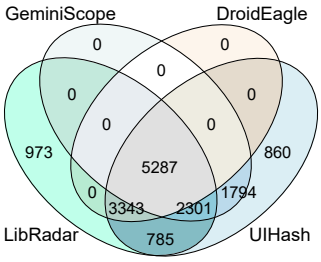
Method	LibRadar	SimiDroid	Manifest	Resource
$\frac{filtered*}{\text{UIHash } FP}$	42/48 (87.5%)	48/48 (100%)	48/48 (100%)	48/48 (100%)
$\frac{\text{UIHash } TP}{missed*}$	87/92 (94.6%)	461/526 (87.6%)	314/450 (69.8%)	6,039/6,643 (90.9%)

Table 8: UIHash works with other app similarity measures. The first row shows our false positive app pairs and pairs filtered by other methods, and the second row lists the missed app pairs of other methods and the pairs we detected.

the clustering analysis can mitigate the burden of searching for similar UIs on a large scale by removing mundane UIs.

5.5.2 Complementary Strength with Related Solutions

Settings. We take all the 15,297 similar app pairs in RePack as ground truth to evaluate the complementary strength of the solutions. In the Android app analysis platform (Figure 5), we deploy UIHash and four other methods, namely LibRadar [47], SimiDroid [37], Manifest-based, and Resource-based, to detect app similarity (We provide more details in Appendix B). We incorporate UIHash with the above methods in two ways. First, as a UI-based method, UIHash can detect similar apps that other methods fail to discover. Second, other methods can improve UIHash by filtering its false positives. Note that for UIHash, if any UI pair in two apps are similar, we flag the app pair as similar. For other detection approaches, two apps are potentially similar when their similarity score is not less than 0.5.



Results. Table 8 lists the results of corporating UIHash with other app similarity detection methods. As the first row shows, all the methods effectively filter out UIHash's false positives. Specifically, by incorporating SimiDroid, Manifest-based comparison, or Resource-based comparison, UIHash's precision reaches 1.0 as all the 48 false positives generated by UIHash are similar considering beyond-UI features. On the other hand, by taking UIHash as a complimentary detector, all the other four methods reduce their false negatives significantly (the second row): the drops are from 69.8% to 94.6%. It is also worth noticing that by combining UIHash and other methods, we improve the ground truth in the RePack dataset. Table 9 shows four app pairs detected as "false" positives by UIHash. By checking their similarity via other tools, we confirm that they are similar app pairs missed by RePack.

Finally, we combine LibRadar—which detected the most similar apps among non-UI-based methods in our experiment, and UI-based baselines including GeminiScope and DroidEagle. Then, we examine whether UIHash can strengthen the combination. Figure 19 shows that UIHash and the combination helps each other detect 5.9% and 6.8% more similar apps in RePack-e. It suggests that when studying app similarity, utilizing a reasonable combination of multiple app features will outperform a single-feature-based detection.

APK Pair	L	S	M	R	RP
pet.app46 imdroid.dina.hamel	1	0.99	0.88	0.44	✗
com...floppyspace com...stone	0.63	0.54	1	0.27	✗

[1] **L**, **S**, **M** and **R** denotes LibRadar, SimiDroid, Manifest-based, and Resource-based comparisons, respectively.
[2] **RP** indicates whether the pair is disclosed in RePack.

Table 9: New similar app pairs in RePack found by UIHash and their similarity scores given by other approaches.

(G ∪ D ∪ L) ∪ U	U ∪ (G ∪ D ∪ L)
14,483 **+860** (+5.9%)	14,370 **+973** (+6.8%)

Figure 19: Similar app pairs detected by GeminiScope (G), DroidEagle (D), LibRadar (L), and UIHash (U).

6 Discussion

Necessity for Dynamic Analysis. Despite runtime UI collecting still has work to do in terms of performance and coverage [31], we choose dynamic UI information as the detection basis, considering: ① *Active evasion attacks.* According to

our empirical study, adversaries can build layout files with advanced evasion techniques. Therefore, we cannot capture accurate UI visual appearances with only static layout trees; ② *Runtime UI adjustments.* It is a common practice to update UIs at runtime, and dynamic analysis works for obtaining UI properties with runtime updates; ③ *Protected app source code.* While benign apps adopt obfuscation [2] and packers [75] to protect codes from reverse-engineering, Android malware also increasingly leverages these techniques to evade detection [71]. Besides, Android apps could mask their runtime behaviors via anti-emulator techniques [7, 78]. As a countermeasure, we make UIHASH's UI extraction module easy to deploy on both emulators and physical devices.

Defense against GUI Squatting Attack. UIHASH by design can detect spoofing UIs generated by GUI squatting attacks [14], the state-of-the-art method for developing phishing apps. To fabricate a UI, the attack specifies control attributes (e.g., `width`, `height` and margins) with fixed values analyzed from the original screenshot. Each layout file resulting from this attack contains a single root ViewGroup with all the remaining controls as its children. This new layout structure usually differs significantly from the original one. Thus, GUI squatting attacks can easily evade tree-based detection. Nevertheless, UIHASH can detect these spoofing UIs based on UI# similarity, raising the bar of GUI squatting attacks.

Threat to Vadility. Android apps can use `FLAG_SECURE` flag to prevent specified UIs from being captured. While we can gain root access and employ an Xposed mod [4] to bypass this flag, we refrain from implementing such a solution, as apps involved in privacy-sensitive tasks may require device integrity (e.g., by Attestation API [23]). To extend UI capture capabilities, we can integrate UIHASH with heuristic GUI testing tools [27, 43]. UIHASH can also benifit from Chrome DevTools [21] when handling `WebView`.

For generality, we divide the screen equally when abstracting UI. It's worth mentioning that optimizing grid parameters, such as employing unevenly distributed grids to prioritize specific screen areas, could improve UIHASH's effectiveness in some scenarios. We leave this as a subject for future research.

7 Related Work

There has been active research inspecting app similarity based on different app features, including code [19, 28, 55, 73], static assets (e.g., images, icons, and XML files) [35, 44, 85] and UI. We categorize Android UI similarity detections into two groups based on their detection basis (static layout tree structure or runtime screenshot image). To our best knowledge, we are the first to discuss active evasion attacks from both tree-based and image-based aspects.

Tree-based Detections. Sun et al. propose DroidEagle [70], a system for similar UI detecting by measuring their tree edit distance (TED) or tree hashing. TED is also the metric for similarity measuring in other works such as FUIDroid [45] and RepDroid [79]. In addition to comparing trees, researchers also conduct pairwise similarity comparison on UI components [52], and feature engineering based on tree node attribute [67] or hierarchy structure [30] to compare UI similarity. Patil et al. [58] build a tree-based graph and train a graph matching network (GMN) for UI similarity detection.

All the above approaches take layout trees or hierarchy trees of UI as input. However, they do not use visual-appearance-related features like control visual type and size. Moreover, various active evasion attacks are available to modify trees, resulting in tree-based detection bypassing.

Screenshot-based Detections. Another research stream of UI-based similar app detection is based on extracting and comparing screenshot features. Perceptual hash (pHash) is a popular image descriptor [34, 49, 51, 56]. For example, Malisa [49] detects repackaging apps by calculating hash values of screenshots for a rough sampling and making further confirmation via layout trees.

Screenshot-based methods are not robust against simple UI modifications (e.g., changing background color or image contents) and adversarial noises (or tiles) [68, 69]. In contrast, UIHASH focuses on representing UI's visual appearance features instead of making strict pixel-level comparison.

8 Conclusion

In this paper, we propose a novel approach, UIHASH, to detect similar Android UIs based on their visual features perceived by users. Aiming to sketch UI appearances, we abstract them into #-shaped grids, which we refer to as UI#. We then develop a neural network architecture to distill visual features from UI# representations and compare their similarity. We evaluate UIHASH using 52,390 real-world apps. The experiment results demonstrate UIHASH's accuracy and robustness in detecting similar UIs. We also discover that similar UIs generated by active evasion attacks are already prevalent in the wild, invalidating existing tree-based and screenshot-based detection methods.

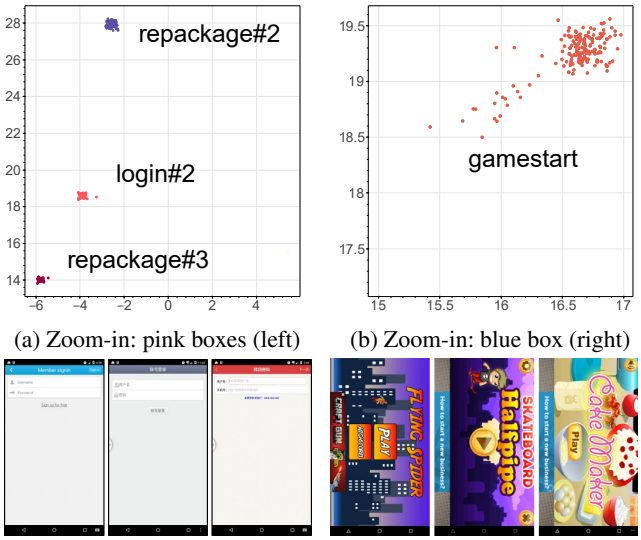
A Active Invasion Attack via Invisible Views

An effective way for adversaries to implement an active invasion attack is by inserting any number of invisible views (view groups or controls) into a layout tree, as Listing 3 shows. The imperceptible views contribute nothing to UI's visual appearance but break down the tree-based detections. Note that many view attributes are available for such active invasion attacks. For example, the last `Button` in Listing 3 makes its size zero by position-related (instead of size-related) attributes.

B Design and Evaluation Details

Control Types for Reidentification. We illustrate the control types for reidentification in Table 10. All images in a specific type share specific image characteristics, except for the type *Others*, which consists of images shown on UIs and uncommon controls (e.g., rating bar).

Baselines for App Similarity. We provide more details of the baselines for calculating app similarity as follows: 1) LibRadar [47]: an accurate and anti-obfuscation tool for scanning third-party libraries. Given two library set L_a and L_b, their similarity score is given by $\max\{[L_a \cup L_b]/[L_a - L_b], [L_a \cup L_b]/[L_b - L_a]\}$. 2) SimiDroid [37]: an app comparison framework that yields method signatures and representations of statements at the source code level. 3) Manifest-based comparison: app comparison based on metadata (e.g., package), components, and permissions. We measure app similar-



Type	Description	Examples
Input	areas to enter texts	
Button	clickable rectangles or icons	
CheckBox	small areas to check off	
List	consecutive items in one template	
Spinner	areas with a mark to show a drop list	
Tab	banners for navigating	
Text	areas to show text contents	
Toggle	switches to make a boolean choice	
Bar	bars to show progress or fix values	
Others	controls that do not belong to the above types	

Table 10: Control types for reidentification.

(a) Zoom-in: pink boxes (left)

(b) Zoom-in: blue box (right)

(c) Screenshots of `login#2`

(d) Screenshots of `gamestart`

Figure 20: UI samples for different clusters.

ity as that of LibRadar. 4) Resource-based comparison: we apply pHash [80] to find similar images and icons between two apps and search for identical static resources of other types by checksum comparison. Given the resource file sets of two apps F_a and F_b, the number of similar images P_s, and the number of other identical resource files, R_s, the similarity score is given by $\max\{[P_s+R_s]/[F_a-F_b],[P_s+R_s]/[F_b-F_a]\}$.

More Details of UI# Clusters. We illustrate more zoom-in plots and UI screenshots for the clustering results in Figure 18a. We find another *login* UI pattern as Figure 20c shows, which is different to `login#1` (Figure 18c). Besides, UIs in `repackage#2` and `repackage#3` correspond to two repackaging bundles (with 24 "India Newspapers" apps and 18 "Software Stills" apps, respectively). For UIs in the `gamestart` cluster, despite different background images, colors, texts, and fonts, they are still grouped as they share a similar appearance to achieve the same design goal (starting game and showing an advertisement at the bottom of the screen).

Age	<20	$[20,40)$	$[40,60)$	≥ 60	Others
Male	15	120	25	2	5
Female	12	56	54	5	2
Others	4	8	0	3	8

Table 11: Gender and age demographics of participants.

C User Study Details

We list the survey questions of our user study in Listing 4, and summarize participant demographics in Table 11. Our exit survey reveals that 81.2% of users have experienced UI changes in their frequently-used apps, while 8.5% do not notice any UI changes. Specifically, all users spending less than one hour per day on apps or have no frequently used apps report a lack of awareness of app UI changes.

A. Demographic Survey

A1. What is your age? (age range or "perfer not to say")
A2. What is your gender? (gender or "perfer not to say")
A3. Are you skilled in using your smartphone?

B. UI Similarity Evaluation

B1–B12. Would you perform login on this screen? (pic)
○ Yes, I accept to log in ○ No, I reject logging in
B13. What factors prevented you from signing in? Select (zero to all) options in order of importance.
☐ Background color or image contents
☐ The position relationship of interface elements (such as buttons and input boxes)
☐ Texts on the screen
☐ Size of interface elements
☐ Style (such as fonts, borders, and colors) of interface elements (such as buttons and input boxes)
☐ Else: (*please fill in the blank*)

C. Exit Survey

C1. How much time do you spend per day on phone apps?
○ <1 h ○ ≥ 1 h but <2 h ○ ≥ 2 h but <4 h ○ ≥ 4 h
C2. How many apps do you use frequently?
○ 0 ○ 1–3 ○ 4–6 ○ 7–8 ○ >8
C3. How many apps you have used have UI changes with version updates?
○ All / Almost all (80%–100%)
○ Most (60%–80%)
○ About one–half (40%–60%)
○ A few (20%–40%)
○ None / Hardly any (0–20%)
○ I do not concern about app UIs
C4. Are you good at manipulating your smartphone?
○ No, I am not good at manipulating my smartphone
○ Yes, I can manipulate my smartphone smoothly

[2]Carleton University, Ottawa, Canada

Abstract

Besides developers' code, current Android apps usually integrate code from third-party libraries, all of which may include code for TLS validation. We analyze well-known improper TLS certificate validation issues in popular Android apps, and attribute the validation issues to the offending code/-party in a fine-grained manner, unlike existing work labeling an entire app for validation failures. Surprisingly, we discovered a widely used practice of overriding the global default validation functions with improper validation logic, or simply performing no validation at all, affecting the entire app's TLS connections, which we call *validation hijacking*. We design and implement an automated dynamic analysis tool called *Marvin* to identify TLS validation failures, including validation hijacking, and the responsible parties behind such insecure practices. Among 7826 apps from a Chinese app store and Google Play analyzed by Marvin, we found many occurrences of insecure TLS certificate validation instances (55.3% of the Chinese apps and 6.4% of the Google Play apps). Validation hijacking happens in 34.3% of the insecure apps from the Chinese app store and 21.1% of insecure Google Play apps. A network attacker can exploit these insecure connections in various ways, e.g., to compromise PII, app login and SSO credentials, to launch phishing and other content modification attacks, including code injection. We observed that most of these vulnerabilities are related to third-party libraries used by the apps, not the app code created by app developers. The technical root cause enabling validation hijacking appears to be the specific modifications made by Google in the OkHttp library integrated with the Android OS, which is used by many developers by default, without being aware of its potential risks. Overall, our findings provide valuable insights into the responsible parties for TLS validation issues in Android, including the validation hijacking problem.

† Equal contribution.

1 Introduction

According to GlobalStat [47], Android smartphones have exceeded 72% of the smartphone market share in 2023, indicating the increasing importance of Android security. Despite the success and prevalence of TLS for app security, its use is marked with many security issues (see e.g., [29, 35, 36, 50]). Existing studies are exemplified by Wang et al. [50, 51] identifying vulnerable TLS implementations with code snippets; and Oltrogge et al. [35] demonstrating that Google's Network Security Configuration (NSC) and Google Play Safeguards failed to detect vulnerable TLS implementations.

Among the various ways TLS can go wrong, we focus on the validation of the TLS certificate, which is the foundation of establishing secure communication. Existing research largely considers validation issues per-app, even though validation functions from several entities, including the app developer and authors of various libraries (e.g., ads, analytics) used in a given app, may be involved in an app's TLS connections. Beyond finding the responsible parties behind TLS validation problems, perhaps more importantly, existing work also does not explore how or whether these parties can affect each other's validation effort without the other parties' knowledge. Note that stealthy data collection by third-parties is a well-studied problem in the literature (e.g., [24, 26, 42, 44, 49]).

In this paper, we detail the design and implementation of an analysis tool called *Marvin*[1] to attribute TLS certificate validation problems to more specific parties, e.g., the app developer or various libraries included in the app, i.e., not just the app as a whole. When validation mistakes happen in a library affecting other entities in the app (e.g., the app developer and other libraries), the impact can be significantly higher (compared to an app developer's faulty TLS validator) as a library may be used by a large number of apps. Using Marvin, we systematically analyze insecure TLS connections in Android apps resulted from improper certificate validation

[1]Marvin is the paranoid but super-intelligent Android in The Hitchhiker's Guide to the Galaxy series: https://en.wikipedia.org/wiki/Marvin_the_Paranoid_Android.

by: 1) exercising the states of the apps with UI interaction to maximize the coverage of connections; 2) tracing real-time code execution for TLS validation-related functions; and 3) capturing corresponding network traffic with a man-in-the-middle proxy (mitmproxy [15]). We use certificates with common and well-documented validation issues in our proxy, so that the statistics from the measurements and the attribution results are self-evident and built on verified grounds.

For each established connection through the proxy, i.e., when the invalid certificate is accepted by the app, Marvin extracts various metadata for attribution purposes, e.g., destination address, app name, functions involved in the validation. Our fine-grained attribution process led us to discover a highly insecure practice we term as *validation hijacking*: the app's or an included library's code globally setting default insecure TLS validation functions, resulting in a significant number of certificates being validated by the set function (simply bypassing the validation in many cases), unbeknownst to the code initiating the connections (after such global modifications), e.g., the app developer's code or a third-party library's code.

We use Marvin to analyze a set of representative apps (in terms of user base) collected from Google Play and 360 Mobile Assistant (Qihoo 360, a popular Chinese app store [18], which allows automated app download). Marvin identifies many instances of validation issues, a majority of which are in Chinese apps due to their inclusion of a few very popular but problematic SDKs, e.g., Tencent Bugly [17]. We traced back the root cause of validation hijacking to specific modifications that honor the improper override (introduced by Google) to the OkHttp library included in the Android OS, although other HTTP libraries can also cause similar issues.

Our seemingly straightforward approach is faced with several challenges. For instance, numerous apps (especially those from the Chinese app store) are protected with strong state-of-the-art commercial packers, mainly against dynamic analysis as well as code obfuscation, rendering execution tracing very difficult. Furthermore, our attribution process requires tracing Java interfaces, which cannot be directly hooked; instead, their implementations need to be hooked, necessitating an exploration of the entire code loaded into memory to identify their implementation and utilize Java reflection to match them with their definitions for the hooking process. Some apps also do not adhere to the system proxy settings, and network traffic encompasses a mix of connections originating from the entire Android platform, system apps, and the target app, making it difficult to capture and filter traffic from the target app only.

We partially address such challenges so as to be able to conduct our analysis, and ensure that our findings are correct and the reported numbers are a lower bound (i.e., we may have false negatives, but no false positives). For example, we make use of eBPF [9], a kernel-level restricted but privileged execution environment, to avoid being detected, to separate a target app's network traffic, and to redirect connections not respecting the system proxy setting.

Contributions and notable findings.

1. We design and implement *Marvin*, an automated tool to perform a large-scale automated analysis of common TLS certificate validation issues, and to identify the responsible code/party for such validation failures, including a novel but very damaging case we call *validation hijacking*. We will open source Marvin.
2. We report on the prevalence of TLS validation failures across 7826 Android apps from two different app stores, consisting of 2765 Chinese ecosystem apps and 5061 Google Play apps—all automatically analyzed by Marvin. We identified that 55.3% of the apps in the Chinese app store and 6.4% of the Google Play apps have at least one connection with its TLS certificate not properly validated, which can lead to MITM attacks.
3. We conduct a fine-grained attribution, which, for the first time, attributes the TLS certificate validation failures to either an app's code, or the code of one of the multiple libraries an app uses. Such attribution should make a significant difference in remediation (vs. simply criticizing insecure developer practices). No past studies identified the truly responsible party behind such failures—i.e., the entity performing faulty validation, which indeed can be different than the originator of the TLS connection.
4. We draw attention to a pervasive but never discussed phenomenon, TLS certificate *validation hijacking*, especially, given many instances of such hijacking as detected by Marvin: 524/1529 (34.3%) of the Chinese apps, and 68/322 (21.1%) of the Google Play apps with TLS validation issues suffer from validation hijacking.
5. We identify the high-profile libraries which perform validation hijacking by overriding `setDefaultSSLSocketFactory()` or `setDefaultHostnameVerifier()`, e.g., Tencent Bugly, Baidu Location SDK, and Bytedance SDK. However, as we uncover, such hijacking is ultimately enabled by Google's modifications to the OkHttp library (the default Android HTTP client).
6. We show concrete issues resulting from the identified TLS validation issues, both in terms of information disclosure and content modification attacks by an on-path network adversary. We found that 88.8% of the Chinese apps and 37.6% of the Google Play apps with TLS validation issues use insecure TLS channels to transmit sensitive information. Our case studies with selected apps highlight the severity of the identified risks (tested on our own accounts): user credentials including one-time passwords and SSO login credentials (e.g., Google, Facebook, Twitter) compromise allows account takeover, in-app phishing, and even remote code execution.

We will open-source our tool on: https://github.com/Madiba-Research/Marvin.

Disclosure. In the process of disclosing our findings, we reached out to Google and the libraries that hijack the TLS verifiers, including Bugly. We also contacted all the developers of the vulnerable apps mentioned in this work. For Google and Bugly, we contacted them via their bug hunters' platform, as well as through email communication for remaining cases, except for `com.newsweekly.livepi`, where we utilized their in-app contact form due to the absence of an email address. Developer email addresses for Google Play apps were directly obtained from the Google Play Store. However, for Chinese apps, as contact information on the 360 Mobile Assistant website was unavailable, we relied on various sources, including the apps themselves, their respective websites, and development websites, to acquire email addresses. Throughout our communication with all involved parties, we meticulously outlined the identified vulnerability, its associated risks, and provided detailed information on potential remediation methods. Additionally, we offered app developers a fallback methodology to partially rectify their code if removing the insecure library proved challenging. Google acknowledged the issue after multiple interactions, stating they cannot address it "without introducing app compatibility risks". They also mentioned exploring the possibility of introducing warnings or errors to Android Studio when this behavior is observed, along with other mitigation methods. On the other hand, Bugly refused to accept our finding as an issue for their library. The remaining vendors did not respond to us (as of Feb. 21, 2024).

2 Related Work

In this section, we summarize related work from the literature, and discuss the unique aspects of our work.

TLS security analysis of mobile apps. In general, TLS problems identified in apps may involve two cases: defects in a given implementation such as the use of weak cipher suites [40], and improper use/choice/configuration of TLS libraries [51]. Fahl et al. [30] performed the first in-depth study of the widespread SSL problems through studying code snippets and advice in developer forums, and interviewing app developers. They revealed that customized SSL functions as used by developers, and their partial understanding of SSL are the two main reasons for weakening SSL security. Georgiev et al. [31] demonstrated that SSL certificate validation is completely broken in many security-critical apps and libraries, such as Amazon's EC2 Java library and Google AdMob, and attributed these vulnerabilities to badly designed APIs of SSL implementations, e.g., JSSE, OpenSSL and GnuTLS. Oltrogge et al. [35] discovered that Google Play failed to detect vulnerable TLS implementations in their investigation of the effectiveness of Google's Network Security Configuration (NSC) and Google Play Safeguards. Possemato et al. [36] performed an extensive study on Google network defense mechanisms and found that network security policy in apps can downgrade security by allowing cleartext protocols or by trusting the union of CAs from both System and User KeyStore. Additionally, they noticed that several popular ad libraries require apps to weaken their security policy.

Wang et al. [50,51] employed both static and dynamic analysis techniques to identify the vulnerable implementations of TLS in Android apps. Their tool, DCDroid [50], uncovered four types of vulnerable implementations of TLS (i.e., `X509TrustManager`, `HostNameVerifier`, `WebViewClient`, `X509HostnameVerifier`). However, it could only detect simple vulnerable TLS implementations (e.g., by implementing the standard Java interface with a few or even a single instruction), and may fail to identify complex ones. In practice, TLS functions can be improperly implemented in various ways, which does not affect our methodology. DCDroid also found some apps to be vulnerable because they invoked vulnerable third-party SDKs; however, the entity that was validating the certificate was not identified. Applicable to all the aforementioned studies, no fine-grained attribution was conducted (e.g., identifying the responsible parties for validation failures, and validation hijacking between parties).

System proxy and dynamic analysis evasion. Most existing dynamic analysis studies do not consider proxy evasion by Android apps (e.g., [33,41,44,51]), which may have affected the reported results, i.e., missing connections from such apps. However, two studies [25,37] addressed this issue by using API hooking. Nevertheless, this approach is also not fully reliable as many apps are becoming aware of dynamic binary instrumentation (DBI). In contrast, the use of eBPF in Marvin at the kernel level is impossible for the apps to detect without root access. With regard to dynamic analysis evasion/detection, NCScope [56], a hardware-assisted tool to scrutinize native code of potentially packed apps, leveraged ETM (a hardware feature of ARM processors) and eBPF to collect real execution traces and relevant memory data of apps. However, NCScope can only detect the presence of self-protection and anti-analysis mechanisms but not evade them (i.e., the app still crashes).

Third-party code identification. Pradeep et al. [38] conducted a comparative analysis of certificate pinning with an exclusive focus on third-party components in apps. To differentiate between first-party and third-party code, they set the following threshold: if a code path was found in more than five apps, it was categorized as a third-party source. Muslukhov et al. [32] attributed whether a package name corresponds to an app, a library, or a possible library, by searching an exhaustive list of package names for libraries and potential libraries; such lists of course become stale with time.

Sensitive data leakage. Wang et al. [49] uncovered a new attack vector: malicious libraries strategically target other vendors' SDKs integrated in the same host app to harvest private user data. They found 42 distinct libraries stealthily harvesting data from 16 popular SDKs, affecting over 19K apps. Nguyen et al. [33] performed a large-scale measurement of 86,163 Android apps to understand the current state

of GDPR's explicit consent violation. They found that 24,838 apps share personal data without the user's explicit consent. Pourali et al. [37] implemented ThirdEye to detect privacy issues via non-standard and covert channels. They identified that 2887/12,598 (22.92%) apps used *custom encryption* (where data is encrypted by an app before being sent over the TLS channel) for network transmission and storing private content in shared device storage. Reardon et al. [42] found that Jiguang's SDK (a Chinese SDK) evasively monitors user's activities and collects user information, e.g., GPS location, identifiers (e.g., device serial, IMEI), and the names of the installed apps. Although we identified several highly popular libraries involved in TLS validation hijacking, we are unsure about their motives, or whether they are even aware of it.

Novelty. Compared to previous work, we have achieved fine-grained detection and attribution of TLS certificate validation issues. Notably, no past work attributed to the truly responsible party behind a TLS validation failure—i.e., no distinction was between the connection originators and faulty validators, which as we found can be different. More critically, we bring attention to and measure the prevalence of what we call certificate validation hijacking—a completely new phenomenon, unidentified by any past work. Accordingly, our fine-grained attribution cases with their measurements demonstrate the chaos of TLS certificate validation practices between multiple parties in the Android development cycle. We also leverage kernel-level instrumentation to handle DBI-aware apps, to maximize analysis coverage, which can help future dynamic analysis frameworks.

3 High-level System Design

In this section, we provide an overview of our design behind Marvin. The primary goal of Marvin is to analyze TLS certificate validation issues in Android apps, and attribute such issues to responsible part of an app (e.g., the app developer's code or a specific library included in the app). Specifically, we aim to examine TLS certificate validation issues in four different cases based on hosts. Hereafter, we refer to TLS connections to unique destination addresses with one or more of the four validation issues (see below) as *insecure connections*. We investigate the root cause of a validation failure or hijack, and attribute it to either the app or one of its libraries.

Selected TLS certificate validation issues. We consider the following four cases adapted from `badssl.com` to cover the most obvious checks for our analysis. Additional tests can be easily added to Marvin albeit at the expense of increased time requirement for analyzing each app. (1) *Unverified Certificate Signature*. The app accepts any received certificate without performing any signature validation, although it may still check the expiry date and domain name. (2) *Self-signed Certificate*. The app performs signature validation on the received certificate using the public key contained in the certificate itself. Nonetheless, it may still verify the expiry date and domain name. (3) *Expired Certificate*. The app performs secure domain and signature validation on the received certificate, but it disregards the validity time of the certificate. (4) *Domain Mismatch*. The app securely checks the expiry date and performs signature validation on the received certificate, but it skips matching the certificate domain and server names.

Threat model. We assume a network-based attacker, positioned anywhere between a faulty app (i.e., an app with a TLS validation error) and the server(s) it connects to, in line with the Dolev-Yao [27] threat model, i.e., the attacker can read/manipulate the network traffic. The attacker also needs to identify faulty apps before launching the attack, e.g., via simple TLS validation tests (being able to use mitmproxy could be enough). This attack can result in a wide range of consequences, including but not limited to session hijacking, credential/PII theft, phishing attacks, and malware/code injection. We assume no other capabilities for the attacker.

3.1 Attribution of Validation Issues

When certificate validation is not performed properly for a specific TLS connection, we would like to pinpoint where the issue likely stemmed from, unlike in previous studies (e.g., [46, 50]) where the issue was merely identified to have occurred in a monolithic app.

The common practice in Android app development involves incorporating third-party libraries (DEX/native) in developers' own code, producing a single app package, containing code from multiple parties. For instance, the "Fitdays" (`cn.fitdays.fitdays`) app with 1M+ downloads contains `com.tencent.bugly.proguard` (third-party code) package in its code, which improperly handles TLS certificate validation. In contrast, the "Playit" (`com.playit.videoplayer`) app, with 100M+ downloads, improperly modifies the default TLS verifiers, affecting TLS certificate validation in various third-party code, including Facebook, Unity3d, and AppLovin SDKs. It is important to note that the presence of a certificate validation issue may or may not be under the control of the app/library developer, depending on the specific code segment responsible for the issue. This distinction is crucial in determining the appropriate remedial actions.

Determination of third-parties. To the best of our knowledge, there exists no universal, accurate and automated way to partition an app based on vendors (e.g., not scalable if based on an exhaustive list [32, 45]). Therefore, we follow Pradeep et al. [38] (in their case for certificate paths), to consider any package name appearing in more than 5 apps as a third-party library, as opposed to code written by the app developer. Although a library can consist of multiple packages, which may or may not have common package names, using packages as an approximation for libraries is still valid since multiple packages can be seen as a way of modularizing a library. Additionally, if vendor information becomes available, package-level attribution can be aggregated to the vendor

level. Likewise, we apply the same threshold for determining third-party domain names, i.e., if a domain is contacted by over 5 apps, we consider it to be a third-party domain name, as opposed to the app's domain.

Validation overrides and hijacking. Some Android app developers may override the standard Java interface (e.g., from classes `HostnameVerifier` and `X509TrustManager`) with custom code, e.g., to make use of certain TLS features (cf. [50, 51]). However, this customization may lead to one or multiple of the aforementioned improper validation cases. From our observation, TLS certificate validation is composed of: a hostname verifier to check for Domain Mismatch, and the rest of the validation often in the form of callbacks in the trust manager (including checks for the other three cases above). Correspondingly, this is reflected in the overrides, `HostnameVerifier.verify()` and `X509TrustManager.checkServerTrusted()`.

Aside from the aforementioned regular overrides, we observe that the validation override can be done in a way that *globally* affects all subsequent TLS certificate validations in the HTTPS protocol if they use the `HttpsURLConnection` class with default values for socket factory and hostname verifier; alarmingly, this phenomenon is prevalent (as observed in our results). Technically, Android provides two static public methods, namely `setDefaultSSLSocketFactory()` and `setDefaultHostnameVerifier()` to override the default TLS validation environment globally, stored statically in `HttpsURLConnection`, without any concurrency control. While these functions are well-documented and their use is not new, third-party libraries performing such global overrides can have severe security implications (e.g., bypassing certificate validation unbeknownst to the app developer). We note that this might be either intentional or just inadvertent.

```
1 private static HttpsURLConnection a(URL url, int i) throws NoSuchAlgorithmException,
2 KeyManagementException, IOException {
3     SSLContext sSLContext = SSLContext.getInstance("TLS");
4     sSLContext.init(null, new TrustedManager[]{new b()}, new SecureRandom());
5     HttpsURLConnection.setDefaultSocketFactory(sSLContext.getSocketFactory());}
6     HttpsURLConnection.setDefaultHostnameVerifier(new a());
7     HttpsURLConnection httpsURLConnection = (HttpsURLConnection) url.openConnection();
8     return httpsURLConnection;
9 }
```

Listing 1: Global TLS certificate validation override in Tencent Bugly (a widely used library)

We define TLS certificate *validation hijacking* as when either an app or a library attempts to validate its certificate by invoking standard libraries or its own implementation, but the validation code is overridden by another party, which does not perform any validation checks, or lacks any required checks as defined in RFC 5280 [43]. Consequently, the certificate validation is ultimately carried out by the other party rather than the app or the library's code. Listing 1 shows an example where Tencent Bugly [17] (a popular Chinese library for exception reporting) performs global overrides in its ProGuard helper SDK (which is different from the Android's ProGuard optimizer and obfuscator); this causes certificate validation of the entire app, including other libraries, to be through Bugly's code, which turned out to be insecure as we found.

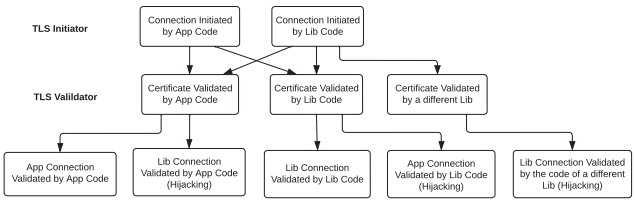

Figure 1: Overview of our attribution cases (except the racing hijacking case involving multiple parties)

Attribution cases. Based on the aforementioned observations, we consider our fine-grained attribution of the validation issues in six cases as follows; see also Fig. 1. Note that we consider (and have confirmed from the results) that the standard validation code is properly implemented and hence not reflected in the attribution (as no issues occurred).

1) App connection validated by app code. This refers to when the app developer uses custom code or overrides standard code to validate the certificate for connections initiated by the app developer, but does so improperly. Although insecure, the impact of this practice is limited to an app developer's connections alone, in a given app.

2) Library connection validated by library code. Similarly, a library included in the app can also perform certificate validation of connections initiated by itself, through either custom code or overrides. The impact of this case is also limited to an individual library, but considering a library is potentially used by many apps, the connections from that library will be vulnerable in all apps using the library.

3) App connection validated by library code (hijacking). Due to validation hijacking, once a library calls one or both of the set default functions, all Java-based HTTPS connections that utilize the default verifier within a given app will be validated by the override functions of this library, which the app developer may be unaware of. In this case, the victim connections are initiated by the app developer.

4) Library connection validated by app code (hijacking). Likewise, when the code calling the set default functions is written by the app developer, the victim connections can also be initiated by a library included in the app, which may not be anticipated by the library developer.

5) Library connection validated by the code of a different library (hijacking). In this case, both the victim connection and the code causing the global override are from libraries included by the app, but different libraries (e.g., Tencent improperly validating a connection's certificate initiated by Google).

6) Race condition with multiple callers (hijacking). The global override functions may also be called by multiple parties in the same app. As each call to set the default functions will affect certificate validation for all Java-based HTTPS connections that utilize the default verifiers, it will always be the last call that takes effect. As the consequence is determined by timing, aside from showing the presence of this issue, we

do not measure the timings to find out who wins (which can vary across different runs).

3.2 Technical Challenges, Solutions, Overview

We highlight several unique technical challenges faced in the attempt to achieve our analysis objectives and our solutions.

Traffic separation/redirection. As our analysis target is a specific app, we must separate its traffic from that of other apps on the operating system. By default, each network connection does not necessarily have any identifier specific to an app. Moreover, we encounter a challenge where certain apps (almost 70% of apps from the Chinese store) disregard the proxy configuration set in the device settings for some of their connections. Instead, they establish direct connections to their intended destinations, bypassing the designated proxy server. To address these issues, we need a mechanism capable of identifying such connections, linking them to their originating apps, and redirecting them to our proxy server. In contrast to other approaches that either overlooked [33, 44] this issue or relied on VPNs [41, 51] or API hooking [25, 37], we leverage eBPF [9], which operates at the kernel level (requiring no changes to the kernel and remaining undetectable by apps), to intercept system events. Specifically, we utilize eBPF to hook into the Linux kernel's `cgroup` feature, enabling us to attach our instrumentation to specific resource allocation events within the OS. For network connections, we use the programs `connect4` (for IPv4) and `connect6` (for IPv6), corresponding to TCP socket creation in the Linux kernel.

To achieve traffic separation, considering that each Android app is assigned a unique user ID, we can trace the origin of each socket by logging the user IDs associated with their creation through the `cgroup` feature. We opt for user IDs over process IDs due to the possibility of an app having multiple dynamically generated process IDs.

For traffic redirection, we employ `eBPF` to create a hook in the `cgroup` feature, intercepting, logging, and modifying socket destinations during resource allocation, especially for HTTP/S ports. This interception occurs if the destination address does not match that of our proxy server. By leveraging the user ID of the app, this approach allows us to selectively forward app traffic in a granular manner. Although this methodology requires root access, alternative methods are not sufficient for our task. For instance, `iptables` which also requires root access, does not support the log feature in Android, which is used to enumerate the connections. VPNs do not require root access but can be easily detected [20], and traffic capturing from the WiFi access points does not allow us to perform traffic separation.

Dynamic analysis evasion. We also observe that a significant number of apps employ robust evasion techniques to counter dynamic analysis, particularly function hooking. This means the app being analyzed will crash (among other misbehavior) once hooking is detected, thus prematurely terminating our analysis. This behavior is known as dynamic binary instrumentation (DBI) detection. There have been a number of studies on "Android packers" [23, 28, 56], with academically proposed "unpackers" [53–55], most of which tend to be no longer up-to-date (packing and unpacking are like an arms race). Note that packers can usually detect rooting, emulation, debugging, and function hooking with a highly obfuscated native library (`.so`). We find a significant portion of the packed apps making use of very strong commercial Android packers, for which we are not aware of any unpackers (academic or commercial), to the best of our knowledge; example packers include Ijiami [11], Bangcle [6], Netease [16], 360 [2], and Ali [3], among many others. For instance, the Ijiami packer employs direct syscalls (the assembly instruction) to examine the app's memory maps for any signs of tampering by offset calculation. Hence, app-specific tweaks are necessary to avoid detection (which is manual and not scalable). To maximize our analysis coverage, we discuss how we deal with DBI detection (included in most packers) in Section 4.2.

Overview of Marvin. In brief, we run the target app by interacting with its UI in an automated manner to trigger as many connections as possible, and meanwhile intercept its traffic with mitmproxy [15] (Sec. 4.2 under "TLS Interception") with invalid certificates. We prepare certificates corresponding to the aforementioned 4 validation issues (Sec. 3) for the proxy, and thus any connections ending up in the intercepted traffic (meaning problematic certificates accepted) will match with the improper validation in the app's code. In parallel, we employ dynamic analysis via eBPF for traffic separation/redirection (Sec. 3.2 under "Traffic separation/redirection") and Frida hooking [34] to record the stack traces of a pre-determined set of functions in the apps to serve two purposes: i) to aid in the attribution analysis of the certificate validation issues; and ii) to gain a better understanding of what is sent in the HTTPS (including custom-encrypted) traffic. We further explain the implementation details in Sec. 4.

4 Implementation of Marvin

Our analysis with Marvin is conducted in two phases: 1) execution and data collection; 2) analysis and attribution; see Figure 2 for an overview. We utilize Python and JavaScript to implement the detection of TLS certificate validation vulnerabilities and fine-grained attribution (approx. 3.3K LOC). We used Python script to create TLS passthrough and certificate exchange features, which were seamlessly integrated into mitmproxy as addons. This allowed us to intercept and store only insecure TLS connections. For traffic separation and redirection, we leveraged eBPF programs as explained in Sec. 3.2, developed in C. For the dynamic analysis, i.e., hooking network and certificate validation functions, we used Frida for which hooks were written in JavaScript. Moreover, we made modifications to ThirdEye [37] to manage the orchestration of app executions and detect custom encryption

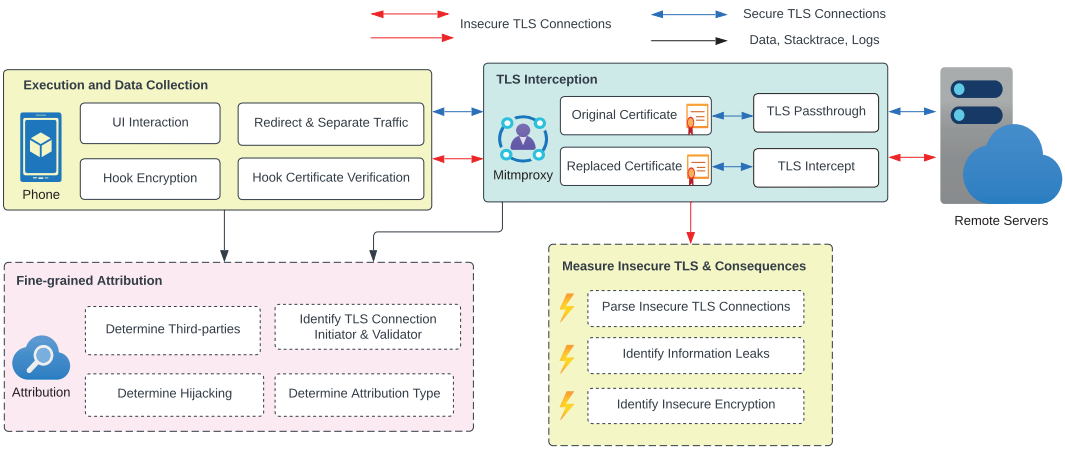

Figure 2: Components and workflow of Marvin

channels. Finally, we developed Python scripts to perform our analysis over the collected data.

4.1 Preparing the Analysis Environment

We first explain several considerations for preparing the environment and one-time actions before detailing the execution, data collection, and data analysis phases.

Root detection evasion. As mentioned in Sec. 3.2, the state-of-the-art commercial packers also provide features to detect and evade dynamic analysis. However, among these features, we must address root detection, as our method requires root permissions to set up the dynamic analysis tools, such as eBPF and Frida. To obtain root access, we utilized Magisk [14], and configured it to run as part of the Zygote process (a system-level process in Android that serves as a parent process for all app processes). Marvin scans the `AndroidManifest.xml` file of each installed app to automatically extract their package names and services, which are then added to the Magisk denylist. This denylist prevents apps and services from accessing the Zygote process and any associated root privileges, which reduces the chance of root detection.

Attaching and adapting eBPF programs. We utilized the *bpftool* tool within the *eadb* [8] environment (a Debian-based shell environment to run BCC, bpftrace, and bpftool on Android) to attach our *eBPF* programs to the kernel. However, *eadb* lacked native support for *cgroup* that we used, prompting us to enhance it by adding functionality for cgroup-based eBPF programs. Subsequently, we packaged our programs into a Magisk service module, enabling automatic execution after device boot, which allowed Marvin to maintain the continuous operation of our eBPF programs on the devices, facilitating the separation and redirection of app network traffic.

4.2 Execution and Data Collection

In this phase, Marvin automatically installs and executes the selected apps on configured Android devices, and then runs a mitmproxy for each of four types of invalid certificates. At this point, the eBPF programs are already running (as discussed above), and certain functions of the target apps (mainly for attribution) are hooked using Frida (with Javascript code). Finally, Marvin starts the user interaction simulator on the phone to explore the apps and trigger network connections. We discuss individual aspects of this phase below.

UI interaction. To maximize execution path coverage to trigger network connections, Marvin needs to simulate a user's interaction with the app's UI, e.g., tapping and entering text. To this end, we utilized the ThirdEye UI interaction module and improved its interaction speed by adjusting the timing parameters, and updating its duplicate element detection approach, wherein each UI item is interacted with twice to induce the app to create connections again in case the certificate validation was correct (hence connection aborted), as explained below under "Inducing apps to re-establish connection".

TLS interception. The key to our analysis of certificate validation issues is the ability to intercept the TLS traffic, replace the certificates, and observe how the app reacts. Therefore, Marvin launches mitmproxy and replaces the server's certificate with four types of misconfigured certificates corresponding to the four types of validation issues, for each server contacted by the app. If the proxy server receives a TLS error about validation failures (which is expected from the app), Marvin adds the server's SNI and IP address to a whitelist, and the proxy works as an SNI server without replacing the certificate. If the certificate is accepted without errors, Marvin flags it as improper validation (hence an insecure connection).

Certificate generation and replacement. Marvin generates the four types of misconfigured certificates as discussed in Sec. 3 per connection on-the-fly using the OpenSSL library, except for the case of testing domain mismatch. This approach avoids the mixing of results from across different validation

issue types. For instance, if a self-signed certificate contains incorrect Subject Alternative Names (SANs), it is difficult to distinguish if the rejection is due to domain mismatch or the use of a self-signed certificate. Marvin only imports our trusted root certificate on the phone for testing the case of expired certificates. Additionally, we generate a valid certificate using Let's Encrypt for a test domain to check domain mismatch scenarios. This approach helps us achieve greater coverage if an app uses a hardcoded root certificate store instead of that of the OS (cf. `rustls` library).

Reverting to original certificate for correct validation. In the case of correct certificate validation, our replaced certificate will be rejected leading to a failed connection, which may affect the app's functionality, preventing us to see subsequent potentially improper validation. To address this issue, we rely on TLS protocol alert messages to identify failures due to correct TLS certificate validation. We developed an add-on for mitmproxy that utilized the `tls_failed_client` event hook, capturing TLS connection data when the proxy server received a TLS error from the client. In this case, we whitelist the combination of server IP address and TLS Server Name Indication (SNI) and forward the connection to the SNI proxy without modifying the original certificate.

Proxy implementation. Marvin utilizes three types of proxies for TLS interception, namely HTTP forward, HTTP transparent, and SNI proxy, leveraging mitmproxy for their implementation. When apps respect the system proxy, they automatically utilize the forward proxy, which can capture both their original HTTP method and the CONNECT method. However, certain apps do not adhere to the system proxy settings and establish direct connections with their server. As mentioned in Sec. 3.2, these connections are forcefully forwarded to the server, but the apps do not use the CONNECT method. This makes reconstructing the original HTTP messages to the CONNECT method challenging. To overcome this issue, we enable the transparent proxy functionality mode in the proxy server, which resolves the problem by modifying the destination socket address without reconstructing the HTTP messages. We also incorporate the SNI proxy functionality, which enables Marvin to redirect connections that undergo TLS certificate validation appropriately without interception.

Finally, our data collection includes all insecure HTTPS connections obtained either through the proxy server or redirected from eBPF, encryption/decryption data from ThirdEye, SDK certificate validation functions and device information (e.g., MAC address, phone number, and device email).

Inducing apps to re-establish connection. As mentioned earlier, if the app rejects the certificate, Marvin reverts to the original certificate for subsequent connections. However, the app may not automatically attempt to re-establish the connection after the failure. To address this issue, we modify our UI interactor to interact with each UI object twice, potentially triggering a re-establishment of connections caused by a UI event. If the interactor does not discover any new UI elements to explore, which could be the cause of the failed reconnection, the interactor relaunches the app to check again.

Handling DBI-aware apps. Although we are unable to defeat most commercial packers as mentioned in Sec. 3.2, to maximize analysis coverage, we have implemented a fallback mode to handle DBI detection. This mode involves performing a preliminary check to determine if the app crashes/freezes upon opening. If a crash/freeze is detected, we restart the analysis with our DBI tool (i.e., Frida) disabled. We utilize the `logcat` command and the corresponding user ID of the app to identify such crashes. Additionally, we monitor the appearance of non-responsive windows by checking the `mCurrentFocus` value through the `dumpsys activity activities` command. The presence of a non-responsive window indicates that the app has become frozen. This way, Marvin can automatically continue the analysis of these apps at the cost of losing fine-grained attribution.

4.3 Analysis and Attribution

In this section, we discuss the approaches Marvin applied to collect and process data from the execution phase and to perform attribution of certificate validation issues.

Identification of certificate validation issues. To filter out traffic from a target app, Marvin compares the network records obtained through eBPF with the insecure TLS connection records from the proxy for each misconfigured certificate type during the data collection phase. If any insecure connection from the app is detected, we perform the attribution process to determine the origin of the improper certificate validation.

Identification of certificate validation origins. At this point, Marvin has obtained per-app insecure connection information with certificate validation issues, but this is only from the network perspective (i.e., traffic). The next step for Marvin is to hook the specific functions responsible for the certificate validation issues for fine-grained attribution. Rahaman et al. [39] introduced a static analysis tool for detecting cryptographic vulnerabilities in Java, which demonstrated various cryptographic API misuses. Inspired by their approach, we have identified that the `checkServerTrusted()` (in the `X509TrustManager` class) and `verify()` (in the `HostnameVerifier` class) interfaces, and the `createSocket()` method (in the `SSLSocketFactory` class) can be misused for improper certificate validation. Hence, to obtain stack traces and certificate information, we used Frida to create hooks for these functions and integrated them with Marvin. It is worth noting that Java interfaces cannot be individually hooked; instead, their implementations must be employed for hooking. To identify the implementations of the certificate verifier interfaces, we first leveraged Frida's enumeration feature to list all methods with the same function signature within the app. Subsequently, we employed Java reflection to confirm that their declaring class matches that of the interface's class.

Mapping a TCP connection to a TLS session is challenging as our target functions work at different semantic levels, e.g., the `verify()` function does not have access to any socket information. To address this issue, we start our flow from `createSocket()` and record the socket information. Then, in `checkServerTrusted()`, with access to both certificate information and socket information, we create a hash of the certificate chain serials and map it with the socket information (the certificate serials are different for each connection due to on-the-fly certificate generation; see Sec. 4.2 under "Certificate generation and replacement"). Finally, in `verify()`, we can extract the SNI name, and we re-calculate the hash of the certificate chain serials and check if they match with the socket information. This allows our tool to accurately trace and map the connections and their corresponding TLS certificate validation functions.

Performing attribution. We examine the stack traces to check if the entity creating the TLS connection (highlighted in blue in the stack traces in Listing 2 to Listing 7) is the same entity executing the validation function (highlighted in red in the listings, if different). The lines in between are from standard network libraries (e.g., OkHttp) and thus the pattern is straightforward to parse. We provide a list of stack traces for each type of attribution from Listing 2 to Listing 7. In Listing 2, the entity `com.datayes.common` triggered the TLS certificate validation (blue, bold, line=5) and also performed the actual validation (blue, bold, line=1), hence, this case being classified as "app connection validated by app code" (not hijacked);

Listing 3 highlights the same issue for library code. Listing 4 shows a validation hijacking case where `com.dnurse.main.ui` created the TLS connection, while `com.tencent.bugly.proguard` invoked `checkServerTrusted` to perform the certificate validation. Therefore, this case is categorized as "app connection validated by library code" (hijacking). A reversed hijacking case is shown in Listing 5. Listing 6 demonstrates a case where both the victim and improper actor are libraries (but different ones). The package `com.umeng.commonsdk`, a popular library, established a TLS connection with its remote server, but the certificate validation was performed by `com.kuaishou.weapon` (another popular library). Listing 7 shows a scenario where multiple certificate validation hijackings occurred (but the actual consequence may depend on execution timing); here, the certificate validation was initially done by Tencent Bugly, followed by Baidu which overrode the default verifier thereafter.

Listing 7: Multiple hijacking actors (race condition)

Detecting information leaks. We collect traffic from the affected communications due to validation issues, including hijacking. We then proceed to perform deep packet inspection, a detailed examination of network traffic that includes the analysis of both HTTPS headers and bodies, to identify information leaks that may have occurred due to insecure TLS certificate validation, as well as extracting potential custom encryption channels (additional encryption on top of a standard protocol) using the data from ThirdEye [37].

5 Results

Experimental setup and app dataset. We run the selected apps on two Pixel 7, and one Pixel 6 phone with Android 13 factory images, and the analysis scripts on three desktop PCs with Ubuntu 22.04 (Intel Core i7-10700 CPU, 48GB RAM, and two i7-8700 CPUs with 16GB RAM).

For the dataset to represent popular Android apps, we download top-rated apps from 360 Mobile Assistant (Qihoo 360 Appstore, a popular Chinese app store [1]) for Chinese apps, and Google Play apps from Google Play store based on the rank of APKPure [4], covering a variety of categories, such

as online shopping, entertainment, travel, office tools, and finance. These apps are distinct and demonstrate unique characteristics from the perspective of both functionality and security [48]. We eventually collected a total of 4121 Chinese apps and 5452 Google Play app as our dataset to start with.

Marvin executed each app four times, with each run dedicated to testing a specific certificate problem. For each run, it typically required around three minutes to explore and interact with UI elements (i.e., around 12 minutes per app). However, if custom encryption is detected during a certificate validation test, Marvin will run the app twice for this specific certificate test in order to detect insecure custom encryption. In such scenarios, Marvin executes the apps between 4–8 times, varying based on the detection of custom encryption. Each app took approximately 12–24 minutes to conduct a comprehensive analysis of the four types of certificate validation issues and identify any potential insecure custom encryption.

During the testing phase, we observed that 2096/4121 (50.9%) of Chinese apps experienced crashes (either handled by their developers or not), and 948 of them did not generate network traffic, while 2147/5452 (39.4%) of Google Play apps crashed, 275 of them without network traffic. After we disabled Frida, 329/948 (34.7%) Chinese apps and 163/275 (59.3%) Google Play apps started to connect to their remote servers, indicating the presence of anti-hooking mechanisms in these apps. We were unable to attribute all the remaining crashes to a specific cause on a per-app basis. Examples of speculated causes include root detection, certificate pinning, and device incompatibility. We also observed that 408 of the Chinese apps and 140 of the Google Play apps generated no network traffic despite no crashing. Hereafter, we exclude the apps without observed network traffic from reported results, and consider the adjusted totals of 2765 and 5061, for Chinese apps and Google Play apps, respectively.

5.1 Certificate Validation Issues

We found that 1529/2765 (55.3%) of Chinese apps were identified to have at least one of the four certificate validation issues; in contrast, the percentage of insecure Google Play apps was much lower: 322/5061 (6.4%). In terms of each certificate validation issue, for Chinese apps, 1307/2765 (47.3%) were identified with unverified certificate signatures, 1375/2765 (49.7%) trusted self-signed certificates, 1310/2765 (47.4%) accepted expired certificates, and 1059/2765 (38.3%) ignored mismatched domain in the certificate validation. For Google Play apps, 244/5061 (4.8%) were identified with unverified certificate signatures, 243/5061 (4.8%) trusted self-signed certificates, 231/5061 (4.6%) accepted expired certificates, and 236/5061 (4.7%) ignored mismatched domain in the certificate validation. We also grouped the apps based on the number of insecure TLS connections, e.g., apps with 1 to 10 insecure TLS connections, 11 to 20, 21 to 30, and over 30; see Table 1. In the four certificate test cases, Chinese apps established a significantly higher percentage of insecure TLS connections; see Table 5 (in the appendix).

We observe that 1) the percentage of apps from the Chinese app store possessing certificate validation issues is notably higher compared to Google Play apps; 2) the proportion of apps in both Google Play and the Chinese app store with each validation issue does not show a significant difference; and 3) for both the affected number of apps and the resulting insecure connections, Chinese apps are significantly higher than Google Play apps, primarily due to the use of a small number of highly popular but faulty libraries in Chinese apps.

5.2 Attribution Results

Attributed insecure apps. We were able to attribute the insecure connections of the four certificate validation types to 1014/1529 (66.3%) Chinese apps and 139/322 (43.2%) Google Play apps; see Table 2. We also observe that 1) for the non-hijacking cases, improper validation happens more to libraries in Chinese apps (48.9%), while for Google Play apps it is more caused by the app code itself (30.7%). This leads to more overall apps being affected in the Chinese app store (as a popular faulty library can make many apps vulnerable).

Attributed insecure TLS connections. We first group the parties (app vs. library code) initiating the insecure TLS connections. For Chinese apps, the average percentage of insecure TLS connections created by libraries is 76.5% across four certificate test cases, while the connections initiated by apps themselves (i.e., app code) account for 23.5%; this trend is reversed in Google Play apps (16.2% from libraries and 83.8% from apps, see Table 8 in the appendix). We then identify the entities responsible for these insecure TLS connections, i.e., which code performs the insecure validation. We were able to attribute 68.4% insecure TLS connections in Chinese apps (10.0% were from app code, and 58.4% were from libraries), see Table 3. In contrast, we could attribute 44.5% of insecure TLS connections for Google Play apps (21.0% from app code, and 23.6% from libraries). We could attribute more Chinese apps due to the prevalence of a few faulty libraries (which we could attribute) in them. Moreover, in Google Play apps, the percentage of insecure TLS connections caused by faulty library validators was merely 7.7%, while faulty validators in app code led to 36.8% of insecure TLS connections.

Libraries involved in hijacked validation. We identified the libraries that call `setDefaultSSLSocketFactory()` and `setDefaultHostnameVerifier()` with insecure validation functions, and thereby, hijack certificate validation; see Table 4. For example, Bugly (`com.tencent.bugly`) overrides the default SSL socket factory through `setDefaultSSLSocketFactory()`. This results in hijacking Android OkHttp's TLS connections for non-Bugly TLS connections in apps that utilize Bugly. ByteDance SDK (`com.bytedance.sdk`) [7] is another popular library, designed to log events in mobile apps and send them to TikTok for targeted ads, measurement,

Certificate Type	Chinese Apps (#apps, % of apps)				Google Play Apps (# apps, % of apps)			
	[1, 10]	[11, 20]	[21, 30]	>30	[1, 10]	[11, 20]	[21, 30]	>30
Unverified Certificate Signature	910 (32.9%)	214 (7.7%)	95 (3.4%)	88 (3.2%)	208 (4.1%)	20 (0.4%)	4 (0.1%)	12 (0.2%)
Self-signed Certificate	971 (35.1%)	216 (7.8%)	99 (3.6%)	89 (3.2%)	208 (4.1%)	21 (0.4%)	5 (0.1%)	9 (0.2%)
Expired Certificate	938 (33.9%)	206 (7.5%)	83 (3.0%)	83 (3.0%)	200 (4.0%)	14 (0.3%)	9 (0.2%)	8 (0.2%)
Domain Mismatch	805 (29.1%)	151 (5.5%)	64 (2.3%)	39 (1.4%)	216 (4.3%)	9 (0.2%)	6 (0.1%)	5 (0.1%)
Total	1287 (46.5%)	406 (14.7%)	195 (7.1%)	128 (4.6%)	298 (5.9%)	32 (0.6%)	14 (0.3%)	15 (0.3%)

Table 1: The number and percentage of apps that established insecure TLS connections (grouped in different ranges) in each type of certificate validation issue among Google Play and Chinese apps. Total denotes the number and percentage of unique apps that possess one or multiple of the four types (de-duplicated).

Attribution Type	#App (CHN)	#App (GP)
App connection validated by app code	361 (23.6%)	99 (30.7%)
Library connection validated by library code	747 (48.9%)	28 (8.7%)
App connection hijacked by library code	102 (6.7%)	12 (3.7%)
Library connection hijacked by app code	194 (12.7%)	50 (15.5%)
Cross-library hijacking	360 (23.5%)	23 (7.1%)

Table 2: The fine-grained attribution results; percentages are calculated over all insecure apps; App (CHN) denotes Chinese apps; App (GP) denotes Google Play apps. Note that the same app may be counted under more than one attribution type.

and conversion optimization; this SDK overrides the default SSL socket factory using `setDefaultSocketFactory()`. Developers also often incorporate the Baidu Location SDK (`com.baidu.location`) [5], to leverage Baidu services to access accurate location data and enable location-based features within their apps. Similar to Bugly, Baidu SDKs also override the default SSL socket factory through `setDefaultSSLSocketFactory()`. Note that the Bugly SDK is also found in 12 Google Play apps in our dataset.

Race conditions in certificate validation. We noticed that in 417 (27.3%) insecure Chinese apps, multiple parties (e.g., two libraries, or an app and a library) did the override, leading to uncertainty about validation logic, determined by timing. Specifically, the effective validation function relies on who set the default SSL Socket Factory or default Hostname verifier the last, right before a given validation call. For example, in `com.lingan.yunqi`, we observed that `com.kepler.sdk` called `setDefaultSSLSocketFactory()` first, and consequently validated the certificate of `ap1.qiyukf.com`. Later, Bugly (`com.tencent.bugly`) invoked `setDefaultSSLSocketFactory()`, and thus hijacked the validation for `baichuan-sdk.alicdn.com` and `baichuan-sdk.taobao.com`. We also observed apps in which both `setDefaultSSLSocketFactory()` and `setDefaultHostnameVerifier()` functions were invoked. For instance, in the case of `com.mobivans.onestrokecharge`, Bugly modified the default SSL socket factory by invoking `setDefaultSSLSocketFactory()`, which validated the certificate of the host `i.sdkyounger.com`. Subsequently, `com.kuaishou.weapon` called `setDefaultHostnameVerifier()`, and used its faulty verifier for `android.bugly.qq.com`, `i.sdkyounger.com`, `ulog.umeng.com`, etc.

5.3 Information Leaks

We perform deep packet inspection to detect information leaks resulting from insecure TLS connections vulnerable to MITM attacks, due to improper certificate validation. In the Chinese app dataset, we found that 1358/1529 (88.8%) of the apps transmit sensitive information using insecure TLS connections. Among them, 1354 (99.7%) use plain insecure TLS, 453 (33.4%) use custom encryption on top of insecure TLS, and 163 (12.0%) use weak/broken custom encryption on top of insecure TLS. For the Google Play dataset, we observed that 278/322 (86.3%) of the apps transmit sensitive information through plain insecure TLS connections. We group the leaked information into five distinct categories: Device, Network, Network Location, Location, and User Assets (see Table 7 in the appendix). We noticed that some apps use custom encryption to transmit user data. However, it is unclear whether the developers are aware of the TLS validation issues and thus attempted to (poorly) mitigate such issues, or if they are trying to conceal their activity on the network.

6 Case Studies

To further demonstrate the severity and practicality of the identified TLS certificate validation hijacking instances, we selectively analyze several apps (from different categories) for their susceptibility, and implement the exploits on our own devices. We group the exploit consequences to facilitate the discussion here. Note that for all the account takeover, impersonation, phishing attacks, and PII disclosure, we used our own devices for both attacker and victim devices on our local WiFi network, and our own test accounts and PII—i.e., the example attacks did not affect any user or provider. It is also reflected in all the studied cases that the victim party (e.g., end-users, app developers, identity providers, ad networks) is *unaware of such hijacking and not to blame*. We summarize our attacks and consequences in Table 6 (in the appendix).

Account takeover and impersonation. Android apps support various methods for user authentication, including app-specific login, and the use of third-party identity providers (IdPs) like Facebook, X/Twitter, and Google. Compared to affecting a single app, we have found a more worrisome fact that the SDKs used to interact with such IdPs can also be affected by certificate validation hijacking. For example, Di-

Connection	Validation Code	Hijacked	Attribution	# Connection (Chinese)	# Connections (Google Play)
App connection	App code	No	AppConnectionValidatedByAppCode	3840 (7.8%)	1311 (19.9%)
Lib connection	Lib code	No	LibConnectionValidatedByLibCode	12,531 (25.4%)	266 (4.0%)
App connection	Lib code	Yes	AppConnectionHijackedByLibCode	1075 (2.2%)	72 (1.1%)
Lib connection	App code	Yes	LibConnectionHijackedByAppCode	4623 (9.4%)	1118 (17.0%)
Lib connection	Another Lib's code	Yes	LibConnectionHijackedByLibCode	11,598 (23.6%)	170 (2.6%)

Table 3: The fine-grained attribution result of insecure TLS connections

voom (`com.divoom.Divoom`, available on Google Play for pixel art editing, 500K+ downloads) employs X/Twitter and Facebook for user authentication, in addition to its independent login component, and uses Bugly for bug reporting. Notably, Bugly replaces the default TLS certificate verifier with its insecure verifier upon app launch. Divoom's independent login component utilizes the Square OkHttp implementation, ensuring its login form remains unaffected. However, it relies on FBAndroidSDK [10] and Twitter4J [19] libraries to interact with the IdPs, which are dependent on Android's OkHttp implementation, and thus vulnerable to Bugly's validation hijacking. We managed to eavesdrop on the OAuth traffic (i.e., MITM), and get the OAuth access token, and and extract user data from the corresponding X/Twitter (e.g., Tweets, lists, collections, profile information, and account settings) and Facebook (e.g., user email) accounts, as well as access the user's Divoom account.

Apart from SSO services, we also observed some apps' independent logins being affected by such hijacking and thus exposed credentials such as (hashed) long-term/one-time passwords. For instance, among the apps from the Qihoo appstore, `asia.share.superayiconsumer` is affected by the Baidu location service; and `com.guixue.m`, and `ch999.app.UI` are affected by Bugly.

Several apps also undermine their own login pages by customizing TLS validation functions. Such apps include: `cn.yonghui.hyd`, `android.jianzhilieren`, and `cn.mopon.film.xflh`. On the other hand, `com.belugaedu.amgigorae` uses a secure login page, but it fetches certain parts of its content remotely as HTML code without proper certificate validation, which we exploited for a demo phishing attack (see Fig. 3 in the appendix).

Ad modification and phishing. Ad networks/platforms typically use HTML5 to load and render ad content. Given the prevalence of ads on Android and the ease of modification of HTML, such content becomes an attractive target for attackers seeking to launch phishing attacks by modifying ads to mimic the app's legitimate login form. We found that the majority of ad platforms in the Google Play Store dataset, including AppLovin, Amazon Ads, and Facebook Ads, employ the Android OkHttp library, making them vulnerable to the TLS certificate verifier override.

For instance, *Paint by Number: Coloring Game* (`com.paint.bynumber.color.coloringgames`, 100M+ downloads), employs Bugly for bug reporting, and utilizes AppLovin, Facebook Ads, and Amazon Ads for displaying ads. By exploiting the validation hijacking by Bugly, we successfully manipulated the ad content loaded by AppLovin (from the network) for a phishing attack (see Fig. 4 in the appendix). Conversely, as discussed earlier, overriding the default TLS certificate verifier can also be performed by the app itself and can affect other third-party SDKs and libraries within it. For example, Playit (`com.playit.videoplayer`, a video player app with 100M+ downloads) uses various ad SDKs, including Flat Ads, Moloco, Smaato Ads, and AppLovin, among others. This app's code overrides the default TLS certificate verifier with an insecure one, affecting all the ads SDKs, opening the door to phishing attacks the same way (as in Fig. 4).

Remote code execution. Surprisingly, we observed that 53 apps in the Chinese dataset transmit Dalvik Executable files (dex files) over TLS connections hijacked by Bugly (and thus made vulnerable to MITM). 17 of these apps transmit Dalvik data to their servers, while 41 apps receive such data (five apps perform both). Such transmission of executable code over insecure connections exposes the apps (and perhaps the app servers) to code injection attacks, allowing malicious actors to manipulate the behavior of the app/server (cf. [52]). We randomly selected a few apps for manual analysis to understand the impact of this phenomenon. For `com.android.tutuerge`, a heavily packed app with 10M+ downloads, the transmitted binary is used to load a video player. For verification, we modified the transmitted binary using Apktool and the app performed no integrity checks before loading the binary into memory. This phenomenon can have significant implications for the security and privacy of user data within the app; e.g., to abuse the app's permissions to collect privacy-sensitive data, place a keylogger, and compromise user credentials.

Sensitive information leakage. Apps that access various sensitive information from the phone and send it to their remote endpoints, may expose sensitive PII to network attackers due to certificate validation hijacking. Examples include: `asia.share.superayiconsumer` exposes a user's GPS location due to TLS validation hijacking by Baidu (com.baidu.location); `cn.com.jschina.news` leaks GPS location, contact names, phone manufacturer, operator, and installed packages due to Bugly validation hijacking; and `com.newsweekly.livepi` exposes device fingerprinting information due to validation hijacking by Alibaba log service.

7 Prevalence, Root Cause, Mitigation, and Limitations

Prevalence of certificate validation function override. In the dynamic analysis, we observed 519/2765 (18.8%) Chinese apps, and 152/5061 (3.0%) Google Play apps involved default validation function override regardless of whether it is secure or not. Among them, 391/519 (75.3%) of the Chinese app cases and 17/152 (11.2%) of the Google Play cases were insecure, caused by a third-party library.

Dynamic analysis is subject to limited code coverage by nature, e.g., even though our UI instrumentation is quite comprehensive, we still may miss validation issues for TLS connections that are initiated only after login (as our login coverage is only partial). To better understand the prevalence of such insecure override functions in apps, we conducted a static analysis using Androguard [21] on our dataset. This analysis is aimed to cover override functions in both first-party and third-party code that were not triggered in the dynamic analysis. Subsequently, we employed the attribution results from our dynamic analysis to match with the class names in the static analysis, identifying vulnerable third-party code. Specifically, our analysis revealed that 1634/4121 (39.7%) Chinese apps and 1094/5452 (20.1%) Google Play apps contain calls to the default certificate validation override functions. Furthermore, we identified 684/1634 (41.9%) Chinese apps and 54/684 (7.9%) Google Play apps that utilize a third-party library that we identified as insecure from our dynamic analysis. Consequently, through a combination of dynamic and static analyses, we observed 1937/4121 (47.0%) Chinese apps and 1162/5452 (21.3%) Google Play apps utilizing these override functions, with 927/1937 (47.9%) Chinese apps and 57/1162 (4.9%) Google Play apps incorporating insecure validation functions through their third-party libraries; see Table 4 for the number of occurrences of popular insecure libraries among the apps through both static analysis and dynamic analysis with their intersection.

SDK Name	SDK Package	$\lvert D \rvert$	$\lvert S \rvert$	$\lvert D \cap S \rvert$	$\lvert D \cup S \rvert$
Tencent Bugly	com.tencent.bugly	342	444	138	684
Baidu Location	com.baidu.location	39	107	17	129
Bytedance	com.bytedance.sdk	32	251	7	276
JingDong Kelper	com.kepler.sdk	14	27	7	34
Kuaishou	com.kuaishou.weapon	9	21	4	26
Alibaba Log	com.alibaba.mtl	5	1	0	6

Table 4: Example high-profile libraries that hijack certificate validation; D represents libraries found in dynamic analysis, S represents libraries found in static analysis; $D \cap S$ denotes libraries observed in both dynamic and static analyses, while $D \cup S$ denotes libraries observed in either dynamic or static analysis.

Note that we only use the static analysis to reflect the prevalence of the insecure override issue from a different angle, and the presence of a certificate validation function override in the static analysis may not mean it is actually used/called, e.g., dead code that is never reached at runtime.

Root cause. The behavior of HTTP implementations varies in terms of retrieving default values for `SSLSocketFactory` and `HostnameVerifier`, as we observe in various libraries like Apache HttpClient, Volley, and Square OkHttp. While these libraries typically abstain from retrieving such values, Android's OkHttp implementation notably does so post-initialization, potentially utilizing insecure validation functions. Conversely, Square OkHttp (from version 1.5, March 2014) remains immune by refraining from retrieval before an HTTPS call. As we observed, third-party libraries often prefer Android OkHttp, while first-party Android app code predominantly opts for Square OkHttp. We also identified instances where the default certificate verifier was overridden with an insecure verifier, yet Android's OkHttp continued to produce secure HTTPS requests. Further investigation revealed that this behavior is due to the use of an HTTP connection pool inherited from Square OkHttp. New HTTP/S connections in a pool continue to reuse previously available TLS connections (prior to hijacking), although they remain vulnerable and exploitable by an attacker resetting the connection to induce the library to establish a new TLS connection. Android appears to have incorporated the use of `DefaultSSLSocketFactory`, encompassing `X509TrustManager` and `DefaultHostnameVerifier`, to address issues related to the SPDY protocol [22]. Lastly, the multifaceted role of `SSLSocketFactory` in TLS customization, including cipher list modification, may further justify the utilization of such values.

It is also worth noting that validation override is not limited to Android OkHttp. Through manual code investigation, we found that other libraries (e.g., *jcabi-http* [13] and *ion* [12]) exhibit similar behaviors, although we did not encounter any calls to their code in our dataset. In short, although all the validation problems we found in our dataset are due to Android OkHttp, other HTTP client implementations with similar behavior can also cause the same issues.

Mitigation for global override. Possible solutions to mitigate the global certificate verifier override can be implemented/enforced by the Android OS (in the longer-term), and by developers (for immediate benefit). The Privacy Sandbox as introduced in Android 13, which separates the runtime environment of libraries/SDKs from that of the app, may address this issue if adopted and enforced. However, we did not observe any apps that use this feature in our work. If developers cannot use the Privacy Sandbox, possibly due to incompatibility with third-party SDKs, they can consider alternative short-term solutions. For example, they can use public key pinning, or re-assign the Android default `SSLSocketFactory` and `HostnameVerifier` for *every* `SSLSocketFactory` class that initiates a connection (i.e., to prevent the use of a hijacked verifier). Developers can also use other HTTP clients (e.g., Square OkHttp, Apache) that do not introduce the problematic override behaviors as in the default Android OkHttp.

Limitations. Our findings are a lower bound of the actual val-

idation failures due to the following factors. (i) In the face of strong commercial packers, for a small portion of the packed apps with DBI detection, we analyze them up to when they crash after which Frida hooking is turned off, i.e., additional attribution data is unavailable. (ii) Certain DBI-aware apps may not crash but avoid misbehavior silently. (iii) Although we identified all the app validation issues on both the native and Java sides, we were unable to hook native certificate validation functions due to functions in .so libraries being not standardized, or the libraries often being obfuscated; as a result, we could not collect attribution data from such native functions. Furthermore, our determination of third-party code/hostnames can be further augmented with an exhaustive list (accurate but not scalable, cf. Muslukhov et al. [32]).

8 Conclusion

We shed light on the significant threat posed by improper TLS certificate validation in the Android ecosystem, especially when overriding/hijacking the default validation functions is possible unbeknownst to the parties involved in an app's operation. We conducted an automated analysis and attributed the improper validation to specific packages in an app, as opposed to the entire app. We revealed that third-party libraries play a more critical role in improper TLS validation compared to app code, which developers may be unable to address easily. The root cause as we identified is not however these third-party developers, but Google's modifications to Android's default OkHttp implementation, which Android security team, as of writing did not take any steps to rectify. Our findings emphasize the urgent need for increased awareness among app developers regarding TLS security.

Appendix

Effectiveness of eBPF Traffic Redirection

To demonstrate the prevalence of such proxy evasion apps and confirm the effectiveness of introducing eBPF for traffic redirection, we conducted experiments on both Chinese and Google Play apps. We evaluate the eBPF redirection effectiveness from the following aspects: 1) How many apps do not respect the system proxy? 2) How many HTTPS connections are redirected to our proxy? We found that 1979/2765 (71.6%) Chinese apps had at least one connection in either HTTP or HTTPS protocols that did not respect system proxy (i.e., these apps will not be fully analyzed by existing work [33, 44] , and 1928/2765 (69.7%) had their HTTPS traffic not utilized the system proxy. Our eBPF program redirected a total of 103952 HTTPS connections to our proxy. In Google Play apps, we noticed that 3394 (67.1%) apps had at least one connection that did not respect the system proxy in either HTTP or HTTPS protocols, and 3387 apps had at least one HTTPS connection redirected to our proxy (a total of 211838 HTTPS connections).

Table 7: On-device information transmission for Chinese and Google Play apps involves an insecure, improperly verified TLS certificate, with or without custom encryption (applied on top of the TLS protocol). These statistics are listed in the Regular, Encrypted, and Insecurely Encrypted columns. The overall column represents the number of apps that utilize either regular HTTPS or custom encrypted channels. In the Encrypted columns, the security level is unknown. In the Insecurely Encrypted columns, it means the app used a symmetric algorithm with a hard-coded or fixed key, or transmitted its key on a channel encrypted by a hard-coded key or fixed key.

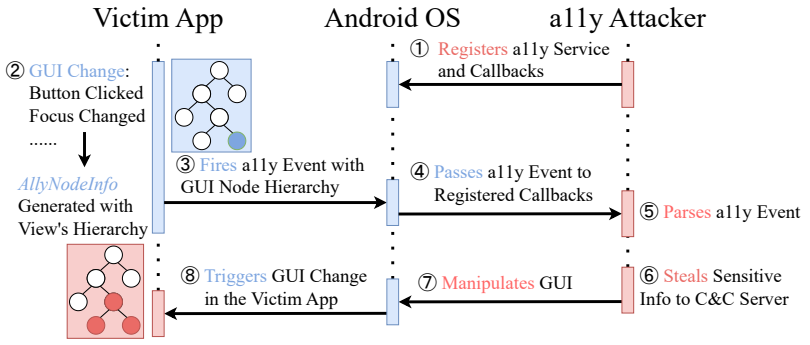
Abstract

The Android accessibility (a11y) service is widely abused by malware to conduct on-device monetization fraud. Existing mitigation techniques focus on malware detection but overlook providing users evidence of abuses that have already occurred and notifying victims to facilitate defenses. We developed DVa, a malware analysis pipeline based on dynamic victim-guided execution and abuse-vector-guided symbolic analysis, to help investigators uncover a11y malware's targeted victims, victim-specific abuse vectors, and persistence mechanisms. We deployed DVa to investigate Android devices infected with 9,850 a11y malware. From the extractions, DVa uncovered 215 unique victims targeted with an average of 13.9 abuse routines. DVa also extracted six persistence mechanisms empowered by the a11y service.

1 Introduction



Android's accessibility service [1], called a11y, provides extensive utilities to assist users in better navigating their phones. It stands as an exception to Android's app-isolated sandbox design in the sense that it grants a11y apps the ability to examine and navigate foreground graphical user interface (GUI) screens of other apps or the Android OS. These powerful capabilities are thus widely abused by malware to conduct more intrusive attacks on user-controlled information and services [2], [3]. In fact, these capabilities enable malware to conduct on-device fraud [4] and simplify traditional account takeover practices (e.g., ransomware, RAT). Because of a11y malware's powerful capabilities, traditional malware mitigation techniques that merely detect and delete malware are inadequate. Users of compromised devices need to know what damage could have occurred during the infection to facilitate restitution. In addition, the developers of victim apps need to know how they are targeted to proactively deploy defenses.

*Co-corresponding author.

Regarding a11y security, several works have proposed data-flow restraints [5], [6] to counteract the proof-of-concept (PoC) attacks [7]–[10]. However, our research revealed (§6.3) that modern a11y malware can still evade the most recent Android security patch [11] and state-of-the-art (SOTA) data-flow constraint defense [5]. Techniques also have been proposed to identify the misuse of a11y service in benign apps [7], [12]–[14]. However, without considering the targets of these misuses, an investigator will fall short of understanding their in-context abuse vectors because generic a11y service routines can mean drastically different things in different contexts. A malware analysis technique that provides proof of abuse capabilities to the device owner and alerts targeted apps of the abuse vectors to aid proactive defense remains an unresolved matter.

To achieve these capabilities, the existing malware detection engine (e.g., Google Play Protect) needs to send detected malware to the backend, accurately dissect the malware's a11y abuse vectors, and send the targeted victim and abuse vector report to the device user and the developers of affected victim apps. Unfortunately, such a technique is very challenging to implement. Malware may not perform abuse vectors without certain conditions (e.g., the absence of victim apps), making it difficult for investigators to examine the abuse intentions. As such, the abuse report that the device user receives must be specific to the victim apps installed on the user's device. Compounding this issue, modern a11y malware complicates victim identification by dynamically loading the abuse routines and encoding the targeted app names. As a result, it remains largely impossible for investigators to identify all targeted victim apps and alert them to the discovered abuse techniques specific to each app.

During our research, we found that a11y malware relied on Android APIs and broadcast a11y events to probe the information of the installed apps on the user's device. This gives investigators an opportunity to mimic the presence of the target victim apps and drive the execution in an isolated environment without modifying the victim's device. After a11y malware probes the information of the installed app, it

(a) Steps an a11y attacker uses to illicitly interact with a victim app.

```
public class malwareA11yService extends A11yService{
  @Override
  public void onA11yEvent (A11yEvent e) {
    // parse a11y event properties
    int type = e.getEventType();
    CharSequence name = e.getPackageName();
    ...
    // parse the a11y node structures
    A11yNodeInfo node = e.getRecord().getSource();
    // malicious code to record GUI states
    CharSequence nodeText = node.getText();
    nodeText.sendToCnC();
    ...
    // malicious code to manipulate GUI screen
    node.performAction(ACTION_CLICK);
    ...
  }
}
```

(b) Sample malware a11y event handling logic.

Figure 1: Overview of malware workflow to abuse the Android a11y service. Steps used to parse and manipulate a victim app's GUI by an a11y service registered by an attacker is shown in (a). The a11y attacker's actions are highlighted in red. A sample implementation logic of the malicious a11y service to achieve the abuse illustrated in (a) is shown in (b).

would choose to load the dynamic a11y abuse routines accordingly. Such trigger-based behaviors allow the investigators to attribute the a11y abuse routines to the trigger — specific victim apps. Attackers have infinite ways to implement each a11y abuse routine. However, these routines still rely on the a11y APIs exposed by the Android system. This enables investigators to uncover the abuse vectors by evaluating its a11y action sequences. These abuse vectors can be reported to all corresponding victim apps to enable blocking or mitigation. Lastly, by comparing the attributed abuse vectors with the installed apps on the victim's device, the investigators can inform the device users of their targeted apps and the damage they may face.

We developed DVa[1], a malware analysis pipeline to uncover a11y malware's targeted victims and victim-specific abuse vectors. It can operate as a backend malware analysis service for Google Play Protect, activated when an a11y malware is detected on the user's device. With the malware APK, DVa adopts a novel lightweight *victim modeling and reconstruction* approach to guide malware to reveal its targeted victims (§3.1). Using dynamic execution traces, DVa further utilizes an abuse-vector-guided symbolic execution strategy to identify and attribute abuse routines to victims (§3.2). Finally, DVa detects a11y-empowered persistence mechanisms (§3.3) to understand how malware obstructs legal queries or removal attempts.

Using DVa, we conducted investigations of five Google Pixel 3 devices infected with 9,850 malware samples collected from VirusTotal [15] that request a11y permissions from August 2022 to December 2022. DVa uncovered 215 unique victim apps across seven categories abused by 4,291 a11y malware samples. DVa found that *Banking* and *Crypto* apps are the most popular targets abused by 3,579 and 1,130 malware samples across 55 and 23 families, respectively. DVa also detected an average adoption of 13.9 unique abuse routines targeting custom UIs of each victim app with an average of 21.1 illicit a11y API calls. To persist on user devices, DVa uncovered that malware adopts six persistence mechanisms empowered by a11y. The most abused mechanism is *Permission Revocation Prevention*, exploited by 92% of malware. Lastly, we have made DVa available at: https://github.com/CyFI-Lab-Public/DVa.

[1] **D**etector of **V**ictim-specific **a**11y abuse

2 Overview

Android apps' GUI contains substantial user-controlled sensitive information [16], [17]. Although the Android *a11y service* is designed to help users better interact with their devices, its ability to peek into the on-screen element hierarchy and to simulate user interactions provides a new perspective of malware to abuse victims.

2.1 Abusing Android a11y Service

Malware uses the eight steps shown as circled numbers in Figure 1a to illegally acquire sensitive information or conduct malicious GUI actions. First, the malware registers an *a11y service* to the Android system that can retrieve changes in window contents, as shown in ①. After the user confirms the binding of the service, whenever something notable [18] happens in the GUI such as when a window changes, a button is clicked, a textbox is focused, etc. (Step ②), the *View* element in which the change occurred fires an *a11y event* to the system, as shown in Step ③. The relationship between the *View* and other elements in the GUI is represented as a GUI tree data structure, as illustrated in the tree in the blue box of Figure 1a. The *a11y event* contains properties of the changed *View*, together with the node hierarchy of the GUI tree the *View* resides in. These properties of the changed *View* and its relationship with other

```
1 public class cerberusA11yService extends A11yService{
2     @Override
3     protected void onServiceConnected() {
4         // hash encoded new targeting victims
5         List<String> newVictimHashes = secretDict.getNewVictimHashes();
6         for (PackageInfo pi : pm.getInstalledPackages()) {
7             // check existence and validity of targeting victims
8             if (newVictimHashes.contains(pi.packageName.hash())) {
9                 if (pm.getLaunchIntentForPackage(pi.packageName).isValid()) {
10                    ...
11                    // load tailored new a11y attack code from CnC
12                    requestNewPayload(pi.packageName.hash());
13                    classLoader.loadClass(newPayload);
14                }
15            }
16        }
17    }
18    @Override
19    public void onA11yEvent (A11yEvent e) {
20        // existing victims
21        List<String> victims = getVictimPackageNames();
22        if (victims.contains(e.getPackageName())) {
23            // existing overlay attack code to steal credentials
24            loadOverlay();
25            keyLog();
26            ...
27        }
28        // new code targeting chime mobile banking app
29        if (e.getPackageName().hash() == newVictimHashes[0]) {
30            // new a11y automatic transaction attack routine
31            if (e.checkGUIState() == homePage) {
32                findAndClickTransferPageButton();
33                findAndFillTransactionTarget();
34                ...
35                findAndClickTransfer();
36            }
37        }
38        // additional routines targeting 11 more victims
39        ...
40    }
41 }
```

New DCL a11y Abuse Code

Figure 2: Dynamically loaded automatic transaction abuse routine targeting the Chime banking app extracted by DVa.

elements are represented as an *a11y node info* data structure, as shown in the blue circle inside the tree.

After the Android OS receives an *a11y event*, it dispatches the event to all registered a11y services that listen for such an event through a callback, as shown in step ④. The callback is handled by a declared `onA11yEvent` handler in the malware's registered *a11y service*. A sample a11y event handler is illustrated in Figure 1b. This handler can then parse the *a11y event* (Lines 4-9 Figure 1b, ⑤ Figure 1a), steal information fetched from the event (Lines 10-13 Figure 1b, ⑥ Figure 1a), and subsequently manipulate the GUI according to the GUI node hierarchy contained in the event (Lines 14-16 Figure 1b, ⑦ ⑧ Figure 1a). The GUI manipulation is realized by issuing *a11y actions* that can mimic user interactions such as pressing a button, scrolling the screen, inputting text, etc. It can also be realized by sending *a11y global actions* to simulate global controls such as returning to the home screen, locking the screen, etc.

2.2 Uncovering 0-Day Abuse Evidence from a11y Malware

DVa's benefit over standard malware analysis techniques is that it dynamically models victim-specific a11y information that malware is probing for. With DVa, an investigator will have access to exclusive live interaction between the malware and this a11y information. In fact, lacking this evidence, traditional techniques are incapable of fully extracting malware's targeted victims and abuse vectors.

Consider the Cerberus malware studied extensively by malware analysts. Based on DVa's analysis of a Google Pixel 3 device infected with the Cerberus malware[2], DVa discovered a previously unknown *automatic transaction* abuse vector targeting 12 new victims.

Existing Malware Analysis Reports. Cerberus is widely considered to be a RAT targeting multiple banking, utility, and social media apps, capable of stealing users' credentials [19], [20]. Lines 20-27 of Figure 2 show the existing credential stealer abuse capabilities targeting financial institutions. When Cerberus receives an a11y event, it compares the source of the event with a hard-coded victim package name. If the source matches with a targeted victim, the malware then receives and loads overlay screen resources tailored to attack identified victim apps (Line 24). The `onA11yEvent` handler will also trigger text logging capabilities after loading the overlay screens to illicitly acquire users' credentials (Line 25). DVa's analysis also revealed all 89 targeted victims with the credential stealer abuse found by industry reports.

DVa's Malware Analysis Discovery. In addition, DVa uncovered 0-day dynamically loaded automatic transaction abuse routines targeting 12 additional victims, as shown in the highlighted red box of Figure 2. Lines 3-9 of Figure 2 show the victim discovery routines that lead to the loading of new abuse code. When the a11y service is connected, Cerberus dynamically queries packages installed on the device and compares them with a secret dictionary of hashes of the new victims' package names. When a package matches, it then executes multiple verification routines such as `getLaunchIntentForPackage()`, `getPackageInfo()`, and `getInstallSourceInfo()` to determine the validity of the victim app states. Only when all victim states are verified will Cerberus proceed to request and load tailored abuse code targeting the victim, as shown in Lines 11-13 of Figure 2. Investigators without DVa may notice these routines statically, but they cannot decode the victim hash in Line 8 to understand the conditions for triggering dynamic code loading. To overcome this, DVa creates a lightweight victim-information model that mimics benign apps' static characteristics and dynamic behaviors of 37K unique popular apps. With access to this model, DVa then remodels all interface functions the malware relies on to acquire victim states such as package query APIs, package installation states APIs, a11y event queries, etc. to mimic the live interactions as if all 37K benign apps are present on the user's device. Through this modeling, DVa guides Cerberus to execute the whole victim parsing routine and trigger dynamic code loading. DVa then extracts the secret victim package names that matched Cerberus's hash dictionary. DVa found the Chime mobile banking app's package name

[2]MD5: 9236f4009503b4216e6773741b9d8ec0

(com.onedebit.chime) along with 11 other package names, thus confirming Cerberus's undiscovered victim targets.

With the dynamically loaded abuse routines, DVa also revealed the code containing the newly discovered automatic transaction capability. Lines 28-37 show an example of the capability targeting the Chime mobile banking app. However, even when faced with such routines, a traditional malware analysis technique is unable to attribute the capability to its targeted victim because the trigger conditions of those routines are unknown. Symbolic execution into the entire app at this point will lead to state explosion. DVa uses a novel abuse-vector-guided symbolic analysis to extract routines listed in Lines 32-35 of Figure 2. After solving the symbolic constraints, DVa determines that these routines all depend on the value of the a11y event package name and its GUI state, whose symbolic value assignment occurs in Lines 29 and 31. DVa solves the symbolic hash constraint in Line 29 to derive a concrete hash value. DVa then matches this hash value with a hash observed in the dynamic execution traces and reports the plaintext victim package name that generated the hash. As such, DVa attributes Lines 32-35 to the Chime mobile banking app that the malware targets. Finally, by modeling the a11y API invocation sequences in Lines 32-35 in the context of the victim target's GUI screen, DVa reveals that each one is capable of navigating to the transactions page, selecting the transaction targets, filling the transaction amount, and sending the transaction requests, etc.

2.3 Threat Model

DVa's goal is to identify the victims targeted by a11y malware and attribute a11y abuse vectors to each victim. We assume the user's Android device is infected with malware that requests the a11y permission and the user has already granted the requested permissions. This is reasonable because a11y malware has been infiltrating the Google Play Store [21] and can trick users into granting a11y permissions [22]. DVa's scope of abuse vector detection covers malware actions conducted by a11y APIs and targeting specific victim apps. That said, malware actions that complement a11y abuse but are conducted without a11y APIs (e.g., displaying overlay screens with SYSTEM_ALERT_WINDOW) are not considered by DVa. Additionally, a11y actions that do not have a specific targeted victim app (such as recording screenshots with a fixed interval and recording keystrokes whenever there is keyboard input) are outside the scope of DVa.

3 Methodology

DVa is a backend service that conducts analysis on a11y malware detected by an on-device AV engine (e.g., Google Play Protect). DVa takes the malware APK in the user-data disk of an Android device from adb [23] as input[3]. DVa pulls the list of installed applications from adb as victim app candidates on the device. DVa requires no prior knowledge of malicious a11y apps. For each a11y malware sample, DVa outputs its targeted victim apps, victim-specific a11y abuse vectors, and persistence mechanisms enabled by a11y.

3.1 Victim Detection

The first goal of DVa is to identify victim apps on users' devices that might have already been abused, as well as potential victim apps that can be abused. However, identifying all possible victims is not as easy as it seems. To evade the security vetting system of the application stores, a11y malware dynamically loads payloads locally or fetched from C&C servers during runtime. Specifically, the most advanced a11y malware loads attack payloads only after scanning installed apps on victim devices, checking victim app configurations, and receiving acknowledgments from C&C servers [24]. This dynamic loading practice could easily make static analysis ineffective since the payload is not available at the time of the investigation. Worse still, even if the payload is available, the wide adoption of victim information encoding and encryption schemes makes decoding them statically challenging. While dynamic analysis with a SOTA sandbox can fake certain environmental parameters and statuses in system API calls, it cannot generate customized data structures such as a11y events that malware is checking for.

To overcome these challenges, DVa uses dynamic hooks to mimic the existence of both targeted victims apps (§3.1.1) and their generated a11y events (§3.1.2).

3.1.1 Dynamic Victim-Guided Execution

DVa first must be able to intervene with malware's victim-probing process and guide it to believe that the victims are present and valid. On Android, the access points to scan the status of installed apps are the package manager APIs [25].

Algorithm 1 presents DVa's strategy to model victim query APIs. DVa keeps a predetermined victim database (Π) containing each victim app's traits and properties. The victim candidates are collected by querying the top-25 Android apps in 34 categories across 92 countries from market intelligence platforms AppBrain [26] and SensorTower [27]. Currently, the database contains 37K unique Android packages. As shown in Lines 2-28 of Algorithm 1, for each package manager API, DVa applies a dynamic hook and models it to return customized information containing legitimate victim information. If the query is generic, DVa returns the handle to the system's default handler, as shown in Lines 5-7. If the hooked API queries the information of a single (specific)

[3] In a real-world scenario, Google Play Protect can use its internal extraction method to obtain the malware APK.

Algorithm 1: DVa's victim query modeling.

```
   // Victim model, Π_x is model of a single victim
1  Π = {Π_1, Π_2, Π_3, .....};
   // Model all Android packageManager APIs, override
      before-method handler
2  @Override
3  Function Object beforePmMethod():
4      switch pm do
           // API queries Generic info
5          case G do
               // Use default system handler
6              return;
7          end
           // API queries Individual package info
8          case I do
               // Model of a single victim app
9              Π_x = Π.get(pm.param.packageName);
10             R = new pm.returnType;
               // Pierce back custom victim fields
11             for field ∈ pm.returnType do
12                 a = Π_x.get(field);
13                 R.set(a);
14             end
15             R.pad();
16             return R;
17         end
           // API queries Collective info of packages
18         case C do
19             R = new pm.returnType;
               // Pierce back custom victim field from
                  many victim apps
20             for package ∈ pm.param.packageNames do
21                 Π_x = Π.get(package);
22                 field = Π_x.get(pm.returnType);
23                 R.set(package, field);
24             end
25             R.pad();
26             return R;
27         end
28     end
29 end
```

package (e.g., App X), DVa looks up the associated victim model Π_x. DVa then pierces all fields required in the API return value from Π_x and returns the custom value (Lines 8-17) such as package name, app icon, package install time, package launch intent, etc. Similarly, when the hooked API queries collective information of several packages (e.g., Apps A, B ... N), DVa obtains the required fields from each victim model $\Pi_A, \Pi_B ... \Pi_N$, and pierces them together (Lines 18-27). By returning the device status that malware is looking for, DVa tricks it into believing that its target victims, together with their traits, exist and are valid. DVa is also able to handle general anti-dynamic-analysis techniques equipped by the malware (detailed in Appendix A).

3.1.2 Mimicking Victim a11y Events

For advanced malware that eavesdrops on device window states and launches victim-specific attacks only after the user

Algorithm 2: DVa's large-scale triggers of victim a11y events.

```
   // Trigger startup events for each victim model
1  for Π_x ∈ Π do
2      ae = a11yEvent.obtain();
       // Mimics an app startup event
3      ae.setEventType(WINDOW_STATE_CHANGED);
       // Pierce together a11y event with victim model
4      for field ∈ a11yEvent do
5          Π_xField = Π_x.get(field);
6          ae.set(Π_xField);
7      end
       // Broadcast victim a11y event to the malware
8      am = getSystemService(Context.a11yService);
9      am.sendA11yEvent(ae);
10 end
```

instantiates the victim app, DVa needs to automatically fire victim app a11y events on a large scale to trigger the malware's victim-specific attack routines.

Algorithm 2 presents DVa's strategy for triggering victim a11y events on a large scale. For each victim model Π_x in the victim database Π, DVa obtains a default a11y event. DVa then lets the event mimic the change in the foreground GUI when a user first opens up the victim app by setting the event's type to `WINDOW_STATE_CHANGED`. For each field in the a11y event, DVa queries the victim model Π_x and populates the a11y event with the acquired custom victim trait, as shown in Lines 4-7 of Algorithm 2. The fields populated in the event contain key information that represents the GUI screen during the initiation of a victim app such as event time, content change type, view locations, view content, etc. DVa then acquires the system a11y manager and broadcasts the customized a11y event, as shown in Lines 8-9. This tricks malware to believe that a victim app is open and loads targeted abuse routines.

With DVa's capability of mimicking victim existence and triggering victim a11y events on a large scale, investigators can now notify users of victim apps targeted on their device as well as notify developers of additional malware targets.

3.2 Abuse Vector Detection

After identifying the targets of a11y malware, DVa next finds unique abuse vectors empowered by the a11y service. However, detecting abuse vectors from the dynamic victim-guided execution is challenging. Specifically, the a11y event structures, embedded with trees of GUI elements that malware looks for, are enormous considering all victim apps.

3.2.1 a11y Capabilities

To accurately model the abuse vectors, we first systematically categorize the capabilities of a11y APIs according to the official a11y API doc [1], [18], [28]. Since an a11y abuse relies on the Android a11y service, the malware has to use

Table 1: A11y capabilities, generic a11y techniques, and a11y-empowered abuse vectors in the context of victim apps.

a11y Capabilities[1]	**Sample APIs or Identifiers**
a11yService	
GlobalAction	`performGlobalAction()`, `dispatchGesture()`, `findFocus()`, `takeScreenshot()`, `takeScreenshotOfWindow()`
a11yEvent	
QuerySourceNode	`getSource()`, `getPackageName()`, `getRecord()`
QueryViewChange	`TYPE_VIEW_CLICKED`, `TYPE_VIEW_SELECTED`, `TYPE_VIEW_TEXT_CHANGED`, `TYPE_VIEW_TEXT_SELECTION_CHANGED`
QueryWindowChange	`TYPE_WINDOW_STATE_CHANGED`, `TYPE_WINDOW_CONTENT_CHANGED`, `TYPE_WINDOWS_CHANGED`
QueryNotiChange	`TYPE_NOTIFICATION_STATE_CHANGED`
OtherQueries	`TYPE_VIEW_HOVER_ENTER`, `TYPE_TOUCH_INTERACTION_START`, `TYPE_ANNOUNCEMENT`, `TYPE_SPEECH_STATE_CHANGE`
a11yNodeInfo	
QueryNodeInfo	`findA11yNodeInfoByText()`, `getBoundsInScreen()`, `getText()`, `getPackageName()`, `isPassword()`
NodeAction	`performAction()`
a11y Techniques	**Action Models**
Read	
EvdpText[2]	`QueryWindowChange` → `QuerySourceNode` → `QueryNodeInfo(Text)`
EvdpClick	`QueryViewChange` → `QuerySourceNode` → `QueryNodeInfo(ViewProperties)`
EvdpGesture	`QueryGestureDetection`
ScreenLog	`QueryWindowChange` → `QuerySourceNode` → `QueryNodeInfo(Text)` ‖ `GlobalAction(Screenshot)` → `FileWrite` ‖ `DBWrite` ‖ `InternetSend`
Inject	
FillText	`NodeAction(FillText)`
InjClick[3]	`NodeAction(Click)` ‖ `GlobalAction(Back/Home)`
InjGesture	`GlobalAction(Gesture)`
Abuse Vectors	**Technique Models**
Auto Transaction	`QueryWindowChange(FinancialStackTrace)` ↔ `ScreenLog && InjClick` ‖ `ScreenLog && FillText`
Steal Credentials	`QueryWindowChange(LoginScreen)` → `ScreenLog` ‖ `EvdpText`
Steal Auth. Code	`GetLaunchIntent(Auth./SMS)` → `SendIntent` → `EvdpText` ‖ `ScreenLog`
Hide/Delete Noti.	`QueryNotiChange` → `InjClick && InjGesture`
USSD Code	`GetLaunchIntent(Phone)` → `SendIntent` → `ScreenLog` → `InjClick`
Fake Calls	`QueryWindowChange(Phone)` → `EvdpText && InjClick` → `LaunchActivity`
Ransom Screen	`QueryWindowChange` ‖ `EvdpClick` ↔ `InjClick` ‖ `LaunchActivity`

1: Excluding APIs that are default callbacks, used to construct objects, acquire handles, and misc APIs.
2: Eavesdrop Text. 3: Inject Click.

capabilities provided by the service [1], the `a11yEvent` [18] dispatched to the service, or the `a11yNodeInfo` [28] embedded within the `a11yEvent`. The a11y capabilities section in Table 1 shows the categorization of official APIs based on their purpose supplemented by sample APIs or identifiers within the categories. For example in Row 5 of Table 1, for an app to query the information of an on-screen element, it has to use APIs provided by the `a11yEvent` class that can query the source nodes, such as `getSource()` or `getPackageName()`. Similarly, for an app to click on an on-screen element on behalf of the user, it has to rely on node action API `performAction()` supplemented by the `click` action provided by the `a11yNodeInfo` class, as shown in Row 12 of Table 1. DVa uses these a11y capabilities as basic blocks for modeling a11y behaviors.

3.2.2 a11y Techniques

Next, DVa models the generic techniques an app can achieve using the above capabilities. Since an a11y service receives an event whenever notable changes occurred in the GUI [18], it can read the event to understand what changes occurred. Based on this knowledge, the service can then inject inputs on behalf of the user to conduct actions based on the conditions of the GUI change. A11y Techniques section in Table 1 shows the techniques that can either read screen changes or inject input and their action models.

To detect these techniques, given malware's a11y event handler, DVa uses it as the entry point to build a static Call-Graph (CG). Within the CG build, DVa sets the sink functions as the last action function in any of the techniques. For each sink function marked, DVa then queries its caller methods in the CG until it finds the a11y event handler or reaches the top parent. DVa then selects the call sequences that originate from the a11y event handler as candidates and constructs Control-Flow-Graphs (CFG) for each function within the call chain using the built-in CFG constructor in Soot [29].

To confirm the complete action model and to resolve parameters of action APIs to concretize actions, DVa starts symbolic execution from the entry point along each CFG. DVa first marks the input *a11y event* parameter as symbolic. Whenever DVa encounters an unseen variable, it introduces a new symbolic label. If any part of the variable is reassigned, DVa propagates the label and marks the new variable as symbolic. When encountering branches, DVa duplicates the

Table 2: Malware's a11y-empowered persistence mechanisms, their triggering conditions, and their a11y behaviors.

Persistence Mechanisms	Triggers	Behaviors
Disable Device Protection	Security Settings Screen	Back / Return Home
Prevent Info Lookup / Uninstall	App Detail Setting Screen	Back / Return Home
Prevent a11y Permission Revocation	a11y Settings Screen	Back / Return Home
Escalating Privileges	a11y Permission Granted	Permission Screen with Screen Navigation
Uninstall Other Apps	Uninstall Package Setting(w/ Permission)	Screen Navigation
Disable Power Options	Power Options Dialog	Back / Return Home

symbolic label, continues execution, and records along both directions. DVa ends the traversal along a path when it successfully reaches the targeted sink APIs that it is searching for, or when it encounters new functions not in the marked call chains, indicating an irrelevant path. After completing traversal along all call paths, DVa checks the validity of each call path by confirming the symbolic labels' existence in each intermediate routine. It also concretizes sink APIs to exact actions by matching the value of the symbolic parameters in the APIs back to their original value. For example, DVa confirms a path to contain the *InjClick* technique when the parameter of the node action resolves to the identifier of `ACTION_CLICK` instead of other actions.

3.2.3 Victim-Specific Abuse Vectors

Preliminary Study. Next, DVa resolves the action models in the context of the victim app to detect abuse vectors of a11y malware. We started by searching for reports of a11y malware published between 2017 and 2022 (reviewing and cataloging results from the Google search query: Android accessibility malware) [2]–[4], [19], [20], [30]–[39]. We also queried in VirusTotal [15] and manually investigated all 43 unique a11y malware appended in the above reports and found the seven abuse vectors, as listed in Table 1.

Dynamic Victim Stack Trace. DVa first searches for any routines that examine the state of an a11y event in the previously detected a11y techniques action models that match with any dynamic victim detection stack traces. A match implies that the following technique is specifically targeting the victim detected in the dynamic victim-guided execution. For example, as shown in Row 24 of Table 1, when a QueryWindowChange call of a detected `ScreenLog` and consecutive `InjClick` or `FillText` technique has a matching stack trace from a financial victim app up until the call, DVa marks the trace to be an *Auto Transaction* abuse vector and attributes it to the specific financial victim app.

To match additional abuse vectors to the victim app, DVa compares the concretized parameter solved in symbolic constraints of the a11y event query APIs against other such APIs from all detected abuse vector call sequences. If the same value is resolved in another call, DVa confirms that it also constitutes the abuse routine against the same victim.

Other Victim Hints. DVa also looks for other call sequences before or after a11y techniques to infer victim abuse vectors. DVa scans the marked technique call sequences for intent crafting and firing functions and uses the resolved symbolic value in the parameters to infer victims. For example, when DVa detects that before invocations to `EvdpText` or `ScreenLog` in a call sequence, an activity launch intent is concretized to the *Google Authenticator's* package name, it is marked with the *Steal Authentication Code* abuse vector.

With DVa's ability to model a11y-specific abuse vectors and match dynamic victim traces, an investigator can attribute the abuse vectors to each previously detected victim and notify users and victim app developers of victim-specific assets and behaviors targeted by a11y malware.

Extendability of DVa. We designed DVa to be modular and extendable to detect new abuse vectors. When a new malware emerges with novel techniques or abuse vectors, the investigator can easily extend DVa by (1) adding the abuse vector's sink API into DVa's sink list and (2) adding the new action sequence in DVa's symbolic model.

3.3 Persistence Mechanism Detection

Aside from abusing victims, a11y malware modifies the user's interaction with system settings to persist for as long as possible on user devices. DVa next detects how malware utilizes a11y service to do so and notify users about possible changes to system settings. To achieve this, DVa invokes the triggers of persistence mechanisms that malware looks for and deploys dynamic hooks to capture their a11y responses.

Triggers to a11y Behaviors. Table 2 Column 1 lists the mechanisms empowered by a11y service malware use to persist on user devices. Since malware tries to adopt them as early as possible after installation and acquiring a11y permissions, DVa tries to match the triggering conditions listed in Table 2 Column 2 for each of the mechanisms, satisfy them, and trigger them to observe malware's reactions to them. For example, to examine if malware prevents a user from looking up its information and uninstalling it, DVa crafts an intent to open the app detail menu of the malware in *Settings* and sends it to navigate to the screen; to examine if malware prevents users from powering off or restarting the device, DVa sends an action to open the device power options dialog. A similar strategy is adopted to trigger other mechanisms listed, except for when testing for escalation of privileges, in which case DVa dumps the malware's runtime permissions and device admin apps when the foreground

Table 3: Validation of the victims, abuse vectors, and persistence mechanisms detected by DVa together with AVClass2 labels of the top-10 a11y malware families.

D#	Family	# Victims				# Vectors					# P Mechs.[1]					AVClass2 CLASS & BEH Labels
		GT	D[2]	TP	FN	GT	D	TP	FP	FN	GT	D	TP	FP	FN

	Total[3]	220	206	206	14	55	54	53	1	1	55	55	55	0	0	—

1: Persistence Mechanisms. 2: DVa's detection result. 3: Indicates total instances of detection, including duplicates.

activity stabilizes after granting the a11y permission.

Intercepting a11y Behaviors. To interpret a11y responses of the mechanisms, DVa applies dynamic hooks to capture their a11y actions (listed in Table 2 Column 3). For example, after DVa triggers the power options dialog, if back or return home actions to send users away from the screens are captured, DVa confirms malware's abuse of a11y service to persist on a user device through *disable power options*. With DVa's persistence mechanisms detction, investigators can notify users of illicit changes to their device configurations.

4 Validating Our Techniques

4.1 Implementation

Abuse-vector-guided symbolic analysis in DVa is implemented in Java (7.3K lines) leveraging Soot [29], used in top-tier research [40]. Dynamic hooks leverage EdXposed [41] with 1.6K lines of Java code. Dynamic analysis management is implemented in Python (1.3K lines). AVClass2 [42], a SOTA malware labeling tool is used to classify malware families. For deriving malware labels, we used the latest PyPI avclass-malicialab 2.8.7 with -t flag to extract all CLASS and BEH (behavior) tags from VirusTotal reports. The victim application dataset is queried from AppBrain [26] and SensorTower [27], SOTA Android market intelligence services. Benign application icons and UI screens are collected from Google Image Search. We used an Ubuntu 20.04 LTS system to host DVa's static analysis module. DVa's dynamic analysis and a11y malware are hosted on 5 Google Pixel 3 (64GB, 4GB RAM) phones running Android 9.0 (Pie).

4.2 Validation Setup

Due to the physical disk size limitation, we installed the top-300 banking apps across all regions together with 100 other apps evenly distributed among the other five categories of apps such as crypto, authentication, social media, communication, and shopping apps on each device. Then we used AVClass2 [42] to label our malware dataset and randomly picked samples from the top-10 malware families until we found two samples in each family with industry reports and live C&C response, resulting in 20 samples. The C&C response is determined by matching with at least one of the contacted IP addresses in VirusTotal's malware relation reports. We installed the two samples from each family onto the five devices respectively in two batches and dumped the disk image, resulting in 10 device investigations, as listed in Column 1 of Table 3. We manually reverse-engineered these malware samples using Jadx [43] and used industry reports to derive the ground truth[4].

4.3 Validation Results

Table 3 presents DVa's validation results. Column 2 shows the top-10 a11y malware families that are installed on each device investigation. Columns 3, 7, and 12 show the ground truth (GT) number of abused victim apps, abuse vectors, and categories of a11y-empowered persistence mechanisms. The following columns present DVa's detection on the respective tasks. DVa's evaluation metrics, including True Positives (TP), False Positives (FP), and False Negatives (FN), are presented in the rest of the columns.

Victim Detection. As shown in Column 5 of Table 3, DVa correctly identified (TP) 206 instances of targeted victims. Our manual investigation together with industry reports revealed 220 instances, indicating DVa's 94% accuracy in detecting victims. In Row 6, DVa produced 11 FNs while detecting victims for the Anubis family. With investigation, we found that while matching abuse code with dynamic execution trace, DVa's symbolic engine failed to reconstruct the victim package names. This is due to Anubis's adoption of a complex customized data structure for encoding victim

[4]Note that DVa does not need nor have access to the ground truth data.

information. We confirmed that this is a rare behavior. Additionally, while investigating devices 1 and 8, DVa introduced 2 FNs in a Spynote sample and 1 FN in an Androlua sample. We found that the 3 FN victims – *Cajasur*, *Kutxabank*, and *Banca Móvil Laboral Kutxa* – were reported in industry reports but were not installed on the devices. After installing them manually, DVa observed the abuse vectors and confirmed them as victims.

Abuse Vectors Detection. As shown in Columns 7 and 9 in Table 3, DVa successfully detected (TP) 53 categories of abuse vectors among 55 categories in the GT, yielding a 96% detection accuracy. As shown in Row 5, DVa introduced 1 FP while analyzing Spymax malware on device 4. We manually investigated and found that it contained a screen navigation error handler to immediately return to the malware's screen after failed attempts to parse the on-screen element tree, making DVa incorrectly attribute its abuse vector. We confirmed that this is a rare occurrence. DVa also introduced 1 FN while investigating device 5. Due to the unreachability of Anubis malware's C&C server for remote code loading, DVa was unable to detect the *ScreenLog* behavior in industry reports, which is solely contained in the dropped payload.

Persistence Mechanisms Detection. Shown in Columns 12-16 of Table 3, DVa achieved 100% accuracy, detecting 55 instances of persistence routines.

Comparison with AVClass2. To understand the advantage of DVa in reporting fine-grained abuse vectors specific to a11y, we compared DVa's result with labels reported by the SOTA malware intelligence engine AVClass2. The last column of Table 3 shows all class and behavior tag labels reported by AVClass2's extraction from VirusTotal reports. As observed in all rows, the labels reported are high-level and coarse-grained without containing evidence of detailed abuse behaviors. For example in Row 4, the only labels reported for the Spymax malware are *spyware* and *grayware*, which do not contain evidence of targeted victim or specific techniques abused as reported by DVa. Similarly in Row 2, although the labels contain *bankbot*, *execdownload*, and *infosteal*, no specific bank victims or abuse vectors that constitute infosteal or executable download are evident.

4.4 Coverage Assessment

Next, we evaluated how much of an advantage DVa's abuse vector modeling provides over a generic data-flow analysis. We hypothesized that a generic data-flow analysis would over-taint paths and lead to false positives in discovering a11y abuse and be insufficient in detecting behaviors reliant on dynamic execution traces. We compared victims, abuse vectors, and persistence mechanisms extracted from paths explored by DVa and those explored by the SOTA taint data-flow analysis tool, FlowDroid [40].

Experiment Setup. We used FlowDroid's latest stable-build version (2.11.1) as the starting point to derive data-flow path coverage. The input APKs are the ones repackaged with dynamically loaded DEX files extracted by DVa. We set the source function to be the `onA11yEvent` handler and the sink functions to be all functions declared in `a11y service`, `a11y event`, and `a11y node info` classes (in total 246 functions). We found that initially, FlowDroid was unable to track data-flow from the `onA11yEvent` callback function because it doesn't have a concrete invocation. Because of this issue, we modified FlowDroid's source tracking logic of the `onA11yEvent` handler to taint the first assignment statement of the function parameter instead. We used the standard CHA algorithm for FlowDroid to generate the CG.

Table 4: Comparison of victims, abuse vectors, and persistence mechanisms detected by DVa versus FlowDroid.

D#	Family	DVa			FlowDroid				
		V[1]	PAV[2]	PM[3]	V	PAV	FP	FN	PM
1	Spynote	11	207	6	0	1,348	1,165	24	0
2	Hqwar	5	63	4	0	418	360	5	0
3	Bianlian	20	217	6	0	1,719	1,540	38	0
4	Spymax	17	236	7	0	1,968	1,771	32	0
5	Anubis	78	746	8	0	3,458	2,767	55	0
6	Fakecall	4	51	3	0	342	300	9	0
7	Cerberus	29	269	7	0	1,317	1,097	49	0
8	Androlua	14	199	6	0	813	639	25	0
9	Mobtes	16	182	4	0	1,006	847	23	0
10	Mobtool	12	157	4	0	1,291	1,143	9	0
	Total	206	2,327	55	0	13,680	11,629	269	0

1: Detected victims. 2: Paths flagged with a11y abuse.
3: Detected persistence mechanisms.

Assessment result. Table 4 shows the victims detected, number of paths flagged with a11y abuse, and persistence mechanisms detected by DVa and FlowDroid. The FP and FN columns for DVa are omitted because they were discussed in Table 3. FP and FN columns for FlowDroid are derived by manually examining the data-flow paths. As discussed in §4.3, we counted seven FP paths that DVa flagged in the Spymax samples as TP for FlowDroid in Row 4. For the Anubis samples in Row 5, we omitted FN paths for both DVa and FlowDroid because the payload containing the reported behavior was statically unavailable. As shown in the *Total* row of Columns 4 and 7, DVa flagged 2,327 paths with a11y abuse, while FlowDroid flagged a total of 13,680. However, in Column 8 we see that FlowDroid incurred FP in 11,629 (85%) paths that do not constitute a11y abuse. This is because FlowDroid does not have access to the abuse vector modeling and flags irrelevant paths with generic a11y APIs. Column 9 shows that 269 paths were marked by DVa as a11y abuse but not traversed by FlowDroid. We found that these paths contain global action system APIs such as `dispatchGesture()` and `findFocus()` for which FlowDroid does not have pre-extracted method summaries, thus breaking the taint propagation. Additionally, Columns 3 and 6 show the number of victims detected along the paths

with a11y abuse. While DVa extracted 206 victim apps, we manually verified the paths flagged by FlowDroid and found that 0 victim apps could be resolved with the data-flow paths alone. This is because the constraints along all paths can only be resolved to one-way encoded hashes and cannot be further matched. With the help of execution traces that DVa extracted in victim-guided dynamic analysis, DVa has a unique advantage in resolving statically unsolvable victim constraints. Finally, Columns 5 and 10 show the number of persistence mechanisms detected. While DVa reported a total of 55 instances of persistence mechanisms, the data-flow paths alone generated by FlowDroid cannot derive any of them because their trigger conditions and sink actions are unknown and unmodeled by FlowDroid.

5 Findings

To help gather large-scale malware behavioral insights from a11y malware, we deployed DVa on 5 Google Pixel 3 phones. These phones were repetitively infected with each of the 9,850 malware collected from VirusTotal [15] from August 2022 to December 2022. The selection criteria for the samples that they be (1) are labeled by at least five antivirus engines, ensuring that they are indeed malware [44] and (2) contain the `BIND_A11Y_SERVICE` permission declaration string in the app manifest file, which indicates that they abuse the Android a11y service. Out of the 9,850 samples collected, 7,700 samples are labeled by AVClass2 [42] spanning 197 families. The rest of the 2,150 samples contain no family labels and are treated as singleton malware.

DVa's dynamic analysis has an average runtime of 110 seconds per sample. Since DVa is deployed on a backend server, this overhead is acceptable. The execution overhead on the frontend user's device is negligible (no more than the current Google Play Protect).

5.1 Targeted Victims

Table 5 presents the identified victims grouped by category in Column 1, their most popular geolocation country code in Column 2, victim count and victim median download number in Columns 5 and 6, and their abused malware count and family count in Columns 7 and 8. As shown in Columns 5, 7, and 8 in the *Total* row, DVa detected a total of 4,291 malware samples spanning 65 families abusing 215 victim apps. DVa reported no targeted victims for the other 5,559 samples. Upon further investigation, we found that 4,614 of the samples did not have any live C&C responses, so we excluded them from the victim-detection evaluation. For the other 945 samples, we manually investigated 10 random samples and found that six of them are generic utility apps that misuse the a11y service such as file manager, overlay widget, notification modifier apps, etc. In fact, prior work [7], [45] confirmed that benign apps also misuse the a11y service to achieve functionality purposes. These utility apps do not target specific victim apps, so we exclude them from the victim-detection evaluation.

Of the 4,291 malware samples with detected victims, 2,575 require C&C response to drop victim-specific information and still have live C&C connections. The rest of the 1,716 malware samples contain local abuse routines that are present statically or loaded at runtime. Column 6 in the *Total* row shows that the median download number is 10M+ across all 215 abused victim apps. Columns 1 and 5 show the abused victim apps' categories along with their ranked victim app count in each category. The 215 victim apps span a total of seven categories – Banking, Crypto, Shopping, Social Media, Transportation, Authentication, and Communication. Banking apps are the most abused victim app category with 159 (74%) apps targeted by 3,579 (83%) malware samples across 55 (85%) families, corroborating the banking apps' vulnerability to a11y-based attacks found by prior work [46]. Following Banking apps are Crypto and Shopping apps, with, respectively, 16 (7%) and 13 (6%) victim apps abused by 1,130 (26%) and 257 (6%) malware samples across 23 (35%) and five (8%) families. As shown in the *Auth.* category row, although only five authentication apps (e.g., Microsoft Authenticator, Google Authenticator) are abused, they are abused by a majority of 3,022 (70%) malware samples across 52 (80%) families. The median victim app download numbers in Column 5 reveal that Social Media apps are the most popular apps that are targeted, with a median of 1B+ downloads. Communication apps such as Gmail, WhatsApp, etc. are the next most popular apps, with a median of 100M+ downloads. All victim app categories have at least a median of 5M+ downloads, indicating a large batch of renowned victim apps targeted by a11y malware.

Takeaway. DVa identified 215 victim apps spanning seven categories abused by 4,291 a11y malware samples across 65 families. *Banking* apps are the most widely targeted category, with 74% of all victim apps falling in the category and targeted by 83% a11y malware samples across 85% families. Seventy percent of a11y malware samples also target a set of five *Authentication* apps, extending their capabilities into infiltrating other benign apps. A11y malware targets renowned victim apps with a median download of over 10M across all categories. With the victim targets extracted, investigators can compare the targets with existing services on the user's device to identify abuse tha has already occured, as well as notify developers of malware targets that have not yet been abused.

5.2 Abuse Vectors

After extracting the victims of a11y malware, DVa helps investigators extract abuse vectors and attribute them to the victims. Columns 3, 4, 9, 10, and 11 of Table 5 present the a11y techniques and abuse vectors tailored for each category of victim apps. Columns 3 and 4 show the different abuse

Table 5: Categories of victim apps, a11y malware that target them, and abuse vectors statistics.

1: Average Abuse Vectors per victim app per malware. 2: Medium download number of abused victim apps.
3: Average of System a11y Query APIs used per a11y Technique. 4: Average of System a11y Action APIs used per a11y Technique.
5: 1,235 samples contain no AVClass family name. *: Not a sum of subtotals, multiple targeted victims per malware.
†: Excluding Others Column.

vectors and their average numbers targeting each victim.

As shown in the *Total* row of Column 4, a malware sample adopts an average of 13.9 vectors to target each victim. Looking at the *Subtotal* rows of Column 4, malware targeting a *Banking* or *Crypto* victim implements an average of 21.1 and 24.1 abuse vectors toward each victim, 52% and 73% higher than the average. This indicates that malware targeting these two categories adopts more event checks to handle a diverse set of window change events. Comparing the subrows of each victim category, the most adopted abuse vector across banking, crypto, shopping, and transportation apps is *Steal Credentials*, followed by *Auto Transactions*. The

Authentication apps are also targeted with 13.7 *Steal Credentials* abuse vectors, accounting for 79% of all abuse vectors. This corroborates the feasibility of a11y abuse proposed by prior PoC attacks [9], [47], [48].

Column 9 of Table 5 shows the a11y techniques used by each abuse vector. We further categorize APIs adopted by the techniques into *query APIs* (those that query window states) and *action APIs* (those that conduct GUI actions) in Columns 10 and 11. As shown in the *Total* row of Columns 10 and 11, an a11y technique routine on average adopts 19.0 APIs to query the state of on-screen elements and 2.1 APIs to perform a11y actions. In the *Subtotal* rows of Column 10, we observe that an average of 29.0 and 25.4 query APIs are used in each a11y technique that targets *Banking* and *Crypto* apps, 53% and 34% more than that of the category average. This indicates that malware employs more a11y node checks to properly handle more on-screen elements that are present on each banking and crypto app screen.

The *Subtotal* rows of Column 11 show that the average number of a11y actions performed is similar across each category, having an average of 2.1 a11y action APIs to perform each a11y technique. This shows that the differences that malware adopts in handling victim UIs lies in the queries of on-screen elements instead of the actions to them. Instead of focusing on the actions that malware performs in an abuse technique, it is more important to measure the query strategy of the UI that malware deploys against each victim.

Takeaway. DVa extracted an average of 19.0 a11y query APIs and 2.1 actions APIs in each a11y technique to deploy 13.9 abuse vectors towards each victim app. A11y malware implements more handler routines to parse UI screens (52% and 73% higher than average) as well as more on-screen element query routines (53% and 34% higher than average) to abuse *Banking* and *Crypto* apps. The most frequently adopted abuse vectors are *Steal Credential* and *Auto Transaction* across most categories of victims. Although a11y action APIs are used to perform concrete a11y actions on elements, the query API usage is the pattern that differentiates abuse routines across different victim categories. With victim-specific abuse vectors extracted, investigators can enrich the notification to both users and victim developers with concrete abuse behaviors to guide loss remediation and develop proactive defenses.

5.3 Persistence Mechanisms

After extracting victim-specific abuse vectors adopted by a11y malware, DVa then helps investigators understand what a11y-empowered mechanisms malware adopts to persist on users' devices. Table 6 presents the persistence mechanisms adopted by the top-10 malware families. Columns 1-2 list the malware families and their respective sample counts. Columns 3, 4, 5, 8, and 9 show the number in each family that adopts mechanisms to disable device protection, prevent app info lookup/uninstallation, prevent a11y permission revocation, uninstall other apps, and disable device power options. Columns 6 and 7 show the number of samples that can escalate to device admin privilege and other privileges. As shown in the *Total* row, preventing a11y permission revocation, preventing info lookup, and disabling device protection are the three most widely adopted persistence mechanisms, observed in 9,102 (92%), 9,024 (92%), and 8,741 (89%) malware samples. Disabling power options is the least adopted, used by only 1,852 (19%) malware samples. Although 4,861 (49%) samples escalate privileges, only 157 (2%) of them (all from the *Fakeapp* family) escalate to device admin. Although the powerful device admin privilege can be illegally escalated by abusing a11y permission, very few malware samples choose to do that to avoid static and runtime antivirus scans since it is a strong indicator of malware. Similarly, few malware samples employ the intrusive mechanism of disabling power options to avoid alerting users. This adoption trend indicates that most malware deploys a11y-based measures to turn off system malware scanning and prevent users from querying, disabling, or uninstalling them.

Table 6: A11y-empowered persistence mechanisms used by the top-10 a11y malware families.

Family	#	D.P.[1]	P.L.[2]	P.R.[3]	E.P.[4]		U.A.[5]	P.O.[6]
					Adm.	Others		
Spynote	1,421	1,278	1,397	1,378	0	1,281	1,071	0
Hqwar	1,400	1,291	1,270	1,306	0	1,183	989	1,277
Bianlian	545	523	539	521	0	0	0	0
Spymax	461	429	446	451	0	384	351	0
Anubis	449	413	443	443	0	0	278	0
Fakecalls	351	319	290	303	0	323	0	0
Cerberus	349	244	305	305	0	0	102	0
Androlua	298	278	242	238	0	256	108	0
Mobtes	245	214	227	219	0	0	210	220
Mobtool	212	168	188	194	0	0	0	0
Others	4,119	3,584	3,677	3,744	157	1,277	979	355
Total	9,850	8,741	9,024	9,102	157	4,704	4,088	1,852

1: Disable device protection. 2: Prevent info lookup/uninstall.
3: Prevent a11y permission revocation. 4: Escalate privileges.
5: Uninstall other apps. 6: Disable power options.

Takeaway. DVa extracted six categories of a11y-empowered persistence mechanisms. Most malware abuses a11y to prevent users from revoking a11y permission (92%), looking up malware info / uninstalling malware (92%), and disabling Google Play Protect (89%). More intrusive behaviors such as preventing users from turning off or restarting the device (19%) and escalating to device admin privilege (2%), are less common to avoid antivirus detection and alerting users. Investigators now can understand how a11y malware persists on users' devices and notify users of malware's illicit modifications to system settings.

6 Case Studies

6.1 a11y 2FA Stealer

Authenticator apps use 2FA codes to provide users additional protection against compromised static passwords. In our experiments, DVa found that 471/545 malware samples from the Bianlian family can steal 2FA codes generated from the Google Authenticator app. Of the initial 545 Bianlian samples, DVa found that 224 implemented dynamic loading of their a11y service class or a11y event handlers. After DVa's victim-guided dynamic analysis, DVa captured and repackaged new DEX payloads from 144 samples using dynamic class loaders. With DVa's abuse-vector-guided symbolic analysis from the `onA11yEvent` handler, DVa found that 471 malware samples contained valid execution paths to *EvdpText* and *ScreenLog* techniques with the victim package name resolved to the Google Authenticator App, confirming their 2FA code stealing capability. The routines start with malware creating and sending an `Intent` that launches the main activity of the app. Then, the malware checks for package names of the `WINDOW_STATE_CHANGED` event to confirm the start of the app. After that, the malware creates an iterator from the source node of the event (a `ViewGroup` containing all child elements of the main activity) to capture all user's 2FA codes. Within each child view representing a 2FA code, the malware uses customized parsing logic tailored for the app to extract the text element of the code and the account name associated with the code.

a11y Blocking by 2FA Apps. Although a11y malware can steal 2FA codes, authenticator apps can choose to block untrusted a11y services from accessing the code. We picked the top-11 authenticator apps listed on the Google Play Store, installed them on one Google Pixel 4 device running Android 14, and manually registered 2FA code for *Twitch* in all apps. We then installed a custom app with an a11y service that listens for and parses a11y events from the views in each app that contain the 2FA codes. Only two of the 11 apps protect their 2FA codes from untrusted a11y services. We observed that the text properties of 2FA code fields in the *2FAS* (com.twofasapp) and *Dashlane* (com.dashlane.authenticator) apps are set to null, confirming their protection against untrusted a11y services. We manually reverse engineered the apps and found that both protect their views containing 2FA codes with the `A11yDataSensitive` property to block interaction with untrusted a11y services.

6.2 a11y Ransomware

DVa detected 131 instances of the Doublelocker malware that abuses a11y service for ransom, indicating new strategies for mobile ransomware. DVa also reported the *privilege escalation* persistence mechanism. DVa found that the malware automatically brings up device administration and default home app user dialog and utilizes hard-coded a11y node parsing routines to locate and click the confirm buttons without user acknowledgment. By escalating to the default home app, the malware ensures that whenever a user tries to press the *Home* button or the *Back* button, the malware is relaunched instead. This renders the device unusable to the user, achieving an intrusive abuse and persistence measure. The main activity captured by DVa indicates a classic ransom screen, asking users to send an equivalent of 50 US dollars worth of bitcoin to an attacker's account.

Traditional ransomware requires multiple user interactions to achieve its purpose. As DVa observed in the Doublelocker family, all user interactions required for the malware to achieve its ransom purpose is granting the a11y permission, thus increasing the attack's success rate.

Table 7: Effectiveness of the newest security patch and data-flow defense in eliminating a11y malware behaviors.

Behaviors	OS 9	OS 13	OS 13+DFD*
ScreenNav	13	9	6
Autofill	2	2	1
ScreenLog	7	5	0
Prevent Info Lookup	7	4	4
Prevent a11y Revocation	9	5	3
Escalating Privileges	3	2	2
Disable Power Options	1	1	1
Total	42(100%)	28(67%)	17(40%)

*: Data-Flow Defense.

6.3 Defenses Against a11y Malware

To understand how SOTA defenses are (in)effective at preventing a11y malware abuse, we evaluated how a11y malware behaves under the newest Android security patch (Android 13.0.0_r31) [11] and the most recent data-flow defense framework proposed by Huang et. al. [5]. We re-implemented the defense framework as stated in the study [5] as a patch to the AOSP that constrains data-flow from user inputs to non-GUI actions and from the GUI event change to non-user-perception APIs. We deployed DVa on one Google Pixel 4 device with the latest Android security patch and another one with our re-implemented defense framework. We evaluated using 14 malware samples that target Android SDK Level 33 (Android 13) from the dataset.

Table 7 shows the effectiveness of the previous two defenses. Column 2 shows the baseline behaviors extracted by DVa from the 14 malware samples. In total, 42 instances of malware behaviors are extracted under Android 9. Column 3 shows the behaviors extracted by DVa on the newest Android security patch (Android 13). Four malware failed to install with manifest malformed errors due to the incompatibility of code on Android 13. Of the remaining 10 malware samples, the system initially blocked the installation

of eight of them with Google Play Protect scanning. However, all eight malware samples successfully bypassed such scanning after we added a trivial asset (one JSON file in APK assets) and reinfected the re-signed APK. In particular, aside from the signature scanning, 100% of malware behaviors are observed under Android 13. Column 4 shows the effectiveness of the data-flow defense framework on Android 13. It successfully eliminated *ScreenLog* behaviors from all malware due to the constraints set to prevent information leakage from a11y events. However, 6/13 (46%) *screen navigation* behaviors still persist. Upon investigation, we found that malware relies on hardcoded screen coordinates not associated with a11y events to navigate GUI, thus circumventing the constraints. A similar technique is also utilized to prevent restriction to 4/7 (57%) illegal *info lookup prevention* behaviors, etc.

Shown in the Total row of Table 7, 67% of malicious a11y behaviors are still observed in the latest Android security patch and 40% can still bypass the SOTA data-flow defense framework on top of the latest Android security patch.

7 Discussion

Malware Detection. Since DVa acts as an add-on service to existing malware detection engines, DVa relies on identified a11y malware. Google Play Protect already has signature-based and behavior-based malware detection [49] incorporated. Researchers have also proposed methods to distinguish benign and malicious a11y apps based on explicit user intention used as sources for a11y actions [5].

Limitations. Although DVa can be extended to adapt to new abuse vectors, it still relies on the modeling of explicit functionalities defined by a11y APIs. That said, DVa will fail to detect abuse that relies on side-channel exploitation of a11y APIs. Additionally, although DVa optimizes its symbolic exploration strategy based on abuse vectors, path explosion and unsolvable constraints are still possible when malware adopts overly complex a11y event handlers, as seen in the Anubis samples in §4.3. Since DVa relies on dynamic analysis, malware can deploy new evasion techniques and time-sensitive behaviors to hinder the analysis. Although not observed in §4.3, malware could implement stringent runtime checks to find a very rare a11y event. Since DVa can only reconstruct a finite set of a11y events in dynamic analysis, DVa will miss detecting malware capabilities if they do so. If this happens, DVa's victim model can be extended to incorporate these a11y events.

Implementation Alternatives. While designing DVa, we considered alternative methods to implement victim detection. Fuzzing could be used to enumerate victim apps' properties. However, fuzzing would generate many a11y events that do not make sense in the context of any real victim app and risk alerting the malware of our analysis. Honeypots could be deployed to mimic the dynamic traits of victim apps and record abuse behaviors. However, honeypots passively execute malware, which would not drive the malware's execution through victim-generated a11y events. DVa's victim-guided dynamic analysis resolves both of these challenges by actively generating a11y events in the context of real victim apps' behaviors.

Future of Android's a11y Malware. Although Android 14 allows developers to restrict a11y information delivered to unvetted a11y services by checking the `A11Y_TOOL` flag [50], we expect future malware to subvert its vetting process. Since the process is manual and conducted at Google Play Store's submission stage, malware can still infiltrate the store by loading malicious code dynamically or through app updates just as it did before [21], [51].

Developer's Defense. App developers can choose not to broadcast a11y events if untrusted a11y services are found on a user's device [52]. However, this sacrifices the usability of the app because legitimate a11y services would also be blocked. The Coinbase app [53] adopted an out-of-band a11y verification that malware could not intercept: It displays a view that a11y cannot interact with, instructing users to shake the device to approve the use of an untrusted a11y service. Another approach is to protect an app's GUI in a more fine-grained manner. Specifically, wrap only the minimal views containing sensitive information with a11y delegates [54] to customize their exposed a11y events and declare `a11yDataSensitive` on views so that untrusted a11y services cannot interact with them.

8 Related Work

Benign Misuse of a11y Service. Benign services such as antivirus engines [45] and utility apps [7] can abuse the a11y service to automate legitimate tasks. Multiple works have focused on evaluating the misuse of the a11y service. Chen et al. [12] proposed dynamic analysis to automatically extract a11y issues while traversing the Android apps. Salehnamadi et al. [13] proposed Latte to automatically assess the functional correctness of an app's a11y features. Naseri et al. [14] conducted a study on how a11y functionalities are misused commonly by Android apps. Unlike detecting and analyzing benign misuse of the a11y service, focuses on dissecting malicious use of a11y to target victim apps.

Attacks on a11y Service. The a11y service provides malware with a unique surface [47] to launch phishing attacks [55] and make them more evasive [56]. Multiple works also focus on proposing PoC attacks that exploit the a11y service [9], [48]. Lei et al. [57] exposed a side channel of using consecutive content queries to guess passwords through a11y service. Mehralian et al. [58] exposed information leakage through overly accessible elements in Android's a11y service. Jang et al. [8] evaluated the a11y support for four operating systems and identified 12 attacks on them. Fratantonio et al. [10] uncovered an attack that can

control the UI feedback of an Android device should the malware be granted both the SYSTEM_ALERT_WINDOW and a11y permissions. Motivated by these attacks, DVa focuses on understanding a11y abuse conducted by real malware and the victims they target.

Mobile Banking Security. E-banking fraud [59]–[61] and attacks [62]–[65] have led to huge financial losses worldwide. Mobile banking apps are vulnerable to malware attacks [66], [67]. Multiple works focus on evaluating the security measures imposed by these apps [68], [69]. Chen et al. [70] exposed weaknesses in mobile banking apps' sensitive data storage and transmission, confirming their proneness to being targeted by malware, as illustrated by DVa. Botacin et al. [46] evaluated the security flaws of Brazilian mobile banking apps, uncovering their susceptibility to UI and a11y-based attacks. Corroborating the security flaws in mobile banking apps, DVa contributes to this field of research by detecting a11y abuse vectors exploiting real victim banking apps targeted by mobile a11y malware.

Defenses Against a11y Abuse. Defenses have been proposed to restrict malicious usage of the a11y service [71], [72]. Fernandes et al. [6] proposed data-flow restriction on Android apps that only allows declared data-flow patterns by users while blocking all other undeclared flows. Huang et al. [5] introduced a more fine-grained sandbox design across the a11y service lifecycle that uses least-privileged data-flow constraints to secure the Android a11y service. §6.3 shows how existing defenses are ineffective in eliminating all a11y malware abuse – motivating the need for malware analysis techniques like DVa.

Malware Analysis. Some works use taint analysis [73], [74], API trace analysis [75]–[79], and network traffic analysis [80]–[82] to reveal malware behaviors. However, to attribute a11y attack vectors, DVa uses symbolic analysis [83]–[86] to match the constraints of a11y behaviors to their targets. Inspired by forced execution [87]–[89], DVa uses victim modeling to guide the execution of malware and loading of victim-specific abuse payloads.

9 Conclusion

We introduced DVa, a malware analysis pipeline to notify users and victims of a11y abuse vectors. Using DVa, we conducted analysis for 9,850 malware samples extracted from Google Pixel devices to uncover 215 victim apps that were abused with an average of 13.9 abuse vectors and six categories of persistence mechanisms empowered by a11y.

A Prerequisites for Analysis

DVa initiates the investigation by pulling a list of registered a11y services from the user's device using the *a11y manager* API and matching it with the identified malware's a11y service name. For each identified a11y service, DVa then finds the package it belongs to and extracts its base APK file from the user's internal `app-data` storage directory. During our extraction, we encountered multiple families of malware with anti-static and anti-dynamic techniques to thwart analysis. Here, we briefly describe strategies DVa adopts to bypass them.

A.1 Packed Malware and Dynamic Code Loading (DCL)

Malware heavily relies on packers to hide static malicious payloads by decrypting and loading them only after the application is loaded on a device. Some malicious payloads are loaded only after dynamic environment checks. To accurately collect all malicious payloads for static analysis, DVa deploys dynamic hooks to class loaders and utilize code reflection to locate and dump them. For each direct and indirect subclasses of `ClassLoader`, such as `BaseDexClassLoader`, `PathClassLoader`, etc., DVa deploys dynamic hooks on the `loadClass` API to capture every DCL attempt. Before the control logic is handed back to the routine, DVa intercepts the `ClassLoader` parameter and uses reflection to gather the path lists, dex elements, dex files being loaded, and the paths of the loaded files. DVa then copies the loaded files from the path in malware's internal storage, unzips them if necessary, and collects the final dex payload. After bypassing dynamic victim checks, DVa gathers all dumped payloads, eliminates duplicated ones, zips, and signs them into an APK for static analysis.

A.2 Anti-Dynamic Techniques

To avoid detection, malware also halts malicious code execution when it detects dynamic environment traces that suggest they are being analyzed. We observed multiple techniques such as emulator detection and side-channel inference on dynamic analysis framework artifacts used to hinder analysis. We reverse-engineered a11y malware from major families and deployed the following counteractions. DVa circumvents them first by running dynamic analysis on real Android devices. To counter side-channel inferences when malware infers the existence of a dynamic analysis framework by differentiating exception types when querying their class loaders, DVa applies dynamic hooks and directly throws `ClassNotFoundException`. Similarly, to counter malware from querying the existence of artifacts used by dynamic analysis frameworks in the file system, DVa applies dynamic hooks to file IO APIs and throws `FileNotFoundException` when detecting such queries.

SoK: State of the Krawlers – Evaluating the Effectiveness of Crawling Algorithms for Web Security Measurements

Aleksei Stafeev
CISPA Helmholtz Center for Information Security

Giancarlo Pellegrino
CISPA Helmholtz Center for Information Security

Abstract

Web crawlers are tools widely used in web security measurements whose performance and impact have been limitedly studied so far. In this paper, we bridge this gap. Starting from the past 12 years of the top security, web measurement, and software engineering literature, we categorize and decompose in building blocks crawling techniques and methodologic choices. We then reimplement and patch crawling techniques and integrate them into `Arachnarium`, a framework for comparative evaluations, which we use to run one of the most comprehensive experimental evaluations against nine real and two benchmark web applications and top 10K CrUX websites to assess the performance and adequacy of algorithms across three metrics (code, link, and JavaScript source coverage). Finally, we distill 14 insights and lessons learned. Our results show that despite a lack of clear and homogeneous descriptions hindering reimplementations, proposed and commonly used crawling algorithms offer a lower coverage than randomized ones, indicating room for improvement. Also, our results show a complex relationship between experiment parameters, the study's domain, and the available computing resources, where no single best-performing crawler configuration exists. We hope our results will guide future researchers when setting up their studies.

1 Introduction

Web security measurements have become invaluable tools for empirical investigations exploring various security and privacy-related issues from real distributions, such as the prevalence of in-the-wild vulnerabilities [37, 45, 56] and the effectiveness of defense mechanisms [59, 78] at scale, to name a few. An essential technique enabling such measurements is *web crawling*, which starts from a list of seed websites, e.g., Alexa, Tranco [62], and CrUX [1], and then iteratively browses web pages to discover as many states as possible.

Crawlers' effectiveness in finding new states relies on determining whether a state is new via *page similarity* algorithms, and executing the appropriate actions, using *navigation* algorithms. Both types of algorithms have been challenged by increasingly dynamic pages and complex web interface logic, leading to partial exploration, thus missing potentially vulnerable states, ultimately affecting the precision and accuracy of web measurement studies. Over the past decades, the research community has proposed new crawling techniques to address these shortcomings, often combining novel page similarity and navigation algorithms, e.g., `EotS` [20], `Black Widow` [25], and `FeedEx` [27]. Although web crawlers have become more sophisticated, their impact has been limited as prior works use rather elementary crawling techniques.

Assessing the effectiveness of crawlers and their use in empirical studies is challenging, primarily because prior works have only marginally addressed comparative evaluations of crawling techniques. Most comparative evaluations are often conducted in isolation when assessing a new approach's effectiveness, using heterogeneous experimental parameters, testbeds, and datasets, making results difficult to transfer across papers. Only recently, independent comparative studies [4, 80] measured the accuracy and precision of different crawling algorithms. However, either they covered only page similarity from domains like computer vision, leaving out approaches used in practice [80], or evaluated web automation tools like Puppeteer [2] and Selenium [3], which do not implement any crawler algorithm. As a result, we still know little about crawlers' effectiveness as used in security evaluations.

In this paper, we bridge this gap with one of the first systematizations of the current state-of-the-art web crawling techniques—both proposed and used in practice—and an assessment aimed at measuring performance in concrete application scenarios such as testing and data collection in live websites. As a first step, we review the past 12 years of publications from the top venues in security, privacy, and web measurements, i.e., 7,840 papers, identifying 403 conducting a measurement, identifying algorithms, parameters, and methodologies for collecting data through crawling. We then review prior works proposing new crawlers in the top three software engineering conferences (917 papers), identifying

additional 27 papers that proposed, in total, 35 crawling techniques proposing the first taxonomy of crawling algorithms. Finally, we reimplement and patch 27 algorithms and variants into our evaluation framework called `Arachnarium` and run them against popular web applications and in-the-wild websites to measure code coverage, link, and JavaScript source code discovery. We also assess the impact of the methodological choices identified in our literature review, estimating the impact of algorithmic and parameter adjustments. Finally, we summarize and put into perspective our findings within the research community. We offer concrete inputs for future large-scale security studies and insights on the current state-of-the-art algorithms in the web crawling domain for security testing.

Overall, we observed that descriptions of methodological parameters and algorithms are often insufficient, incomplete, and not self-contained, making reimplementation challenging. For example, 24 papers in the crawling algorithms survey do not contain sufficient details about the implemented algorithms. We discovered that breadth-first search (BFS) and URL comparison are the two most popular techniques among the ones with adequate descriptions. The empirical evaluation of all techniques shows that randomized algorithms, in particular randomized BFS, offer better performance than standard algorithms, providing a general increase of average coverage, from +8% in LoCs up to +21% for JavaScript source code. Our results also identified time breakpoints after which a crawling algorithm performance increment becomes more appreciable, i.e., 30, 50, and 100 seconds for code, link, and JS source code coverage.

To summarize, we make the following contributions:

- We present a systematization of knowledge of web crawlers as used in security and privacy, and web empirical measurements based on the review and analysis of 403 papers;
- We decompose the identified algorithms and organize them in a taxonomy of proposed and used-in-practice crawling algorithms;
- We propose and release `Arachnarium`, a framework for the comparative evaluation of web crawlers against real-size web applications and live websites;
- We evaluate algorithms both individually and in combination, assessing their performance across metrics extracted from real application scenarios identified in our survey, revisiting the impact of prior methodologic decisions;
- We present 14 insights, lessons learned, and recommendations for our community and researchers developing and using crawlers.

Open Science Statement — We release `Arachnarium` source code[1] and experiment data[2].

2 Systematization

The first part of our paper is a systematization of large-scale security and web measurement studies using crawlers as a means of data acquisition (Section 2.1). Then, we systematize prior work proposing and combining new techniques, where we decompose and organize them in a taxonomy for crawling algorithms (Section 2.2).

General methodology — Two researchers executed the survey and systematization of this section. Both defined selection criteria, analysis rules, and executed data collection. One read and processed each paper and the other one validated results via random sampling. We detail the remaining steps of our analysis in the remaining sections.

2.1 Web Measurements

2.1.1 Analysis Methodology

Survey criteria — We selected all published papers from the security and web measurements conferences of the past 12 years (from 2010 to 2022). We selected the USENIX Security Symposium, the IEEE S&P Symposium, the ACM CCS, the NDSS Symposium, the ACM IMC, the ACM WWW and the PET Symposium, covering a total of 7,840 papers, and performed a keyword-based search to identify web measurement papers. We downloaded papers matching any of these keywords: `tranco`, `alexa`, and the combination of `top` and `site`. We did not include the keyword `CrUX` as it began publishing rankings in 2022 [66]. Whenever available, we used the web interface for the full-text keyword-based search, i.e., ACM and IEEE. USENIX Security, NDSS, and PETS do not have a web interface with full-text search support and thus we downloaded all papers and performed the keyword search on our server. In total, the papers matching our keywords are 1,057 papers.

Systematization criteria — We processed the 1,057 papers as follows. First, we located and annotated the text containing a description or instantiation of the paper's methodology, such as paragraphs, sentences, tables, and appendices. Then, we identified and enumerated the relevant features presented in their methodologies. These features include the specific algorithms used, such as the navigation strategy and the page similarity algorithm, and experimental parameters, such as navigation depth, navigation limit, page load limit, and the collected resources. In addition, we manually noted the topics of a paper and the crawling objectives in the paper. For the topics, we compiled a list of topics starting from the top-level topics extracted from the HotCRP paper submission page and removed or merged duplicated terms. For the objectives, we noted the resource being collected and the purpose of the data collection via crawlers.

Collected sources — Out of the 1,057 papers matching our keywords, we discarded 654 papers because they did not em-

ploy automated crawling. The final number of papers considered in this survey is 403.

2.1.2 Results

Algorithms used in practice — Of the 403 surveyed papers, only 32.3% of them (i.e., 130 papers) navigate websites whereas the remaining 273 papers (i.e., 67.7%) visit a single page only, thus not relying on neither a navigation nor a page similarity algorithm.

Table 1 shows the result of our analysis distributed over the navigation algorithms. We say that the algorithm is *specified* if the paper presents or mentions the name of the algorithm being used. We say *unspecified* if the paper uses an algorithm, but it does not specify which one. We also consider two other categories for algorithms. When an algorithm is not used, we say that the algorithm is *none*. For example, consider the case of a methodology that does not navigate web pages. Finally, when a paper does not use any navigation strategy, we say that the similarity algorithm is *not applicable* (*N/A*).

Specified vs unspecified algorithms — More than half of the papers navigating websites (i.e., 84 papers which is 64.6%) specify precisely both the navigation strategy and the page similarity, including when page similarity is not used. On the other hand, 35.4% of the papers navigating websites do not specify (i) the navigation strategy (i.e., 18 papers), (ii) the page similarity (i.e., eight papers), or (iii) both (i.e., 20 papers).

Navigation strategies — 70.8% of the papers navigating websites (i.e., 92 papers, amounting to 22.8% of surveyed papers) specify the exact navigation strategy. The most common strategy is randomized (36 papers, e.g., [31, 42, 58]). Other 27 papers (e.g., [21, 72]) use the breadth-first search (BFS), whereas 19 papers (e.g., [11, 68]) use custom strategies. Next, eight papers employed search engines to retrieve URLs of popular domains to visit (e.g., [6, 44]). Finally, two papers (i.e., [19, 35]) use the depth-first search (DFS). The remaining papers either use a navigation strategy but do not specify one (i.e., 38 papers) or do not go beyond the first page (i.e., 273 papers).

Page similarity — In total, 78.5% of the papers navigating websites (i.e., 102 papers) specify the way they handle page deduplication. More than half of them specify the deduplication algorithm, with URL matching being the most used with 54 papers (e.g., [21, 35]). In contrast, only four papers (i.e., [39, 73, 81, 84]) use DOM-based algorithms. The remaining papers navigating websites either do not use page deduplication collecting all pages (i.e., 44 papers) or use one but do not specify which one (i.e., 28 papers).

Topics — When looking at the topics, the most popular three are web security, privacy, and measurement. In total, 339 are at least on one of these three topics, with web security measurements being more represented than privacy measurements (i.e., 84 papers vs 60).

No Crawling — Among the 273 papers that did not navigate websites, we looked for the rationales behind such a decision. We first searched for them in the problem statement, research questions, methodology, and limitations text. Alternatively, we looked for similar papers in the same domain or with a similar problem setting to infer the necessity of not navigating pages. When we could not find similar papers, we determined whether crawling was necessary based on the paper's objectives. Table 3 shows the results of our analysis, where we count the number of papers that do not navigate sites over the objectives and the need to crawl. Overall, 105 papers did not need to navigate webpages as collecting more data by visiting more webpages from the same website is unnecessary as it produces duplicated data points. The remaining 168 papers

Objective	Need navigation *No*	*Yes*	*Tot.*

Table 3: The distribution of no navigation papers.

did not navigate not because it was unnecessary but as a trade-off for the limited resources or as an arbitrary choice. When aggregating papers by objectives, we observe two distinct clusters and one outlier paper, which we will discuss next.

The first cluster is of papers that do not need to crawl. Among these, to mention a few, we have a line of works (48 papers) that need to analyze specific pages found in URL feeds, e.g., phishing [40], or papers that probe specific endpoints to detect vulnerable or malicious websites (20 papers), e.g., typosquatting domains [75]. We also have works on censorship (e.g., [63,79]) that measure or circumvent blocking (13 papers) and network routing (13 papers). In all these cases, navigating web pages with a crawler is unnecessary.

The second cluster is dominated by the papers studying website fingerprinting (44 papers), evaluating browser enhancements (25 papers), measuring tracking prevalence (14 papers), and analyzing embedded resources (14 papers). These works could benefit the most from using crawlers. The authors often explicitly discuss or acknowledge the implication of not crawling. For example, the authors limit the scope of the study to a lower-bound analysis (e.g., [12,50]) or crawl only a limited selection of websites (e.g., [24]).

Finally, 22 papers collected JavaScript files to find malicious or vulnerable scripts. All of them will benefit from collecting more samples except for one. In Zeng et al. [83], the authors look for homepages that include a specific JavaScript library, and from those, they select only ten pages to conduct a user study. While navigating pages increases sample variety, that will not translate into a better dataset for user studies as participants are subject to fatigue, thus justifying a smaller sample set.

Crawling parameters — Of the 403 papers, 388 papers specify at least one experimental parameter, such as navigation depth, navigation limit, or page load limit. Conversely, 204 papers define at most two parameters. Finally, only 199 papers specify all the parameters. Still, the majority of the papers describing the crawling techniques specify a parameter.

Collected resources — One of the most collected types of resources is network messages and fields (229 papers) to extract domain names and IP addresses (e.g., [71]) or HTTP headers like cookies (e.g., [38,55]). The second most common type of collected resource is information about the browser execution environment (148 papers), which is then used to study the relevance and prevalence of vulnerabilities or assess new defense mechanisms. For example, Lekies et al. [46] collected dynamic JavaScript to evaluate the cross-site scripting inclusion vulnerability risks. Another example is Soni et al. [70], where a crawler collected JavaScript from popular websites to evaluate their proposed JavaScript signing method. Finally, HTML code (139 papers) and screenshots (30 papers) are common too, especially in works analyzing malicious pages such as phishing (e.g., [33,41]). The rest (19 papers) collect miscellaneous metrics, such as memory snapshots or power consumption (e.g., [47,69]).

2.2 Crawling Algorithms

2.2.1 Analysis Methodology

Survey criteria — For the second part of our systematization, we focused on papers proposing new crawlers by adding to our previous seed of papers the ones published over the past three years in the top three software engineering conferences, i.e., IEEE/ACM ICSE, the ACM ESEC/FSE, and the IEEE/ACM ASE. We downloaded all titles, abstracts, and papers matching one of these keywords: crawling, testing, web automation, web application scanning, large-scale web measurements, in-the-wild and large-scale analyses. Then, we read and searched for the pseudo-algorithm, diagrams, techniques, tool names, URLs to the source code, or any other references detailing how the technique works. If the paper included the URL to the code, we downloaded it and manually reviewed it, searching for the module implementing the crawling logic.

We extended our survey to *referred papers, tools, and prototypes* listed in the evaluation and related work sections. For example, the evaluation section of `Black Widow` [25] contains back-to-back experiments with two web application scanners from prior academic works, i.e., Enemy of the State (`EotS`) [20] and `jÄk` [61], and four non-academic tools, i.e., `Arachni` [43], `Skipfish` [82], `GNU Wget` [57], `w3af` [65] and `ZAP` [76]. Whenever we identified a new paper, we reviewed it using the same criteria as before. Starting from 24 seed papers across security and software engineering venues, we identified additional 35 papers. However, the resulting 59 pa-

Table 4: Overview of the identified tools and algorithms.

pers included eight papers that were previously analyzed in Section 2.1 and another 24 papers that didn't include names and details of the algorithms deployed. As a result, we studied the remaining 27 papers.

Systematization criteria — We analyzed the tools and techniques and decomposed them into their building block algorithms. For that, we reviewed the pseudo-algorithms, text descriptions, and source code when available, looking for the algorithms used for page similarity and navigating web pages.

Collected sources — Our survey identified 27 papers from security and software engineering venues that contain sufficient details about the used algorithms. The analysis of these papers identified, in total, 25 tools and techniques.

2.2.2 Results

The results of our systematization are in Tables 4 and 11. Table 4 lists and maps the names of crawling techniques and the building block algorithms. Table 11 lists and briefly describes the individual building block algorithms.

Page similarity — Our survey identified 27 distinct page comparison techniques, which we organize in six groups.

Many tools, i.e., 14, use exactly one algorithm. Ten tools support multiple algorithms, two of which allow to select one at a time (i.e., `Crawljax` [51], and Lucca et al. [17]) whereas the others combine multiple algorithms in a single function. For example, `jÄk` [61] sums the metrics of the DOM trees and of the registered JavaScript event handlers. The remaining paper (i.e., `Artemis` [7]) does not specify the page comparison algorithm used when visiting websites.

When looking at the objects used for page similarity, prior works and tools covered multiple types and levels of granularity. For example, URL-based approaches range from comparing the full URL to comparing URL components (i.e., URL path, fragment, and query string). We can make a similar observation on the DOM-based method, where current approaches can use entire DOM trees, e.g., for the tree-edit distance (RTED algorithm [60]) or a node-by-node comparison. Alternatively, existing approaches determine similarity by looking at specific HTML tags such as input tags, button tags, HTML forms, hyperlinks, and text. The HTTP response messages' various fields have also been considered for comparison. Among these, we have the HTTP response code, the cookie headers, all HTTP headers, and the HTTP request method. Finally, prior work has proposed using algorithms from the computer vision domain to create image distance functions as a metric for page similarity.

Table 11 presents all the identified algorithms grouped by the object. We note that the DOM tree-based category is the most popular. However, there is a wide range of approaches. The most popular DOM tree-based approach is tree edit distance [60]. The most popular algorithm is the URL exact match algorithm, used by most of the surveyed papers, both by crawlers proposed by prior work (i.e., [25, 85]), tools (i.e., [43, 57, 65, 76]) and in large-scale, in-the-wild studies (i.e., [37]).

Navigation Strategies — For the navigation strategy, all tools except for four (`Dagger`, `Manku`, `Lucca`, and `Broder`) implement a navigation strategy which we can group in six families, i.e., BFS, DFS, depth-limited BFS (JAW), randomized navigation, reinforcement learning-based navigation, and code-coverage driven navigation. Of these, 20 tools implement one strategy only, and one tool (i.e., `Crawljax`) implements multiple ones, which can be selected with a configuration parameter.

The BFS and randomized algorithms are the two most used navigation strategies among all the surveyed papers and tools. Most randomized strategies are based on a random selection of links to visit, whereas the other two combine systematic exploration with randomized elements. The first is a variant of the BFS strategy with shuffled URLs within a node. The second one selects a random URL after path exhaustion.

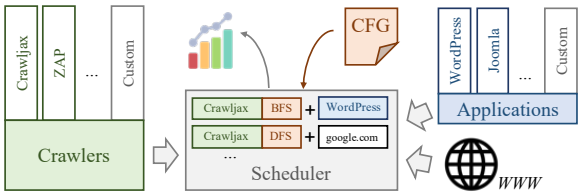

Figure 1: Architecture of Arachnarium.

3 Arachnarium: An Evaluation Framework

In this section, we present our experimental setup, implemented by our tool Arachnarium.

3.1 Architecture Overview

Arachnarium is a fully-extensible and scalable framework that enables the comparative evaluation of hundreds of parallel crawler configurations against real websites and web applications, at scale. Figure 1 shows an overview of the architecture. Arachnarium has four main components, i.e., the crawler module, the web application module (optional), the scheduler module, and the analysis module. The crawler and web applications modules rely on Docker [32], allowing us to scale experiments by running parallel experiments of the same web application and crawlers concurrently. The web application module can be disabled when testing live websites.

The primary input of Arachnarium is a configuration file specifying the tests to execute. An Arachnarium test defines the crawler, the web application to test (local or live), and the test parameters. The parameters can be command-line arguments for the tool or configuration options for the web application. The configuration file also specifies global experiment parameters, such as the time budget assigned for individual experiments or the number of concurrent executions. When running a test, the scheduler first deploys the web application container if needed, performs initial health checks to determine if the application is up and running (i.e., HTTP GET probes), and then executes the crawler. When the test reaches the maximum execution time, Arachnarium halts the test. The data generated by the crawlers (navigation maps and log files) and by the web application (coverage data and log files) remains in the storage for post-processing.

Users can extend Arachnarium with new crawlers or applications by providing a `docker-compose` file—nowadays a commonly available artifact, and enabling the provided code instrumentation module. This paper's version of Arachnarium fully supports PHP-based web applications and can instrument the PHP interpreter to measure code coverage through the XDebug interface [64]. Finally, the analysis module collects each test's activity log and returns statistics about crawler performance.

3.2 Testbeds

The evaluation in this paper covers two types of web applications: standalone web applications and live websites.

DS1: Standalone Web Applications — DS1 consists of web applications from prior works (i.e., [20, 25, 80]), which contain both modern applications (e.g., WordPress without plugins) and old ones but repeatedly-used in prior work (e.g., SCARF). We initialized these webapps with database records and configuration shared by the authors of [25] and [80] and deployed them locally. Each web application of DS1 is fully supported and integrated into Arachnarium.

DS2: Popular Websites — The second dataset is a list of popular websites. Reproducing results on live websites is generally challenging because of the transient nature of webpages' content and structure, which can change over time. In the recent work, Hantke et al. [29] showed that web archives could help improve reproducibility. However, they may not be an adequate choice for our evaluation. Web archives are created and maintained by crawling live websites; hence the used crawlers would bias our evaluation, and most importantly, our results would have been limited by the coverage of these crawlers. Accordingly, in this paper, we opt for live websites from *Chrome User Experience Report* (CrUX) [1], which is one of the most accurate lists reflecting sites popularities [66]. Arachnarium fully supports DS2.

3.3 Metrics

We intend to evaluate crawling algorithms' performance which can be helpful in common and practical deployment scenarios. We identify these scenarios and metrics from our systematization in Section 2, which are all implemented by Arachnarium.

M1: Code coverage — One of the application scenarios of crawlers is automated web testing, where crawlers are used in black-box application scanners to explore the attack surface to collect endpoints for the detection of vulnerabilities via ad-hoc tests. Crawlers also support other vulnerability detection techniques, such as server-side code analysis techniques [5], where a crawler provides execution traces to a concolic execution engine. In all these scenarios, crawlers are a means to discover new pages and reach deeper states, which ultimately can be measured via code coverage. Arachnarium obtains code coverage of a web application via the XDebug interface [64].

M2: JavaScript source coverage — Our survey showed that artifacts from the JavaScript engine, e.g., JavaScript code, are the second most collected data items. For example, Lekies et al. [46] collect dynamic JavaScript to evaluate the cross-site scripting inclusion vulnerability risks. Therefore, the second metric we consider in our experiments is the amount of unique JavaScript code retrieved by a crawler. In this paper,

Type	Description	Metric
DS1	WordPress v5.1.0 (CMS), OwnCloud v10.10.0 (Cloud storage), PrestaShop v1.7.5-1 (eCommerce), Joomla v3.9.6 (CMS), Drupal v8.6.15 (CMS), Vanilla v2.0.17.10 (Forum), phpBB v2.0.23 (Forum), SCARF v2007 (Conf mgmt), HotCRP v2.102 (Conf mgmt), WackoPicko v2021 (Benchmark for scanners), AddressBook v8.2.5 (Benchmark used by [80])	M1
DS2	CrUX, random 2000 websites from Top10K	M2-3

Table 5: Datasets for our experiments.

`Arachnarium` extracts all script tags from the visited pages and calculates the SHA-512 hashes on the inline and external JS code to determine uniqueness.

M3: Link coverage — The most common collected artifacts are network messages like HTTP requests the crawler generates when navigating a page, like clicking on links. Link coverage is also an established metric when benchmarking web application scanners in black-box settings (see, i.e., [20, 25, 61]) as the server-side component is unaccessible and thus unable to determine coverage via executed code. Accordingly, `Arachnarium` uses link coverage as the third metric by extracting all anchor tags from the visited pages and using exact string matching of the `href` attribute.

3.4 Evaluated Crawlers

Table 6 shows the list of techniques that we evaluated and are available in `Arachnarium`. We identified 39 candidate techniques, of which 35 are candidate building block algorithms. Section 3.4.1 presents the reimplementation rules that we followed when creating `Arachnarium`[3]. The remaining four techniques are tools implementing both page similarity and navigation strategy. These algorithms are interconnected from one to another, for which we could not decouple them tested as a whole. Section 3.4.2 presents these tools.

3.4.1 Candidate Building Block Algorithms

Our survey identified 35 basic algorithms that we considered for the integration into `Arachnarium` extensions of `Crawljax`. The integration was difficult because of incomplete information, missing code, or reference implementations, resulting in 23 implementations.

Code Available — If we were able to run the source code, then we integrated the code in `Arachnarium` for the evaluation. In two cases, i.e., `jÄk` and `EotS`, we were unable to run the code successfully. For `jÄk`, we could not resolve the no-longer supported version of the QT library. In this case, we used the paper and the source code as a reference implementation to reimplement the basic algorithms. For `EotS`, we obtained a Docker image from the authors; however, the code kept crashing. We tried to reimplement `EotS`; however, we could not find a way to isolate the algorithms without affecting the implementation.

Code Not Available — When the source code was unavailable, we used the reference implementation to reimplement the crawlers. We fully reimplemented the algorithms in two cases, i.e., `ProCrawl` and `FeedEx`.

Missing Details — For all other cases, we did not have sufficient details to reimplement the algorithms. Appendix A.2 list the missing details. Also, we discarded the *Tree Equality* algorithm because it compares two DOM trees node by node and returns false as soon as one single node differs. We con-

[3] We reimplemented the algorithms of this section as extensions of `Crawljax`.

Table 6: Evaluated algorithms.

sider such an approach too brittle and did not consider it for the evaluation.

Proposed Variants — We also considered five techniques derived from popular and promising algorithms by recent works. We designed variants for URL equality, as the most used technique across all papers of our surveys, and RTED, the best performing in Yandrapally et al. [80].

Variants of URL Equality — URL Equality is one of the most popular page similarity techniques identified according to our survey. A drawback of this approach is its sensitivity to small changes, e.g., path or query string alterations result in a different page. That may not be true in practice, as different URL paths and parameters may not indicate a state change. Accordingly, we consider two variants. The first one, called **URL Path Equality**, is a string comparison between URLs considering only the domain and the path. The second one called **URL Path Equality & QS**, includes in the comparison the query string of the URL; however, it ignores the value of the query string parameters.

Variants of RTED — RTED calculates the tree edit distance between two trees, which prior work showed it outperforming other techniques [80]. RTED implementations currently run in polynomial time, which can be impractical in many scenarios. Accordingly, we consider three variants to simplify the complexity of comparing two trees. We observe that a DOM tree can include multiple identical subtrees (widgets) in lists, e.g., menu items and lists of products. Therefore, we could reduce the size of a DOM tree by collapsing lists of identical widgets. We call this variant **RTED with DOM Transformation #1**. We further observe that similar pages can share widgets, and we could use those widgets for the comparison. We say that two pages are similar if they share the same widgets. We call this variant ¬ **RTED with DOM Transformation #2**. Finally, we also relax the widget definition to any subtree on a page, even when the subtree appears only once. This way, a page can be seen as a set of widgets. We say that two pages are similar if both have the same set of widgets. We call this variant ¬ **RTED with DOM Transformation #3**.

3.4.2 Compound Tools

Finally, we integrated in `Arachnarium` four tools, i.e., `Arachni`, `Skipfish`, `Wapiti`, and `ZAP`. As these tools are used for security testing, they run tests while crawling, which are likely to exercise new branches or exceptions, increasing coverage. Accordingly, we turned off all vulnerability detection features. We could not evaluate `WebExplor` because we were not able to resolve the exact way the Gestal algorithm is used when processing a webpage. We asked the authors for the source code, but they never answered our emails. Finally, while we managed to run `EotS`, it was unstable with a high rate of crashes, making it particularly challenging to collect data reliably; thus, we discarded it.

4 Experiments and Results

In this section, we evaluate the crawling algorithms' performances and methodological choices when used to collect data. After presenting the design of our experiments (Section 4.1), we present our results. First, we determine, if any, the best-performing algorithms looking at total coverage at the end of each run and at the coverage speed (Section 4.2) . Then, we compare coverage results to determine how much surface a crawler can discover than others, using two baselines (Section 4.3). Finally, we assess the methodological decisions our survey identified and evaluate their impact (Section 4.4).

Reducing Experiment Complexity — `Arachnarium` implements 17 page similarity algorithms and six navigation strategies, which amounts to a total of 102 crawler configurations to test. As a preliminary step, we reduce the number of page similarity algorithms to test, discarding those that perform poorly. We run all the page similarity implementations using only BFS three times against DS1 (self-hosted web applications) instead of DS2 (live sites) to reduce traffic load on them. At the end of each run, we calculated the maximum across three runs and the total unique LoCs executed. We selected the top ten page similarity algorithms with the highest average weighted rank based on code coverage and used them for the main experiments (see below). The complete results of this experiment are in the data repository. The top ten algorithms selected for the rest of this paper are ¬RTED Tr. 2, TLSH, ¬RTED Tr. 3, SimHash, URL Path Eq. & QS, URL Path Eq., URL Eq., Phash, `ProCrawl`, and Block-mean.

4.1 Experiment Design

This section presents the design of experiments and the measurements of this paper.

4.1.1 Experiments

The first experiment (*Exp1*) measures code coverage in DS1. For that, we combine the top 10 page similarity algorithms from our preliminary experiment with all six navigation strategies. The second experiment (*Exp2*) measures the coverage of JavaScript source code and links against dataset DS2. Running all crawler configurations multiple times against the same sites can generate unwanted traffic. Accordingly, we sample increasingly large random samples from disjoint CrUX Top 10K buckets. More specifically, we randomly select 200 domains from the Top 1K, 800 from the Top 5000 (excluding the Top 1K), and 1K from the Top 10K (excluding the Top 5K), resulting in a dataset of 2K random domains. We visit these 2K domains using the same top 10 performing page similarity algorithms and top five navigation strategies of Exp1 by code coverage.

4.1.2 Coverage Data

In our experiments, we run a crawler configuration three times against the same target site, i.e., a self-hosted web application (DS1) or a live website (DS2). For each action the crawler performs, we collect the timestamped coverage data, i.e., executed unique lines of code or discovered unique script and link tags. Then, we sum the unique coverage data points per run and pick the greatest. Collecting coverage data from the live sites (Exp2) was not as reliable as from self-hosted web applications (Exp1) because of external factors such as connection timeouts or temporary site unavailability, resulting in sites with partial coverage data. Instead of scheduling more runs to compensate for the missing data points, and thus increasing website loads, we use the coverage data of the first successful run among the three attempts.

4.1.3 Experiment Measurements

Absolute coverage — We calculate the total coverage of a crawler on a given dataset as the sum of the coverage for each target site in the dataset. We also calculate the coverage of individual algorithms, i.e., page similarity or navigation, by averaging the total coverage data runs over the other algorithm, e.g., page similarity over navigation and vice versa.

Relative coverage — This definition of total coverage is *absolute* and cannot show whether two crawlers discovered the exact same states or different ones. For example, if two crawlers covered 100 unique lines of code each, the absolute coverage metric will rank them as equivalent. However, as each crawler implements a different algorithm, it can happen that while both total 100 lines of code, these lines may not be the same ones. Accordingly, we introduce the notion of *relative* total coverage to quantify the extent to which two crawlers covered the same and different areas of a target site. We define the relative coverage as the increment (or decrease) of the total coverage of a crawler over a *baseline*.

Baseline 1: Popularity — As we aim to assess methodologic decisions, e.g., status quo, we set as a first baseline the coverage for the most *popular* algorithms from our surveys. Our survey on crawling algorithms shows that DOM tree techniques are the most used similarity algorithm used by crawlers. However, the DOM tree is a family including several specific implementations, e.g., RTED or tree equality. None of these implementations is more popular than URL Eq. – the second most popular one. The survey of web measurement papers also reveals that URL Eq. is the most commonly used technique to deduplicate pages. Accordingly, we select URL Eq. for the baseline. The web measurement survey shows that randomized strategies are mostly used for the navigation strategy. However, many papers do not clarify the exact type of randomized algorithms,e.g., Rnd BFS and Rnd State. The crawler algorithms survey, however, shows that BFS is the most popular one. Accordingly, we select BFS for the baseline.

Baseline 2: Global coverage — Finally, we compare the coverage of each crawler against the union of the coverage of all crawlers except for the one evaluated. For the comparisons, we use the difference set for the increments and decreases and the intersection set for the known surface. Increment or decrease from this *global* baseline can precisely determine unique features of crawlers in discovering the target sites' surface that others cannot discover.

Hardware and software configuration — We run `Arachnarium` with a maximum of 12 parallel workers, a wait time after page reloads of 500 ms, and an interval between actions of 500 ms. We run our experiments on a GNU/Linux Debian 11 system running on two AMD EPYC 7h12 64-Core Processors with 2TB of RAM. We configured `Arachnarium` to run inside on RAMFS of 300GB to speed up disk I/O operations and avoid disk write bottlenecks.

4.2 Best-performing Algorithms

We now compare crawler configurations and algorithms using the total absolute coverage to determine the best-performing algorithms from two angles: the total coverage at the end of each run and the coverage growth over time.

4.2.1 Total Coverage

First, we determine the total coverage of individual configurations and individual algorithms at the end of each run.

Configurations — We first start with configurations, i.e., pairs of a navigation strategy and a page similarity. Table 9 shows an excerpt of the results with the top two deterministic and non-deterministic best-performing configurations in each metric. The complete table is in Table 12 (Appendix). When looking at the total coverage (code, link, and JS), the randomized algorithms, especially the random BFS, are consistently among the top best-performing configurations. For example, the randomized BFS covers ranks from five to eight of the best-performing configurations. It ranks first when collecting URLs and JavaScript code when using URL comparison, i.e., ignoring URL QS values. When switching the page similarity to ¬RTED Tr. 3, the randomized BFS ranks first also in code coverage. Among the deterministic navigation strategy, the best-performing configuration is BFS with ¬RTED Tr. 2, ranking only fifth. For link coverage, `JAW` is second when used with URL Path Eq. & QS. BFS with ¬RTED Tr. 3 is ranked first when collecting JavaScript code.

In general, the links and JavaScript metrics are positively correlated with LoCs, meaning that high coverage in the LoCs very likely results in a high coverage in the other two metrics, too. The pairwise Pearson coefficients and p-values of Table 12 (Appendix) are $0.5454/8.05E-03$ for LoC-Links and $0.6587/1.59E-65$ for LoC-JS.

Page Similarity	LoC Sum	LoC R.	LoC +/-%	Links Sum	Links R.	Links +/-%	JS Sum	JS R.	JS +/-%
Block-Mean	220.482	8	-3.1%	186.049	9	-37.6%	23.847	9	-25.2%
Phash	220.451	9	-3.2%	121.267	10	-59.4%	14.383	10	-54.9%
ProCrawl	214.134	10	-3.2%	189.492	8	-36.5%	24.262	8	-23.9%
SimHash	232.092	4	+2.0%	296.302	3	-0.7%	26.415	7	-17.2%
TLSH	240.015	3	+5.4%	265.314	7	-11.1%	31.351	5	-1.7%
URL Eq.(baseline)	227.634	6	-	298.345	2	-	31.902	4	-
URL Path Eq.	221.873	7	-2.5%	276.634	6	-7.3%	28.737	6	-9.9%
URL Path Eq. & QS	230.282	5	+1.2%	**338.922**	1	+13.6%	33.350	2	+4.5%
¬RTED Tr. 3	240.089	2	+5.5%	288.962	5	-3.1%	**34.524**	1	+8.2%
¬RTED Tr. 2	**242.509**	1	+6.5%	292.565	4	-1.9%	33.158	3	+3.9%

Table 7: Average sum coverage, ranking, and % increase over the baseline of all navigation strategies.

Navigation	LoC Sum	LoC R.	LoC +/-%	Links Sum	Links R.	Links +/-%	JS Sum	JS R.	JS +/-%
BFS (baseline)	**228.748**	3	-	**250.373**	2	-	27.080	4	-
DFS	226.236	5	-1.1%	248.389	4	-0.8%	**27.243**	2	+0.6%
FeedEx	214.781	6	-6.1%	-	-	-	-	-	-
JAW	227.983	4	-0.3%	248.247	5	-0.8%	27.139	3	+0.2%
Rnd BFS	**247.207**	1	+8.1%	**280.467**	1	+12.0%	**32.853**	1	+21.3%
Rnd State	228.781	2	0.0%	249.450	3	-0.4%	26.650	5	-1.6%

Table 8: Average coverage and ranking of all page similarity algorithms.

Individual Algorithms — When looking at the average coverage per algorithm, three page similarity algorithms emerge as the top performing ones: ¬RTED Tr. 2 for LoCs, URL Path Eq. & QS for links, and ¬RTED Tr. 3 for script tags, whereas the worst performing ones are ProCrawl for code coverage and Phash for both links and JS. Similarly, Rnd BFS is by far the best-performing algorithm in all metrics. Table 7 and Table 8 show the average code coverage for each page similarity and navigation technique, respectively.

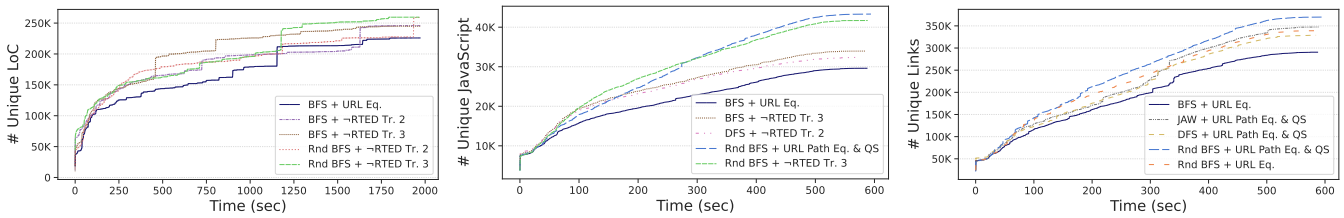
Total Coverage Increase — We now look at the coverage increase over the most popular configuration, i.e., BFS and URL Eq., should one select a different navigation strategy or page similarity algorithm. The results are in Tables 7 and 8.

In general, five similarity algorithms obtain a better code coverage than the full URL equality, with a percentage increase ranging from a +1.2% for URL Path Eq. & QS to +6.5% for ¬RTED Tr. 2 (Table 7). When collecting links and JavaScript source code, fewer algorithms perform better, however, with a more evident increase in coverage. For example, switching to URL Path Eq. & QS can increase, on average, coverage by 13.6%. When collecting JavaScript code instead, three similarity algorithms perform better than URL Eq., from +3.9% for ¬RTED Tr. 2 to +8.2% for ¬RTED Tr. 3. No other page similarity algorithm helps improve LoCs coverage URL Eq. We note, however, that algorithms such as Block-Mean, Phash, and ProCrawl can instead degrade performances significantly, especially for links and JavaScript. For example, Phash can decrease link coverage by more than a half, e.g., almost -60%.

When looking at the navigation strategy results (Table 8), in all cases, switching to random BFS can increase coverage significantly, with a gain of +8.1%, +12%, and +21% for code, links and JavaScript coverage. Only FeedEx recorded a minimum low among the six strategies, with a -6.1% code coverage. Other strategies have an almost-negligible loss of performance, i.e., from about -1.6% to -0.3%.

Configuration	LoC		Links		JS	
BFS + ¬RTED Tr. 2	**245.816**	5	298.696	14	31.594	13
BFS + ¬RTED Tr. 3	**244.946**	9	289.184	20	**33.960**	7
DFS + ¬RTED Tr. 2	241.565	16	291.458	17	**32.372**	10
JAW + URL Path Eq. & QS	226.454	30	**347.421**	2	31.297	15
DFS + URL Path Eq. & QS	229.749	27	**328.731**	4	30.732	19
Rnd BFS + ¬RTED Tr. 3	**259.600**	1	313.742	9	**41.691**	2
Rnd BFS + URL Path Eq. & QS	244.838	10	**369.810**	1	**43.319**	1
Rnd BFS + URL Eq.	252.530	3	**339.134**	3	39.655	3
Rnd BFS + ¬RTED Tr. 2	**259.028**	2	324.179	6	37.850	4

Table 9: Top two deterministic and non-deterministic best-performing configurations.



4.2.2 Coverage Growth over Time

Total coverage does not include the temporal dimension and cannot be used to examine the velocity a crawler can explore the surface of a site. In this section, we look at the timestamped coverage data and calculate the cumulative coverage over time. We focus only on the two deterministic and non-deterministic best-performing configurations in each metric using as a reference point the most common configuration from our survey, i.e., BFS with URL Eq. (Figure 2). All configurations tend to perform consistently better than BFS with URL Eq. over time. However, the differences are less appreciable with short crawls, and the breakpoints of these short crawls vary with the metrics. For example, when collecting links, the benefits of the selected configurations start being noticeable after 30 seconds. For JavaScript, the breakpoint is about 50 seconds, whereas for code coverage is about 100 seconds.

4.3 Coverage Analysis w/ Baselines

We now look at the coverage of each configuration relative to two baselines to precisely determine the fraction of the surface covered by crawlers over the most popular algorithms and against the global coverage.

Increment over Popular Algorithms — In terms of unique lines of code, the surface discovered by both the baseline and the configurations ranges from 73.2% by random state with ¬RTED Tr. 2 to the almost identical overlap of 98.2% by JAW with URL Eq. When looking at the set differences, the randomized BFS with ¬RTED Tr. 3 almost includes the entire baseline with only 0.9% of missed LoCs and, at the same time, extends it with a considerably large new surface of about 25.4% of the total.

(a) LoC (b) JavaScript (c) Links

Figure 2: Cumulative coverage over time of the two deterministic and non-deterministic best-performing configurations in each metric with a baseline on BFS + URL Eq.

The relative coverage over links and JavaScript follows a different distribution, where the overlaps with the baseline lose relevance against the differences, i.e., missed and unique links/scripts. For example, at most, a fifth of the unique links and JavaScript code is shared with the baseline configuration, i.e., 8.7% of the baseline surface. The largest overlap is 21.4% by `JAW` with URL Eq. The coverage differences between configurations and the baseline are far more significant, covering from 76% up to 91% of the discovered links and JavaScript code. Such a stark difference is likely caused by the presence of dynamically generated links and JavaScript, which are generated and discovered in one run only, thus being missed by the others. We explore this aspect later.

Increment over Global Coverage — Similarly to the baseline coverage, the configurations' global coverage varies greatly across metrics. The best-performing configuration (random BFS with ¬RTED Tr. 3) covers 78.9% of the global coverage, whereas the worst-performing one (`FeedEx` with SimHash) reaches 54.9%. In comparison, the coverage is significantly lower when counting links and JavaScript. The best-performing configuration for links and JavaScript (random BFS with ¬RTED Tr. 2) is well below the worst LoC coverage, i.e., 19.4% and 23.8%.

4.3.1 Commonly Discovered Surface

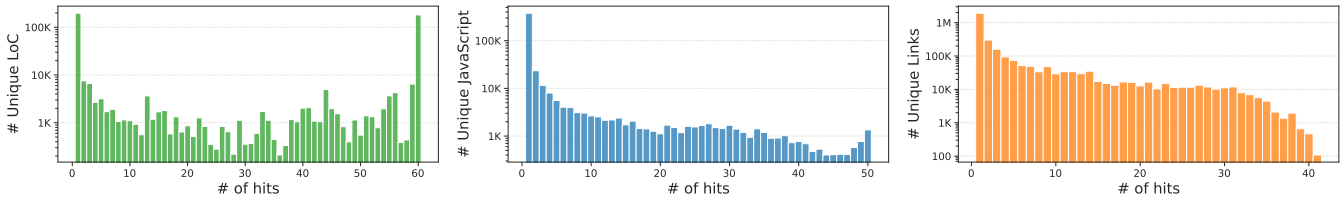
To help interpret coverage results, we look at the coverage following a resource-centric approach. We count how many times a configuration run has hit a unique line of code, link, and script tag. Figure 3 shows the histogram of the number of hits in a log scale. Live websites contain several dynamically generated resources, including links and JS code. Dynamic content deflates total coverage as these links and JS scripts are unique to one crawling session. These resources are visible in Figure 3, where more than 1.9M links and 376K scripts were never visited by more than one crawler. Code coverage shows slightly different properties. On the one hand, we see also 196K unique lines of code being executed exactly once. These LoCs can be, for example, instructions regenerating cached data like UI templates. However, we can also see the dominant effect of boilerplate code, such as initialization procedures like loading configuration files and plugins, that is executed at each HTTP request. At $x = 60$, we see all configurations (ten page similarity algorithms × six navigation strategies) executed 181K unique lines of code.

# crawls	LoC Rnd	LoC Det	JavaScript Rnd	JavaScript Det	Links Rnd	Links Det
1	100%	100%	100%	100%	100%	100%
2	+4.76%	+2.00%	+65.08%	+60.34%	+62.11%	+58.43%
3	+8.14%	+3.47%	+101.66%	+94.51%	+95.87%	+87.91%

Table 10: Average cumulative increment for the consecutive re-crawls for random and deterministic configurations.

4.4 Crawling Parameters

Navigating vs no navigating — 273 papers of our survey stop at the first page during a visit. Increasing the limit to two pages, the average coverage increases by +29.34% new lines of code, +101.96% new links, and +83.65% for LoCs, links, and JavaScript code, respectively. When pushing the limit to 10 pages, we observe a more significant increase of +100.91%, +253.95%, and +194.36%. Figure 4 shows the cumulative increment of coverage over the number of visited pages up to 50 pages.



Single- vs re-crawling — Table 10 shows that additional re-crawls are likely to increase coverage across all metrics. Moreover, on average, randomized algorithms gained a more significant increase in comparison to deterministic ones.

5 Discussion

5.1 Lesson learned

5.1.1 Significant Challenges to Reimplementations

Our systematization in Section 2 showed a rather complex landscape in presenting the methodology, mostly characterized by scattered and incomplete descriptions, which ultimately affected our reimplementation.

(a) LoC (b) JavaScript (c) Links

Figure 3: Distribution of the number of times an element, e.g., unique line of code, link, and script, is hit by a configuration run.

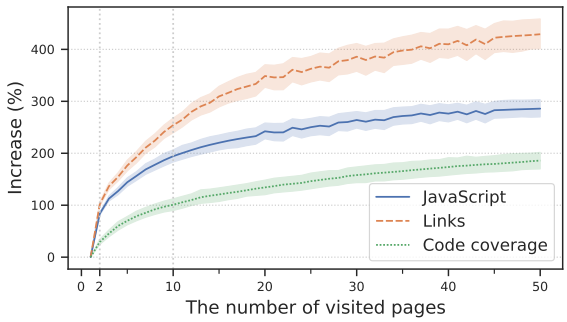


Figure 4: Cumulative increment percentage over the number of visited pages.

#1 - Insufficient descriptions — Insufficient descriptions occur in many papers and manifest themselves differently. The first one is not specifying all parameters, including the specific algorithms used in a study. In total, our review of large-scale studies in Section 2.1 shows that 38, 29, 34, 25, and 196 papers did not specify, respectively, the navigation strategy, page similarity, navigation depth, navigation limits, and page load waiting time (See Table 1). The second one is insufficient or missing details of crawling algorithms. For example, our systematization of existing algorithms in Section 2.2 could not determine the algorithms of 24 papers.

#2 - Scattered and heterogeneous descriptions — The second insight of our survey is that the text describing the crawler configuration or other parameters is scattered across the papers, making their localization hard and an error-prone task. Here, we welcome standardized, well-marked areas of a paper describing the methodology and algorithms in papers.

#3 - Lack of code and algorithmic details — We could not integrate ten of the analyzed algorithms into `Arachnarium` as we could not reimplement them. The main reason was the lack of sufficient details in the text and the source code's absence to attempt a new implementation. We strongly encourage our community to adopt even more stringent publication rules where source code and artifacts accompanying research become the norm, not the exception.

5.1.2 No Winner, Complex Landscape

Our results revealed a rather complex landscape, with randomized algorithms generally performing better.

#4 - Commonly used algorithms do not perform the best — URL Eq. is a commonly used page similarity algorithm that does not rank first in any metric. On average, switching to ¬RTED Tr. 2can improve coverage for LoCs (+6.5%), URL Path Eq. for links (+13.6%), and ¬RTED Tr. 3 for JavaScript (+8.2%). On the other hand, BFS is the commonly used navigation strategy, which also does not rank first on average. Switching to the randomized version, we observe an increase from +8.1% (LoCs) to +21.3% (JS).

#5 - No outperforming configuration — Our results show that no single configuration ranked first on both absolute and global coverage metrics. However, randomized BFS combined with many page similarity algorithms is consistently among the top-performing configurations.

#6 - Randomized navigation is a good choice also with limited resources — 36 large-scale web measurements used randomized visit strategy with strict navigation limits to collect resources from a landing page under limited time constraints, e.g., five links only. Our results indicate that such a data collection strategy allows us to balance coverage well with the given resources.

#7 - Algorithms not suited for the job — Our results also identified algorithms performing poorly across all metrics, especially for live crawls. Examples are Phash, `ProCrawl`, Block-Mean. Results also suggest that SimHash may be unfit when collecting JavaScript source code. Among the crawling strategy, `FeedEx`, which combines a coverage-driven metric, ranked last with a -13.11% from random BFS.

#8 - Crawling with metrics — We observed that crawler configurations perform differently across the metrics, and we recommend selecting the algorithm based on the targeted metrics.

#9 - Crawling with limited resources — Running crawlers takes, in general, time and computing resources. With a tight budget, e.g., crawling sessions below 30, 50, and 100 seconds, we notice that the algorithm choice does not significantly affect coverage. However, we note that coverage can dramatically improve by using a navigation technique with a depth

of five or more.

#10 - No crawling — Most papers, i.e., 168, that do not navigate pages work on attack or defense techniques against website fingerprinting and online tracking and collect HTTP headers. For these papers, crawling could have provided more sample variety. However, crawling live websites can be expensive, and authors often need to balance the number of websites of their study and navigation depth to keep the data collection manageable. Most of these works also discuss such a decision and the impact on the results, scope, and conclusions. Here, our empirical measurement of coverage over the number of visited pages estimates the coverage loss for these methodologic choices.

5.1.3 Future Directions

Not having a silver-bullet solution indicates that new efforts in creating better crawling techniques are needed.

#11 - Alternatives to crawling are unexplored — Crawlers are not the only approach that could be used to explore websites. For example, over the past decades, many UI testing approaches have been proposed (e.g., [26, 54]) where they tend to reason on the UI structure and logic to explore deeper behaviors. Prior work has shown improvement over random test generation [26]; however, these techniques have not been used in web measurements yet, and their potential and impact are largely unexplored.

#12 - No better than random crawling — Perhaps, the most disappointing result is that randomized strategies performed, in average, better than all other techniques, including security testing tools. That suggests that, despite the efforts, visiting with random clicks performs better than current heuristics. Not being better than random algorithms calls for additional efforts to devise and build better crawling algorithms. At the same time, our results indicate that randomized algorithms should be included in all evaluations when proposing a new technique to precisely measure when a new idea achieves a significant and relevant result.

#13 - Security testing tools lag behind — None of the commercial-grade security testing tools are at par with the crawler configurations. The best-performing tool is `Arachni`, which ranked 38th in code coverage whereas (-24.5% from the first, i.e., random BFS with ¬RTED Tr. 3), by contrast, `ZAP` ranked last, i.e., 63rd (-33% from the first).

#14 - New web application surface as a shared contribution — We can also observe interesting properties of the current state-of-the-art of web crawling in global coverage. The total number of lines of code discovered at least by two configurations is 87% (non-unique LoC). Interestingly, for the remaining 13%, no two crawlers discovered it, suggesting that this fraction results from the union of disjoint, unique capabilities of each algorithm.

5.2 Ethical Considerations and Threat to Validity

Ethical Considerations — Our experiments intend to provide a better view of crawler behavior in real-world scenarios. However, automated interaction with public-facing websites necessitates careful risk evaluation. We anticipated three possible risks.

The first risk is the accidental collection of PIIs in webpages and URLs. Our crawlers visit webpages that can be reached by any human user when browsing the public, unauthenticated pages of a website with a browser. Our crawlers neither forge URL strings nor log in and stay on the website, thus minimizing the risk of collecting sensitive data. The risk of collecting PIIs is further reduced by the types of websites used in our study and by our sampling strategy. The top 10K CrUX tends to contain websites of global corporations, which are unlikely to store PIIs in webpages or URLs in public pages reachable from a homepage. In addition, we did not collect pages from all top 10K sites but from a random sample of 2K sites, further mitigating the risk of collecting PIIs accidentally.

Second, our experiments collected web pages via hundreds of crawler runs, which can flood websites with thousands of requests per second. To avoid hampering website availability, we implemented in `Arachnarium` the following constraints: (i) `Arachnarium` runs at most 12 concurrent crawlers, (ii) two crawlers cannot visit the same domain in parallel, (iii) each crawler runs in a single-thread and single-browser mode, executing actions sequentially, not concurrently, and (iv) each action is executed every 0.5s. ASN-based checks can further mitigate the risk of flooding smaller websites; however, small sites are unlikely to be in our dataset as the top 10K CrUX tends to contain globally available sites, using robust hosting, network, and CDN providers, e.g., top shared ASNs of our 2K dataset include Cloudflare, Amazon, and Akamai. As smaller websites are more likely to be present in low-ranked domains, researchers wanting to repeat our experiments on those sites should avoid running two crawlers against sites hosted by the same provider.

The third risk is collecting content website owners want to avoid being indexed and shared, e.g., the price of products, and they can specify their policy in `robots.txt`. However, our crawlers collect and extract URLs and script tags from the HTML code and do not index and share web content. Hence, when considering the interaction between harm and benefits of our work, we concluded that not honoring `robots.txt` was an acceptable trade-off in this specific instance, given the precautions we took.

Finally, the artifacts that we will share with the community will not contain the raw data collected (URLs or code, which are subject to removal from our systems) but redacted data, i.e., SHA256 hashes of URLs.

Threat to Validity — The DS1 dataset contains 11 web applications, three orders of magnitude smaller than the 2K

websites in DS2. Confirming the full generalizability of our experiments requires expanding the DS1 dataset, which is hard to do at scale. We mitigated this external validity threat by selecting web applications that are relevant and real-size, e.g., WordPress, Joomla, and Drupal, and used in the literature [20,25,80]. Similarly, our evaluation used three coverage metrics, and future researchers can already use our results when planning their experiments. While we observed a strong correlation between LoC and link and JS coverage, the correlation may not hold for other metrics, and additional experiments with new metrics are needed. However, to minimize this risk, we designed `Arachnarium` to be extendable and configurable, providing a platform for researchers to select experimental parameters. Finally, Figure 3 shows a large fraction of JavaScript and links, each discovered by one crawler run. These links and JavaScript code are likely temporary, e.g., dynamically generated links, which can result in overestimating the covered and missed surface.

6 Related Works

Crawler evaluations — To the best of our knowledge, this is the first systematization of knowledge on crawlers and their impact on security measurements. The two closest prior works to ours are Yandrapally et al. [80] and Ahmad et al. [4]. Yandrapally et al. [80] evaluated different page similarity algorithms selected from different domains: information retrieval, web testing, and computer vision. Our work differs in two main aspects. First, we cover both page similarity algorithms and navigation strategies, exploring their combinations. Second, we consider algorithms that are used in practice. Ahmad et al. [4] evaluated a mix of crawlers, e.g., `GNU Wget` and `ZAP`, and web automation tools, e.g., Selenium and Puppeteer, focusing on aspects such as the ability to manipulate HTTP parameters or disabling cookies. As opposed to this work, our paper focuses on the algorithmic nature of crawlers, looking at their ability to find and identify pages, i.e., via navigation and page de-duplication, also exploring their combinations.

Prior works [20,25,61] evaluate the presented tool against the other tools, e.g., `Black Widow` is tested against `Skipfish`, `w3af` and `ZAP`, using different testbeds, parameters, and metrics. While these evaluations show us the performance of one tool against the other, results can hardly be transferred across papers. Our paper addresses this issue by proposing a comparative evaluation framework, `Arachnarium`, that can be used to define and execute reproducible experiments against web applications..

Reproducibility in web measurements — Reproducibility in web measurements is an open problem. For example, Jueckstock et al. [34] and Demir et al. [16] pointed out that reproducing prior measurements is hard in practice, whereas Hantke et al. [29] showed that web archives could be used to reproduce web security results. As opposed to these works, our paper does not reproduce prior works. Instead, it intends to evaluate the adequacy of the algorithms used to collect data in web measurements and provide insights to future researchers to help select the parameters of their studies.

Alternatives to crawling — Crawling is one of the many dynamic analysis techniques that could be used in web measurements, including both white-box and black-box approaches. Unfortunately, white-box approaches such as [5,8,9] require the server-side source code for the analysis, which is not available in practice. On the other hand, black-box approaches do not require the source code and, like crawlers, implement a variety of heuristics to explore and test the target web application. Among those, a line of work closely related to crawlers is UI testing, where many automated approaches have been proposed to test UIs for functional errors (e.g., [26,54]. The goal of our study is to systematize and test techniques that are used in empirical studies. Our survey could not find the use of UI testing approaches; therefore, we did not consider them in our study.

7 Conclusion

This paper presents a systematization of knowledge about web crawling algorithms for web security measurements. After identifying and analyzing 403 papers from top venues in security, privacy, web, and measurements, and 27 papers from the top venues in software engineering, we created a taxonomy with 35 algorithms and mapped their use in empirical analyses. Then, we proposed and used `Arachnarium`, a framework for comparative analysis of crawlers, in a comprehensive empirical evaluation of proposed crawling techniques and parameters. From our systematization and evaluation, we distilled 14 insights, lessons learned, and recommendations for our community and future researchers.

A Appendix

A.1 Classification of the Identified Approaches

Table 11 shows a classification of the identified building block algorithms.

A.2 Excluded Algorithms

This section presents the reasons why we could not implement certain crawling algorithms.

`AutoBlackTest`, `KAFE`, `Dagger`, and `LigRE` do not specify which DOM elements are used or filtered to determine similarity. `WebExplor` and Fetterly et al [28] provided insufficient details on the algorithm application. Lucca et al. [17, 18] and Broder et al. [10] do not specify the threshold used in the similarity algorithms. `Artemis` does not provide enough parameters to reimplement the algorithm without the source code. We also could not modify our reference implementation to accomodate the state clustering approach used in Crescenzi et al. [15].

Name	Algorithm	Tools
Page Similarity: Page URL		
URL Equality	True if the URL strings are the same	Black Widow, JAW, SecuBat, GNU Wget, w3af
Page Similarity: DOM Tree		
Tree Equality	True if the two trees are identical	KAFE
RTED	True if $\texttt{RTED}(t_i,t_j) > c$ for a threshold c, where RTED calculates the minimum of node edit operations that transform one tree into the other one	Crawljax, FeedEx
UI Controls	True if the ratio of common UI controls (e.g., input tags) is greater than a threshold c	AutoBlackTest
Root-Link Paths	True if the ration of common root-to-link paths is greater than a threshold c	Crescenzi
Page Similarity: HTML Code		
SimHash	True if the Hamming distance of two 64-bit fingerprint digests is greater than a threshold c	Crawljax, Manku
TLSH	True if the distance of two locality-sensitive hash digests is greater than a threshold c	Crawljax
Common Shingles	True if the fraction of common shingles is greater than a threshold c	Broder
TAF	True if $\texttt{TAF}(t_i,t_j) > c$, where TAF is the difference of the tag and attribute frequency function of two trees	Lucca
LevenSeq	True if $\texttt{LevenSeq}(s_i,s_j) > c$, where LevenSeq is the Levenstein distance between the sequences of the tags and attributes	Lucca
Page Similarity: Screenshots		
Color histogram	True if χ^2 distance between two color histograms is greater than a threshold c	Crawljax
Perceptual hash	True if Hamming distance of two 128-bit hash digests is greater than a threshold c	Crawljax
Block-mean	True if Hamming distance of two 256-bit hash digests is greater than a threshold c	Crawljax
PDiff	True if the number of common pixels is greater than a threshold c	Crawljax
SSIM	True if the structural distortion value is greater than a threshold c	Crawljax
SIFT	True if the common SIFT key-points are greater than a threshold c	Crawljax
Page Similarity: Combined Algorithms		
jÄk	True if the mean value of the fractions of common forms, hyperlinks, and event handlers is greater than a threshold c	jÄk
ProCrawl	True if buttons, text, and links are the same	ProCrawl
WebExplor	True if page URL strings are the same and the Gestalt Pattern Matching of the HTML codes is greater than a threshold	WebExplor
Dagger	Iterative use of different approaches, respectively, the fraction of common shingles (sequence of hashes of a page), the fraction of different tags, and the fraction of different tags per DOM level	Dagger
LigRE	True if the form prefix trees are the same and the common rooted depth link prefix trees are greater than a threshold c	LigRE
EotS	True if the rooted link prefix trees are the same (precondition)	EotS
Fetterly	True if the URL Rabin fingerprints match and SimHash is greater than a threshold c	Fetterly
Arachni	True if the HTML code and the cookie sets are the same	Arachni
ZAP	True if the HTML code, the HTTP headers, and the request methods are the same	ZAP
Wapiti	True if URL strings (without query string values) and the HTTP methods are the same	Wapiti
Skipfish	True if the word length distributions and the HTTP response codes are the same	Skipfish
Navigation Strategies		
DFS	The Depth-First Search traverses a website by navigating to the most recently discovered page after completing the actions on the current one. The actions are executed in the order of encounter	EotS, Crawljax, ProCrawl, LigRE
JAW	The Iterative Deepening Depth-First Search inspired technique traverses a website iteratively using a BFS approach with a depth limit. The actions are executed in the order of encounter	JAW
BFS	The Breath-First Search traverses a website by navigating to the most early discovered page after completing the action on the current one. The actions are executed in the order of encounter	Crawljax, jÄk, Cookie Hunter, Cached+Confused, KAFE, SecuBat, Crescenzi, Arachni, Wapiti, GNU Wget, w3af, ZAP
Rnd BFS	The Breath-First Search with random action selection traverses a website using the regular BFS for state selection and follows it by random action selection at the selected state	Crawljax
Rnd State	The Random State traverses a website by randomly selecting a state and executing actions on that state in the order of encounter	Black Widow
RL-based	The Reinforcement Learning-based approach learns a policy with an appropriate definition of reward and state	WebExplor, AutoBlackTest
FeedEx	FeedEx calculates a score for each visited page: a combination of code coverage impact, path diversity, and DOM diversity. When selecting the next page, it chooses the page with the highest score	FeedEx
Artemis	Artemis fires sequences of events on the web page. The algorithm prioritizes sequences with low branch coverage.	Artemis

Abstract

With the increasing popularity of APIs, ensuring their security has become a crucial concern. However, existing security testing methods for RESTful APIs usually lack targeted approaches to identify and detect security vulnerabilities. In this paper, we propose VoAPI[2], a vulnerability-oriented API inspection framework designed to directly expose vulnerabilities in RESTful APIs, based on our observation that the type of vulnerability hidden in an API interface is strongly associated with its functionality. By leveraging this insight, we first track commonly used strings as keywords to identify APIs' functionality. Then, we generate a stateful and suitable request sequence to inspect the candidate API function within a targeted payload. Finally, we verify whether vulnerabilities exist or not through feedback-based testing. Our experiments on real-world APIs demonstrate the effectiveness of our approach, with significant improvements in vulnerability detection compared to state-of-the-art methods. VoAPI[2] discovered 7 zero-day and 19 disclosed bugs on seven real-world RESTful APIs, and 23 of them have been assigned CVE IDs. Our findings highlight the importance of considering APIs' functionality when discovering their bugs, and our method provides a practical and efficient solution for securing RESTful APIs.

1 Introduction

Application Programming Interfaces (APIs), as the contract between information providers and information users, are gaining immense popularity as they effectively facilitate communication and data exchange between diverse web applications. It also enables businesses to harness their data and services well to support innovative scenarios and broaden their impact. Currently, it has been widely used and spanned across various scenarios, such as cloud services [1, 2], content management systems (CMS) [3–6], and Internet of Things (IoT) [7, 8] devices. Among different architectural styles for API development, REST [9] (REpresentational State Transfer) has emerged as a widely embraced approach, with APIs adhering to this style commonly known as RESTful APIs.

Unfortunately, numerous security issues [10, 11] have arisen in APIs in recent years, resulting in significant repercussions for providers and users. For instance, a vulnerability [10] in a Facebook API interface exposed millions of users' private information. As we see, API security has become a critical concern, especially for service providers. Meanwhile, APIs have increasingly become a focal point for attackers, making them a common target in various services. Hence, proactively identifying and addressing API flaws is vital in safeguarding services and their users. Detecting vulnerabilities early on is an essential strategy to ensure the protection of these systems.

Currently, API testing has gained significant popularity as a solution to enhance API security, and a considerable amount of research has been conducted in this field. However, existing testing methods for RESTful APIs often encounter limitations when it comes to identifying security vulnerabilities, especially in black-box testing scenarios [12–17]. These methods heavily rely on the API's status feedback, which means they may not detect certain logical vulnerabilities (e.g., SSRF) that do not affect the normal functioning of APIs. On the other hand, white-box testing methods [17–21] require source code security audits, which can be time-consuming, inefficient, and prone to generating false positives. Gray-box testing methods [22, 23] require access to the internal state of API execution, offering a more comprehensive view. Nevertheless, the diverse code frameworks used in API implementations present a challenge in developing a unified detection approach. Furthermore, testing methods tailored to specific architectures [24] have limited scope and are difficult to extend beyond their original application scenarios.

In addition, several other methods [12, 15, 16, 25–32] have been proposed that leverage OpenAPI[1] specifications to en-

[1]OpenAPI [33] (i.e., Swagger) stands as the most widely used specification for describing RESTful API interfaces. A Swagger-based specification outlines the usage guidelines for RESTful APIs, including the types of service requests accepted, the expected response format, and other relevant details.

able unified testing of APIs. These methods include functional testing [12, 15, 16, 25–29, 34], compliance testing [30], and security testing [31, 32]. Parts of these approaches [26–29] utilize OpenAPI specifications to parse HTTP requests and generate fuzzing test cases that adhere to syntax rules. Conversely, some methods [12, 15, 16, 25, 34] use OpenAPI specifications to infer the dependencies between requests and generate test messages that align with the API interaction context. This enables effective testing of API functionality, as well as the identification of exceptions and specific security vulnerabilities.

Despite the emergence of various testing approaches, it is noteworthy that most of these methods do not effectively utilize the specific characteristics of security vulnerabilities to implement vulnerability-targeted testing strategies. Instead, they primarily rely on the detection of "500 Internal Server Errors" as an indication of capturing bugs within API interfaces. Consequently, this approach leads to limited visibility and low testing efficiency. For example, when dealing with a large-scale API project similar in scale to GitLab, RESTler [12], on average, requires more than 5 hours to perform a comprehensive test. Furthermore, the security vulnerabilities uncovered by these tools, such as RestTestGen [16], represent only a small fraction of these bugs, with the majority being functional issues that primarily impact the reliability of APIs.

Based on our analysis of publicly disclosed API vulnerabilities in recent years, we observed that there exists a clear correlation between different API security vulnerabilities and the functionality of APIs. For instance, file upload interfaces can pose a risk of malware uploads, while proxy interfaces may harbor SSRF vulnerabilities. Building upon this observation, we propose the core concept of our method, which involves *identifying API functions associated with vulnerabilities within API specifications and conducting targeted security testing on those functions*. This approach aims to achieve **vulnerability-oriented API inspection**, thereby facilitating the effective discovery of bugs across a wide range of APIs.

There are three challenges in realizing vulnerability-oriented API inspection in practice. The first challenge is efficiently differentiating between various functional interfaces in an API and identifying functions that may have security vulnerabilities. The second challenge is effectively generating valid test cases based on different function interfaces and corresponding security vulnerability types. The last challenge is generating test sequences that comply with protocol states, incorporating the related test cases, and successfully executing the function interfaces.

To address these challenges, we propose VoAPI^2, a **V**ulnerability-**O**riented **API I**nspection framework designed to directly expose vulnerabilities in RESTful APIs. Our approach begins by identifying semantic keywords associated with potentially weak functions within the API specification. It then integrates a suitable corpus and employs a stateful request sequence that aligns with the execution context of the corresponding functions. By utilizing inspection payloads tailored to different vulnerability types, we can effectively assess these candidate functions for potential vulnerabilities.

We evaluated our tool on 7 real-world RESTful APIs, which resulted in the discovery of 7 zero-day vulnerabilities and 19 disclosed bugs. Out of these vulnerabilities, 23 have been verified and acknowledged by the respective vendors, and have been assigned CVE IDs. The experiment results demonstrate that VoAPI^2 surpasses the state-of-the-art methods by a significant margin, not only in terms of the number of identified bugs but also in terms of detection efficiency.

In summary, we make the following contributions:

- We propose and implement a novel method, VoAPI^2, to automatically reveal the vulnerability of RESTful APIs. It can perform vulnerability-oriented testing based on API specifications to effectively capture defects in RESTful APIs, and output the corresponding PoC. We will release the source code as well as the experiment data at https://github.com/NSSL-SJTU/VoAPI2.
- We evaluated our tool with several state-of-the-art methods. The experiment results demonstrate that VoAPI^2 surpasses all these methods by a significant margin, not only in terms of the number of identified bugs but also in terms of detection efficiency.
- We conducted an evaluation of VoAPI^2 on 7 real-world RESTful APIs, and VoAPI^2 identified 26 vulnerabilities, including 7 previously-unknown and 19 known security bugs. All zero-day bugs have been reported to vendors and fixed; four of them have been assigned CVE IDs.

2 Problem and Approach Overview

In this section, we first provide the background of vulnerabilities in RESTful API. Then, we present a motivation example, and our method to detect the hidden vulnerability in the sample. At last, we discuss the associated challenges and present an overview of our solution.

2.1 Vulnerability of RESTful API

REST, short for REpresentational State Transfer, is a widely adopted software architecture style for network applications. It is commonly utilized within the context of HTTP, and an API adhering to this style is referred to as a RESTful API. While existing tools are available for testing REST APIs, many of them primarily focus on assessing the reliability of these APIs rather than specifically targeting potential security vulnerabilities. However, similar to web applications, REST APIs are also vulnerable to various security threats, as demonstrated by the presence of such vulnerabilities in the CVE database. These vulnerabilities encompass issues like

```yaml
/Images/Remote:
  get:
    operationId: GetRemoteImage
    parameters:
      description: The image url.
      in: query
      name: imageUrl
      required: true
      schema:
        description: The image url.
        format: uri
        type: string
    responses:
      "200":
        content:
          image/*:
            schema:
              format: binary
              type: string
        description: Remote image returned.
      "404":
        content:
          # omitted
        description: Remote image not found.
    summary: Gets a remote image.
    tags:
      - RemoteImage
```

Figure 1: **Specification of an API endpoint.**

Server-Side Request Forgery, Unrestricted File Upload, OS Command Injection, Path Traversal, and more.

Motivation Example. OpenAPI, formerly known as Swagger, provides a specification for describing RESTful APIs. Typically, the specification document is presented in JSON or YAML format and encompasses the resources and operations of the RESTful API. It comprises a collection of Schema Objects, which encompass various elements such as API service endpoints (commonly referred to as paths), CRUD operations (such as `GET`, `POST`, `PUT` and `DELETE`) performed on an endpoint, input parameters, and expected responses. Each schema object follows a predefined structure with corresponding parameter types. Users can leverage the specification to generate valid API operations and communicate with API services by presenting them as HTTP requests.

Figure 1 illustrates a simplified fragment of the OpenAPI specification for Jellyfin [3], an open-source media management system. This fragment specifies an API endpoint, `/Images/Remote`, which supports a single CRUD operation, `GET`. It defines the input parameters and expected response for this endpoint. Specifically, the input parameter is named "`imageUrl`" (Line 7), which is required and used to specify the URL of the image (Line 10). The corresponding schema (Line 9) designates the parameter type as a string (Line 12). The response section includes the HTTP status code and response message (Line 13). Furthermore, this example includes a "`summary`" field (Line 25), which typically provides a brief description of the API's functionality (similar to the "`description`" field). Additionally, there is a "`tags`" field

Figure 2: **Exploitation process of CVE-2021-29490.**

(Line 26) that offers category tags to classify the API.

In Jellyfin (version 10.7.3 and earlier), there exists a Server-Side Request Forgery (SSRF) vulnerability (CVE-2021-29490 [35]) in the aforementioned API endpoint. Exploiting this vulnerability requires the attacker to send a GET request to the `/Images/Remote` API with testing payloads (e.g., `http://LAN_IP/ssrf`) in the query parameter "`imageUrl`". The root cause of this vulnerability is the lack of filtering for the remote resource address specified by the "`imageUrl`" parameter in the backend of the API service. This oversight allows attackers to freely access internal resources by sending an HTTP request (i.e., the testing payload) from the Jellyfin server, as depicted in Figure 2.

As we see, the vulnerability in the motivation sample is closely related to the functionality of the corresponding API endpoint. Specifically, the SSRF bug typically arises in the API path responsible for retrieving a remote resource. As demonstrated in this example, the purpose of this API endpoint is to fetch a remote image, as indicated in its summary (Line 25). The parameter "`imageUrl`" is utilized to specify the address of the resource (Line 5). Consequently, if the backend of this API interface fails to rigorously validate input parameters, it may result in an SSRF vulnerability.

2.2 Observation and Our Method

Current security testing methods for APIs suffer from two primary efficiency issues and most of them cannot detect the vulnerability hidden in the motivation sample. *Firstly, they are time-consuming.* For example, RESTler [12] required over five hours to test four groups of API interfaces in the open-source code management software GitLab, with the longest effective request sequence length tested remaining at just three. This inefficiency can be attributed to testing tools needing to traverse all interfaces indiscriminately, rather than focusing on a specific API interface in-depth. *Secondly, existing testing tools heavily rely on service status feedback from API endpoints to gauge testing effectiveness, resulting in the identification of mostly service-disrupting bugs.* For instance, RESTler discovered 28 bugs causing GitLab [36] service unavailability, while RestCT [25] identified eight similar issues in Bing Maps [37] and GitLab.

Table 1: **Statistical Data of Known APIs' Vulnerabilities.** Here we list the disclosed API bugs of six common types that we collected from the CVE database. **#Bug** indicates the number of disclosed bugs. **#Ratio** indicates the proportion of common functionality in all vulnerable functions.

CWE ID	Vulnerability Type	#Bug	Functionality Summary of Vulnerable APIs	#Ratio	Keywords
CWE-434	Unrestricted Upload of File	42	Most of them focus on uploading.	83%(35/42)	"upload","submit","import", etc.
CWE-918	Server-Side Request Forgery	21	Most of them need to request a remote source, like Proxy interfaces.	81%(17/21)	"remote","proxy","URL", etc.
CWE-22	Path Traversal	31	They are responsible for handling file through a "Path" variable.	52%(16/31)	"path","dir","file", etc.
CWE-78	OS Command Injection	55	Most of them are used to set configurations through commands executed in OS shell.	40%(22/55)	"CMD","command","system", etc.
CWE-89	SQL Injection	70	They are responsible for handling SQL database.	53%(37/70)	"SQL","database","select", etc.
CWE-79	Cross-site Scripting	55	They present front-end pages that show text.	35%(19/55)	"display","content","view", etc.

Furthermore, these testing methods often lack a targeted strategy and approach based on specific security vulnerabilities. Instead, they primarily rely on detecting generic bugs through feedback such as "500 Internal Server Errors" from API endpoints. Consequently, this leads to an indiscriminate and inefficient testing approach, with the majority of detected bugs being functional issues rather than genuine security vulnerabilities.

Observation. According to the motivation sample, we **observe** that we can assess the functionality of APIs by examining certain feature strings commonly used to define API features in the specification, such as the presence of `remote` in the current example. Meanwhile, the keyword `remote` is also strongly associated with the type of vulnerability (SSRF). To validate our observation that the category of vulnerability present in an API interface is strongly linked to the functionality of that interface via some keywords, we gathered data from the CVE database on the most common types of revealed API vulnerabilities (e.g., Unrestricted Upload and SSRF) and selected vulnerabilities that had been disclosed in CVE records with specific details, such as the exact location of the bug within the API interface.

Based on our collected data[2], we first conduct a word frequency analysis on the API paths and parameters of API interfaces according to these vulnerabilities' CVE descriptions. Then, combining with expert knowledge (analyze the root cause of these vulnerabilities), we extract high-frequency words that also reflect the functionality of these vulnerable APIs, such as "upload" and "submit," and mapped these for the functionalities (e.g., File Upload function) and vulnerabilities (e.g., Unrestricted Upload of File). Finally, we try to construct a mapping from the vulnerability type to the corresponding function functionality and its feature strings frequently applied in context.

Our analysis results are presented in Table 1, which shows that, on average, 57% of vulnerable API interfaces affected by a specific type of bug belonged to the same functionality. These findings confirm the validity of our intuition for these common vulnerabilities. Additionally, we identified a group of commonly used strings in specific functionality as keywords. For example, in an upload interface, we may observe frequently used strings such as "`upload`", "`submit`", and "`import`" which can be used as keywords to identify corresponding interfaces from API specifications and support subsequent bug detection, as shown in Table 1. It is also important to note that these six types of vulnerabilities are the mainstream of web vulnerabilities, collectively accounting for over 70% of the total [38].

Our Method. Building upon our observation and verification result, we propose the core concept of our method, which involves *identifying API functions associated with vulnerabilities within API specifications and conducting targeted security testing on those functions*. This approach aims to achieve *vulnerability-oriented API inspection*, thereby facilitating the effective discovery of bugs across a wide range of RESTful APIs. Different from the previous method, it considers the API functionality when identifying and testing for vulnerabilities.

2.3 Challenges and Our Approach

There are three challenges in realizing vulnerability-oriented API inspection in practice.

C1: How to efficiently differentiate between various functional interfaces in an API and identify functions that may have security vulnerabilities? API documentations usually contain a large number of APIs, but only a small portion of them may have security vulnerabilities. Hence, it is crucial to employ a method that can identify candidate APIs, enabling us to enhance testing efficiency and minimize ineffective test requests.

C2: How to generate test case sequences that comply with protocol states and trigger the vulnerable functional interfaces? API invocations are state-based and often require a series of pre-request actions (request sequences) to fulfill the execution

[2]All the vulnerability context information and keywords gathered during this construction process can be found at the link: https://github.com/NSSL-SJTU/VoAPI2/CVE-Information.xlsx.

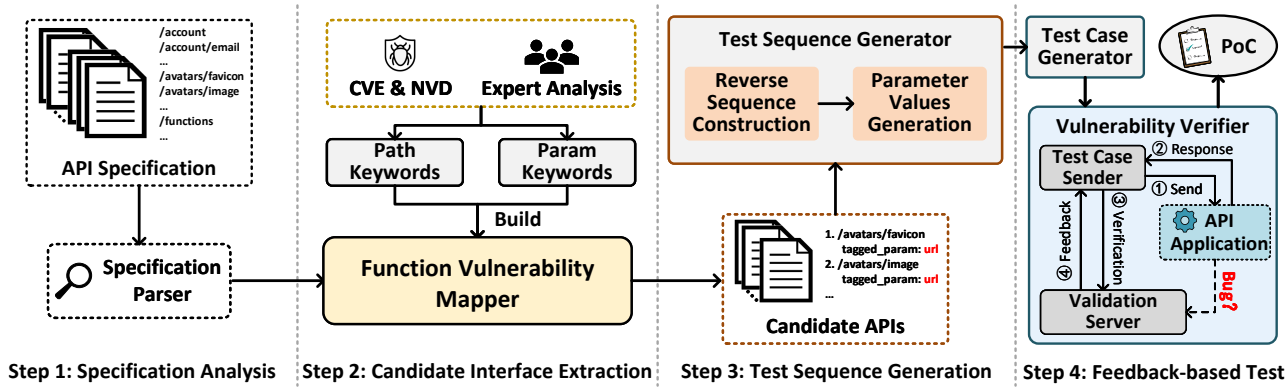

Figure 3: **System Architecture of VoAPI^2.** VoAPI^2 first analyzes the API specification and identifies semantic keywords associated with potentially weak functions within the API specification. It then integrates a suitable corpus and employs a stateful request sequence that aligns with the execution context of the corresponding functions. By utilizing inspection payloads tailored to different vulnerability types, VoAPI^2 can effectively assess these candidate functions for potential vulnerabilities.

dependencies of the API, such as providing required input parameters, in order to ensure the proper execution of the API. Making standalone API calls is usually considered invalid.

C3: How to effectively generate valid test cases based on different functional interfaces and corresponding security vulnerability types? (1) Different types of vulnerabilities have distinct principles and require different detection methods. (2) Overly complex test messages can significantly increase the cost of testing while compromising efficiency and accuracy. (3) Verifying the presence of vulnerabilities may necessitate additional triggering requests. Therefore, the design of test messages and checkers should strive to encompass a comprehensive range of real-world scenarios.

To solve these challenges, we design VoAPI^2 to detect various vulnerabilities in REST APIs effectively. To solve the first challenge, we identify and extract the relevant functional APIs from the API specifications by utilizing semantic keywords (e.g., path keywords and parameter keywords). With a focus on vulnerability analysis, we identify potential vulnerability types and their possible locations within these functional APIs. And then, we employ reverse sequence construction and parameter values generation methods, which is expanding on the techniques used in RESTler and RestCT, to generate test requests that adhere to the protocol's state transitions. This ensures the proper context for executing the candidate APIs. At last, to address different vulnerability types, we create specific test corpora. By combining the test sequences developed for candidate APIs and the marked potential vulnerability locations, we incorporate tailored test data into the corresponding parameters, resulting in comprehensive test cases. The presence of potential vulnerabilities in candidate APIs is assessed by the feedback received from the backend checker, enabling timely adjustments to the testing strategy when necessary.

3 Design

Overview. As shown in Figure 3, our approach begins by identifying semantic keywords associated with potentially weak functions within the API specification. It then integrates a suitable corpus and employs a stateful request sequence that aligns with the execution context of the corresponding functions. By utilizing inspection payloads tailored to different vulnerability types, we can effectively assess these candidate functions for potential vulnerabilities.

3.1 Semantic Keyword Collection

VoAPI^2 utilizes semantic keywords to identify APIs that exhibit specific functionalities. As shown in Table 1, APIs related to file uploads are often vulnerable to arbitrary file uploads. The functionality of an API is typically indicated by its access path, as demonstrated by `/Images/Remote` in Figure 1. On the other hand, the parameters of an API provide specific details about its intended function. For instance, a file upload API is likely to include the keyword "`upload`" in its access path, while the parameters are expected to involve the keyword "`file`".

In this part, we follow a two-step process to extract API access path and parameter keywords. First, we collected 544 vulnerabilities related to APIs with publicly available detailed descriptions from sources such as CVE [39] and NVD [40] to build a dataset. We then clustered these vulnerabilities based on their CWE (Common Weakness Enumeration) IDs and ranked the CWE IDs according to the number of vulnerabilities they encompassed. We selected the six clusters of CWE IDs with the highest proportion. Using this dataset as a foundation, we analyzed the types of API functions associated with these CWE IDs and created mappings between the CWE ID and the corresponding API functionality. Specifically, we

Table 2: **Keywords of API paths and parameters.** Here we list the mappings between Vulnerability Type and API Type as well as the corresponding number of keywords collected in the Semantic Keyword Collection module.

Vulnerability Type	#Keywords		API Type
	API path	API parameter	
SSRF	10	22	Resource Request APIs
Unrestricted Upload	12	8	File Upload APIs
Path Traversal	12	3	Path Processing APIs
Command Injection	12	7	System Configuration APIs
SQL Injection	11	4	Database Operation APIs
XSS	15	12	Text Display APIs

analyzed vulnerabilities within these six CWE clusters and obtained functional descriptions for the vulnerable APIs from various sources, including source code, API documentation comments, and vulnerability descriptions. We conducted word frequency analysis and leveraged expert experience to identify the frequently occurring API functionalities within these six CWE clusters. Finally, we established the mappings as shown in Table 2 (i.e., Vulnerability Type and API Type).

Next, we conducted a statistical analysis of the words found in the API access paths and parameters, and gathered two distinct clusters of semantic keywords: one for API paths and another for parameters. In detail, we extracted the paths and parameters from each vulnerable API in the dataset. We then performed word frequency analysis on these paths and parameters, and sought input from human experts to identify the keyword collections. By incorporating the additional insights and expertise from the experts, we refined and expanded the existing keyword collections. This process allowed us to establish meaningful connections between the keywords, the corresponding API functionalities, and the vulnerability types. These strings serve as semantic keywords that reflect the function of the respective category. The number of each type's keywords is listed in Table 2.

3.2 Candidate Interface Extraction

In this module, we analyze the API specification to identify interface functions that may potentially have vulnerabilities by searching for semantic keywords in the API documentation. The process involves the following steps. Firstly, VoAPI^2 utilizes the RESTler Compile Module to analyze the API specification and generate a grammar file (shown in Listing 1). This grammar file contains information about parameters, responses, and the dependencies between individual requests.

And then, VoAPI^2 parses grammar files based on the following three patterns: (1) the API access path is identified by locating the string "`Endpoint:`"; (2) the API request method is identified by locating the string "`method:`"; (3) The API parameters are identified by finding the line above the `restler_fuzzable_string` and checking if they are surrounded by parentheses "`()`". Taking the grammar file in

```
1  # Endpoint: /Images/Remote, method: Get
2  request = requests.Request([
3      primitives.restler_static_string("GET "),
4      primitives.restler_basepath(""),
5      primitives.restler_static_string("/"),
6      primitives.restler_static_string("Images"),
7      primitives.restler_static_string("/"),
8      primitives.restler_static_string("Remote"),
9      primitives.restler_static_string("?"),
10     primitives.restler_static_string("imageUrl="),
11     primitives.restler_fuzzable_string("fuzzstring", quoted=
           False),
12     primitives.restler_static_string(" HTTP/1.1\r\n"),
13     primitives.restler_static_string("Accept: application/
           json\r\n"),
14     primitives.restler_static_string("Host: localhost\r\n"),
15     primitives.restler_refreshable_authentication_token("
           authentication_token_tag"),
16     primitives.restler_static_string("\r\n"),
17 ],
18 requestId="/Images/Remote"
19 )
```

Listing 1: **Sample of Candidate Interface Extraction.**

Listing 1 as an example, we obtained the API access path `/Images/Remote` (Line 1), the API request method `Get` (Line 1) and the unique parameter of this API `imageUrl` (Line 10).

By applying these patterns, VoAPI^2 is able to extract relevant information from the grammar file and help identify the API functions that are associated with potential vulnerabilities. VoAPI^2 utilizes the semantic keywords generated by the previous module to check for their presence in the paths and parameters of a given API. Based on this analysis, VoAPI^2 categorizes the API functions and assigns them potential vulnerability types (one or more). Our statistical analysis of past API vulnerabilities indicates that all parameters could be vulnerable when an API includes path keywords but lacks parameter keywords. As a result, we employ the following strategy to extract and classify API functions: (1) APIs that solely consist of path keywords without any parameter keywords are identified as candidate APIs, and all parameters of these APIs are marked as test parameters; (2) APIs that contain parameter keywords are also recognized as Candidate APIs, but only the parameters corresponding to the parameter keywords are designated as test parameters.

The extracted candidate APIs are categorized into corresponding functional categories based on the keywords, and potential vulnerability types are mapped, which guides the selection of testing corpus and methods. VoAPI^2 categorizes the candidate API functions and their corresponding potential vulnerability types as shown in Table 2.

3.3 Test Sequence Generation

This module is designed to create a sequence of API requests that accurately reflect the state transitions of the API under testing. Since API calls often depend on the current state, a single request is often inadequate to thoroughly test an API. To address this, VoAPI^2 employs reverse sequence construction techniques to identify other APIs that one candidate API depends on, thereby forming a series of requests that precisely

Algorithm 1 Reverse Sequence Construction Algorithm

```
1:  function GENERATE_SEQUENCE(candidate_api)
2:      S ← candidate_api
3:      i ← -1
4:      while True do
5:          producers ← FIND_PRODUCERS(S[i])
6:          for producer ∈ producers do
7:              if IS_VALID_PRODUCER(producer, S) && not
    IS_DUPLICATE(producer, S) then
8:                  S.INSERT(0, producer)
9:          if S[i] == S[0] then
10:             Break
11:         else
12:             i = i − 1
13:     return S
```

capture the state transitions of the API being tested.

3.3.1 Reverse Sequence Construction

We list the reverse sequence construction algorithm in Algorithm 1 and illustrate the algorithm by using `GET /database/collections/{collectionId}/documents /{documentId}`, an API of Appwrite [5]. It initializes a sequence set `S` with the candidate API (`candidate_api`) and proceeds to reverse-traverse the set *S*, starting from the end (`S[-1]` is `candidate_api`). This process involves identifying all producer APIs of the candidate API. For example, for the sample API, it searches the `responses` field in the API documentation for potential producers. It uses string fuzzy matching to match the producers of the parameters (i.e., `collectionId`, `documentId`) of `candidate_api`. Among these producer APIs, only those that meet the *producer-consumer relationship*, *CRUD semantic* constraints and *resource hierarchy* constraints (we explain the three key definitions and their corresponding constraints used in this algorithm in the following segments.) are retained and appended to the front end of the sequence set `S` (Line 6-8). The algorithm then continues the reverse-traversal process, identifying the producers of the preceding API until it reaches the beginning of the sequence `S` (Line 9-10).

Producer-Consumer Relationship. In the context of the API testing framework, the Producer-Consumer Relationship refers to a rule that governs the execution order of API requests based on their input parameters. If the input parameter of request `A`, which can be located in the Path, Query, Header, Form, or Body, is derived from the response description of request B using heuristic string matching, then request `B` must be executed before request `A`. In other words, request `B` acts as the producer of the input parameter for request `A`. In cases where the same input parameter corresponds to multiple producers with the same path but different request methods, a *priority system* is used to select and add a single producer to the producer set. The priority is determined as follows: `POST` takes precedence over `PUT`, `GET`, and `PATCH`. For the sample API, its all potential producers contains:
P_1="`GET /account`" (P represents Producer),
P_{n_1}="`GET /database/collections`",
P_{n_2}="`POST /database/collections`",
P_{n_3}="`GET /database/collections/{collectionId}`",
P_{n_4}="`POST /database/collections/{collectionId}/documents`",
and so on. And according to the strategy of the *priority system*, the producer P_{n_1} will be removed because it shares the same path as P_{n_2} but has a lower priority.

CRUD Semantics. CRUD is an acronym that stands for `CREATE`, `READ`, `UPDATE`, and `DELETE`. According to the CRUD semantics, a resource (and all its sub-resources) should not be accessed before its creation or after its deletion. In reverse sequence construction, the CRUD semantic constraints only apply to a pair of producers and consumers. For example, because the consumer's request method is `GET`, if there is a producer with a request method of `DELETE`, we need to remove it from the producer set.

Resource Hierarchy. In RESTful APIs, the hierarchical relationships between resources are indicated by the forward slash "/" in the URLs of the resources. For example, `/user/{id}` is a direct sub-resource of `/user`, whereas there is no direct relationship between `/user` and `/team`. We need to remove producers that do not satisfy the resource hierarchy relationship. For example, the producer P_1 that does not have a resource relationship with `candidate_api` will be removed.

After applying these three constraints to filter out invalid producers from the producer set, we are left with three valid producers: "`POST /database/collections`", "`GET /database/collections/{collectionId}`", "`POST /database/collections/{collectionId}/documents`".

3.3.2 Parameter Values Generation

In order to create a concrete request, each input-parameter, such as `imageUrl` (Line 7) in Figure 1, in the sequence needs to be assigned a value domain. VoAPI[2] utilizes one of the following strategies to determine the value domain for each input-parameter based on RestCT [25]:

- CONSUMER. This strategy uses the resources from the producer's response message (i.e., http response message for one request). If an input-parameter `p` corresponds to a resource in the producer's response message, then the resource is used as the value domain for `p` during runtime.
- SPECIFICATION. This strategy uses the values described in the API specification. If an input-parameter `p` has an enum or default field, then the corresponding value is directly used as the value domain for `p`. Otherwise, the strategy searches for all input parameters with the same name as p and selects sample values at random from their example fields to use as the value domain for `p`.
- FORMAT. This strategy uses the values from the preset formatting dictionary. If an input-parameter `p`'s name can

Table 3: **Sample Testing Corpus for Different API Types.**

API Type	Sample in Testing Corpus
Resource Request API	http://IP:PORT/ssrf/{0}
File Upload API	evil files (evil.jsp, evil.asp, evil.php, etc)
Path Processing API	/etc/passwd; C://Windows//win.ini
System Configuration API	curl http://IP:PORT/command/{0}
Database Operation API	1" or "1"="1; SQLMap
Text Display API	<img src='http://IP:PORT/xss/{0}'>

be matched to a preset formatting dictionary, then the corresponding value is used as the value domain for `p`. The VoAPI^2 preset formatting dictionary is mainly designed for parameters that have specific formatting requirements, such as email (which requires a valid email format) and password (which requires a length of at least 8 characters).

- SUCCESS. This strategy uses the values from the previous successful requests (identified by a 200 HTTP status code). If an input-parameter `p` has the same name as an input-parameter from a previous successful request, then the value for that input-parameter is used as the value domain for `p`. If the value for the same input-parameter was generated using the RANDOM strategy, then the value is mutated to increase the diversity of test inputs and avoid creating duplicates.
- RANDOM. This strategy generates a random value to use as the value domain for an input-parameter `p` if none of the above strategies can determine a value domain for `p`.

VoAPI^2 applies these strategies in decreasing priority until a value domain is determined for each input-parameter.

3.4 Feedback-based Testing and Verification

This module consists of two parts: Test Case Generator and Feedback-based Vulnerability Verifier. For each candidate API in the test sequence, Test Case Generator generates valid test cases with the assistance of the test sequence generation module. These test cases are then sent to the API application by the Feedback-based Vulnerability Verifier to detect the presence of corresponding vulnerabilities.

3.4.1 Test Case Generator

The test case generator leverages the output of the Test Sequence Generator module to generate test cases that target potential vulnerabilities in the APIs. Specifically, it generates test cases by inserting the testing corpus into the marked testing parameter positions. For the unmarked parameters, the values assigned by the Test Sequence Generation module are utilized. As shown in Table 3, we collected some test cases and built the testing corpus for different categories of APIs. For instance, to address variations in server-side architectures, we gathered and designed malicious file upload test cases (e.g., `evil.jsp` and `evil.php`) tailored to different programming languages. For another example, we developed a comprehensive set of payloads (e.g., `"../"*9+"etc/passwd"`) that attempt to bypass various types of path checks to explore path traversal vulnerabilities in APIs that handle file paths. More importantly, we design an extensible interface to scale the test corpus. For example, in addition to employing conventional SQL injection test cases (e.g., 1" or "1"="1), we augment the Test Case Generator by integrating one existing powerful detection tool (i.e., SQLMap [41]) to help determine the presence of vulnerabilities with sophisticated corpus.

3.4.2 Feedback-based Vulnerability Verifier
